Aristolochiaceae

See also Herbal medicines

General Information

The family of Aristolochiaceae contains three genera:

1. *Aristolochia* (dutchman's pipe)
2. *Asarum* (wild ginger)
3. *Hexastylis* (heartleaf).

Aristolochia species

Plants belonging to the genus of *Aristolochia* are rich in aristolochic acids and aristolactams.

In the UK, the long-term (2 and 6 years) use of *Aristolochia* species in Chinese herbal mixtures, taken as an oral medication or herbal tea, resulted in Chinese-herb nephropathy with end-stage renal insufficiency (1). In reaction to these reports, the erstwhile Medicines Control Agency banned all *Aristolochia* species for medicinal use in the UK.

In June 2001, the FDA issued a nationwide alert, recalling 13 "Treasure of the East" herbal products containing aristolochic acid. Before this alert, the FDA had issued several warnings:

- On 4 April 2001 a "Dear Health Professional" letter was sent, drawing attention to serious renal disease associated with the use of aristolochic acid-containing dietary supplements or "traditional medicines." Health professionals were urged to review patients who had had unexplained renal disease, especially those with urothelial tract tumors and interstitial nephritis with end-stage renal insufficiency, to determine if such products had been used.
- On 9 April 2001 a letter was sent to industry associations, detailing the reported cases of renal disease associated with aristolochic acid.
- On 11 April 2001 the FDA cautioned consumers to immediately discontinue any dietary supplements or "traditional medicines" that contain aristolochic acid, including products with "Aristolochia," "Bragantia," or "Asarum" listed as their ingredients.

In a related action, Health Canada first issued a warning on aristolochic acid in November 1999 that this ingredient posed a Class I Health Hazard with a potential to cause serious health effects or death (2) and warned consumers not to use the pediatric product Tao Chih Pien. This Chinese product, sold in the form of tablets, is said to be a diuretic and a laxative. It is not labeled to contain aristolochic acid. However, the Chinese labeling says that it contains Mu Tong, a traditional term used to

© 2006 Elsevier B.V. All rights reserved.

describe numerous herbs, including aristolochia; subsequent product analysis showed that Tao Chih Pien does indeed contain aristolochic acid. Health Canada advised individuals in possession of this product not to consume it and to return it to the place of purchase. It also issued a Customs Alert for the product to prevent the importation and sale of Tao Chih Pien and advised Canadians not to consume Longdan or Lung Tan Xi Gan products, since they may also contain aristolochic acid.

The product Longdan Qiegan Wan ("Wetness Heat" Pill) was removed from the Australian Register of Therapeutic Goods following the detection of aristolochic acid by laboratory testing by the Therapeutic Goods Administration (3).

In 2002 the Medicines Safety Authority of the Ministry of Health in New Zealand (Medsafe) ordered the withdrawal of several traditional Chinese medicines sold as herbal remedies (4). The products included Guan Xin Su He capsules, Long Dan Xie Gan Wan Pills, and Zhiyuan Xinqinkeli sachets.

In 2004 the UK's Medicines and Healthcare products Regulatory Agency, with the co-operation of Customs and Excise, seized a potentially illegal consignment of 90 000 traditional Chinese medicine tablets, Jingzhi Kesou Tanchuan, which reportedly contained *Aristolochia*.

In December 2004 the Hong Kong authorities warned the public not to take the product Shen yi Qian Lie Hui Chin, as laboratory tests showed that it contained aristolochic acid.

Adverse effects

Several review articles have covered the toxicology of *Aristolochia* (5–8).

Liver

Hepatitis has been attributed to *Aristolochia* (9).

- A 49-year-old woman developed signs of hepatitis. All the usual causes were ruled out. The history revealed that she had recently started to use a Chinese herbal tea to treat her eczema. Examination of the herbal mixture showed that it contained *Aristolochia debilis* root and seven other medicinal plants.

Like *Aristolochia fangchi*, *A. debilis* contains the highly toxic aristolochic acid and was therefore the likely cause of the toxic hepatitis.

Urinary tract

Aristolochic acid is a potent carcinogen and can cause serious kidney damage, "Chinese herb nephropathy," which can be fatal (10). Renal fibrosis has also been reported (11).

Numerous reports from many countries have confirmed that plants from the *Aristolochia* species are the cause of the nephropathy (12,13), and the toxic agent has been confirmed to be aristolochic acid (14).

- A 46-year-old Chinese woman, living in Belgium and China, developed subacute renal insufficiency (15). Her creatinine concentration had increased from 80 μmol/l (November 1998) to 327 μmol/l (January 2000). During the preceding 6 months she had taken a patent medicine bought in China "for waste discharging and youth keeping." The package insert did not list any herbs of the *Aristolochia* species. Kidney biopsy showed extensive hypocellular interstitial fibrosis, tubular atrophy, and glomerulosclerosis. Analysis of the Chinese medicine demonstrated the presence of aristolochic acid. She required hemodialysis in June 2000 and received a renal transplant 4 months later.
- A 58-year-old Japanese woman with CREST syndrome (calcinosis, Raynaud's syndrome, esophageal sclerosis, sclerodactyly, and telangiectasia) developed progressive renal dysfunction (16). Renal biopsy showed changes typical of Chinese herb nephropathy. Analyses of Chinese herbs she had taken for several years demonstrated the presence of aristolochic acid. Oral prednisolone improved her renal function and anemia.
- A 59-year-old man developed renal insufficiency after self-medication for 5 years with a Chinese herbal remedy to treat his hepatitis (17). Renal biopsy showed signs characteristic of Chinese herb nephropathy. Analysis of the remedy proved the presence of aristolochic acids I and II.

In Belgium, an outbreak of nephropathy in about 70 individuals was attributed to a slimming formulation that supposedly included the Chinese herbs *Stephania tetrandra* and *Magnolia officinalis*. However, analysis showed that the root of *S. tetrandra* (Chinese name Fangji) had in all probability been substituted or contaminated with the root of *Aristolochia fangchi* (Chinese name Guang fangji) (18,19). The nephropathy was characterized by extensive interstitial fibrosis with atrophy and loss of the tubules (20). At least one patient had evidence suggestive of urothelial malignancies (21). The same remedy was apparently also distributed in France, and two cases have been reported from Toulouse and one possible case from Nice (22).

Subsequently, Belgian nephrologists re-investigated 71 patients who were originally affected by this syndrome (23). Using multiple regression analysis, they showed that the original dose of *Aristolochia* was the only significant predictor of progression of renal insufficiency. The risk of end-stage renal insufficiency in these patients increased linearly with the dose of *Aristolochia*.

In Japan two cases of Chinese herb nephropathy were associated with chronic use of *Aristolochia manchuriensis* (Kan-mokutsu) (24). The diagnosis was confirmed by renal biopsy and the toxic constituents were identified as aristolochic acids I, II, and D.

Taiwanese authors have reported 12 cases of suspected Chinese herb nephropathy, confirmed by renal biopsy (25). Renal function deteriorated rapidly in most patients, despite withdrawal of the Aristolochia. Seven patients underwent dialysis and the rest had slowly progressive renal insufficiency. One patient was subsequently found to have a bladder carcinoma. Other cases have been reported from mainland China (26) and Taiwan (27).

Because of fear of malignancies the Belgian researchers who first described the condition have advocated prophylactic removal of the kidneys and ureters in patients with Chinese herb nephropathy. Of 39 patients who agreed to this, 18 (46%) had urothelial carcinoma, 19 of the others had mild to moderate urothelial dysplasia, and only two had normal urothelium (28). All tissue samples contained

© 2006 Elsevier B.V. All rights reserved.

aristolochic acid-related DNA in adducts. The original dose of *Aristolochia* correlated positively with the risk of urothelial carcinoma.

Animal experiments have shed more light on Chinese herb nephropathy (29). Salt-depleted male Wistar rats were regularly injected with two different doses of aristolochic acid or with vehicle only for 35 days. The histological signs of Chinese herb nephropathy were demonstrated only in animals that received the high dose of 10 mg/kg. The authors presented this as an animal model for studying the pathophysiology of Chinese herb nephropathy.

Tumorigenicity

Aristolochic acid I and aristolochic acid II are mutagenic in several test systems. A mixture of these two compounds was so highly carcinogenic in rats that even homeopathic *Aristolochia* dilutions have been banned from the German market. The closely related aristolactam I and aristolactam II have not been submitted to carcinogenicity testing, but these compounds similarly show mutagenic activity in bacteria.

When 19 kidneys and urethras removed from 10 patients with Chinese herb nephropathy who required kidney transplantation were examined histologically, there were conclusive signs of neoplasms in 40% (30).

One patient who had a urothelial malignancy 6 years after the onset of Chinese herb nephropathy later developed a breast carcinoma that metastasised to the liver (31). The urothelial malignancy contained aristolochic acid-DNA adducts and mutations in the p53 gene, and the same mis-sense mutation in codon 245 of exon 7 of p53 was found in DNA from the breast and liver tumors. However, DNA extracted from the urothelial tumor also showed a mutation in codon 139 of exon 5, which was not present in the breast and liver.

Asarum heterotropoides

The Chinese herbal medicine Xu xin (32) is made from the leaves and aerial parts of *Asarum heterotropoides*. It is used for the symptomatic relief of colds, headaches, and other pains.

Adverse effects

The volatile oil of Xu xin causes the following adverse effects: vomiting, sweating, dyspnea, restlessness, fever, palpitation, and nervous system depression. Death can result from respiratory paralysis at high doses.

Arsenic

General Information

Arsenic is a metallic element (symbol As; atomic no. 33), which exists in several allotropic forms. Various ores contain crystalline forms of arsenic salts: cobaltite contains cobalt arsenic sulfide; mispickel (arsenopyrite) iron arsenic sulfide; orpiment arsenic trisulfide; proustite (ruby silver ore) silver arsenic sulfide; realgar arsenic sulfide; and tennantite copper arsenic sulfide.

Arsenic has a long history of medicinal uses. Thomas Fowler introduced it in the form of potassium arsenite (Fowler's solution) in the late 18th century to treat ague and Sir David Bruce used it in the late 19th century to treat trypanosomiasis. In the early 20th century Paul Ehrlich synthesized and tested a large series of arsenicals, in the hope of finding one that was effective in syphilis, and emerged with arsphenamine (Salvarsan, compound 606). Subsequently other arsenicals were synthesized, such as neoarsphenamine (for syphilis) and tryparsamide and acetarsol (for trypanosomiasis).

In recent times arsenic and arsenicals have been considered obsolete in medicine, because of their limited therapeutic value, multisystem toxicity, and apparent carcinogenic properties (SED-8, 502) (SED-9, 368). However, arsenic compounds have been used to treat various types of leukemia (1–3), including acute promyelocytic leukemia, chronic myelogenous leukemia, and multiple myeloma (4). Arsenic trioxide is effective in acute promyelocytic leukemia, achieving a complete remission rate of 60–90% (5,6). It is particularly used in patients who are resistant to all-trans retinoic acid (7). Arsenic trioxide is also emerging as a therapy for multiple myeloma (8).

Reports continue to be published on incidents related to the use of traditional herbal medications from China and elsewhere that contain arsenic among other toxic substances (9,10).

There are still occasional cases of patients with late effects from obsolete formulations such as Fowler's solution or neoarsphenamine (SEDA-16, 231). As late as 1998 a case of severe chronic poisoning resulting in fatal multiorgan failure including hepatic portal fibrosis and subsequent angiosarcoma was traced back to exposure to arsenical salts used for the treatment of psoriasis many years before (11) (SEDA-22, 243). In some non-Western countries arsenic is apparently still being used in dentistry for devitalization of inflamed pulp and sensitive dentine, and cases have been described in which this has resulted in arsenical necrosis of the jaws, affecting the maxilla or mandible (12). Some exposure to arsenic may still be occurring from traditional remedies of undeclared composition, and as with other metals there may be environmental contact, notably from semiconductor materials.

General adverse effects

Chronic arsenic poisoning is marked by edema of the eyelids and face, mucosal inflammation, pruritus, anorexia, vomiting, and diarrhea. Long-term use of small doses can produce keratinization and dryness of the skin, sometimes with frank dermatitis and pigmentation; alopecia can follow, and basal cell epithelioma is a late effect (13). In the long run, as in the fatal cases noted in the introduction of this monograph, there is serious damage to internal organs.

The adverse effects of arsenic trioxide have been described in a patient with recurrent acute promyelocytic leukemia resistant to all-trans retinoic acid (14).

- A 15-year-old African American girl, with multiple recurrent acute promyelocytic leukemia that had resisted conventional chemotherapy, was given arsenic trioxide (As_2O_3) 10 mg intravenously for 28 days and again for a further 28 days after a 4-week break. She had a complete remission by morphological, cytogenetic, and molecular criteria. About 6 months later she again relapsed and had another course of arsenic trioxide, which produced a morphological, but not a cytogenetic or molecular, remission. Arsenic trioxide was well tolerated. Skin dryness was treated with topical moisturizers. Gastrointestinal upset, including mild nausea without vomiting or cramping pain, occurred only during intravenous therapy. No other toxicity was noted.

In acute promyelocytic leukemia arsenic trioxide can cause a syndrome similar to the retinoic acid syndrome (15), with fever, skin rash, edema, pleural effusion, pericardial effusion, and acute respiratory failure.

- A 37-year-old woman with acute promyelocytic leukemia was treated with all-trans retinoic acid, idarubicin, and cytosine arabinoside, with complete remission after one course. However, she had an episode of retinoic

© 2006 Elsevier B.V. All rights reserved.

acid syndrome with fever, edema, and pericardial effusion, which resolved after all-*trans* retinoic acid was withdrawn. When her leukemia relapsed she was treated with arsenic trioxide 10 mg/day. Leukocytosis again developed, with symptoms (fever, skin rash, and edema) resembling the retinoic acid syndrome, which was quickly relieved by steroids. She received two courses of arsenic trioxide each for 30 days and her complete blood count returned to normal 2 weeks after the second course of treatment. The bone marrow also reached complete remission.

Organs and Systems

Cardiovascular

Atrioventricular block is very rare after arsenic trioxide treatment for refractory acute promyelocytic leukemia (16).

- A 34-year-old woman with acute promyelocytic leukemia was given arsenic trioxide solution 0.1%, 10 ml/day for 7 days. A generalized skin rash appeared, and her serum transaminases rose. An electrocardiogram was normal. A second course of arsenic trioxide was used about 3 months later. She felt palpitation and mild dyspnea and had complete atrioventricular block. Echocardiography showed a normal left ventricle. A ^{201}thallium myocardial perfusion scan did not show a perfusion defect. Arsenic trioxide was withheld. Sinus rhythm returned 3 days later. Complete atrioventricular block recurred later when arsenic trioxide was re-administered, albeit in a lower dosage for a shorter period of time.

The heart block due to arsenic trioxide in this case was reversible and did not correlate with the patient's leukemic status.

In 19 patients with hematological malignancies given arsenic trioxide 10–20 mg in 500 ml of 5% dextrose/isotonic saline over 3 hours daily for up to 60 days, there were three cases of torsade de pointes (17).

Nervous system

In a case of a rapidly progressive neuropathy with arsenic, a contributory role of thiamine deficiency was implied (18).

- A 46-year-old woman with acute promyelocytic leukemia was given arsenic trioxide 10 mg/day for 28 days. On day 33 she complained of numbness in the legs and on day 37 all four limbs were paralysed and areflexic. Her speech was inaudible and she had bulbar paralysis. Nerve conduction studies showed a generalized reduction in sensory action potentials. Thiamine deficiency was confirmed and she was given parenteral thiamine (100 mg/day). By the next day the power in her arms had dramatically improved and her speech had become audible. Over the next 5 days, she regained full power in the arms. Subsequently she was given arsenic trioxide 5 mg/day for 28 days with oral thiamine, without neurological deterioration this time. The power in her legs continued to improve.

The members of a family in India, in the business of preparing and manufacturing indigenous medicines containing arsenicals, consumed a home-made vitalizer for health which accidentally got contaminated with arsenicals (19).

- A 50-year-old woman developed severe vomiting, abdominal colic, and diarrhea, which persisted for 5–6 days and 2 weeks later developed tingling, numbness, paresthesia, and gradually progressive weakness of all four limbs. She had gross hyperpigmentation of the face, arms, and upper chest, hyperkeratosis of the palms, and transverse white lines (Mees' lines) in the finger nails. She had a symmetrical, predominantly distal, peripheral sensorimotor neuropathy in all four limbs. Meanwhile, her 52-year-old husband and her 28-year-old son developed severe gastrointestinal problems. Her husband died within 48 hours of onset and the son developed severe wasting, weakness, and a sensorimotor flaccid quadriparesis, similar to that of his mother. Two younger sons, aged 22 and 20 years, and an 18-year-old daughter were out of town but returned after the death of their father. They also developed severe diarrhea, vomiting, abdominal pain, and tingling of the hands and feet within 2–3 weeks. Arsenic concentrations were found in the hair and nails, and the concentrations were directly proportional to the severity of the illness. They were given dimercaprol, and 6 months later all had significant clinical improvement.

Arsenic-induced neurotoxicity in a child was caused by the use of an Indian ethnic remedy.

- A 5-year-old child who had been taking Indian ethnic remedies for congenital bilateral retinoblastoma became anorexic and restless, with nausea, fatigue, paresthesia, and progressive weakness of the legs (20). A year later he developed vomiting, cough, hoarseness, and a recurrent fever. Blood tests showed a severe normochromic anemia and a leukopenia with relative and absolute neutropenia. Electromyography showed a moderate distal chronic axonal polyneuropathy. The urinary arsenic concentration was not high (15 μg/g creatinine; reference range below 40 μg/g), but the hair arsenic concentration was 6.6 mg/kg (reference range below 1 mg/kg). Chronic arsenic poisoning was diagnosed. Arsenic (184 mg/g) was found in one of the ethnic remedies.

Hematologic

Leukocytosis has been commonly noted with arsenic trioxide, but this adverse effect usually resolves spontaneously and is generally not treated. However, one death has been reported.

- A 27-year-old woman (21) with acute promyelocytic leukemia was given arsenic trioxide 0.15 mg/kg/day intravenously. Her white cell count was 8.2×10^9/l; after two doses it rose to 15×10^9/l and after three doses to 21×10^9/l. The white blood cell count continued to rise to 101×10^9/l on day 7 and 213×10^9/l on day 8; the platelet count was 61×10^9/l. Arsenic trioxide was withdrawn. Later that day she became confused with slurred speech and right-sided weakness. A CT scan showed a left middle cerebral artery infarct.

© 2006 Elsevier B.V. All rights reserved.

Twelve hours later she had a generalized seizure. The white blood cell count was now 292 $\times$ 10^9/l and chemotherapy with idarubicin and cytarabine was started. She continued to deteriorate and died on day 15.

Liver

Arsenic salts can cause liver damage (11).

- A 60-year-old man, a heavy drinker, with psoriasis of the palms and soles was treated with arsenical salt derivatives from 1972 to 1982. In 1984 he had an upper gastrointestinal hemorrhage. Only hyperkeratosis and palmar erythema were observed. His liver enzymes were raised. Endoscopy showed an antral ulcer with signs of recent bleeding and grade IV esophageal varices with no evidence of bleeding. Liver biopsy showed preservation of the parenchymal architecture, fibrous expansion of the portal spaces, and minimal lymphocytic infiltration. The diagnosis was portal fibrosis compatible with idiopathic portal hypertension. When he died of multiorgan failure in 1997, autopsy showed a moderately differentiated multifocal hepatic angiosarcoma with bone, gastric, and splenic metastases.

This patient had both idiopathic portal hypertension and hepatic angiosarcoma, in which the common causative factor was the chronic use of arsenical salts for the treatment of psoriasis. In a review of the literature the authors found only five other cases in which both diseases were associated, while exposure to arsenical salts was found in only one of them.

- A 50-year-old man developed upper gastrointestinal bleeding, with no history of alcohol abuse, viral hepatitis, hepatotoxic drugs, or any family history of liver disease (22). He had thalassemia minor and psoriasis, for which he had taken Fowler's solution, 2 ml/day for 5 years. Fowler's solution is a solution of potassium arsenite that contains 10 mg of arsenic trioxide. He had palmar and plantar hyperkeratosis, splenomegaly, and signs of hypovolemia, normal liver function tests, negative viral serological markers and autoantibodies, and high arsenic excretion in the urine. Abdominal ultrasonography and color Doppler showed marked wall thickening of the portal vein and its intrahepatic branches, with signs of portal hypertension and partial splenic vein thrombosis. Endoscopy showed grade III esophageal varices, with signs of recent bleeding. Liver biopsy showed venous wall hyperplasia, with signs of cellular regeneration tending toward a focal nodular pattern and terminal hepatic vein fibrosis. The wedge hepatic pressure was 12 mmHg and the free hepatic venous pressure 5 mmHg; splenoportography confirmed partial obstruction of the splenic vein.

Skin

Human papillomavirus has been implicated as a co-factor in the pathogenesis of arsenic-induced skin tumors (23).

- A 38-year-old Pakistani woman developed verrucose papules on her palms and soles 3 years after she had been treated orally with an herbal solution by a traveling Indian doctor for a period of 12 months for "white spot disease." She had widespread depigmented macules on the trunk and limbs, suggestive of vitiligo, and multiple hyperkeratotic papules on her palms and soles, some of which were coalescing into large leathery plaques. Histological examination showed compact hyperkeratosis, intermittent columns of parakeratosis, and an akanthotic epidermis with minor nuclear atypicality. Polymerase chain reaction analysis with degenerate primers identified an atypical human papillomavirus; sequencing showed an RX-variant of HPV, type 23. There were no other signs of chronic arsenic intoxication, and clinical, radiographic, and laboratory investigations showed no evidence of an internal malignancy.

Musculoskeletal

The use of arsenical paste in dental medicine can lead to severe toxicity. Severe alveolar bone necrosis has been reported as a result of leakage of an arsenical devitalization paste into the periodontium (24).

- An 18-year-old woman with dental pain had a tooth devitalized with an arsenical paste and soon after developed excruciating pain and denudation of bone. She had slightly inflamed gums and loss of the mesial papillary gingivae. The surrounding bone was exposed to a height of 3–4 mm and the exposed bone had a greyish color. The non-vital tooth was preserved by root canal treatment and flap surgery to remove necrotic bone and the associated root, and 3 months later a definitive cuspal coverage restoration was placed over the tooth. At 1 year the patient reported that the tooth was functional without any problems.

Arsenobenzol

General Information

Arsenobenzol has been used to treat syphilis (1,2) and as a topical antiseptic in combination with cortisone and silver colloid (3). Like other compounds with an arsenic base, it can cause gastrointestinal complaints, but also polyneuritis and encephalopathy. Adrenaline prevented the development of encephalopathy and was helpful in treating hemorrhagic encephalopathy (SEDA-11, 597).

Artemisinin derivatives

General Information

The herb Qinghaosu (*Artemisia annua*) has been known to Chinese medicine for centuries and was used in the treatment of fevers, in particular malaria fever; it is not clear why it did not become more widely used elsewhere. The plant can be grown in locations other than China, and field studies in propagating and growing the plant are being carried out in many parts of the world. In 1979 the Qinghaosu Antimalarial Coordinating Research Group reported their experience with four formulations of qinghaosu in both *Plasmodium vivax* and *Plasmodium falciparum* malaria (SEDA-13, 818) (SEDA-17, 326) (1).

Artemisinin is an antimalarial constituent isolated from Qinghao. It is a sesquiterpene lactone with an endoperoxide bridge, structurally distinct from other classes of antimalarial agents. Several derivatives of the original compound have proved effective in the treatment of *Plasmodium falciparum* malaria and are currently available in a variety of formulations: artesunate (intravenous, rectal, oral), artelinate (oral), artemisinin (intravenous, rectal, oral), dihydroartemisinin (oral), artemether (intravenous, oral, rectal), and artemotil (intravenous). Artemisinic acid (qinghao acid), the precursor of artemisin, is present in the plant in a concentration up to 10 times that of artemisinin. Several semisynthetic derivatives have been developed from dihydroartemisinin (1).

Artemether

Artemether is a methyl ether derivative of dihydroartemisinin. It is dispensed in ampoules for intramuscular injection suspended in groundnut oil and in capsules for oral use. Like artesunate and artemisinin it has been used for both severe and uncomplicated malaria. Artesunate is probably faster-acting than the other two.

Artemotil (arteether)

Artemotil is the ethyl ether derivative of dihydroartemisinin. It was the choice of the WHO for development and was considered less toxic, because one would expect it to be metabolized to ethanol rather than methanol. It is also

more lipophilic than artemether, a possible advantage for accumulation in brain tissues. The beta anomer was chosen since it is a crystalline solid and relatively easy to separate from the alpha anomer, which is liquid; it was necessary to choose a single anomer because of the more complex rules for the development of a drug with two anomers in the USA.

Artesunate

Artesunate is a water-soluble hemisuccinate derivative, available in parenteral and oral formulations. The parenteral drug is dispensed as powdered artesunic acid. Neutral aqueous solutions are unstable. Artesunate is effective by the intravenous, intramuscular, and oral routes in a dose of 10 mg/kg given for 5–7 days. The combination with mefloquine is very effective even against highly multiresistant strains of *Plasmodium falciparum*; the combination must be given for at least 3 days.

None of these medications has yet been registered for use in Europe or North America. In recent years there has been a substantial increase in our knowledge of their safety, efficacy, and pharmacokinetics. Higher cure rates are achieved when they are combined with longer-acting antimalarial drugs, such as mefloquine. After years of continued use, the sequential use of artesunate and mefloquine remains an effective treatment in areas of multidrug resistance in South-East Asia and provides an impetus for the evaluation of other artesunate-containing combination regimens for the treatment of uncomplicated malaria, such as artemether + benflumetol (2–6).

Mechanism of action

All three *Artemisia* derivatives are quickly hydrolysed to the active substance dihydroartemisinin. They produce a more rapid clinical and parasitological response than other antimalarial drugs. There are no reports of significant toxicity, and as late as 1994 there was no convincing evidence of specific resistance, but chloroquine-resistant *Plasmodium berghei* is resistant to artemisinin as well. The recrudescence rate is fairly high (1).

The mode of action is not fully known. There is strong evidence that the antimalarial activity of these drugs depends on the generation of free radical intermediates; free radical scavengers, such as ascorbic acid and vitamin E, therefore antagonize the antimalarial activity.

Drug activation by iron and heme may explain why endoperoxides are selectively toxic to malaria parasites. The malaria parasites live in a milieu of heme iron, which the parasite converts into insoluble hemozoin. Chloroquine, which binds heme, antagonizes the antimalarial activity of artemisinin.

Observational studies

Some impression of possible adverse effects in humans can be gained from a primarily pharmacokinetic study, in which artemotil solution in sesame oil was given intramuscularly. The half-life was 25–72 hours. Adverse effects in 23 subjects after the single dose included local pain in two, bitter taste and dryness of the mouth in one, and a mild but slightly itching papular rash that persisted for 14 days in another. There were no biochemical or electrocardiographic changes. Similar adverse effects were seen after 5 days of therapy in 14 of the 27 subjects; there was local pain in three, metallic taste in two, flu-like symptoms in three, and in two a maculopapular rash, which receded within 24 hours. One subject developed shivering, clammy hands and feet, dizziness, headache, nausea, and a metallic taste in the mouth, all lasting for about an hour, but the same reaction occurred after an injection of sesame oil only. Apart from some increase in eosinophil count in all groups, there were no significant hematological changes (7).

In 25 patients with acute uncomplicated *Plasmodium falciparum* malaria treated with artemotil (3.2 mg/kg followed by either 1.6 mg/kg or 0.8 mg/kg), the most frequent adverse events were headache, dizziness, nausea, vomiting, and abdominal pain; two patients complained of mild pain at the site of injection (8).

In a postmarketing surveillance study of artemotil in 300 patients, 294 (98%) were cured, five improved, and one did not show any change (9). The adverse effects were mild headache, nausea, vomiting, and giddiness.

Combination therapy

The artemisinin derivatives are limited by an unacceptable incidence of recrudescence with monotherapy, and they therefore need to be used in combination. A summary of prospective trials that looked specifically for adverse effects showed that artemisinins alone are very well tolerated (10). The same study showed no evidence of adverse interactions of artesunate with mefloquine, with an incidence of adverse effects similar to that expected from malaria and mefloquine (25 mg/kg) together. Reducing doses of mefloquine increases recrudescence rates to unacceptable levels (11). Combinations of artemisinins with quinine, co-trimoxazole, and doxycycline are well tolerated.

Artemether + benflumetol

A large trial of the first fixed-dose combination of an artemisinin derivative likely to be licensed (artemether + benflumetol) had disappointing relapse rates compared with mefloquine monotherapy (6). In the 126 patients who took artemether + benflumetol there were no adverse effects attributed to drug treatment. However, less than 70% of patients were cured at 28 days. Benflumetol may be more effective at higher concentrations (12) but toxicity studies are lacking.

Artesunate + lumefantrine

There has been a meta-analysis of 15 trials from Africa, Europe, and Asia of the use of varying doses of artesunate plus lumefantrine compared with several alternative antimalarial drugs in 1869 patients conducted by the manufacturers Novartis into its clinical safety and tolerability in the treatment of uncomplicated malaria (13). The most common adverse events were gastrointestinal—nausea (6.3%), abdominal pain (12%), vomiting (2.4%), anorexia (13%)—or central nervous—headache (21%) or dizziness (16%). There were 20 serious adverse events with artesunate plus lumefantrine, but only one (hemolytic anemia) was possibly due to artesunate plus lumefantrine. There was no QT prolongation associated with artesunate plus lumefantrine.

© 2006 Elsevier B.V. All rights reserved.

Artesunate + mefloquine

Artesunate has been combined with mefloquine in areas with a high prevalence of multiresistant *Plasmodium falciparum* in Thailand and the Thai-Burmese border. In a study reported in 1992 in 127 patients who were followed for 28 days, group A took artesunate 100 mg immediately and then 50 mg every 12 hours for 5 days (total 600 mg), group M took mefloquine 750 mg and another 500 mg 6 hours later, and group AM took first artesunate and then the two doses of mefloquine (14). Fever and parasite clearance time were significantly shorter in the two groups treated with artesunate. Table 1 gives the results and adverse effects. The combination of artesunate with mefloquine was more effective than either drug alone. However, the trial design was such that the patients who took both drugs were in fact treated twice, so the findings did not prove synergism between the two drugs.

In a second Thai study, 652 adults and children were treated with artesunate plus mefloquine (15). A single dose of artesunate 4 mg/kg plus mefloquine 25 mg/kg gave a rapid response but did not improve cure rate. Artesunate given for 3 days in a total dose of 10 mg/kg plus mefloquine was 98% effective. The incidence of vomiting was significantly reduced by giving the mefloquine on day 2 of the treatment. There were no adverse effects attributed to artesunate.

Artesunate plus pyrimethamine + sulfadoxine

In Irian Jaya, a randomized, controlled trial ($n = 105$; 88 children) of oral artesunate (4 mg/kg od for 3 days) with pyrimethamine (1.25 mg/kg) + sulfadoxine or pyrimethamine + sulfadoxine alone (same dose) showed reduced gametocyte carriage and reduced treatment failure rates (RR = 0.3; 95% CI = 0.1, 1.3) in the combination group (16). Self-limiting adverse events of combination treatment were mild diarrhea (2.1%), rashes (4.3%), and itching (2.1%).

In a double-blind, randomized, placebo-controlled trial in Gambian children with uncomplicated falciparum malaria treated with pyrimethamine + sulfadoxine (25/500 mg; $n = 600$) or pyrimethamine + sulfadoxine combined with two regimens of oral artesunate (4 mg/kg, $n = 200$ or 4 mg/kg od for 3 days, $n = 200$), there were mild adverse events, such as headache, anorexia, nausea, vomiting, abdominal pain, and diarrhea, in a high proportion of children (56%) (17). Combination treatment with artesunate was associated with more rapid parasite clearance and less gametocytemia. Three-dose artesunate conferred no additional benefit over the one-dose regimen.

Artesunate + tetracycline

In a comparison between oral artesunate (700 mg over 5 days) plus tetracycline (250 mg at 6-hour intervals) and quinine (600 mg quinine sulfate at 8-hour intervals) for 7 days, artesunate was more effective and better tolerated in uncomplicated malaria (see Table 2) (18). Convulsions occurred in one case.

Dihydroartemisinin + piperaquine

The novel combination (Artekin™) of dihydroartemisinin and piperaquine has been assessed in 106 patients (76 children and 30 adults) with uncomplicated *Plasmodium falciparum* malaria in Cambodia (19). The respective doses of dihydroartemisinin and piperaquine, which were given at 0, 8, 24, and 32 hours, were 9.1 mg/kg and 74 mg/kg in children and 6.6 and 53 mg/kg in adults. All the patients became aparasitemic within 72 hours. Excluding the results in one child who died on day 4, there was a 97% 28-day cure rate (99% in children and 92% in adults). Patients who had recrudescent infections used low doses of Artekin. Adverse effects, most commonly gastrointestinal complaints, were reported by 22 patients (21%) but did not necessitate premature withdrawal.

Comparative studies

Three large clinical trials (in Kenya, the Gambia, and Vietnam) compared intramuscular artemether with intravenous quinine in severe malaria tropica (SEDA-20, 259). The treatments were similarly efficacious. There were no serious adverse effects.

Placebo-controlled studies

In a double-blind, randomized study in Vietnam ($n = 227$), extending the duration of oral artemisinin monotherapy 500 mg/day from 5 to 7 days did not reduce recrudescence rates (total 23%) (20).

Table 1 Adverse effects of artesunate with or without mefloquine in acute uncomplicated malaria tropica

	Mefloquine	Artesunate	Artesunate + Mefloquine
Total number of patients (M/F)	39/4	38/4	39/3

Vomiting (%)	9 (26)	30 (91)
Tinnitus (%)	0	29 (88)
Convulsions (%)	1 (3)	0
Bradycardia (%)	7 (23)	Not done

General adverse effects

The safety of the peroxide antimalarial drugs has been reviewed (21). In animal studies, high doses of artemotil and artemether have been associated with hemopoietic, cardiac, and nervous system toxicity. Some subclinical neurotoxicity has been reported, with a discrete distribution in the brain stems of rats and dogs after multiple (high) doses (22). Dogs given high doses (15 mg/kg artemether for 28 days) had a progressive syndrome of clinical neurological defects with terminal cardiorespiratory collapse and death. There has been no evidence of neurotoxicity in man, but the human dosage of these ethers is of course lower. Reviews of clinical trials have reaffirmed the high tolerability of the artemisinins (11,23). Adverse effects have been chiefly limited to the GI tract. Most reported adverse events were described as mild and transient and none resulted in withdrawal of treatment.

Organs and Systems

Cardiovascular

Sinus bradycardia and a reversible prolongation of the QT interval have been reported (SEDA-21, 293).

A combination of artemether + lumefantrine (co-artemether, six doses over 3 days) followed by quinine (a 2-hour intravenous infusion of 10 mg/kg, not exceeding 600 mg in total, 2 hours after the last dose of co-artemether) was given to 42 healthy volunteers in a double-blind, parallel, three-group study (14 subjects per group) to examine the electrocardiographic effects of these drugs (24). Co-artemether had no effect on the QT_c interval. The infusion of quinine alone caused transient prolongation of the QT_c interval, and this effect was slightly but significantly greater when quinine was infused after co-artemether. Thus, the inherent risk of QT_c prolongation by intravenous quinine was enhanced by prior administration of co-artemether. Overlapping therapy with co-artemether and intravenous quinine in the treatment of patients with complicated or multidrug-resistant *Plasmodium falciparum* malaria may result in a modest increased risk of QT_c prolongation, but this is far outweighed by the potential therapeutic benefit.

The effects on the QT_c interval of single oral doses of halofantrine 500 mg and artemether 80 mg + lumefantrine 480 mg have been studied in 13 healthy men in a double-blind, randomized, crossover study (25). The length of the QT_c interval correlated positively with halofantrine exposure but was unchanged by co-artemether.

Nervous system

Although in animals several of the artemisinin derivatives have produced a characteristic neurological lesion, there is no good evidence of neurotoxicity in man. A study in mice suggested that intramuscular artemether is significantly more neurotoxic than intramuscular artesunate (26).

In one case, an inadequately treated non-immune subject developed neurological symptoms after relapse and re-treatment; the symptoms were ascribed to artemether (27), although the well-recognized post-malaria neurological syndrome was much more likely, which the authors did not discuss (28).

One man developed ataxia and slurred speech after taking a 5-day course of oral artesunate (SEDA-21, 293).

A study of brain-stem auditory-evoked potentials showed no electrophysiological evidence of brain-stem damage in adults treated with artemisinin derivatives (29).

Neurotoxicity from artemether is related to drug accumulation due to slow and prolonged absorption from intramuscular injection sites. In mice, high doses of intramuscular artemether (50–100 mg/kg/day for 28 days) resulted in an unusual pattern of selective damage to certain brain-stem nuclei, especially those implicated in hearing and balance (30).

Fluid balance

Sodium artesunate inhibits sodium chloride transport in the thick ascending limb of the loop of Henle and therefore has a diuretic effect.

- In two men, aged 16 and 32 years, with falciparum malaria who were given four intravenous doses of sodium artesunate 60 mg, neither of whom had received diuretics or vasoactive drugs, there was a diuresis (6 l/day) accompanied by a natriuresis (31).

Hematologic

A transient dose-dependent reduction in reticulocyte count has been reported in healthy subjects (SEDA-21, 294).

Body temperature

Drug fever has been reported in healthy subjects taking artemether, artesunate, and artemisinin (SEDA-21, 294).

Second-Generation Effects

Pregnancy

Artemisinin derivatives (artesunate and artemether) for the treatment of multidrug-resistant *Plasmodium falciparum* malaria have been evaluated in 83 Karen pregnant women in Thailand; 55 women were treated for recrudescent infection after quinine or mefloquine, 12 for uncomplicated hyperparasitemic episodes, and 16 had not declared their pregnancy when treated (32).

© 2006 Elsevier B.V. All rights reserved.

Artesunate and artemether were well tolerated and there was no drug-related adverse effect. Overall, 73 pregnancies resulted in live births, three in abortions and two in still-births; five women were lost to follow-up before delivery. There was no congenital abnormality in any of the neonates, and the 46 children followed for more than 1 year all developed normally.

Artemisinin derivatives have been studied in 461 pregnant women in a prospective cohort study in Thailand over 8 years (33). Oral artesunate monotherapy was associated with a treatment failure rate of 6.6%. Artesunate and artemether were well tolerated. The rates of abortions (including 44 first-trimester exposures), stillbirths, or congenital abnormalities were 4.8%, 1.58%, and 0.8% respectively, and were not significantly different from pregnant controls. These results are reassuring, but further information is needed before the safety of artesunate in pregnancy can be confirmed.

Drug Administration

Drug formulations

When the sesame oil vehicle in beta-artemotil was replaced by Cremophor (polyethoxylated castor oil) the total exposure in rats was 2.7-fold higher, owing to increased systemic availability (34). Anorexia and gastrointestinal toxicity from artemotil in sesame oil were significantly more severe than with artemotil in Cremophor. However, histological examination of the brain showed neurotoxic changes, which were worse with the castor oil formulation.

Drug administration route

A crossover pharmacokinetic study of single-dose rectal artesunate (10 or 20 mg/kg as a suppository) or intravenous artesunate (2.4 mg/kg) in moderate falciparum malaria in 34 Ghanaian children has been reported (35). The intravenous route gave much higher peak concentrations but more rapid elimination of artesunate and its active metabolite dihydroartemisinin than the rectal route. Rectal artesunate had higher systemic availability in the low-dose group than in the high-dose group (58% versus 23%). This is lower than published estimates of the systemic availability of oral artesunate (61–85%) (36). Parasite clearance kinetics were comparable in the two groups. There were no adverse events attributable to the drug. The results of Phase III and Phase IV studies of rectal artesunate as an alternative to parenteral antimalarial drugs in African children are awaited.

Drug–Drug Interactions

Chloroquine

Although an early report suggested antagonism between chloroquine and artemisinin (37), more recent evidence suggests the opposite, that is a synergistic effect between the two (38,39).

Deferoxamine

Co-administration of artemisinin derivatives, such as artesunate, with deferoxamine may be useful in patients with cerebral malaria, because of the combination of rapid parasite clearance by the former and central nervous system protection by the latter. Artesunate has been studied alone and in combination with deferoxamine in a single-blind comparison (40). Adverse effects were generally mild and there were no differences between the two regimens.

Omeprazole

Artemisinin induces its own elimination and that of omeprazole through an increase in CYP2C19 activity and that of another enzyme, as yet to be identified (41).

Articaine

See also Local anesthetics

General Information

Articaine is an aminoamide that also contains an ester group, which is rapidly hydrolysed by plasma esterases. It is 4-methyl-3([2-(propylamino)propionamido)]-2-thiophenecarboxylic acid, methyl ester hydrochloride. The thiophene group increases its lipid solubility while the ester group enables it to undergo plasma esterase hydrolysis as well as hepatic enzyme metabolism. Articaine is formulated as a 4% solution with adrenaline. It is the most widely used local anesthetic agent in dentistry in some parts of Europe.

The rapid breakdown of articaine to an inactive metabolite means that it has low systemic toxicity. However, the risk of intravascular injection is high in dentistry, and articaine can cause central nervous system and cardiovascular toxicity. However, articaine is slightly more potent than lidocaine and causes less nervous system toxicity (1).

The safety of articaine has been studied in a series of three randomized trials (2). The adverse effects deemed to be related to articaine were headache, paresthesia/hyperesthesia after injection, infection, and rash. There was one case of mouth ulceration. The overall incidence of adverse effects was comparable to that of lidocaine.

Organs and Systems

Cardiovascular

The incidence of hypotension and headache after spinal anesthesia was similar to that encountered with lidocaine (SED-12, 256) (3).

Nervous system

Four cases of persistent lingual paresthesia or hyperesthesia after inferior dental block with articaine have been reported (4). Although resolution of neurological complications usually occurs within 2 weeks, the authors reported that the symptoms in their cases persisted for 6–18 months and noted that they were aware of another four cases of persistent paresthesia with articaine that had not been formally reported.

Skin

- An 11-year-old boy developed severe dermatomyositis only a few days after injection of articaine in the jaw for tooth extraction; cause and effect were not established (SEDA-10, 105).

Artificial sweeteners

General Information

Acesulfame

Acesulfame is an artificial sweetener derived from acetoacetic acid. It is used in a wide range of non-medicinal products (1).

Aspartame

Aspartame is a dipeptide that is used as an artificial sweetener. It is completely hydrolysed in the gastrointestinal tract to methanol, aspartic acid, and phenylalanine (2).

Aspartame appears to be a safe sweetener, and despite numerous studies of its safety during the past three decades, the incidence of serious adverse effects has been difficult to determine in controlled studies. Since one of the metabolic products of aspartame is phenylalanine, excessive use of aspartame should be avoided by patients with phenylketonuria (3–5). Toxicity of another possible metabolic product, methanol, is unlikely, even when aspartame is used in extraordinary amounts (6,7).

Aspartame has reportedly caused angioedema and urticaria (SEDA-21, 526).

Cyclamates

Sodium cyclamate is a potent sweetening agent. It has been subjected to numerous safety and carcinogenicity studies. Animal data led to warning against excessive and indiscriminate use a long time ago, causing the World Health Organization in 1967 to adopt a safety limit of 50 mg/kg. However, in 1982 a joint FAO/WHO expert committee on food additives revised this recommendation to allow for a maximum daily intake of up to 11 mg/kg of sodium or calcium cyclamate (as cyclamic acid) (8). Nevertheless, since in certain climates and populations the amount of cyclamates in soft drinks and other beverages can exceed these limits, more epidemiological data are needed to evaluate, for example, a possible association with cancer of the uropoietic system (9) and with histological and radiological abnormalities of the small intestine and malabsorption (10).

Saccharin

Saccharin and its salts are potent sweeteners, about 300 times as sweet as sucrose. It is used to sweeten foods and beverages.

Sorbitol

Sorbitol, a polyhydric alcohol, is used as a sweetening agent in many oral medicinal liquids. In addition to enhancing the palatability of these liquids, it improves solution stability and reduces crystallization of syrup

© 2006 Elsevier B.V. All rights reserved.

vehicles (11). It is used as a sweetener in many sugar-free food products and confectioneries. Sorbitol-containing food products are often recommended for patients with diabetes, because sorbitol does not raise blood glucose concentrations or require insulin for its metabolism (12).

Organs and Systems

Cardiovascular

Two patients with Raynaud's phenomenon (13) and one man with fibromyalgia had all used aspartame 6–15 g/day (0.12–0.16 mg/kg/day) as well as a dietary drink containing aspartame, and no other risk factors were identified. All three described regular keyboarding to the extent of 30 hours per week but had used wrist rests, "stretch breaks," and other steps to optimize their work practices. Complete resolution of symptoms occurred over 2 weeks after they had eliminated aspartame from the diet, despite no changes in the intensity of keyboarding or other work practices. Nerve conduction velocities had been within normal limits before the withdrawal of aspartame and were not repeated.

Nervous system

Headaches can follow aspartame ingestion (14). Up to July 1991 the FDA had received over 5000 reports of adverse effects in a passive surveillance program; in this and other studies the main complaints were of neurological symptoms, and headaches accounted for 18–45% of cases (15). It appears that some people are particularly susceptible to headaches caused by aspartame and may want to limit their consumption (16). In a double-blind, crossover study using volunteers with self-identified headaches after aspartame, some were particularly susceptible, and their headaches were attributed to aspartame (17).

Aspartame can alter brain wave activity in epileptic children (18). It has been associated with seizures, but only anecdotally (19).

In three non-obese individuals (two women and one man), it was suspected that heavy use of aspartame was causally related to symptoms of carpal tunnel syndrome (20). All three reported moderate pain and tingling in the hands, especially at night, using a self-administered questionnaire for the assessment of severity of symptoms and functional status (21). Given the ubiquity of aspartame—one manufacturer has stated that it is used in 5000 products—physicians may want to inquire about its use in patients who report symptoms of carpal tunnel syndrome.

Psychological, psychiatric

Aspartame has been associated with mood disturbances, but only anecdotally (19).

Gastrointestinal

Sorbitol is slowly absorbed by passive diffusion in the small intestine. After oral administration, it increases osmotic pressure in the bowel by drawing in water, and is thus an osmotic laxative, sometimes leading to diarrhea (22). Bacterial fermentation of sorbitol in the large bowel is associated with increased flatulence and abdominal cramping. Sorbitol 10 g can cause flatulence and bloating, and 20 g abdominal cramps and diarrhea.

Many healthy individuals are intolerant of sorbitol, and develop abdominal cramping and diarrhea with less than the usual laxative dose (23). It has been suggested that more than 30% of healthy adults, irrespective of ethnic origin, cannot tolerate 10 g of sorbitol (24).

Certain other patients are especially sensitive to the gastrointestinal effects of sorbitol; for example, diabetics can be prone to sorbitol intolerance, because of altered gastrointestinal transit time and motility. Some of them also have a higher consumption of sorbitol-containing dietary foods. Patients on chronic hemodialysis can be predisposed to sorbitol intolerance as a result of carbohydrate malabsorption (25).

Kayexalate (sodium polystyrene sulfonate) in sorbitol is commonly used to treat hyperkalemia in patients with renal insufficiency. Case reports have documented intestinal necrosis after the administration of kayexalate in sorbitol (26,27). In one study, there was an incidence of 1.8%, and the authors concluded that sorbitol-associated complications may not be uncommon postoperatively (28). Furthermore, it has been suggested that some cases of idiopathic colonic ulcers in patients with renal failure are due to the effects of sorbitol. While kayexalate crystals, which are purple, irregular, and jagged, can be an incidental finding and are not known to cause injury, they are a helpful histological clue to the possibility that sorbitol has been administered (29).

Five cases of extensive mucosal necrosis and transmural infarction of the colon have been reported after the use of kayexalate and sorbitol enemas to treat hyperkalemia in uremic patients (30). The authors also studied the effects of kayexalate sorbitol enemas in normal and uremic rats and concluded that sorbitol was responsible for colonic damage and that the injury was potentiated in uremic rats. When sorbitol alone or kayexalate sorbitol were given, extensive transmural necrosis developed in 80% of normal rats and in all the uremic rats.

Following reports of colonic necrosis, the Pharmaceutical Affairs Bureau of Japan has revised the product information for enemas of polystyrene sulfonate cation exchange resin suspension in sorbitol solution for potassium removal (31). Although a causal relation has not been established definitively, the Bureau has decided that sorbitol solution should not be used for enemas of sodium polystyrene sulfonate cation exchange resins.

Immunologic

The role of aspartame in hypersensitivity reactions is controversial, although there have been case reports (32). In a multicenter, randomized, double-blind, placebo-controlled, crossover study, aspartame was more likely than placebo to cause urticaria or angioedema (33).

Aspartame can cause granulomatous septal panniculitis (34).

Lobular panniculitis has been described in a 57-year-old diabetic man who ingested large amounts of aspartame as a sweetener, in soft drinks and other

© 2006 Elsevier B.V. All rights reserved.

products. He stopped taking aspartame and the tender subcutaneous nodules disappeared (35).

Long-Term Effects

Tumorigenicity

Acesulfame

The studies on the basis of which acesulfame gained approval showed no evidence in animals of mutagenicity, teratogenicity, or adverse reproductive effects; a 2-year toxicology study in beagles showed no untoward adverse effects. The incidence of lymphocytic leukemia was slightly increased in high-dosed female mice, but not beyond the spontaneous variation with this strain. No other evidence of potential carcinogenicity was obtained, and it has been concluded that at the estimated level of exposure, acesulfame and its metabolites are not a health hazard (36).

Aspartame

It has been suggested that aspartame may be linked to the increase in incidence of brain tumors. Brain tumor incidence increases in the USA occurred in two distinct phases, an early modest increase that may have primarily reflected improved diagnostic technology, and a later-sustained increase in the incidence and shift toward greater malignancy that must be explained by some other factor(s) (37). Evidence potentially implicating aspartame includes an early animal study that showed an exceedingly high incidence of brain tumors in aspartame-fed rats compared with no brain tumors in concurrent controls, the finding that aspartame has mutagenic potential, and the close temporal association (aspartame was introduced into US food and beverage markets several years prior to the sharp increase in brain tumor incidence and malignancy). The authors concluded that the carcinogenic potential of aspartame needs to be reassessed.

Saccharin

Saccharin has been considered to be a possible human carcinogen on the basis of animal experiments. This suspicion has now been discredited. There is no evidence that people with diabetes, who consume larger quantities of saccharin than non-diabetics, are at greater risk of developing bladder cancer (38) or other malignancies. However, in the USA, saccharin-containing medicines are required to carry the following warning: "Use of this product may be hazardous to your health. This product contains saccharin which has been determined to cause cancer in laboratory animals" (39).

Susceptibility Factors

Individuals with mood disorders are thought to be particularly sensitive to aspartame, and it has been suggested that its use in such patients should be discouraged (40).

Asclepiadaceae

See also Herbal medicines

General Information

The genera in the family of Asclepiadaceae (Table 1) include milkweed and periploca.

Asclepias tuberosa

Asclepias tuberosa (pleurisy root) contains cardenolides such as uzarigenin, coroglaucigenin, and corotoxigenin, the coumarins isorhamnetin, kaempferol, quercetin, and rutin, the steroid sitosterol, and the triterpenoids amyrin, friedelin, and lupeol.

Table 1 The genera of Asclepiadaceae

Araujia (araujia)
Asclepias (milkweed)
Calotropis (calotropis)
Cryptostegia (rubbervine)
Cynanchum (swallow-wort)
Funastrum (twinevine)
Gonolobus (gonolobus)
Hoya (hoya)
Marsdenia (marsdenia)
Matelea (milkvine)
Metaplexis (metaplexis)
Morrenia (morrenia)
Oxypetalum (oxypetalum)
Periploca (periploca)
Stapelia (stapelia)
Xysmalobium (xysmalobium)

Adverse effects

Because it contains cardenolides, *Asclepias* can have digitalis-like effects and potentiate digitalis toxicity (See monograph on Cardiac glycosides). Interference with assays of plasma digoxin concentrations is also possible (1).

Xysmalobium undulatum

Xysmalobium undulatum (xysmalobium) contains the cardiac glycoside ascleposide. It has been used topically to treat wounds (2). Its adverse effects are likely to be those of other cardiac glycosides (see monograph on Cardiac glycosides).

Ascorbic acid (vitamin C)

See also Vitamins

General Information

The Average Requirement of ascorbic acid is 30 mg/day. The Population Reference Intake is 45 mg/day for adults. The Lowest Threshold Intake, for which considerable evidence exists, is 12 mg/day (1). These estimates have been supported by the relevant committee of the European Union. A communication from the US National Academy of Sciences, as part of the revision of US Dietary Reference Intakes, while estimating rather higher average requirements of ascorbic acid than the EU committee, does (100 mg/day) also proposed a "tolerable upper intake

© 2006 Elsevier B.V. All rights reserved.

level" of less than 1 g of ascorbic acid/day (2). "Normal" plasma ascorbic acid concentrations are 60–80 μmol/l (2).

In spite of the lack of unequivocal evidence of a beneficial effect of large doses of ascorbic acid for preventing or treating the common cold, the use of ascorbic acid for this indication is still widespread.

The adverse effects of high-dose ascorbic acid have been reviewed in the context of its pharmacokinetics (3). Pharmacokinetic analysis shows that there is no justification for the use of megadoses of ascorbic acid (4). The body goes to great lengths to avoid excess accumulation of vitamin C, and has at least three ways of accomplishing this. First, absorption of vitamin C from the gut is highly saturable, ensuring that the amount that is absorbed reaches a maximum at relatively low doses. Secondly, the kidney rapidly excretes vitamin C, because its reabsorption from the renal tubules after filtration by the renal glomerulus is also highly saturable. Virtually all the vitamin C that is absorbed from the gut is thus excreted in the urine. For example, when the daily dose is increased from 200 to 2500 mg (from 1.1 to 14 mmol) the mean steady-state plasma concentration increases only from about 12–15 mg/l (from 68 to 85 mol/l)—no matter how high a dose of vitamin C you take orally there is a limit to the plasma concentration that can be reached. Thirdly, tissue uptake is also saturable. An increase in plasma concentration of vitamin C is not associated with a parallel increase in tissue concentration (5). Indeed, the tissue vitamin C concentration, measured in leukocytes, saturates at 100 mg/day (6) or plasma concentrations of 14 μg/ml (80 mol/l) (5). So no matter how much you take, all you do is increase the concentrations in your urine and gut, and that can cause adverse effects (7). Vitamin C is partly excreted as oxalate, and very high doses can lead to hyperoxaluria and kidney stones (8), particularly after intravenous use and in people with renal insufficiency. Adverse effects in the gut include nausea, abdominal cramps, and diarrhea (9).

General adverse effects

Hot flushes, headache, fatigue, insomnia, nausea, vomiting, and diarrhea have been observed with large doses, but it is difficult to tell to what extent these are real rather than placebo effects. The best evidence of problems caused by high doses relates to stone formation, mainly in patients with chronic renal insufficiency. Certain hematological and metabolic effects have been reported in premature infants; however, these have not been corroborated (10). Several cases of hemolysis have been reported. Respiratory and cutaneous allergies to ascorbic acid have been described (11). Tumor-inducing effects have not been reported.

Organs and Systems

Respiratory

Ascorbic acid 3 g/day for 6 days causes a significant loss of high altitude resistance, persisting for 2 weeks after withdrawal of treatment. High doses may therefore constitute a risk in people who take them under conditions in which the oxygen supply suddenly becomes impaired, and is also undesirable in people with pathological hypoxia, for example due to respiratory diseases (12).

A trial in 868 children showed that in those with high plasma ascorbic acid concentrations, the duration of upper respiratory infection was greater than in those with low concentrations (13). This finding, which contrasted with the optimistic expectations of other workers, requires confirmation.

Metabolism

Dehydroascorbic acid appears to have a diabetogenic effect and ascorbic acid causes increased excretion of glucose. High ascorbic acid concentrations can delay the insulin response to a glucose challenge and prolong postprandial hyperglycemia (14).

An increase in serum cholesterol has been reported in patients with atherosclerosis taking high doses of ascorbic acid (9).

Metal metabolism

Binding of zinc and copper by high doses of ascorbic acid has been reported (9).

Hematologic

Under experimental conditions, ascorbic acid 5 g/day increased the lytic sensitivity of erythrocytes to hydrogen peroxide (15). Similar doses, given with mandelamine or antibiotics, lower urinary pH and have a small effect on blood pH; in patients with sickle-cell anemia such doses can precipitate a crisis (9). The erythrocytes of premature infants can be damaged by ascorbic acid (SEDA-14, 332); reduced glutathione concentrations and increased Heinz-body formation have been seen (16). Possible explanations may be higher glucose consumption and increased glycolytic enzyme activities compared with erythrocytes in adults, accompanied by increased sensitivity to hemolysis (17).

Also at risk of hemolysis are patients with glucose-6-phosphate dehydrogenase deficiency, in whom ascorbic acid can denature hemoglobin and reduce erythrocyte glutathione concentrations; one such case proved fatal (18). This was further demonstrated by reports of hemolytic effects (19); in two young subjects with glucose-6-phosphate dehydrogenase deficiency hemolysis was induced by excessive intake of "fizzy drinks" fortified with ascorbic acid (20).

Gastrointestinal

Nausea, abdominal cramps, and diarrhea are not uncommon (9). In runners taking daily doses of 1 g of ascorbic acid for reduction of musculoskeletal symptoms, mild diarrhea is common (21). Ascorbic acid stones have been found to obstruct the ileocecal valve (22).

Urinary tract

Ascorbic acid 4 g/day increases uric acid clearance in volunteers (23), although it does not reduce protein-bound uric acid in blood. Ascorbic acid 4–12 g/day causes acidification of the urine, which can cause precipitation of urate and cystine and consequently formation of urate stones or cystinuria. Ascorbic acid is excreted largely as oxalate, and hyperoxaluria results when large doses are

© 2006 Elsevier B.V. All rights reserved.

taken. In patients with pre-existing oxalosis, gram doses of ascorbic acid further increase oxalate excretion (9,24).

Whether this increased oxalate excretion has consequences in terms of stone formation depends very much on the dosage and duration of treatment. In a small study in healthy individuals short-term, high-dose ascorbic acid (4 g in 5 days) did not affect the risk factors associated with calcium oxalate kidney stone formation (8). A prospective study of the association between doses of pyridoxine and ascorbic acid and the risk of symptomatic kidney stones was undertaken in a large cohort of US nurses. Ascorbic acid was not associated with a higher risk of stone formation (25).

In a study to determine the biochemical and physicochemical risks of high doses of ascorbic acid a man with no history of nephrolithiasis took ascorbic acid 2 g qds while following his normal diet (26). The study was planned to last 9 days. However, he developed significant hematuria on the eighth day. Urinary oxalate and ascorbic acid concentrations were increased. The intestinal absorption of ascorbic acid falls from almost 100% at normal doses to 20% at a dose of 5 g/day (27), and the high concentrations of ascorbic acid in this study suggest that, irrespective of the quantity converted to oxalate, at least 35% of the ingested ascorbic acid had been absorbed. The relative supersaturation of oxalate and the Tiselius risk index both increased. Increases in the calcium oxalate relative supersaturation (28) and Tiselius index (29) are powerful physicochemical indicators of increases in the crystal-forming potential of the urine. In this case the increases in both measures were impressively substantiated by scanning electron microscopy, which showed large crystals and crystal aggregates in the urine. The authors suggested that the passage of these crystals caused irritation and epithelial injury manifesting as hematuria.

Oxalate-induced renal damage has been related to excessive doses of ascorbic acid (30).

- A 31-year-old man developed a headache, nausea, and vomiting. He had taken ascorbic acid, 2–2.5 g/day and before the onset of symptoms up to 5 g/day. He had a raised serum creatinine (1000 μmol/l). Renal ultrasound showed increased cortical echogenicity, and a renal biopsy showed acute tubular necrosis and massive oxalate deposition. He was given pyridoxine and two sessions of hemodialysis.

Various forms of renal damage, notably tubulointerstitial nephropathy, have been associated with long-term use of high dosages of ascorbic acid, for example 3 g/day (31).

Skin

Cutaneous allergy has been described with ascorbic acid (11).

Contact dermatitis has been attributed to ascorbic acid in a cosmetic anti-ageing cream (32).

- A 47-year-old woman developed eczema of the face, consisting initially of edematous lesions on the eyelids and then spreading to the rest of the face and the folds of the neck. Patch tests to a cosmetic cream she had used before the start of the eczema (Active C dry skin, La Roche Posay Laboratory) gave positive results (++D2 and D3). Subsequent patch tests with the ingredients showed positive results only to ascorbic acid. Oral provocation tests with ascorbic acid 50–2000 mg were negative. Withdrawal of the cream resulted in complete healing of the eczema without relapse over 6 months.

Musculoskeletal

In animal experiments, high doses of ascorbic acid adversely influenced skeleton stability. In chicks, supplementary ascorbic acid 220 mg/kg in the food increased mobilization of calcium and phosphate from the skeleton, as demonstrated by ^{45}Ca studies and determination of acid phosphatase activity in plasma. Increased ascorbic acid also resulted in increased oxygen consumption and decreased lactic acid production by cultured chick tibiae; in growing swine, large doses (about 1 g/day for 32 days) led to a significant increase in the excretion rate of hydroxyproline, indicating an increased rate of collagen breakdown (SED-8, 803) (33). The relevance of these old findings to humans has never been confirmed.

Immunologic

As noted above, ascorbic acid can sometimes cause immune reactions. Ascorbic acid and citric acid are used as food additives, ascorbic acid (E300) as an acidifier, an antioxidant, and an additive in wheat, and citric acid as an acidifying complex-binding agent. Because additives are widely used in foods, beverages, and drugs, people with allergies or intolerance have to be carefully instructed. Caution must also be taken when scratch tests are performed with these substances (34).

- A 62-year-old man had frequent angioedema, and a scratch test was performed with several food additives. Scratching with 1% ascorbic acid and 1% citric acid in vaseline resulted in a +3 reaction, and 20 minutes later he developed angioedema with swelling of the glottis, reddening of the face and hands, itching, vertigo, tachycardia, and hypotension. He was given a glucocorticoid and an antihistamine and recovered within half an hour.

Second-Generation Effects

Fertility

Earlier evidence that ascorbic acid in gram doses might reduce fertility was disputed; however, a case of sterility apparently due to ascorbic acid has been described (9).

Teratogenicity

Animal teratological evidence is not entirely uniform, but very high doses in rats and mice have been given without deleterious effects on the fetus (35).

Susceptibility Factors

Genetic factors

Patients with idiopathic (genetic) hemochromatosis constitute a risk group with regard to ingestion of large doses of ascorbic acid, which can lead to deterioration in cardiac function (36).

© 2006 Elsevier B.V. All rights reserved.

Age

An esophageal stricture, with ulceration, inflammation, and fibrosis, has been reported in an elderly patient who had taken ascorbic acid for 2 months (37). A 500 mg tablet of ascorbic acid dissolves only slowly and is in vitro associated with a shift in saliva pH from 6.2 to 2.8. Since elderly individuals usually have less frequent esophageal contractions, it is not uncommon for this group to have a capsule lodged for a time in the esophagus (SEDA-13, 348) and it is entirely possible that cases like the above are more frequent than previously thought.

Renal disease

The use of ascorbic acid in patients with renal insufficiency should be carefully monitored to avoid accelerated development of secondary oxalosis; hyperoxalemia has been reported to be aggravated by ascorbic acid supplementation in regular hemodialysis patients (38). The pharmacological mechanism has been clarified in animal experiments (SEDA-15, 414) (39).

Other features of the patient

Ascorbic acid has been thought to precipitate widespread tumor hemorrhage and necrosis with disastrous consequences in patients with very rapidly proliferating and widely disseminating tumors. These observations suggest that ascorbic acid should be prescribed with extreme caution for persons with advanced cancer (40).

Drug–Drug Interactions

Amphetamines

Decreased renal tubular reabsorption of amphetamines can be caused by ascorbic acid (40).

Aspirin

Enhanced drug crystalluria with aspirin can be caused by ascorbic acid (40).

Fluphenazine

Ascorbic acid may lower serum fluphenazine concentrations by liver enzyme induction and by interference with absorption (41).

Iron

Ascorbic acid promotes the absorption of iron, a reason for caution in giving high doses to patients with iron overload (SEDA-9, 324). In particular, patients with hemochromatosis, polycythemia, and leukemia who present with marked iron overload should keep their intake of ascorbic acid to a minimum (42). However, ascorbic acid can also interfere with the distribution of iron in the body in these patients. One consequence is that in patients with iron overload who also have scurvy, iron tends to be deposited in the reticuloendothelial system rather than the parenchymal cells, which may reduce the risks of damage to the liver, heart, or endocrine glands. It has conversely been noted that in beta-thalassemia major with iron overload, ascorbic acid can be associated with deterioration in cardiac function (43).

Isoprenaline

Ascorbic acid in large doses (5 g/day) reduces the chronotropic effect of isoprenaline (44).

Oral anticoagulants

The effect of ascorbate in reducing prothrombin time is potentially dangerous during oral anticoagulant therapy. In one patient taking dicoumarol the prothrombin time fell from 19 seconds to normal values after intake of ascorbic acid. A similar effect was noted in a patient with thrombophlebitis given ascorbic acid 16 g/day (9). Earlier data suggested that even doses of 200 mg may have resulted in a slight increase in mortality from thromboembolism in patients in a geriatric unit (45).

Tricyclic antidepressants

Decreased renal tubular reabsorption of tricyclic antidepressants can be caused by ascorbic acid (40).

Vitamin B_{12}

Because ascorbic acid in the gastrointestinal tract can reduce the vitamin B_{12} content of food, patients with vitamin B_{12} deficiency should always be questioned about their intake of ascorbic acid (40).

Interference with Diagnostic Tests

Tests for plasma ethinylestradiol concentrations

Plasma ethinylestradiol concentrations increase when it is taken with ascorbic acid. This interaction is of significance in women taking oral contraceptives (SEDA-6, 328).

Tests for urinary glucose

The presence of high concentrations of ascorbic acid in the urine can interfere with tests for urinary glucose. With concentrations as low as 200 μg/ml, tests performed with glucose oxidase paper can be inhibited, giving a false negative result (46).

Ascorbic acid can also result in false positive tests for glucose in urine (Benedict's test, Clinitest) and blood. Any reports of glycosuria or hyperglycemia in patients taking ascorbic acid must therefore be regarded with suspicion unless a specific (for example chromatographic) test for glucose has been performed (9).

Tests for occult blood

There were false negative tests for occult blood after the ingestion of moderately high doses of ascorbic acid (250 mg) (47). Quantities in excess of this are excreted and can affect tests for occult gastric or stool blood (7,48,49). Lack of ascorbic acid can, because of its effect on iron distribution, alter laboratory indices for iron overload, causing the plasma iron or ferritin levels (or the degree of iron excretion after a challenge with deferoxamine) to be considerably less than the degree of

© 2006 Elsevier B.V. All rights reserved.

severity of iron overload that would normally lead one to expect (50).

Tests for serum enzymes

Ascorbic acid interferes with the autoanalyser determination of serum transaminases and lactic dehydrogenase (7,9). Serum bilirubin concentrations may be reduced by ascorbic acid, so that the presence of liver disease may be masked (9).

Asparaginase

See also Cytostatic and immunosuppressant drugs

General Information

Asparaginase is an enzyme that acts by breaking down the amino acid L-asparagine to aspartic acid and ammonia. It interferes with the growth of malignant cells that cannot synthesize L-asparagine. Its action is reportedly specific for the G_1 phase of the cell cycle. It is used mainly for the induction of remissions in acute lymphoblastic leukemia.

Nomenclature

Colaspase and crisantaspase are the British Approved Names of asparaginase obtained from cultures of *Escherichia coli* and *Erwinia carotovora* respectively.

Organs and Systems

Nervous system

In a review of 28 central nervous system thrombotic or hemorrhagic events and eight peripheral thromboses related to L-asparaginase, the median time from initial treatment to adverse reaction was 16–17 days (1). Most patients recovered completely, although five cases had residual neurological deficits and one died from superior sagittal sinus thrombosis. Five patients with cerebral thrombosis complicating asparaginase/prednisone/vincristine induction therapy for acute lymphoblastic leukemia were found to have a reduced platelet count after the event and, in three of them, sequential changes in von Willebrand factor multimer pattern (2). The other two patients were only studied at presentation and their multimer pattern was not appreciably different to pooled plasma from seven controls without thromboses. The findings were consistent with thrombotic complications caused by platelet agglutination by plasma Von Willebrand factor.

Metabolism

Asparaginase can reduce insulin production (3) and precipitate diabetic ketoacidosis (4,5).

Hematologic

Thrombosis and hemorrhage are well-recognized complications in 1–2% of patients receiving asparaginase. This is due to a coagulopathy, which has been variously attributed to reduced concentrations of fibrinogen, factors IX, XI, VIII complex, antithrombin III, and plasminogen (6).

In one study, 12 children in complete remission treated with daily asparaginase alone were investigated for platelet and clotting abnormalities (7). Changes in prothrombin time, partial thromboplastin time, and fibrinogen remained close to the reference range, and platelet function was normal. There were reduced concentrations of physiological inhibitors of coagulation (protein C and antithrombin III). Thrombosis was uncommon. These results are consistent with those of another study of asparaginase as a single agent in 14 children with acute lymphoblastic leukemia (8). There was severe deficiency of antithrombin III and protein C, with co-existing hypocoagulability; equilibrium between the two partly explained the lack of thromboembolic phenomena. The hypocoagulability was due to hypofibrinogenemia and reduced concentrations of vitamin K-dependent factors.

Three patients developed bilateral venous sinus thromboses after receiving asparaginase; the diagnosis and follow-up of this complication have been succinctly reviewed (9). In another patient receiving asparaginase, central nervous system thrombosis was associated with a transient acquired type II pattern of von Willebrand's disease (10).

Mouth and teeth

Acute parotitis has been attributed to L–asparaginase in association with hyperglycemia (11).

Liver

Most patients who receive asparaginase develop liver function abnormalities, which can be fatal (12). This adverse effect is of major concern in patients who are also taking other hepatotoxic drugs, such as methotrexate and mercaptopurine. Jaundice and increased serum bilirubin and transaminases occur often, and hepatomegaly and fatty deposits occur occasionally.

Pancreas

Pancreatitis has been reported in up to 16% of children receiving asparaginase for a variety of neoplasms (13). Pseudocyst formation has been described (14).

Immunologic

Asparaginase can cause allergic reactions (15), which increase with the number of doses within a cycle and the number of exposures, irrespective of drug-free intervals. There is a pegylated formulation (PEG-ASNase; Oncaspar™) with a prolonged half-life and different allergenic properties from conventional asparaginase-containing formulations. These claims have been investigated, and the authors concluded that although the hypersensitivity rate was

© 2006 Elsevier B.V. All rights reserved.

lower, it was still significant; furthermore, there was no cross-sensitivity in previously treated patients (16). There were no allergic reactions to pegylated asparaginase compared with 30% with non-pegylated asparaginase in 70 children with acute lymphoblastic leukemia or non-Hodgkin's lymphoma, and other toxic effects were also less common (17).

Astemizole

See also Antihistamines

General Information

Astemizole is a second-generation antihistamine that has been withdrawn from the market because of the association with life-threatening cardiac arrhythmias.

Organs and Systems

Cardiovascular

Astemizole is metabolized by CYP3A4 to desmethylastemizole and norastemizole, although these metabolites may not be free of the potential to prolong the QT interval.

- A 77-year-old woman with QT interval prolongation and torsade de pointes had been taking astemizole 10 mg/day for 6 months (1). She had markedly raised plasma concentrations of astemizole and was also taking cimetidine.

However, cardiac dysrhythmias in patients taking antihistamines may be related to other factors, and in this case the patient was also taking another antihistamine and had a history of hepatitis.

Nervous system

The incidence of sedation with astemizole has been reported to be similar to placebo in most studies (2–4) (SEDA-14, 136) (SEDA-18, 183).

Skin

PLEVA (pityriasis lichenoides et varioliformis) has been convincingly ascribed to astemizole by reappearance after rechallenge (SEDA-18, 4).

Stevens–Johnson syndrome has been reported with astemizole (SEDA-20, 162).

Drug Administration

Drug overdose

Two cases of overdosage with astemizole (200 mg in a 2-year-old child and 200 mg in a 16-year-old girl) were associated with cardiovascular complications (5). The

© 2006 Elsevier B.V. All rights reserved.

authors recommended that patients should be observed for at least 24 hours after overdosage with astemizole.

Asteraceae

See also Herbal medicines

General Information

The genera in the family of Asteraceae (Table 1) (formerly Compositae) include various types of asters (daisies), arnica, chamomile, goldeneye, marigold, snakeroot, tansy, thistle, and wormwood.

Table 1 The genera of Asteraceae

Acamptopappus (goldenhead)
Acanthospermum (starburr)
Achillea (yarrow)
Achyrachaena (blow wives)
Acmella (spotflower)
Acourtia (desert peony)
Acroptilon (hard heads)
Adenocaulon (trail plant)
Adenostemma (medicine plant)
Adenophyllum (dogweed)
Ageratum (whiteweed)
Ageratina (snakeroot)
Agoseris (agoseris)
Almut aster (alkali marsh aster)
Amberboa (amberboa)
Amblyolepis (amblyolepis)
Amblyopappus (amblyopappus)
Ambrosia (ragweed)
Ampel aster (climbing aster)
Amphipappus (chaffbush)
Amphiachyris (broomweed)
Anacylus (anacylus)
Anaphalis (pearly everlasting)
Ancistrocarphus (nest straw)
Anisocoma (anisocoma)
Antennaria (pussytoes)
Anthemis (chamomile)
Antheropeas (e aster bonnets)
Aphanostephus (doze daisy)
Arctium (burrdock)
Arctotheca (capeweed)
Arctotis (arctotis)
Argyroxiphium (silver sword)
Argyranthemum (dill daisy)
Argyrautia (arhyrautia)
Arnica (arnica)
Arnoglossum (Indian plaintain)
Arnoseris (arnoseris)
Artemisia (sagebrush, wormwood)
Asanthus (brickell bush)
Aster (aster)
Astranthium (western daisy)
Atrichoseris (atrichoseris)
Baccharis (baccharis)
Bahia (bahia)
Baileya (desert marigold)
Balduina (honeycombhead)
Balsamorhiza (balsam root)

Yermo (desert yellowhead)
Youngia (youngia)
Zinnia (zinnia)

Delayed hypersensitivity reactions to the Asteraceae (Compositae) can arise from sesquiterpene lactones. To detect contact allergy to sesquiterpene lactones, a mixture of lactones (alantolactone, costunolide, and dehydrocostus lactone) is used. However, Compositae contain other sensitizers, such as polyacetylenes and thiophenes. In a prospective study, the lactone mixture was complemented with a mixture of Compositae (containing ether extracts of arnica, German chamomile, yarrow, tansy, and feverfew) to detect contact allergy to Compositae (1). Of 346 patients tested, 15 (4.3%) reacted to the mixture of Compositae, compared with eight of 1076 patients (0.7%) who gave positive results with the lactone mixture, indicating the importance of the addition of Compositae allergens to the lactone mixture. However, the authors warned that patch-testing with these mixtures can cause active sensitization.

- Compositae dermatitis occurred in a 9-year-old boy with a strong personal and family history of atopy. Positive patch test reactions were 2+ for dandelion (*Taraxacum officinale*), false ragweed (*Ambrosia acanthicarpa*), giant ragweed (*Ambrosia trifida*), short ragweed (*Ambrosia artemisifolia*), sagebrush (*Artemisia tridentata*), wild feverfew (*Parthenium hysterophorus*), yarrow (*Achillea millifolium*), and tansy (*Tanacetum vulgare*), and 1+ for *Dahlia* species and English ivy (*Hedera helix*) (2). Patch tests were negative for another 30 plants, including cocklebur (*Xanthium strumarium*), dog fennel (*Anthemis cotula*), fleabane (*Erigeron strigosus*), sneezeweed (*Helenium autumnale*), and feverfew (*Tanacetum parthenium*).

An Austrian study has re-confirmed the importance of testing with not only a mixture of Compositae and a mixture of sesquiterpene lactones, but also with additional plant extracts when there is continuing clinical suspicion of allergy to one of the Compositae (3). By using additional short ether extracts, the authors found two of five patients who had otherwise been overlooked.

Achillea millefolium

Achillea millefolium (yarrow) can cause contact dermatitis (4); a generalized eruption following the drinking of yarrow tea has also been reported (5).

- A female florist from North Germany, who ran a flower shop from 1954 to 1966 had to quit her job because of contact allergy to chrysanthemums and primrose. After a further 12 years she started to suffer occasionally from redness of the pharynx and stomachache after drinking tea prepared from yarrow and camomile. Skin tests were positive to chrysanthemum with cross-reactions to sunflower, arnica, camomile,

© 2006 Elsevier B.V. All rights reserved.

yarrow, tansy, mugwort, and frullania (a lichen that does not occur in the Northern part of Germany). Patch-testing with primin showed high-grade hypersensitivity to Primula.

A. millefolium contains sesquiterpene lactones, polyacetylenes, coumarins, and flavonoids. Extracts have often been used in cosmetics in concentrations of 0.5–10%. *A. millefolium* was weakly genotoxic in *Drosophila melanogaster*. In provocative testing, patients reacted to a mix of *Compositae* that contained yarrow, as well as to yarrow itself. In clinical use, a formulation containing a 0.1% extract was not a sensitizer and alcoholic extracts of the dried leaves and stalks of the flower were not phototoxic (6). However, positive patch tests to *A. millefolium* have been reported (7).

Anthemis species and *Matricaria recutita* (chamomile)

Chamomile is the vernacular name of *Anthemis* genus and *Matricaria recutita* (German chamomile, pinhead). The former are more potent skin sensitizers (delayed-type) than the latter, presumably because they can contain a higher concentration of the sesquiterpene lactone, anthecotullid. Cross-sensitivity with related allergenic sesquiterpene lactones in other plants is possible.

Adverse effects

Internal use of chamomile tea has been associated with rare cases of anaphylactic reactions (8) and its use in eyewashes can cause allergic conjunctivitis (9).

Arnica montana

Arnica montana (arnica) contains a variety of terpenoids and has mostly been used in the treatment of sprains and bruises but is also used in cosmetics.

Ingestion of tea prepared from *Arnica montana* flowers can result in gastroenteritis reference.

- A 27-year-old woman presented with a rapidly enlarging necrotic lesion on her face and left leg together with malaise and high fever (10). She reported that she had applied a 1.5% arnica cream to her face before these symptoms had occurred. The diagnosis was Sweet's syndrome elicited by pathergy to arnica. She was treated with prednisolone and her skin lesions disappeared within 3 weeks.

Of 443 individuals who were tested for contact sensitization, 5 had a positive reaction to *A. montana* and 9 to *Calendula officinalis* (marigold); a mixture of the two was positive in 18 cases (3). Sensitization was often accompanied by reactions to nickel, *Myroxylon pereirae* resin, fragrance mix, propolis, and colophon.

Artemisia species

There are about 60 different species of Artemisia, of which the principal are *Artemisia absinthium*, *Artemisia annua*, *Artemisia cina*, and *Artemisia vulgaris*.

Artemisia absinthium

The volatile oil of *A. absinthium* (wormwood), which gives the alcoholic liqueur absinthe its flavor, can damage the nervous system and cause mental deterioration. This toxicity is attributed to thujones (alpha-thujone and beta-thujone), which constitute 0.25–1.32% in the whole herb and 3–12% of the oil. Alcoholic extracts and the essential oil are forbidden in most countries.

Artemisia annua

Artemisia annua, known in China as Qinghaosu, contains artemisinin, which has antimalarial activity. Several derivatives of the original compound have proved effective in the treatment of *Plasmodium falciparum* malaria and are currently available in a variety of formulations: artesunate (intravenous, rectal, oral), artelinate (oral), artemisinin (intravenous, rectal, oral), dihydroartemisinin (oral), artemether (intravenous, oral, rectal), and artemotil (intravenous). Artemisinic acid (qinghao acid), the precursor of artemisin, is present in the plant in a concentration up to 10 times that of artemisinin. Several semisynthetic derivatives have been developed from dihydroartemisinin (11). The artemisinin derivatives are the subject of a separate monograph.

Artemisia cina

Artemisia cina (wormseed) contains the toxic lactone, santonin, which was formerly used as an antihelminthic drug, but has now been superseded by other less toxic compounds.

Artemisia vulgaris

Artemisia vulgaris (common wormwood) contains the toxic lactone, santonin, which was formerly used as an antihelminthic drug, but has now been superseded by other less toxic compounds. Depending on the origin of the plant, 1,8-cineole, camphor, linalool, and thujone may all be major components. Allergic skin reactions (12) and abortive activity have been described.

Calendula officinalis

Calendula officinalis (marigold) contains a variety of carotenoids, saponins, steroids, sesquiterpenoids, and triterpenoids.

Of 443 individuals who were tested for contact sensitization, five had a positive reaction to *A. montana* and nine to *C. officinalis*; a mixture of the two was positive in 18 cases (3). Sensitization was often accompanied by reactions to nickel, *Myroxylon pereirae* resin, fragrance mix, propolis, and colophon.

Callilepis laureola

Callilepis laureola (impila, ox-eye daisy) contains the toxic compound atractyloside and related compounds. The plant is responsible for the deaths of many Zulu people in Natal, who use its roots as a herbal medicine.

Adverse effects

Necropsy records of 50 children who had taken herbal medicines made from *C. laureola* showed typical hepatic and renal tubular necrosis (13). In young Black children the plant causes hypoglycaemia, altered consciousness,

© 2006 Elsevier B.V. All rights reserved.

and hepatic and renal dysfunction. This syndrome can be hard to distinguish from Reye's syndrome.

Acute renal insufficiency has been attributed to *C. laureola* (14).

Chrysanthemum vulgaris

Chrysanthemum vulgaris (common tansy) contains essential oils and thujone in such amounts that even normal doses can be neurotoxic (15).

Cynara scolymus

Cynara scolymus (artichoke) contains a variety of flavonoids, phenols, and sesquiterpenoids, including cynarapicrin, cynaratriol, cynarolide, and isoamberboin. It has been used to lower serum cholesterol, with little evidence of efficacy (16).

Adverse effects

Two vegetable warehouse workers developed occupational rhinitis and bronchial asthma by sensitization to *C. scolymus* (17). Skin prick tests to artichoke were positive and IgE specific for artichoke was found. Nasal challenge with artichoke extract triggered a reduction in peak nasal inspiratory flow of 81 and 85%. One patient had a reduction in peak expiratory flow rate of up to 36% after exposure to artichoke in the workplace.

Allergic contact dermatitis (18) and occupational contact urticaria (19) have also been reported.

Echinacea species

Echinacea species (coneflower, black Sampson hedgehog, Indian head, snakeroot, red sunflower, scurvy root) have become increasingly popular, particularly for the prophylaxis and treatment and prevention of cold and flu symptoms. However, the claimed efficacy of *Echinacea* in the common cold has not been confirmed in a randomized, double-blind, placebo-controlled trial (20) or a systematic review (21). *Echinacea* is claimed to have antiseptic and antiviral properties and is under investigation for its immunostimulant action. The active ingredients are glycosides (echinacoside), polysaccharides, alkamides, and flavonoids.

Adverse effects

Between July 1996 and November 1998, the Australian Adverse Drug Reactions Advisory Committee received 37 reports of suspected adverse drug reactions in association with *Echinacea* (22). Over half of these ($n = 21$) described allergic-like effects, including bronchospasm ($n = 9$), dyspnea ($n = 8$), urticaria ($n = 5$), chest pain ($n = 4$), and angioedema ($n = 3$). The 21 patients were aged 3–58 (median 31) years and 12 had a history of asthma ($n = 7$) and/or allergic rhinitis/conjuctivitis/hayfever ($n = 5$). *Echinacea* was the only suspected cause in 19 of the 21 cases. The symptoms began at variable times, within 10 minutes of the first dose to a few months, and all but two cases occurred within 3 days of starting treatment. At the time of reporting 17 of the patients had recovered, 2 had not yet recovered, and the outcome was unknown in the other two cases.

Hematologic

Possible leukopenia has been associated with long-term use of *Echinacea* (23).

Skin

Recurrent erythema nodosum has been attributed to *Echinacea*.

- A 41-year-old man, who had taken *Echinacea* intermittently for the previous 18 months, had four episodes of erythema nodosum, preceded by myalgia and arthralgia, fever, headache, and malaise (24). The skin lesions resolved within 2–5 weeks and responded to oral prednisolone. He was advised to discontinue *Echinacea* and 1 year later remained free from further recurrence.

Immunologic

Intravenous administration of *Echinacea* has been associated with severe allergic reactions. Oral ingestion can cause allergic skin and respiratory responses (25).

Five cases of adverse drug reactions have been attributed to oral *Echinacea* extracts (26). Two of the patients had anaphylaxis and one had an acute attack of asthma. The authors also tested 100 atopic subjects and found that 20 of them, who had never before taken *Echinacea*, had positive reactions to skin prick tests.

An anaphylactic reaction to *Echinacea angustifolia* has been reported (27).

- A 37-year-old woman who took various food supplements on an irregular basis self-medicated with 5 ml of an extract of *E. angustifolia*. She had immediate burning of the mouth and throat followed by tightness of the chest, generalized urticaria, and diarrhea. She made a full recovery within 2 hours.

The basis for this anaphylactic reaction was hypersensitivity to *Echinacea*, confirmed by skin prick and RAST testing. However, others have challenged the notion of a causal relation in this case (28). Nevertheless, the author affirmed his belief that *Echinacea* was the causal agent and reported that at that time *Echinacea* accounted for 22 of 266 suspected adverse reactions to complementary medicines reported to the Australian Adverse Drug Reaction Advisory Committee (28).

Sjögren's syndrome has been attributed to *Echinacea* (29).

Teratogenicity

Of 412 pregnant Canadian women who contacted a specialized information service between 1996 and 1998 with concerns about the use of *Echinacea* during pregnancy, 206 had already taken the remedy and the other 206 eventually decided not to use it (30). In the *Echinacea* group, 54% had taken it during the first trimester of pregnancy; 12 babies had malformations, six major and six minor. The figures in the control group were seven and seven respectively. Thus, there was no difference in the incidence of birth defects. However, the study lacked sufficient power to generate reliable data.

Eupatorium species

Several *Eupatorium* species, such as *Eupatorium cannabinum* (hemp agrimony) and *Eupatorium purpureum*

© 2006 Elsevier B.V. All rights reserved.

(gravel root), have hepatotoxic potential due to the presence of pyrrolizidine alkaloids, which are covered in a separate monograph.

There is no evidence of pyrrolizidine alkaloids in *Eupatorium rugosum* (white snakeroot) but this plant also has poisonous properties, which are attributed to an unstable toxin called tremetol. Transfer from cow's milk to humans can produce a condition known as milk sickness, including trembles, weakness, nausea and vomiting, prostration, delirium, and even death.

Inula helenium

Large doses of the root of *Inula helenium* (elecampane) can cause vomiting, diarrhea, cramps, and paralytic symptoms.

Petasites species

Petasites species have hepatotoxic potential, owing to the presence of pyrrolizidine alkaloids, which are covered in a separate monograph. Extracts of *Petasites hybridus* (blatterdock, bog rhubarb, butterbur, butterdock) contain little in the way of these alkaloids (31). Butterbur has been used to treat allergic rhinitis and asthma and in the prevention of migraine.

Senecio species

Many species of *Senecio*, such as *Senecio jacobaea* (ragwort) and *Senecio longilobus* (thread leaf groundsel), contain hepatotoxic amounts of pyrrolizidine alkaloids (which are covered in a separate monograph). Honey made from *Senecio* plants also contains pyrrolizidine alkaloids (32).

Adverse effects

Veno-occlusive disease has been attributed to *Senecio* after chronic use (33,34).

- Hepatic veno-occlusive disease occurred in a 38-year-old woman who had occasionally consumed "Huamanrripa" (*Senecio tephrosioides*) as a cough remedy for many years (35). She had abdominal pain, jaundice, and anasarca. A hepatic biopsy showed pronounced congestion with a centrilobular predominance, foci of necrosis, and in some areas a reversed lobulation pattern. During the next 13 months she was hospitalized four times with complications of portal hypertension.
- An infant developed hepatic veno-occlusive disease after having been fed a herbal tea known as gordolobo yerba, commonly used as a folk remedy among Mexican-Americans; there was acute hepatocellular disease and portal hypertension, which progressed over 2 months to extensive hepatic fibrosis (36).

In one case hepatic damage due to *Senecio* mimicked Reye's syndrome (37).

Silybum marianum

Silybum marianum (holy thistle, lady's thistle, milk thistle, St. Mary's thistle) has been used to treat liver problems, such as hepatitis, and prostatic cancer. It contains a variety of lignans, including silandrin, silybin, silychristin, silydianin, silymarin, and silymonin.

Adverse effects

- A 57-year-old Australian woman presented with a 2-month history of intermittent episodes of sweating, nausea, colicky abdominal pain, fluid diarrhea, vomiting, weakness, and collapse (38). She was taking ethinylestradiol and amitriptyline and had taken milk thistle for 2 months. A thorough check-up showed no abnormalities. On reflection she realized that all her attacks had invariably occurred after taking the milk thistle. She stopped taking it and had no symptoms until a few weeks later, when she tried another capsule and had the same symptoms.

This idiosyncratic reaction to milk thistle seems to be a rarity. The Australian authorities knew of only two other adverse drug reactions associated with milk thistle.

Immunologic

Anaphylactic shock has been reported after the use of a herbal tea containing an extract of the fruit of the milk thistle (39).

Drug interactions

Milk thistle inhibits CYP3A4 and uridine diphosphoglucuronosyl transferase in human hepatocyte cultures (40).

In 10 healthy subjects silymarin 160 mg tds had no effect on the pharmacokinetics of indinavir 800 mg tds (41). In a similar study silymarin 175 mg tds had no effect on the pharmacokinetics of indinavir 800 mg tds (42).

Tanacetum parthenium

Tanacetum parthenium (feverfew, bachelor's buttons, motherherb) has been used in the prevention of migraine, with some benefit (43), and for rheumatoid arthritis, without (44).

Adverse effects

As *Tanacetum parthenium* is rich in allergenic sesquiterpene lactones, such as parthenolide, it is not surprising that contact dermatitis has been observed (SEDA-11, 426). The most common adverse effect of oral feverfew is mouth ulceration. A more widespread inflammation of the oral mucosa and tongue, swelling of the lips, and loss of taste have also been reported.

Feverfew inhibits platelet aggregation (45), and its concomitant use with anticoagulants such as warfarin is therefore not advised.

Tussilago farfara

Tussilago farfara (coltsfoot) has hepatotoxic potential owing to the presence of pyrrolizidine alkaloids (see separate monograph).

- An 18-month-old boy who had regularly consumed a herbal tea mixture since the 3rd month of life developed veno-occlusive disease with portal hypertension and severe ascites (46). Histology of the liver showed centrilobular sinusoidal congestion with perivenular bleeding and parenchymal necrosis without cirrhosis. The child was given conservative treatment only and recovered completely within 2 months.

The tea contained peppermint and what the mother thought was coltsfoot (*T. farfara*), analysis of which

© 2006 Elsevier B.V. All rights reserved.

revealed high amounts of pyrrolizidine alkaloids. Seneciphylline and the corresponding *N*-oxide were identified as the major components, and the child had consumed at least 60 μg/kg/day of the toxic pyrrolizidine alkaloid mixture over 15 months. Macroscopic and microscopic analysis of the leaf material indicated that *Adenostyles alliariae* (Alpendost) had been erroneously gathered by the parents in place of coltsfoot. The two plants can easily be confused especially after the flowering period.

Atenolol

See also Beta-adrenoceptor antagonists

General Information

Although atenolol, a hydrophilic cardioselective beta-adrenoceptor antagonist with no partial agonist activity, is generally regarded as one of the safest beta-blockers, severe adverse effects are occasionally reported. These include profound hypotension after a single oral dose (1), organic brain syndrome (2), cholestasis (3), and cutaneous vasculitis (4).

Organs and Systems

Nervous system

Atenolol is hydrophilic, making it less likely to cross the blood–brain barrier. However, nervous system effects are occasionally reported.

- A 54-year-old man developed progressive memory loss after taking atenolol 100 mg/day for 3 years. Four weeks after withdrawal, he completely recovered his memory (5).

Atorvastatin

See also HMG Co-A reductase inhibitors

General Information

Atorvastatin is an HMG Co-A reductase inhibitor. Pooled data from 21 completed and 23 continuing trials representing 3000 patient-years have shown that constipation, flatulence, dyspepsia, abdominal pain, headache, and myalgia occur in 1–3% of patients. Under 2% of atorvastatin-treated patients discontinued treatment because of an adverse event (1). Serious events in this review amounted to one patient with pancreatitis and one with cholestatic jaundice (1). There were no differences in adverse effects in 177 patients randomized for 52 weeks to either simvastatin or atorvastatin (2).

Organs and Systems

Nervous system

A peripheral neuropathy has been reported with atorvastatin.

- A 60-year-old woman had painless horizontal diplopia, vertigo, blurry vision, and paresthesia in both arms after taking atorvastatin 10 mg/day (3). Neurological improvement began 2 days after drug withdrawal. Antiacetylcholine receptor antibodies were 10 times the upper limit of the reference range.

Although some features of this patient's external ophthalmoplegia were similar to myasthenia and there was a reversible rise in antiacetylcholine receptor antibody titer, a negative edrophonium test and a negative repetitive stimulation test on electromyography argued against a myasthenia-like drug reaction.

Sensory systems

In 696 patients taking atorvastatin and 235 taking lovastatin for 1 year there were no significant differences in the distribution of lenticular opacities or cortical opacities and spokes between the two drugs (4).

Hematologic

Thrombocytopenia occurred in a 46-year-old man coinciding with atorvastatin treatment; he had already tolerated simvastatin (5).

Pancreas

Pancreatitis has been observed with atorvastatin (6).

© 2006 Elsevier B.V. All rights reserved.

Skin

Potentially life-threatening toxic epidermal necrolysis occurred in a 73-year-old moderately obese woman with type 2 diabetes and hypertension after she had taken 40 mg of atorvastatin (7).

- A 59-year-old man developed urticaria while taking atorvastatin for hypercholesterolemia (8). Scratch tests with his medications gave a strong positive reaction only with atorvastatin. Atorvastatin was withdrawn and his urticaria resolved over the next 10 days.

Linear IgA bullous dermatosis (9) and dermographism (10) have been described in patients taking atorvastatin.

Musculoskeletal

In one study of 133 patients there was myalgia in 3% of those taking atorvastatin, but no patient had persistent increases in creatine kinase activity above 10 times the top of the reference range (11).

Immunologic

A hypersensitivity reaction to atorvastatin has been reported.

- Antinuclear and antihistone antibodies developed in a 26-year-old man who was taking atorvastatin (12). He had constitutional symptoms and slight headaches but no definite symptoms of lupus. After some months without medication he became seronegative and asymptomatic.

This case was similar to other previous reports with other statins.

Drug–Drug Interactions

Ciclosporin

Rhabdomyolysis occurred when atorvastatin was combined with ciclosporin for 2 months in a woman with systemic lupus erythematosus and a renal transplant (13).

Terfenadine

Atorvastatin, although a substrate for CYP3A4, does not affect blood terfenadine concentrations to a clinically significant extent (14).

Warfarin

In 12 patients chronically maintained on warfarin, atorvastatin 80 mg/day for 2 weeks reduced mean prothrombin times slightly, but only for the first few days of the 2-week treatment period (15). Thus, atorvastatin had no consistent effect on the anticoagulant activity of warfarin and adjustments in warfarin doses should not be necessary.

Atovaquone

General Information

Atovaquone is a hydroxynaphthaquinone that is effective in the prevention and treatment of murine *Pneumocystis jiroveci* pneumonitis. It also has effects against *Toxoplasma gondii* and *Plasmodium falciparum*. Food increases its absorption. The maximum serum concentration is dose-dependent, but absorption is reduced at doses above 750 mg. The maximum concentration occurs after 4–6 hours, with a second peak 24–96 hours later, suggesting enterohepatic cycling. The half-life is 77 hours.

Observational studies

In a 3-week study with test doses of 100–3000 mg/day, atovaquone was well tolerated. Three patients reported increased appetite; two of these had transient sinus arrhythmia. One of the 24 patients had a transient

© 2006 Elsevier B.V. All rights reserved.

maculopapular rash that resolved without withdrawal. There were no abnormalities in hematological parameters or renal function. Two patients had slightly raised serum bilirubin concentrations and one each had raised transaminase activities. Two other patients had mildly increased transaminase activities, but both were known to have chronic hepatitis B (SEDA-13, 828).

Comparative studies

Atovaquone 250 mg tds has been compared with co-trimoxazole 320/1600 mg/day for 21 days in the treatment of *P. jiroveci* pneumonia in 408 patients. Therapeutic efficacy was similar, but atovaquone was much better tolerated, with a far lower incidence of rash, liver dysfunction, fever, nausea, and pruritus, and no neutropenia, chills, headache, renal impairment, or thrombocytopenia (1). However, pre-existing diarrhea was associated with an increased mortality in the atovaquone group.

Of 39 patients who had bone marrow transplants and who were randomized to receive either co-trimoxazole or atovaquone as prophylaxis in an open-label trial, eight taking co-trimoxazole withdrew because of presumed drug reactions, although in five of these the reported neutropenia and thrombocytopenia could have been a consequence of transplantation itself or of other drugs (2). None of 16 patients treated with atovaquone withdrew. This rate of reported adverse effects with co-trimoxazole is higher than usually reported in clinical practice with prophylactic dosages.

A study conducted by the AIDS Clinical Trials Group (ACTG) has shown that among patients who cannot tolerate treatment with co-trimoxazole, atovaquone and dapsone are similarly effective in preventing *P. jiroveci* pneumonia. Among patients who did not originally take dapsone, atovaquone was better tolerated and it might be the preferred choice for prophylaxis of *P. jiroveci* pneumonia in this setting (3). Inexplicably the rate of *P. jiroveci* pneumonia showed a greater fall in patients who discontinued the study drugs compared with those who continued to take them.

When atovaquone was compared with intravenous pentamidine in the treatment of mild and moderate *Pneumocystis jiroveci* pneumonia in an open trial, the success rates were similar. However, withdrawal of the original treatment was much more frequent with pentamidine (36%) than atovaquone (4%) (4). However, the authors' conclusion that the two approaches have a similar success rate has been challenged, and their series was small (5,6). Treatment-limited adverse effects occurred in only 7% of patients given atovaquone, compared with 41% given pentamidine. They included cases of rash and an increase in creatinine concentrations; atovaquone (unlike pentamidine) produced no vomiting, nausea, hypotension, leukopenia, acute renal insufficiency, or electrocardiographic abnormalities, but it did cause one case of dementia (4).

Combinations

Atovaquone + azithromycin

Human babesiosis has been traditionally treated with quinine plus clindamycin, a combination that has been compared with atovaquone plus azithromycin in a randomized, multicenter, unblinded study (7). The treatments were both completely effective. There were considerably fewer adverse events with azithromycin plus atovaquone than with quinine plus clindamycin.

Atovaquone + proguanil

Atovaquone acts synergistically with proguanil, and the combination of these two drugs (Malarone®) is highly efficacious in the treatment of uncomplicated malaria (8), including that against multidrug resistant forms, and in prophylaxis (9). It has not yet been widely marketed, so data on rare adverse effects are currently sparse.

An inpatient study of 79 patients given proguanil + atovaquone compared with 79 patients given mefloquine showed no malaria-independent adverse effects (10). Although there was a significant transient increase in liver enzymes, this was probably of limited clinical importance.

Prophylaxis with either one or two tablets containing atovaquone 250 mg plus proguanil hydrochloride 100 mg (one quarter or one half of the daily treatment dose), taken once-daily for 10 weeks, prevented *P. falciparum* malaria in 100% of semi-immune adults in a highly endemic area of Kenya (11). Children in Gabon taking daily Malarone at approximately one quarter of the treatment dose were similarly protected (12). Gastrointestinal adverse effects, including abdominal pain and vomiting, were relatively common in the initial parasite clearance phase of the pediatric study (when a full treatment course was given) and there was one case of repeated vomiting in the parasite clearance phase of the adult study. In both studies, the regimens were well tolerated in the prophylaxis phase (no difference from placebo). This efficacy and tolerability profile may be applicable to malaria prevention outside Africa. The use of the combination is predicted to reduce the development of resistance to each drug. Furthermore, atovaquone eliminates parasites during the hepatic phase of infection (causal prophylaxis), potentially removing the requirement to continue prophylaxis for several weeks after return from a malarious area, a period when compliance with current regimens is likely to be poor.

Proguanil plus atovaquone has been studied for chemoprophylaxis of malaria in African children (12) and in travelers (13) and is formulated as a combination of proguanil 100 mg plus atovaquone 250 mg for daily dosing. Atovaquone is a hydroxynaphthoquinone that inhibits the electron transport system (bc1 system) of parasites. Proguanil plus atovaquone is active against hepatic stages of *P. falciparum*, making it unnecessary to continue 4 weeks of prophylaxis after return from an endemic region. Current recommendations are that proguanil plus atovaquone should be continued for 1 week after returning from a malaria-endemic region.

In a comparison of proguanil plus atovaquone with proguanil (100 mg/day) plus chloroquine (155 mg base weekly) in travelers, proguanil plus atovaquone was 100% effective in the prevention of malaria (13). Those who took proguanil plus atovaquone ($n = 540$) had significantly fewer adverse events than those who took proguanil plus chloroquine ($n = 543$) (22% versus 28% respectively), particularly less diarrhea, abdominal pain, and vomiting. Only one person who took proguanil plus

© 2006 Elsevier B.V. All rights reserved.

atovaquone had to discontinue prophylaxis owing to adverse events, as opposed to ten who had to discontinue proguanil plus chloroquine. There have been no other studies of similar size on the use of proguanil plus atovaquone. This combination is becoming established for the prophylaxis of malaria and the results of further phase IV studies are awaited.

The use of proguanil plus atovaquone has been reviewed (14). Neuropsychiatric adverse events were more frequent with mefloquine, whereas other adverse events occurred with similar frequencies as with chloroquine plus proguanil and mefloquine. Proguanil plus atovaquone is contraindicated in severe renal insufficiency. Co-administration of proguanil plus atovaquone with rifampicin is not recommended because of reductions in plasma atovaquone concentrations.

General adverse effects

Mild rashes are fairly common, and more serious rashes, like erythema multiforme, are rare. Gastrointestinal upsets, including abdominal pain, nausea, and diarrhea, are common. Mild nervous system disturbances have been mentioned (SEDA-18, 286) (15). Other adverse effects include fever.

Organs and Systems

Gastrointestinal

In a prospective efficacy trial of atovaquone suspension (750 mg od or 250 mg tds for 1 year) in *P. jiroveci* prophylaxis in 28 liver transplant recipients intolerant of co-trimoxazole, the adverse events reported included diarrhea ($n = 7$) and bloating or abdominal pain ($n = 3$) (16). No patient had developed *P. jiroveci* pneumonia by 37 months. This is a smaller dose than approved for *Pneumocystis* prophylaxis in HIV infection (1500 mg/day). Further studies in recipients of solid organ transplants are needed to confirm the efficacy of this prophylactic dose.

Atovaquone suspension (1500 mg orally bd) plus either pyrimethamine (75 mg/day after a 200 mg loading dose) or sulfadiazine (1500 mg qds), as treatment for acute *Toxoplasma* encephalitis (for 6 weeks) and as maintenance therapy (for 42 weeks), has been studied in a randomized phase II trial in HIV-positive patients (17). There were good responses in 21 of 28 patients who received pyrimethamine and nine of 11 who received sulfadiazine. Of 20 patients in the maintenance phase, only one relapsed. Of 40 eligible patients, 11 discontinued treatment as a result of adverse events, nine because of nausea and vomiting or intolerance of the taste of the atovaquone suspension.

Drug Administration

Drug formulations

Atovaquone suspension (750 mg bd; $n = 34$) or tablets (750 mg tds; $n = 20$) have been retrospectively compared in the treatment of *P. jiroveci* pneumonia in HIV-positive individuals (18). Efficacy was similar (74 and 70% successfully treated). Atovaquone suspension was associated with nausea in one patient and a rash in another.

Drug–Drug Interactions

Zidovudine

The metabolism of the antiviral nucleoside zidovudine to the inactive glucuronide form in vitro was inhibited by atovaquone (19,20).

Atracurium dibesilate

See also Neuromuscular blocking drugs

General Information

Atracurium is a muscle relaxant with approximately one-fifth the potency of pancuronium (initial doses of 0.3–0.6 mg/kg and maintenance doses of 0.2 mg/kg being commonly used), an onset of action of 1.2–4 minutes (depending on the dose and the investigator), a medium duration of effect similar to (or slightly longer than) vecuronium, a rapid spontaneous recovery (slightly longer than vecuronium), and a virtual lack of accumulation. Atracurium-induced neuromuscular block is easily reversed by neostigmine.

In contrast to other non-depolarizing drugs, atracurium is completely broken down at normal blood pH and temperature by Hofmann elimination, principally (although to disputed degrees) by nucleophilic substitution and enzymatic ester hydrolysis (1–4). Four metabolites are known, laudanosine being the main biotransformation product. Of the other metabolites, the acrylate esters might possibly give rise to adverse effects. Acrylates are highly reactive pharmacologically and are potentially toxic, theoretically having the capacity to form immunogens and to alkylate cellular nucleophils (3), but so far no effects have been reported (5,6).

In animal experiments, atracurium in large concentrations, many times those providing complete neuromuscular blockade, causes vagal blockade and changes attributed to histamine release; at high dosages some hypotension is seen, possibly because of histamine release; alkalosis diminishes the neuromuscular block, and acidosis prolongs it (7). In cats, high doses of some of the breakdown products of atracurium produced dose-dependent neuromuscular blockade, hypotension, and autonomic effects (5). However, it was considered that these effects were of no pharmacological significance, in view of the low potencies of these substances and the quantities likely to be found in man. From interaction studies in cats (8) it was concluded that the action of atracurium is enhanced by D-tubocurarine, halothane, gentamicin, neomycin, and polymyxin, and antagonized by adrenaline and transiently by suxamethonium. Pretreatment with suxamethonium did not affect the subsequent block by atracurium in cats. Ciclosporin has also been reported to potentiate atracurium in cats (SEDA-12, 118) (9).

In man, histamine release by atracurium is common. The clinical significance of this is disputed, but it can cause minor transient skin reactions. Systemic effects of histamine release are much rarer than cutaneous manifestations.

Organs and Systems

Cardiovascular

There have been reports of hypotension (SEDA-15, 125) (10–12), attributed to histamine release by atracurium. A large prospective surveillance study involving more than 1800 patients given atracurium showed a 10% incidence of adverse reactions, with moderate hypotension (20–50% decrease) in 3.5% of patients (13). In one study cardiovascular stability was maintained with atracurium up to doses of 0.4 mg/kg (14). However, at higher doses (0.5 and 0.6 mg/kg) arterial pressure fell by 13 and 20% and heart rate increased by 5 and 8% respectively. These effects were maximal at 1–1.5 minutes. Since these cardiovascular effects were associated with facial flushing, it was suggested that they might have resulted from histamine release. In a subsequent study the same investigators linked significant cardiovascular changes to increased plasma histamine concentrations at a dose of atracurium of 0.6 mg/kg (15). Injecting this dose slowly over 75 seconds caused less histamine release and adverse hemodynamic effects (16). However, other investigators found no correlation between histamine plasma concentrations and hemodynamic reactions after atracurium administration (17).

Cardiovascular effects, apart from those resulting from histamine release, appear to be almost entirely limited to bradycardia. From animal studies, vagolytic (7) and ganglion-blocking (18) effects are very unlikely to occur at neuromuscular blocking doses, and these predictions appear to

© 2006 Elsevier B.V. All rights reserved.

be borne out by investigations in man, cardiovascular effects being reported only at high dosages associated with signs suggestive of histamine release (14,15,19). The bradycardia (20–22) is occasionally severe, but, as with vecuronium, the explanation seems to be that the bradycardic effects of other agents used during anesthesia are not attenuated by atracurium as they are by alcuronium, gallamine, or pancuronium, which have vagolytic (or sympathomimetic) effects. The possibility that bradycardia can be caused by one of the metabolites, such as laudanosine (SEDA-12, 115), which is structurally similar to apomorphine, has yet to be excluded. An animal study has suggested that noradrenaline release from sympathetic nerve terminals can be increased by very large doses of atracurium, probably because of high concentrations of laudanosine (SEDA-14, 117) (23). Clinically, cardiovascular effects from this source would only be expected in circumstances that produced much higher than usual laudanosine concentrations.

Hypoxemia has been incidentally reported (SEDA-15, 125) (24), and most probably resulted from an increase in right-to-left cardiac shunting (in a patient with a ventricular septal defect and pulmonary atresia). Atracurium (0.2 mg/kg) may have produced a fall in systemic vascular resistance, perhaps from histamine release; pancuronium was subsequently given without incident.

Nervous system

The major metabolite of atracurium, laudanosine, can cross the blood–brain barrier (CSF/plasma ratios of 0.3–0.6 are found in dogs) (25) and produce strychnine-like nervous system stimulation, which at high plasma concentrations (around 17 ng/ml) leads to convulsions in dogs (25–27). CSF/plasma ratios of laudanosine in man have been reported to be between 0.01 and 0.14 after a 0.5 mg/kg dose of atracurium in a study in which the highest laudanosine concentration was 14 ng/ml (28). Much higher CSF laudanosine concentrations (mean 202 ng/ml, highest 570 ng/ml) were measured after larger atracurium doses (0.5 mg/kg/hour) during intracranial surgery (SEDA-15, 126) (29).

Patients in whom the blood–brain barrier is not intact, such as during neurosurgical procedures, may be at risk from exposure of the brain to unpredictable concentrations of laudanosine (and other drugs). Two patients had fits but these were not thought to be related to laudanosine (29). Under normal circumstances plasma concentrations in man will be far below those required for significant central nervous stimulation. However, the half-life of laudanosine (25) is considerably longer than that of atracurium (30), so that there is a possibility of laudanosine accumulation if many repeated doses or prolonged infusions of atracurium are given.

Skin

Minor skin reactions lasting 5–30 minutes occur in 10–50% of patients according to various studies and are not usually associated with obvious systemic effects (10,31–34). They are probably due to histamine release. A 42% incidence of cutaneous flushing has been reported in 200 patients; the effect was dose-dependent, being 18% at 0.4 mg/kg, 33% at 0.5 and 0.6 mg/kg, and 73% at 1 mg/kg (35). One patient in this study, in the 1 mg/kg group, developed generalized erythema, hypotension, tachycardia, and bronchospasm.

Immunologic

There have been reports of angioedema (10) and bronchospasm (11,36), attributed to histamine release. A large prospective surveillance study involving more than 1800 patients given atracurium showed a 10% incidence of adverse reactions, with bronchospasm in 0.2% of patients (13).

Extreme sensitivity to an intradermal skin test (0.003 mg), some 24 hours after a severe skin reaction to the intravenous administration of atracurium, has been described (37).

Severe systemic reactions after atracurium administration may be due to antibody-mediated anaphylaxis (38) rather than non-specific histamine liberation. It has been suggested that systemic effects from non-specific histamine release are dose-dependent.

Second-Generation Effects

Fetotoxicity

Placental transfer of atracurium occurs (39). In 46 patients undergoing cesarean section (SEDA-17, 18), while the Apgar scores did not differ between neonates whose mothers had received atracurium (0.3 mg/kg) or tubocurarine (0.3 mg/kg), the neurological and adaptive capacity scores (NACS) at 15 minutes (but not at 2 and 24 hours) after birth were lower after atracurium. The NACS values were normal in 83% of the babies in the tubocurarine group and in 55% of those in the atracurium group. The difference was primarily due to lower scores for active contraction of the neck extensor and flexor muscles. These results cannot be satisfactorily explained by partial curarization in some neonates of the atracurium group because the placental transfer of atracurium was lower in the atracurium group; the umbilical vein concentrations of atracurium after clamping of the umbilical cord being approximately one-tenth of the EC_{50} for block of neuromuscular transmission in neonates.

Susceptibility Factors

Age

It has been recommended that doses also be reduced in small neonates less than 3 days old, particularly if their core temperatures are less than 36°C (40), since the breakdown of atracurium is pH- and temperature-dependent.

In elderly patients atracurium infusion requirements appear not to be reduced and its effects are not prolonged (41), probably because the action of atracurium is independent of routes of elimination that are affected by age.

Other features of the patient

Temperature and pH

The breakdown of atracurium is pH-dependent and temperature-dependent. Alkalosis reduces neuromuscular blockade by atracurium, and acidosis prolongs it.

© 2006 Elsevier B.V. All rights reserved.

Hypothermia, during cardiopulmonary bypass, has been reported as reducing atracurium requirements by half (42); pH changes may also have occurred.

Burns

Burns are associated with resistance to atracurium (43), as for several other non-depolarizing neuromuscular blocking agents. The EC_{50} is increased and dose requirements may be increased by up to 2–3 times. The resistance varies with the burn area and the time from injury (SEDA-12, 116), being maximal at 15–40 days in patients repeatedly anesthetized.

Dystrophia myotonica

Patients with dystrophia myotonica may be extremely sensitive to atracurium according to a case report (SEDA-10, 110) (44). Resistance to atracurium and higher than normal concentrations of acetylcholine receptors in muscle biopsies have been reported in a patient with multiple sclerosis (SEDA-13, 105) (45).

Pheochromocytoma

It has been suggested (46) that atracurium is unsuitable for use in patients with a pheochromocytoma, since increases in catecholamine concentrations, which are associated with hypertension and other unwanted cardiovascular effects, occur after the injection of relatively large doses (0.6–0.7 mg/kg). However, in an earlier report catecholamine concentrations did not increase and there were no untoward cardiovascular effects after atracurium (47). Nevertheless, considering atracurium's potential for histamine release (which can secondarily lead to increases in circulating catecholamines), vecuronium or pipecuronium are probably better choices in this condition.

Renal and hepatic insufficiency

Renal and liver dysfunction appear to have little effect on the neuromuscular blocking action of atracurium (30,48,49), although resistance has been reported in end-stage renal insufficiency (37% greater ED_{50} values and shorter duration of bolus doses) (SEDA-13, 103) (50,51).

Laudanosine metabolism may be reduced in liver disease (52), and in renal insufficiency higher plasma concentrations and an apparently delayed elimination of laudanosine have been reported (53). Prolonged infusion of atracurium in intensive care (for 38–219 hours) led to slowly increasing plasma laudanosine concentrations, which appeared to plateau after 2–3 days (54). The maximum plasma laudanosine concentrations in six patients were 1.9–5 μg/ml. There was no evidence of cerebral excitation. Nevertheless, caution is urged in patients with severe hepatic dysfunction (55,56), particularly if associated with renal insufficiency, when repeated bolus doses or an infusion of atracurium are given over a prolonged period.

Drug–Drug Interactions

Aminoglycoside antibiotics

Another interaction that has been reported not to occur in man is potentiation by the aminoglycoside antibiotics, gentamicin and tobramycin (57). In animals, however, gentamicin was found to enhance atracurium blockade (8), so further investigation is required to clarify this point.

Azathioprine

Azathioprine has been reported to reduce atracurium blockade transiently and to a clinically insignificant extent (50).

Carbamazepine

In contrast to reports on other non-depolarizing neuromuscular blocking agents, resistance to atracurium has not been found in patients taking long-term carbamazepine (SEDA-13, 104) (58).

Diisopropylphenol

The intravenous anesthetic agent, diisopropylphenol, is said to potentiate atracurium (59).

D-Tubocurarine

Small doses of D-tubocurarine (0.05 or 0.1 mg/kg) administered 3 minutes before atracurium potentiated its action synergistically (SEDA-12, 117) (60).

Halothane

From animal experiments (8) it seems likely that drug interactions with atracurium will be similar to those for other non-depolarizing neuromuscular blocking agents. Laudanosine has been reported to increase the MAC for halothane in animals (61).

In man, potentiation and prolongation of the action of atracurium by halothane (62–64) have been reported, as has potentiation after 30 minutes of isoflurane anesthesia (65). Whether the dose of atracurium should be reduced from that used during balanced anesthesia by 20, 30, or 50% when patients are anesthetized with inhalational anesthetics can only be decided in the case of an individual patient if neuromuscular monitoring is available, since many other variables, such as the tissue concentrations of the volatile anesthetic and the response of the individual patient to the neuromuscular blocking drug, will influence the overall blocking effect.

Isoflurane

A synergistic interaction between isoflurane and atracurium (high doses) has been incriminated in the causation of an increased incidence of generalized tonic-clonic seizures after neurosurgical operations (SEDA-15, 125) (66).

Ketamine

Ketamine has been shown to prolong the action of atracurium slightly (67).

Pancuronium

Small doses of pancuronium (0.5 or 1 mg) administered 3 minutes before atracurium potentiated its action synergistically (SEDA-12, 117) (60).

© 2006 Elsevier B.V. All rights reserved.

Phenytoin

In contrast to reports about other non-depolarizing neuromuscular blocking agents, resistance to atracurium has not been found in patients taking long-term phenytoin (SEDA-13, 104) (68).

Suxamethonium

Prior administration of suxamethonium potentiates the action of atracurium by about 30% (69).

Tamoxifen

Tamoxifen has been associated with prolonged atracurium block in a patient with breast cancer (SEDA-12, 117) (70).

Atropine

See also Anticholinergic drugs

General Information

Atropine is an anticholinergic drug that is mainly used today in premedication and occasionally to treat bradycardia in the acute phase of myocardial infarction.

Organs and Systems

Cardiovascular

In a classic study, more than a generation ago, of patients given atropine sulfate intravenously as premedication in a total dose of 1 mg, dysrhythmias occurred in over one-third of the subjects, and in over half of those younger than 20 years.

In adults, atrioventricular dissociation was common and in children atrial rhythm disturbances (1). In volunteers, atropine in doses of 1.6 mg/70 kg/minute causes episodes of nodal rhythm with absent P waves on the electrocardiogram (2); the episodes occurred before the heart rate had increased under the influence of the drug. In healthy men being anesthetized for dental surgery a dose of only 0.4 mg atropine intravenously 5 minutes before induction caused reductions in mean arterial pressure, stroke volume, and total peripheral resistance (3).

Second- or third-degree heart block occurred in three of 23 male heart transplant recipients given intravenous

© 2006 Elsevier B.V. All rights reserved.

atropine (SEDA-22, 156). The mechanism is unknown but it appears that particular caution is needed when atropine is used in this group of patients.

The use of atropine in myocardial infarction to increase the heart rate succeeds as a rule, but in some patients with second-degree heart block the ventricular rate is slowed by atropine, resulting in bradycardia. In contrast, other patients can have tachycardia, and even ventricular fibrillation has been seen, occasionally even in doses as low as 0.5 mg (4).

Possible precipitation of acute myocardial infarction has been discussed by two American emergency medicine specialists (5).

- A 62-year-old woman developed chest pain and sinus bradycardia (41/minute). She had third-degree heart block and was given atropine 1 mg intravenously. Three minutes later, her chest pain increased and the electrocardiogram now showed an acute inferior myocardial infarction, confirmed by serum markers. Angioplasty recanalized the right coronary artery.

The authors discussed the possibility, suggested by others, that atropine can precipitate acute myocardial infarction in an ischemic setting. They concluded that while this may be true, on the whole the advantages of successfully correcting bradycardia outweigh the risks of this rare complication.

Respiratory

Atropine increases the rate and depth of respiration, probably as a reaction to the increase in the dead space resulting from bronchodilatation (5).

Sensory systems

Transient central blindness has followed an intravenous injection of atropine 0.8 mg in the course of spinal anesthesia; blink reflex and pupillary response to light and accommodation were lost; vision returned slowly after some hours after the instillation of pilocarpine (6).

Psychological, psychiatric

Atropine can cause slight memory impairment, detectable if special studies of mental function are performed (SEDA-13, 115).

Immunologic

Hypersensitivity to atropine is most usually seen in the form of contact dermatitis and conjunctivitis. One case of anaphylactic shock after intravenous injection of atropine has been reported (SEDA-14, 122).

Body temperature

Atropine was thought to have produced hypothermia in a boy aged 14 who was being treated with paracetamol (acetaminophen) and cooling blankets for hyperthermia (7). As atropine can cause hypothermia in animals, a causal relation cannot be excluded, even if a concomitant action with paracetamol is assumed.

Second-Generation Effects

Fetotoxicity

Atropine methylbromide crosses the placenta less readily than atropine; when given close to term, it has much less effect on the fetal heart rate than on the maternal heart rate (8).

Susceptibility Factors

In Down's syndrome, atropine produces an abnormally large degree of pupillary dilatation, probably because of a genetically abnormal response; there is also a much greater acceleration of the heart rate than that produced by atropine in healthy subjects.

In congenital albinism, by contrast, the duration of dilatation of the pupil is much shorter than usual; the response to homatropine, scopolamine, and pilocarpine appears to be normal.

Drug Administration

Drug formulations

A total of 1077 patients continued to take extended-release tolterodine 4 mg/day after participating in a randomized trial, about 78% of those who completed the double-blind phase of the study (9). Of the patients who took open treatment, 71% were still doing so after 12 months. The only significant adverse effect was a dry mouth in 13%, while 3.3% complained of constipation. There was no serious systemic toxicity of any kind and efficacy was judged to be at least equivalent to that of the immediate-release formulation.

Drug administration route

Atropine administered by aerosol has a selective effect on the airways because of its low systemic absorption. Adverse effects are those of atropine and atropine-like drugs, but systemic effects are unlikely after topical administration. Two patients developed the signs and symptoms of angle-closure glaucoma after receiving aerosolized atropine. Patients with shallow anterior chambers or possible prior angle-closure glaucoma are probably at greater risk (10). Atropine methylnitrate, a quaternary ammonium derivative, is more selective than atropine sulfate because it is less readily absorbed.

In a child with regular akinetic seizures, atropine sulfate eye-drops increased the frequency of seizures (11).

Drug overdose

When parasympathicolytic or anticholinergic agents are used to dilate the pupils, it is important to recognize systemic anticholinergic intoxication, because the outcome can be fatal without treatment. In patients who are confused or have difficulty speaking, large fixed pupils, and fever, anticholinergic intoxication has to be considered.

- A 3-year-old boy with amblyopia was vomiting, had difficulty in walking, had fever, was agitated, and had a warm red skin and dilated pupils that did not respond

© 2006 Elsevier B.V. All rights reserved.

to light (12). An empty bottle of atropine eye-drops was found in his home, and suspected anticholinergic intoxication was confirmed. He made a full recovery following treatment with physostigmine.

It should also be remembered that there are other sources of atropine.

- A 52-year-old woman was confused and had dysarthria and difficulty in walking and swallowing (13). That same day she had eaten berries that she thought were bilberries, but were instead *Atropa belladonna* (deadly nightshade).

Drug–Drug Interactions

Paracetamol

Atropine slows the rate of absorption of paracetamol (14).

Azapropazone

See also Non-steroidal anti-inflammatory drugs

General Information

Azapropazone is structurally related to phenylbutazone and probably shares the same adverse effects: gastrotoxicity, skin reactions, headache, vertigo, edema, and renal impairment. A review of a very large series described azapropazone adverse effects in 1724 patients (18%), causing withdrawal in 3.7%. Surprisingly, however, there were no phenylbutazone-type blood dyscrasias (SED-11, 176) (1). Azapropazone should be prescribed only for patients with active rheumatic diseases who have failed to respond to other NSAIDs (2).

Organs and Systems

Hematologic

Hemolytic anemia has been reported (SEDA-10, 79) (SEDA-12, 83). A high percentage of patients taking azapropazone had a positive direct Coombs' test, but this did not persist after treatment had been stopped for several weeks (SEDA-12, 83). Hemolytic anemia has also been described in combination with pulmonary alveolitis, which suggests an allergic or immune reaction (3). Photosensitivity is often reported: 190 reports of photosensitivity were submitted to several national drug-monitoring centers in Europe in 1985 (SEDA-10, 79) (SEDA-12, 83).

Skin

Photosensitivity is more frequent with azapropazone than with almost any other NSAID (4).

Immunologic

Patients with aspirin intolerance often also react to many other NSAIDs. Azapropazone seems to be a safe alternative in these patients, according a study that showed good tolerance of the drug in patients with aspirin intolerance (5).

Susceptibility Factors

Renal disease

Because of increases in unbound drug and reduced clearance in renal insufficiency, the dosage should be carefully adjusted in patients with renal disease (SEDA-11, 92).

Hepatic disease

Because of increases in the unbound drug and reduced clearance, the dosage should be carefully adjusted in patients with liver disease (SEDA-11, 92).

Drug–Drug Interactions

Oral anticoagulants

Azapropazone has the same pattern of interactions as phenylbutazone with oral anticoagulants (SEDA-2, 98).

Phenytoin

Azapropazone has the same pattern of interactions as phenylbutazone with phenytoin (6,7).

Tolbutamide

Azapropazone has the same pattern of interactions as phenylbutazone with tolbutamide (8).

Azathioprine and mercaptopurine

General Information

Azathioprine, a prodrug converted to 6-mercaptopurine, is widely used as a post-transplant immunosuppressant and in various autoimmune or chronic inflammatory disorders, such as rheumatoid arthritis, dermatomyositis, systemic lupus erythematosus, skin diseases, and inflammatory bowel diseases.

Adverse effects usually occur during the first two months of treatment, do not correlate with the daily dose, and result in treatment withdrawal in 14–18% of patients, mainly because of bone marrow suppression, gastrointestinal symptoms, hypersensitivity reactions, and infections (1–3). Immediate or long-term adverse effects are of particular concern outside the field of immunosuppression where other treatment options are frequently available, but in any field of use the adverse effects of these drugs weigh heavily.

Observational studies

In a follow-up study of 157 patients receiving azathioprine or mercaptopurine for Crohn's disease, the long-term risks (mainly hematological toxicity and malignancies) over 4 years of treatment were deemed to outweigh the therapeutic benefit (4). In contrast to these findings, both drugs were considered efficacious and reasonably safe in patients with inflammatory bowel disease, provided that patients are carefully selected and regularly investigated for bone marrow toxicity (5). Similar opinions were expressed regarding renal transplant patients. Conversion from ciclosporin to azathioprine in selected and carefully monitored patients had beneficial effects, by improving renal function, reducing cardiovascular risk factors, and reducing financial costs, without increasing the incidence of chronic rejection and graft loss (6).

Experience in children with juvenile chronic arthritis or chronic inflammatory bowel disease has also accumulated, and the toxicity profile of azathioprine or mercaptopurine appears to be very similar to that previously found in the adult population (SEDA-21, 381) (SEDA-22, 410).

The "azathioprine hypersensitivity syndrome"

The complex of azathioprine-associated multisystemic adverse effects is referred to by the misnomer "azathioprine hypersensitivity syndrome." This well-characterized reaction has been described in numerous case reports and includes various symptoms which can occur separately or concomitantly; they comprise fever and rigors, arthralgia, myalgia, leukocytosis, cutaneous reactions, gastrointestinal disturbances, hypotension, liver injury, pancreatitis, interstitial nephritis, pneumonitis, and pulmonary hemorrhage (SED-13, 1121) (SEDA-20, 341) (SEDA-21, 381) (SEDA-22, 410) (7). Isolated fever and rigors are sometimes observed, and severe renal and cardiac toxicity or leukocytoclastic cutaneous vasculitis are infrequent. Symptoms usually occur within the first 6 weeks of treatment and can mimic sepsis. The initial febrile reaction is often misdiagnosed as infectious, and could be associated with acute exacerbation of the underlying disease, for example myasthenia gravis (SEDA-21, 381) (SEDA-22, 410). Hypersensitivity associated with reversible interstitial nephritis can also be mistaken for an acute rejection episode (8). This syndrome should therefore be promptly recognized to avoid unnecessary and costly investigations, and further recurrence on azathioprine rechallenge.

Organs and Systems

Respiratory

Although azathioprine-associated pulmonary toxicity mostly occurs as part of the azathioprine hypersensitivity reaction, isolated interstitial pneumonitis has been reported in a 13-year-old girl with autoimmune chronic active hepatitis (9).

Acute upper airway edema has been observed after a single dose of azathioprine (10).

- A 57-year-old woman with a history of several drug allergies underwent renal transplantation for end-stage

© 2006 Elsevier B.V. All rights reserved.

polycystic kidney disease and 1 hour later was given intravenous azathioprine 400 mg. She developed profound hypotension and bradycardia within 30 minutes, reversed by sympathomimetics. Shortly after extubation, she had severe breathing difficulties with loss of consciousness. Laryngoscopy showed massive swelling of the tongue and upper airways. Later, while still taking glucocorticoids, she was rechallenged with azathioprine and had milder hypotension and edema of the airways.

Even if no clear mechanism can account for this adverse effect, positive rechallenge strongly suggested that azathioprine was the culprit.

Hematologic

Hematological toxicity is the most commonly reported severe adverse effect of azathioprine, and is marked by predominant leukopenia, thrombocytopenia, and pancytopenia (SED-13, 1120). In a 27-year survey of 739 patients treated with azathioprine 2 mg/kg for inflammatory bowel disease, dosage reduction or withdrawal of the drug because of bone marrow toxicity was necessary in 37 patients (5%) (11). There was moderate or severe leukopenia in 3.8% of patients; in three patients pancytopenia resulted in severe sepsis or death.

Leukopenia is the most serious adverse effect of azathioprine in patients with inflammatory bowel disease (12). It is variable and unpredictable and occurs 2 weeks to 11 years after the start of treatment (median 9 months); most cases recover 1 month after withdrawal.

Dual therapy with ciclosporin and prednisone has been compared with triple therapy with ciclosporin, prednisone, and azathioprine in a randomized trial in 250 renal transplant patients (13). Patients in the triple therapy group had less frequent severe episodes of acute rejection and more frequent episodes of leukopenia than the double therapy group (28% versus 4%). There were no other differences in the adverse effects profiles, in particular the incidence of infectious complications.

Macrocytic anemia and isolated thrombocytopenia without severe clinical consequences have sometimes been observed. Pure red cell aplasia can occur, but the few relevant reports concern only isolated instances involving renal transplant patients (14,15). The facts in one patient suggested that parvovirus B19 infection resulting from the immunosuppressive effects of azathioprine should also be considered as a possible indirect cause (16). Although blood cell disorders usually occur in the first 4 weeks of treatment, strict and regular surveillance of blood cell counts continuing for as long as treatment is maintained is usually recommended, since delayed hematological toxicity remains possible.

- Immune hemolytic anemia has been reported in a 67-year-old man taking mercaptopurine for chronic myelomonocytic leukemia (17). Serology showed a positive direct antiglobulin test and confirmed the presence of mercaptopurine drug-dependent antibodies. He improved and the direct antiglobulin test was no longer positive 20 days after mercaptopurine withdrawal.

Aplastic anemia due to azathioprine therapy after corneal transplantation has reportedly caused bilateral macular hemorrhage (18).

- A 38-year-old man underwent therapeutic penetrating keratoplasty for non-healing fungal keratitis in his left eye. Although the infection was controlled, he underwent a second corneal transplantation after 2 years. Since there was corneal vascularization in three quadrants, he was given oral azathioprine postoperatively. Four months later he developed gastrointestinal bleeding and a sudden reduction in vision in both eyes. His platelet count was less than 30×10^9/l, his hemoglobin 4.1 g/dl, and a bone marrow aspirate was hypocellular. There were macular hemorrhages in both eyes. The hemorrhages resolved within 2 months.

Gastrointestinal

Gastrointestinal disturbances with nausea, vomiting, and diarrhea are frequent in patients taking azathioprine or mercaptopurine. Diarrhea may be isolated or part of the azathioprine hypersensitivity syndrome. In two patients with azathioprine-induced diarrhea proven by positive rechallenge, the period of sensitization ranged from 1 week to 1 year (19).

In two cases, azathioprine caused severe gastrointestinal symptoms that could have been easily confused with an acute exacerbation of the underlying inflammatory bowel disease (20).

- A 32-year-old man with ulcerative colitis improved with prednisolone, mesalazine, and antibiotics. The dose of prednisolone was reduced and the disease flared up again. He was therefore given azathioprine and an increased dose of prednisolone, with rapid clinical improvement. After 3 weeks, he reported increasing abdominal pain, worse diarrhea, and weight loss of 3 kg. He stopped taking azathioprine and the pain improved. Because of progressive disease and active pancolitis at colonoscopy, he was given high-dose prednisolone, mesalazine, and ciprofloxacin, without improvement. He was therefore given intravenous azathioprine, but developed devastating diarrhea and weight loss of more than 6 kg in 24 hours, his CRP rose from 5 to 305 μg/ml, and he developed hypovolemic shock. He recovered after treatment with parenteral nutrition for 7 days.
- A 50-year-old woman with Crohn's disease and active disease throughout the colon was given prednisolone, mesalazine, and azathioprine 50 mg/day. After 3 weeks, the dose of azathioprine was increased to 100 mg/day, but she developed nausea, severe diarrhea, and abdominal tenderness. The symptoms subsided after azathioprine was withdrawn. She was then given mercaptopurine, without significant adverse effects.

Liver

Although rarely severe, any increase in liver enzyme activity justifies careful and regular monitoring of liver function and the results may be a reason for withdrawing treatment (SED-8, 1118) (21). In a retrospective study, hepatitis was found in 21 (2%) of 1035 renal transplant patients, and it was suggested that hepatitis B or C

© 2006 Elsevier B.V. All rights reserved.

infection increases the risk of azathioprine hepatotoxicity (22). In 29 cardiac transplant recipients who had had probable azathioprine-induced liver dysfunction, cyclophosphamide was given, with improvement of liver enzyme activities and no increase in the rate of graft rejection or significant changes in the doses of other immunosuppressive drugs (23).

Azathioprine can cause reversible cholestasis (24), perhaps due to bile duct injury (25).

Direct hepatocellular injury with acute cytolytic hepatitis has been reported rarely (SEDA-21, 381).

In one patient, azathioprine-induced lymphoma with massive liver infiltration was the probable cause of fulminant hepatic failure (SEDA-21, 381).

Other histological features that have been described include lesions of the hepatic venous system (peliosis hepatis, sinusoidal dilatation, perivenous fibrosis, and nodular regenerative hyperplasia) and these can be associated with portal hypertension (SEDA-16, 520) (SED-13, 1120) (21). Particularly severe and potentially fatal veno-occlusive liver disease has been reported in patients with renal and allogeneic bone marrow transplants taking chronic treatment (26) (SEDA-12, 386), but complete histological reversal can be observed (SEDA-20, 341).

- In a 33-year-old man azathioprine-induced veno-occlusive disease was treated with a transjugular intrahepatic portosystemic shunt over 26 months, with progressive worsening 15 months after renal transplantation (27).

Four patients with renal transplants developed hepatic veno-occlusive disease after immunosuppression with azathioprine. The diagnosis was based on typical histopathological findings: perivenular fibrosis, trilobular sinusoidal dilatation and congestion, and perisinusoidal fibrosis. The patients presented with severe progressive portal hypertension followed by fulminant liver failure and death. The disease was associated with cytomegalovirus infection, and it was not related to the dose of azathioprine (26). Veno-occlusive liver disease has also been described shortly after liver transplantation (28,29). A history of acute liver rejection affecting the hepatic veins was supposedly a contributing factor in these patients, and the presence of non-inflammatory small hepatic vein lesions was a possible early indicator of hepatotoxicity. Liver biopsy should therefore be considered in liver recipients who have biological features of hepatitis, so that treatment can be withdrawn rapidly if necessary.

Azathioprine allergy can be associated with biochemical hepatitis and a normal liver biopsy, apart form marked lipofuscin deposition (30). These findings, combined with patchy isotope uptake on technetium scintigraphy, are suggestive of focal hepatocellular necrosis.

It has been suggested that there is an increased risk of azathioprine-induced liver damage in renal transplant patients with chronic viral hepatitis (SEDA-20, 341) (SEDA-23, 402).

- Fatal fibrosing cholestatic hepatitis has been reported in a 63-year-old cardiac transplant patient with acquired post-transplant hepatitis C virus infection whose immunosuppressive regimen included azathioprine (31). Histology showed several features of azathioprine hepatotoxicity, namely veno-subocclusive lesions and nodular regenerative diffuse hyperplasia, suggesting a pathogenic role of azathioprine.

In 79 renal transplant patients with chronic viral hepatitis, azathioprine maintenance treatment ($n = 34$) was associated with a poorer outcome than in 45 patients who discontinued azathioprine (32). Cirrhosis was more frequent in the first group (six versus one), and more patients died with a functioning graft (14 versus two), mostly because of liver dysfunction ($n = 5$) or infection ($n = 6$). These results suggest that azathioprine further accelerates the course of the liver disease in these patients.

- A 50-year-old woman with nodular sclerosis developed azathioprine-induced hepatotoxicity within the first weeks of treatment (33), the usual time-course. Positive rechallenge confirmed the role of azathioprine.

However, delayed occurrence of hepatitis is also possible.

- Canalicular cholestasis with portal fibrosis and ductal proliferation has been reported after 24 years of azathioprine in a 57-year-old woman with myasthenia gravis (34).

An unusual diffuse liver disease with sinusoidal dilatation (SEDA-11, 392) has been described.

Pancreas

Pancreatitis due to azathioprine or mercaptopurine has usually been reported as part of the hypersensitivity syndrome (SEDA-16, 520) (SEDA-20, 341). It has mostly been observed in patients with inflammatory bowel disease, and required withdrawal of treatment in 1.3% of patients with Crohn's disease (3). Pancreatitis was not dose-related within the therapeutic range of doses and often recurred in patients who were rechallenged with either drug (SEDA-20, 341) (35). Fatal hemorrhagic pancreatitis occurred in one patient, but a role of concomitant drugs was also possible (SEDA-20, 341). Pancreatitis or hyperamylasemia were not significantly different in renal transplant patients randomly assigned to receive azathioprine or ciclosporin, and other causative factors were found in most patients with pancreatitis (36).

In a review of definite or probable drug-associated pancreatitis spontaneously reported to the Dutch adverse drug reactions system during 1977–98, azathioprine was the suspected drug in four of 34 patients, two of whom had positive rechallenge (37). Although most of the carefully described reports of azathioprine-induced pancreatitis were found in patients with inflammatory bowel disease, transplant recipients can also suffer this complication.

- Over a year after renal transplantation, a 48-year-old man, who took azathioprine, ciclosporin, and prednisolone, developed acute necrotizing pancreatitis (38). Improvement was obtained after azathioprine withdrawal, but he again took azathioprine and had similar symptoms within 30 hours after a single dose.
- Pancreatitis has been reported after a progressive increase in dose of 6-thioguanine in a 10-year-old infant (39). She had had two previous episodes of pancreatitis after mercaptopurine.

© 2006 Elsevier B.V. All rights reserved.

The chemical structure of 6-thioguanine, which results from the metabolism of azathioprine/mercaptopurine, is very similar to that of mercaptopurine. Therefore, a history of previous adverse effects with mercaptopurine should be anticipated in patients considered for 6-thioguanine treatment.

Skin

Rashes or other allergic-type cutaneous reactions are usually noted during the azathioprine hypersensitivity syndrome. Isolated but convincing reports point to the occurrence of vasculitis with microscopic polyarteritis (SEDA-21, 381) and Sweet's syndrome, which recurred after subsequent azathioprine exposure (SEDA-22, 410).

Pellagra with a photosensitivity-like rash and skin peeling syndrome has also been noted (SEDA-21, 381).

Musculoskeletal

Severe myalgia and symmetrical polyarthritis are sometimes reported in patients taking azathioprine. Eight cases of azathioprine-associated arthritis were identified in the WHO Drug Monitoring Database, including six cases with a typical hypersensitivity syndrome and two cases in whom joint involvement was the only reported symptom (40). Rhabdomyolysis has also been reported as a possible feature of the azathioprine hypersensitivity syndrome (SEDA-20, 341).

In two patients with Crohn's disease, azathioprine was suspected to have caused severe gait disorders with an inability to walk (41). Within 1 month of treatment, both had joint pains or diffuse arthralgias that were the presumed cause of pseudoparalysis of the legs. In one patient other causes were carefully ruled out and similar symptoms recurred shortly after azathioprine was re-introduced.

Immunologic

The distinction between relapse of the treated disease, systemic sepsis, and acute azathioprine allergy can be difficult, as has been shown in three patients with vasculitic disorders (42).

Allergic reactions to azathioprine were recorded in 2% of patients with Crohn's disease taking azathioprine (3), and there was no evidence to suggest that the incidence depended on the underlying disease. The more rapid recurrence and/or the severity of symptoms following rechallenge were in keeping with a putative immune-mediated reaction, but no immunological mechanism has been conclusively demonstrated (SED-13, 1121) (43,44). In one patient, progressively rising doses of azathioprine were successfully administered, despite positive skin prick tests (SEDA-21, 382). Anaphylactic shock has been occasionally reported (45). Delayed contact hypersensitivity with a positive patch test was described in a pharmaceutical handler of azathioprine (46).

Allergic reactions to mercaptopurine or azathioprine are well described, but a true immunoallergic reaction has never been convincingly demonstrated. Desensitization has been successfully performed in isolated patients (47), and this has been more extensively addressed in a retrospective analysis of the charts of patients treated for inflammatory bowel disease (48). Of 591 patients observed over a 28-year period, 16 (2.7%) developed allergic reactions, which mostly consisted of fever ($n = 14$), joint pains ($n = 6$), or severe back pain ($n = 5$). Symptoms commonly appeared within 1 month and lasted 5 days on average. All nine patients rechallenged with mercaptopurine had similar but less severe symptoms. Further rechallenge with azathioprine in six of these patients caused symptoms in five of them. Careful desensitization with mercaptopurine or azathioprine was attempted in five patients, and resulted in tolerance and therapeutic success in four. The last patient, who had a previous history of mercaptopurine-induced sepsis-like syndrome with renal insufficiency, had a similar reaction only after one-quarter of the dose of azathioprine. This study suggests that a direct switch from mercaptopurine to the parent drug azathioprine cannot be recommended in patients who developed allergic reactions to mercaptopurine, and that desensitization should not be attempted in patients with previous life-threatening hypersensitivity reactions.

A genetic predisposition is suspected, with a possible association between the hypersensitivity syndrome and the Bw4 and Bw6 phenotypes (SED-13, 1121). Mercaptopurine has sometimes been re-administered safely after a severe hypersensitivity reaction to azathioprine (49), suggesting a major role for the imidazole moiety of azathioprine. However, typical allergic reactions to mercaptopurine can also occur (SEDA-21, 381).

Infection risk

Infections, in particular bacterial and viral (cytomegalovirus, *Herpes simplex* virus, Epstein–Barr virus), and also protozoal and fungal infections, are major causes of morbidity and mortality in the post-transplantation period, whatever the immunosuppressive regimen used (50–52). Based on an analysis of medical and autopsy records, infections were found to be the cause of death in 70% of transplant patients, with bacteria (50%) or fungi (29%) the most common pathogens (53).

The frequency, course, and severity of *Herpes zoster* infection have been retrospectively evaluated in a sample of 550 patients treated with 6-mercaptopurine for inflammatory bowel disease (54). Twelve patients aged 14–73 years developed shingles after an average of 921 days, an incidence that was about two-fold higher than in the general population. Only three patients were still taking glucocorticoids at the time of onset of the shingles, and leukopenia was not associated with the occurrence of the infection. In nine patients, the course of the infection was 7–71 days and was uncomplicated. Two patients had more severe symptoms and suffered from postherpetic neuralgia. The last patient, a 14-year-old boy, had a brief episode of *H. zoster* during initial treatment and had *H. zoster* encephalitis at the age of 23 years, 16 months after 6-mercaptopurine had been restarted. From this report, it appears that 6-mercaptopurine can be restarted after brief discontinuation in patients who are expected to benefit from it.

- Fatal Epstein–Barr virus-associated hemophagocytic syndrome was reported in a young man taking azathioprine and prednisone for Crohn's disease (55).

© 2006 Elsevier B.V. All rights reserved.

Donor-specific blood transfusion in the preparation for transplantation was complicated by a higher incidence of cytomegalovirus infection in patients receiving azathioprine (56).

Long-Term Effects

Tumorigenicity

Because of the varied indications for azathioprine and mercaptopurine, it is difficult to determine whether there is an increased incidence of cancer specifically related to prolonged drug exposure. Data from the Cincinnati Transplant Tumor Registry, published in 1993, helped to define comprehensively the characteristics of neoplasms observed in organ transplant recipients (57). Skin and lip cancers were the most common, and non-Hodgkin's lymphomas represent the majority of lymphoproliferative disorders, with an incidence some 30- to 50-fold higher than in controls. An excess of Kaposi's sarcomas, carcinomas of the vulva and perineum, hepatobiliary tumors, and various sarcomas has also been reported. In contrast, the incidence of common neoplasms encountered in the general population is not increased. In renal transplant patients, the actuarial cumulative risk of cancer was 14–18% at 10 years and 40–50% at 20 years (58,59). Skin cancers accounted for about half of the cases. Very similar figures were found in later studies (SEDA-20, 341).

While there is no doubt that the incidence of malignancies is increased in the transplant population, there have been controversies as to which factors (duration of treatment, total dosage, the degree of immunosuppression, or the type of immunosuppressive regimens) are the most relevant in determining risk. Partial or complete regression of lymphoproliferative disorders and Kaposi's sarcomas after reduction of immunosuppressive therapy argues strongly for the role of the degree of immunosuppression (57). The incidence of cancer was also significantly higher in renal transplant patients taking triple therapy regimens compared with dual therapy (60). Similarly, aggressive immunosuppressive therapy may account for the higher incidence of lymphomas in patients with cardiac versus renal allografts.

In a large multicenter study in more than 52 000 kidney or heart transplant patients between 1983 and 1991, the rate of non-Hodgkin's lymphomas in the first post-transplantation year was 0.2% in kidney and 1.2% in heart recipients, and fell substantially thereafter (61). Initial immunosuppression with azathioprine and ciclosporin and prophylactic treatment with antilymphocyte antibodies or muromonab were associated with a significantly increased incidence of non-Hodgkin's lymphomas compared with other immunosuppressive regimens, which confirmed the major role of the level of immunosuppression. Later studies confirmed that immunosuppression per se rather than a single agent is responsible for the increased risk of cancer (SEDA-20, 340). Finally, the most striking difference between conventional and modern immunosuppressive regimens, including ciclosporin, was the average time to the appearance of tumors, in particular skin cancers and lymphomas, which was shorter in ciclosporin-treated patients (62,63). There was an increased incidence of non-Hodgkin's lymphomas in patients receiving long-term azathioprine and prednisolone for rheumatoid disease, although the latent period was longer than in other patients, perhaps reflecting a different pathogenesis (64).

Multiple factors with complex interactions are involved in the observed pattern and increased incidence of neoplasms. They include severely depressed immunity with an impaired immune surveillance against various carcinogens, the activation of several oncogenic viruses, and a possible mutagenic effect of the drugs. Viruses, such as papillomavirus, cytomegalovirus, and Epstein–Barr virus, are believed to play an important role in the development of several post-transplant cancers. From a theoretical point of view, the use of antiviral drugs active against herpes viruses, which are commonly implicated as co-factors, can be expected to produce a reduction in the incidence of post-transplant lymphoproliferative disorders.

Long-term treatment with azathioprine has been associated with transitional carcinoma of the bladder and non-Hodgkin's lymphoma in a single case (65).

- A 59-year-old man who had had a testicular non-Hodgkin's lymphoma for 9 years, developed diplopia and ptosis due to myasthenia gravis with antibodies to the acetylcholine receptor. He was given pyridostigmine and prednisolone. After 6 months he developed pernicious anemia, and he was given vitamin B_{12} injections. An attempt to reduce the dose of prednisolone failed, and he was therefore given azathioprine and the dose of prednisone was progressively reduced. Two years later he developed a transitional carcinoma of the bladder (pTa g1), which was removed by transurethral resection. Seven years later he developed a swollen tender right testis due to a B cell lymphoma. He tolerated chemotherapy (CHOP) poorly and died 2 months later.

In renal transplant recipients, premalignant dysplastic keratotic lesions increased in frequency by 6.8% per year after the first 3.5 years after transplantation, and were ultimately observed in all 167 patients within 16 years of transplantation (66). No relation with sun exposure or skin type was found. The great majority of these patients were taking prednisolone and azathioprine, but azathioprine was considered as the main causative factor, possibly due to a carcinogenic effect rather than to immunosuppression itself.

Several isolated reports and epidemiological studies have addressed the risk of cancer in non-transplant patients treated with azathioprine. Promptly reversible Epstein–Barr virus-associated lymphomas have been reported as single cases, as have reports of acute myeloid leukemia with 7q deletion, rapidly aggressive squamous cell carcinomas, soft tissue carcinomas, or fatal Merkel cell carcinomas in patients taking long-term azathioprine maintenance (SED-13, 1122) (SEDA-20, 342) (SEDA-21, 382) (SEDA-22, 410). Although epidemiological studies allow a more accurate estimate, conflicting results have emerged and there is as yet no definite evidence that azathioprine actually increases the risk of cancer.

An increased risk of non-Hodgkin's lymphomas, possibly related to treatment duration, has been found in

© 2006 Elsevier B.V. All rights reserved.

patients with rheumatoid arthritis (67). There was no evidence that azathioprine increased the overall incidence of any cancer in 259 patients with rheumatoid arthritis on immunosuppressive treatment (azathioprine in 223) and matched for age and sex (but not for disease duration and severity) with unexposed patients (68). However, death more often resulted from malignancies in those taking azathioprine.

In cases of inflammatory bowel disease, no overall increased incidence of cancer was noted after a median of 9 years follow-up in 755 patients who had taken less than 2 mg/kg/day of azathioprine over a median period of 12.5 years (69). Only colorectal cancers (mostly adenocarcinoma) were more frequent, but their incidence was also increased in chronic inflammatory bowel diseases. More specifically, there was no excess of non-Hodgkin's lymphoma, but the power of the study to detect an increased risk of this disorder was low.

Another group of investigators has estimated that the potential long-term risk of malignancies outweighs the therapeutic benefit, but this conclusion was based on the follow-up of only 157 patients treated for Crohn's disease (4).

In 626 patients with inflammatory bowel disease who had taken azathioprine for a mean duration of 27 months (mean follow-up 6.9 years), there was no increased risk of cancer (colorectal or other) (70).

In a case-control study using a database of 1191 patients with multiple sclerosis, 23 cancers (17 solid tumors, two skin tumors, and four hemopoietic cancers) were found. The relative risk of cancer was 1.3 in patients treated for less than 5 years, 2.0 in those treated for 5–10 years, and 4.4 in those treated for more than 10 years; however, none of these later changes was significant (71). Nevertheless, there was a significant association for cumulative dosages in excess of 600 g. Taken together, these results suggest a low risk of cancer in non-transplant patients, but they cannot exclude a possible dose-related increase in risk during long-term treatment.

Skin carcinoma (predominantly squamous-cell carcinoma), cancer of the lip, Kaposi's sarcoma, and carcinoma of the cervix and anus are reported to be more common following azathioprine than in the general population (72).

Mercaptopurine is not considered to be leukemogenic, but this assumption has been disputed in a study of 439 children who received mercaptopurine as part of their maintenance therapy for acute lymphoblastic leukemia (73). Five patients developed secondary myelodysplasia or acute myeloid leukemia 23–53 months after diagnosis, a consequence that was attributed to mercaptopurine. These five patients had significantly lower TPMT activity, and two were classified as heterozygous for TPMT deficiency on genotype analysis. Although the number of evaluable patients was small, the suggestion was that a subset of patients with low TMPT activity might have an increased leukemogenic risk when exposed to mercaptopurine with other cytotoxic agents. Whether these findings can be extrapolated to patients without cancers is not known.

Of 550 patients with inflammatory bowel disease treated for a mean of 8 years, 25 (4.5%) developed a malignancy, with an overall incidence of 2.7 neoplasms per 1000 years of follow-up (74). The numbers of the most commonly observed cancers, such as bowel cancers ($n = 8$), breast cancers ($n = 3$), or single cases of other cancers, did not seem to be higher than expected in the general population or in the inflammatory bowel disease population. Although mercaptopurine was suspected in two cases of testicular carcinoma, two cases of lymphoma, and one case of leukemia, the authors emphasized the small risk of malignancies compared with the beneficial results of mercaptopurine in inflammatory bowel disease.

Second-Generation Effects

Pregnancy

Even though azathioprine is teratogenic in animals, human experience allows no firm conclusions, being limited to single case reports of birth defects after first trimester exposure to azathioprine. More convincingly, there was no evidence of increased risk or of a specific pattern of congenital anomalies among hundreds of infants born to azathioprine-treated transplant patients (75–77), but large series with adequate long-term follow-up are still lacking. The absence of inosinate pyrophosphorylase, an enzyme that converts azathioprine to its active metabolites, in the fetus was suggested to account for these reassuring data. Other potential risks, that is miscarriages or stillbirths, were also within the normal range, and intrauterine growth retardation did not appear to be specifically related to azathioprine use. Potential neonatal consequences of maternal azathioprine maintenance during the whole pregnancy should be borne in mind, in view of isolated reports of immunohematological immunosuppression, pancytopenia, cytomegalovirus infection, and chromosome aberrations. Unfortunately, the extent of this risk has not been carefully evaluated.

Teratogenicity

Maternal azathioprine treatment during pregnancy is clearly teratogenic in animals, but the mechanisms are not known. A large number of reports have described the outcome of pregnancies following the use of immunosuppressant drugs, in particular in renal transplant patients, and hundreds of pregnancies have been analysed (75). The largest experience is that derived from the National Transplantation Pregnancy Registry which has been built up in the USA since 1991 (76). This registry has accumulated data on more than 900 pregnancies, of which 83% followed kidney transplantation. Overall, the immunosuppressant drug regimens commonly used in transplant patients (azathioprine or ciclosporin) do not appear to increase the overall risk of congenital malformations or produce a specific pattern of malformation. Risk factors associated with adverse pregnancy outcomes included a short time interval between transplantation and pregnancy (that is less than 1–2 years), graft dysfunction before or during pregnancy, and hypertension (78).

Possible long-term effects of in utero exposure to immunosuppressants are still seldom investigated. There have been no reports that physical and mental development or renal function are altered. In one study, there were changes in T lymphocyte development in seven children born to mothers who had taken azathioprine or

© 2006 Elsevier B.V. All rights reserved.

ciclosporin, but immune function assays were normal, suggesting that development of the fetal immune system was not affected (79).

In 27 clinical series, the frequency of congenital anomalies among infants of patients who took azathioprine after renal transplantation ranged from 0 to 11% (80).

The consequences of paternal mercaptopurine exposure on the outcome of pregnancies have been retrospectively studied in 57 men with inflammatory bowel disease: 23 men had fathered 50 pregnancies and had taken mercaptopurine before conception; of these, 13 pregnancies were conceived within 3 months of paternal mercaptopurine use (group 1A) and 37 pregnancies were conceived at least 3 months after paternal mercaptopurine withdrawal (group 1B); the other 34 men, who fathered 90 pregnancies, had not been exposed to mercaptopurine before conception (group II) (81). Of the 140 conceptions, two resulted in congenital anomalies in group 1A, whereas there were no congenital anomalies in the other groups. One child had a missing thumb, and the other had acrania with multiple digital and limb abnormalities. The overall number of complications (spontaneous abortion and congenital anomalies) was significantly higher in group 1A (4/13) compared with both group IB (1/37) and group II (2/90). Although the retrospective nature of this study and the limited number of evaluable patients precluded any definitive conclusion, the observed congenital anomalies were similar to those found in the offspring of female rabbits treated with mercaptopurine during pregnancy, and suggested that paternal mercaptopurine treatment should ideally be discontinued at least 3 months before planned conception.

Whereas neutropenia and immune deficiencies can affect neonates born to transplant patients, the exact role of azathioprine is difficult to establish. A report has suggested that such effects should also be expected in neonates born to patients taking azathioprine for other conditions (82).

- A 27-year-old woman, who took azathioprine (125 mg/day) and mesalazine (3 g/day) during her whole pregnancy, delivered a normal boy who had febrile respiratory distress after 36 hours. Chest X-ray showed interstitial pneumonitis and thymus hypoplasia. There was severe neutropenia (20×10^6/l), lymphopenia (24×10^6/l), and hypogammaglobulinemia. His clinical condition improved over the next 26 days with immunoglobulin treatment and antibiotics, but B lymphocytes and IgM were still undetectable.

Lactation

Very few data on breastfed infants from azathioprine-treated mothers are available. Breastfeeding is not recommended owing to the potential risk of immunosuppression, growth retardation, and carcinogenesis.

Susceptibility Factors

Genetic factors

The complex metabolism of azathioprine and mercaptopurine is subject to a pharmacogenetic polymorphism that is relevant to the degree of efficacy and toxicity attained in a given individual. Thiopurine methyltransferase (TPMT) is one of the key enzymes regulating the catabolism of thiopurine drugs to inactive products. Owing to an inherited autosomal codominant trait, a significant number of patients have intermediate (11%) to low or undetectable (0.3%) TPMT activity (83). These patients produce larger amounts of the active 6-thioguanine nucleotides and may therefore be unusually sensitive to commonly used dosages and an increased risk of myelotoxicity (SED-13, 1120) (SEDA-21, 381).

Monitoring azathioprine therapy by measuring erythrocyte 6-thioguanine concentrations and TPMT activity is thought to ensure optimal immunosuppressive effects and to reduce the likelihood of hematological toxicity (84,85). Low or completely absent erythrocyte TPMT activity and high concentrations of erythrocyte 6-thioguanine metabolites have been found in patients with severe azathioprine-induced bone marrow toxicity, as compared to those without bone marrow toxicity (86,87). However, intracellular concentrations of thiopurine nucleotides alone did not always correlate with hematological toxicity (88). In patients in whom TPMT deficiency was not clearly demonstrated, low lymphocyte 5'-nucleotidase activity and xanthine oxidase deficiency or other factors have been postulated as possible causes of hemotoxicity, suggesting that bone marrow toxicity is probably multifactorial (87,89,90). Although not all investigators recommend systematic pretreatment screening for purine enzyme activities, evidence of deficiency of purine enzymes could well be sought when early bone marrow toxicity occurs.

In a retrospective analysis of 106 patients with inflammatory bowel disease, to evaluate the importance of thiopurine methyl transferase (TPMT) activity in the management of azathioprine therapy in inflammatory bowel disease, the relation between inherited variations in TPMT enzyme activity and azathioprine toxicity was confirmed (91).

In 3291 patients receiving azathioprine, 10% had a low TPMT activity and 15 (1 in 220 or 0.46%) had no detectable enzymatic activity at all (92), slightly more common than has been reported in other studies (1 in 300). This makes the economics of screening, to avoid myelosuppression in patients receiving azathioprine, attractive.

Of 78 patients treated with azathioprine for systemic lupus erythematosus, 10 developed azathioprine-associated reversible neutropenia (93). Only one of these patients was homozygous for TPMT deficiency, but he had the most severe episode (aplastic anemia).

In one study, 14 of 33 patients with rheumatoid arthritis had severe adverse effects (mostly gastrointestinal toxicity, flu-like reactions or fever, pancytopenia, and hepatotoxicity) within 1–8 weeks after azathioprine was started (94). The adverse effects subsided after withdrawal in all patients, but all eight patients who were rechallenged developed the same adverse effect. A baseline reduction in TPMT activity was significantly associated with the occurrence of these adverse effects in seven of eight patients, with a relative risk of 3.1 (95% CI = 1.6–6.2) compared with patients with high TPMT activity (seven of 25 patients). Another prospective evaluation in 67 patients with rheumatic disorders showed that TPMT genotype analysis is useful in identifying patients at risk of azathioprine toxicity (95). Treatment duration was

© 2006 Elsevier B.V. All rights reserved.

significantly longer in patients with the wild-type TPMP alleles than in those with mutant alleles, and that was due to the early occurrence of leukopenia in the latter.

In 22 children with renal transplants, high erythrocyte TPMT activity, measured 1 month after transplantation, correlated positively with rejection episodes during the first 3 months, and this was probably due to more rapid azathioprine catabolism (96). As suggested in a study of 180 patients with acute lymphoblastic leukemia, determination of genetic polymorphisms in TMPT can be useful in predicting potential toxicity and in optimizing the determination of an appropriate dose in patients who are homozygous or heterozygous for TMPT deficiency (97).

In 30 heart transplant patients taking azathioprine, the myelosuppressive effects of azathioprine/mercaptopurine were predicted by systematic genotypic screening of thiopurine methyltransferase deficiency (98). However, myelosuppression can also be observed in patients without the thiopurine methyltransferase mutation. Of 41 patients with leukopenia or thrombocytopenia taking azathioprine/mercaptopurine for Crohn's disease, four were classified as low methylators, seven as intermediate methylators, and 30 as high methylators by genotypic analysis (99). Thus, only 27% of the patients had the typical mutations associated with enzyme deficiency and a risk of myelosuppression. The delay in bone marrow toxicity was shorter in the four homozygous patients (median 1 month) than in the others (median 3–4 months). Many other causes, including viral infections, associated drugs, or another azathioprine/mercaptopurine metabolic pathway, were suggested to account for most of the cases of late hemotoxicity. This confirmed that continuous hematological monitoring is required, even in patients with no thiopurine methyltransferase mutations.

Drug–Drug Interactions

Allopurinol

Allopurinol inhibits xanthine oxidase, which is involved in the inactivation of azathioprine and mercaptopurine, and bone marrow suppression is a well-known complication of the concomitant use of allopurinol and azathioprine (SEDA-16, 114) (SEDA-20, 342). A reduction in the dosage of azathioprine or mercaptopurine by at least two-thirds and careful hematological monitoring during the first weeks of the combination has been proposed if combined use with allopurinol is required. However, compliance with these above guidelines was observed in only 58% of 24 patients with heart or lung transplants (100). In addition, although adequate azathioprine dosage reduction reduces the incidence of cytopenias, the risk persists even after the first month of the combination.

Because of the possible risks of reduced immunosuppression if the dose of azathioprine is reduced when allopurinol is given, cyclic urate oxidase can be given instead, as has been shown in six hyperuricemic transplant patients treated with azathioprine (101).

Aminosalicylates

In vitro studies have suggested that sulfasalazine and other aminosalicylates can inhibit TPMT activity, predisposing to an increased risk of bone marrow suppression in patients taking azathioprine or mercaptopurine. This was not clinically substantiated until an extensively investigated case was reported of leukopenia and anemia in a patient treated with both olsalazine and mercaptopurine (SEDA-21, 382). A further inhibiting effect of olsalazine was suggested in this patient, who had a relatively low baseline TPMT activity.

In 16 patients with Crohn's disease taking a stable dose of azathioprine, plus sulfasalazine or mesalazine, mean 6-thioguanine nucleotide concentrations fell significantly over 3 months; withdrawal of the aminosalicylates had no effect on the clinical and biological evolution of Crohn's disease in these patients (102).

Coumarin anticoagulants

Azathioprine or mercaptopurine have been sometimes involved in reduced warfarin and acenocoumarol activity, and increased warfarin dosages may be necessary (103). Similar findings were found in a patient taking maintenance phenprocoumon (SEDA-21, 382).

- Two patients required an approximate three-fold increase in the weekly anticoagulant dosage while taking azathioprine or mercaptopurine (104,105).

A pharmacokinetic interaction is the most likely cause, but the mechanism (impaired absorption or enhanced anticoagulant metabolism) is unknown.

Isotretinoin

The combination of isotretinoin and azathioprine was reported to have a synergistic effect on the occurrence of curly hair in three transplant patients with ciclosporin-induced acne (SEDA-20, 342).

Methotrexate

In 43 patients with rheumatoid arthritis, methotrexate was thought to have increased the risk of the azathioprine-induced hypersensitivity syndrome (106).

Azelastine

See also Antihistamines

General Information

Azelastine is a second-generation antihistamine, a phthalazinone compound with antiallergic and bronchodilator properties (SEDA-12, 375) (SEDA-15, 155) (SEDA-17, 199) (SEDA-18, 182, 184) (SEDA-19, 171–172) (SEDA-20, 162) (SEDA-21, 172) (SEDA-22, 178). It is available as a nasal spray and in oral form for the treatment of allergic rhinitis and asthma as well as dermatoses. It reduces rhinorrhea, sneezing, and nasal congestion. Azelastine is effective against exercise-induced asthma and allergen challenge in patients with extrinsic asthma. It can inhibit histamine release

© 2006 Elsevier B.V. All rights reserved.

from mast cells and inhibit histamine- and leukotriene-mediated bronchospasm (1).

Comparative studies

There have been three double-blind, randomized, parallel-group comparisons of the effects of azelastine nasal spray (1.1 mg/day) with combined treatment with oral loratadine (10 mg/day) and budesonide nasal spray (336 μg/day) in 1070 patients with allergic rhinitis unresponsive to monotherapy (2). The primary outcome measure was the percentage of patients who needed additional therapy for rhinitis after 7 days of treatment, and this was 32–46% across the three studies, with no significant difference between the two treatment groups. The most common adverse event with azelastine was a transient after-taste (8% compared with 1% in the combined group) and the most common adverse event for combined treatment was headache (6% compared with 5% in the azelastine group). Rhinitis and somnolence were the other commonly reported adverse events, in 3 and 2% with azelastine, and 1 and 1% in the combined group. The authors concluded that monotherapy with azelastine is as effective and as well tolerated as combination therapy in improving symptoms in moderate to severe allergic rhinitis, and this seems to be a reasonable claim.

Azelastine has been compared with the potent antihistamine cetirizine in the treatment of pruritic dermatoses. Taste disturbance occurred in 9.7% of patients taking azelastine and headaches in 10.4% of patients taking cetirizine (3).

Similar complaints regarding taste or smell were noted in some patients when azelastine nasal spray was used alongside budesonide (4) or ebastine (5) in allergic rhinitis in equieffective doses.

General adverse effects

In controlled studies, azelastine nasal spray produced a high incidence of itching and burning of the nasal mucosa together with taste disturbance and sometimes unpleasant smell. Sedation does not seem to be frequent; in most studies, the frequency of fatigue and drowsiness was not significantly different from placebo. In an open trial in which 119 patients with various types of pruritic dermatoses were treated with oral azelastine, 27 patients reported mild adverse effects such as drowsiness (15 cases, 12.5%) and a bitter after-taste (six cases, 5%). In four patients the treatment was withdrawn because of adverse effects (SEDA-15, 2).

Organs and Systems

Sensory systems

There have been several reports of a bitter taste associated with azelastine nasal spray for the treatment of allergic and non-allergic rhinitis compared with placebo in adults and children (6–8). Azelastine has also been reported to alter taste perception for several hours after ingestion (9).

Azelastine eye drops (0.025 and 0.05%) can produce slight reactions at the site of application and a bitter or unpleasant taste (10).

Azipranone

General Information

Azipranone is a cough suppressant claimed to have effects comparable to those of codeine (1). Limited evidence suggests that its adverse effects are no different from those of placebo (SEDA-9, 157).

Azithromycin

See also Macrolide antibiotics

General Information

Observational studies

In 3995 patients who took azithromycin 1.5 g in divided doses over 5 days or who took 1 g as a single dose for urethritis/cervicitis adverse events occurred in 12% (1). In patients over 65 years the rate was 9.3%, and in children under 14 years of age it was 5.4%. The most common adverse effects were gastrointestinal (9.6%); central nervous system and peripheral nervous system effects were reported in 1.3%. Overall, 59% of the adverse events were considered mild, 34% moderate, and only 6% severe, involving mainly the gastrointestinal tract. Adverse events resulted in withdrawal in 0.7% of patients, lower than the rate reported with other macrolides. Treatment-related rises in liver enzymes were uncommon (under 2%), as was leukopenia (1.1–1.5%).

Phase II/III clinical trials in the USA have yielded data on 1928 children aged 6 months to 15 years who took azithromycin for infections that included acute otitis media ($n = 1150$) and streptococcal pharyngitis ($n = 754$) (2). Most took a 5-day course of azithromycin (5–12 mg/kg/day). There were adverse effects in 190 patients (9.9%): diarrhea (3.1%), vomiting (2.5%), abdominal pain (1.9%), loose stools (1%), and rash (2.5%). In three comparisons with co-amoxiclav, the overall incidence of adverse effects was significantly lower with azithromycin (7.7 versus 29%), with withdrawal rates of 0.3 versus 3.6%. However, the incidence of adverse effects was significantly greater with azithromycin than with penicillin V in comparisons in patients with streptococcal pharyngitis (13 versus 6.7%). In conclusion, it appears that the safety and tolerability of azithromycin is similar in children and adults.

In an open study, children with end-stage lung disease or chronic airflow limitation unresponsive to conventional therapy were treated with long-term azithromycin. Seven children (mean age 12 years), all of whom were colonized with *Pseudomonas aeruginosa* and who took azithromycin for more than 3 months, were studied. There was a significant improvement in FVC and FEV_1 (3). The mechanism whereby azithromycin works is unknown, but it may be other than antibacterial. It has been hypothesized that the effect may be due to upregulation of a P glycoprotein, a member of the family of multidrug resistant proteins, since erythromycin upregulates P glycoprotein expression in a monkey model. Multidrug resistance (MDR) is homologous to CFTR, and previous in vitro experiments have shown that the MDR and CFTR genes can complement each other (4). However, direct proof of this hypothesis is lacking at the moment.

Of 42 adult HIV-positive patients with confirmed or presumed acute toxoplasmic encephalitis who received azithromycin 900, 1200, or 1500 mg/day plus pyrimethamine, 28 responded to therapy during the induction period (5). Six patients withdrew during the induction period because of reversible toxic effects (three with raised liver enzymes, two with hearing loss, one with neutropenia). Treatment-terminating adverse events occurred most often among the patients who took 1500 mg/day.

In an open, prospective trial gingival hyperplasia due to ciclosporin was successfully treated with azithromycin 250 mg/day for 5 days in 30 of 35 patients, who reported esthetic satisfaction and disappearance of bleeding and pain (6). There was no change in ciclosporin concentration or renal function after azithromycin.

Comparative studies

The tolerability of azithromycin oral suspension, 10 mg/kg od for 3 days, has been assessed in children in a review of 16 multicenter studies (7). Of 2425 patients, 1213 received azithromycin and 1212 received other drugs. The incidence of treatment-related adverse events was significantly lower in those who took azithromycin, while withdrawal rates were similar. There were significantly fewer gastrointestinal events with azithromycin and their duration was significantly shorter.

Co-amoxiclav

In a multicenter, parallel-group, double-blind trial in 420 evaluable patients aged 6 months to 16 years with community-acquired pneumonia, the therapeutic effect of azithromycin (once-daily for 5 days) was similar to that of co-amoxiclav in children under 5 years and to that of erythromycin tds for 10 days. Treatment-related adverse events occurred in 11% of those given azithromycin and 31% in the comparator group (8).

Azithromycin (500 mg/day for 3 days) has been used to treat acute periapical abscesses (9). Of 150 patients treated with azithromycin 18 reported a total of 26 adverse events. Slightly more (24 out of 153) treated with co-amoxiclav reported 34 adverse events, but this difference did not reach statistical significance. Most of the adverse events (44/60) were gastrointestinal, mostly diarrhea or abdominal pain. There were no significant differences between the two groups in the severity of adverse events or in the number of withdrawals because of adverse events.

Fluoroquinolones

In a multicenter, open, randomized comparison of levofloxacin 500 mg/day orally or intravenously and azithromycin 500 mg/day intravenously for up to 2 days plus ceftriaxone 1 g/day intravenously for 2 days in 236 patients, the most common drug-related adverse events in those given azithromycin were diarrhea (4.2%), vein disorders (2.5%), and pruritus (1.7%) (10).

Other macrolides

The incidence of disseminated MAC infection has increased dramatically with the AIDS epidemic. Treatment regimens for patients with a positive culture for MAC from a sterile site should include two or more drugs, including clarithromycin. Prophylaxis against disseminated MAC should be considered for patients with a CD4 cell count of less than 50×10^6/l (11). In a randomized, open trial in 37 patients with HIV-associated disseminated MAC infection, treatment with clarithromycin + ethambutol produced more rapid resolution of bacteremia, and was more effective at sterilization of blood cultures after 16 weeks than azithromycin + ethambutol (12).

© 2006 Elsevier B.V. All rights reserved.

Tetracyclines

Compared with tetracycline, azithromycin had a favorable short-term effect on childhood morbidity in a mass trial for trachoma in rural Gambian villages, and adverse effects were limited (13).

Treatment of facial comedonic and papulopustular acne with azithromycin (500 mg/day for 4 days in four cycles every 10 days) may be at least as effective as minocycline (100 mg/day for 6 weeks). Both were well tolerated and mild adverse effects were reported in 10% of patients given azithromycin and 12% of those given minocycline (14).

Placebo-controlled studies

In 169 patients with acute infective rhinitis, azithromycin (500 mg/day for 3 days) resulted in a better cure rate after 11 days than placebo; however, after 25 days the results for both improvement and cure were equal (15).

In a randomized, double-blind, placebo-controlled multicenter trial in 174 HIV-infected patients with CD4 cell counts of under 100×10^6/l, azithromycin (1200 mg once a week) was safe and effective in preventing disseminated MAC infection, death due to MAC infection, and respiratory tract infections (16).

In a triple-masked, randomized, placebo-controlled study in 1867 women, prophylaxis with azithromycin 500 mg 1 hour before IUCD insertion did not affect the rate of IUCD removal, the frequency of medical attention after insertion, or the risk of upper genital tract infection at 90 days (17). Women were at low risk of sexually transmitted disease according to self-reported medical history. Gastrointestinal adverse effects were infrequent (3% azithromycin; 2% placebo). Fewer women taking azithromycin (0.7%) than those taking placebo (1.3%) were treated with antibiotics for pelvic tenderness; however, this difference was not statistically significant. Since cervical infections increase the risk of pelvic infection in women who use IUCDs, generalization of these results may be difficult (18).

In a meta-analysis of randomized, controlled trials of 3–5 days of azithromycin or other antibiotics that are typically given in longer courses for upper respiratory tract infections, there were no significant differences in bacteriological outcomes (19). Azithromycin was withdrawn because of adverse events in only 37 (0.8%) of 4870 patients.

Organs and Systems

Cardiovascular

Torsade de pointes and cardiorespiratory arrest have been reported in a patient with congenital long QT syndrome who took azithromycin (20). In a prospective study of 47 previously healthy people, there was a modest statistically insignificant prolongation of the QT_c interval without clinical consequences after the end of a course of azithromycin 3 g/day for 5 days (21).

Sensory systems

Ears

Azithromycin can cause ototoxicity. In one study, 8 (17%) of 46 HIV-positive patients had probable ($n = 6$) or possible ($n = 2$) ototoxicity with azithromycin (22). The effects were hearing loss (88%), tinnitus (37%), plugged ears (37%), and vertigo (25%), developing at a mean of 7.6 weeks (1.5–20 weeks) after the start of long-term azithromycin therapy for *Mycobacterium avium* infection. The symptoms resolved in a mean of 4.9 weeks (2–11 weeks) after withdrawal.

Sensorineural hearing loss has been attributed to azithromycin (23).

- A 35-year old Caucasian man with AIDS and multiple opportunistic infections, including *Mycobacterium kansasii* and *Mycobacterium avium* complex (MAC) disease developed moderate to severe primary sensorineural hearing loss after 4–5 months of therapy with oral azithromycin 500 mg/day. Other medications included ethambutol, isoniazid, rifabutin, ciprofloxacin, co-trimoxazole, fluconazole, zidovudine (later switched to stavudine), lamivudine, indinavir, methadone, modified-release oral morphine, pseudoephedrine, diphenhydramine, megestrol acetate, trazodone, sorbitol, salbutamol by metered-dose inhaler and nebulizer, ipratropium, and oral morphine solution as needed. Significant improvement of the hearing impairment was documented 3 weeks after drug withdrawal.

A literature review identified several cases of ototoxicity in HIV-positive patients treated with azithromycin for *M. avium* complex infection. In four series, 14–41% of such patients had some degree of hearing loss. However, some patients were also taking other potentially ototoxic drugs, which may have contributed to the high frequency of hearing loss reported. Hearing loss improved markedly after withdrawal of azithromycin. Hearing loss may be more common and probably more severe with high-dose azithromycin than with high-dose clarithromycin.

- A 47-year-old woman who had a left lung transplantation 3 months earlier and who was taking ticarcillin + clavulanate and aztreonam for sinusitis, was given co-trimoxazole, ticarcillin + clavulanate, azithromycin (500 mg/day intravenously), and ganciclovir for presumed pneumonia (24). Other drugs included tacrolimus, mycophenolate, prednisone, lansoprazole, diltiazem, itraconazole, warfarin, alendronate, ipratropium bromide, folic acid, and nystatin. The next day, rimantadine and vancomycin were added, and co-trimoxazole was reduced. A neurological examination to assess symptoms of peripheral neuropathy noted no hearing deficit. On day 3, vancomycin, ticarcillin + clavulanate, and ganciclovir were withdrawn. On the fifth day, mild tinnitus and reduced hearing developed and gradually progressed to complete deafness. After eight doses, azithromycin was withdrawn, and 20 days later her hearing was back to baseline.

Low-dose exposure to azithromycin has been associated with irreversible sensorineural hearing loss in otherwise healthy subjects (25). Even a single oral dose of azithromycin altered the conjunctival bacterial flora of children from a trachoma endemic area (26). However, the clinical significance is not yet clear.

Psychological, psychiatric

Azithromycin can cause delirium (27).

© 2006 Elsevier B.V. All rights reserved.

Hematologic

The effects of combining azithromycin and rifabutin have been studied in 50 subjects with or without HIV infection, of whom 19 took azithromycin 1200 mg/day and rifabutin 600 mg/day, and 31 took azithromycin 600 mg/day and rifabutin 300 mg/day (28). Neutropenia was the most common adverse event, in 33 of 50 subjects. Low-grade nausea, diarrhea, fatigue, and headache were also common, and most subjects had more than one type of event. There was no significant pharmacokinetic interaction between the two drugs.

Gastrointestinal

In a review of 12 clinical studies most of the adverse events in those taking azithromycin affected the gastrointestinal system, and were reported in 138 (8.5%) azithromycin-treated patients (29). Abdominal pain, diarrhea, nausea, and vomiting were the most frequently reported gastrointestinal adverse events.

Gastrointestinal symptoms were the most common adverse effects reported in a trial of azithromycin in disseminated *Mycobacterium avium* complex in 62 patients with AIDS (30). Erythromycin is a motilin receptor agonist (31–33). This mechanism may be at least partly responsible for the gastrointestinal adverse effects of macrolides. Azithromycin may act on gastrointestinal motility in a similar way to erythromycin, as it produces a significant increase in postprandial antral motility (34).

Liver

Azithromycin can cause intrahepatic cholestasis (35).

- A 33-year-old woman and a 72-year-old man developed cholestasis after they had taken a 5-day course of azithromycin. The woman was given colestyramine and underwent six courses of plasmapheresis; 2 months later, her total bilirubin and serum transaminases were back to normal (36). After withdrawal of azithromycin, the man's symptoms resolved within 1 month and his liver enzymes returned to normal (37).

Skin

- A 19-year-old man with infectious mononucleosis developed a maculopapular, non-pruritic rash after one dose of azithromycin 500 mg (38).

Immunologic

Occupational allergic contact dermatitis has been attributed to azithromycin (39).

- A 32-year-old pharmaceutical worker had been loading reactors at three different stages of azithromycin synthesis for the past 3 years and had been exposed to airborne powders. He wore overalls and latex gloves. His symptoms had persisted for 1 year in the form of pruritus, erythema, vesicles, and scaling of the face and forearms. A positive patch test and a positive workplace challenge were considered reliable in the diagnosis of occupational allergic contact dermatitis induced by azithromycin. After transfer to another work station that excluded exposure to azithromycin, he had no further work-related symptoms.

Hypersensitivity to azithromycin has been reported (40).

- A 79-year-old man developed fever, mental changes, a rash, acute renal insufficiency, and hepatitis after he had completed a 5-day course of oral azithromycin (500 mg initially then 250 mg/day). With intravenous hydration only, his fever abated and his urinary output and renal and hepatic function returned to normal over the next 4 days. His mental status improved significantly. The skin rash was followed by extensive desquamation.

Azithromycin has been associated with Churg–Strauss syndrome in a patient with atopy (41).

Second-Generation Effects

Pregnancy

In two randomized trials in pregnant women with cervical *Chlamydia trachomatis* infection, women were randomized to oral amoxicillin 500 mg tds for 7 days or oral azithromycin 1 g in a single dose (42,43). The two drugs had similar efficacy. Adverse effects were common in both groups: 40% of those who took azithromycin reported moderate to severe gastrointestinal adverse effects compared with 17% of those who took amoxicillin.

Susceptibility Factors

Renal disease

In eight patients a single 500 mg oral dose of azithromycin was not substantially removed by continuous ambulatory peritoneal dialysis in the absence of peritonitis. Azithromycin cannot be recommended for widespread use in CAPD at present. However, the successful use of azithromycin in treating peritonitis, perhaps because of an intracellular drug transport mechanism, has been reported (44).

Drug–Drug Interactions

Antacids

Owing to interference by antacids, azithromycin should be given at least 1 hour before or 2 hours after antacids. Antacids containing aluminium and magnesium reduce peak serum concentrations, but the total extent of azithromycin absorption is not altered (45).

Antihistamines

The effects of azithromycin 250 mg/day on the pharmacokinetics of desloratadine 5 mg/day and fexofenadine 60 mg bd have been studied in a parallel-group, third-party-blind, multiple-dose, randomized, placebo-controlled study (46). There were small increases (under 15%) in the mean plasma concentrations of desloratadine. In contrast, peak fexofenadine concentrations were increased by 69% and the AUC by 67%. There were no changes in the electrocardiogram.

© 2006 Elsevier B.V. All rights reserved.

Carbamazepine

A retrospective analysis of 3995 patients treated with azithromycin did not show any pharmacokinetic interactions in patients who were also taking various other drugs, including carbamazepine (1,45).

Ciclosporin

When azithromycin is used concomitantly with ciclosporin, blood ciclosporin concentrations need to be monitored (47).

Cimetidine

A retrospective analysis of 3995 patients treated with azithromycin did not show any pharmacokinetic interactions in patients who were also taking various other drugs, including cimetidine (1,45).

Cytochrome P450

Azithromycin has a 15-membered ring and does not induce or inhibit cytochrome P450 in rats (48).

Digoxin

When azithromycin is used concomitantly with digoxin, serum digoxin concentrations need to be monitored (47). While data on the effects of azithromycin on the intestinal metabolism of digoxin have not been reported so far, it is likely that it will affect *Eubacterium lentum*, like other macrolides.

Methylprednisolone

A retrospective analysis of 3995 patients treated with azithromycin did not show any pharmacokinetic interactions in patients who were also taking various other drugs, including methylprednisolone (1,45).

Midazolam

In an open, randomized, crossover, pharmacokinetic and pharmacodynamic study in 12 healthy volunteers who took clarithromycin 250 mg bd for 5 days, azithromycin 500 mg/day for 3 days, or no pretreatment, followed by a single dose of midazolam (15 mg), clarithromycin increased the AUC of midazolam by over 3.5 times and the mean duration of sleep from 135 to 281 minutes (49). In contrast, there was no change with azithromycin, suggesting that it is much safer for co-administration with midazolam.

Piroxicam

In 66 patients undergoing oral surgery, treatment with azithromycin impaired the periodontal disposition of piroxicam (50).

Rifamycins

An interaction involving azithromycin with rifabutin, and less commonly rifampicin, was observed in patients with MAC infections (51).

Terfenadine

The potential interaction of azithromycin with terfenadine has been evaluated in a randomized, placebo-controlled study in 24 patients who took terfenadine plus azithromycin or terfenadine plus placebo (52). Azithromycin did not alter the pharmacokinetics of the active carboxylate metabolite of terfenadine or the effect of terfenadine on the QT interval.

Theophylline and other xanthines

A retrospective analysis of 3995 patients treated with azithromycin did not show any pharmacokinetic interactions in patients who were also taking various other drugs, including theophylline (1,45).

In two double-blind, randomized, placebo-controlled studies there was no inhibition of the metabolism of theophylline by azithromycin (53,54). However, there has been a report of reduced theophylline concentrations after withdrawal of azithromycin (55). The authors concluded that the mechanism of interaction was best explained by concomitant induction and inhibition of theophylline metabolism by azithromycin, followed by increased availability of unbound enzyme sites as azithromycin was cleared from the system.

Warfarin

A retrospective analysis of 3995 patients treated with azithromycin did not show any pharmacokinetic interactions in patients who were also taking various other drugs, including warfarin (1,45).

Zidovudine

Zidovudine does not affect azithromycin concentrations and azithromycin does not affect zidovudine concentrations (56).

Food–Drug Interactions

Owing to interference by food (57), azithromycin should be given at least 1 hour before or 2 hours after food.

Bacille Calmette–Guérin (BCG) vaccine

See also Vaccines

General Information

Bacille Calmette–Guérin (BCG) vaccine is a suspension of living tubercle bacilli of the Calmette–Guérin strain. It is used mainly prophylactically against tuberculosis, but also as a means of stimulating the immune response in malignant disease. There are variations in the characteristics of BCG vaccines, depending on the strain of BCG derived from the original BCG strain and employed for vaccine production. BCG is generally used intradermally, except for instillation in intravesical immunotherapy. The risk of adverse effects after BCG immunization is related to the BCG strain, the dose, the age of the vaccinee, the technique of immunization, and the skill of the vaccinator.

Therapeutic uses of BCG

In addition to its use in preventing tuberculosis, BCG has been used as an immunostimulant or immunomodulator. The degree of safety of this procedure differs with the technique and the purpose for which it is used. In most areas, the use of BCG to counter cancer has proved disappointing, although it is still used to some extent, generally as an adjunct to other forms of treatment (1–7). More encouraging is the use of intravesical instillation of BCG for recurrent superficial transitional cell carcinoma of the bladder, for which it now constitutes the treatment of choice.

BCG immunotherapy in bladder tumors

Intravesical instillation of BCG has been used to treat superficial bladder carcinoma and interstitial cystitis. Many reports have confirmed the efficacy of BCG in the treatment of transitional cell bladder cancers and have delineated its adverse effects (SEDA-12, 273) (SEDA-13, 278) (SEDA-15, 344) (SEDA-16, 375) (SEDA-17, 366) (SEDA-18, 328) (SEDA-20, 287) (SEDA-21, 328) (SEDA-22, 336). The exact mechanism of its antitumor activity is unknown, but live BCG provokes an inflammatory response that includes activation of macrophages, a delayed hypersensitivity reaction, and stimulation of T and B lymphocytes and natural killer cells.

In general, BCG immunotherapy of bladder cancer is considered to be relatively safe. However, it does have adverse effects, including fever, arthritis/arthralgia, bladder irritability, bladder contracture, cytopenias, cystitis, disseminated intravascular coagulation, respiratory failure, epididymitis, hepatitis, loss of bladder capacity, miliary tuberculosis, pneumonitis, polyarthritis, prostatitis, pyelonephritis, pseudotumoral granulomatous renal mass, rhabdomyolysis, renal granulomas, renal insufficiency, skin abscess, tuberculous aneurysm of the aorta and femoral artery, ureteral obstruction, vertebral osteomyelitis, and psoas abscess. A small number of reports of life-threatening adverse effects after BCG instillation have been published, including disseminated BCG infection (8–11), some fatal. These tragic cases illustrate many points of critical importance to all urologists using BCG. BCG should never be given at the same time as tumor resection or transurethral resection of the prostate. The dose of BCG given intravesically corresponds to a potentially lethal intravenous dose. Intravasation as a result of catheterization, tumor resection or biopsy, or cystitis has occurred in two-thirds of the reported cases of systemic BCG infection.

In a review of those observed among 195 patients with bladder cancer treated with various substrains of BCG, there were frequent but mild to moderate local adverse effects, with irritative cystitis leading to frequency and dysuria in 91% of patients and hematuria in 43% (12). Low-grade fever (24%), malaise (24%), and nausea (8%) also occurred. These symptoms usually occurred after two or three instillations and lasted for about 2 days. It has been stated that these frequent adverse effects did not seriously affect the quality of life of patients (13). Additional information was obtained from a multinational retrospective survey in order to cover the whole scope of severe and/or systemic complications associated with BCG immunotherapy, and to propose guidelines for management (14). Among 2602 patients in this survey, more than 95% had no serious adverse effects. Apart from fever higher than 39°C (2.9%) and major hematuria (1%) serious adverse effects comprised granulomatous prostatitis (0.9%), granulomatous pneumonitis and/or hepatitis (0.7%), arthritis and arthralgia (0.5%), epididymo-orchitis (0.4%), life-threatening BCG sepsis (0.4%), skin rashes (0.3%), ureteric obstruction (0.3%), bladder contracture (0.2%), renal abscesses (0.1%), and cytopenias (0.1%). There was no major difference in incidence among the different substrains used. Lowering the dose of BCG in an attempt to reduce the incidence of adverse effects produced somewhat contrasting results, with a reduced incidence of various adverse effects but no significant difference (or an apparently increased incidence) in the case of pollakiuria, hematuria, fever, and headache (SEDA-20, 287) (15).

Other rare complications have been seldom reported, namely cryoglobulinemia with evidence of disseminated BCG infection (16), ruptured mycotic aneurysm of the abdominal aorta (17), bladder wall calcification (18), rhabdomyolysis (19), iritis or conjunctivitis with arthritis or Reiter's syndrome (20,21), and severe acute renal insufficiency due to granulomatous interstitial nephritis, which can occur even in the absence of other systemic complications (22).

In 1990, the US Food and Drug Administration approved the marketing of BCG Live (intravesical) for use in the treatment of primary or relapsed carcinoma in situ of the urinary bladder, with or without associated papillary tumors. BCG is not recommended for treatment of papillary tumors that occur alone. The drug is marketed by Connaught Laboratories as TheraCys and by Organon as TiceBCG. The manufacturers recommend a 6-week induction course of weekly intravesical BCG, usually starting 1–2 weeks after biopsy or after transurethral resection of papillary tumors. Follow-up

© 2006 Elsevier B.V. All rights reserved.

courses of treatment at 3, 6, 12, and 24 months or monthly for 6–12 months after initial treatment are recommended.

Influence of dosage

The degree of success of different doses of BCG vaccine (100–120 mg, 20–50 mg, or a much smaller dose of 1 mg) in preventing tumor relapse has been described in patients with superficial bladder cancers (23). Adverse reactions were dose-related. The authors considered that endovesical instillation of BCG vaccine 1 mg would be the optimal dosage for prevention of relapse.

In 108 patients with bladder cancer, tumor relapse was prevented by the use of BCG vaccine 1 mg (24). Inguinal lymphadenitis and dysuria have occurred (SEDA-20, 287).

Comparison of BCG strains

In a comparison of 56 patients who received BCG instillations using Berna strain BCG and 32 patients who received Pasteur strain BCG for treatment of superficial bladder cancer, the patients who received Pasteur strain BCG had the highest tumor-free rate but had significantly more toxicity (25). The answer to another difficult question connected with the use of intravesical BCG, that is whether the treatment increases the incidence of second primary malignancies, has been sought (26,27). It was suggested that BCG immunotherapy could accelerate the growth and cause metastatic spread of a growing second primary malignancy that had remained undetected at the start of BCG therapy, and that the time relation between the starting point of second primary tumor development and the starting point of BCG treatment might be crucial in determining whether BCG eradicates the tumor or accelerates its growth. However, in 153 patients there was no evidence that intravesical BCG did increase the incidence of second primary malignancies (26). The matter is therefore still unresolved.

Comparison of different regimens for carcinoma in situ of the bladder

The efficacy and adverse effects of various alternative treatment regimens for carcinoma in situ of the bladder have been compared with those of instillation of BCG in 21 patients. All were treated initially with intravesicular instillations of Keyhole-Limpet Hemocyanin (first course: 20 mg weekly for six weeks; second course: 20 mg monthly for 1 year or bimonthly for 2 subsequent years). Patients who did not respond to two courses were treated with regular instillations of BCG Connaught strain 120 mg. Eleven patients were free from tumor tissue after the first or second course of Keyhole-Limpet Hemocyanin. Ten patients had to have a cystectomy because of persistence or progression of carcinoma after hemocyanin or hemocyanin with subsequent BCG. However, instillations of BCG caused severe dysuria in 60% and fever in 40% of patients, whereas hemocyanin treatment had only minor adverse effects (28). Combined therapy with mitomycin C and BCG was more effective in 28 patients with carcinoma in situ of the bladder than mitomycin alone (29). Compared with BCG monotherapy there were only a few adverse effects. The success rates were comparable.

Two different methods of treating superficial bladder cancer have also been compared in a randomized, multicenter trial, setting transurethral resection only against transurethral resection plus adjuvant mitomycin C and BCG instillation (30). The rate of progression was comparable in the two groups; at a medium follow-up of 20 months there was a reduction in recurrence rates with the combination therapy. Adverse effects occurred most often during or after BCG instillation. Other investigators have found the same degree of efficacy of the same regimen in reducing the incidence of recurrence of superficial urothelial cancer after transurethral bladder resection in 99 patients (31).

Treatment of adverse effects after intravesical instillation of BCG

The prompt recognition of risk factors for severe complications, namely traumatic catheterization or concurrent cystitis, that increase BCG absorption, and treatment of early adverse effects, is expected to reduce the incidence of severe adverse effects. Severe local and systemic adverse effects can be successfully treated with tuberculostatic drugs for up to 6 months (14).

Severe local and systemic adverse effects of BCG treatment can be treated successfully with tuberculostatic drugs, to most of which BCG is very susceptible, for up to 6 months (32). The effects of isoniazid on the incidence and severity of adverse effects of intravesical BCG therapy have been analysed in patients who received BCG with ($n = 289$) and without ($n = 190$) isoniazid (33). The authors concluded that prophylactic oral administration of isoniazid (300 mg/day with every BCG instillation) caused no reduction in any adverse effect of BCG. In contrast, transient liver function disturbances occurred slightly more often when isoniazid was used. The polymerase chain reaction has been used to monitor BCG in the blood after intravesical BCG instillation (22 patients) as well as after antituberculosis therapy (34). The early and fast diagnosis of BCG in the blood was considered to be potentially valuable in initiating specific early treatment of BCG complications.

General adverse effects of prophylactic BCG immunization

BCG immunization is generally well tolerated. Locally a small papule appears which scales and ultimately leaves a scar; however, abnormal reactions can occur. The most common adverse local reaction, suppurative lymphadenitis, has been reported in 0.1–10% of immunized children under 2 years of age. Faulty immunization technique is the most frequent cause of severe abnormal BCG primary reactions (35). The most serious generalized complications of BCG immunization involve disseminated infection with the BCG bacillus and BCG osteitis. Allergic reactions are unusual, but severe anaphylactic reactions can occur, especially when the product is used as an immunostimulant.

© 2006 Elsevier B.V. All rights reserved.

Tuberculin

Mammalian tuberculin purified protein derivative (tuberculin PPD) is the active principle of old tuberculin. A small test dose in a healthy individual, given intracutaneously, is likely to produce only a little local pain and pruritus. If tuberculous infection is present, the local reaction is more marked, with vesiculation, ulceration, and even granuloma annulare or necrosis.

If more than a minimal dose is used in cases of tuberculous infection, a severe and even fatal generalized anaphylactic reaction can develop within about 4 hours of the injection (36).

People who are engaged in manufacturing PPD can easily become sensitized to it, and severe allergic reactions can occur if they later inhale even small quantities (37).

Lymphangitis after tuberculin testing is rare (SED-11, 686).

Acute panuveitis has been reported (38). The episodes developed after each of two tests carried out at intervals of 8 years and responded well to glucocorticoid therapy.

Organs and Systems

Cardiovascular

A mycotic aneurysm, a rare complication of intravesical BCG therapy, has been reported (17).

- A 71-year-old man with bladder carcinoma in situ received six instillations of BCG at weekly intervals followed 3 months later by three booster instillations at weekly intervals. Four months later an inflammatory aortic aneurysm, which had ruptured into a pseudoaneurysm, was diagnosed and excised. *Mycobacterium bovis* was found. After treatment with isoniazid and rifampicin he recovered. There was no sign of tumor in the bladder at cystocopy 8 months after the last BCG instillation.

Respiratory

There have been two reports of micronodular pulmonary infiltrates (BCG pneumonitis) associated with fever, chills, and night sweats following multiple instillations of intravesical BCG (39). Both patients were 71 years old. The reactions, including radiographic infiltrates, resolved spontaneously or after steroid therapy.

Nervous system

There have been two reports of tuberculous meningitis after BCG immunization in immunocompetent individuals, in two French children aged 4.5 and 5 years (40) and in a 22-year-old woman from Cambridge, UK (41).

Polyneuritis has been attributed to BCG immunization (42).

Sensory systems

Responding to the question of whether accidental inoculation of one drop of BCG vaccine into the eye of a health-care worker could be a risk, Pless (personal communication) has reported the case of a urologist who developed a corneal ulcer after a similar accident.

Endogenous endophthalmitis (SEDA-15, 344) and bilateral optic neuritis (43) have been reported after BCG immunization.

Hematologic

Clinical trials in BCG-vaccinated newborns in different countries have variously found a dose–effect relation for the risk of suppurative lymphadenitis:

- Croatia (SED-12, 799)
- French Guyana (SEDA-16, 373)
- Germany (SED-12, 798)
- Hong Kong (SED-12, 799)
- Hungary (SED-12, 798)
- India (SEDA-18, 328)

or a strain-dependent relation:

- Austria (SEDA-16, 374) (SEDA-17, 366)
- Germany (SED-12, 798)
- India (SEDA-18, 328)
- Saudi Arabia (SED-12, 799)
- Togo (SED-12, 799)
- Turkey (SED-12, 799)
- Zaire (SED-12, 799)

Since 1984, WHO's Expanded Programme on Immunization has received many reports from various countries of an increased incidence of suppurative lymphadenitis after BCG immunization. Careful investigations of risk factors have been carried out, particularly in Zimbabwe and Mozambique (1987, 1988). Those studies established a strong association between an increased risk of lymphadenitis within 6 months of immunization and both the use of the Pasteur BCG strain, and programmatic errors, such as poor injection technique, poor technique in reconstituting and mixing the freeze-dried vaccine with diluent, or an incorrectly administered dose of vaccine. The incidence of lymphadenitis was 9.9% with the suspect Pasteur strain versus 0% with two other strains used under the same conditions. Experience gained in other countries has suggested that when Pasteur strain BCG vaccine is administered properly, the rate of lymphadenitis in newborns should not exceed 1%. The increased occurrence of lymphadenitis may require both a reactogenic strain and poor technique (44). A rare case of BCG lymphangitis occurring 11 years and again 18 years after immunization has been reported (45).

Liver

Granulomatous neonatal hepatitis has been reported after BCG immunization (46).

Skin

Since the initial report of lupus vulgaris following BCG immunization in 1946, about 60 cases have been published, mostly following (multiple) revaccination.

© 2006 Elsevier B.V. All rights reserved.

The risk of developing lupus vulgaris following primary immunization is extremely low.

- Lupus vulgaris occurred in a 7-year-old girl after only a single BCG immunization (47). She was treated with conventional antituberculosis therapy with an excellent response.
- Six months after BCG vaccination, an 18-year-old man developed lupus vulgaris on his right shoulder (48). He was successfully treated with rifampicin, isoniazid, and ethambutol. He had had lupus vulgaris after BCG vaccination on his left shoulder 8 years before.

Acute febrile neutrophilic dermatosis (49) and eczema vaccinatum (50) have been reported after BCG immunization.

Musculoskeletal

Arthritis and arthralgia are well-known adverse effects of intravesical BCG instillation as part of therapy of bladder cancer (SED-13, 925). The etiology and the different clinical pictures of BCG immunotherapy have been discussed (51). Considering that mycobacteria are potent stimulators of the immune system and especially of T cells, it is not surprising to observe T cell-mediated aseptic arthritis after BCG therapy. The authors suggested that the site of immune stimulation is critical, since intradermal injection produces a clinical presentation similar to reactive arthritis, and intravesical therapy causes a clinical picture identical to Reiter's syndrome.

In a large worldwide analysis of BCG adverse effects (1948–74) co-ordinated by the International Union Against Tuberculosis and Lung Disease (SED-12, 795) there were 272 cases of lesions of bones and joints, including synovial lesions. However, case reports of arthritis after BCG vaccination in healthy individuals are rare. Polyarthritis has been reported in a 33-year-old healthy woman 3 weeks after BCG vaccination (52).

Osteitis

Osteitis occurred in <0.1–30/100 000 vaccinees and has been reported mainly among infants immunized with BCG in the neonatal period in the Scandinavian countries. A retrospective study showed that BCG osteitis was present in Sweden from 1949 onwards. The reported incidence was one per 40 000 in children born between 1960 and 1969 (53,54). In Sweden, the reported incidence of osteitis rose to one per 3000 and one per 4000 for children vaccinated in the neonatal period during 1972–75. Compulsory notification of BCG adverse effects to the Swedish Adverse Drug Reaction Committee was introduced at that time.

The incidence of BCG osteitis correlates closely with the BCG vaccine used. Between 1960 and 1970, when the vaccine based on the Gothenburg strain was prepared in Sweden, the incidence of BCG osteitis was 7.3 per 100 000 vaccinees. There was a significant increase to 37 per 100 000 in the early 1970s, when the vaccine was prepared in Copenhagen using the same Gothenburg strain. Because of the increased incidence, in 1978 the vaccine was replaced by a BCG vaccine made by Glaxo, UK. Since then, the incidence has been similar to that reported in the 1960s (6.4 per 100 000 vaccinees) (55).

Following a report of 10 cases of BCG osteitis in Finland (56), the medical records of 222 children with BCG osteitis registered from 1960 to 1988 in Finland were analysed (55). The most common sites of osteitis were the metaphyses of the long bones; the legs were affected more often (58%) than the arms (14%). There was also osteitis of the sternum (15%) and ribs (11%). With adequate treatment, the prognosis for children with BCG osteitis was good, but six children were left with sequelae, with abnormalities of the limbs in five cases and pronounced cheloid formation in the other.

In Czechoslovakia, BCG osteitis was not diagnosed before 1981. However, from March 1980 onwards another BCG vaccine (Moscow strain) was introduced (57), and after 1981 12 cases of BCG osteitis were diagnosed (58). Most of the cases developed between 7 and 24 months after immunization, but some occurred later. The risk of osteitis rose to 35 per million in the period 1982–85. There were 28 cases of BCG osteomyelitis during the period from 1980 to June 1985, when Russian BCG vaccine containing a higher amount of culturable particles was used, and only 11 cases during the period from July 1985–89, by which time the dose of vaccine had been halved (59). During the last 2 years of the second period there was only one case in each immunized birth cohort. Elsewhere, an infant developed BCG osteomyelitis of the upper spine, a very rare complication described only three times before (60).

Six cases of BCG osteitis in Switzerland occurred in 1980–85 (61). Reports from various countries, for example New Zealand (62) and India (63), have emphasized the increasing knowledge of BCG osteitis. BCG osteitis has never been reported in the UK with use of the Glaxo vaccine. Table 1 shows rates of BCG osteitis in different countries (64).

Sexual function

- Following a 6-week course of intravesical BCG a 65-year-old man with carcinoma of the bladder developed a BCG-derived inflammatory infiltrate of the penis. The induration and lesions resolved after treatment with isoniazid and ethambutol (65).

Immunologic

The incidence of adverse effects after BCG immunization has been extensively investigated by the Committee on Prophylaxis of the International Union Against Tuberculosis and Lung Disease (IUATLD). Retrospective studies including 51 countries worldwide and collecting data from 1948–74, according to organ and system category, have been published (SED-12, 795) (64,66). The IUATLD carried out a second

Table 1 Rates of BCG osteitis in different countries

Country	Number of vaccinees (all age groups) (millions)	BCG osteitis	
		Number	Rate per million vaccinees
Finland	2.79	128	45.9
Sweden	3.42	121	35.4
Denmark	2.28	4	1.75
West Germany	9.03	14	1.55
Norway	2.32	2	0.86
East Germany	8.68	5	0.58
Switzerland	2.17	1	0.46
France	16.2	6	0.37
Austria	2.86	1	0.35
Yugoslavia	17.4	2	0.11
Europe (33 countries)	498	284	0.57
Israel	1.92	3	1.56
Algeria	8.05	2	0.25
Japan	166	2	0.01

(prospective) 6-country study (1979–83) (67), using the classification system already used in the retrospective study. The mean risk of local complications and suppurative lymphadenitis was low: 0.387 per 1000 vaccinees or 0.093 per 1000 with positive bacteriological/histological findings, respectively. There were 21 cases of disseminated BCG infections and allergic manifestations recorded in four countries. The estimated risks of serious disseminated BCG infection were higher than calculated previously (except for bone and joint lesions), but very low when comparing the benefit and risks of BCG immunization, especially in infants (67).

Anaphylactic reactions

Allergy to BCG exceptionally occurs when intravesical BCG is used as an immunoenhancing agent. An anaphylactic reaction has been reported (68).

Three cases of anaphylactic reactions to BCG have been described in young children, one (in a 3-month-old girl) being fatal (69).

An acute shock-like syndrome developed 30 minutes after BCG immunization of a newborn girl.

Non-IgE-mediated anaphylactic (anaphylactoid) reactions suspected to be caused by dextran as used in BCG vaccines have been described (SEDA-16, 375).

Disseminated BCG infection

Dissemination of BCG infection occurs in under 0.1/100 000 vaccinees and is usually associated with severe abnormalities of cellular immunity. Data collected on cases immunized between 1948 and 1974 (from the retrospective IUATLD study) are shown in Table 2 (64,66).

Many authors have provided detailed reports of disseminated BCG infection after BCG immunization at birth in newborns with various underlying immunodeficiency syndromes (severe combined immunodeficiencies, cellular immunodeficiency syndromes, X-linked chronic granulomatous disease or autosomal recessive chronic granulomatous disease) (70–72) and include patients with AIDS. 108 cases of disseminated BCG infection reported worldwide since 1951, including 30 cases of disseminated infection during 1974 to 1994 in France, have been analysed (73,74). Four well-defined immunodeficiency conditions predispose to disseminated BCG infection: severe combined immunodeficiency, chronic granulomatous disease, Di George syndrome, and AIDS. About half the cases of disseminated BCG infection occur in the absence of any well-defined underlying immunological defect. However, there is little doubt that children with idiopathic BCG infection are immunodeficient, and there is good evidence

Table 2 Number of complications recorded until December 1977 in a retrospective study of adverse effects of BCG worldwide among cohorts vaccinated during 1948–74

Adverse effect	Patients in 187 countries ($n = 1\,470\,208\,160$)		Patients in 51 countries in which some cases were recorded in any category ($n = 1\,053\,402\,835$)		Cases proven bacteriologically and/or histologically	
	Number	Rate	Number	Rate	Number	Rate
1 Abnormal BCG primary complex[a]	6602	4.49	6602	6.27	1100	1.04
2 and 3. Disseminated BCG infection: generalized and/or localized lesions (non-fatal and fatal)[b]	1072	0.73	1072	1.02	561	0.53
4. Syndromes or disease clinically associated with BCG immunization[c]	1838	1.25	1838	1.74	7	0.01
All categories	9512	6.47	9512	9.04	1668	1.58

[a] Such cases have often been proven bacteriologically and/or histologically.
[b] Until now, such cases have never been proven either bacteriologically or histologically.
[c] For these seven cases, TB lesions were seen at post-mortem examination, but BCG etiology was doubtful.

that their immunodeficient status is inherited: four pairs of siblings and one pair of cousins were found among 60 children with idiopathic disseminated BCG infection; in addition, among the 50 single-case families, parental consanguinity was found in 7 of 24 families for whom information was available.

There have been reports of disseminated BCG infection in children with chronic granulomatous disease which can result in prolonged and relapsing local complications to BCG immunization (75–77). In a series of autopsies, 26 of 36 children who had been given BCG shortly after birth showed tuberculoid granulomas at various sites. None of the infants had histological evidence of immune deficiency (SEDA-8, 301) (78).

- Recovery from BCG sepsis has been documented in a 7-year-old girl with immunodeficiency (79).
- Two other infants with severe combined immunodeficiency who had developed BCG dissemination after neonatal BCG immunization were treated successfully by bone marrow transplantation and tuberculostatic therapy (80).

However, recovery may not always be complete.

- One girl in her third year, who had been immunized against tuberculosis at birth, developed an abscess of the associated lymph nodes (which were extirpated) and some weeks later developed intestinal BCG dissemination, which appeared to be cured by tuberculostatic treatment. Despite this, at the age of 22 years she developed a left-sided hemiplegia due to aneurysms and thrombosis of cerebral arteries, and 4 years later an oculomotor nerve paralysis was diagnosed. She died at 26 from recurrent intestinal BCG dissemination, which developed at the end of a pregnancy (a healthy premature child was born).

The autopsy confirmed the diagnoses and showed acid-fast bacilli in the adventitia of the basilar artery; the paralysis of the oculomotor nerve was caused by the brain lesion. Defective function of macrophages was suggested as the possible cause of the underlying immunological abnormality (81).

- A 7-week-old infant died under circumstances reminiscent of SIDS; the histopathological examination revealed disseminated BCG infection, no abnormalities of the immune system were detected (82).
- X-ray and CT scan examinations suggested a teratoma in a 1-year-old girl who had received BCG vaccine at birth; however, histology and microbiology revealed the diagnosis of mediastinal BCGitis (83).

Histiocytosis

Cases of fatal histiocytosis have been reported in babies with immune defects immunized with BCG shortly after birth (84).

- One boy who had been immunized shortly after birth developed ipsilateral axillary lymphoma at the age of 6 months. Microscopically the picture was typical of BCG histiocytosis. The child survived. The underlying immunological disturbance was considered to be a temporary derangement of T lymphocyte function (SEDA-8, 300) (85).

Safe immunization with BCG: the WHO view

Taking into account the results of the investigations mentioned above, the WHO made the following recommendations to ensure safe and effective vaccination:

1. Pasteur BCG vaccine should be supplied only to countries using the product without problems. In no case should the vaccine be sent to a country which has been successfully using another product unless the country specifically requests this product.
2. UNICEF supplies of BCG vaccine should specify the doses to be given to infants (0.05 ml), and when possible 0.05 ml syringes should be supplied with the vaccine to reduce the likelihood of too large a dose being given.
3. WHO will supply to country programs a short protocol to assess the incidence of BCG-associated lymphadenitis using a standard case definition. Evidence of a rate greater than 1% would be the basis for investigating the problem and for reviewing the vaccine strain being used.

Additionally it is recommended that training in the technique of BCG immunization should be re-emphasized (44).

Treatment

Erythromycin for a period of 2–4 weeks resolved troublesome post-BCG-lesions in six patients (86). The effect of erythromycin on the atypical mycobacteria was described as early as 1957 (87), but its use for treatment of BCG lesions has not previously been reported. Erythromycin has been used to treat cold abscesses (88).

Neonates with suppurative lymphadenitis have been treated with isoniazid (10 mg/kg/day for 3–9 months) (89). The treatment resulted in complete resolution of the adenitis. There was no significant difference between infants with ruptured nodes and those with intact nodes.

There was no statistical difference between patients who received different forms of treatment for suppurative lymphadenitis: 36 patients received erythromycin, 21 isoniazid, and 21 isoniazid + rifampicin (90). When lymphadenitis developed rapidly (within 2 months), the incidence of spontaneous drainage and suppuration was reported to be significantly higher than in patients with slowly developing processes. Total surgical excision is recommended in these rapidly evolving cases.

Long-Term Effects

Tumorigenicity

The effects of immunization with BCG have been studied extensively (91–94) (SEDA-7, 323) (95,96). On the whole the results are inconclusive, with little good evidence of either preventive or tumor-inducing effects.

Second-Generation Effects

Pregnancy

No harmful effects of BCG vaccine on the fetus have been seen. Nevertheless, it is prudent to avoid immunization of women during pregnancy, unless there is immediate excessive risk of unavoidable exposure to infective tuberculosis (97).

Susceptibility Factors

Disseminated BCG infection is usually associated with severe abnormalities of immunity. BCG for prevention of tuberculosis should therefore not be given to persons with impaired immune responses, such as occur in congenital immunodeficiency, leukemia, lymphoma, generalized malignancy, or AIDS, and when immunological responses have been suppressed by glucocorticoids, alkylating agents, antimetabolites, or radiation (97). The risks are greater in the debilitated or the very young.

Reports on complications after BCG immunization in HIV-positive individuals and patients with AIDS have been published. Disseminated BCGitis has been described (98–101), for example involving the spleen and mediastinal and mesenteric lymph nodes in one case and the liver and the lung in another case (100) or leading to pneumonitis (102). In one case BCG lymphadenitis occurred 30 years after BCG immunization in a 36-year-old patient with AIDS (103). Surgical excision and biopsy revealed a puriform abscess. Pathological examination established the diagnosis of Kaposi's sarcoma; no granulomatous changes were found. BCG was grown. The authors believe that the BCG lymphadenitis was due to a late reactivation of the bacillus.

BCG reactions in HIV-positive and HIV-negative children have been compared in African children. The rates of local adenitis were equal (104,105). These results have been confirmed by a number of other studies, among them one in Haiti. The Haitian investigators found that the risk of complications after BCG vaccination in HIV-infected children is low and that the risk does not outweigh the benefits of BCG vaccination in populations at high risk of tuberculosis during infancy and childhood. Mild or moderate adverse effects occurred in 19 (9.6%) of 166 infants born to HIV-seronegative mothers as compared with 4 (31%) of 13 HIV-infected infants (106).

Organisms of the *Mycobacterium avium* complex (MAC) commonly cause disseminated bacterial infection among patients with AIDS. There is evidence that immunoprophylaxis against MAC infection may be possible. A heat-killed *Mycobacterium vaccae* vaccine was given in a three-dose schedule to 12 HIV-infected adults with CD4 cell counts below 300×10^6/l (107). The vaccine was well tolerated and produced detectable immunological responses in 3 of 11 subjects who completed the trial.

The WHO has recommended that individuals with clinical (symptomatic) AIDS or other clinical manifestations of HIV-infection should not receive BCG (108). The Global Advisory Committee on Vaccine Safety has noted that there has been repeated reference to local or disseminated BCG infection several years after BCG immunization in HIV-infected persons (109). However, the Committee has not recommended a change in immunization policy (BCG immunization recommended in asymptomatic HIV-infected persons; not recommended in symptomatic HIV-infected persons), but surveillance for BCG-immunized, HIV-infected persons should be continued for 5–7 years.

Bacitracin

General Information

Bacitracin has mostly dermatological uses. It can cause allergic reactions of the delayed type. A shock-like picture after local application has occurred in a hypersensitive individual (1). Since bacitracin is nephrotoxic, it should not be given intraperitoneally to patients with renal impairment.

Observational studies

In a randomized study of the effects of a triple antibiotic ointment (polymyxin B + bacitracin + neomycin) and simple gauze-type dressings on scarring of dermabrasion wounds, the ointment was superior to the simple dressing in minimizing scarring; the beneficial effect on pigmentary changes was especially pronounced (2).

Organs and Systems

Sensory systems

Inadvertent injection of bacitracin ointment into the orbit can cause a postoperative orbital compartment syndrome.

- Acute proptosis, chemosis, reduced vision, and ophthalmoplegia occurred after endoscopic sinus surgery in a 73-year-old woman (3). The orbit was tense and the intraocular pressure was 54 mmHg. The presence of bacitracin ointment was established by computed tomography.

Immunologic

Bacitracin is one of the most important clinical allergens (4). Anaphylaxis rarely occurs after topical administration of bacitracin ointment (5,6).

- A 45-year-old man developed a near-fatal anaphylactic reaction after he applied bacitracin ointment to an excoriated area on his foot. He had had a similar, but less severe, episode 4 years earlier. IgE antibodies to bacitracin were positive.
- A 24-year-old man injured in a motorcycle accident was treated with viscous lidocaine and bacitracin zinc ointment for extensive abrasions on the extremities. Five minutes later, he developed symptoms of severe anaphylaxis and required adrenaline, antihistamines, intravenous fluids, and glucocorticoids. Two weeks later, only the prick test to bacitracin zinc ointment was positive.

Anaphylaxis has also been reported after bacitracin nasal packing (7).

- A 48-year-old man underwent uneventful septorhinoplasty, after which his right nostril was packed with 6 ft of vaseline gauze placed in the finger of a latex glove coated with bacitracin ointment. Within seconds, his oxygen saturation fell from 97 to 94% (and increased to 97% with 100% oxygen), but blood pressure and heart rate were unchanged. After the left nostril had been packed, his oxygen saturation fell to 89%, no pulse wave was registered and an electrocardiogram showed a

© 2006 Elsevier B.V. All rights reserved.

heart rate of 39/minute with first-degree atrioventricular block, and the blood pressure was not obtainable by non-invasive measurement. Cardiopulmonary resuscitation was successful, but the patient remained intubated for 2 days because of concerns about facial and upper airway edema. Later he gave a history of an episode of irritation and swelling after nasal application of polymyxin B and bacitracin ointment 2–3 weeks before surgery. Skin prick testing was positive for bacitracin but negative for latex, polymyxin, cefazolin, and saline.

Cases of anaphylaxis have also been reported after bacitracin irrigation (8,9).

- A 65-year-old man undergoing elective sternal debridement and rewiring was given a prophylactic infusion of vancomycin 1 g preoperatively. Anesthesia was induced with thiopental, suxamethonium, and fentanyl, and maintained with fentanyl, vecuronium, and isoflurane. A few minutes after wound irrigation with bacitracin (about 25 U/ml), his blood pressure fell precipitously, necessitating intravenous fluids and adrenaline. His face and arms were flushed. Afterwards, he reported having had a rash several years before after the use of an over-the-counter ointment composed of polymyxin B, bacitracin, and neomycin.
- A 9-year-old child with a repaired myelomeningocele and congenital hydrocephalus who had undergone four previous shunt revisions in the past had two episodes of anaphylaxis during insertion of the ventriculoperitoneal shunt. The shunt tubing had been soaked in a solution of bacitracin 2500 U/ml. A skin prick test was positive for bacitracin.

Thiomersal, a mercury derivative of thiosalicylic acid, is a preservative used in several types of consumer products, including cosmetics, ophthalmic and otolaryngological medications, and vaccines. In a retrospective study in 574 patients, people who were allergic to thiomersal were more likely to be allergic to bacitracin (10).

Long-Term Effects

Drug resistance

Although there is evidence of acquired resistance to bacitracin in enterococci and staphylococci isolated from animals (11), a review found no evidence that the prevalence of such resistance has increased over time or in relation to the use of bacitracin in man or in animals (in which bacitracin is used as a growth promoter) (12).

Drug Administration

Drug contamination

Commercial bacitracin comprises more than 30 different substances, but the major antibiotic isoforms A and B account for about 60% of the mixture. An impurity has been identified in some but not all bacitracin lots (13). The impurity is a powerful subtilisin-type protease capable of cleaving many proteins, including protein disulfide isomerase, myosin, and a variety of artificial substrates. Investigators using bacitracin are therefore reminded to determine whether their bacitracin is contaminated by a protease. If it is, careful reinterpretation of the results or retesting with an enzyme-free bacitracin reagent may be warranted.

Interference with Diagnostic Tests

Semen detection

In forensic medicine, the detection of semen may be critical, and identification due to Wood's lamp-induced fluorescence has been suggested to be helpful. In a study to investigate whether semen can be distinguished from other products, none of 41 physicians was able to differentiate semen from other products using a Wood's lamp; however, some ointments and creams that contained bacitracin were mistaken for semen (14).

Baclofen

General Information

Baclofen is a chlorophenyl derivative of gamma-aminobutyric acid (GABA), a naturally occurring inhibitory neurotransmitter in the brain and spinal cord. It is of proven therapeutic value in reducing the severity of flexor or extensor spasms resulting from spinal cord injury or disease. The recommended oral dose is 5 mg tds, which can be carefully increased; however, the total daily dose should not exceed 80 mg (20 mg qds). It is also used for the treatment of intractable hiccups, especially in patients with uremia.

The most commonly reported adverse effects are drowsiness, dizziness, fatigue, confusion, hypotension, and nausea.

Organs and Systems

Nervous system

Altered consciousness is a major adverse effect of baclofen, because of its GABA-mimetic effects. While this reflects global nervous system depression, other adverse effects, such as seizures and dyskinesias, are probably better explained by selective effects on different brain areas. A case of akinetic mutism associated with baclofen might be an example of this (1).

- A 76-year-old man with a history of cognitive decline of unknown origin had severe contractures with increasing pain in his legs. He was given baclofen 10 mg tds, and 2 days later had difficulty following commands. Another 2 days later he could not speak and would not follow commands, although he was alert with his eyes open. He had no spontaneous movements, but would withdraw to painful stimuli. The electroencephalogram showed intermittent, bilateral, symmetrical, sharp waves. Computed tomography and laboratory tests showed no specific abnormalities. Baclofen was withdrawn and he improved over the next 4 days, after which there was no difference to his prebaclofen condition.

The authors explained that akinetic mutism occurs when bilateral frontal lobe or diencephalic–mesencephalic dysfunction interrupts the limbic circuitry. As symptoms were observed immediately after the start of treatment and resolved completely after withdrawal, the condition was probably caused by baclofen. It is not known why baclofen in this case impaired neuronal activity specifically in these areas. The authors found only one previous report describing the case of a 57-year-old woman with end-stage renal insufficiency, who developed akinetic mutism after a single dose of baclofen (2). In this case, the symptoms resolved after dialysis. Therefore, adverse effects of baclofen should be suspected if neuropsychiatric symptoms occur after baclofen treatment has been started. Electroencephalography and computerized tomography may be necessary to exclude other causes.

Because the systemic effects of baclofen can cause a reduced level of consciousness, intrathecal administration via a catheter is widely used to avoid systemic effects. However, because a continuous infusion is required, implantable pumps containing a very concentrated solution of baclofen are used to avoid frequent refills. Inadvertent subarachnoid bolus administration of a concentrated solution will produce cranial spread of baclofen within the CSF, resulting in cerebral effects. This is most likely to occur when a new catheter or pump is implanted or during surgical revision of a catheter or implantable pump in cases of malfunction. A report of coma after implantation of a baclofen pump in five out of nine consecutive children illustrates this (3). The authors suggested that these children should be monitored in the recovery room for 5 hours postoperatively, in order to cover both the peak effect of any baclofen bolus and the additive effects of other perioperative CNS suppressants, such as opioids, benzodiazepines, or sedative antiemetics. In another report of transient coma after perioperative intrathecal bolus administration it was shown that the management of this complication can require admission to an intensive care unit (4).

Impairment of speech, memory, and mental acuity, associated with an abnormal electroencephalogram, has been described in a young patient taking normal doses (20 mg bd); gradual withdrawal restored the patient and electroencephalogram to normal (SEDA-12, 119) (5). Abnormal electroencephalographic changes have also been reported in a patient with deteriorating multiple sclerosis who developed encephalopathy 48 hours after starting baclofen in low dosage (10 mg tds), but this patient also had renal impairment; withdrawal led to reversal of symptoms in this case (6).

Epilepsy, progressing to status epilepticus, has been ascribed to baclofen (80 mg/day); the fits stopped on gradual withdrawal of the baclofen (7). In contrast to other reports, this patient had no history of seizures.

An elderly patient with a 4-year history of Alzheimer's disease developed chorea 2 weeks after starting a trial of baclofen (SEDA-16, 23). The dosage had been gradually increased to 15 mg tds. The chorea resolved within 24 hours after the baclofen was withdrawn. The authors suggested that the chorea might have resulted from the combination of the GABA-agonist drug and deficient cholinergic function in Alzheimer's disease.

A case of aseptic meningitis after intrathecal administration of baclofen has been reported but, as viral causes could not be ruled out, the causative role of baclofen was unclear (8).

Psychological, psychiatric

Euphoria or depression can occur, and mania has been reported in a patient with schizophrenia (9).

Gastrointestinal

A possible effect of intrathecal baclofen on intestinal motility has been proposed (10). Triggered by two cases of paralytic ileus in patients receiving continuous intrathecal baclofen, the authors reviewed the case notes of 14 patients and summed the days without bowel movements before and after intrathecal baclofen therapy. Intestinal function deteriorated in 10 patients, was unchanged in one, and improved in three. They therefore

© 2006 Elsevier B.V. All rights reserved.

advised that intestinal activity should be closely observed in patients receiving intrathecal baclofen. However, they felt that treatment could be continued, even in particularly sensitive patients, if prokinetic, laxative, or eubiotic drugs were used to promote peristaltic function.

Liver

Rarely, deterioration in liver function tests (increases in aspartate transaminase and alkaline phosphatase) can occur (SEDA-6, 132).

Musculoskeletal

With regard to its effects on spinal GABA receptors, intrathecal baclofen has been compared with intrathecal fentanyl for postoperative pain treatment in six children (mean age 4.2 years) with cerebral palsy undergoing bilateral dorsal rhizotomy (11). Both intrathecal baclofen and intrathecal fentanyl reduced postoperative pain. However, three of five children had severe muscle weakness after intrathecal baclofen 1–1.5 μg/kg, which prompted the authors to discontinue their study. An accompanying editorial dealt with the possible mechanisms of action of spinal GABA agonists on postoperative pain, suggesting that the effects on sensory processing probably cannot be separated from the changes in motor function (12). Therefore, this report of muscle weakness should not prompt us to close the file on intrathecal baclofen for pain treatment. More experience is needed and different dose regimens should be tested.

Sexual function

Intrathecal baclofen caused a reduction in erection rigidity and duration in eight of nine men. When ejaculation was possible before the start of baclofen treatment it disappeared or was more difficult to obtain during treatment. These effects resolved after withdrawal of baclofen (13).

Body temperature

Febrile reactions after intrathecal baclofen stopped a patient from receiving this treatment for spinal spasticity (14).

- A 33-year-old woman with spasticity caused by a myelopathy after numerous operations on her spine received a single bolus dose of baclofen 50 μg via a lumbar puncture, which resulted in complete resolution of her spasticity for almost 24 hours. However, her temperature increased to 39.0°C within 2 hours after the injection, and she had flu-like symptoms. Influenza was assumed to be the most likely explanation, as a child in her house had influenza at that time. Subsequently, an intrathecal catheter was placed and a baclofen pump implanted. However, her temperature rose again after baclofen administration had been started and the pump was halted. Subsequently, several attempts were made to restart the infusion, followed each time by spikes of fever. In the end, continuous intrathecal baclofen therapy had to be abandoned, and the fever did not recur. Several investigations to identify other causes of fever were mostly negative. However, based on bilateral hilar adenopathy on the chest X-ray and increased concentrations of angiotensin-converting enzyme, sarcoidosis was suspected.

The authors claimed that this was the first report of this problem. Referring to the observation that baclofen injection into the cerebral ventricles can produce fever in rats (15), they assumed that rostral spread of baclofen could have initiated a thermoregulatory response via the chemotrigger zone in the third ventricle. They suggested that a percutaneous subarachnoid catheter could facilitate the decision to either proceed with or abort surgical catheter or pump implantation when baclofen is associated with fever.

Long-Term Effects

Drug tolerance

Tolerance to intrathecal baclofen developed in three of 23 patients with spinal spasticity (16).

Drug withdrawal

Like many other agents that act at the GABA receptor, abrupt termination of long-term administration of baclofen can result in withdrawal symptoms, even after intrathecal administration (17,18). Patients can present with different symptoms, not all of which would be considered classical of drug withdrawal.

Clinical presentation

Common presenting features are muscular hyperactivity, hyperthermia, metabolic derangements, and rhabdomyolysis when baclofen therapy is abruptly discontinued, and several deaths have occurred (19). Clinicians should be suspicious of baclofen withdrawal if patients taking baclofen present with fever, muscle cramps, and hypotension. A case of brain death due to baclofen withdrawal with severe hypotension and hyperthermia up to 43°C has underscored the need for immediate and aggressive treatment (20).

Sudden withdrawal can cause hallucinations and grand mal convulsions or worsening of pre-existing epilepsy (SED-9, 206) (21,22).

There is a similarity between baclofen withdrawal and the neuroleptic malignant syndrome.

- A 36-year-old man with paraplegia after a spinal cord injury became disoriented (23). He had marked rigidity in both arms and legs, he was sweating and pyrexial (38°C), and his heart rate was 112/minute. His serum creatine kinase was raised at 2668 U/l and rose to 2982 U/l on day 3. At that time, baclofen was restarted. Within 3 days he was fully oriented. Over 2 weeks his creatine kinase activity gradually fell to normal and his temperature settled. It turned out that he had neglected to take any medication for several days before admission.

The authors believed that symptoms in this case resembled the neuroleptic malignant syndrome, based on the combination of muscle rigidity, pyrexia, signs of autonomic disturbance, and altered consciousness. They did not think that the raised serum creatine kinase activity was associated with rhabdomyolysis,

© 2006 Elsevier B.V. All rights reserved.

stating that there was no evidence from urinalysis to suggest this. Unfortunately, they did not specify whether there was myoglobin in the urine or not. Creatine kinase activities up to 40 000 U/l have been noted during baclofen withdrawal (24), compared with which creatine kinase activity in this case was much lower, suggesting only moderate muscle damage. One might assume that muscle damage after baclofen withdrawal correlates with the duration and intensity of muscular hyperactivity. In addition, prolonged muscular hyperactivity may be expected to be followed by an increase in both body temperature and heart rate, owing to hypermetabolism and sympathetic activation. Sweating will result from sympathetic activation and a thermoregulatory response to hyperthermia and is not necessarily an autonomic disturbance. Disorientation is also an expected symptom of baclofen withdrawal. In conclusion, this patient's combination of symptoms could have been explained by baclofen withdrawal alone. Assuming that disturbances in central dopaminergic systems could have been involved, as in neuroleptic malignant syndrome, is speculative.

This is not the first report of similarities between the neuroleptic malignant syndrome and baclofen withdrawal (18,20,24). In addition, hyperthermia seems to be common in baclofen withdrawal (20).

- A 14-year-old child receiving continuous intrathecal baclofen treatment developed a fever of up to 40°C and painful muscle spasms, attributed to baclofen withdrawal due to failure of the intrathecal catheter. The symptoms resolved promptly after reintroduction of intrathecal baclofen (25).

If intrathecal baclofen has to be interrupted or cannot be restarted immediately, enteral baclofen should be given. However, finding the appropriate dose for this can be difficult and close observation of the patient is required, as illustrated in the following report (26).

- A 34-year-old man who was receiving continuous intrathecal baclofen (700 micrograms/day) for muscle spasticity after a spinal cord injury developed a fever, and infection of the implanted baclofen pump was suspected. The device was removed and he was given replacement therapy with oral baclofen (40 mg tds). He developed a tremor 12 hours after pump removal and his heart rate increased to 120/minute. Another 12 hours later he was somnolent, agitated, and confused, and had visual hallucinations. His blood pressure rose to 198/108 mmHg and his temperature to 40°C. This was followed by atrial fibrillation with a ventricular rate of 170/minute. The dose of oral baclofen was increased to 80 mg tds and he was given intravenous lorazepam 6–8 mg every 4 hours. During the following 24 hours his blood pressure, pulse, and temperature normalized and he recovered fully.

Management

Baclofen should always be withdrawn gradually. If a patient stops taking baclofen, a blood sample for baclofen serum concentration measurement should be taken if possible, to confirm the diagnosis post hoc if hyperthermia occurs. If a patient taking long-term baclofen presents with similar symptoms, baclofen withdrawal should be considered. If this is not effective and the patient deteriorates, with hyperthermia, increasing creatine kinase activity, and metabolic sequelae, dantrolene can be given.

Dantrolene is life-saving in malignant hyperthermia associated with volatile anesthetics and suxamethonium and is also the drug of choice for the treatment of neuroleptic malignant syndrome. Dantrolene has therefore been suggested as an additional therapeutic option in baclofen withdrawal (18), but there is only limited experience (24). In one case of baclofen withdrawal, dantrolene was given with success (24).

It should be stressed that baclofen withdrawal is a potentially fatal emergency. Because of the risk of rhabdomyolysis, disseminated intravascular coagulation, acute renal insufficiency, and other organ complications, patients should be transferred to the intensive care unit and given parenteral baclofen.

Since it has been hypothesized that the baclofen withdrawal syndrome might have similarities with the serotonin syndrome caused by overdose of serotonin reuptake inhibitors or amphetamines, the serotonin receptor antagonist cyproheptadine has been used in combination with oral baclofen and a benzodiazepine in four patients with baclofen withdrawal syndrome after continuous intrathecal baclofen therapy (27). The authors claimed that their patients improved significantly when cyproheptadine was given. Body temperature fell by at least 1.5°C and heart rate fell from 120–140/minute to under 100/minute. Muscular tone and myoclonus improved. Two patients also reported that itching was less intense. All this was felt to be temporarily related to the repeated administration of cyproheptadine. The authors concluded that cyproheptadine was a useful adjunct for the treatment of baclofen withdrawal syndrome. However, one of their patients suffered severe brain damage during withdrawal and subsequently died of pulmonary complications. This illustrates that early intensive care is required.

Second-Generation Effects

Fetotoxicity

Convulsions have been attributed to withdrawal of baclofen after in utero exposure (28).

- A 7-day-old baby was admitted to hospital with generalized convulsions, which did not respond to phenobarbital, phenytoin, clonazepam, lidocaine, or pyridoxine. A variety of investigations all gave negative results. Electroencephalography 4 days later showed prolonged episodes of epileptic activity. At that time baclofen withdrawal was suspected, as the paraplegic mother had been taking baclofen 20 mg tds throughout pregnancy. The baby was given baclofen 0.25 mg/kg qds and 30 minutes after the first dose the convulsions stopped. The baclofen was then slowly withdrawn over 2 weeks. An MRI scan of the brain on day 17 suggested a hypoxic ischemic insult in the perinatal period, which was considered to have been secondary to convulsions.

© 2006 Elsevier B.V. All rights reserved.

As convincingly presented by the authors, baclofen withdrawal was the most likely explanation for the convulsions. In discussing the possible mechanisms of the delayed onset of convulsions the authors assumed that a secondary increase in baclofen serum concentration due to redistribution might have prevented earlier onset of the withdrawal symptoms. This is of course speculative; nothing is known about baclofen pharmacokinetics in neonates. On the other hand, the authors stated that the mother had noted some abnormal movements starting on the second day postpartum, which might have represented the first signs of withdrawal. The half-life of baclofen in adults is 3–6 hours, and adults usually become symptomatic 24–72 hours after baclofen is reduced or withdrawn (20). In conclusion, baclofen withdrawal should be suspected if postnatal convulsions occur after intrauterine exposure. The first priority in such a case is to rule out other causes, such as infections, electrolyte disturbances, and intracranial pathology, and to prevent secondary brain damage due to prolonged convulsions. Baclofen should probably be considered at an early stage, as it might be the most effective anticonvulsant in such cases.

Susceptibility Factors

Renal disease

As 70% of baclofen is excreted unchanged in the urine (29), accumulation and overdosage of baclofen can occur in patients with end-stage renal disease. Confusion, drowsiness, and coma after standard doses have been reported (30). In addition, abdominal pain was a common adverse effect of baclofen in patients with severe renal insufficiency (31). Toxic reactions characterized by a psychotic syndrome and myoclonus have also been reported (32). Patients with severely impaired renal function typically present with altered consciousness after very small doses of baclofen (31). Symptoms of overdose may resolve after hemodialysis (30,31).

- An 82-year-old man with left ventricular dysfunction and gout had worsening renal function (33). He was taking lisinopril, furosemide, naproxen, allopurinol, and baclofen 20 mg tds. As no reason could be found for the use of baclofen the dose was halved and then stopped 10 days later. The next day he had visual hallucinations, confusion, and agitation, and required sedation with diazepam. He was afebrile, with normal inflammatory markers, and a CT scan of the brain showed only cerebral atrophy. Baclofen was reintroduced, with complete resolution of neuropsychiatric symptoms within 48 hours.

Other features of the patient

Generally, patients with a history of seizures, convulsive disorders, or psychiatric disturbances, and also elderly patients with cerebrovascular disease, should be regarded as patients at risk of developing the more serious side effects (SED-9, 206).

Drug Administration

Drug administration route

Intrathecal baclofen is becoming increasingly popular for the treatment of severe spasticity in an attempt to reduce the incidence and severity of systemic adverse effects. However, hypotonia, respiratory depression, and coma can occur. Severe arterial hypotension also has been observed in two of 23 patients (16). Occasionally, nervous system suppression can be severe enough to require mechanical ventilation. Adverse effects have been seen not only with high doses (2000 micrograms/day produced flaccid quadriplegia with total areflexia) (SEDA-12, 119) (34), but also after a single bolus dose of 80 micrograms in a patient known to be very sensitive to the action of baclofen (SEDA-15, 128) (35).

Drugs injected directly into the cerebrospinal fluid have a tendency to produce unpredictable effects, their spread being influenced not only by the volume administered, but also by the concentration of the drug, its specific gravity in relation to that of cerebrospinal fluid, the positioning of the patient (head-up or head-down), and on the speed of injection of bolus doses. Truncal muscle spasms can also increase the spread of drug within the cerebrospinal fluid. All these parameters need to be taken into consideration. Standardization is required as a first step. Rapid bolus injection in particular can produce unexpectedly severe adverse effects.

Drug overdose

Overdose, which may be absolute or relative (due to impaired renal excretion or in elderly patients who develop adverse effects at lower dosages), leads to severe hypotonia, mental confusion and somnolence, respiratory depression, and eventually apnea, bradycardia, cardiac conduction abnormalities, hypotension, and coma. Convulsions can occur and hypertension has been reported. It is possible that during recovery the picture may be complicated by an acute withdrawal syndrome, with agitation, psychosis, tremor and dystonic movements, convulsions, and hallucinations (SEDA-11, 126) (36–40).

Physostigmine is rapidly effective in reversing not only the respiratory depression but also the coma and hypotonia seen in cases of intrathecal baclofen overdosage (SEDA-15, 128) (35). The doses recommended for physostigmine salicylate are 1–2 mg intravenously over 5–10 minutes, which may have to be repeated after 30–40 minutes, as the action of physostigmine is fairly short. However, physostigmine may be ineffective when large doses of baclofen are involved (41), and it also has adverse effects of its own, so that the above dosage guidelines should not be exceeded. In particular, bradycardia and cardiac conduction defects can be worsened (cardiac arrest has been reported in connection with baclofen) and it should not be used in these circumstances, respiratory support and symptomatic treatment being recommended (42).

Phaclofen is a more specific baclofen antagonist (43), but more research is required to ascertain if it can be safely used in the treatment of baclofen overdose.

Drug–Drug Interactions

Tricyclic antidepressants

Tricyclic antidepressants can potentiate the muscle relaxant effects of baclofen, resulting in severe hypotonic weakness (44); the combination has also been incriminated in the causation of short-term memory impairment (SEDA-11, 127) (45).

Bambuterol

See also Beta$_2$-adrenoceptor agonists

General Information

The efficacy of long-acting beta$_2$-adrenoceptor agonists in patients with chronic obstructive pulmonary disease remains unclear, but their role in treatment regimens, particularly in comparison with oral theophylline, has been reviewed (1).

Bambuterol is a beta$_2$-adrenoceptor agonist, a biscarbamate ester prodrug of terbutaline (SEDA-18, 188) (SEDA-22, 188). It is available as the hydrochloride salt in 10 and 20 mg tablets. It escapes first-pass elimination and is concentrated in lung tissue after absorption from the gastrointestinal tract. It is hydrolysed to terbutaline primarily by an enzyme, butyrylcholinesterase, found in lung tissue. Terbutaline is therefore formed preferentially in the lung, and as a result bambuterol should have a more selective effect than terbutaline. The effect of bambuterol lasts for 24 hours. Peak plasma concentrations of terbutaline occur 4–7 hours after the administration of bambuterol. Maximum therapeutic benefit occurs 1 week after starting treatment.

Except for suppression of plasma butyrylcholinesterase, the adverse effects of bambuterol are those of a beta$_2$-adrenoceptor agonist and are related to the plasma concentration of terbutaline. Plasma butyrylcholinesterase returns to control values about 2 weeks after stopping treatment (SEDA-22, 188).

Placebo-controlled studies

Oral bambuterol 20 mg at night has been compared with inhaled salmeterol 50 μg bd for persistent nocturnal symptoms in 117 asthmatics already taking inhaled corticosteroids in a randomized, double-blind, placebo-controlled trial for 6 weeks (2). The treatments resulted in significant and equivalent improvements in nocturnal and daytime asthma symptoms, peak flow, and the use of short-acting beta-adrenoceptor agonists. Drug-related adverse events included headache (six with bambuterol, two with salmeterol), tremor (three in each group), cramps (two with bambuterol), and palpitation (three with bambuterol, one with salmeterol). Four patients taking bambuterol withdrew owing to possible drug-related adverse effects (insomnia, headache, flushing, and mental excitation) compared with one patient taking salmeterol (tremor). Bambuterol appears to be a safe and effective alternative to inhaled long-acting beta$_2$-adrenoceptor agonists for poorly controlled nocturnal symptoms in asthma.

Comparative studies

The comparative safety and efficacy of oral bambuterol given once daily and oral terbutaline given three times daily in children with asthma aged 2–12 years has recently been reported in two large similar trials from the same research group. In the first study they reported results from 3 months of treatment in 155 children aged 2–6 years (3); in the second study they reported results from 12 months of treatment in 130 children aged 2–12 years (4). Both were double-blind studies with a 2:1 bambuterol:terbutaline randomization pattern. In both studies, the bambuterol and terbutaline regimens were similarly efficacious in reducing asthma symptoms and improving peak expiratory flow rate. In the 3-month study, the most commonly reported adverse event was restlessness, reported in over 85% of patients in both treatment groups; other adverse events were described as mild to moderate, and overall there was no difference in the safety profile of the two drugs. In the 12-month trial, one subject in each treatment group withdrew because of an adverse event (urticaria and dermatitis). The most commonly reported adverse events attributable to the drugs were headache and tremor, which respectively occurred in 9 and 0% with terbutaline and 6 and 2% with bambuterol. Other adverse events were not described in detail. It seems that oral bambuterol has an efficacy and safety profile similar to that of oral terbutaline, with the advantage of once-daily dosing. The caveat is that inhaled therapy has fewer systemic adverse effects and is the route of choice.

Bambuterol once a day and modified-release salbutamol bd both produced a significant reduction in the severity of nocturnal asthma, but bambuterol caused significantly less tremor (5).

Organs and Systems

Cardiovascular

A retrospective study of prescriptions from three cohort studies suggested a possible adverse effect of oral bambuterol: cardiac failure. A cohort of 12 294 patients who received at least one prescription for nedocromil acted as the control group and was compared with 15 407 patients given inhaled salmeterol and 8098 patients given oral bambuterol. Questionnaires were sent to each prescriber asking for details of significant medical events after the first prescription (prescription event monitoring). From this information, rates and relative risks of non-fatal cardiac failure and ischemic heart disease were calculated. The age- and sex-adjusted relative risk of non-fatal cardiac failure associated with bambuterol was 3.41 (CI = 1.99, 5.86) compared with nedocromil. When salmeterol was compared with nedocromil the relative risk for developing non-fatal cardiac failure was 1.1 (CI = 0.63, 1.91). The adjusted relative risks of non-fatal ischemic

© 2006 Elsevier B.V. All rights reserved.

heart disease with bambuterol and salmeterol compared with nedocromil were 1.23 (CI = 0.73, 2.08) and 1.07 (CI = 0.69, 1.66) respectively. In the month after the first prescription, the relative risk of non-fatal ischemic heart disease was 3.95 (CI = 1.38, 11.31), when bambuterol was compared with nedocromil. The authors concluded that care should be exercised when prescribing long-acting oral beta$_2$-adrenoceptor agonists for patients at risk of cardiac failure.

This study at best generates the hypothesis that the oral use of a particular beta$_2$-agonist is linked to an increased risk of cardiac disease. However, the study had several flaws. The three cohorts of patients were not strictly comparable: they were not treated concurrently nor were they sufficiently matched for age and diagnosis before prescription of the study drugs. It took nearly 3 years to recruit the patients, who preferred or needed an oral agent. A smaller proportion of patients in this cohort were treated for "asthmatic wheeze"—57 versus 70% in the salmeterol cohort. More of the bambuterol patients were given the drug for other indications, such as dyspnea, bronchitis, cough, chest infection, emphysema, and bronchitis—15 versus 2.8%. The salmeterol cohort consisted mostly of patients who were changing to a longer-acting agent and those using nedocromil were mostly changing from cromoglicate. The bambuterol group was more heterogeneous. Some patients with impending or undiagnosed heart failure may have presented with dyspnea, cough, or wheeze and received bambuterol. During the first month the correct diagnosis would become evident.

A review of the preclinical studies, clinical studies, and postmarketing surveillance data has given no support to the proposed association between bambuterol and cardiac failure. The UK Committee on Safety of Medicines has received no spontaneous reports of cardiac failure due to bambuterol. Data from the WHO database, INTDIS, show no reports of cardiac failure with bambuterol, in contrast to ten reports for salmeterol.

So, there is no evidence that oral beta$_2$-adrenoceptor agonists cause cardiac failure. The epidemiological study proposing the link is inadequate, and the authors themselves have emphasized the need for prospective, randomized trials.

Drug–Drug Interactions

Mivacurium

Bambuterol has been reported to alter the metabolism of mivacurium (6). Bambuterol has a dose-dependent inhibitory effect on plasma cholinesterase activity and prolongs the effects of suxamethonium. Bambuterol 10 mg was given to 28 patients 2 hours before an elective operation requiring general anesthesia. The study was originally designed as a randomized, blinded trial, but was converted to an open study. The patients given bambuterol had a 67–97% fall in plasma cholinesterase activity, leading to reduced clearance of mivacurium. This resulted in a shorter onset and a 3- to 4-fold prolongation of action of the neuromuscular blockade produced by standard doses of mivacurium.

Barium sulfate

General Information

Oral barium sulfate is theoretically non-toxic, but constipation and abdominal pain are not uncommon after barium meals or barium enemas (1). The main risk is that collections of barium will remain in the colon; they can persist for 6 weeks or longer in elderly patients or cases of colonic obstruction; barium fecoliths may even have to be removed surgically. Prolonged stasis of barium can occur after a barium enema into the distal loop of a colostomy. Residues in the appendix have caused appendicitis. Toxic dilatation of the colon can be aggravated by barium sulfate.

Organs and Systems

Cardiovascular

Electrocardiographic changes have been recorded during administration of barium enemas and could represent a hazard in cases of cardiac disease (2–4).

Respiratory

Aspiration of barium sulfate into the lungs during barium meal examination can cause significant respiratory embarrassment, particularly in patients with poor respiratory function. It is recommended that water-soluble low-osmolar contrast media, which are less harmful, should be

used instead of barium if there is a possibility of aspiration during examination of the upper gastrointestinal tract.

Aspiration of barium sulfate can cause obstruction of the small air passages, compromising respiratory function, and can cause inflammation in the bronchial tree and lung parenchyma (5).

- A 68-year-old woman, with a history of alcohol abuse and a leiomyoma of the stomach, aspirated barium sulfate and became dyspneic and developed hypoxia (PaO_2 46 mmHg). At bronchoscopy the bronchial mucosa was coated with barium and a chest X-ray showed heavy alveolar deposition of barium sulfate distributed over the entire lung, with some predominance in the lower zones. The patient developed a fever (39°C) and a leukocytosis (12×10^9/l) the day after aspiration. She was given cefotiam 2000 mg and metronidazole 500 mg intravenously every 8 hours. The fever resolved within 2 days and *Staphylococcus aureus* was cultured from the bronchial fluid. She was discharged 2 days later, but the chest X-ray continued to show persistent alveolar deposition of the barium sulfate with only a slight improvement compared with the initial X-ray.
- A 60-year-old man with carcinoma of the hypopharynx aspirated barium into both lower lobes. He became hypoxic (PaO_2 64 mmHg) and barium was extracted at bronchoscopy. He was given prophylactic antibiotics (cefotiam 2000 mg and metronidazole 500 mg intravenously every 8 hours for 4 days). A chest X-ray 6 days later showed residual barium deposition in the lower lobes. No further respiratory complications occurred.

The authors recommended that bronchoscopy should be performed early after aspiration to extract barium from the bronchial tree, and that prophylactic antibiotic therapy is important to prevent lung infection.

Gastrointestinal

Perforation

After a barium enema, perforation occurs rarely in children and debilitated adults or when the colon is already weakened by inflammatory, malignant, or parasitic diseases. Perforation can be triggered by manipulations involved in giving the barium enema or can result from hydrostatic pressure. In one case, perforation followed air contrast insufflation for barium enema in a patient in whom the sigmoid colon became trapped in an inguinal hernia.

At least 12 cases of perforation of the colon by barium enema, with four deaths, were reported in a series of publications (SED-12, 1165) (6–8). The incidence of perforation was about 1 in 6000 examinations. Even sterile barium sulfate can cause marked peritoneal irritation, with considerable fluid loss into the peritoneal cavity, but in practice it is usually a mixture of barium and feces that escapes and this, not surprisingly, produces severe peritonitis and dense adhesions. Mortality has been reported to be 58% with conservative treatment, and as high as 47% with surgical intervention (9). Early operation is indicated, and large volumes of intravenous fluids improve the prognosis. Patients who recover can develop fibrogranulomatous reactions and adhesions, which can lead to bowel obstruction or ureteric occlusion.

Perforation can occur elsewhere than in the colon; in one case a duodenal ulcer was apparently made to perforate. In both this and another case of perforation of a sigmoid diverticulum the complication was not immediately recognized, the duodenal perforation only being detected 5 days after administration of the barium meal (SEDA-17, 535).

In air-contrast examinations, colonic perforation can actually precede the administration of the barium enema itself. In such cases it is due to the preparatory insufflation of air if this is conducted with excessive enthusiasm in a high-risk patient (for example an elderly patient with a hitherto unrecognized epigastric hernia) (10).

Extraperitoneal perforation and leakage of barium may cause few immediate symptoms, but delayed endotoxic shock can develop some 12 hours later, often causing death. Bowel infarction can also result. Barium granulomata can occur, causing painful masses, rectal strictures, or ulcers. On proctoscopy, an ulcer with a whitish base can mimic a carcinoma. In one rare case, perforation of a barium enema into a sigmoid abscess was followed by intravasation into the portal venous system (11).

Baroliths

Baroliths are rare complications of barium contrast examinations and are usually seen in colonic diverticula. They are often asymptomatic but may be associated with abdominal pain, appendicitis, and bowel obstruction or perforation. A case of ileal obstruction by a barolith has been reported (12)

- An 83-year-old woman developed postprandial abdominal pain. Physical examination and laboratory tests were normal. She underwent gastroscopy, abdominal ultrasound, small bowel barium meal, and a double-contrast barium enema, all of which were normal, although a moderate amount of barium refluxed into the small bowel during the double-contrast examination. She continued to have postprandial abdominal pain and weight loss. A repeat abdominal X-ray 6 months after the barium enema showed an unremarkable bowel gas pattern without evidence of obstruction. However, there was a 4.5 cm triangular radio-opaque structure in the right lower quadrant, consistent with retained barium, possibly in a diverticulum. A small bowel barium meal showed that the retained barium was intraluminal within a loop of ileum. At laparotomy, a hardened short segment of ileum was resected and histology showed an intraluminal barolith adjacent to a carcinoid tumor.

In this case, narrowing of a loop of ileum secondary to a carcinoid tumor caused interference with the flow of barium and caused the development of a barolith.

Immunologic

Hypersensitivity reactions to products used during barium meal examinations are extremely rare. Barium sulfate is generally regarded as an inert and insoluble compound that is neither absorbed nor metabolized and is eliminated

© 2006 Elsevier B.V. All rights reserved.

unchanged from the body. However, some studies have shown that very small amounts of barium sulfate can be absorbed from the gastrointestinal tract. Plasma and urine barium concentrations can be increased after oral barium sulfate. In addition, there are many additives in commercially prepared barium products, some of which can cause immune responses. A patient with a history of a severe reaction to barium agents should not receive barium products again (SEDA-22, 503).

Reactions to other constituents of barium sulfate enemas have been recognized (SEDA-18, 441) and could be as common as one in 1000. They vary from urticarial rashes to severe anaphylactic reactions, and can be particularly severe in patients with asthma (13). Hypersensitivity to the latex balloon catheter used in double contrast barium enemas appears to be a common mechanism (14), but hypersensitivity to glucagon, to the preservative methylparabens, or to other additives seems to be responsible in some cases. Insofar as the latex balloon is concerned, thorough washing will remove the allergen responsible for the reaction (15).

Infection risk

Transient bacteremia was recorded in 11.4% of a series of 175 patients who had undergone barium enema examination; it appeared almost at once and lasted up to 15 minutes (16). Although a second study elsewhere failed to confirm these findings, a subsequent fatal case of staphylococcal septicemia in an elderly patient with an immune deficiency suggests that the risks are not merely theoretical (17).

Drug Administration

Drug additives

Tannic acid (up to 1.5%) was at one time added to barium enemas in order to improve the quality of the radiological picture. Tannic acid is hepatotoxic and fulminant liver disease very occasionally resulted. Although it was perhaps avoidable, being apparently associated mainly with higher tannic acid concentrations, mucosal damage, or a prior tannic acid washout of the bowel, the risks have made this technique obsolete.

Drug administration route

Accidental administration of a barium enema into the vagina instead of the rectum can occur and can be very hazardous; in some of these patients there has been fatal rupture of the vagina, with venous intravasation of the barium.

Barium given orally can be inhaled, and if there is incoordination of swallowing, inhalation of thick paste can cause fatal asphyxiation (18); aspiration of barium can also cause fatal pneumonia (19).

Accidental venous intravasation of barium during administration of a barium enema usually has a high immediate mortality, due to barium embolism in the lungs, but it occasionally causes few symptoms. In one intermediate case there was hypotension and evidence of disseminated intravascular coagulation (SEDA-9, 407); the patient recovered after intensive treatment.

Drug overdose

A fatal case of poisoning resulted from the use of barium sulfide, which had been mistaken for barium sulfate (SED-8, 1022) (20). Isolated cases of barium encephalopathy have been attributed to absorption of barium after the use of barium sulfate (SEDA-15, 498).

Barnidipine

See also Calcium channel blockers

General Information

Barnidipine is a dihydropyridine with antihypertensive activity and tolerability similar to that of other calcium antagonists of the same class. The most frequent adverse events are edema, headache, and flushing, but barnidipine does not cause reflex tachycardia (1).

Reference

1. Malhotra HS, Plosker GL. Barnidipine. Drugs 2001;61(7): 989–96.

Basidiomycetes

See also Herbal medicines

General Information

Basidiomycetes are fungi that include mushrooms, puffballs, and bracket fungi.

Lentinus edodes

Lentinus edodes (shiitake) is an edible mushroom that contains a polysaccharide, lentinan. Its use is occasionally associated with skin reactions (1,2).

Adverse effects

Most adverse effects of *Lentinus edodes* occur in shiitake workers.

Respiratory

Lentinus edodes can cause an interstitial hypersensitivity pneumonitis called mushroom worker's lung, associated with IgG antibodies against shiitake spore antigens; those who cultivate white button mushrooms (*Agaricus bisporus*) or the oyster mushroom (*Pleurotus* species) have only low titers (3).

Workers at a shiitake farm developed cough and sputum production after a variable period of exposure to shiitake mushrooms (4). All four had abnormal diffusing capacity and three had abnormal spirometry. Chest X-rays showed an interstitial pattern in one case. Pulmonary function tests fell significantly during several days of work, with a more than 20% fall in forced vital capacity and/or maximal mid-expiratory flow. Antigens to shiitake spore antigens, in common with antigens from other cultivated mushrooms (*Agaricus* and *Pleurotus*), were demonstrated by ELISA.

Bronchial asthma has been attributed to shiitake (5).

Skin

Skin reactions due to *Lentinus edodes* are not uncommon (1,2).

- A 42-year-old female shiitake grower developed skin lesions while planting shiitake hyphae into bed logs (6). She complained of repeated eczematous skin lesions during the planting season, from March to July, for 10 years. Each day she handled 7000 pieces of small conic blocks made of beech, with shiitake hyphae attached to their surface, and altogether 300 000 pieces each season. Patch tests with extracts of shiitake hyphae were positive. In contrast, female shiitake growers with skin lesions associated with work other than planting, and without skin lesions, were negative on patch-testing.

Drug interactions

Lentinan inhibits CYP1A (7), but the relevance of this to drug interactions in man is not known.

Basiliximab

See also Monoclonal antibodies

General Information

Basiliximab is a chimeric (human/mouse) anti-interleukin-2 receptor monoclonal antibody used in the prophylaxis of acute renal transplant rejection. It acts by binding the alpha chain of interleukin-2 receptors on activated T lymphocytes. Initially positive results in phase III trials have not been generally confirmed (1,2).

Compared with placebo, basiliximab was not associated with any specific adverse effects in early studies (3). However, severe hypersensitivity reactions can occur and can be associated with the cytokine release syndrome.

Organs and Systems

Respiratory

There have been reports of non-cardiogenic pulmonary edema in three adolescent renal transplant recipients, one of whom died (4).

Immunologic

Basiliximab is composed of murine sequences (30%), which can cause IgE-mediated hypersensitivity reactions. Important warnings have been released by the manufacturers regarding the possible risk of severe hypersensitivity reactions within 24 hours of initial exposure or after re-exposure after several months, based on 17 reports that included cardiac and/or respiratory failure, bronchospasm, urticaria, cytokine release syndrome, and capillary leak syndrome.

- A 42-year-old Hispanic woman, with end-stage renal disease, anemia, hypertension, and a history of an anaphylactic reaction to basiliximab, was scheduled to receive a living donor transplant and received basiliximab uneventfully (5). However, owing to donor infection the procedure was cancelled and rescheduled for 2 weeks later. Within 10 minutes after basiliximab reinduction she developed an anaphylactic reaction. In an attempt to find another induction therapy for this patient, skin testing was performed for daclizumab without response. She therefore received full-dose induction with daclizumab before her organ transplant without adverse effect.
- A child had anaphylactic shock when he received a second course of basiliximab at the time of a second renal transplantation (6). There were antibasiliximab IgE antibodies in the serum, but no IgE reactivity toward a control murine IgG_{2a} monoclonal antibody, suggesting that the IgE response was directed exclusively against basiliximab idiotypes. There was no IgE reactivity against the humanized anti-interleukin-2 receptor monoclonal antibody daclizumab. The patient's basophils harvested months after the anaphylactic shock produced leukotrienes in vitro on exposure to basiliximab.

Daclizumab, a humanized monoclonal antibody, is composed of only 10% murine antibody sequences and therefore is less immunogenic. These findings suggest that despite the similar compositions of human and mouse antibody protein sequences the IgE responsiveness is significantly different.

Drug–Drug Interactions

Ciclosporin

Basiliximab can inhibit ciclosporin metabolism transiently in children with renal transplants (7). Despite the use of lower daily doses, ciclosporin trough concentrations were significantly higher during the first 10 days after transplantation in 24 children who received basiliximab at days 0 and 4 after transplantation compared with 15 children who did not receive basiliximab. Ciclosporin dosage requirements again increased by 20% to achieve the target blood concentration at days 28–50 after transplantation. It is noteworthy that all seven acute episodes of rejection in the basiliximab group occurred during this period of time. However, these results have been debated, and there were no changes in ciclosporin dosage requirements in 54 children with liver transplants (8).

Batanopride

General Information

Batanopride is a substituted benzamide with 5-HT_3 receptor antagonist activity. It is claimed to be free of dopaminergic properties. Clinical studies have concentrated on its use in patients suffering severe vomiting as a result of cytostatic therapy, but have run into problems because of poor tolerance at effective doses. The most important dose-limiting adverse effect is severe hypotension (1) but diarrhea and electrocardiographic changes also occur.

Comparative studies

In a randomized, double-blind comparison of intravenous batanopride 0.2–6.0 mg/kg and methylprednisolone 250 mg before cancer chemotherapy in 208 patients, the highest dose of batanopride was associated with a higher complete protection rate than the control group, but also had higher incidences of diarrhea, hypotension, and electrocardiographic abnormalities (2).

Organs and Systems

Cardiovascular

In a double-blind, randomized, crossover comparison of batanopride and metoclopramide in 21 chemotherapy-naive patients who received cisplatin at least 70 mg/m^2, the study was terminated when hypotension was observed after infusion of batanopride at other institutions testing similar drug schedules, although the authors themselves saw no cases of hypotension after treatment with batanopride (3). However, they did note asymptomatic prolongation of the QTc interval, PR interval, and QRS complex.

Susceptibility Factors

Renal disease

In 27 subjects with various degrees of renal function who were given an intravenous infusion of a single dose of batanopride 3.6 mg/kg over 15 minutes, the half-life was significantly prolonged from 2.7 hours in those with normal renal function to 9.9 hours in those with severe renal impairment (creatinine clearance below 30 ml/minute) (4). This was associated with a significant reduction in renal clearance. There were no differences in plasma protein binding or steady-state volume of distribution. There were significantly lower renal clearances of all three of the metabolites of batanopride in those with impaired renal function.

Bemetizide

See also Diuretics

General Information

Bemetizide is chemically unrelated to the thiazides, but it shares many of their actions and adverse effects.

Susceptibility Factors

Age

The pharmacokinetics and pharmacodynamics of a fixed combination of bemetizide 25 mg and triamterene 50 mg have been evaluated in 15 elderly patients (aged 70–84 years) and 10 young volunteers (aged 18–30 years) after single doses (on day 1) and multiple doses (at steady state on day 8) (1). Mean plasma concentrations of bemetizide, triamterene, and the active metabolite of triamterene, hydroxytriamterene, were significantly higher in the elderly subjects after single and multiple doses, and urine flow and sodium excretion rates fell in tandem with the accumulation of these drugs. The glomerular filtration rate, which is reduced in elderly people, was further reduced at higher concentrations of bemetizide and triamterene, which may explain why there were limited diuretic and saliuretic effects after multiple doses. This study clearly points to a modulating effect of the degree of renal function on the diuretic actions of these compounds in elderly people.

Drug–Drug Interactions

Triamterene

In 1988 the Federal German Health Authorities issued a warning about fixed combinations of the thiazide bemetizide and triamterene that they could cause allergic vasculitis (2). Thiazides can occasionally cause allergic vasculitis and it is not clear on what basis the combination might be more likely to cause the same problem.

Benazepril

See also Angiotensin converting enzyme inhibitors

General Information

Safety data derived from the controlled trials submitted in the benazepril New Drug Application for hypertension have been reviewed (1). In more than 100 trials involving 6000 patients with hypertension or congestive heart failure, the types and incidences of adverse effects were comparable with those of other ACE inhibitors.

Organs and Systems

Pancreas

Benazepril has been associated with pancreatitis (2).

- A 70-year old man with type II diabetes had severe epigastric pain 30 minutes after taking his first dose of 5 mg benazepril and lasting 6–8 hours. The next day he had the same pain, complicated by vomiting. Benazepril was withdrawn and he was unable to eat for 4 days. He later developed severe epigastric pain, nausea, and vomiting 30 minutes after taking a third dose. Laboratory findings confirmed pancreatitis and imaging showed a mildly edematous inflamed pancreas. He improved progressively with bowel rest and pethidine. He was symptom-free 2 months after discharge.

Benorilate

General Information

Benorilate is an acetylsalicylic ester of paracetamol. It is slowly absorbed unchanged from the gastrointestinal tract but is rapidly hydrolysed to its components, aspirin and paracetamol. Thereafter its effects and kinetics are those of the two moieties. However, the delay in its metabolism reduces the incidence of direct gastric irritation, delays its onset of action, and prolongs its duration of action (1,2).

Drug Administration

Drug overdose

In cases of suspected benorilate overdosage, both salicylate and paracetamol should be assayed.

Benoxaprofen

See also Non-steroidal anti-inflammatory drugs

General Information

Since benoxaprofen, like zomepirac, provided an experience from which several lessons can be learnt, it deserves to be briefly reviewed, even though it was withdrawn 10 years ago. Some newer drugs may have some of its chemical or pharmacological characteristics and, consequently, its problems. Benoxaprofen was originally launched in 1980, with claims of a favorable adverse effects profile and "unique disease-modifying properties" in rheumatoid arthritis. These claims appeared to have been based on the fact that it was a relatively more potent inhibitor of leukotriene production and a less potent inhibitor of prostaglandin synthesis than other NSAIDs. Having passed all preclinical and clinical tests and satisfied the safety requirements set by regulatory authorities in many countries (despite rejection in several on grounds of safety), benoxaprofen was then suspended by the UK Committee on Safety of Medicines in 1982, about 18 months after marketing. Shortly afterwards it was withdrawn worldwide by its manufacturers (1). Benoxaprofen was associated with a very high incidence of adverse effects, prominent effects on the skin and nails and liver reactions, which sometimes proved fatal, particularly in elderly people.

The case led to considerable regulatory and medicolegal discussions in the 10 years after withdrawal. In the USA the company was charged by the Food and Drug Administration with misbranding the drug in press statements and associated materials, which contained a misleading headline implying that the drug was harmless, even though the company was aware of a report of deaths related to the use of benoxaprofen. The company's intense marketing campaign was heavily criticized (SEDA-8) and it was noted that the recommendation of the WHO that drugs likely to be used in elderly people should be investigated in them at an early stage had certainly been disregarded in the premarketing phases. In the UK

© 2006 Elsevier B.V. All rights reserved.

the company rejected patients' demands to establish a compensation scheme and offered instead a financial settlement that the patients rejected as inadequate. The case shows how some legal systems are inadequate for dealing with mass claims of personal injury due to drugs.

Organs and Systems

Gastrointestinal

The hope of better gastric tolerance of benoxaprofen was not fulfilled, and the incidence of this type of reaction was actually higher in elderly patients.

Liver

Fatal liver damage was observed particularly in the UK and tended to occur in elderly subjects. The complication initially presented as jaundice or raised liver enzymes (including alkaline phosphatase). Surprisingly, biochemical and histological liver changes were not consistent with major hepatocellular damage. There were three reports of primary biliary cirrhosis, but a causal relation was not proven (SEDA-12, 84).

Urinary tract

All types of kidney damage were reported, ranging from a transitory fall in glomerular filtration rate and reversible renal insufficiency (part of multisystem disease with circulating LE cells) to the nephrotic syndrome.

Skin

Cutaneous adverse effects were the most frequent problem and (together with hepatic complications) the most serious: 63% of 300 patients treated for 6 months complained of one or more adverse effects (total 259 reactions); 70% were cutaneous; photosensitivity led to withdrawal in 30% of cases. Multiple subepidermal cysts (milia) on sun-exposed skin areas and onycholysis (13% of patients) were documented. Other skin reactions included rashes, hypertrichosis, erythema multiforme, and Stevens–Johnson syndrome (2). Phototoxicity persisted for many months after withdrawal (SEDA-12, 84); although a later study on persistent photosensitivity as a sequel to benoxaprofen in 42 subjects failed to confirm the link between photosensitivity and the drug (3), this was contrary to the overwhelming experience in the field. In retrospect, it seems likely that one problem was that benoxaprofen had largely been studied during the winter months, whereas in the UK it was launched in the summer.

Benzalkonium chloride

See also Disinfectants and antiseptics

General Information

Quaternary ammonium compounds are surface-active agents. Some of them precipitate or denature proteins and destroy microorganisms. The most important disinfectants in this group are cationic surface-active agents, such as benzalkonium chloride, benzethonium chloride and methylbenzethonium chloride, and cetylpyridinium chloride; the problems that they cause are similar.

Benzalkonium chloride is composed of a mixture of alkyldimethylbenzylammonium chlorides. The hydrophobic alkyl residues are paraffinic chains with 8–18 carbon atoms. Benzalkonium chloride is used as a preservative in suspensions and solutions for nasal sprays and in eye-drops. Depending on the concentration of the solution, local irritant effects can occur. In nasal sprays it can exacerbate rhinitis (1) and in eye-drops it can cause irritation or keratitis (2).

A total of 125 ophthalmologists in private practice located throughout France examined 919 glaucomatous patients treated with eye-drops which either did or did not contain a preservative; the proportion of patients who experienced discomfort or pain during instillation was 58% for eye-drops containing a preservative and 30% for eye-drops with no preservative (2). Moreover, the proportion of patients presenting at least one symptom of eye irritation (sensation of itching or burning, sensation of a foreign body in the eye, and flow of tears) was greater with preservative-containing eye-drops (53 versus 34%). The experience of discomfort during instillation was more often associated with problems later on. The patient's

complaints were correlated with objective signs of conjunctival damage (conjunctival redness, conjunctival follicles), or corneal damage (superficial punctate keratitis). A higher proportion of patients treated with eye-drops containing a preservative had at least one conjunctival sign (52 versus 35%) or superficial punctate keratitis (12 versus 4%). In 164 patients whose treatment was changed from eye-drops containing a preservative to eye-drops with no preservative and who were examined a second time (mean interval between visits 3.3 months) the frequency of all symptoms and objective signs fell by a factor of 3 to 4.

Organs and Systems

Respiratory

An asthmatic patient whose salbutamol formulation was replaced by another containing benzalkonium chloride as an excipient developed bronchospasm as a result (3).

Benzalkonium chloride is used as a preservative in nebulizer solutions and can cause secondary paradoxical bronchoconstriction in patients with bronchial asthma. Although nebulizers containing beta-adrenoceptor agonists may also contain benzalkonium chloride, reports are more common with anticholinergic drugs. This is probably because of the more rapid onset and larger effect of sympathomimetic-induced bronchodilatation compared with anticholinergic drugs (4).

Ear, nose, throat

Benzalkonium chloride accentuated the severity of rhinitis medicamentosa and increased histamine sensitivity in a 30-day study with oxymetazoline nasal spray in healthy volunteers (5,6).

Sensory systems

Benzalkonium chloride is used in eye-drops in concentrations of 0.033 or 0.025%. At a dilution of 1:1000 (0.1%), a drop applied to the human cornea causes mild discomfort that persists for 2 or 3 hours. Slit-lamp examination within 90 seconds shows fine grey clots (epithelial keratitis) in the corneal epithelium. Within 10 minutes, a grey haze can be seen on the corneal surface; superficial desquamation of the conjunctival epithelium can follow. The superficial irritation and disturbances disappear in a day or less.

Patients with glaucoma, dry eyes, infections, or iritis, sometimes use solutions containing benzalkonium chloride often enough and for long enough to cause damage. In these patients, there is a higher incidence of endothelial damage, epithelial edema, and bullous keratopathy, and because of the severity of the disease, additional damage from the medication can be overlooked. This is especially true in patients with defective epithelium or corneal ulcers, in whom the medication can penetrate well and who can be most vulnerable. There have been analogous results in investigations of benzethonium chloride, cetrimonium bromide, cetylpyridinium chloride, decyldodecylbromide, hexadecyl, and tetradecyltrimethylammonium bromide (SEDA-11, 490).

Immunologic

Life-threatening anaphylactic reactions that rarely occur during general anesthesia are mostly due to neuromuscular blockers. They may be due to cross-allergy mediated by drug-specific IgE antibodies to the quaternary ammonium moiety of the neuromuscular blocker molecule, perhaps with a contribution from IgE-independent mechanisms. Quaternary ammonium compounds, such as benzalkonium, in cosmetics and toiletries may play a role in sensitization (7).

Allergic reactions can occur after topical use, but are fairly rare. Allergic contact dermatitis has been reported in some cases. Allergic rhinitis on contact has also been reported.

In a study of the efficacy and acceptability of benzalkonium chloride-containing contraceptives (vaginal sponges, pessaries, and creams) in 56 women, one developed an allergic reaction with edema of the vulva (4). Non-allergic local irritation, itching, and a burning sensation were reported in nine women and nine husbands.

Infection risk

The bactericidal activity of benzalkonium chloride is limited to the Gram-positive and some of the Gram-negative bacteria, but *Pseudomonas* species are especially resistant and can cause severe infection. Too often it is not realized that the disinfectant can be contaminated with active multiplying resistant organisms.

Pseudomonas bacteremia has been attributed to the use of material in open-heart surgery that was stored in accidentally contaminated benzalkonium solutions, and after cardiac catheterization caused by inadequate disinfection of the catheters with benzalkonium solutions. In 1961, about 15 patients were reported with *Pseudomonas* infections caused by cotton pledgets kept in a contaminated aqueous solution used for skin antisepsis before intravenous and intramuscular injection (8). In 1976 there were outbreaks of *Pseudomonas cepacia* infections in two American general hospitals (9) and pseudobacteremia (*Pseudomonas cepacia* or *Enterobacter*) caused by contamination of blood cultures in 79 patients in whom contaminated aqueous benzalkonium solutions were used for skin and antisepsis before venepuncture and due to contamination of the samples (SEDA-11, 490) (10).

Benzatropine and etybenzatropine

See also Anticholinergic drugs

General Information

Benzatropine and etybenzatropine (ethylbenzatropine) are anticholinergic drugs. They represent attempts to combine atropine-like and antihistaminic effects in single molecules. The dose is determined individually and varies from 0.5 to 6 mg/day for benzatropine and 6 to 30 mg/day for etybenzatropine. Although the adverse reactions are essentially those of the anticholinergic drugs, sedation is very likely to occur and these drugs should not be used in patients who need to drive motor vehicles. Benzatropine has also been reported to cause rash, peripheral numbness, and muscular weakness.

Organs and Systems

Cardiovascular

A paradoxical sinus bradycardia in a psychotic patient was attributed to benzatropine since it abated when benzatropine (but not others) was withdrawn (SEDA-17, 174).

Psychological, psychiatric

Benzatropine can cause slight memory impairment, detectable if special studies of mental function are performed (SEDA-13, 115) (SEDA-15, 137).

Second-Generation Effects

Teratogenicity

There have been two cases of "small left colon" in infants whose mothers had taken various psychotropic drugs, including benzatropine, late in pregnancy; the causal link was not at all clear (SEDA-6, 142).

Drug–Drug Interactions

Paroxetine

When paroxetine was introduced in a patient taking benzatropine and haloperidol, the circulating concentrations of benzatropine rose and delirium occurred (SEDA-22, 157) (1).

Benzbromarone

General Information

Benzbromarone is a benzofuran derivative chemically related to amiodarone. It increases uric acid excretion by non-specifically inhibiting its tubular reabsorption.

It is used in patients with venous disorders to prevent, retard, or reverse varicose degenerative changes in the vessel wall.

Benzbromarone causes diarrhea (3–4% of patients), urate and oxalate stones, urinary sand, renal colic, and allergy in a small number of patients (1). Liver damage, which reverses after withdrawal, has been described (SEDA-18, 108).

Organs and Systems

Liver

After reports of several cases of acute hepatitis (SEDA-16, 205) benzbromarone was withdrawn from the market in several European countries (SEDA-17, 244). Liver damage reportedly reverses after withdrawal (SEDA-18, 108)

Drug–Drug Interactions

Anticoagulants

As benzbromarone is a coumarin derivative, it can potentiate the effects of anticoagulants, which act as vitamin K antagonists.

Benzethonium chloride and methylbenzethonium chloride

See also Disinfectants and antiseptics

General Information

Quaternary ammonium compounds are surface-active agents. Some of them precipitate or denature proteins and destroy microorganisms. The most important disinfectants in this group are cationic surface-active agents, such as benzalkonium chloride, benzethonium chloride and methylbenzethonium chloride, and cetylpyridinium chloride; the problems that they cause are similar.

In an extensive report, the Expert Panel of the American College of Toxicology (1) has concluded that both benzethonium chloride and methylbenzethonium chloride can be regarded as safe when applied to the skin at a concentration of 0.5% or when used around the eye in cosmetics at a maximum concentration of 0.02%. In clinical studies, benzethonium chloride produced mild skin irritation at 5%, but not at lower concentrations. Neither ingredient is considered to be a sensitizer.

Drug Administration

Drug overdose

The Paris Poison Center has received reports on 45 cases of acute accidental poisoning, with 18 deaths (2). All the victims were mentally disturbed patients who had ingested Airsane HP 800, a water-soluble powder packed in a sachet; it contains a mixture of quaternary ammonium compounds and was left in the patients' rooms by hospital workers. Symptoms were corrosive burns of the mouth, pharynx, esophagus, and sometimes of the respiratory tract.

Benzimidazoles

See also Individual agents

General Information

The benzimidazoles are a group of compounds that include albendazole, flubendazole, mebendazole, niridazole, triabendazole, and triclabendazole.

The newer broad-spectrum benzimidazoles have a wide spectrum of antihelminthic activity, killing larval and adult cestodes as well as intestinal nematodes, with generally low mammalian toxicity, apart from a potential for teratogenicity and embryotoxicity. The principal members of the group are mebendazole, its fluorine analogue flubendazole, and the better-absorbed albendazole. Mebendazole and albendazole are active orally in a single dose for a wide range of intestinal nematodes and are being used increasingly in the treatment of hydatid disease, in which experience is rapidly advancing. Flubendazole is very poorly absorbed and causes local tissue reactions at the site of injection when given parenterally.

None of the benzimidazoles is known to be safe in pregnancy and animal studies and their spectrum of toxicity suggest that they should be avoided. The absence of reports of harm in human pregnancy does not mean that no harm can occur.

The antihelminthic activity of the benzimidazoles is thought to result from selective blockade of glucose uptake by adult worms lodged in the intestine and their tissue-dwelling larvae, resulting in endogenous depletion of glycogen stores and reduced formation of adenosine triphosphate, which appears to be essential for parasite reproduction and survival. However, benzimidazole antihelminthics may also have antiparasitic activity by binding to free β-tubulin, thereby inhibiting the polymerization of tubulin and microtubule-dependent glucose uptake (1).

Uses

Ankylostomiasis

In 13 British soldiers with cutaneous larva migrans after a 2-week jungle training exercise in Belize the median incubation period was 10 (range 4–38) days; in 12 there were skin lesions on the calves or shins, and only two had foot or ankle lesions (2). Ten received oral thiabendazole, one oral mebendazole, one oral albendazole, and one topical thiabendazole. All those treated with oral thiabendazole complained of unpleasant reactions, predominantly nausea, vomiting, and dizziness. The one patient treated with topical thiabendazole returned with a new lesion 12 months later. He was then treated with systemic albendazole, with rapid resolution of symptoms. A 45-year-old woman developed larva migrans 20 days after lying on a beach in Singapore and was treated with thiabendazole 50 mg/kg in two doses for one day; she had no adverse effects (3).

The treatment of cutaneous larva migrans in 56 Italian patients aged 2–60 years has been retrospectively reviewed (4). All 13 patients treated with cryotherapy reported that it was painful, but none had recurrent disease or scarring. A further six patients were treated with oral thiabendazole 25–50 mg/kg/day for 2 days, and one had both thiabendazole and cryotherapy. In all cases there was regression of itching and skin lesions, but they had nausea, diarrhea, and dizziness while taking oral thiabendazole. No adverse effects were reported in 36 patients who were treated with albendazole 400 mg/day for 3 days (two were also treated with cryotherapy). Despite the low dose, larval migration was stopped in 1–2 days. Although a prompt and definitive cure was achieved in all 56 patients, albendazole was considered the treatment of choice given its minimal adverse effects. Until about 1980, surgery was the only treatment

© 2006 Elsevier B.V. All rights reserved.

available for larval infections with *Echinococcus granulosus* or *Echinococcus multilocularis*. However, cysts are not always amenable to surgical removal, and operation is associated with the risk of rupture, leading to anaphylactic shock and re-infection; a proportion of cases are in any case not fit enough for surgery. The benzimidazoles have been used in varying high dosages over extended periods, initially to treat inoperable hydatid cysts and before surgery in attempts to sterilize cysts.

Echinococcosis

The epidemiology, clinical presentation, and treatment of alveolar echinococcosis of the liver have been described in French patients followed between 1972 and 1993 (5). From 1982 benzimidazoles were used. Of 117 patients, 72 took either albendazole or mebendazole for 4–134 months. The most common adverse effects were an increase in alanine transaminase activity to more than five times the top of the reference range (in six patients taking albendazole and in three taking mebendazole). Neutropenia (leukocyte count below 1.0×10^9/l) occurred in two patients taking albendazole. Alopecia occurred in four patients taking mebendazole. Minor adverse effects of albendazole included malaise, anorexia, and digestive intolerance in one patient each. In 13 patients treatment had to be withdrawn because of adverse effects ($n = 10$) or non-adherence to therapy ($n = 3$).

While mebendazole is used in continuous therapy of human alveolar echinococcosis, albendazole has been used in cyclic treatment. One treatment cycle consists of 28 days followed by a washout phase of 14 days without treatment, intended to reduce toxicity. Whether albendazole can also be used on a continuous basis has recently been studied in an open observational study in 35 patients with alveolar echinococcosis (in seven of 35 patients a curative operation was performed) (6). The outcome (lack of progression) was compared with the results obtained with continuous treatment with mebendazole or cyclic albendazole. Albendazole 10–15 mg/kg/day and mebendazole 40–50 mg/kg/day were equally effective. Seven patients were treated with continuous albendazole for an average of 28 (range 13–50) months. All patients taking continuous albendazole had stable or even regressive disease. The continuous dosing regimen was well tolerated without increased toxicity or higher rates of adverse reactions. Therefore, continuous dosing of albendazole is a promising alternative in cases of inoperable or progressive alveolar echinococcosis.

Prolonged cyclic albendazole treatment (for more than 9 years) was safe and effective in a patient with isolated cervical spine echinococcosis in whom surgery was performed without preoperative antihelminthic therapy because of a delay in diagnosis (7).

There have been several studies of the efficacy of albendazole in preventing recurrences of hydatid disease and cyst fluid spillage complications after surgery. In one Turkish study 22 of 36 patients with echinococcosis were treated with albendazole after surgical intervention (8). There was no significant benefit of perioperative albendazole over operation alone, although the recurrence rate of hepatic echinococcosis was lower than in historical controls. In contrast, in another study in 22 patients with hepatic echinococcosis there was a clear benefit of peri- and postoperative cyclic albendazole (12–15 mg/kg/day in four divided doses) (9). There were no cases of secondary hydatid disease or recurrence after a mean follow-up of 20 months. In two cases there were liver function abnormalities, which normalized after withdrawal.

Neurocysticercosis

Cysticercosis is caused by the larval stage of the pork tapeworm *Tenia solium*. Neurocysticercosis is the most severe and common clinical manifestation in humans and probably the most frequent parasitic infection of the central nervous system. *T. solium* is endemic in Latin America, Asia, and sub-Saharan Africa. However, with the advent of computerized neuroradiology and improved serological tests, neurocysticercosis is increasingly being diagnosed throughout the world.

Controversies in the management of neurocysticercosis have been described (10–12). The management of the neurological complications of cysticercosis and in particular the role of antiparasitic drugs are issues of debate. It is commonly believed that the use of antiparasitic drugs and steroids should be individualized, based on the presence of active or inactive disease, the location of the cysts, and the presence or absence of complications such as hydrocephalus.

Some imidazoles have been used to treat parenchymal brain cysticerci. Initially, flubendazole (40 mg/kg for 10 days) was given to 13 patients with neurocysticercosis, with promising results. However, owing to its poor intestinal absorption, the use of flubendazole is limited. Albendazole is usually well absorbed and well tolerated, and albendazole serum concentrations are not significantly affected by glucocorticoids or anticonvulsants. Albendazole was given in daily doses of 15 mg/kg for 30 days. Further studies, however, showed that a treatment course could be shortened from 30 to 8 days without affecting efficacy. Direct comparative trials have shown that albendazole usually destroys 75–90% of parenchymal brain cysts, whereas praziquantel destroys 60–70%. The advantage of albendazole over praziquantel is limited not to its better efficacy, but also to better penetration of the subarachnoid space, allowing destruction of meningeal cysticerci. It also costs less than praziquantel.

Benznidazole

General Information

Benznidazole, a nitroimidazole, is used in the treatment of *Trypanosoma cruzi* infections and Chagas' disease, and is recommended for use in urogenital trichomoniasis, all forms of amebiasis, giardiasis, and anaerobic infections. Its adverse effects are similar to those of metronidazole (SEDA-13, 833). Drowsiness, dizziness, headache, and ataxia occur occasionally. With prolonged and/or high doses, transient peripheral neuropathy and epileptiform seizures can be seen. Other frequently mentioned adverse effects are unpleasant taste, furred tongue, nausea, vomiting, and gastrointestinal disturbances. Skin rash and pruritus can occur. One case each of erythema multiforme and of toxic epidermolysis have been reported. Benznidazole causes a disulfiram-like effect with ethanol.

Placebo-controlled studies

In a double-blind, randomized, clinical trial, benznidazole 5 mg/kg/day for 60 days was compared with placebo in children in the indeterminate phase of infection by *Trypanosoma cruzi* (1). In general, treatment was well tolerated. The treated children had a significant reduction in mean titers of antibodies against *T. cruzi* measured by indirect hemagglutination, indirect immunofluorescence, and ELISA. At 4-year follow-up, 62% of the benznidazole-treated children and no placebo-treated child were seronegative for *T. cruzi*. Xenodiagnosis after 48 months was positive in 4.7% of the benznidazole-treated children and in 51% of the placebo-treated children.

General adverse effects

The adverse effects of benznidazole can be classified into three groups (2,3):

1. symptoms of hypersensitivity—dermatitis with skin eruptions (usually occurring at 7–10 days of treatment), generalized edema, fever, lymphadenopathy, and joint and muscle pains;
2. bone marrow suppression, thrombocytopenia, and agranulocytosis being the most severe manifestations;
3. peripheral polyneuropathy, paresthesia, and polyneuritis.

In a Cochrane systematic review the incidence of adverse effects was less than 20% (4). In one study, under 5% of participants complained of a variety of minor symptoms, but rash and pruritus were reported more commonly. In children the drug was well tolerated and there were no severe adverse effects. The only study in adults reported a non-quantified variety of mild adverse effects (skin reactions, peripheral neuropathy, digestive disturbances), but it was said that they were less intense than those seen with nifurtimox.

Long-Term Effects

Mutagenicity

Like metronidazole, benznidazole is mutagenic. In tests for chromosomal aberrations and induction of micronuclei in cultures of peripheral lymphocytes from children with Chagas' disease, there were increases in micronucleated interphase lymphocytes and of chromosomal aberrations after treatment with benznidazole (4).

Drug–Drug Interactions

Disulfiram

Like metronidazole, benznidazole has a disulfiram-like effect if alcohol is taken (5).

Benzocaine

See also Local anesthetics

General Information

Benzocaine is a poorly soluble local anesthetic, an ester of para-aminobenzoic acid. It is used in many countries as a component of some free-sale formulations for topical use, for example in skin creams, as a dry powder for skin ulcers, as throat lozenges, and as teething formulations for young children. It is also used in aerosol sprays when anesthetizing the oropharynx. Relatively high concentrations of local anesthetic are required to be effective topically, increasing tissue penetration and the risk of subsequent toxicity. Benzocaine formulations are available in concentrations of 1–20%.

Organs and Systems

Hematologic

Methemoglobinemia is a classical complication of benzocaine (SEDA-12, 256) (SEDA-21, 135) (SEDA-22, 141). The problem arises in both adults and children (1–4), and the risk has led to criticism of its free availability. It has, amongst other things, been suggested that it should be eliminated from products for use in children, that concentrations in over-the-counter products should be limited, and that there should be explicit label warnings of the hematological risk (SED-12, 256) (SEDA-17, 135) (1). Early diagnosis and treatment are crucial, as the condition is potentially fatal, particularly in neonates.

Five cases of benzocaine-induced methemoglobinemia were reported in 1998, following its use for transesophageal echocardiography (5–8). Methemoglobin concentrations over 15% can lead to cyanosis, whilst concentrations over 70% lead to circulatory collapse and death (7,8). The degree of methemoglobinemia depends on the total dose of drug and any factors that enhance systemic absorption. The elderly and neonates are particularly susceptible to methemoglobinemia, as are those with inherited methemoglobin reductase deficiency or the abnormal hemoglobin M. Adequate monitoring and observation of patients both during and after transesophageal echocardiography is essential, as this rare complication of benzocaine and other local anesthetics, such as prilocaine, is both potentially fatal and eminently treatable.

- Severe methemoglobinemia was suspected in a 1-year-old infant after topical application of 10% benzocaine ointment around an enterostomy; on postoperative day 3 the SpO_2 was 90% and arterial blood was dark red in color (9).

The authors pointed out the serious potential for toxicity in infants of a local anesthetic that is commonly used for this purpose in adults.

However, adult cases have been reported with Cetacaine (a proprietary mixture of 14% benzocaine, 2% tetracaine, and 2% butylaminobenzoate) (10–12) and with benzocaine alone (13).

Cetacaine spray used to anesthetize the oropharynx before endoscopy led to dyspnea, central cyanosis, and an oxygen saturation of 80%; methemoglobinemia was diagnosed, and the patient recovered rapidly with methylthioninium chloride 1 mg/kg over 5 minutes.

- A 77-year-old woman received two sprays of Cetacaine for an attempted emergency nasotracheal intubation. After intubation she became cyanosed. The arterial blood was chocolate-brown in color and the SaO_2 by CO oximetry was 54–58%, despite a high PaO_2. The methemoglobin concentration was 39% and she was treated with methylthioninium chloride. Three weeks later Cetacaine again caused cyanosis with a drop in SpO_2 to 76% and a methemoglobin concentration of 24%, which resolved spontaneously.
- A 74-year-old man received Cetacaine spray to his oropharynx for transesophageal echocardiography. His SpO_2 fell to 85%. He became drowsy, then unresponsive, cyanotic, and apneic, and required intubation. His PaO_2 was 37 kPa (280 mmHg), SaO_2 40%, and methemoglobin concentration 60%. Intravenous methylthioninium chloride produced an immediate improvement in the cyanosis and the methemoglobin concentration fell to 0.6%.
- A 71-year-old man received 20% benzocaine spray to the upper airway for bronchoscopy. His SpO_2 gradually fell to under 85% and he required intubation. His methemoglobin concentration was 19%, SaO_2 75%, and PaO_2 44 kPa (329 mmHg). After intravenous methylthioninium chloride the methemoglobin concentration fell to 1.8%.

Several other cases of methemoglobinemia after the administration of topical benzocaine formulations have been reported (14–19). All recovered completely without sequelae after the intravenous administration of methylthioninium chloride 1–2 mg/kg.

- A 69-year-old man developed methemoglobinemia (68%) after pharyngeal anesthesia using 20% benzocaine 15 ml (swish and swallow) for transesophageal echocardiography (20). He responded to intravenous methylthioninium chloride, but a diagnosis of non-Q wave myocardial infarction was made on the basis of raised cardiac enzymes and a normal electrocardiogram.

Whether benzocaine-induced methemoglobinemia is a hypersusceptibility or collateral reaction is controversial. There has been a retrospective review of 188 benzocaine exposures in children under 18 years of age, reported to four regional poison information centers, in 1993–96 (21). Mean and median ingested dosages were 87 and 50 mg/kg respectively and 55% patients had an exposure over 40 mg/kg. In all, 92% patients were asymptomatic. Reported symptoms included oral numbness ($n = 8$), vomiting ($n = 3$), and oral irritation, dizziness, and nausea ($n = 1$ each). Methemoglobin concentrations were measured in eight patients, seven of whom had concentrations over 1%. A child, who had

© 2006 Elsevier B.V. All rights reserved.

had 5–10 applications of over-the-counter teething gel applied in 24 hours, had a methemoglobin concentration of 19% and was the only patient to have cyanosis. The authors concluded that accidental ingestion of over-the-counter benzocaine-containing products rarely causes cyanosis. The lack of dose dependence suggests that this reaction is a hypersusceptibility reaction.

Four cases of methemoglobinemia have again been described after the use of benzocaine spray for topical anesthesia of the airways.

- A 42-year-old woman had a superior laryngeal nerve block with lidocaine, topical anesthesia with benzocaine spray, and intravenous midazolam for awake fiberoptic intubation (22). Her SpO_2 fell from about 85% to about 30%, and despite high-frequency jet ventilation with 100% oxygen she had persistent SpO_2 readings in the low 80s. Her arterial blood was chocolate-brown in color, with a PaO_2 of 44 kPa (330 mmHg) and an oxyhemoglobin saturation (SaO_2) of 51%. This discrepancy between PaO_2 and SaO_2 suggested methemoglobinemia, and co-oximetry showed a concentration of 51%. Methylthioninium chloride 140 mg produced an immediate improvement in her color, and her SaO_2 improved over the next 10 minutes.
- An elderly man received benzocaine 20% spray to the throat in preparation for transesophageal echocardiography. He became unwell 1 hour later, with lethargy, central cyanosis, hypoxia, dyspnea, tachypnea, and tachycardia (23). His arterial blood was burgundy-colored and the methemoglobin concentration was 41%. He was treated with two doses of methylthioninium chloride 2 mg/kg and was weaned from oxygen within 10 hours.
- Significant methemoglobinemia occurred in a 65-year-old man on re-exposure to topical 20% benzocaine spray for anesthesia of the airways in preparation for awake fiberoptic intubation (24). This occurred despite exposure 3 days before to 14% benzocaine for the same procedure. During attempted intubation, he suddenly desaturated to 80% and had significant hypotension and bradycardia, necessitating external cardiac massage and cricothyroid puncture. His SaO_2 did not improve significantly, despite seemingly adequate resuscitation with 100% oxygen and intravenous adrenaline. His arterial methemoglobin concentration was 55%. Methylthioninium chloride 100 mg intravenously led to rapid improvement in the SaO_2, allowing surgery to continue.
- A 57-year-old man developed severe methemoglobinemia after receiving topical benzocaine spray and lidocaine jelly during awake fiberoptic intubation (25). After intubation, his oxygen saturation fell to 65% on 100% oxygen. He was cyanosed and had dark arterial blood sample with normal gas tensions. His methemoglobin concentration was 60% and treatment with methylthioninium chloride was successful.

These cases illustrate the importance of co-oximetry on grounds of clinical suspicion. Methemoglobin concentrations of 10–15% can cause dark-colored blood and cyanosis. Concentrations of 20–45% can cause lethargy, dizziness, headache, and collapse. Higher concentrations (50–70%) can cause seizures, dysrhythmias, coma, and death.

Skin

Granuloma gluteale adultorum is a rare skin condition of unknown etiology, characterized by reddish purple granulomatous nodules on the gluteal surfaces and groin areas.

- Granuloma gluteale adultorum occurred in a 40-year-old woman who presented with a 3-year history of the condition associated with the use of topical benzocaine (26).

Immunologic

Benzocaine can cause sensitization, and being a para-aminobenzoic acid derivative it can cross-react with paraphenylenediamine, sulfonamides, aniline dyes, and related local anesthetics. However, in a recent retrospective study of 5464 patients it was concluded that benzocaine allergy is not common in the UK, confirming earlier reports that benzocaine should not be used as a single screening agent for local anesthetic allergy (27).

Allergic contact dermatitis has been attributed to local benzocaine (28).

- A 72-year-old woman was treated for thoracic *Herpes zoster* with oral aciclovir and topical benzocaine 20% ointment. She subsequently developed painful pruritic erythematous dermatitis in the area of the lesions, spreading to her arm. The dermatitis was initially misdiagnosed as aciclovir resistance, but on patch testing she had a positive reaction to benzocaine.

The authors highlighted the problem in diagnosing allergic contact dermatitis in patients who have other skin lesions in that area. They emphasized the importance of patch testing to identify the causative agent.

Benzodiazepines

See also Individual agents

General Information

The benzodiazepines typically share hypnotic, anxiolytic, myorelaxant, and anticonvulsant activity. Because their efficacy and tolerability are generally good, especially in the short term, they have been used extensively and are likely to continue to be used for many years to come. However, their less specific use in the medically or psychiatrically ill, and in healthy individuals experiencing the stresses of life or non-specific symptoms has often been inappropriate and sometimes dangerous (SEDA-18, 43). The pharmacoepidemiology of benzodiazepine use has been carefully studied in various countries (1), including the USA (2) and France, where 7% of the adult population (17% of those over 65 years) are regular users (3). In Italy, consumption of benzodiazepines remained stable (50 defined daily doses per 1000 population) from 1995 to 2003, while expenditure increased by 43% to €565M per annum (4). The need to limit spending on pharmaceutical products, as well as the very real likelihood of inducing iatrogenic disease (for example cognitive impairment, accidents, drug dependence, withdrawal syndromes), has prompted many reviews and policy statements aimed at discouraging inappropriate use. Despite this, the available evidence suggests that there continues to be expensive and inappropriate use in several countries (5).

A comprehensive review of manufacture, distribution, and use has described the rather marked international variation in use of the drugs and the role of the International Narcotics Control Board, a United Nations agency, in the restriction of these drugs (1). Most countries are signatories to the UN Convention on Psychotropic Substances 1971, and are thus obliged to implement controls on the international trade in abusable drugs, including benzodiazepines. Some countries, such as Australia and New Zealand, have imposed further stringent controls on certain drugs, such as flunitrazepam, which are thought to have particular abuse liability (6). A wide-ranging discussion of benzodiazepine regulation has pointed out both the potential merits of the approach and the fact that some restrictions in the past have turned out to be counterproductive (7).

A comprehensive review of benzodiazepine-induced adverse effects and liability to abuse and dependence, in which it was concluded that most benzodiazepine use is both appropriate and helpful (2), has been challenged (8–10). Balanced clinical reviews of benzodiazepine use (11,12) include sets of recommendations on appropriate prescribing and avoiding adverse effects, including tolerance/dependence. Similarly, guidelines for the management of insomnia and the judicious use of hypnotics have been reviewed (13,14). Benzodiazepines are often over-prescribed in hospital (SEDA-17, 42), and their continued prescription after discharge constitutes a significant source of long-term users. Anxiety symptoms and insomnia are common in the medically ill population and can be due to specific physical causes, a reaction to illness, or a co-morbid psychiatric illness, such as depression. Moreover, caffeine, alcohol, nicotine, and a variety

© 2006 Elsevier B.V. All rights reserved.

of medications can cause insomnia (15). Accordingly, the systematic assessment of such patients allows remediable causes to be identified and the use of hypnosedatives to be minimized. Elderly people and medically ill patients are susceptible to the adverse effects of benzodiazepines, and alternatives are worth considering (11,16), particularly given evidence that behavioral therapies can be more effective and more durable than drug therapy (17).

The important advantages of the benzodiazepines over their predecessors are that they cause relatively less psychomotor impairment, drowsiness, and respiratory inhibition, and are consequently relatively safe in overdose. However, it must be emphasized that these advantages are relative, and that the low toxicity potential does not apply when they are combined with other agents, particularly alcohol (18) and opioids (19).

As well as the added toxicity seen in co-administration with other CNS depressants, benzodiazepines facilitate self-injurious behavior by disinhibiting reckless or suicidal impulses (20). Benzodiazepines are commonly used in both attempted and completed suicide (21). A German study has suggested that hypnosedatives are the commonest drugs used in self-poisoning, that most are prescribed by physicians, and that in nearly half of those taking them chronically, adverse effects were considered to be a possible cause of self-poisoning (22). Before prescribing any drugs of this class, clinicians are exhorted to assess both suicidality and alcohol problems; there is a quick screen for the latter, the Alcohol Use Disorders Identification Test (AUDIT), which consists of a 10-item questionnaire and an 8-item clinical procedure (23).

Hypersensitivity reactions are rare. A few cases of anaphylaxis have been described, although usually these have been with the injectable forms and may have involved the stabilizing agents (24). Serious skin reactions to clobazam (SEDA-21, 38) and tetrazepam (25) have been reported. Lesser reactions have also been reported with diazepam, clorazepate (via *N*-methyldiazepam) (26), and midazolam (SEDA-17, 44, 45).

Tumor-inducing effects have been observed in animals (SEDA-6, 39), but human reports are essentially negative.

First-trimester exposure appears to confer a small but definite increased risk (from a baseline of 0.06% up to 0.7%) of oral cleft in infants (27). However, second-generation effects are infrequent and usually reversible (28), although some doubt remains about the extent of developmental delay in children who have been exposed in utero (27). A review has emphasized that concerns about second-generation effects are mainly theoretical, and has concluded that some agents (for example chlordiazepoxide) are probably safe during pregnancy and lactation and that others (for example alprazolam) are best avoided (29).

Pharmacokinetics

As far as is currently known, benzodiazepines and similar drugs (zopiclone, zolpidem) act by a single mechanism, interacting at the GABA receptor complex to enhance the ability of GABA to open a chloride ion channel and thereby hyperpolarize the neuronal membrane. It is usual, therefore, to classify benzodiazepines, and recommend their clinical use, on the basis of their duration of action or their half-life. While this is without doubt a useful classification, it is simplistic and does not take into account other important pharmacokinetic factors.

The first factor that is considered significant is the metabolism of benzodiazepines to pharmacologically active metabolites. Many newer benzodiazepines intended for use as long-acting anxiolytic or sedative agents were in fact intended to be so metabolized to ensure stable blood concentrations over prolonged periods. Drugs with long durations of effect, attributable at least in part to the formation of active metabolites, are listed in Table 1. Individuals vary considerably in their metabolism of benzodiazepines, and interpatient variation in concentrations of the parent compounds and of (generally active) metabolites is usual. In addition, ethnicity plays a major role in determining the frequency of poor and extensive metabolizers, with notable differences between Caucasians and East Asians (30).

Another, often neglected, aspect of the pharmacokinetics of benzodiazepines is their rate of onset of action, since their properties and therapeutic benefits depend to a considerable degree on the rapidity of onset of their perceived effects. Within a given drug class, the more rapidly the hypnotic effect occurs, the greater the abuse potential. For most drugs of abuse, it is the affective and behavioral changes associated with a rapid rise in drug blood concentration that is sought, whether the drug is abused by intravenous injection, nasal or bronchial absorption, or (as with alcohol) rapid oral absorption from an empty stomach (31). Diazepam and flunitrazepam are effective hypnotics because they are rapidly absorbed and there is a quick rise in blood concentrations, even though after tissue redistribution and loss of their immediate effects they have long half-lives. It also explains the preference, and so the increased liability for abuse, for drugs like diazepam (31) and flunitrazepam, especially when the latter is snorted (32). In general, polar molecules, such as lorazepam, oxazepam, and temazepam (all of which have a hydroxyl group), gain access to the

Table 1 Benzodiazepines with active metabolites that have long half-lives; metabolism and predominant metabolite half-lives

Chlorazepate	1	40–100
Quazepam	1.5	15–35
Rapid absorption, slow elimination, but rapid redistribution		
Diazepam	1	20–70
Flunitrazepam	1	10–40
Nitrazepam	1	20–30
Rapid absorption, rapid elimination, rapid redistribution		
Lormetazepam (soft capsules)	1	8–20
Temazepam (soft capsules)	1	8–20
Rapid absorption, rapid elimination		
Brotizolam	1	4–7
Zolpidem	1.5	2–5
Zopiclone	1.5	5–8
Rapid absorption, very rapid elimination		
Midazolam	0.3	1–4
Triazolam	1	2–5

CNS more slowly than their more lipophilic cousins. Since temazepam is much more quickly absorbed from a soft gelatin liquid-containing capsule than from a hard capsule or tablet, it is the preferred form for both hypnotic use (Table 2) and recreational use (and for this reason is restricted in some countries). Kinetic differences between drugs and between formulations partially explain why comparing equipotent doses of benzodiazepines is difficult.

The route of metabolism can also be significant, particularly in those with liver disease or who are taking concomitant hepatic enzyme inhibitors, such as erythromycin (SEDA-20, 31). The complex interaction between hepatic dysfunction and benzodiazepines has been reviewed (33); these drugs more readily affect liver function in individuals with liver disease and may also directly contribute to hepatic encephalopathy, as shown by the ability of benzodiazepine antagonists to reverse coma transiently in such patients (33). Elderly people appear to be at increased risk only if they are physically unwell, and particularly if they are taking many medications.

Rapid absorption, often followed by rapid redistribution to tissue stores with consequent falls in brain and blood drug concentrations, plays a significant role in the quick onset and cessation of perceived effects, but long-term actions, for example mild sedative and antianxiety effects, are a consequence of slow hepatic clearance, either by hydroxylation and subsequent conjugation to a glucuronide or by microsomal metabolism to other possibly pharmacologically active metabolites. Agents that are subject to microsomal metabolism and/or oxidation accumulate more rapidly in patients with reduced liver function (for example frail elderly people); only the metabolism of drugs such as oxazepam, lorazepam, and temazepam, which predominantly undergo glucuronidation, is not affected by liver function (Table 3) nor suffer from interference by drugs, such as cimetidine, estrogens, or erythromycin, which compete for the enzyme pathways (see Drug–Drug Interactions).

Pharmacodynamics

The use of techniques of molecular biology to clone the benzodiazepine receptor and the other components of the GABA receptor/chloride channel complex has shown that there are likely to be many variant forms of the receptor, owing to the multiplicity of protein subunits that constitute it. This has given rise to the hope that more selective agonist drugs, for example the "Z drugs" (zaleplon, zolpidem, and zopiclone), may produce fewer adverse effects (35,36); however, this hope appears to have been overoptimistic (10). There are also many ways in which different drugs interact with receptor sites to produce their effects, including agonism, partial agonism, antagonism, inverse agonism (contragonism), and even partial inverse agonism; this increases the complexity considerably. The

suggestion that partial agonists (such as alpidem and abecarnil) have greater anxiolytic than sedative potency (37), or that they will be less likely to give rise to abuse (35) or dependence (38), is yet to be established.

Medicolegal considerations

Medicolegal problems, especially with the use of triazolam, have been discussed (SEDA-13, 33); debate continues on the interpretation of evidence that points to an increased incidence of adverse behavioral effects with triazolam (39), flunitrazepam, and other short-acting high-potency agents (12). A review has highlighted a substantial rate (0.3–0.7%) of aggressive reactions to benzodiazepines, and the fact that a majority so affected may have intended a disinhibitory effect, with clear forensic implications (40). High rates of benzodiazepine consumption, much of it illicit, continue in prison populations.

Efforts to restrict benzodiazepines in New York State (2,7) and to ban triazolam (Halcion) in the UK (7,41) and the Netherlands (42)(SEDA-4,V) have likewise been fraught with controversy. For example, the requirement to use triplicate prescription forms in New York has been effective in reducing prescription volumes, including arguably necessary and appropriate prescriptions (43). A 1979 suspension of triazolam availability in the Netherlands was overturned in 1990, while a 1993 formal ban in the UK has remained in force (44). Two extensive reports have included recommendations for resolving the special problems posed by the Halcion controversy (44,45).

General adverse effects

Benzodiazepines have a high therapeutic index of safety, with little effect on most systems (other than the CNS) in high doses. However, their toxicity increases markedly when they are combined with other CNS depressant drugs, such as alcohol or opioid analgesics. Medically ill and brain injured patients are particularly susceptible to adverse neurological or behavioral effects (SEDA-18, 43) (SEDA-20, 30) (46).

The most frequent adverse effect which occurs in at least one-third of patients is drowsiness, often accompanied by incoordination or ataxia. Problems with driving, operating machinery, or falls can result, particularly in the elderly, and can be an important source of morbidity, loss of physical function, and mortality (47,48). Memory impairment, loss of insight, and transient euphoria are common; "paradoxical" reactions of irritability or aggressive behavior have been well documented (11) and appear to occur more often in individuals with a history of impulsiveness or a personality disorder (40), and in the context of interpersonal stress and frustration (49). Tolerance to the sedative and hypnotic effects generally occurs more rapidly than to the anxiolytic or amnestic effects (1).

Physical dependence on benzodiazepines is recognized as a major problem, and occurs after relatively short periods of treatment (50,51), particularly in patients with a history of benzodiazepine or alcohol problems. Abrupt withdrawal can cause severe anxiety, perceptual changes, convulsions, or delirium. It can masquerade as a return of the original symptoms in a more severe form (rebound), or present with additional features (SEDA-17, 42) (11). Up to 90% of regular benzodiazepine users have adverse symptoms on withdrawal. The differences between rebound, withdrawal syndrome, and recurrence have been reviewed in detail (3).

Rebound insomnia or heightened daytime anxiety can occur, particularly after short-acting benzodiazepine hypnotics (12,52,53), and constitute a major reason for continuing or resuming drug use (11).

The use of intravenous benzodiazepines administered by paramedics for the treatment of out-of-hospital status epilepticus has been evaluated in a double-blind, randomized trial in 205 adults (54). The patients presented either with seizures lasting 5 minutes or more or with repetitive generalized convulsive seizures, and were randomized to receive intravenous diazepam 5 mg, lorazepam 2 mg, or placebo. Status epilepticus was controlled on arrival at the hospital in significantly more patients taking benzodiazepines than placebo (lorazepam 59%, diazepam 43%, placebo 21%). The rates of respiratory or circulatory complications related to drug treatment were 11% with lorazepam, 10% with diazepam, and 23% with placebo, but these differences were not significant.

Intranasal midazolam 0.2 mg/kg and intravenous diazepam 0.3 mg/kg have been compared in a prospective randomized study in 47 children (aged 6 months to 5 years) with prolonged (over 10 minutes) febrile seizures (55). Intranasal midazolam controlled seizures significantly earlier than intravenous diazepam. None of the children had respiratory distress, bradycardia, or other adverse effects. Electrocardiography, blood pressure, and pulse

© 2006 Elsevier B.V. All rights reserved.

oximetry were normal in all children during seizure activity and after cessation of seizures.

Organs and Systems

Cardiovascular

Hypotension follows the intravenous injection of benzodiazepines, but is usually mild and transient (SED-11, 92) (56), except in neonates who are particularly sensitive to this effect (57). Local reactions to injected diazepam are quite common and can progress to compartment syndrome (SEDA-17, 44). In one study (58), two-thirds of the patients had some problem, and most eventually progressed to thrombophlebitis. Flunitrazepam is similar to diazepam in this regard (59). Altering the formulation by changing the solvent or using an emulsion did not greatly affect the outcome (60). Midazolam, being water-soluble, might be expected to produce fewer problems; in five separate studies there were no cases of thrombophlebitis, and in two others the incidence was 8–10%, less than with diazepam but similar to thiopental and saline (61).

Respiratory

Respiratory depression has been reported as the commonest adverse effect of intravenous diazepam (56), especially at the extremes of age. Midazolam has similar effects (62). All benzodiazepines can cause respiratory depression, particularly in bronchitic patients, through drowsiness and reduction in exercise tolerance (63). Rectal administration of, for example, diazepam can offer advantages in unconscious or uncooperative patients, and is less likely than parenteral administration to produce respiratory depression.

A previous report that rectal and intravenous diazepam can cause respiratory depression in children with seizures (SEDA-24, 84) has been challenged (64,65). The authors of the second comment stated that this complication does not occur when rectal diazepam gel is used without other benzodiazepines; they also recommended that during long-term therapy families should be instructed not to give rectal diazepam more than once every 5 days or five times in 1 month.

In a prospective study of children admitted to an accident and emergency department because of seizures, there were 122 episodes in which diazepam was administered rectally and/or intravenously; there was respiratory depression in 11 children, of whom 8 required ventilation (66). The authors questioned the use of rectal or intravenous diazepam as first-line therapy for children with acute seizures.

Nervous system

Falls

The role of different types of benzodiazepines in the risk of falls in a hospitalized geriatric population has been examined in a prospective study of 7908 patients, consecutively admitted to 58 clinical centers during 8 months (67). Over 70% of the patients were older than 65 years, 50% were women, and 24% had a benzodiazepine prescription during the hospital stay. The findings suggested that the use of benzodiazepines with short and very short half-lives is an important and independent risk factor for falls. Their prescription for older hospitalized patients should be carefully evaluated.

In a case-control study using the Systematic Assessment of Geriatric Drug Use via Epidemiology (SAGE) database, the records of 9752 patients hospitalized for fracture of the femur during the period 1992–1996 were extracted and matched by age, sex, state, and index date to the records of 38 564 control patients (68). Among older individuals, the use of benzodiazepines slightly increased the risk of fracture of the femur. Overall, non-oxidative benzodiazepines do not seem to confer a lower risk than oxidative agents. However, the latter may be more dangerous among very old individuals (85 years of age or older), especially if used in high dosages.

In a similar case-control study, 245 elderly patients were matched with 817 controls (69). Benzodiazepines as a group were not associated with a higher risk of hip fracture, but patients who used lorazepam or two or more benzodiazepines had a significantly higher risk.

Effects on performance

All benzodiazepines can cause drowsiness and sedation, and can affect motor and mental performance. Driving is one motor and mental task that is particularly likely to be impaired (SEDA-7, 46), with dangerous consequences; hypnosedatives, like alcohol, impair both actual driving performance (70) and laboratory psychomotor tests (35), and are over-represented in blood samples from delinquent drivers (71). As with alcohol, the maximal impairment occurs while the drug blood concentrations are rising (72), rather than when they have peaked, are stable, or are falling. Somewhat surprisingly, zopiclone 7.5 mg, but not triazolam 0.25 mg, produced deficits in simulated aircraft flight performance 2 and 3 hours after the dose (73). The motor and mental performance reductions induced by hypnotics, especially in elderly people (74), result in an increased incidence of falls (SEDA-21, 38) which can cause hip fractures (75). Agents with short half-lives, including the "Z drugs", were previously thought to carry a reduced risk or even none, but earlier reassuring data have been supplanted by convincing evidence of harm, particularly during the first 2 weeks of prescription (48,76).

Fit young subjects had no impairment of their exercise ability after temazepam or nitrazepam, although nitrazepam caused a subjective feeling of hangover (77).

Seizures

Benzodiazepines can provoke seizures and occasionally precipitate status epilepticus.

- A 28-year-old man with complex partial status, which lasted for 2 months, had a paradoxical worsening of seizure activity in response to diazepam and midazolam (78).

Of 63 neonates receiving lorazepam, diazepam, or both in an intensive care unit, 10 had serious adverse events, including 6 with seizures (57).

Psychological, psychiatric

Cognition

The amnestic effects of benzodiazepines are pervasive and appear to derive from disruption of the consolidation of short-term into long-term memory (79). Amnesia appears to underlie the tendency of regular hypnotic users to overestimate their time asleep, because they simply forget the wakeful intervals (80); in contrast, the same patients underestimate their time spent asleep when drug-free. This amnestic property (SEDA-17, 42) (SEDA-19, 33) has been used to advantage in minor surgery, particularly with midazolam and other short-acting compounds (although male doctors and dentists are advised to have a chaperone present when performing benzodiazepine-assisted procedures with female patients). However, unwanted amnesia can occur, particularly with triazolam, when used as a hypnotic or as an aid for travelers (81,82). The combination of a short half-life and high potency, especially when it was used in the higher doses that were recommended when the drug was initially launched, makes triazolam particularly likely to cause this problem. Studies of low-dose lorazepam (1 mg) in healthy young adults have shown specific deficits in episodic memory (SEDA-21, 38) (SEDA-19, 35). Flurazepam and temazepam have initiated relatively few reports of adverse effects on memory, although flurazepam did cause daytime sedation. Temazepam was uncommonly mentioned in adverse reaction reports, but was also reported more often as being without adequate hypnotic effect. Ironically, temazepam produces more, and oxazepam less, sedation than other benzodiazepines in overdose (83).

The role of benzodiazepines in brain damage has been reviewed (SEDA-14, 36). Cognitive impairment in long-term users can be detected in up to half of the subjects, compared with 16% of controls, but the issue of reversibility with prolonged abstinence is unresolved. Cognitive toxicity is more common with benzodiazepines than other anticonvulsants, with the possible exception of phenobarbital (84).

Patients often have memory deficits after taking benzodiazepines and alcohol. In a study of hippocampal presynaptic glutamate transmission in conjunction with memory deficits induced by benzodiazepines and ethanol, reductions in hippocampal glutamate transmission closely correlated with the extent of impairment of spatial memory performance. The results strongly suggested that presynaptic dysfunction in dorsal hippocampal glutamatergic neurons would be critical for spatial memory deficits induced by benzodiazepines and ethanol (85).

When the relation between benzodiazepine use and cognitive function was evaluated in a prospective study of 2765 elderly subjects, the authors concluded that current benzodiazepine use, especially in recommended or higher dosages, is associated with worse memory among community-dwelling elderly people (86).

In a prospective study, 1389 people aged 60–70 years were recruited from the electoral rolls of the city of Nantes, France (Epidemiology of Vascular Aging Study) (87). A range of symptoms was examined, including cognitive functioning and symptoms of depressive anxiety, and data were also collected on psychotropic and other drugs, as well as tobacco use and alcohol consumption at baseline and thereafter at 2 and 4 years. Users of benzodiazepines were divided into episodic users, recurrent users, and chronic users. Chronic users of benzodiazepines had a significantly higher risk of cognitive decline in the global cognitive test and two attention tests than non-users. Overall, episodic and recurrent users had lower cognitive scores compared with non-users, but the differences were not statistically significant. These findings suggest that long-term use of benzodiazepines is a risk factor for increased cognitive decline in elderly people.

Delirium

Excessive anxiety and tremulousness, hyperexcitability, confusion, and hallucinations were all reported more often with triazolam than with temazepam or flurazepam, when spontaneous reporting was analysed (81). Whether this is dose-related, and perhaps related to the rapid changes in blood concentration with triazolam, is not clear. Delirium is common, particularly in elderly people, who may have impaired drug clearance, and must always be regarded as possibly drug-induced. Of considerable relevance to hospital practice is the finding of a three-fold increased risk of postoperative delirium in patients given a benzodiazepine (88). Dose- and age-related increases in adverse cognitive and other central nervous effects from benzodiazepines (82) are well documented. The use of these drugs in elderly people has been reviewed, with recommendations about maximizing the benefit-to-harm balance in this group of individuals who are susceptible to cognitive and other adverse effects (89,90).

Sleep

The benzodiazepines typically suppress REM sleep, with consequent rebound dreaming and restlessness on withdrawal, leading to poorer sleep patterns (SEDA-12, 42) (91).

The use of benzodiazepines, particularly the short-acting compounds such as triazolam, for the induction of sleep has provoked much discussion (SEDA-17, 42). The debate rages over the risks and benefits of short-acting compounds, in inducing bizarre behavior or rapid withdrawal with daytime anxiety, compared with the possibility of hangover sedation and performance deficits with longer-acting compounds (92). The treatment of sleep disorders is multifaceted, because of the complex nature of sleep and the variety of factors that can give rise to sleep disorders (82). Consequently, such treatment should be selected and proffered carefully, with due regard for all the factors, not treated cavalierly with the latest flavor-of-the-month benzodiazepine receptor agonist. Non-drug treatments are effective (17) and should be considered first; pharmacological treatment should take into consideration any pre-existing factors, for example anxiety, depression, the duration and nature of medical problems (including any painful condition), concomitant medications, and other substance use (13).

Psychoses

Depression is commonly seen (93), either during benzodiazepine treatment or as a complication of withdrawal (SEDA-17, 42). Relief of anxiety symptoms can uncover pre-existing depression, rather than causing depression

© 2006 Elsevier B.V. All rights reserved.

per se. In addition to their euphoriant effects in some individuals, benzodiazepines can directly increase irritability and depression and, less commonly, lead to full-blown manic episodes (94,95).

Review of a Canadian adverse drug reactions database showed several cases of previously unreported benzodiazepine-induced adverse effects, including hallucinations and encephalopathy (96), although whether benzodiazepines alone were responsible is difficult to confirm. Visual hallucinations have also been reported in association with zolpidem (97).

Benzodiazepine withdrawal, like alcohol withdrawal, can cause schizophreniform auditory hallucinations (98).

Behavior

While they are generally regarded as being tranquillizers, benzodiazepines and related hypnosedatives can release aggression and induce antisocial behavior (99), particularly in combination with alcohol (100) and in the presence of frustration (49). Aggression can occur during benzodiazepine intoxication and withdrawal (99). Non-medical use of flunitrazepam (101) seems particularly likely to reveal paradoxical rage and aggression, with consequent forensic problems. The combination of abnormal disinhibited behavior and amnesia produced by benzodiazepines can be singularly dangerous. Anecdotal cases suggest that hypnosedatives can also disinhibit violent behavior in individuals taking antidepressants. A literature review of behavioral adverse effects associated with benzodiazepines (clonazepam, diazepam, and lorazepam) has shown that 11–25% of patients with mental retardation have these adverse effects (102). In two controlled studies, lorazepam was more likely to provoke aggression than oxazepam (103,104).

Gastrointestinal

Nausea due to benzodiazepines has been reported as being commoner in children, but the incidence does not usually greatly exceed that found with placebo. Gastrointestinal disturbances are more common with the newer non-benzodiazepine agents, for example zopiclone and buspirone (105,106).

Liver

Jaundice has been reported after benzodiazepines, although in only a few cases have they been the only drugs involved (SED-12, 97).

Sexual function

Female orgasm is inhibited by some central depressant and psychotropic drugs, including antipsychotic drugs, antidepressants, and anxiolytic benzodiazepines (107). A survey of patients with bipolar affective disorder taking lithium showed that the co-administration of benzodiazepines was associated with a significantly increased risk (49%) of sexual dysfunction in both men and women (108). Reduced libido is uncommonly reported, as is sexual inhibition, but the actual incidences of these complications may be considerably higher. Hypnosedatives, particularly flunitrazepam and gammahydroxybutyrate, are implicated in sexual assault and "date rape" (109).

Long-Term Effects

Drug tolerance

Animal studies have suggested a possible mechanism for tolerance, in that chronic treatment of rats with triazolam reduced the mRNA coding for certain GABA receptor proteins (110).

Drug dependence

The likelihood and possible severity of dependence on benzodiazepines has been discussed (50).

Drug withdrawal

The likelihood and possible severity of withdrawal from benzodiazepines has been discussed, especially with regard to the newer short-acting compounds (50).

Withdrawal symptoms occur in at least one-third of long-term users (over 1 year), even if the dose is gradually tapered (111). Symptoms come on within 2–3 days of withdrawal of a short-acting or medium-acting benzodiazepine, or 7–10 days after a long-acting drug; short-acting benzodiazepines tend to produce a more marked withdrawal syndrome (35). Lorazepam and alprazolam are particularly difficult to quit. Symptoms usually last 1–6 weeks, but can persist for many months, leaving the patient in a vulnerable state, with likely recurrence of the original disorder and of self-medication. Withdrawal symptoms can occur within 4–6 weeks of daily long-acting benzodiazepine use (112), and possibly earlier in susceptible individuals.

Symptoms on withdrawal are variable in nature and degree. Rebound insomnia can occur one or two nights after withdrawal of short-acting drugs. Anxiety is common, with both psychological and physical manifestations, including apprehension, panic, insomnia, palpitation, sweating, tremor, and gastrointestinal disturbances. Irritability and aggression also occur, notably after triazolam. Depression has been reported after benzodiazepine withdrawal (113). There may be increased or distorted sensory perceptions, such as photophobia, altered (metallic) taste, and hypersensitivity to touch and pain. Flu-like muscle aches and spasms, unsteadiness, and clumsiness are common. Perceptual distortions include burning or creeping of the skin and apparent movement or changes in objects or self (111). General malaise with loss of appetite can occur. As with alcohol, paranoid psychosis, delirium, and epileptic fits are possible on withdrawal (SED-12, 97). With careful handling, often involving psychological and sometimes adjunctive pharmacological support, motivated patients who depend on benzodiazepines can usually be successfully withdrawn. In particular, the combination of gradual dose-tapering and cognitive behavioral therapy can be helpful (114). Guidelines on the management of such patients have been concisely presented (51).

Second-Generation Effects

Teratogenicity

Benzodiazepines readily pass from the mother to fetus through the placenta (115). There may be a risk of

© 2006 Elsevier B.V. All rights reserved.

congenital malformations, particularly oral cleft, if a pregnant woman takes a benzodiazepine during the first trimester, but the data are inconsistent across drugs (alprazolam having the most clearly defined risk), and any overall effect is probably small (27,28). The risk of benzodiazepine-induced birth defects thus remains uncertain (116), despite two cases of fetal-alcohol syndrome reported after benzodiazepine exposure alone (117).

The occurrence of congenital abnormalities associated with the use of benzodiazepines (alprazolam, clonazepam, medazepam, nitrazepam, and tofisopam) during pregnancy has been analysed in a matched case-control study (118). The cases and controls were drawn from the Hungarian Case-Control Surveillance of Congenital Abnormalities from 1980 to 1996. Of the 38 151 pregnant women who delivered babies without congenital anomalies, 75 had taken benzodiazepines during pregnancy, compared with 57 of 22 865 who delivered offspring with anomalies. Thus, treatment with these benzodiazepines during pregnancy did not cause a detectable teratogenic risk. However, the true relevance of these findings needs to be supported by prospective case ascertainment.

Fetotoxicity

Benzodiazepines readily pass from the mother to fetus through the placenta (115). There is a further concern about cognitive development after in utero exposure to benzodiazepines. It now appears that the slowed intellectual progress seen in some children exposed in utero will "catch up" in most cases by age 4 (28). Unfortunately, the impact of sedative-hypnotic use during pregnancy is often complicated by the abuse of multiple agents and poor maternal nutrition and antenatal care, and may be further confounded by social and environmental deprivation, which the infant often faces after birth (28,119). More definite but short-lived problems occur with benzodiazepines given in late pregnancy and during labor; here floppiness, apnea, and withdrawal in the infant can pose problems (28,120) but usually resolve uneventfully (SEDA-21, 38). Pregnant women should avoid benzodiazepines if possible, especially during late pregnancy and labor; if required, chlordiazepoxide appears to have the best established record (29). On the other hand, alprazolam should be avoided, and temazepam plus diphenhydramine appears to be a particularly toxic combination in late pregnancy, based on animal research and one case report of fetal activation followed by stillbirth (121).

Lactation

Benzodiazepines are secreted into the milk in relatively small amounts (28). During lactation, longer-acting agents are relatively contraindicated, particularly with continued administration beyond 3–5 days, owing to the likelihood of infant sedation (120,122). Short-acting benzodiazepines and zopiclone are probably safe, especially if restricted to single doses or for short courses of therapy (28,123). Zopiclone and midazolam, for example, become undetectable in breast milk 4–5 hours after a dose (124).

Susceptibility Factors

Age

The safety of benzodiazepines in neonates has been assessed in a retrospective chart review of 63 infants who received benzodiazepines (lorazepam and/or midazolam) as sedatives or anticonvulsants (57). Five infants had hypotension and three had respiratory depression. In all cases of respiratory depression, ventilatory support was initiated or increased. Significant hypotension was treated with positive inotropic drugs in two cases. Thus, respiratory depression and hypotension are relatively common when benzodiazepines are prescribed in these patients. However, both depression and hypotension could also have been due to the severe underlying illnesses and concomitant medications. Matched controls were not studied.

Other features of the patient

Benzodiazepines are more likely to cause adverse effects in patients with HIV infection and other causes of organic brain syndrome (46).

Drug Administration

Drug overdose

Overdosage of benzodiazepines alone is generally thought to be safe, but deaths have occasionally been reported (125–127). In 204 consecutive suicides seen by the San Diego County Coroner during 1981–1982, drugs were detected in 68%, and anxiolytics and hypnotics in 11% and 12% respectively; although benzodiazepines were found in under 10% of the group as a whole, they were found in one-third of those who died by overdose (128). In one series of 2827 intentional cases of poisoning, in which there were ten deaths, three were associated with benzodiazepines; death was related to a delay between ingestion and medical intervention (129), and advanced age has also been described as a risk factor (130). In other cases death has been attributed to combined overdose with other drugs, such as alcohol (126), oxycodone (131,132), tramadol (133), and amitriptyline (134).

Concomitant benzodiazepine overdose has also been reported to be an independent risk factor in the development of hepatic encephalopathy (OR = 1.91; CI = 1.00, 3.65) and renal dysfunction (OR = 1.81; CI = 1.00, 3.22) in patients who take a paracetamol overdose (135).

Drug–Drug Interactions

Antibiotics

Antibiotics (erythromycin, chloramphenicol, isoniazid) compete for hepatic oxidative pathways that metabolize most benzodiazepines, as well as zolpidem, zopiclone, and buspirone (SEDA-22, 39) (SEDA-22, 41).

Macrolides cause increases in the serum concentrations, AUCs, and half-lives and reductions in the clearance of triazolam and midazolam (136–138). These changes can result in clinical effects, such as prolonged psychomotor impairment, amnesia, or loss of

© 2006 Elsevier B.V. All rights reserved.

consciousness (139). Erythromycin can increase concentrations of midazolam and triazolam by inhibition of CYP3A4, and dosage reductions of 50% have been proposed if concomitant therapy is unavoidable (140).

Antifungal imidazoles

Antifungal imidazoles (ketoconazole, itraconazole, and analogues) compete for hepatic oxidative pathways that metabolize most benzodiazepines, as well as zolpidem, zopiclone, and buspirone (SEDA-22, 39, 41–43).

Antihistamines

The potentiation of sedative effects from benzodiazepines when combined with centrally acting drugs with antihistamine properties (for example first-generation antihistamines, tricyclic antidepressants, and neuroleptic drugs) can pose problems (141). Antihistamines that do not have central actions do not interact with benzodiazepines as in the case of mizolastine and lorazepam (142), ebastine and diazepam (143), and terfenadine and diazepam (141).

Calcium channel blockers

Diltiazem and verapamil compete for hepatic oxidative pathways that metabolize most benzodiazepines, as well as zolpidem, zopiclone, and buspirone (SEDA-22, 39) (SEDA-22, 41).

Central stimulants

Caffeine and other central stimulants can reverse daytime sedation from benzodiazepine use. There was a positive effect of caffeine (250 mg) on early-morning performance after both placebo and flurazepam (30 mg) given the night before (144,145), particularly in terms of subjective assessments of mood and sleepiness. However, one cannot assume that the alerting effect of caffeine necessarily reverses the amnestic, disinhibiting, or insight-impairing effects of benzodiazepines. Indeed, caffeine can actually worsen learning and performance already impaired by lorazepam (146). Other drugs with direct or indirect CNS stimulant activity (theophylline, ephedrine, amphetamine, and their analogues) have similar effects and can counteract the effects of benzodiazepines, at least subjectively. Another worrying feature of stimulant use, particularly in drug misusers, is that it commonly increases the perceived need for hypnosedatives.

Cimetidine

Cimetidine can impair benzodiazepine metabolism and lead to adverse effects (SEDA-18, 43). In contrast, a few benzodiazepines are metabolized exclusively by glucuronide conjugation (lorazepam, oxazepam, temazepam), and are therefore unaffected by concomitant therapy with cimetidine and other oxidation inhibitors (121).

Clozapine

Caution has been recommended when starting clozapine in patients taking benzodiazepines (SEDA-19, 55). Three cases of delirium associated with clozapine and benzodiazepines (147) have been reported. There have been several reports of synergistic reactions, resulting in increased sedation and ataxia, when lorazepam was begun in patients already taking clozapine (148).

- Syncope and electrocardiographic changes (sinus bradycardia of 40/minute with deep anteroseptal inverted T waves and minor ST changes in other leads) have been observed with the concurrent administration of clozapine (after the dosage was increased to 300 mg/day) and diazepam (30 mg/day) in a 50-year-old man (149).

CNS depressants

The interactions of benzodiazepines with other nervous system depressants, especially alcohol and other GABAergic drugs, have been reviewed (150). Other drugs with nervous system depressant effects (opioids, anticonvulsants, general anesthetics) also can add to, and complicate, the depressant action of benzodiazepines.

Phenothiazines and butyrophenones can counteract intoxication from lysergic acid diethylamide (LSD); benzodiazepines can inhibit this useful effect of antipsychotic drugs (151).

Disulfiram

Disulfiram competes for hepatic oxidative pathways that metabolize most benzodiazepines, as well as zolpidem, zopiclone, and buspirone (SEDA-22, 39) (SEDA-22, 41).

Enzyme inducers

Enzyme induction can be problematic with co-administration of benzodiazepines and rifampicin or certain anticonvulsants (phenobarbital, phenytoin, carbamazepine). However, despite enzyme stimulation, the net effect of adding these anticonvulsants can be augmentation of benzodiazepine-induced sedation.

Rifampicin, and presumably other enzyme inducers, reduces concentrations of zolpidem, zopiclone, and buspirone (SEDA-22, 42). Drugs that are solely glucuronidated (lorazepam, oxazepam, and temazepam) are not affected.

HIV protease inhibitors

Some protease inhibitors (saquinavir) compete for hepatic oxidative pathways that metabolize most benzodiazepines, as well as zolpidem, zopiclone, and buspirone (SEDA-22, 39) (SEDA-22, 41).

Levodopa

The question of whether starting a benzodiazepine in patients taking levodopa is followed by a faster increase in antiparkinsonian drug requirements has been studied using drug dispensing data for all the residents in six Dutch cities (152). All were 55 years old or older and had used levodopa for at least 360 days. There were 45 benzodiazepine starters and 169 controls. Antiparkinsonian drug doses increased faster in the benzodiazepine group, but the difference was not significant (RR = 1.44; 95% CI = 0.89, 2.59).

© 2006 Elsevier B.V. All rights reserved.

Lithium

In 18 patients treated with benzodiazepines and/or antipsychotic drugs there were increased chromosomal aberrations and increased sister chromatid exchange, but there were no significant differences between this group and another group of 18 patients taking lithium in addition to benzodiazepines and/or antipsychotic drugs (153).

Moxonidine

Moxonidine can potentiate the effect of benzodiazepines (154).

Muscle relaxants

Laboratory investigations have shown that some benzodiazepines can produce biphasic effects on the actions of neuromuscular blocking agents (155,156), higher doses potentiating the effects (155,157); however, several human investigations have failed to show a significant effect (158–160). It has been suggested that agents that are added to commercial formulations of some benzodiazepines to render them more water-soluble may mask the benzodiazepine effect (160).

Nevertheless, some interactions of benzodiazepines with muscle relaxants used in anesthesia have been described. Diazepam has been reported to potentiate the effects of tubocurare (161) and gallamine (162) and to reduce the effects of suxamethonium (162). However, in 113 patients undergoing general anesthesia, intravenous diazepam 20 mg, lorazepam 5 mg, and lormetazepam 2 mg did not potentiate the neuromuscular blocking effects of vecuronium or atracurium (160).

In 113 patients undergoing general anesthesia, intravenous midazolam 15 mg slowed recovery of the twitch height after vecuronium and atracurium compared with diazepam. The recovery index was not altered (160). However, in another study in 20 patients, midazolam 0.3 mg/kg did not affect the duration of blockade, recovery time, intensity of fasciculations, or adequacy of relaxation for tracheal intubation produced by suxamethonium 1 mg/kg, nor the duration of blockade and adequacy of relaxation for tracheal intubation produced by pancuronium 0.025 mg/kg in incremental doses until 99% depression of muscle-twitch tension was obtained (159). Furthermore, in 60 patients undergoing maintenance anesthesia randomly assigned to one of six regimens (etomidate, fentanyl, midazolam, propofol, thiopental plus nitrous oxide, or isoflurane plus nitrous oxide), midazolam did not alter rocuronium dosage requirements (163).

Neuroleptic drugs

Because of the frequency of co-administration of benzodiazepines with neuroleptic drugs, it is important to consider possible adverse effects that can result from such combinations. In a brief review, emphasis has been placed on pharmacokinetic interactions between neuroleptic drugs and benzodiazepines, as much information on their metabolic pathways is emerging (164). Thus, the enzyme CYP3A4, which plays a dominant role in the metabolism of benzodiazepines, also contributes to the metabolism of clozapine, haloperidol, and quetiapine, and neuroleptic drug plasma concentrations can rise. Intramuscular levomepromazine in combination with an intravenous benzodiazepine has been said to increase the risk of airways obstruction, on the basis of five cases of respiratory impairment; the doses of levomepromazine were higher in the five cases that had accompanying airways obstruction than in another 95 patients who did not (165).

Omeprazole

Omeprazole can impair benzodiazepine metabolism and lead to adverse effects (SEDA-18, 43).

Opioids

Fentanyl competes for hepatic oxidative pathways that metabolize most benzodiazepines, as well as zolpidem, zopiclone, and buspirone (SEDA-22, 39) (SEDA-22, 41).

Oral contraceptives

Oral contraceptives alter the metabolism of some benzodiazepines that undergo oxidation (alprazolam, chlordiazepoxide, diazepam) or nitroreduction (nitrazepam) (166). For these drugs, oral contraceptives inhibit enzyme activity and reduce clearance. There is nevertheless no evidence that this interaction is of clinical importance. It should be noted that for other benzodiazepines that undergo oxidative metabolism, such as bromazepam or clotiazepam, no change has ever been found in oral contraceptive users. Some other benzodiazepines, such as lorazepam, oxazepam, and temazepam, are metabolized by glucuronic acid conjugation. The clearance of temazepam was increased when oral contraceptives were co-administered, but the clearances of lorazepam and oxazepam were not (167). Again, it is unlikely that this is an interaction of clinical importance.

Selective serotonin reuptake inhibitors (SSRIs)

Some SSRIs (notably fluvoxamine and to a lesser extent fluoxetine) and their metabolites inhibit hepatic oxidative enzymes, particularly CYP2C19 and CYP3A, that metabolize most benzodiazepines, as well as zaleplon, zolpidem, zopiclone, and buspirone (SEDA-22, 39) (SEDA-22, 41) (168,169). Apart from fluvoxamine, SSRIs do not generally have a clinically prominent effect on hypnosedative effects; studies vary from those that have found that fluoxetine has a moderate but functionally unimportant impact on diazepam concentrations (170) to results that suggest significant aggravation of the cognitive effects of alprazolam when co-prescribed with the SSRI (171).

Tricyclic antidepressants

Four patients developed adverse effects attributable to combinations of benzodiazepines with tricyclic antidepressants, including exacerbations of delusional disorder (172).

Nefazodone competes for hepatic oxidative pathways that metabolize most benzodiazepines, as well as zolpidem, zopiclone, and buspirone (SEDA-22, 39) (SEDA-22, 41).

Benzoxonium chloride

See also Disinfectants and antiseptics

General Information

Benzoxonium is a quaternary ammonium compound with antibacterial, antiviral, and antimycotic activity. It can be used in topical disinfection, disinfection of surgical instruments, inhibition of plaque formation, and in veterinary products.

Organs and Systems

Immunologic

Contact allergic reactions have been rarely reported, with potential cross-reactivity with benzalkonium chloride and domiphen bromide (1,2).

- A 37-year-old woman developed intense burning and pruritic eczema where she had applied a cream containing benzoxonium for seborrheic dermatitis for 5 months (3). The reaction disappeared on withdrawal of the cream. Patch tests were positive to benzoxonium chloride 0.1% aqueous on days 2 and 4. Patch tests with benzalkonium chloride and benzoxonium chloride in 20 controls were negative.

Benzoyl peroxide

General Information

Benzoyl peroxide is an antimicrobial and keratolytic agent used in the treatment of acne; it is also added to some foods. It is a catalyst for cross-linking in the production of plastics and is occasionally used in acrylic resin systems (for example composite dental fillings, dental prostheses) in which it is formed during the cross-linking process.

Organs and Systems

Skin

Allergic contact dermatitis has been attributed to topical benzoyl peroxide in a variety of settings (1–4).

- An 80-year-old man developed dermatitis in his leg amputation stump. He had been using stretching tapes containing benzoyl peroxide, and a patch test showed a positive reaction to benzoyl peroxide (1% in petrolatum) on days 2 and 3 (5).

Benzydamine

General Information

Benzydamine is 1-benzyl-3-(3-dimethylaminopropoxy)-*H*-indazole, used for medical purposes as the hydrochloride. It has analgesic, anti-inflammatory, antipyretic, and local anesthetic effects. In the past it has been especially used in the symptomatic treatment of edematous postoperative or traumatic swelling, non-specific inflammation of the upper respiratory tract, and inflammation of connective tissues and joints. Nowadays, Tantum verde is the only such formulation listed in Germany; it is used for the treatment of oral and pharyngeal inflammation from any cause, for example radiotherapy-induced mucositis, stomatitis, Vincent's angina, necrotic oropharyngeal neoplasms, after surgical operations on the mouth and

© 2006 Elsevier B.V. All rights reserved.

pharynx, after intubation, and after endoscopic laryngeal surgery. It can be administered as a spray, a gargle solution, a rinsing solution, or lozenges.

Organs and Systems

Skin

Skin reactions, including photosensitivity and contact dermatitis (when used topically), have been reported (1–7).

- A 67-year-old woman with pharyngitis gargled with Tantum verde, and after 3 weeks, during a holiday, developed an erythematous rash on sun-exposed skin, worsening within the next few days (8). She had not used a sunscreen. There were mainly well-demarcated areas of eczema on the face, neck, neckline, forearms, and lower legs. After oral and topical corticosteroids, the skin lesions improved within a few days.

There have been two other case reports of photoallergic dermatitis after local pharyngeal treatment with formulations containing benzydamine (6). This presumably occurs because of oral or intestinal absorption.

Benzyl alcohol

See also Disinfectants and antiseptics

General Information

Benzyl alcohol is commonly used as a preservative in multidose injectable pharmaceutical formulations. For this purpose, concentrations in the range of 0.5–2.0% are used and the whole amount of benzyl alcohol injected is generally very well tolerated. Concentrations of 0.9% are used in Bacteriostatic Sodium Chlorine (USP), which is often used in the management of critically ill patients to flush intravascular catheters after the addition of medications or the withdrawal of blood, and in Sterile Bacteriostatic Water for injection (USP), used to dilute or reconstitute medications for intravenous use. The content of benzyl alcohol in a lot of injectable pharmaceutical formulations needs to be considered carefully. The view still taken in many countries that the additives and excipients in medicines are trade secrets must be deplored. The duty to declare them is only realized in some countries.

The toxic effects of benzyl alcohol include respiratory vasodilatation, hypertension, convulsions, and paralysis.

Organs and Systems

Nervous system

The data on reported cases of neurological disorders after intrathecal chemotherapy with methotrexate or cytosine arabinoside that could be attributed to benzyl alcohol or to other preservatives have been reviewed in the context of a case of flaccid paraplegia after intrathecal administration of cytosine arabinoside diluted in bacteriostatic water containing 1.5% benzyl alcohol (1). Most commonly, flaccid paraparesis, with absent reflexes, developed rapidly, often with pain and anesthesia. Very often there was full recovery. The prognosis depended mainly on the concentration of the preservative and on the time of exposure. In some cases, the paralysis ascended to cause respiratory distress, cardiac arrest, and death. Only preservative-free sterile CSF substitute or saline, or preferably the patient's own CSF, should be used to dilute chemotherapeutic agents (SEDA-11, 475).

Skin

Allergic contact dermatitis, characterized by erythema, palpable edema, and raised borders, was attributed to benzyl alcohol (2). In this case, the benzyl alcohol was present as a preservative in an injectable solution of sodium tetradecyl sulfate, a sclerosing agent used for the treatment of varicose veins. The author provided a list of 151 injectable formulations (48 for subcutaneous administration) that contained benzyl alcohol as a preservative in the range 0.5–2.0%. The list included hormones and steroids, antihypertensive drugs (reserpine), vitamin formulations (vitamins B_{12} and B_6), ammonium sulfate, antihistamines, antibiotics, heparin (17 brands), tranquillizers, and sclerosing agents (sodium morrhuate and sodium tetradecyl sulfate).

- A patient with a contact allergic reaction to a topical antimycotic drug formulation that contained benzoyl alcohol had positive patch tests on day 4 and a positive repeated open application test to benzoyl alcohol 5% in petroleum jelly (3).

The authors noted that although contact allergic reactions to benzoyl alcohol are rarely reported, they can be responsible for contact allergy to topical glucocorticoid formulations.

Immunologic

Various allergic reactions have been attributed to benzyl alcohol.

© 2006 Elsevier B.V. All rights reserved.

- A 55-year-old man developed fatigue, nausea, and diffuse angioedema shortly after an intramuscular injection of vitamin B12 containing benzyl alcohol (4).
- In another male patient, fever developed, and a maculopapular rash occurred on his chest and arms after an injection of cytarabine, vincristine, and heparin in a dilution solution containing benzyl alcohol (5).

Susceptibility Factors

Age

A gasping syndrome in small premature infants who had been exposed to intravenous formulations containing benzyl alcohol 0.9% as a preservative has been described (SEDA-10, 421) (SEDA-11, 475) (6–8). The affected infants presented with a metabolic acidosis, seizures, neurological deterioration, hepatic and renal dysfunction, and cardiovascular collapse. Death was reported in 16 children who received a minimum of 99 mg/kg/day of benzyl alcohol. This metabolic acidosis is caused by accumulation of the metabolite benzoic acid and is mainly related to an excessive body burden relative to body weight, so that the load of the metabolite may exceed the capacity of the immature liver and kidney for detoxification. The FDA has recommended that neither intramuscular flushing solutions containing benzyl alcohol nor dilutions with this preservative should be used in newborn infants.

In a review of the hospital and autopsy records of infants admitted to a nursery during the previous 18 months, 218 patients had been given fluids containing benzyl alcohol as flush solutions and they were compared with 218 neonates admitted during the following 18 months (9). Withdrawal of benzyl alcohol as a preservative had no demonstrable effect on mortality, but the development of kernicterus was significantly associated with benzyl alcohol in 15 of 49 exposed patients, and no cases occurred after withdrawal of the preservative. However, this apparent association was not confirmed in a 5-year study of the use of benzyl alcohol as a preservative in intravenous medications in a neonatal intensive care unit (10). In 129 neonates who died between the ages of 2 and 28 days, there was no difference in the rate of kernicterus and the exposure to benzyl alcohol between neonates who developed kernicterus and the control group of unaffected infants who were born during the same period and who were of the same birth weight and gestation age. In this study, only estimates of the extent of exposure to benzyl alcohol were given, rather than exact doses and serum concentrations.

Bephenium

General Information

Bephenium hydroxynaphthoate is an antihelminthic drug that has been used in the treatment of hookworm infections due to *Ancylostoma duodenale* in a single dose (1). It is well tolerated, and reactions are confined to mild gastrointestinal disturbances (unpleasant taste, nausea, abdominal pain, and sometimes also vomiting and diarrhea), headache, and dizziness. It is reputed to be safe in pregnancy but is better avoided in conditions in which purgation could be dangerous; these naturally include the last few months of pregnancy, because of the risk of miscarriage.

Reference

1. Botero D. Chemotherapy of human intestinal parasitic diseases. Annu Rev Pharmocol Toxicol 1978;18:1–15.

Bepridil

See also Antidysrhythmic drugs

General Information

Bepridil is an antidysrhythmic drug with unusual pharmacological properties in that it belongs to both class I and class IV. In other words, it blocks both the fast inward sodium current and the slow outward calcium current in excitable cardiac cells (SEDA-13, 141). It was withdrawn because of its serious prodysrhythmic effects.

Bepridil has been the subject of a brief general review (1) and its pharmacokinetics have been specifically reviewed (2). Although it is highly protein-bound, bepridil does not take part in protein-binding displacement interactions (2).

© 2006 Elsevier B.V. All rights reserved.

The main adverse effect of bepridil is torsade de pointes due to QT interval prolongation. After intravenous infusion bepridil can cause local reactions (3) and phlebothrombosis (4). Other minor adverse effects that have been reported include urticaria (5), gastrointestinal disturbances (especially diarrhea) (6,7), and dizziness (6–8). Hepatic enzymes can rise (9,10).

Organs and Systems

Cardiovascular

Bepridil can cause hypotension after rapid intravenous injection (6,11), but not during long-term oral therapy (12,13).

Bepridil prolongs the QT interval (3,7,8,14), an effect that is dose-related (14). It can therefore cause dysrhythmias, including polymorphous ventricular tachycardia, the risk of which is greater in patients with potassium depletion, those with pre-existing prolongation of the QT interval, those with a history of serious ventricular dysrhythmias, and those who are also taking other drugs that prolong the QT interval (15).

Of 75 elderly patients who took bepridil 200 mg/day, 23 had prolongation of the QT interval. The factors that were associated with this were hypokalemia, bradycardia, renal insufficiency, and an increased plasma bepridil concentration (16).

Drug–Drug Interactions

Antidysrhythmic drugs

Because it prolongs the QT interval, bepridil can potentiate the effects of other drugs with the same effect (for example other Class I antidysrhythmic drugs and amiodarone).

Beta-adrenoceptor antagonists

The effect of a beta-blocker (metoprolol 30–40 mg/day or bisoprolol 2.5–5.0 mg/day for 1 month) on the change in QT interval, QT dispersion, and transmural dispersion of repolarization caused by bepridil has been studied in 10 patients with paroxysmal atrial fibrillation resistant to various antidysrhythmic drugs (17). Bepridil significantly prolonged the QTc interval from 0.42 to 0.50 seconds, QT dispersion from 0.07 to 0.14 seconds, and transmural dispersion of repolarization from 0.10 to 0.16 seconds. The addition of a beta-blocker shortened the QTc interval from 0.50 to 0.47 seconds, QTc dispersion from 0.14 to 0.06 seconds, and transmural dispersion of repolarization from 0.16 to 0.11 seconds. The authors therefore suggested that combined therapy with bepridil and a beta-blocker might be useful for intractable atrial fibrillation.

Bepridil does not interact with propranolol (8).

Digoxin

Bepridil does not interact with digoxin (18).

Phenazone

Bepridil increases the rate of clearance of phenazone (antipyrine) and might therefore be expected to enhance the rate of clearance of other drugs that are metabolized (19).

Beraprost

See also Prostaglandins

General Information

Beraprost is a stable, orally active analogue of PGI_2. It has been tested in patients with intermittent claudication in a randomized, placebo-controlled trial (1). Beraprost improved walking distance more often than placebo. It also reduced the incidence of critical cardiovascular events, but the trial was not powered for statistical validation of this effect. As with iloprost, headache and flushing were the most common adverse effects.

Berberidaceae

See also Herbal medicines

General Information

The genera in the family of Berberidaceae (Table 1) include lychee and soapberry.

Table 1 The genera of Berberidaceae

Achlys (achlys)
Berberis L (barberry)
Caulophyllum (cohosh)
Diphylleia (umbrellaleaf)
Epimedium (epimedium)
Jeffersonia (jeffersonia)
Mahonia (barberry)
Nandina (nandina)
Podophyllum (may apple)
Vancouveria (insideout flower)

Berberis vulgaris

Barberry (pipperidge bush) is a vernacular name for *Berberis vulgaris* (the European barberry), but it can also refer to *Mahonia aquifolium* and *Mahonia nervosa*. In the USA only the *Mahonia* species have had official status as a source of barberry, but *Berberis vulgaris* is said to serve similar medicinal purposes and to contain similar principles. Its root bark yields the quaternary isoquinoline alkaloid berberine and several other tertiary and quaternary alkaloids. Berberine is also found in *Hydrastis canadensis* (goldenseal) and *Coptis chinensis* (goldenthread).

Adverse effects

In man berberine has positive inotropic, negative chronotropic, antidysrhythmic, and vasodilator properties (1) and there is experimental evidence that it can cause arterial hypotension (2,3).

Berberine displaces bilirubin from albumin and there is therefore a risk of kernicterus in jaundiced neonates (4).

In a study of the effect of berberine in acute watery diarrhea, oral doses of 400 mg were well tolerated, except for complaints about its bitter taste and a few instances of transient nausea and abdominal discomfort. However, patients with cholera given tetracycline plus berberine were more ill, suffered longer from diarrhea, and required larger volumes of intravenous fluid than those given tetracycline alone (5).

Caulophyllum thalictroides

Caulophyllum thalictroides (blue cohosh) contains vasoactive glycosides and quinolizidine alkaloids that produce toxic effects on the myocardium in animals.

Adverse effects

Heart failure occurred in the fetus of a mother who used blue cohosh.

- A 41-week-old boy weighing 3.66 kg developed respiratory distress, acidosis, and shock shortly after a spontaneous vaginal delivery (6). His 36-year-old mother had a history of adequately controlled hypothyroidism and had taken tablets of blue cohosh for 1 month to induce uterine contractions. Subsequently she felt more contractions and less fetal activity. After delivery, the baby continued to be critically ill for several weeks and required treatment for respiratory failure and cardiogenic shock. He gradually improved and was extubated after 21 days. There were no congenital abnormalities or other reasons to explain the infant's problems. He remained in hospital for 31 days and an electrocardiogram at discharge was consistent with a resolving anterolateral myocardial infection. Two years later he had fully recovered, but cardiomegaly and impaired left ventricular function persisted.

© 2006 Elsevier B.V. All rights reserved.

The authors believed that the consumption of blue cohosh by the mother had caused heart failure in the child.

Dysosma pleianthum

Dysosma pleianthum (bajiaolian), a species of May apple, is a traditional Chinese herbal medicine rich in podophyllotoxin. It has been widely used in China for thousands of years as a general remedy and for the treatment of snake bite, weakness, condyloma accuminata, lymphadenopathy, and tumors.

Adverse effects

Five people developed nausea, vomiting, diarrhea, abdominal pain, thrombocytopenia, leukopenia, abnormal liver function tests, sensory ataxia, altered consciousness, and persistent peripheral tingling or numbness after drinking infusions of bajiaolian (7). These effects were consistent with podophyllum intoxication.

Mahonia species

Barberry is a vernacular name for members of the *Berberis* species, such as *Berberis vulgaris* (European barberry), but is also used to refer to members of the *Mahonia* species, such as *Mahonia aquifolium* and *Mahonia nervosa*. In the USA only the latter species have had official status as a source of barberry, but *Berberis vulgaris* is said to serve similar medicinal purposes and to contain similar principles. Its root bark yields the quaternary isoquinoline alkaloid berberine and several other tertiary and quaternary alkaloids. It has been used to treat a variety of skin conditions (8,9). The literature sometimes cautions that barberry alkaloids can cause arterial hypotension.

Beta$_2$-adrenoceptor agonists

See also Individual agents

General Information

Beta$_2$-adrenoceptor agonists are widely used in asthma and have inevitably been associated with a number of problems. Some of these are attributable to the drugs themselves, others to the formulations in which they are given.

Organs and Systems

Cardiovascular

Eight men with mild asthma underwent measurement of forearm blood flow, a surrogate marker for peripheral vasodilatation (1). All received in sequential order the following: normoxia plus placebo, normoxia plus inhaled salbutamol 800 micrograms, hypoxia (SpO_2 82%) plus placebo, and hypoxia plus inhaled salbutamol 800 micrograms. The period of mask breathing was 60 minutes and inhalation of salbutamol/placebo started after 30 minutes. While there were non-significant differences in blood pressure and potassium concentrations between the different treatments, forearm blood flow increased significantly by 45% in hypoxic patients inhaling salbutamol versus normoxic patients inhaling placebo. The authors concluded that the combination of hypoxia and inhalation of beta$_2$-agonists has serious systemic vascular adverse effects, potentially leading to pulmonary shunting and reduced venous return, which may be associated with sudden death. Furthermore, asthmatic patients in respiratory distress should be given beta$_2$-agonists and oxygen concomitantly whenever possible.

Intravenous and intracoronary salbutamol (10–30 micrograms/minute and 1–10 micrograms/minute respectively), and intravenous isoprenaline (1–5 micrograms/minute), a mixed beta$_1$/beta$_2$-adrenoceptor agonist, were infused in 85 patients with coronary artery disease and 22 healthy controls during fixed atrial pacing (2). Both salbutamol and isoprenaline produced large increases in QT dispersion (QT_{onset}, QT_{peak}, and QT_{end}), more pronouncedly in patients with coronary artery disease. Dispersion of the QT interval is thought to be a surrogate marker for cardiac dysrhythmia (3). The authors concluded that beta$_2$-adrenoceptors mediate important electrophysiological effects in human ventricular myocardium and can trigger dysrhythmias in susceptible patients.

In a blind, randomized study, 29 children aged under 2 years, with moderate to severe acute exacerbations of hyper-reactive airways disease, were treated with either a standard dose of nebulized salbutamol (0.15 mg/kg) or a low dose of nebulized salbutamol (0.075 mg/kg) plus nebulized ipratropium bromide 250 micrograms (4). Standard and low-dose nebulized salbutamol was given three times at intervals of 20 minutes and nebulized ipratropium bromide was given once. Clinical improvement, measured as O_2 saturation and relief of respiratory distress, was similar in both groups. QT dispersion was measured at baseline and after treatment and was

significantly increased only by the standard dose of nebulized salbutamol.

Respiratory

Beta-adrenoceptor agonists can produce or worsen hypoxia acutely in patients with asthma by increasing ventilation–perfusion inequality. It is not known whether this effect is clinically important in patients with asthma not severe enough to require hospital treatment (where supplementary oxygen is standard therapy).

Metabolism

In obstetrics, the classic effects of beta$_2$-adrenoceptor agonists on glucose metabolism can be absent or harmless in the non-diabetic, but dangerous in women with diabetes, in whom they can cause metabolic acidosis (5); the hyperglycemic effect can be aggravated if glucocorticoids are given (as they may be to prevent hyaline membrane disease in prematurity).

Immunologic

The possibility of a causal relation between the administration of beta$_2$-adrenoceptor agonists and reduced serum immunoglobulin concentrations has been raised in various studies. In one study, adults with asthma taking steroids were compared with patients taking beta$_2$-adrenoceptor agonists (6). The patients who were using beta$_2$-adrenoceptor agonists had significantly lower serum IgG concentrations, irrespective of any history of steroid use. However, in patients using both treatments this depressive effect was even more pronounced; its mechanism is unclear.

Beta$_2$-adrenoceptor agonists and the response to allergens

Following inhalation of an allergen by a sensitized asthmatic, an immediate or type I response is seen. This occurs rapidly and is characterized by dyspnea, wheeze, and a fall in the FEV_1 or peak expiratory flow. The response can be prevented or reversed by inhalation of a beta$_2$-agonist. Several hours later, however, a proportion of asthmatics develop a delayed or type III response. This response is prolonged and associated with inflammatory changes in the airways. For some time after it resolves there is an increase in non-specific reactivity of the airways. This can be quantified by measuring the PC_{20} of histamine or methacholine. This is the provocative concentration necessary to cause a 20% fall in the FEV_1 or peak expiratory flow. The delayed response is not prevented by prior inhalation of a beta$_2$-agonist. It can be prevented by prior treatment with cromoglicate or a corticosteroid.

Treatment with a beta$_2$-agonist aerosol, before allergen inhalation, allows inhalation of significantly greater amounts of allergen before the type I response occurs. In asthmatics who only have a type I response before treatment with a beta$_2$-agonist, a late response to the increased allergen dose results. In asthmatics who already have a type III response, this response is increased (7). Treatment with an oral beta$_2$-agonist for 2 weeks increases sensitivity to inhaled allergen. In addition, reversal of allergen-induced bronchoconstriction by an inhaled beta$_2$-agonist is significantly impaired (8). Treatment for 1 week with an inhaled beta$_2$-agonist increases the late (type III) asthmatic response to the same dose of inhaled allergen. The increase in airway reactivity to methacholine following the late response is also increased (9). Sufficient inhaled beta$_2$-agonist needs to be taken to produce this effect. The effect is seen with salbutamol 0.8 mg/day, but not with 0.2 or 0.4 mg/day (10). Pretreatment with an inhaled beta$_2$-agonist not only increases the response to allergen but also attenuates the protective effect of a beta$_2$-agonist against both allergen and methacholine, that is both specific and non-specific airway reactivity is increased (11).

Clearly, the combined use of a regular inhaled beta$_2$-agonist and allergen exposure can cause more airway inflammation than allergen exposure alone. It has been suggested that regular use of beta$_2$-agonists may induce dysfunction of beta-receptors on the mast cells making the mast cells more prone to release mediator (12). Regular treatment with beta$_2$-agonists alone will result in greater airway inflammation and persistent asthma. This emphasizes the importance of regular prophylactic medication with cromoglicate or inhaled corticosteroids.

Death

Increased mortality among asthmatic patients has been correlated with an increase in the use of beta-adrenoceptor agonist aerosols on two occasions, first in the UK in 1966, and then in New Zealand in the late 1970s and 1980s. On both occasions the rise in deaths correlated well with increasing use of beta-agonist aerosols. However, when the death rates subsequently fell, the use of beta-agonist aerosols did not fall to the same extent (SEDA-13, 427) (SEDA-21, 179), suggesting that the correlation may have been due to the way the aerosols were used rather than with the fact of their use.

The sharp rise in asthma mortality in 1977 in New Zealand provoked debate about the safety of beta$_2$-adrenoceptor agonists, especially the short-acting compound fenoterol. This led to the withdrawal of fenoterol in New Zealand and amendment of the American Asthma Guidelines, suggesting caution in the regular use of beta$_2$-agonists (13). Although there is evidence linking fenoterol to increased morbidity and mortality in asthma (14), the underlying mechanisms were not known. It was suggested that the increase in mortality might be linked to fatal cardiac dysrhythmias, developing under conditions of asthma-induced hypoxia and high doses of beta$_2$-adrenoceptor agonists (15).

One likely explanation for the events of 1966 and later can be found in the fact, discussed below, that with progressive use of beta-agonists the response tends to fall, as a result of which the patient takes increasing doses, without relief. An association between increasing use of beta-agonist aerosols and asthma deaths is therefore to be expected, unless this accumulation of dosage can be avoided by proper guidance. There is still a possibility that the association between the use of these products and fatal reactions could have been due to an as yet unrecognized adverse effect of

© 2006 Elsevier B.V. All rights reserved.

beta-agonist aerosols that becomes prevalent only under particular conditions.

Identification of susceptible patients

An alternative explanation for the epidemic of asthma fatalities among users of beta-adrenoceptor agonist aerosols postulates the existence of a subset of asthmatic patients who are more sensitive than others to an adverse effect of beta-agonists. In this view the occurrence of a peak incidence of deaths will eliminate this subset and the overall death rate will thus fall once more without a proportionate reduction in the use of beta-agonists. A subset of asthmatic patients who develop a significant reduction in bronchodilator response to salbutamol after a short period of treatment has indeed been identified, although the number of patients studied was small. The subset developed a significant reduction in the B_{max} for beta$_2$-adrenoceptors in the lung. This was measured in vivo by PET scanning using a beta-antagonist ligand. Patients in the subset were homozygous for glycine at codon 16 on the beta$_2$-adrenoceptor gene (SEDA-21, 180).

However, another and larger study failed to identify any polymorphism or haplotype of the gene associated with fatal/near fatal asthma, and the authors concluded that the beta$_2$-adrenoceptor genotype was not a major factor in fatal or near fatal asthma (16). A third study similarly found no relation between genotype (coding for amino acids 16 and 27) and change in overall asthma control (17).

On the other hand, other workers have found that homozygotes for arginine 16 were 5.3 times (CI = 1.6, 17.7) more likely than homozygotes for glycine 16 to have a positive response to salbutamol, while heterozygotes for codon 16 on the beta$_2$-adrenoceptor gene were 2.3 times (CI = 1.3, 4.2) more likely to have a positive response to salbutamol than homozygotes for glycine 16 (18).

Finally, in a subset of patients with homozygous glycine on codon 16 of the beta$_2$-adrenoceptor gene, lymphocyte beta$_2$-adrenoceptor density was reduced after treatment for 1 week with a long-acting beta$_2$-agonist. There was also a reduction in maximal response to salbutamol (19).

The upshot of all this is that patients who are homozygous for glycine at codon 16 of the beta$_2$-adrenoceptor gene have a reduced bronchodilator response to salbutamol and this response is further reduced by repeated administration, which also causes a reduction in beta$_2$-adrenoceptor number. So far no genotype has been associated with overall asthma control or the frequency of fatal or near fatal attacks of asthma. Further documentation of the effect of the beta$_2$-adrenoceptor genotype on the response to beta$_2$-agonists may lead to the use of alternative bronchodilators in patients who are homozygous for glycine at codon 16.

Long-Term Effects

Drug tolerance

Reduced responsiveness to beta$_2$-adrenoceptor agonists

The bronchodilator effects of short-acting beta$_2$-agonists are not significantly reduced on chronic administration. However the bronchoprotective effect of beta$_2$-agonists, as measured by prevention of the response to spasmogens and exercise, becomes significantly reduced. This has been documented by measuring the PC_{20}, the concentration of methacholine or other spasmogen that provokes a 20% fall in lung function. Bronchoprotection results in a rise in PC_{20} and as bronchoprotection is lost, the PC_{20} falls.

Inhalation of salbutamol four times a day for 1 week did not affect the bronchodilator response to salbutamol, but there was a significant reduction in PC_{20} to methacholine (10).

Co-administration of a corticosteroid may mitigate the loss of bronchoprotective effect. The methacholine PC_{20} for salbutamol was significantly greater after 3 weeks treatment with the inhaled corticosteroid budesonide. However, addition of the long-acting beta$_2$-agonist salmeterol 0.05 mg bd significantly reduced the bronchoprotective effect of salbutamol, despite concurrent treatment with inhaled glucocorticoids (20). The bronchoprotective effect of salmeterol itself fell after only two doses (21). On the other hand, despite the administration of inhaled corticosteroids, the bronchodilator effect of another long-acting beta$_2$-agonist, formoterol, was reduced after treatment for 3 weeks. Administration of prednisolone 50 mg and hydrocortisone 100 mg rapidly reversed the reduction in response (22).

However, it is difficult to extrapolate PC_{20} changes after treatment with beta$_2$-agonists to the clinical outcome. There is an assumption that if PC_{20} falls, the patient is more likely to suffer acute attacks when exposed to spasmogens, allergens, and exercise. However, the loss of bronchoprotective effect has not so far been shown to increase morbidity or mortality in asthmatic patients.

Regular salbutamol has been compared with salbutamol, taken as needed, in mild asthmatics. There was no change in asthma control nor any increase in the frequency or severity of exacerbation (23). As the bronchodilator response is maintained, patients can be advised to use short-acting beta$_2$-agonists to relieve acute bronchoconstriction and if necessary to increase the dose.

The significance of stereoisomers of beta$_2$-adrenoceptor agonists

An alternative hypothesis has been proposed to explain why beta$_2$-agonists lose their bronchoprotective effect while retaining a bronchodilator effect. The beta$_2$-agonists currently available for treating asthma consist of racemic mixtures of equal amounts of two stereoisomers, the *R*-isomer (or L-isomer), which is the beta-adrenoceptor agonist, and the *S*-isomer (D-isomer) which is inactive.

In guinea-pig airways, the constrictor response to platelet activating factor (PAF), histamine, and prostaglandin $F_{2\alpha}$ are all prevented by infusion of racemic isoprenaline. After the isoprenaline is stopped, the constrictor response is markedly potentiated. Infusion of the *S*-isomer alone does not prevent the constrictor responses in contrast to the infusion of racemic isoprenaline. After infusion of the *S*-isomer is stopped there is an increase in the response to the constrictor agents, equivalent to that seen after racemic isoprenaline. This can be compared to asthma, in which prolonged exposure to racemates of beta$_2$-agonists produces a loss of the bronchoprotective effect while maintaining the immediate bronchodilator effect (24).

© 2006 Elsevier B.V. All rights reserved.

Regular exposure to a racemate, especially during or after an allergic reaction, will cause hyper-reactivity to spasmogens, and this could be due to an effect of the *S*-isomer. This effect is not seen immediately, because of beta$_2$-adrenoceptor-mediated bronchodilatation by the *R*-isomer.

Most of the clinical work on this phenomenon has been undertaken with salbutamol. In one major investigation, after administration of racemic salbutamol to healthy volunteers, both the peak plasma concentration of *R*-salbutamol and the systemic availability (measured by the AUC) were higher than when *R*-salbutamol was given in an equivalent dose as the *R*-isomer alone. It was concluded that *R*-salbutamol was more efficiently metabolized in the absence of *S*-salbutamol. *S*-salbutamol is a competitive inhibitor at the active site of the phenol-sulfotransferase enzyme, and its absence allows more *R*-salbutamol to be metabolized, resulting in lower systemic availability of *R*-salbutamol when the *R*-isomer alone is administered. Although the plasma concentrations of *R*-salbutamol were lower, the rise in plasma glucose and fall in plasma potassium were greater when the pure *R*-isomer was given alone. There was also a greater increase in heart rate and finger tremor. The greater potency of *R*-salbutamol given alone suggests inhibition of the effects of the *R*-isomer by the *S*-isomer (25).

In another investigation, a single dose of 1.25 mg nebulized *R*-salbutamol, administered to asthmatics, produced equivalent bronchoprotection, bronchodilatation, tachycardia, and restlessness to that given by 2.5 mg of racemic salbutamol (26). In a further study, asthmatic patients were treated for 28 days with racemic or *R*-salbutamol administered by nebulizer three times a day. Improvement in FEV_1 was similar after *R*-salbutamol 0.63 mg and racemic salbutamol 2.5 mg and greatest with *R*-salbutamol 1.25 mg. Racemic salbutamol 1.25 mg had the least bronchodilator effect, especially after chronic dosing (27).

It is not known if this phenomenon is specific to salbutamol or is shared by other racemic beta$_2$-agonists.

Second-Generation Effects

Pregnancy

Use of beta$_2$-adrenoceptor agonists in threatened premature labor

The adverse effects of the beta$_2$-adrenoceptor agonists when given (as a rule by injection) to arrest premature uterine contractions are very similar to those experienced when the classic drug in the series (salbutamol) is used for other purposes. In the special circumstances of obstetrics, however, there are several particular safety problems.

Choice of drugs

Probably most or all beta$_2$-agonists could be used in obstetrics as well as in asthma, and some are used for both purposes; however, manufacturers have tended to develop their individual compounds for one purpose or the other. Surprisingly, one large survey suggested that when used in pregnancy, salbutamol may be less well tolerated by the mother (stimulation, cardiovascular effects) than the much less selective isoxsuprine (SED-12, 321).

In one large survey, salbutamol was less well tolerated by the mother (stimulation, cardiovascular effects) than the much less selective isoxsuprine (SED-12, 321).

Cardiovascular

None of the beta$_2$-adrenoceptor agonists used to delay delivery can be given in effective doses either orally or by injection without affecting the maternal heart rate (and to a lesser extent the fetal heart rate) in a high proportion of cases. It is not possible to say whether this effect is more likely to occur with certain drugs of this type than with others (particularly because the obstetric situation itself affects the fetal heart rate) (SEDA-17, 145), but in effective doses a maternal heart rate increase of some 30 beats/minute or more is common, with a fetal heart rate increase of up to 20 beats/minute. A substantial proportion of mothers (with intravenous use up to 30%) experience such symptoms as headache, tremulousness, tightness of the chest, palpitation, and flushing. There is clear and direct evidence that tocolytics also exert toxic effects on the myocardial tissue of the infant, especially if given for long periods (28,29). The calcium channel blocker verapamil does not protect either the maternal heart or the fetal heart against the toxic effects of tocolysis (SEDA-9, 126). Pulmonary edema is a rare but potentially life-threatening complication of beta$_2$-agonists (SEDA-10, 115) (30).

Metabolism

In obstetrics the classic effects of beta$_2$-adrenoceptor agonists on glucose metabolism can be absent or harmless in those without diabetes, but dangerous in those with diabetes, in whom they can cause metabolic acidosis (5). The hyperglycemic effect can be aggravated if glucocorticoids are also given (as they may be to prevent hyaline membrane disease in prematurity).

Susceptibility Factors

Age

The use of long-acting beta$_2$-adrenoceptor agonists in the management of asthma in children has been comprehensively reviewed (31). In children, as in adults, regular long-acting beta$_2$-adrenoceptor agonists can produce bronchodilator subsensitivity to short-acting beta-agonists and tolerance to the bronchoprotective effects of long-acting beta-agonists against challenges with exercise and methacholine. The clinical significance of these findings is unclear.

Beta-adrenoceptor antagonists

See also Individual agents

General Information

Many beta-adrenoceptor antagonists (beta-blockers) have been developed, and their adverse effects have been comprehensively reviewed (1). The spectrum of adverse effects is broadly similar for all beta-blockers, despite differences in their pharmacological properties, notably cardioselectivity, partial agonist activity, membrane-stabilizing activity, and lipid solubility (see Table 1). The influence of these properties is mentioned in the general discussion when appropriate and is summarized at the end of the section. Individual differences in toxicity are largely unimportant but will be mentioned briefly.

Although beta-blockers have been available for many years, new members of this class with novel pharmacological profiles continue to be developed. These new drugs are claimed to have either greater cardioselectivity or vasodilatory and $beta_2$-agonist properties. The claimed

[a] Octanol:water partition coefficient
[b] Partial beta$_2$-adrenoceptor agonist

© 2006 Elsevier B.V. All rights reserved.

advantages of these new drugs serve to highlight the supposed disadvantages of the older members of the class (their adverse constrictor effects on the airways and peripheral blood vessels). Strong commercial emphasis is being placed on these new properties, and papers extolling these effects often appear in non-peer-reviewed supplements or even in reputable journals (2).

Although the toxicity of the beta-adrenoceptor antagonists has been fairly well documented, there has been a subtle change in perceptions of their potential benefits and drawbacks. The cardioprotective effect of beta-blockers after myocardial infarction and their efficacy in reducing "silent" myocardial ischemia have persuaded some clinicians to use them preferentially. On the other hand, they can significantly impair the quality of life (3) and are contraindicated in some patients. A few patients cannot tolerate beta-blockade at all. These include patients with bronchial asthma, patients with second- or third-degree heart block, and those with seriously compromised limb perfusion causing claudication, ischemic rest pain, and pregangrene.

General adverse effects

The adverse effects of beta-blockers are usually mild, with occurrence rates of 10–20% for the most common in most studies. Most are predictable from the pharmacological and physicochemical properties of these drugs. Examples include fatigue, cold peripheries, bradycardia, heart failure, sleep disturbances, bronchospasm, and altered glucose tolerance. Gastrointestinal upsets are also relatively common. Serious adverse cardiac effects and even sudden death can follow abrupt withdrawal of therapy in patients with ischemic heart disease. Most severe adverse reactions can be avoided by careful selection of patients and consideration of individual beta-blockers. Hypersensitivity reactions have been relatively rare since the withdrawal of practolol. Tumor-inducing effects have not been established in man.

Fatigue

Fatigue is one of the most commonly reported adverse effects of beta-adrenoceptor antagonists, with reported occurrence rates of up to 20% or more, particularly in those who exert themselves. It has to be viewed alongside the ability to produce fatigue and lethargy by a possible effect on the nervous system. The precise cause of physical fatigue is not known, but hypotheses include impaired muscle blood supply, effects on intermediary metabolism, and a direct effect on muscle contractility (4).

Theoretically, $beta_1$-selective drugs are less likely to alter these variables, and might therefore have an advantage over non-selective drugs. However, this has not always been shown in single-dose studies in volunteers (5,6), although in two such studies atenolol produced less exercise intolerance than propranolol at comparable dosages (7,8). For an unexplained reason, cardioselectivity impaired performance relatively less in subjects with a high proportion of slow-twitch muscle fibers than it did in those whose muscle biopsy specimens showed a high percentage of fast-twitch fibers (9). The muscle fibers of long-distance runners are predominantly of the slow-twitch type, and this probably explains the superiority of atenolol over propranolol when exercise performance was assessed in such subjects (7). The release of lactic acid from skeletal muscle cells is impaired to a greater extent by non-selective beta-blockers than by cardioselective drugs, and cardioselectivity was associated with a less marked fall in blood glucose during and after maximal and submaximal exercise (10,11). Partial agonist activity might have been the reason for the superiority of oxprenolol over propranolol in terms of exercise duration (12).

Differences among beta-blockers

Although there are now many different beta-adrenoceptor antagonists, and the number is still increasing, there are only a few important characteristics that distinguish them in terms of their physicochemical and pharmacological properties: lipid solubility, cardioselectivity, partial agonist activity, and membrane-stabilizing activity. The characteristics of the currently available compounds are shown in Table 1.

Lipid solubility

Lipid solubility (13) determines the extent to which a drug partitions between an organic solvent and water. Propranolol, oxprenolol, metoprolol, and timolol are the most lipid-soluble beta-adrenoceptor antagonists, and atenolol, nadolol, and sotalol are the most water-soluble; acebutolol and pindolol are intermediate (14).

The more lipophilic drugs are extensively metabolized in the gut wall and liver (first-pass metabolism). This first-pass clearance is variable and can result in 20-fold differences in plasma drug concentrations between patients who have taken the same dose. It also produces susceptibility to drug interactions with agents that alter hepatic drug metabolism, for example cimetidine, and can result in altered kinetics and hence drug response in patients with hepatic disease, particularly cirrhosis. Lipid-soluble drugs pass the blood–brain barrier more readily (15) and should be more likely to cause adverse nervous system effects, such as disturbance of sleep, but the evidence for this is not very convincing.

In contrast, water-soluble drugs are cleared more slowly from the body by the kidneys. These drugs therefore tend to accumulate in patients with renal disease, do not interact with drugs that affect hepatic metabolism, and gain access to the brain less readily.

Cardioselectivity

Cardioselectivity (16), or more properly $beta_1$-adrenoceptor selectivity, is the term used to indicate that there are at least two types of beta-adrenoceptors, and that while some drugs are non-selective (that is they are competitive antagonists at both $beta_1$- and $beta_2$-adrenoceptors), others appear to be more selective antagonists at $beta_1$-adrenoceptors, which are predominantly found in the heart. Bronchial tissue, peripheral blood vessels, the uterus, and pancreatic beta-cells contain principally $beta_2$-adrenoceptors. Thus, cardioselective beta-adrenoceptor antagonists, such as atenolol and metoprolol, might offer theoretical benefits to patients with bronchial asthma, peripheral vascular disease, and diabetes mellitus.

Cardioselective drugs may have relatively less effect on the airways, but they are in no way cardiospecific and they should be used with great care in patients with evidence of reversible obstructive airways disease.

The benefits of cardioselective drugs in patients with Raynaud's phenomenon or intermittent claudication have

© 2006 Elsevier B.V. All rights reserved.

been difficult to prove. Because of vascular sparing, cardioselective agents may also be preferable in stress, when adrenaline is released.

Cardioselective drugs are less likely to produce adverse effects in patients with type I diabetes than non-selective drugs. At present, hypoglycemia in patients with type I diabetes mellitus is the only clinical problem in which cardioselectivity is considered important. Even there, any potential advantages of cardioselective drugs in minimizing adverse effects apply only at low dosages, since cardioselectivity is dose-dependent.

Partial agonist activity

Partial agonist activity (17,18) is the property whereby a molecule occupying the beta-adrenoceptor exercises agonist effects of its own at the same time as it competitively inhibits the effects of other extrinsic agonists. The effects of these drugs depend on the degree on endogenous tone of the sympathetic nervous system. When there is high endogenous sympathetic tone they tend to act as beta-blockers; when endogenous sympathetic tone is low they tend to act as beta-agonists. Thus, xamoterol had a beneficial effect in patients with mild heart failure (NYHA classes I and II), through a positive inotropic effect on the heart; however, in severe heart failure (NYHA classes III and IV), in which sympathetic tone is high, it acted as a beta-blocker and worsened the heart failure, through a negative inotropic effect (19).

Partial agonists, such as acebutolol, oxprenolol, pindolol, practolol, and xamoterol, produce less resting bradycardia. It has also been claimed that such agents cause a smaller increase in airways resistance in asthmatics, less reduction in cardiac output (and consequently a lower risk of congestive heart failure), and fewer adverse effects in patients with cold hands, Raynaud's phenomenon, or intermittent claudication. However, none of these advantages has been convincingly demonstrated in practice, and patients with bronchial asthma or incipient heart failure must be considered at risk with this type of compound.

Drugs with partial agonist activity can produce tremor (20).

Drugs that combine $beta_1$-antagonism or partial agonism with $beta_2$-agonism (celiprolol, dilevalol, labetalol, pindolol) or with alpha-antagonism (carvedilol, labetalol) have been developed (21). Both classes have significant peripheral vasodilating effects. Drugs with significant agonist activity at $beta_1$-adrenoceptors have poor antihypertensive properties (22).

Membrane-stabilizing activity

Drugs with membrane-stabilizing activity reduce the rate of rise of the cardiac action potential and have other electrophysiological effects. Membrane-stabilizing activity has only been shown in human cardiac muscle in vitro in concentrations 100 times greater than those produced by therapeutic doses (23). It is therefore likely to be of clinical relevance only if large overdoses are taken.

Use in heart failure

Traditionally, beta-blockers have been contraindicated in patients with heart failure. However, there are some patients with systolic heart failure who benefit from a beta-blocker (24). Early evidence was strongest for idiopathic dilated cardiomyopathy rather than ischemic heart disease (25). However, several randomized controlled trials of beta-blockers in patients with mild to moderate heart failure have been published. These include the CIBIS II trial with bisoprolol (26), the MERIT-HF trial with metoprolol (27), and the PRECISE trial with carvedilol (28). These have shown that cardiac mortality in these patients can be reduced by one-third, despite concurrent treatment with conventional therapies of proven benefit (that is ACE inhibitors).

Diastolic dysfunction can lead to congestive heart failure, even when systolic function is normal (29,30). Since ventricular filling occurs during diastole, failure of intraventricular pressure to fall appropriately during diastole leads to increased atrial pressure, which eventually leads to increased pulmonary and systemic venous pressures, causing a syndrome of congestive heart failure indistinguishable clinically from that caused by systolic pump failure (31). Diastolic dysfunction occurs in systemic arterial hypertension, hypertrophic obstructive cardiomyopathy, and infiltrative heart diseases, which reduce ventricular compliance or increase ventricular stiffness (32). As energy is required for active diastolic myocardial relaxation, a relative shortage of adenosine triphosphate in ischemic heart disease also often leads to co-existing diastolic and systolic dysfunction (33). Beta-blockers improve diastolic function in general, and this may be beneficial in patients with congestive heart failure associated with poor diastolic but normal systolic function.

Beta-blockade reduces mortality in patients with heart failure by at least a third when initiated carefully, with gradual dose titration, in those with stable heart failure (34,35). Similarly, beta-blocker prescribing should be encouraged in people with diabetes, since they have a worse outcome after cardiac events and beta-blockade has an independent secondary protective effect (36,37). The small risk of masking metabolic and autonomic responses to hypoglycemia, which was only a problem with non-selective agents in type I diabetes, is a very small price worth paying in diabetics with coronary heart disease.

Use in glaucoma

It has been more than a quarter of a century since the discovery that oral propranolol reduces intraocular pressure in patients with glaucoma. However, the use of propranolol for glaucoma was limited by its local anesthetic action (membrane-stabilizing activity).

Topical timolol was released for general use in 1978. That timolol is systemically absorbed was suggested by early reports of reduced intraocular pressure in the untreated eyes of patients using monocular treatment. About 80–90% of a topically administered drop drains through the nasolacrimal duct and enters the systemic circulation through the highly vascular nasal mucosa, without the benefit of first-pass metabolism in the liver; only a small fraction is swallowed. Thus, topical ophthalmic dosing is probably more akin to intravenous delivery than to oral dosing, and systemic adverse reactions are potentially serious. However, although patients may give their physicians a detailed list of current medications, they

© 2006 Elsevier B.V. All rights reserved.

often fail to mention the use of eye-drops, about which physicians are often either unaware or do not have time to ask specific questions.

Betaxolol is a $beta_1$-selective adrenoceptor antagonist without significant membrane-stabilizing activity or intrinsic sympathomimetic activity. It may be no more effective than other drugs in reducing intraocular pressure, but it may be safer for some patients, particularly those with bronchospastic disease (but see the section on Respiratory under Drug administration route) (38).

Partial agonist activity of beta-blockers may help to prevent ocular nerve damage and subsequent visual field loss associated with glaucoma. Such damage may be related to a reduction in ocular perfusion, as might occur if an ocular beta-blocker caused local vasoconstriction. An agent with intrinsic sympathomimetic activity might preserve ocular perfusion through local vasodilatation or by minimizing local vasoconstriction. The data are sparse and inconclusive, but carteolol appears to have no effect on retinal blood flow or may even increase it, making it potentially suitable as a neuroprotective drug (38,39).

Organs and Systems

Cardiovascular

A randomized comparison of oral atenolol and bisoprolol in 334 patients with acute myocardial infarction was associated with drug withdrawal in 70 patients (21%) because of significant bradydysrhythmias, hypotension, heart failure, and abnormal atrioventricular conduction (40). Logistic regression analysis suggested that critical events were more likely to occur in patients who were pretreated with dihydropyridine calcium antagonists.

Heart failure

Beta-adrenoceptor antagonists reduce cardiac output through their negative inotropic and negative chronotropic effects. They can therefore cause worsening systolic heart failure or new heart failure in patients who depend on high sympathetic drive to maintain cardiac output. Plasma noradrenaline is increased in patients with heart failure, and the extent of this increase is directly related to the degree of ventricular impairment (41). Since the greatest effect on sympathetic activity occurs with the first (and usually the lowest) doses, heart failure associated with beta-blockade seems to be independent of dosage. Heart failure is one of the most serious adverse effects of the beta-adrenoceptor antagonists (42), but it is usually predictable and can be attenuated by pretreatment with diuretics and angiotensin-converting enzyme inhibitors in patients who are considered to be at risk.

It has been suggested that drugs with partial agonist activity (see Table 1), which have a minimal depressant effect on normal resting sympathetic tone, might cause less reduction in cardiac output (43) and thus protect against the development of cardiac decompensation (44). However, this has not been satisfactorily shown for drugs with high partial agonist activity, for example acebutolol, oxprenolol, and pindolol (45), and these drugs should therefore be given with the same caution as others in compromised patients. Xamoterol, a beta-antagonist with substantial $beta_1$ partial agonist activity, was hoped to be of benefit in mild congestive heart failure (46), but its widespread use by non-specialists in more severe degrees of heart failure resulted in many reports of worsening heart failure (47). Heart failure has also been produced by labetalol (48) and after the use of timolol eye-drops in the treatment of glaucoma (49).

Hypotension

Beta-adrenoceptor antagonists lower blood pressure, probably by a variety of mechanisms, including reduced cardiac output. More severe reductions in blood pressure can occur and can be associated with syncope (42). It has been suggested that this is more likely to occur in old people, but comprehensive studies have stressed the safety of beta-blockers in this age group (50).

- Profound hypotension, resulting in renal insufficiency, has been reported in a single patient after the administration of atenolol 100 mg orally (51); however, large doses of furosemide and diazoxide were also given in this case, and this appears more likely to have been a consequence of a drug interaction.

Cardiac dysrhythmias and heart block

Beta-blockade can result in sinus bradycardia, because blockade of sympathetic tone allows unopposed parasympathetic activity. Drugs with partial agonist activity may prevent bradycardia (52). However, heart rates under 60/minute often worry the physician more than the patient: in a retrospective study of nearly 7000 patients taking beta-adrenoceptor antagonists, apart from dizziness in patients with heart rates under 40/minute (0.4% of the total group), slow heart rates were well tolerated (53).

All beta-blockers cause an increase in atrioventricular conduction time; this is most pronounced with drugs that have potent membrane-depressant properties and no partial agonist activity. Sotalol differs from other beta-blockers in that it increases the duration of the action potential in the cardiac Purkinje fibers and ventricular muscle at therapeutic doses. This is a class III antidysrhythmic effect, and because of this, sotalol has been used to treat ventricular (54–56) and supraventricular dysrhythmias (57). The main serious adverse effect of sotalol is that it is prodysrhythmic in certain circumstances, and can cause torsade de pointes (58,59).

Acute chest pain

Worsening of angina pectoris has been attributed to beta-blocker therapy. The reports include 35 cases in a series of 296 elderly patients admitted to hospital with suspected myocardial infarction; in these 35 the pain disappeared within 7 hours of withdrawing beta-blocker therapy (60).

Worsening of angina has been reported at very low heart rates (61). Propranolol resulted in vasotonic angina in six patients during a double-blind trial, with prolongation of the duration of pain and electrocardiographically assessed ischemia. It has been suggested that this reflects a reduction in coronary perfusion as a result of reduced cardiac output, and also coronary arterial spasm provoked by non-selective agents by inhibition of $beta_2$-mediated vasodilatation

© 2006 Elsevier B.V. All rights reserved.

(62). The latter explanation is controversial, and the use of beta-blockers in patients with arteriographic evidence of coronary artery spasm has not consistently caused worsening of the disorder (63).

Unstable angina has also followed treatment for hypertension with cardioselective drugs such as betaxolol (64).

Peripheral vascular effects

Cold extremities or exacerbation of Raynaud's phenomenon are amongst the commonest adverse effects reported with beta-blockers (5.8% of nearly 800 patients taking propranolol) (42); Raynaud's phenomenon occurs in 0.5–6% of patients (65). The mechanism may be potentiation of the effects of a cold environment on an already abnormal circulation, but whether symptoms can be produced de novo is more difficult to determine. However, a retrospective questionnaire study in 758 patients taking antihypertensive drugs showed that 40% of patients taking beta-blockers noted cold extremities, compared with 18% of those taking diuretics; there were no significant differences among patients taking alprenolol, atenolol, metoprolol, pindolol, and propranolol (66). Similarly, a large randomized study showed that the incidence of Raynaud's phenomenon was the same for atenolol and pindolol (67). In another study, vasospastic symptoms improved when labetalol was substituted for a variety of beta-blockers (68). On the other hand, a small, double-blind, placebo-controlled study in patients with established Raynaud's phenomenon showed that the prevalence of symptoms with both propranolol and labetalol was no greater than that with placebo (69).

Intermittent claudication has also been reported to be worsened by beta-adrenoceptor antagonists, but has been difficult to document because of the difficulty of study design in patients with advanced atherosclerosis. As early as 1975 it was reported from one small placebo-controlled study that propranolol did not exacerbate symptoms in patients with intermittent claudication (70). This has subsequently been supported by the results of several large placebo-controlled trials of beta-blockers in mild hypertension and reports of trials of the secondary prevention of myocardial infarction, in which intermittent claudication was not mentioned as an adverse effect, even though it was not a specific contraindication to inclusion (71). In addition, a comprehensive study of the effects of beta-adrenoceptor antagonists in patients with intermittent claudication did not show beta-blockade to be an independent risk factor for the disease (72). In men with chronic stable intermittent claudication, atenolol (50 mg bd) had no effect on walking distance or foot temperature (73). These findings have been confirmed in a recent meta-analysis of 11 randomized, controlled trials to determine whether beta-blockers exacerbate intermittent claudication (SEDA-17, 234).

Patchy skin necrosis has been described in hypertensive patients with small-vessel disease in the legs who were taking beta-blockers. Characteristically, pedal pulses remained palpable and the lesions occurred during cold weather and healed on withdrawal of the drugs (74–76). Three cases have been reported in which long-lasting incipient gangrene of the leg was immediately overcome when a beta-blocker was withdrawn (77,78), showing how easily these drugs are overlooked in such circumstances. In several cases of beta-blocker-induced gangrene, recovery did not follow withdrawal of therapy, and amputation was necessary (79,80). Thus, when possible, other forms of therapy should be used in patients with critical ischemia or rest pain.

It has also been suggested that beta-blockade may compromise the splanchnic vasculature. Intravenous propranolol reduces splanchnic blood flow experimentally by 29% while reducing cardiac output by only 6% (81).

Five patients developed mesenteric ischemia, four with ischemic colitis, and one with abdominal angina, while taking beta-adrenoceptor antagonists (82). Although causation was not proven, it was possible.

Respiratory

The respiratory and cardiovascular adverse effects of topical therapy with timolol or betaxolol have been studied in a randomized, controlled trial in 40 elderly patients with glaucoma (83). Five of the 20 allocated to timolol discontinued treatment for respiratory reasons, compared with three of the 20 patients allocated to betaxolol. There were no significant differences in mean values of spirometry, pulse, or blood pressure between the groups. This study confirms that beta-blockers administered as eye-drops can reach the systemic circulation and that serious adverse respiratory events can occur in elderly people, even if they are screened before treatment for cardiac and respiratory disease. These events can occur using either the selective betaxolol agent or the non-selective timolol.

Airways obstruction

Since the introduction of propranolol, it has been recognized that patients with bronchial asthma treated with beta-adrenoceptor antagonists can develop severe airways obstruction (84), which can be fatal (85) or near fatal (86,87); this has even followed the use of eye-drops containing timolol (88). Beta-blockers upset the balance of bronchial smooth muscle tone by blocking the bronchial $beta_2$-adrenoceptors responsible for bronchodilatation. They also promote degranulation of mast cells and depress central responsiveness to carbon dioxide (89,90).

Although $beta_1$-selective drugs are theoretically safer, there are reports of serious reductions in ventilatory function (91,92), even when used as eye-drops (93). However, it has been concluded that if beta-blockade is necessary in the treatment of glaucoma, cardioselective beta-blocking drugs should be preferred (94). While cardioselectivity is dose-dependent (95), and higher dosages might therefore be expected to produce adverse effects, metoprolol and bevantolol, even in dosages that are lower than those usually required for a therapeutic effect, may be poorly tolerated by patients with asthma (96).

Whether drugs with partial agonist activity confer any advantage is uncertain. Some of the evidence that patients with asthma tolerate beta-blockers is probably misleading, relating to patients with chronic obstructive airways disease who have irreversible changes and who do not respond to either bronchoconstricting or bronchodilating drugs (97). In contrast, a few patients who have never had asthma or chronic bronchitis develop severe

© 2006 Elsevier B.V. All rights reserved.

bronchospasm when given a beta-blocker. Some, but not all, of these cases (98) may have been allergic reactions to the dyestuffs (for example tartrazine) that are used to color some formulations. Other patients, who need not have a history of chest disease, only develop increased airways resistance with beta-blockers during respiratory infections.

It is against this background that claims that some asthmatic subjects will tolerate certain beta-blockers (99) must be viewed. Some asthmatic patients may indeed tolerate either cardioselective beta-blockers (such as atenolol and metoprolol) or labetalol (100,101), and in patients taking atenolol $beta_2$-adrenoceptor agonists may continue to produce bronchodilatation (102), but in most instances other therapeutic options are preferable (103). Celiprolol is a $beta_1$-adrenoceptor antagonist that has partial $beta_2$-agonist activity. Small studies have suggested that it may be useful in patients with asthma (104), but worsening airways obstruction has been reported (105); it has been concluded that celiprolol has no advantage over existing beta-blockers in the treatment of hypertension (106).

Bronchospasm, which can be life-threatening, can be precipitated by beta-blocker eye-drops. Even $beta_1$-selective antagonists, such as betaxolol, can cause a substantial reduction in forced expiratory volume. Wheezing and dyspnea have been reported among patients using betaxolol: the symptoms resolved after withdrawal. A cross-sectional study has shown that ophthalmologists were more aware than chest physicians about the use of beta-blocker eye-drops by patients with obstructive airways disease; patient awareness was also poor (38,107).

Attention has also been drawn to the increased risks of the adverse effects of beta-blockers on respiratory function in old people (108).

Central ventilatory suppression

Reduced sensitivity of the respiratory center to carbon dioxide has been reported (89,109). The clinical significance of this is unknown, but lethal synergism between morphine and propranolol in suppressing ventilation in animals has been described (110).

Pneumonitis, pulmonary fibrosis, and pleurisy

Pulmonary fibrosis (111) and pleural fibrosis (112) have both been described as infrequent complications associated with practolol. Pulmonary fibrosis has also occurred during treatment with pindolol (113) and acebutolol (114,115). Pleuritic and pneumonitic reactions to acebutolol have been reported (116).

Ear, nose, throat

Nasal polyps, rhinitis, and sinusitis resistant to long courses of antibiotics and surgical intervention have been described in five patients taking non-selective beta-adrenoceptor antagonists (propranolol and timolol) (117). The symptoms resolved when the drugs were withdrawn and did not recur when $beta_1$-selective adrenoceptor blockers (metoprolol or atenolol) were given instead.

Nervous system

Some minor neuropsychiatric adverse effects, such as light-headedness, visual and auditory hallucinations, illusions, sleep disturbances, vivid dreams, and changes in mood and affect, have been causally related to long-term treatment with beta-adrenoceptor antagonists (118,119). Other occasional nervous system effects of beta-blockers include hearing impairment (120), episodic diplopia (121), and myotonia (122).

Although some migraine sufferers use beta-adrenoceptor antagonists prophylactically, there are also reports of the development of migraine on exposure to propranolol or rebound aggravation when the drug is withdrawn (123). Stroke, a rare complication of migraine, has been reported in three patients using propranolol for prophylaxis (124–126). Seizures have been reported with the short-acting beta-blocker esmolol, usually with excessive doses (117). Myasthenia gravis has been associated with labetalol (127), oxprenolol, and propranolol (128), and carpal tunnel syndrome has been reported with long-term beta-blockade, the symptoms gradually disappearing on withdrawal of therapy (129).

Propranolol and gabapentin are both effective in essential tremor. However, pindolol, which has substantial partial agonist activity, can cause tremor (130), and gabapentin can occasionally cause reversible movement disorders. A patient who developed dystonic movements after the combined use of gabapentin and propranolol has been described (131).

- A 68-year-old man with a 10-year history of essential tremor was initially treated with propranolol (120 mg/day), which was only slightly effective. Propranolol was replaced by gabapentin (900 mg/day). The tremor did not improve and propranolol (80 mg/day) was added. Two days later he developed paroxysmal dystonic movements in both hands. Between episodes, neurological examination was normal. When propranolol was reduced to 40 mg/day the abnormal movements progressively disappeared.

This case suggests that there is a synergistic effect between propranolol and gabapentin.

In addition, tiredness, fatigue, and lethargy, probably the commonest troublesome adverse effects of beta-blockers and often the reason for withdrawal (132), may have a contributory nervous system component, although they are probably primarily due to reduced cardiac output and altered muscle metabolism (65) (see also the section on Fatigue in this monograph). In general, a definite neurological association has been difficult to prove, and studies of patients taking beta-adrenoceptor antagonists for hypertension, which incorporated control groups of patients taking either other antihypertensive drugs or a placebo, appear to have shown that the incidence of symptoms that can be specifically attributed to beta-adrenoceptor antagonists is lower than anticipated (133).

The more lipophilic drugs, such as propranolol and oxprenolol, would be expected to pass the blood–brain barrier more readily than hydrophilic drugs, such as atenolol and nadolol, and there is some evidence that they do so (15). In theory, therefore, hydrophilic drugs might be expected to produce fewer neuropsychiatric adverse

© 2006 Elsevier B.V. All rights reserved.

effects. A double-blind, placebo-controlled evaluation of the effects of four beta-blockers (atenolol, metoprolol, pindolol, and propranolol) on central nervous function (134) showed that disruption of sleep was similar with the three lipid-soluble drugs, averaging six to seven wakenings per night, compared with an average of three wakenings per night for atenolol and placebo. Only pindolol, which has a higher CSF/plasma concentration ratio than metoprolol and propranolol, significantly altered rapid eye movement sleep and latency (135). Patients who took pindolol and propranolol also had high depression scores.

In a placebo-controlled sleep laboratory study of atenolol, metoprolol, pindolol, and propranolol, the three lipophilic drugs reduced dreaming (equated with rapid eye movement sleep) but increased the recollection of dreaming and the amount of wakening; in contrast, although atenolol also reduced sleep, it had no effect on subjective measures of sleep (136).

The published data on the effects of beta-blockers on the nervous system have been extensively reviewed (137). The overall incidence of effects was low, and lowest with the hydrophilic drugs. However, a meta-analysis of 55 studies of the cognitive effects of beta-blockade did not show any firm evidence that lipophilic drugs caused more adverse effects than hydrophilic ones (138). Recent data confirming a correlation between lipophilicity and serum concentrations on the one hand and nervous system effects on the other (139) have fuelled this controversy.

Car-driving and other specialized skills

In view of the large numbers of people who take beta-adrenoceptor antagonists regularly for hypertension or ischemic heart disease, the question arises whether these drugs impair performance in tasks that require psychomotor coordination. The occupations under scrutiny include car-driving, the operation of industrial machinery, and the piloting of aeroplanes. The current evidence is conflicting and controversial. One report suggested that propranolol and pindolol given for 5 days impaired slalom driving in a manner comparable with the coordination defects caused by alcohol (140). In contrast, other studies have shown that driving skills were not impaired during long-term beta-blocker therapy and might even be improved (141,142). There is also a suggestion that tolerance to the central effects of these drugs can develop within 3 weeks of starting therapy, provided the dosage does not change (143). Until more information is available from well-controlled studies, it is advisable to inform patients who are starting treatment with beta-blockers that they should exercise special care in the performance of skills requiring psychomotor coordination for the first 1 or 2 weeks.

Sensory systems

Eyes

Keratopathy in association with the practolol syndrome is the major serious ocular effect ascribed to beta-adrenoceptor antagonists. Conjunctivitis and visual disturbances have also been reported, and a case of ocular pemphigoid has been described in a patient taking timolol eye-drops for glaucoma (144). Anterior uveitis has been reported in patients taking betaxolol (145) and metipranolol (146,147). Corneal anesthesia and epithelial sloughing with continuing use of topical beta-blockers have also been reported (148), as have ocular myasthenia and worsened sicca syndrome. Patients who lack CYP2D6 are more likely to have higher systemic concentrations of beta-blockers after topical application, making them susceptible to adverse effects.

- Recurrent retinal arteriolar spasm with associated visual loss has been described in a 68-year-old man with hypertension treated with atenolol (SEDA-17, 236).
- A 60-year-old man with open-angle glaucoma developed an allergic contact conjunctivitis and dermatitis from carteolol, a topical non-cardioselective beta-blocker (149). He had extensive cross-reactivity to other topical beta-blockers, such as timolol and levobunolol. Cross-reactivity among different beta-blockers is possibly due to a common lateral aliphatic chain.

Psychological, psychiatric

Disturbances of psychomotor function

Beta-adrenoceptor antagonists impair performance in psychomotor tests after single doses. These include effects of atenolol, oxprenolol, and propranolol on pursuit rotor and reaction times (150,151). However, other studies with the same drugs have failed to show significant effects (152–156), and the issue has remained controversial. A report that sotalol improved psychomotor performance in 12 healthy individuals in a dose of 320 mg/day but impaired performance at 960 mg/day (157) has been interpreted to indicate that the water-soluble beta-adrenoceptor antagonists would be less likely than the fat-soluble drugs to produce nervous system effects. Both atenolol and propranolol alter the electroencephalogram; atenolol affects body sway and alertness and propranolol impairs short-term memory and the ability to concentrate (158,159). These results suggest that both lipophilic and hydrophilic beta-adrenoceptor antagonists can affect the central nervous system, although the effects may be subtle and difficult to demonstrate.

In 27 hypertensive patients aged 65 years or more, randomized to continue atenolol treatment for 20 weeks or to discontinue atenolol and start cilazapril, there was a significant improvement in the choice reaction time in the patients randomized to cilazapril (160). This study has confirmed previous reports that chronic beta-blockade can determine adverse effects on cognition in elderly patients. Withdrawal of beta-blockers should be considered in any elderly patient who has signs of mental impairment.

In a placebo-controlled trial of propranolol in 312 patients with diastolic hypertension, 13 tests of cognitive function were assessed at baseline, 3 months, and 12 months (161). Propranolol had no significant effects on 11 of the 13 tests. Compared with placebo, patients taking propranolol had fewer correct responses at 3 months and made more errors of commission.

Psychoses

Bipolar affective disorder

Bipolar depression affects 1% of the general population, and treatment resistance is a significant problem. The addition of pindolol can lead to significant improvement in depressed patients who are resistant to antidepressant drugs, such as selective serotonin reuptake inhibitors or phenelzine. Of 17 patients with refractory bipolar depression, in whom pindolol was added to augment the effect of antidepressant drugs, eight responded favorably (162). However, two developed transient hypomania, and one of these became psychotic after the resolution of hypomanic symptoms. In both cases transient hypomanic symptoms resolved without any other intervention, while psychosis required pindolol withdrawal.

Anxiety and depression have been reported after the use of nadolol, which is hydrophilic (163). In a study of the co-prescribing of antidepressants in 3218 new users of beta-blockers (164), 6.4% had prescriptions for antidepressant drugs within 34 days, compared with 2.8% in a control population. Propranolol had the highest rate of co-prescribing (9.5%), followed by other lipophilic beta-blockers (3.9%) and hydrophilic beta-blockers (2.5%). In propranolol users, the risk of antidepressant use was 4.8 times greater than the control group, and was highest in those aged 20–39 (RR = 17; 95% CI = 14, 22).

Organic brain syndrome

The development of a severe organic brain syndrome has been reported in several patients taking beta-adrenoceptor antagonists regularly without a previous history of psychiatric illness (165–167). A similar phenomenon was seen in a young healthy woman who took propranolol 160 mg/day (168). The psychosis can follow initial therapy or dosage increases during long-term therapy (169). The symptoms, which include agitation, confusion, disorientation, anxiety, and hallucinations, may not respond to treatment with neuroleptic drugs, but subsides rapidly when the beta-blockers are withdrawn. Symptoms are also ameliorated by changing from propranolol to atenolol (170).

Schizophrenia

A schizophrenia-like illness has also been seen in close relation to the initiation of propranolol therapy (171).

Endocrine

Prolactin

- Reversible hyperprolactinemia with galactorrhea occurred in a 38-year-old woman taking atenolol for hypertension (172).

Thyroid

Propranolol inhibits the conversion of thyroxine (T4) to tri-iodothyronine (T3) by peripheral tissues (173), resulting in increased formation of inactive reverse T3. There have been several reports of hyperthyroxinemia in clinically euthyroid patients taking propranolol for non-thyroid reasons in high dosages (320–480 mg/day) (174,175). The incidence was considered to be higher than could be accounted for by the development of spontaneous hyperthyroidism, but the mechanism is unknown.

The effect of beta-adrenoceptor antagonists on thyroid hormone metabolism is unlikely to play a significant role in their use in hyperthyroidism. Since D-propranolol has similar effects on thyroxine metabolism to those seen with the racemic mixture, membrane-stabilizing activity may be involved (176).

In one case, beta-adrenoceptor blockade masked an unexpected thyroid crisis, resulting in severe cerebral dysfunction before the diagnosis was made (177).

Metabolism

Hypoglycemia

Hypoglycemia, producing loss of consciousness in some cases, can occur in non-diabetic individuals who are taking beta-adrenoceptor antagonists, particularly those who undergo prolonged fasting (178) or severe exercise (179,180). Patients on maintenance dialysis are also at risk (181). It has been suggested that non-selective drugs are most likely to produce hypoglycemia and that cardioselective drugs are to be preferred in at-risk patients (182), but the same effect has been reported with atenolol under similar circumstances (180).

Two children in whom propranolol was used to treat attention deficit disorders and anxiety became unarousable, with low heart rates and respiratory rates, due to hypoglycemia (183). Hypoglycemia can be caused by reduced glucose intake (fasting), increased utilization (hyperinsulinemia), or reduced production (enzymatic defects). One or more of these mechanisms can be responsible for hypoglycemia secondary to drugs. Children treated with propranolol may be at increased risk of hypoglycemia, particularly if they are fasting. Concomitant treatment with methylphenidate can increase the risk of this metabolic disorder.

However, contrary to popular belief, beta-adrenoceptor antagonists do not by themselves increase the risk of hypoglycemic episodes in insulin-treated diabetics, in whom their use was concluded to be generally safe (184). Indeed, in 20 such patients treated with diet or diet plus oral hypoglycemic agents, both propranolol and metoprolol produced small but significant increases in blood glucose concentrations after 4 weeks (185). The rise was considered clinically important in only a few patients.

However, in insulin-treated diabetics who become hypoglycemic, non-selective beta-adrenoceptor antagonists can mask the adrenaline-mediated symptoms, such as palpitation, tachycardia, and tremor; they can cause a rise in mean and diastolic blood pressures, due to unopposed alpha-adrenoceptor stimulation from catecholamines, because the $beta_2$-adrenoceptor-mediated vasodilator response is blocked (186); they can also impair the rate of rise of blood glucose toward normal (187). In contrast, cardioselective drugs mask hypoglycemic symptoms less (188); because of vascular sparing, they are less likely to be associated with a diastolic pressor response in the presence of catecholamines, although this has been reported with metoprolol (189); and delay in recovery from hypoglycemia is either less marked or undetectable with cardioselective drugs, such as atenolol or metoprolol. Thus, if insulin-requiring diabetics need to be treated with a beta-adrenoceptor antagonist, a

© 2006 Elsevier B.V. All rights reserved.

cardioselective agent should always be chosen for reasons of safety, while allowing that this type of beta-blocker is associated with insulin resistance and can impair insulin sensitivity by 15–30% (SEDA-17, 235), and hence increase insulin requirements.

People with diabetes have a much worse outcome after acute myocardial infarction, with a mortality rate at least twice that in non-diabetics. However, tight control of blood glucose, with immediate intensive insulin treatment during the peri-infarct period followed by intensive subcutaneous insulin treatment, was associated with a 30% reduction in mortality at 1 year, as reported in the DIGAMI study. In addition, the use of beta-blockers in this group of patients had an independent secondary preventive effect (190). The use of beta-blockers in diabetics with ischemic heart disease should be encouraged (37).

In 686 hypertensive men treated for 15 years, beta-blockers were associated with a higher incidence of diabetes than thiazide diuretics (191). This was an uncontrolled study, but the observation deserves further study.

Blood lipids

There is increasing evidence that beta-adrenoceptor antagonists increase total triglyceride concentrations in blood and reduce high-density lipoprotein (HDL) cholesterol. Comparisons of non-selective and cardioselective drugs have shown that lipid changes are less marked but still present with $beta_1$-selective agents (192). Current information suggests that $beta_1$-selective drugs may be preferable in patients with hypertriglyceridemia (193). Topical beta-blockers can cause rises in serum triglyceride concentrations and falls in serum high-density lipoprotein concentrations; this makes them less suitable in patients with coronary heart disease (38,194).

The importance of these effects for the long-term management of patients with hypertension or ischemic heart disease is unknown, but it is recognized that a high serum total cholesterol and a low HDL cholesterol are associated with an increased risk of ischemic heart disease. However, a significant reduction in HDL cholesterol after treatment for 1 year with timolol was of no prognostic significance and did not attenuate the protective effect of the drug (195). In a 4-year randomized, placebo-controlled study of six antihypertensive monotherapies, acebutolol produced only a small and probably clinically irrelevant (0.17 mmol/l) reduction in total cholesterol (196), which was not statistically different from four of the other antihypertensive drugs.

Obesity

It has been suggested that beta-blockers may predispose to obesity by reducing basal metabolic rate via beta-adrenoceptor blockade (197). Thermogenesis in response to heat and cold, meals, stress, and anxiety is also reduced by beta-adrenoceptor blockade, promoting weight gain (SEDA-16, 193). $Beta_3$-adrenoceptors have been implicated in this mechanism (198,199). Since propranolol blocks $beta_3$-receptors in vivo (200), it would be wise on theoretical grounds to avoid propranolol in obese patients; nadolol is another non-selective beta-blocker that does not act on $beta_3$-adrenoceptors.

A systematic review of eight prospective, randomized trials in 7048 patients with hypertension (3205 of whom were taking beta-blockers) confirmed that body weight was higher in those taking beta-blockers than in controls at the end of the studies (201). The median difference in body weight was 1.2 kg (range –0.4–3.5 kg). There was no relation between demographic characteristics and changes in body weight. The weight gain was observed in the first few months of treatment and thereafter there was no further weight gain compared with controls. This observation suggests that first-line use of beta-blockers in obese patients with hypertension should be considered with caution.

Electrolyte balance

Hypokalemia

Adrenaline by infusion produces a transient increase in plasma potassium, followed by a prolonged fall; pretreatment with beta-adrenoceptor antagonists results in a rise in plasma potassium (202). These effects may be mediated via $beta_2$-adrenoceptors (203), and cardioselective drugs should have smaller effects (202). In the Treatment of Mild Hypertension Study (TOMHS), acebutolol did not change serum potassium after 4 years (196).

It has been argued that drug combinations that contain a beta-adrenoceptor antagonist in combination with a thiazide diuretic minimize the hypokalemic effect of the latter; however, marked hypokalemia in the absence of primary hyperaldosteronism has been reported in a patient taking Sotazide (a combination of hydrochlorothiazide and the non-selective drug sotalol) (204). The use of a combination formulation of chlortalidone and atenolol has also produced hypokalemia (205), in one case complicated by ventricular fibrillation after myocardial infarction (206).

In addition to a rise in serum potassium, timolol increases plasma uric acid concentrations (207). In the TOMHS study, acebutolol increased serum urate by 7 μmol/l (196).

Mineral balance

A fall in serum calcium has been reported with atenolol (208), but whether this was causal has been disputed (209).

Hematologic

Thrombocytopenia has been reported in patients taking oxprenolol (210,211) and alprenolol (212,213); it can recur on rechallenge. This effect is presumed to have an immunological basis.

In the International Agranulocytosis and Aplastic Anemia Study the relation between cardiovascular drugs and agranulocytosis was examined: there was a relative risk of 2.5 (95% CI = 1.1, 6.1) for propranolol (214). Other beta-blockers did not increase risk and propranolol had no association with aplastic anemia. There are also anecdotal reports of this association (215).

Gastrointestinal

Mild gastrointestinal adverse effects, such as nausea, dyspepsia, constipation, or diarrhea, have been reported in

© 2006 Elsevier B.V. All rights reserved.

5–10% of patients taking beta-adrenoceptor antagonists (42). A reduction in dosage or a change to another member of the group will usually produce amelioration. Severe reactions of this type are very infrequent, but severe diarrhea, dehydration, hypokalemia, and weight loss, recurring after rechallenge, occurred with propranolol in a single case (216).

Nausea and vomiting have been attributed to timolol eye-drops (217).

- Severe nausea and vomiting occurred in a 77-year-old woman treated with timolol eye-drops for glaucoma. Her weight had fallen by 8 kg (13%). All physical, laboratory, and instrumental examinations were negative. Gastroduodenoscopy and duodenal biopsy were unremarkable and *Helicobacter pylori* was absent. When timolol was replaced by betaxolol, her complaints disappeared and she gained 2 kg. On rechallenge 3 months later she developed severe nausea, vomiting, and anorexia after some days of treatment. She immediately stopped taking the treatment and 4 days later the symptoms disappeared.

Since timolol has been satisfactorily used by millions of patients, the incidence of serious gastrointestinal events appears to be very low. Absence of symptoms after betaxolol therapy in this patient is in agreement with its lower risk of non-cardiac adverse reactions compared with the non-selective agent timolol.

Beta-adrenoceptor antagonists can cause non-anginal chest pain because of esophagitis (218), due to adherence of the tablet mass, resulting in esophageal spasm, inflammatory change, and even perforation.

Sclerosing peritonitis and retroperitoneal fibrosis

Sclerosing peritonitis was described as part of the practolol syndrome (219–221), and it can also occur with other beta-adrenoceptor antagonists (222,223).

Retroperitoneal fibrosis has been reported in patients taking oxprenolol (224), atenolol (225), propranolol (226), metoprolol (227), sotalol (228), and timolol (including eye-drops) (229,230). However, this disorder often occurs spontaneously and has been reported very infrequently in patients taking beta-blockers (231). Thus, in the absence of any causal relation it is most likely that it reflects the spontaneous incidence in patients taking a common therapy. This conclusion has been supported by an analysis of 100 cases of retroperitoneal fibrosis (232).

Liver

Many beta-adrenoceptor antagonists undergo substantial first-pass hepatic metabolism; these include alprenolol, metoprolol, oxprenolol, and propranolol. Hepatic cirrhosis, with consequent portosystemic shunting, can therefore result in increased systemic availability and higher plasma concentrations, perhaps resulting in adverse effects. Beta-blockers may also reduce liver blood flow and cause interactions with drugs with flow-dependent hepatic clearance.

The oxidative clearance of the lipophilic drugs, metoprolol, timolol, and bufuralol, is influenced by the debrisoquine hydroxylation gene locus, resulting in polymorphic metabolism (233). This might result in an increase in the adverse effects of these beta-blockers in poor metabolizers, but to date there is no objective evidence of such an association (234).

Beta-adrenoceptor antagonists, used in the prevention of bleeding from esophageal varices in patients with hepatic cirrhosis, have reportedly caused hepatic encephalopathy in several patients (235–239). Thus, extreme caution is required, particularly because resuscitation can be difficult when beta-blockers are given to patients with gastrointestinal bleeding or encephalopathy (240).

Biliary tract

Biliary cirrhosis was reported as part of the practolol syndrome (241), but there have been no comparable reports with other beta-adrenoceptor antagonists.

Urinary tract

Propranolol reduces renal blood flow and glomerular filtration rate after acute administration, associated with, and probably partly due to, falls in cardiac output and blood pressure (242,243). There has been some argument about whether these effects persist during long-term therapy (244). Despite early suggestions that renal function might be worsened by such therapy, particularly in patients with chronic renal insufficiency (245), the clinical significance of these changes is debatable (246). Claims that nadolol increases renal blood flow and that cardioselective drugs such as atenolol reduce renal blood flow less than non-selective agents in old people (247) are thus probably relatively unimportant. The vasodilating beta-blocker carvedilol maintains renal blood flow whilst reducing glomerular filtration rate, suggesting that renal vasodilatation occurs (248), although a single case of reversible renal insufficiency has been described in a clinical trial in patients with severe heart failure (249).

Skin

Rashes were part of the practolol (oculomucocutaneous) syndrome, but are infrequent with other beta-adrenoceptor antagonists. The eruptions can be urticarial, morbilliform, eczematous, vesicular, bullous, psoriasiform, or lichenoid (250–255).

Beta-blocker eye-drops can cause skin rashes (256).

- A 70-year-old woman treated with topical timolol for glaucoma developed a papular eruption on the arms and back, consistent with prurigo. All tests were within the reference ranges. There was no improvement after 1 month of topical corticosteroids. The eruption cleared completely within 1 month of timolol withdrawal. Betaxolol eye-drops were introduced and the eruption recurred within 1 week. When beta-blocker therapy was replaced by synthetic cholinergic eye-drops (drug unspecified) the eruption cleared completely without any recurrence a year later.
- Allergic contact dermatitis due to carteolol eye drops occurred in a 61-year-old woman (257). Withdrawal of carteolol and the use of timolol instead led to improvement within 10 days, suggesting that in some cases there is no cross-reactivity between different beta-blockers.

© 2006 Elsevier B.V. All rights reserved.

Although cutaneous adverse effects have been previously described after oral beta-blockers, including timolol, this observation further suggests a class effect of topical beta-blockers. This case also suggests a cross-reaction between timolol and betaxolol.

In a review of 588 patients with established psoriasis it was concluded that about two-thirds of such patients are likely to have a flare-up with a beta-adrenoceptor antagonist, regardless of the agent used (258). In patients with vitiligo, beta-blockers rarely exacerbate depigmentation (7/548 patients) (259). In a separate report, topical betaxolol used for glaucoma was associated with periocular cutaneous pigmentary changes (260).

Some patients have positive patch tests and/or a positive response to oral rechallenge. There can also be cross-sensitivity to other beta-blockers in compromised patients. The mechanisms appear to include both immunological and pharmacological effects; in the latter case the drug may modify growth regulation in the epidermis (261).

Contact allergy to topical beta-blockers can occur.

- A 68-year-old woman developed contact allergy after many years of using befunolol (262). Patch-testing showed cross-sensitivity to carteolol. Evidence of such cross-sensitivity has not previously been reported.

Sweat glands

Hyperhydrosis or sweating with beta-blockers has been reported with both oral formulations (sotalol and acebutolol) (263) and topical formulations (carteolol) (264), although the patients described in these reports were not rechallenged to ascertain the link. However, it was suggested that beta-blockade increased exercise-related sweating in healthy volunteers, more so with a non-selective beta-blocker (propranolol), than a selective one (atenolol) (265). The mechanism for this was uncertain, but was thought to be due to an imbalance between beta- and alpha-adrenergic activity. In some instances, clonidine, an alpha-adrenoceptor antagonist, was effective in treating hyperhydrosis (266), whereas in other cases, propranolol was paradoxically effective (267).

Hair

There have been single case reports of alopecia in association with propranolol (268) and metoprolol (269).

Musculoskeletal

It has been suggested that arthralgia is a not an uncommon adverse effect of beta-adrenoceptor antagonists, particularly metoprolol (270), although the association was not confirmed by rechallenge in any patient. A later case-control study in 127 patients attending a hypertension clinic who had arthropathy showed no significant relation between the arthropathy and the use of beta-blockers (271). On the other hand, five cases of metoprolol-associated arthralgia, most with negative serological tests for collagenases, have been reported to the FDA (272).

Muscle cramps have been reported in patients taking beta-blockers with partial agonist activity (273); it has been suggested (274) that this might be a $beta_2$-partial agonist effect, although this has not subsequently been supported (275). However, a crossover study in 78 hypertensive patients suggested that beta-blockers with partial agonist activity (pindolol and carteolol) caused muscle cramps in up to 40% of these patients, with an associated rise in serum CK and CK-MB, although the severity of the cramps did not correlate with the enzyme activities (276).

Sexual function

Uncontrolled studies of the effect of beta-adrenoceptor antagonists on sexual function have often shown a high incidence of absence of erections, reduced potency, and reduced libido (277). Several large controlled trials in hypertension and ischemic heart disease have provided more exact information. In a large-scale, prospective, placebo-controlled study, reduced sexual activity was an adverse effect of sufficient severity to lead to the withdrawal of some patients in the propranolol-treated group (278). In the TOMHS study, the incidence of difficulty in obtaining and maintaining an erection over 48 months was 17% with both acebutolol and placebo (196). In the TAIM study (279), a randomized, placebo-controlled study lasting 6 months, atenolol did not cause a significant increase in erectile problems in men (11%; 95% CI 2, 20%) compared with placebo (3%; 0, 9%). Loss of libido and difficulty in sustaining an erection can be induced in young healthy volunteers (134); although these effects may be more common with lipophilic drugs, such as propranolol (280) and pindolol (281), they have also been reported with atenolol (282).

Peyronie's disease

Peyronie's disease is a fibrotic condition of the penis that has been associated with beta-blockers, such as propranolol (283), metoprolol (284), and labetalol (284). However, 100 consecutive cases of Peyronie's disease included only five men who had taken a beta-blocker before the onset of the condition (285); the authors concluded that the syndrome was likely to be associated with chronic degenerative arterial disease and not with beta-adrenoceptor antagonists.

Immunologic

Leukocytoclastic vasculitis has been reported with sotalol (286).

- A progressive cutaneous vasculitis occurred in a 66-year-old man taking sotalol for prevention of a symptomatic atrial fibrillation. After 7 days he noted a petechial eruption on his wrists and ankles. This progressed during the next days to palpable purpura on the hands, wrists, ankles, and feet. A biopsy specimen showed changes consistent with leukocytoclastic vasculitis. After withdrawal of sotalol the skin rash cleared completely without any other intervention.

Other beta-blockers associated with leukocytoclastic vasculitis include acebutolol, alprenolol, practolol, and propranolol.

Antinuclear antibodies in high titers were detected in a number of patients with the practolol oculomucocutaneous syndrome. Tests in patients taking acebutolol (287,288) and celiprolol (289) have also shown a high

© 2006 Elsevier B.V. All rights reserved.

frequency of antinuclear antibodies. Positive lupus erythematosus cell preparations have been observed in patients taking acebutolol (288).

The lupus-like syndrome was part of the practolol syndrome and has also been attributed to acebutolol (290,291), atenolol (SEDA-16, 194), labetalol (292), pindolol (293), and propranolol (294). However, apart from practolol, it seems to be very rare during treatment with beta-adrenoceptor antagonists.

Anaphylactic reactions have been attributed to beta-adrenoceptor antagonists only very infrequently (295). However, it appears that anaphylactic reactions precipitated by other agents can be particularly severe in patients taking beta-blockers, especially non-selective drugs, and may require higher-than-usual doses of adrenaline for treatment (296–299). The view that allergy skin testing or immunotherapy is inadvisable in patients taking beta-blockers (300) has been disputed, bearing in mind the low incidence of this adverse effect (301).

Long-Term Effects

Drug withdrawal

Interest in the possible effects of the sudden withdrawal of beta-adrenoceptor antagonists followed a 1975 report of two deaths and four life-threatening complications of coronary artery disease within 2 weeks of withdrawal of propranolol (302). Subsequent analyses did not always confirm these findings (303,304), and it has not been easy to distinguish between natural progression and deterioration caused by drug withdrawal under such circumstances. However, a case-control study in hypertensive patients showed a relative risk of 4.5 (95% CI = 1.1, 19) associated with recent withdrawal of beta-blockers and the development of myocardial infarction or angina (305).

The symptoms attributed to the sudden withdrawal of beta-adrenoceptor antagonists (severe exacerbation of angina pectoris, acute myocardial infarction, sudden death, malignant tachycardia, sweating, palpitation, and tremor) are consistent with transient adrenergic hypersensitivity. Unequivocal signs of rebound hypersensitivity have been observed after drug withdrawal in patients with ischemic heart disease (306), but not in hypertensive patients (307–309). The density of beta-adrenoceptors on human lymphocyte membranes increased by 40% during treatment with propranolol for 8 days (310), and hypersensitivity to isoprenaline can be shown in hypertensive patients after the withdrawal of different beta-adrenoceptor antagonists, including propranolol (311), metoprolol (312), and atenolol (313). This hypersensitivity occurs within 2 days of drug withdrawal, can persist for up to 14 days, and is presumed to reflect the up-regulation of beta-adrenoceptors that occurs with prolonged treatment. This phenomenon is said to be diminished by gradual withdrawal of therapy and by the use of drugs with partial agonist activity, such as pindolol (314). Whether this is directly relevant to the effects of the sudden withdrawal of beta-adrenoceptor antagonists in patients with ischemic heart disease is speculative.

Although there is evidence that abrupt withdrawal of long-acting beta-blockers is not associated with the development of the beta-blocker withdrawal syndrome (315), current information suggests that withdrawal of beta-adrenoceptor antagonists, particularly in patients with ischemic heart disease, should be accomplished by gradual dosage reduction over 10–14 days. However, even gradual withdrawal may not always prevent rebound effects (316).

Second-Generation Effects

Pregnancy

Great concern at one time accompanied the use of beta-adrenoceptor antagonists in pregnancy, particularly in the management of hypertension. On theoretical grounds beta-adrenoceptor antagonists might be expected to increase uterine contractions, impair placental blood flow, cause intrauterine growth retardation, accentuate fetal and neonatal distress, and increase the risk of neonatal hypoglycemia and perinatal mortality. There are many anecdotal reports of such complications attributed to beta-adrenoceptor antagonists, often propranolol. However, many of the adverse effects listed above are also potential complications of hypertension in pregnancy, and in the absence of a properly controlled trial of therapy, definite conclusions of cause and effect have been impossible on the basis of these anecdotes alone.

Many of the fears expressed were set aside by a double-blind, randomized, placebo-controlled trial of atenolol in pregnancy-associated hypertension in 120 women (316), which showed that babies in the placebo group had a higher morbidity, that atenolol reduced the occurrence of respiratory distress syndrome and intrauterine growth retardation, and that neonatal hypoglycemia and hyperbilirubinemia were equally common in the treated and placebo groups. Although bradycardia was more common with atenolol, it had no deleterious consequences. However, the offspring of women taking atenolol had lower body weights on follow up, the significance of which is unclear (316).

It is reasonable to consider that beta-adrenoceptor antagonists can be used in pregnancy without serious risks, provided patients are kept under careful clinical observation. Since all beta-blockers cross the placenta freely, major differences in effects or toxicity among the various drugs are unlikely, and in a review of beta-blockers in pregnancy it was concluded that no single beta-blocker is superior (317). However, in a small study in 51 women with pregnancy-induced hypertension the combination of hydralazine and propranolol was associated with lower blood glucose and weight at birth compared with the combination of hydralazine and pindolol (with partial agonist activity), despite similar blood pressure control. It was suggested that beta-adrenoceptor antagonists without partial agonist activity might reduce uteroplacental blood flow (318).

Fetotoxicity

The adverse effects of beta-adrenoceptor antagonists on the fetus have been reviewed (319). Beta blockers cross the placenta, and can have adverse maternal and fetal effects. Studies of the use of beta-blockers during pregnancy have generally been small, and the gestational age

© 2006 Elsevier B.V. All rights reserved.

at the start of the study was generally 29–33 weeks, leaving substantially unanswered the possibility that treatment of more patients and/or longer treatment durations may reveal unrecognized adverse events. These observations underline the fact that the safety of beta-blockers remains uncertain and that they are therefore better not given before the third trimester.

Non-cardioselective beta-adrenoceptor antagonists

Observations derived from uncontrolled studies have shown an association between maternal use of propranolol and intrauterine growth retardation, neonatal respiratory depression, bradycardia, hypoglycemia, and increased perinatal mortality. However, in randomized, placebo-controlled studies of metoprolol and oxprenolol, there was no evidence of effects on birth weight.

- Two infants with features of severe beta-blockade (bradycardia, persistent hypotension), persistent hypoglycemia, pericardial effusion, and myocardial hypertrophy were born before term to mothers taking long-term oral labetalol for hypertension in pregnancy.

Although labetalol is considered to be generally safe in neonates, impaired urinary excretion and lower albumin binding in preterm infants can prolong the half-life of labetalol and increase its systemic availability and toxicity (320).

Cardioselective beta-adrenoceptor antagonists

There is reluctance to use atenolol in pregnancy, especially if treatment starts early. In placebo-controlled studies, birth weight was significantly lower with atenolol groups. The same was true when atenolol was compared with non-cardioselective agents: the weight of infants born to women taking atenolol was significantly lower. When atenolol was started later there was no difference in birth weight between infants born to women treated with atenolol or other beta-blockers, suggesting the relevance of the time of initiation of atenolol. Atenolol should therefore be avoided in the early stages of pregnancy and given with caution in the later stages.

- Fetal bradycardia and pauses after each two normal beats occurred at 21 weeks gestation in a 37-year-old woman using timolol eye-drops for glaucoma; when timolol was withdrawn, the fetal heart rate recovered (321).

The authors concluded that when a woman taking glaucoma therapy becomes pregnant, it is usually possible to interrupt therapy during pregnancy. Treatment may be deferred until delivery of the infant.

Lactation

The list of beta-adrenoceptor antagonists that have been detected in breast milk includes atenolol (322), acebutolol and its active *N*-acetyl metabolite (323), metoprolol (324), nadolol (325), oxprenolol and timolol (326), propranolol (327), and sotalol (328). Most authors have concluded that the estimated daily infant dose derived from breastfeeding is likely to be too low to produce untoward effects in the suckling infant, and indeed such effects were not noted in the above cases. However, in the case of acebutolol it was considered that clinically important amounts of drug could be transferred after increasing plasma concentrations were noted in two breastfed infants.

Susceptibility Factors

Genetic factors

Most beta-blockers undergo extensive oxidation (329). There have been anecdotal reports of high plasma concentrations of some beta-blockers in poor metabolizers of debrisoquine, and controlled studies have shown that debrisoquine oxidation phenotype is a major determinant of the metabolism, pharmacokinetics, and some of the pharmacological effects of metoprolol, bufuralol, timolol, and bopindolol. The poor metabolizer phenotype is associated with increased plasma drug concentrations, a prolonged half-life, and more intense and sustained beta-blockade. There are also phenotypic differences in the pharmacokinetics of the enantiomers of metoprolol and bufuralol.

Renal disease

The hydrophilic drugs atenolol and sotalol are eliminated largely unchanged in the urine; with deteriorating renal function their half-lives can be prolonged as much as 10-fold (330,331). Other beta-adrenoceptor antagonists, for example acebutolol and metoprolol, have active metabolites that can accumulate (332). Massive retention of the metabolite propranolol gluconate has also been reported in patients with renal insufficiency taking long-term oral propranolol (333); this metabolite is then deconjugated, and concentrations of propranolol can be significantly increased in these patients. Thus, in a patient with a low creatinine clearance, either dosage adjustment or a change of beta-blocker may be necessary.

Other features of the patient

Heart failure

Untreated congestive heart failure secondary to systolic pump failure is a contraindication to the use of beta-adrenoceptor antagonists. Patients in frank or incipient heart failure have reduced sympathetic drive to the heart, and acute life-threatening adverse effects can therefore follow beta-blockade. This is one of the recognized potentially serious complications of beta-blockers in the management of thyrotoxic crisis (334). However, patients with heart failure treated with ACE inhibitors and/or diuretics and digoxin may well gain long-term benefit from beta-adrenoceptor antagonists (34,35).

Heart block

Second-degree or third-degree heart block is a contraindication to beta-adrenoceptor blockade. If it is considered necessary for the control of dysrhythmias, a beta-blocker can be given after the institution of pacing.

Acute myocardial infarction

After many trials including thousands of patients, it is increasingly accepted that treatment of acute myocardial infarction with beta-adrenoceptor antagonists is

© 2006 Elsevier B.V. All rights reserved.

beneficial. Given intravenously within 4–6 hours of the onset of the infarction these drugs can prevent ventricular dysrhythmias and cardiac rupture (335,336). When given orally during the first year after infarction, beta-adrenoceptors reduce mortality by about 25% (337) and probably more in diabetic subjects (37). Since heart failure, hypotension, and bradycardia are complications of both myocardial infarction and beta-adrenoceptor blockade, it might be assumed that these effects would be more common when the two are combined. However, reviews of the relevant studies (335,338–346) do not suggest that beta-adrenoceptor antagonists, given after acute myocardial infarction, either acutely intravenously or for secondary prophylaxis, increase the incidence of adverse effects or the risk of any particular adverse effect. Nevertheless, patients were rigorously selected for inclusion in these trials; less careful decisions to treat may carry increased risks.

Bronchial asthma

Beta-adrenoceptor antagonists should not be given to patients with bronchial asthma or obstructive airways disease, unless there are no other treatment options, because of the risk of precipitating bronchospasm resistant to bronchodilators. Celiprolol, a $beta_1$-antagonist with $beta_2$-agonist activity, has a theoretical but unproven advantage. Alternatively, cardioselective drugs should be chosen in the lowest possible dosages and in conjunction with a $beta_2$-adrenoceptor agonist, such as salbutamol or terbutaline, to minimize bronchoconstriction.

Smoking

Some common activities, such as mental effort (347), cigarette smoking, and coffee drinking (348,349), can produce stress associated with increased catecholamine secretion. In the presence of a non-selective beta-adrenoceptor antagonist, there can be a marked diastolic pressor response, due to mechanisms identical to those described above in hypoglycemia in diabetes. This effect may be smaller with cardioselective drugs.

Theoretically, frequent rises in diastolic blood pressure associated with smoking whilst taking a non-selective beta-adrenoceptor antagonist could be harmful; in a patient with ischemic heart disease or hypertension a cardioselective drug might offer advantages. There is no evidence of differences in morbidity or mortality in patients taking non-selective and cardioselective agents, but both the MRC and IPPPSH trials of mild hypertension showed increases in the incidence of coronary events in patients taking non-selective beta-adrenoceptor antagonists who were also cigarette smokers (350). The explanation that cigarette smoking increases the hepatic metabolism of beta-adrenoceptor blockers, reducing their effectiveness (351), does not extend to the use of cardioselective beta-blockers in smokers, as reported in the HAPPHY and MAPHY trials.

Insulin-treated diabetes

Beta-adrenoceptor antagonists may mask the symptoms of hypoglycemia, result in a catecholamine-mediated rise in diastolic blood pressure, and delay the return of blood glucose concentrations to normal. These effects are minimized or abolished by using a $beta_1$-selective drug, and this type of drug should always be used in preference to a non-selective drug in insulin-treated diabetes.

Anaphylaxis

Beta-blockers can make anaphylactic reactions more difficult to diagnose and treat (348). Even patients with spontaneous attacks of angioedema or urticaria can be at risk when given beta-blockers (352).

Drug Administration

Drug administration route

Beta-adrenoceptor antagonists are used as ocular tension-lowering drugs without notable effects on pupillary size or refraction. Their systemic effects are greater than one would expect, since there is no first-pass metabolism after ocular administration and the plasma concentration can therefore attain therapeutic concentrations (353).

The systemic adverse effects of ophthalmic beta-blockers have been reviewed (354). Symptomatic bradycardia from systemic or ophthalmic use of beta-blockers alone suggests underlying cardiac conduction disturbances. $Beta_2$-adrenoceptor blockade can exacerbate or trigger bronchospasm in patients with asthma or pulmonary disease associated with hyper-reactive airways. Occasionally, adverse systemic reactions can be severe enough to require drug withdrawal. Obtaining a careful medical history and checking pulse rate and rhythm and peak expiratory flow rate should identify the vast majority of patients with potential cardiac and respiratory contraindications.

Beta-blockers that are available as eye-drops include timolol, metipranolol, and levobunolol, which are non-selective $beta_1$- and $beta_2$-adrenoceptor antagonists, and betaxolol, a relatively cardioselective $beta_1$-adrenoceptor antagonist. Although selective $beta_1$-blockers are less likely to precipitate bronchospasm, this and other systemic effects can nevertheless occur (SED-12, 1200).

In 165 patients who used timolol 0.5% eye-drops, adverse effects were reported in 23%, including psychiatric effects (40%), cardiovascular effects (19%), respiratory effects (7%), and local effects (26%) (355).

Cardiovascular

Hemodynamic changes after the topical ocular use of beta-blockers sometimes include only small reductions in heart rate and resting pulse rate and an insignificant reduction in blood pressure. However, patients with cardiovascular disorders, especially those with an irregular heart rate and dysrhythmias, are certainly at risk (SEDA-4, 339). Bradycardia, cardiac arrest, heart block, hypotension, palpitations, syncope, and cerebral ischemia and stroke can occur (356). Rebound tachycardia has been reported after withdrawal of ophthalmic timolol (88,357). Continuous 24-hour monitoring of blood pressure has shown that beta-blocker eye-drops for glaucoma can increase the risk of nocturnal arterial hypotension (358).

© 2006 Elsevier B.V. All rights reserved.

Respiratory

Beta-blockers can aggravate or precipitate bronchospasm (SEDA-4, 339) (SEDA-5, 426) and potentially life-threatening respiratory failure can occur.

- A 58-year-old patient using topical timolol maleate for open-angle glaucoma developed cough and dyspnea due to interstitial pneumonitis. Three months after withdrawal of the eye-drops, he was asymptomatic with normal lung function, chest X-ray, and thoracic CT scan (359).

Nervous system

Light-headedness, mental depression, weakness, fatigue, acute anxiety, dissociative behaviour, disorientation, and memory loss can develop a few days to some months after the start of timolol therapy (88). Central nervous system complaints are most common in patients who have the greatest reduction in intraocular pressure (SEDA-5, 426). Patients may be unaware of the symptoms until the medication is stopped.

Sensory systems

Dry eyes have been reported after the systemic or ocular use of timolol (360). A sensation of dryness in the eyes can develop and is usually transitory. There can be a reduction in the Schirmer test and tear film break-up time. Symptomatic superficial punctate keratitis in association with complete corneal anesthesia has been observed (361).

Amaurosis fugax has been reported in association with topical timolol (362).

Endocrine

Ophthalmic beta-blockers can cause hypoglycemia in insulin-dependent diabetes (363). Conversely, in diabetic patients taking oral hypoglycemic drugs, hyperglycemia can develop because of impaired insulin secretion (SEDA-21, 487).

Electrolyte balance

Severe hyperkalemia has been reported in association with topical timolol, confirmed by rechallenge (364).

Skin

Cutaneous changes secondary to instillation of betaxolol have been described (260).

Musculoskeletal

Aggravation of myasthenia gravis has been observed during ophthalmic timolol therapy (365). Bilateral pigmentation of the fingernails and toenails, marked hyperkalemia, and arthralgia after ocular timolol have all been reported (SED-12, 1200).

Sexual function

Erectile impotence can occur after ophthalmic use of beta-blockers (88).

Susceptibility factors

All of the susceptibility factors that apply to systemically administered beta-blockers also apply to eye-drops. This particularly applies to asthma (260).

Glaucoma

Eyes with potential angle closure require a miotic drug and should not be treated with beta-blockers alone. To exclude the risk of precipitating glaucoma in a susceptible individual, gonioscopy is recommended before starting topical beta-adrenoceptor antagonist therapy.

Drug tolerance

Tachyphylaxis can develop after treatment with ophthalmic beta-blockers (366). There are two forms, short-term "escape," which occurs over a few days, and long-term "drift," which occurs over months and years.

Drug overdose

The increasing use of beta-adrenoceptor antagonists appears to have resulted in more frequent reports of severe high-dose intoxication (367,368), in which beta-adrenoceptor antagonists are often taken in combination with sedatives or alcohol. There can be a very short latency from intake of the drug until fulminant symptoms occur (369). The clinical features are well established. Cardiovascular suppression results in bradycardia, heart block, and congestive heart failure, and intraventricular conduction abnormalities are common (370). Ventricular tachycardias with sotalol intoxication may reflect its class III antidysrhythmic properties, leading to prolongation of the QT interval (371) and torsade de pointes, which may respond to lidocaine (372). Bronchospasm and occasionally hypoglycemia can also occur. Coma and epileptiform seizures are often seen (370,373) and may not be secondary to circulatory changes. The outcome is seldom fatal, but 16 fatal cases of intoxication with talinolol (which is $beta_1$-selective) have been described. Deaths have also occurred with metoprolol and acebutolol. Acebutolol has membrane-stabilizing activity, and it has been suggested that drugs with this property carry greater risk when taken in overdose (374). Lipid solubility influences the rate of nervous system penetration of a drug, and overdosage with highly lipophilic drugs, such as oxprenolol and propranolol, has been associated with rapid loss of consciousness and coma (375–377).

Treatment should include isoprenaline (although massive doses may be required), glucagon, and atropine. If a $beta_1$-selective antagonist has been taken, isoprenaline may reduce diastolic blood pressure by its unopposed vasodilator effect on $beta_2$-adrenoceptors (378). The $beta_1$-selective agonist dobutamine may be preferable in such patients (379). A temporary transvenous pacemaker should be inserted if significant heart block or bradycardia occur. Seizures in overdosage with a beta-adrenoceptor antagonist respond poorly to diazepam and barbiturates; muscle relaxants and artificial ventilation may be required. In general, the lipid-soluble drugs are highly protein-bound with a large apparent volume of distribution; forced diuresis or hemodialysis are therefore unlikely to be of use.

Propranolol intoxication can cause central nervous system depression in the absence of clinical signs of cardiac toxicity.

© 2006 Elsevier B.V. All rights reserved.

- A 16-year-old boy developed central nervous system depression and an acute dilated cardiomyopathy after taking 3200 mg of propranolol in a suicide attempt (380). He was treated with gastric lavage, activated charcoal, and mechanical ventilation. Echocardiography showed a poorly contracting severely dilated left ventricle. After intravenous isoprenaline hydrochloride and glucagon, echocardiography showed normal left ventricular size and function. He became fully alert 20 hours later and made a good recovery without sequelae.

Early echocardiographic evaluation is important in beta-blocker overdose and can prevent delay in the diagnosis and treatment of cardiac toxicity.

Two regional poison centers in the USA have reviewed 280 cases of beta-blocker overdose (381). All patients with symptoms developed them within 6 hours of ingestion. Four patients died as a result of overdosage. There was cardiovascular morbidity in 41 patients (15%), requiring treatment with cardioactive drugs. Propranolol, atenolol, and metoprolol were responsible for 87% of the cases and 84% of cardiovascular morbidity. Beta-blockers with membrane-stabilizing activity (acebutolol, labetalol, metoprolol, pindolol, and propranolol) accounted for 62% of beta-blocker exposures and 73% of cardiovascular morbidity. Symptomatic bradycardia (heart rate less than 60/minute) or hypotension (systolic blood pressure less than 90 mmHg) were observed in all cases classified as having cardiovascular morbidity. Beta-blocker exposure was complicated by a history of at least one co-ingestant in 73% of the cases, benzodiazepines and ethanol being the most frequent. Cardioactive co-ingestants were reported in 26% of cases: calcium channel blockers, cyclic antidepressants, neuroleptic drugs, and ACE inhibitors were the most common. Multivariate analysis showed that the only independent variable significantly associated with cardiovascular morbidity was the presence of another cardioactive drug. When patients who took another cardioactive drug were excluded, the only variable associated with cardiovascular morbidity was the ingestion of a beta-blocker with membrane-stabilizing activity.

Two fatal cases of acebutolol intoxication (6 and 4 g) have been reported (382). In both cases, the onset of symptoms was sudden (within 2 hours of ingestion), with diminished consciousness, PR, QRS, and QT prolongation, and hypotension unresponsive to inotropic drugs. In both cases there were episodes of repetitive polymorphous ventricular tachycardia.

These cases have confirmed the potential toxicity of beta-blockers with membrane stabilizing activity; they predispose the patient to changes in ventricular repolarization, which can cause QT prolongation and serious ventricular dysrhythmias. This is generally not seen in cases of propranolol intoxication.

Drug–Drug Interactions

General

Drug interactions with beta-adrenoceptor antagonists can be pharmacokinetic or pharmacodynamic (383–385).

Pharmacokinetic interactions

Absorption interactions

The absorption of some beta-adrenoceptor antagonists is altered by aluminium hydroxide, ampicillin, and food; these are interactions of doubtful clinical relevance.

Metabolism interactions

Beta-adrenoceptor antagonists that are cleared predominantly by the liver (for example metoprolol, oxprenolol, propranolol, and timolol) are more likely to participate in drug interactions involving changes in liver blood flow, hepatic drug metabolism, or both. Thus, enzyme-inducing drugs, such as phenobarbital and rifampicin, increase the clearance of drugs such as propranolol and metoprolol and reduce their systemic availability (386,387). Similarly, the histamine H_2 receptor antagonist cimetidine increases the systemic availability of labetalol, metoprolol, and propranolol by inhibiting hepatic oxidation (388–391). The disposition of drugs with high extraction ratios, such as propranolol and metoprolol, is also affected by changes in liver blood flow, and this may be the mechanism by which hydralazine reduces the first-pass clearance of oral propranolol and metoprolol (392).

Lipophilic beta-adrenoceptor antagonists are metabolized to varying degrees by oxidation by liver microsomal cytochrome P450 (for example propranolol by CYP1A2 and CYP2D6 and metoprolol by CYP2D6). These agents can therefore reduce the clearance and increase the steady-state plasma concentrations of other drugs that undergo similar metabolism, potentiating their effects. Drugs that are affected in this way include theophylline (393), thioridazine (394), chlorpromazine (395), warfarin (396), diazepam (397), isoniazid (398), and flecainide (399). These interactions are most likely to be of clinical significance when the affected drug has a low therapeutic ratio, for example theophylline or warfarin.

Beta-blockers can also affect the clearance of high clearance drugs by altering hepatic blood flow. This occurs when propranolol is co-administered with lidocaine (400), but it appears that this interaction is due more to inhibition of enzyme activity than to a reduction in hepatic blood flow (401). Atenolol inhibits the clearance of disopyramide, but the mechanism is unknown (402). Conversely, quinidine doubles propranolol plasma concentrations in extensive but not poor metabolizers (403) and oral contraceptives increase metoprolol plasma concentrations (404).

Pharmacodynamic interactions

The pharmacodynamic interactions of the beta-adrenoceptor antagonists can mostly be predicted from their pharmacology.

Blood pressure

The antihypertensive effect of beta-blockers can be impaired by the concurrent administration of some non-steroidal anti-inflammatory drugs (NSAIDs), possibly because of inhibition of the synthesis of renal vasodilator prostaglandins. This interaction is probably common to all beta-blockers, but may not occur with all NSAIDs; for example, sulindac appears to affect blood pressure less than indometacin (405–407).

© 2006 Elsevier B.V. All rights reserved.

The hypertensive crisis that can follow the withdrawal of clonidine can be accentuated by beta-blockers. It has also been reported that when beta-blockers are used in conjunction with drugs that cause arterial vasoconstriction they can have an additional effect on peripheral perfusion, which can be hazardous. Thus, combining beta-blockers with ergot alkaloids, as has been recommended for migraine, can cause severe peripheral ischemia and even tissue necrosis (408).

The hypotensive effects of halothane and barbiturates can be exaggerated by beta-adrenoceptor antagonists. However, they are not contraindicated in anesthesia, provided the anesthetist is aware of what the patient is taking.

The combination of caffeine with beta-blockers causes a raised blood pressure (409).

Cardiac dysrhythmias

The bradycardia produced by digoxin can be enhanced by beta-adrenoceptor antagonists. Neostigmine enhances vagal activity and can aggravate bradycardia (410). An apparent interaction between sotalol and thiazide-induced hypokalemia, resulting in torsade de pointes (411), has prompted the withdrawal of the combination formulation Sotazide.

- The co-prescription of sotalol 80 mg bd with terfenadine 60 mg bd (both drugs that can prolong the QT interval) in a 71-year-old lady with hypertension, atrial fibrillation, and nasal congestion was complicated by recurrent torsade de pointes, causing dizzy spells and confusion after 8 days (412). She was treated with temporary pacing, but her symptoms resolved 72 hours after drug withdrawal.

Cardiac contractility

The negative inotropic effects of class I antidysrhythmic agents, such as disopyramide, procainamide, quinidine, and tocainide can be accentuated by beta-blockers; this is most pronounced in patients with pre-existing myocardial disease and can result in left ventricular failure or even asystole (413). Digoxin can obviate the negative inotropic effect of beta-blockers in patients with poor left ventricular function.

Beta-lactam antibiotics

See also Individual agents

General Information

The beta-lactam antibiotics still comprise roughly half of the antibiotic market worldwide. The common structure that defines the whole family of beta-lactam antibiotics is the four-membered, highly reactive beta-lactam ring, which is essential for antimicrobial activity (1). The following simplifying classification is practical:

1. penicillins
2. cephalosporins
3. monobactams (containing no second ring system besides the beta-lactam ring)
4. carbapenems

In addition, beta-lactamase inhibitors also contain the beta-lactam structure.

The crucial event that initiates the antimicrobial effects of beta-lactam antibiotics is binding to and inhibition of bacterial enzymes located in the cell membrane, the so-called penicillin-binding proteins (2). This happens by

© 2006 Elsevier B.V. All rights reserved.

covalent binding, through opening of the beta-lactam ring. Enzyme activities of penicillin-binding proteins are involved in the last steps of bacterial cell wall (peptidoglycan) synthesis, and their inhibition halts cell growth, causing cell death and lysis (3). Beta-lactamases are genetically and structurally closely related to penicillin-binding proteins.

Despite their chemical diversity, their adverse effects profiles share various common aspects. There are several reasons why beta-lactam antibiotics belonging to different classes can cause comparable reactions. Besides the beta-lactam ring, other structural similarities (for example side chains) or antimicrobial activity can be relevant. However, the incidence of a given reaction, and in particular instances also the severity, varies among beta-lactam classes.

Incidence and cause–effect relations

It is difficult to establish clearly the incidence and cause–effect relations of many reactions and hence to identify patients at risk. The following factors are important:

1. The range of recommended daily doses varies by more than an order of magnitude, according to clinical need. Hence, the incidence of some collateral and toxic reactions varies greatly among different populations.
2. Combinations of beta-lactam antibiotics with antimicrobial drugs from other molecular classes are often used, especially in severe infection.
3. The spectrum of potential beta-lactam-antibiotic-induced reactions is especially broad, and in most cases no test procedure is available to distinguish beta-lactam antibiotics from other causes of a reaction, in particular from the consequences of the treated infection.

Relation to dose

Many reactions to beta-lactam antibiotics are clearly not immune mediated. These include bleeding disorders, neurotoxicity, and most cases of diarrhea. In addition, many reactions, the pathogenesis of which is still being discussed, clearly depend on the daily and the cumulative dose of beta-lactam antibiotics and hence the duration of treatment. Although the rare, but well-understood, immune hemolysis after penicillin is seen mostly with high-dose and long-term treatment, dose dependency and time dependency point to direct toxicity rather than to immunological mechanisms. Indeed, direct toxic effects of beta-lactam antibiotics on eukaryotic cells and specific interactions with receptor proteins and enzymes have been shown (4) and may underlie particular reactions.

There are three lines of evidence that beta-lactam antibiotics cause a variety of reactions by toxic mechanisms:

1. Certain reactions are overwhelmingly reported to be dose-dependent and time-dependent.
2. Particular compounds cause adverse effects with unexpectedly high frequencies in certain circumstances (for example cystic fibrosis, bacterial endocarditis, and osteomyelitis) that require particularly high doses and prolonged treatment.
3. Beta-lactam antibiotics affect a variety of cultured eukaryotic cells.

For other reactions, the underlying mechanisms are less clear. The body of individual reports and some published series suggest that their incidence increases disproportionately with prolonged, high-dosage treatment, that is, with accumulation. This is particularly the case in the following reactions:

- severe neutropenia up to total agranulocytosis, as observed with virtually all beta-lactam antibiotics.
- acute interstitial nephritis, seen with methicillin but more rarely also with other beta-lactams, for example penicillin G.
- one type of hepatitis induced by isoxazolyl penicillins;
- varying combinations of symptoms positively referred to or not as "serum sickness-like syndromes."

There have been reports of high overall frequencies of adverse effects after the use of very high cumulative doses of beta-lactam antibiotics in healthy volunteers and in patients with, for example, chronic osteomyelitis, pulmonary exacerbations in cystic fibrosis, and infective endocarditis (5–9). In one series, 23% of patients treated with an average cumulative dose of carbenicillin of 925 g and 68% of those treated with ureidopenicillins 329 g developed adverse effects, including rash, fever, leukopenia, eosinophilia, thrombocytopenia, and hepatic damage, requiring change of therapy in 52% of cases in the latter group (10). Another study included a total of 292 treatment courses with five different beta-lactams for infective endocarditis (6). With a treatment duration of 9 days or less, drug was withdrawn in only 3% because of adverse reactions. However, treatment courses ranging from 10 days to 6 weeks were associated with adverse reactions in 33%, one-quarter of which consisted of neutropenia. Fourteen of 44 patients receiving piperacillin up to 900 mg/kg/day for acute pulmonary exacerbations in cystic fibrosis developed a syndrome that resembled serum sickness; the symptoms were mainly fever, malaise, anorexia, eosinophilia, and rashes (8). The reaction occurred after a minimum of 9 days and the frequency of symptoms was dose-related. All patients who developed the reaction were readmitted at 4–28 months after the initial episode and in every case re-exposure to piperacillin did not evoke the reaction.

The dose-relation of reactions to piperacillin in patients with cystic fibrosis has created a debate about its usefulness in this condition (11–15). However, comparable dose-related patterns and frequencies of adverse effects were found in other patients treated with piperacillin (15) and with other beta-lactam antibiotics (16), as well as in patients with both cystic fibrosis and other conditions (6,10,16). Three later studies showed that piperacillin more often caused fever, rash, and other reactions per treatment course in patients with cystic fibrosis compared with a large variety of other beta-lactam or non-beta-lactam antibiotics (17–19). Of particular interest is a study in which volunteers who took high doses of cefalotin or cefapirin for up to 4 weeks developed comparable syndromes, with an overall incidence of adverse effects of 100% (9). Despite these astonishingly high frequencies, these reactions were predominantly regarded as being allergic, although their pathogenesis was mostly unclear.

© 2006 Elsevier B.V. All rights reserved.

Thus, a disproportionately high frequency of apparently unrelated adverse effects occurs in a relatively small group of patients, those needing high-dose prolonged treatment, who are at particular risk.

Mechanisms

Degradation products spontaneously formed in aqueous solutions, for example culture media, rather than the parent molecules themselves, may be responsible for the observed effects (4). Antiproliferative activities were generally more pronounced with cephalosporins than with penicillins, while monobactams appear to be practically free from such effects. Carbapenems have not been thoroughly studied in this respect, and some data on clavulanic acid and two other beta-lactamase inhibitors do not clearly reflect the same kind of toxicity as observed with penicillins and cephalosporins (20).

The selectivity of beta-lactam antibiotics for bacterial target proteins is not absolute. A specific interaction of modified cephalosporins with mammalian serine proteases has been shown (21) and the affinity of various penicillins for the benzodiazepine receptor may be part of the chain of events leading to neurotoxicity (22) However, most intriguing are observations made in proliferating cultured cells. Biological effects associated with proliferation were dose-dependently inhibited by a large array of beta-lactam antibiotics in a variety of cells from both man and animals (4,23). Resting cells, on the other hand, were not susceptible, even to very high concentrations.

The clinical impact of the inhibitory effects of beta-lactam antibiotics on proliferating eukaryotic cells is as yet unknown, and formal proof of a correlation with toxicity in patients is lacking. However, there are reasons for considering this type of toxicity as the cause of neutropenia and thrombocytopenia (SEDA-13, 230). In dogs, high-dose cefonicid and cefazedone for up to several months caused bone marrow damage, resembling the findings in clinical cases of neutropenia, which could explain peripheral cytopenias (24,25). In addition, mild thrombocytopenia and reticulocytopenia, which have been concomitantly found respectively in 30 and 17% of cases of neutropenia (26), are also paralleled by results in dogs. On the other hand, in the same dogs, IgG associated with erythrocytes, neutrophils, and platelets was found after high-dose treatment with cefazedone (27) Antigranulocyte IgG antibodies in beta-lactam-induced neutropenia have also been described in man (28–30). However, the relevance of these findings is unclear, since high cumulative doses of beta-lactams often induce beta-lactam-specific IgG antibodies in patients with and without adverse effects (6,31). Newer data from human and animal cell culture investigations suggest that ceftazidime-induced myelosuppression could be the consequence of multiple effects on various myeloid and non-myeloid cells in the bone marrow (32–34). They also give hints of a more rational basis for using G-CSF or other cytokines in beta-lactam-antibiotic-induced neutropenia (32,34). Hence, there is still controversy about whether beta-lactam antibiotics can cause neutropenia by both toxic and immunological mechanisms and how both mechanisms could act in concert with each other.

For evaluation of local tolerability, human peritoneal cells (35), human osteoblasts (36), and human as well as animal endothelial cells (37) have been studied in culture. The type of toxicity and rank efficacy among various compounds were congruent with the results from earlier studies on other cells (4,23). The clinical relevance of these data remains to be established.

The Jarisch–Herxheimer reaction

The Jarisch–Herxheimer reaction is a systemic reaction that occurs hours after initial treatment of spirochete infections, such as syphilis, leptospirosis, Lyme disease, and relapsing fever, and presents with fever, rigors, hypotension, and flushing (38,39). In patients with syphilis the reaction is more frequent in secondary syphilis and can cause additional manifestations, such as flare-up of cutaneous lesions, sudden aneurysmal dilatation of the aortic arch (40), and angina pectoris or acute coronary occlusion (SED-8, 559). It can easily be mistaken for a drug-induced hypersensitivity reaction. The underlying mechanism is initiated by antibiotic-induced release of spirochete-derived pyrogens. Transient rises in TNF, IL-6, and IL-8 have been detected (41). The role of TNF-alpha in the pathogenesis of the Jarisch–Herxheimer reaction is further underscored by the observation that in patients undergoing penicillin treatment for louse-borne relapsing fever, pretreatment with anti-TNF antibody Fab fragments partially protected against the reaction (42). The reaction lasts 12–24 hours and can be alleviated by aspirin. Alternatively, prednisone can be used and is recommended as adjunctive treatment of symptomatic cardiovascular syphilis or neurosyphilis.

Organs and Systems

Respiratory

Allergic bronchospasm can principally be a consequence of IgE antibody-mediated allergy to all beta-lactam antibiotics.

Nervous system

Since the first observation of convulsions after intraventricular administration of penicillin more than 50 years ago (43), neurotoxicity has been attributed to most beta-lactam antibiotics. Its manifestations are considered to be the consequence of GABAergic inhibition (44,45)and include clear epileptic manifestations as well as more atypical reactions, such as asterixis, drowsiness, and hallucinations. Epileptogenic activity of beta-lactam antibiotics has also been documented in animals and in brain slices in vitro (46). With penicillins and cephalosporins, integrity of the beta-lactam ring is a prerequisite, and epileptogenic activity is extinguished by beta-lactamase (47,48). However, this may not be true of the carbapenems, the neurotoxicity of which is differently related to their structure (49). However, clinical manifestations are always clearly dose-dependent, and brain tissue concentrations appear to be more relevant than CSF or blood concentrations (46). Accordingly, the major risk factor is impaired renal function, particularly when it is not recognized. Other risk factors are age (very young or very old),

© 2006 Elsevier B.V. All rights reserved.

meningitis, intraventricular therapy, and a history of epilepsy (50).

The neurotoxic potential differs considerably among the various beta-lactam antibiotics, and experimental models have been developed for investigating this (51,52). Currently, imipenem + cilastatin appears to cause the highest frequency of neurotoxic effects (53,54) and the above-mentioned risk factors have been particularly confirmed with this compound (SEDA-18, 261) (55). Quinolone antibiotics, which themselves are proconvulsant, can potentiate excitation of the central nervous system by beta-lactam antibiotics, at least in animals (56,57).

Sensory systems

In vitro, methicillin and ceftazidime in high concentrations produced toxic effects on corneal and endothelial cells of the eye (58,59).

Metabolism

Pivaloyl-containing compounds (baccefuconam, cefetamet pivoxil, cefteram pivoxil, pivampicillin, pivmecillinam) can significantly increase urinary carnitine excretion (60,61). These compounds are esterified prodrugs, which become effective only after the release of pivalic acid, which in turn is esterified with carnitine. Carnitine loss induced by pivaloyl-containing beta-lactams was first described in children and can produce symptoms similar to other types of carnitine deficiency, for example secondary to organic acidurias (60). Carnitine is essential for the transport of fatty acids through the mitochondrial membrane for beta-oxidation. Consequences of its deficiency include skeletal damage, cardiomyopathy, hypoglycemia and reduced ketogenesis, encephalopathy, hepatomegaly, and Reye-like syndromes (62).

The administration of pivaloyl-conjugated beta-lactam antibiotics to healthy volunteers for 54 days reduced mean serum carnitine 10-fold and muscle carnitine, as measured per non-collagen protein, more than 2-fold (62). Long-term treatment of children for 12–37 months to prevent urinary tract infection resulted in serum carnitine concentrations of 0.9–3.6 μmol/l (reference range 23–60 μmol/l). In four cases, muscle carnitine was 0.6–1.4 μmol/g non-collagen protein (reference range 7.1–19) (63).

Although oral carnitine aided the elimination of the pivaloyl moiety, its simultaneous use did not fully compensate for the adverse metabolic effects of pivaloyl-containing beta-lactams (64,65). The consequences of pivaloyl-induced carnitine loss seem to be generally reversible. But as long as the risk of pivaloyl-induced urinary loss of carnitine and particular risk factors are not better defined, it is prudent to use pivaloyl-containing prodrugs only in short-term treatment.

Electrolyte balance

Since beta-lactam antibiotics contain sodium or potassium, they can cause or at least aggravate electrolyte disturbances when given in sufficiently high doses. The most frequent manifestations are hypernatremia and hypokalemia. The sodium content of injectable beta-lactam antibiotics per gram of active compound varies by up to a factor of three (66).

Hematologic

Neutropenia

While in large series of several thousands of patients, neutropenia has generally been reported as an adverse effect in under 0.1–1.0% (SEDA-13, 212), an overview in 1985 estimated that neutropenia (neutrophil count below 1.0×10^9/l) occurs in up to 15% of all patients treated with high-dose intravenous beta-lactam antibiotics for more than 10 days (26). In subsequent series of patients treated for several weeks with various beta-lactam antibiotics, up to 25% developed neutropenia (5,21,67–69).

In one series, 22 of 128 patients receiving cloxacillin for staphylococcal infections became neutropenic (67). Neutropenia appeared, on average, 23 days after the start of therapy. The same authors, in a somewhat bigger population, found neutropenia in 1.1% of patients who received cumulative doses of oxacillin below 150 g, but in 43% (22 of 51) who received more than 150 g (5). Similarly, in 132 patients, cefapirin in a cumulative dose of less than 90 g did not cause neutropenia, but did in 26% (five of 19) of those who used higher total doses (21).

In addition, for a given compound, higher daily doses increase the risk of neutropenia. In one study, seven of 14 patients became neutropenic with a mean dose of penicillin G of 17 g/day after 9–23 days (68), while in another study only 12 of 193 patients developed neutropenia with a mean dose of 11 g/day for an average duration of 20 days (69). A considerable extension of the aforementioned study (68) corroborated this: neutropenia occurred in 35% of those treated with a mean daily dose of 17 g of penicillin G for an average of 23 days, while it was found in only 8% of those who received 12 g for 22 days (6).

Epidemiological studies (7,70) as well as single cases of severe neutropenia observed with newer compounds have invariably confirmed the dose- and time-dependent pattern described above. For example, cefepime, a fourth-generation cephalosporin, possibly or probably caused neutropenia in only 0.2% of 3314 treatment courses, while 7.1% of those who received cefepime for several weeks developed neutropenia (71). Accordingly, high-dose cefepime (150 mg/kg/day) was given for 7–10 days to 43 children for bacterial meningitis without causing neutropenia (72), while there were two cases in adults after total doses of 112 g (over 28 days) and 120 g (30 days) respectively (73).

It is therefore not surprising that after consecutive or simultaneous treatment with more than one beta-lactam antibiotic, neutropenia is similarly observed, suggesting additive toxicity (6,74,75).

There is so far no clear evidence about the different risks of different compounds. The data best fit the assumption that the risk of neutropenia correlates with the cumulative dose, or probably more precisely with the area under the serum concentration versus time curve (AUC). Hence, renal insufficiency is a potential risk factor. In addition, beta-lactam-antibiotic-induced leukopenia has been associated with hepatic dysfunction (76).

Recovery in most cases is rapid and uneventful. In patients who were re-exposed to the same or other

© 2006 Elsevier B.V. All rights reserved.

beta-lactam antibiotics, there was similar dependence of neutropenia on the duration of treatment and the cumulative dose (26). Whether the use of hemopoietic growth factors, and in particular G-CSF, is useful is unclear. There are case reports of positive clinical effects (77–79). However, the recovery time in these reports did not differ from that observed in a large population of untreated patients (26). Theoretically, early use of growth factors could even be counterproductive, since some toxic effects of beta-lactam antibiotics on bone marrow cells appear to be related to the S-phase of the cell cycle (4). On the other hand, G-CSF maintained the proliferative activity of bone marrow cells exposed to ceftazidime in vitro, if it was added at the beginning of the culture process (32).

Neutropenia is accompanied by fever, eosinophilia, and/or a rash in more than 80% of cases.

Hemolytic anemia

Immune hemolytic anemia was originally described with penicillin G, but subsequently also with other penicillins and cephalosporins. It is usually seen during treatment with very high doses after the so-called "drug absorption" mechanism. The beta-lactam antibiotic binds covalently to the erythrocyte surface, forming complete antigens, which can in turn bind drug-specific circulating IgG antibody. Typically, direct and indirect Coombs' tests are positive, but complement is not activated (80–82). Rarely, other immunological mechanisms have been observed, for example the so-called "innocent bystander" type of hemolysis (82), in which complement can be detected on the erythrocyte surface. Some cephalosporins, clavulanic acid, and imipenem + cilastatin can cause positive direct antiglobulin tests (83). The phenomenon is due to non-specific serum protein absorption on to the erythrocyte membrane and is not related to immune hemolytic processes. Detection of non-immunologically bound serum proteins is improved if the reagents used include additional anti-albumin activity (84). The phenomenon is a known source of difficulties in evaluating suspected immune hemolysis or routine cross-matching of blood products (85). The true frequency of the phenomenon is unclear, since it has not been positively sought.

Thrombocytosis

Thrombocytosis is frequently mentioned as an adverse effect of beta-lactam antibiotics. However, it has been suggested that this reflects healing from infection rather than toxicity (86).

Eosinophilia

Virtually all beta-lactam antibiotics can cause eosinophilia, either isolated or in the context of very different reactions.

Bleeding disorders

Treatment with beta-lactam antibiotics can result in impaired hemostasis and bleeding. The true incidence of bleeding is difficult to assess, since many non-antibiotic factors can be involved, such as malnutrition with vitamin K depletion (87), renal insufficiency (88), and serious infection (89). Cancer, the use of cytotoxic drugs, and surgery have made conclusive interpretation of coagulation disorders difficult (90). Between the different beta-lactam antibiotics, the reported incidence of clinical relevant bleeding varies widely, and was highest with moxalactam (22% of patients), now withdrawn (SED-12, 625). With other cephalosporins, bleeding was observed with frequencies ranging from 2.7% (cefazolin/cefalotin) to 8.2% (cefoxitime) (91). Two basic mechanisms have been proposed.

Altered coagulation

Both direct inhibition of the hepatic production of vitamin K-dependent clotting factors and alterations in the intestinal flora, with subsequent reduction of microbial supply of vitamin K, have been implicated (92,93). The relative role of either mechanism is difficult to assess, but experimental support for the flora theory is weak (94,95).

Several of the cephalosporins that contain either a non-substituted *N*-methylthiotetrazole (NMTT) side chain, such as cefamandole, cefamazole, cefmenoxime, cefmetazole, cefoperazone, cefotetan, and moxalactam, as well as a substituted NMTT side chain (ceforanide, ceforicid, or cefotiam), or the structurally similar *N*-methylthiotriazine ring in ceftriaxone and the 2-methyl-1,2,4-thiadiazole-5-thiol (MTD) ring of cefazolin interfere with vitamin K-dependent clotting factor synthesis in the liver (factors II, VII, IX, and X). The molecular mechanism involves dose-dependent inhibition of microsomal carboxylase function, as shown in animals (96), and inhibition of the epoxide reductase system in both animals and man (97–100). Cefoxitin, a non-NMTT compound, was implicated significantly more often than the NMTT-containing compounds cefamandole and cefoperazone (101).

The NMTT must leave the parent antibiotic to inhibit the carboxylation reaction (102). The NMTT molecule leaves the parent cephalosporin either during spontaneous hydrolysis in the blood or during nucleophilic cleavage of the beta-lactam ring by intestinal bacteria, and is reabsorbed from the gut into the portal circulation (103). Studies in healthy volunteers show compound-related differences in the ability of NMTT antibiotics to generate free NMTT, reflecting drug-specific differences in susceptibility to in vitro hydrolysis or differences in gut NMTT production, which may be a function of biliary excretion of the drug (104).

Altered platelet numbers and function

Platelet dysfunction occurs dose-dependently with carbenicillin, ticarcillin, and, infrequently, other broad-spectrum penicillins (105), but the NMTT cephalosporin moxalactam has also been associated with altered platelet function in both healthy subjects and in patients treated with standard regimens (106–110). In contrast, clinical studies including cefotaxime, ceftizoxime, cefoperazone, and ceftracone did not show platelet dysfunction attributable to these compounds (109–111). There is evidence that beta-lactam-antibiotic-induced platelet dysfunction is at least partially irreversible (112).

© 2006 Elsevier B.V. All rights reserved.

From a practical point of view it can be concluded that:

1. the use of cephalosporins containing an NMTT side chain is associated with a risk of dose-dependent inhibition of vitamin K-dependent clotting factor synthesis.
2. platelet dysfunction occurs primarily with the broad-spectrum penicillins, but the NMTT cephalosporins, notably moxalactam, have also been implicated; monitoring of bleeding time should be considered in patients at risk (bleeding history, clinical bleeding, concomitant thrombocytopenia, or the use of other drugs known to interfere with platelet function.
3. the presence of non-antibiotic factors, such as therapy with vitamin K antagonists or NSAIDs, renal insufficiency, hepatic dysfunction, impaired gastrointestinal function, and malnutrition, can increase the risk of bleeding in cephalosporin-treated patients; close monitoring of homeostasis (prothrombin time, bleeding time), as well as prophylactic supplementation with vitamin K or, if necessary, therapeutic administration of fresh-frozen plasma and/or platelets is warranted according to the clinical context.

Gastrointestinal

Gastrointestinal upsets, nausea, and vomiting have been observed with virtually all beta-lactam antibiotics, both oral and parenteral. Even when comparing analogous applications and doses, no particular risk can be clearly ascribed to a given compound. Acute hemorrhagic colitis without pseudomembrane formation has been described after treatment with various penicillins and cephalosporins (SEDA-21, 261).

Antibiotic-induced diarrhea

There are three types of antibiotic-induced diarrhea:

- simple diarrhea due to altered bowel flora; this is quite common, for example it occurs in about 8% of patients who take ampicillin (113).
- diarrhea due to loss of bowel flora and overgrowth of *Clostridium difficile*, with toxin production; this is much less common.
- a rare form of diarrhea that is due to allergy.

Almost all antibacterial agents have been observed to cause diarrhea in a variable proportion of patients (114,115). The proportion depends not only on the antibiotic, but also on the clinical setting (in-patient/out-patient), age, race, and the definition of diarrhea. Severe colonic inflammation develops in a variable proportion of cases, and in some cases pseudomembranous colitis occurs (116–121). Since 1977, much evidence has accumulated that the most important causative agent in antibiotic-associated diarrhea is an anaerobic, Gram-positive, toxin-producing bacterium, *C. difficile* (122–124).

Pseudomembranous colitis was known before the introduction of antimicrobial agents and can still occur without previous antibiotic use, for example after antineoplastic chemotherapy (125) or even spontaneously. However, the number of cases has increased dramatically since antibiotics began to be used (126). Patients treated with lincomycin or clindamycin, cephalosporins, penicillinase-resistant penicillins, or combinations of several antibiotics are at especially high risk (127–130). A low risk is usually associated with sulfonamides, co-trimoxazole, chloramphenicol, and tetracyclines (116). Although few data have yet been published on this subject for the quinolones, they seldom seem to cause diarrhea and pseudomembranous colitis (131).

Presentation

In pseudomembranous colitis the stools are generally watery, with occult blood loss, which is seldom gross. Common findings include abdominal pain, cramps, fever, and leukocytosis. Especially severe forms can run such a rapid course that diarrhea does not occur; they present with symptoms of severe toxicity and shock (132). As a rare complication, marked dilatation of the colon and paralytic ileus can develop, that is, toxic megacolon.

Pseudomembranes are described as initially punctuate creamy to yellow plaques, 0.2–2.0 cm in size, which may be confluent, with "skip areas" of edematous mucosa. Histologically they are composed of fibrin, mucous, necrotic epithelial cells, and leukocytes.

An acute colitis, different from pseudomembranous colitis, was observed in five patients taking penicillin and penicillin derivatives (133). There was considerable rectal bleeding. The radiographic findings were those of ischemic colitis (spasm, transverse ridging, "thumbprinting," and punctuate ulceration). On sigmoidoscopy and biopsy, the mucosa was normal, except for an inflammatory cell infiltration in one case. Conservative treatment resulted in rapid remission.

Occurrence and frequency

Clostridium difficile has been isolated in 11–33% of patients with antibiotic-associated diarrhea, 60–75% of patients with antibiotic-associated colitis, and 96–100% of patients with pseudomembranous colitis (117,134,135). However, about 2% of the adult population are asymptomatic carriers (127). Primary symptomless colonization with *C. difficile* reduces the risk of antibiotic-associated diarrhea (136). Infants up to 2 years seem to be refractory to pseudomembranous colitis, although a high percentage may be carriers of *C. difficile* (135,137). The reasons for this are unknown. It has been speculated that infants lack receptors for the toxin.

There have been several reports of frequent diarrhea in patients treated with combinations of ampicillin or amoxicillin with beta-lactamase inhibitors, such as sulbactam or clavulanic acid (138–141). A double-blind crossover study in healthy volunteers showed disturbances of small bowel motility after oral co-amoxiclav (142).

The appearance of pseudomembranous colitis in clusters of patients (143–146) may explain the wide variation in occurrence, and suggests that the disease may result from cross-contamination among patients rendered susceptible by antibiotic treatment. This is especially true for epidemic outbreaks in hospitals, where the disease may be considered a nosocomial infection favored by serious illness, frequent and prolonged use of broad-spectrum antibiotics (especially cephalosporins), and poor compliance with the rules of hospital hygiene (147). In such an epidemic, a variable proportion of

© 2006 Elsevier B.V. All rights reserved.

patients will harbor the organism as asymptomatic carriers. An additional possible explanation for the large differences in reported frequencies may be the use of different methods of detection and differences in the definition of the disease. If colonoscopy was routinely performed in all patients with diarrhea taking clindamycin, pseudomembranous colitis was found in as many as 10% (148).

Although the first antibiotics reported to cause pseudomembranous colitis were lincomycin and clindamycin, the disease was later described with all other antimicrobial drugs, even topically applied (149). Vancomycin (150) and metronidazole (151), which may be used as specific treatments, have also been implicated.

Susceptibility factors

Besides the type of antibiotic therapy, other factors such as the age of the patient, the severity of the underlying disease, colonic stasis, cytostatic therapy, surgical interventions, and gastrointestinal manipulations are predisposing factors for antibiotic-associated colitis (152–156).

It is still not established if there is a correlation between toxin production or genotype of the *C. difficile* and the clinical manifestations of the infection (157,158). Although hospital-acquired antibiotic-associated colitis is by far the major problem, community-acquired diarrhea associated with *C. difficile* has also been described (159).

Mechanism

Clostridium difficile produces two well-characterized toxins (124,160)—toxin A, an enterotoxin, and toxin B, an extremely potent cytotoxin—which are thought to be responsible for the disease. The toxigenicity of toxins A and B varies between different strains of *C. difficile* and seems to correlate with symptomatic disease (161). Pseudomembranes were found in a higher percentage of patients with stools positive for cytotoxin than in patients whose stools were positive for *C. difficile*, but toxin-negative (153) Although there is also a high association with *C. difficile* (about 20% are toxin-positive) in antibiotic-associated diarrhea without pseudomembranes, it is possible that this microorganism plays no pathogenic role in some of these usually milder forms of the disease. In these cases the diarrhea may be due to impaired metabolism of carbohydrates, altered fatty acid profiles, or the composition and deconjugation of bile acids by quantitatively and qualitatively altered fecal flora (114,115,135).

Diagnosis

The diagnosis of antibiotic-related colitis should be considered in any patient with severe diarrhea during or within 4–6 weeks after antibiotic therapy. The single best diagnostic procedure is sigmoidoscopy, although in a number of cases the typical pseudomembranous lesions may be seen only above the rectosigmoid area (162). Radiographic investigations (barium enema and air contrast) may show typical findings, but are dangerous in advanced cases and should be avoided. Computerized tomography showed typical but not pathognomonic patterns in two patients (163).

Clostridium difficile can be cultured from the stool, and toxins A and B can be assessed by different techniques (116). The most accurate method is still a cytotoxin tissue culture assay. This detects the cytopathic effect of cytotoxin B, which can be neutralized by *Clostridium sordellii* antitoxin, but it takes 24–48 hours to show a result. Alternative tests that produce faster results have been developed. A latex agglutination test lacks sensitivity and specificity, and does not distinguish toxigenic from non-toxigenic strains. An enzyme immunoassay for toxin A may be an acceptable alternative to the cell cytotoxin assay and the results are rapidly available. A dot immunobinding assay has not yet been extensively studied (164).

Management

Therapy consists of withdrawal of the antibiotic when diarrhea occurs and replacement of fluid and electrolyte losses. In less severe cases of antibiotic-associated diarrhea, no further treatment is needed. However, in patients with pseudomembranous colitis, a more intensive approach is usually required. When a toxic syndrome develops, fluid losses within the bowel can be very large. In these cases, a central venous line offers the chance to measure central venous pressure. Usually there is also loss of serum proteins and in some cases blood, which need appropriate replacement. In the rare cases with fulminant colitis and toxic megacolon, surgical intervention may be necessary (165,166).

In pseudomembranous colitis (typical endoscopic findings, positive test for *C. difficile* or its toxin), the preferred treatment is oral metronidazole, 250 mg qds or 500 mg tds (120,167). Metronidazole is as effective as vancomycin 125–250 mg qds, which is significantly more expensive (168). Oral bacitracin 25 000 U qds (169) and oral teicoplanin (170) are acceptable alternatives.

Relapses are similarly frequent after treatment with metronidazole and vancomycin (116). In 189 adult patients, a first relapse occurred in up to 24% and a second relapse in 46% (169). Relapse may be due to sporulation of *C. difficile* and not to the development of resistance. Relapses usually respond to further courses of the initial treatment. Some alternative treatments have been proposed for repeatedly relapsing cases, including the combination of vancomycin with rifampicin for 10 days (171).

The role of anion exchange resins (colestyramine and colestipol), which bind *C. difficile* toxin, is still controversial (172). If ion exchange resins are given at all, they should not be given together with vancomycin, because they also bind the antibiotic (173). Attempts to restore the intestinal flora with *Lactobacillus GG* (174), or with fecal enemas (175) from healthy volunteers have shown some favorable results in less severe cases. However, esthetic and infectious concerns may be an obstacle. It also has been suggested that treatment with *Saccharomyces boulardii* may help prevent the development of antibiotic-associated diarrhea (176). Its value in the prevention and treatment of relapses has still to be demonstrated. Antimotility agents have been associated with an increased incidence of antibiotic-related diarrhea and can worsen symptoms when the disease is already established (177). They should therefore be avoided.

© 2006 Elsevier B.V. All rights reserved.

There is little evidence that re-exposure to the same antibiotic that caused pseudomembranous colitis confers a further risk for relapse. Still, it would be wise to avoid the antibiotics that are most often related to pseudomembranous colitis in a patient who has had this complication.

Liver

Increases in serum transaminases and alkaline phosphatase, largely without additional symptoms, have been reported with the majority of beta-lactam antibiotics. With different compounds the estimated frequencies vary by up to a factor of 10. However, the frequency also depends on patient-related factors; in one study only a minority of transaminase increases could not be explained by factors other than antibiotic treatment (86).

More severe liver disease, presenting as hepatitis and/or intrahepatic cholestasis, has been seen with beta-lactam antibiotics of various classes, the isoxazolyl penicillins being most frequently involved. Co-amoxiclav has repeatedly been associated with cholestatic hepatitis.

Hepatitis is accompanied by fever, eosinophilia, and/or a rash in more than 80% of cases. This hints at the possibility of overlapping pathogenetic steps and sheds some doubt on the reliability of these accompanying symptoms as indicators of immune-mediated reactions, for example serum sickness-like syndromes.

One type of hepatitis is mainly associated with oxacillin (178,179). Eight of 54 patients developed this reaction after a mean cumulative dose of oxacillin 157 g (180).

Prolonged duration of treatment and increasing age were risk factors for flucloxacillin-induced jaundice (181), and cholestatic liver injury has been described most often with flucloxacillin (182,183) and other isoxazolylpenicillins (184). Whether cholestatic hepatitis after the combination of amoxicillin with clavulanic acid (co-amoxiclav) is related to one of these categories is not yet clear.

Urinary tract

Methicillin-induced acute interstitial nephritis follows a similar pattern of dose-dependence and time-dependence to that of neutropenia (185,186). This reaction occurred in 16% of all children treated with high-dose methicillin (187). Nephritis occurred after a mean of 17 days and a mean cumulative dose of 120 g.

With other beta-lactams, mainly penicillin G, acute interstitial nephritis is rare, but it can follow the same pattern (188).

Nephritis is accompanied by fever, eosinophilia, and/or a rash in more than 80% of cases. This hints at the possibility of overlapping pathogenetic steps and sheds some doubt on the reliability of these accompanying symptoms as indicators of immune-mediated reactions, for example serum sickness-like syndromes.

Acute renal insufficiency, with or without skin rash and eosinophilia, has been reported with various beta-lactam antibiotics, most often with methicillin. Hence, the designation "methicillin-nephritis" is still sometimes used. The pathogenesis is largely unknown and is different from the nephrotoxicity of older cephalosporins (cefaloridine and cefalotin).

Skin

Rashes are among the most common adverse reactions to drugs in general and occur in 2–3% of hospitalized patients (189). Most distinct mucocutaneous reactions that can be induced by drugs have been associated with the use of individual beta-lactam antibiotics. These reactions include urticaria, angioedema, maculopapular rash, fixed drug eruption, erythema multiforme, Stevens–Johnson syndrome, toxic epidermal necrolysis, allergic vasculitis, serum sickness-like syndrome, eczematous lesions, pruritus, and stomatitis (190–193). The maculopapular rash, starting on the trunk or areas of pressure or trauma, is more frequent than all other skin manifestations together (189,194). Involvement of mucous membranes, palms, and soles is variable; the eruption can be associated with moderate to severe pruritus and fever. In addition, an indistinguishable rash often accompanies various reactions in other organs.

Pustular drug eruptions due to penicillin (195), amoxicillin (196), ampicillin (197), bacampicillin (198), cefazolin (199,200), cefradine (201), cefalexin (202), cefaclor (203), or imipenem + cilastin (204) seem to form a distinct clinical entity that has to be differentiated from pustular psoriasis, which can be drug-induced as well (204). A history of drug exposure, rapid disappearance of the eruption after the drug is stopped, and eosinophils in the inflammatory infiltrate argue in favor of pustular drug eruptions.

In patients with mononucleosis, aminopenicillins, and, less so, cephalosporins evoke rashes in a much higher percentage than usual (205). The incidence of rashes in infectious mononucleosis without antibiotics is 3–15%, compared with 40–100% with ampicillin. The underlying mechanism is speculative.

Immunologic

The adverse effects of early penicillin use consisted almost exclusively of anaphylaxis. This stimulated extensive research into the immune responses associated with penicillin and made penicillin the most prominent model for immune reactions to drugs.

The pathogenesis of many presumably immunologically mediated reactions to beta-lactam antibiotics is still unknown. Reliable and standardized tests to predict hypersensitivity only exist for a minority of allergic reactions, that is, IgE-mediated reactions. The matter is further complicated by the fact that beta-lactams can readily induce immune responses that by themselves do not necessarily result in disease. This is the case, for example, when antierythrocyte antibodies directed against beta-lactam bound to the erythrocyte surface are formed. This biological property (immunogenicity) has to be distinguished from allergenicity, that is, immune responses causing disease.

Cross-reactivity, that is, hypersensitivity reactions initially induced by one compound but triggered by another, is an important and as yet unresolved problem, complicated by the fact that beta-lactams undergo structural

© 2006 Elsevier B.V. All rights reserved.

modifications after administration, and that different parts of the molecule (such as the nucleus or side chains) can be involved. Data from cross-exposed patients (skin tests or drug challenge) suggest a high degree of cross-reactivity between compounds belonging to the same class and between the penicillins and carbapenems, but a low degree of cross-reactivity between penicillins and cephalosporins and between monobactams and the other beta-lactams.

Mechanisms

Drug allergy or hypersensitivity represents an acquired capacity of the organism to mount an immunologically mediated reaction to a compound. This ultimately involves covalent or exceptionally non-covalent binding to and modification of host molecules (presumably proteins) by the drug, to which the host becomes sensitized (induction phase). Re-exposure to the sensitizing drug can trigger a series of immunological effector mechanisms (effector phase). These can be defined as pathways of inflammation or tissue injury, but they also represent mechanisms of immune protection from infectious agents.

Traditionally, the classification scheme defined by Gell and Coombs (206) distinguishes four types of reactions:

- type I reactions, which are IgE-mediated immediate hypersensitivity reactions.
- type II reactions, which are mediated by cytotoxic IgM and/or IgG.
- type III reactions, which are mediated by immune complexes.
- type IV reactions, which are cell-mediated hypersensitivity responses.

However, this classification fails to account for the complex and sequential involvement of several cell types and mediators in the immune response, as recognized today (207).

IgE-antibody-mediated adverse reactions

IgE-antibody-mediated hypersensitivity can serve as a paradigm to demonstrate some important features of beta-lactam hypersensitivity. Beta-lactams are small molecules that have to combine with a host macromolecule to be recognized by the immune system. In the case of penicillin, this reaction involves coupling of reactive degradation products to a protein-containing carrier (208). There are several degradation pathways, which result in the formation of reactive compounds, most importantly penicilloyl (209), also called the major determinant. Other less abundant degradation products include penilloate, benzylpenicilloate, and benzylpenilloate, the so-called minor determinants.

The complex contains haptens, often multiple, coupled to a protein-containing carrier molecule, and can induce T cell-dependent B cell activation, leading to the formation of antihapten antibodies. The mechanisms that govern the selection of the different immunoglobulin isotypes are reviewed elsewhere (207).

The time required for sensitization is called "latency" and is variable, depending on factors such as route of exposure, hapten dose, and chemical reactivity of the drug, as well as on genetic and acquired host factors. The period between the last exposure to the drug and the first appearance of symptoms has been termed the "reaction time." It is part of the clinical description of an adverse event and may help to attribute it to a specific drug (SED-12, 594).

Once sensitivity has been established, that is, once hapten-specific IgE-producing B cells have been formed, exposure to even small amounts of hapten can induce a cascade of events that lead to immediate reactions, such as anaphylaxis (210). Briefly, preformed IgE antibodies to drug determinants recognize the hapten-carrier complex and fix to the surface of mast cells or basophils, triggering the release of a series of mediators, such as histamine, neutral proteases, biologically active arachidonic acid products, and cytokines. This ultimately leads to a clinical spectrum that ranges from a mild local reaction to anaphylactic shock.

Non-IgE-antibody-mediated immunological reactions

Modification of erythrocyte surface components due to binding of beta-lactams or their metabolic products is thought to be the cause of the formation of antierythrocyte antibodies and the development of a positive Coombs' test implicated in the development of immune hemolytic anemia (211). About 3% of patients receiving large doses of intravenous penicillin (10–20 million units/day) will develop a positive direct Coombs' test (212). However, only a small fraction of Coombs' positive patients will develop frank hemolytic anemia (213). Antibody-coated erythrocytes are probably eliminated by the reticuloendothelial system (extravascular hemolysis) (214), or less often by complement-mediated intravascular erythrocyte destruction (215). Another mechanism implicates circulating immune complexes (anti-beta-lactam antibody/beta-lactam complexes), resulting in erythrocyte elimination by an "innocent bystander" mechanism (82). Similar mechanisms have been implicated in thrombocytopenia associated with beta-lactam antibiotics (216,217).

Contact dermatitis was often observed when penicillin was used in topical formulations and still continues to be described in cases of occupational exposure to beta-lactams (218,219). The underlying mechanism is thought to involve chemical modification of antigen-presenting cells in the epidermis, leading to sensitization of drug-specific T cells (220,221).

The underlying mechanism of a series of clinical entities associated with beta-lactams, such as maculopapular rash, drug fever, eosinophilia, serum sickness-like disease, vesicular and bullous skin reactions, erythema nodosum, and acute interstitial nephritis, is suspected to be immunological but is still largely unknown.

Reactions specific to side chains

Side chain–specific allergic reactions to beta-lactams are a steadily increasing problem (SEDA-21, 260) (222–224). Apart from epitopes generated by the beta-lactam nucleus, side chains attached to it can serve as additional epitopes recognized by the host immune response. Side chain–specific antibodies can be detected in patients who are allergic to beta-lactam antibiotics, even in the absence of reactivity to the mother compound. The clinical

© 2006 Elsevier B.V. All rights reserved.

importance of this is debated. Serious anaphylactic reactions to amoxicillin occurred in three patients who tolerated benzylpenicillin (225). The phenomenon is mostly relevant for patients given semisynthetic penicillins, cephalosporins, carbapenems, and monobactams: compounds derived from each of these classes of drugs share certain side chains that may be cross-recognized by preformed antibody. Diagnosis of side chain–specific allergy requires a panel of diagnostic tools available only at selected research centers.

Pseudoallergy

The term "hypersensitivity" includes both immunoallergic and pseudoallergic reactions. Immunoallergic reactions occur when highly specific mechanisms involving immunological memory and recognition are involved. Pseudoallergic reactions are reactions that mimic immunoallergic reactions, but in which a specific immune-mediated mechanism is not involved. The so-called ampicillin rash is an example of a pseudoallergic reaction. Some major mediators of pseudoallergic reactions have been reviewed (226). The roles of newer putative mechanisms, involving cytokines, kinins, and other host-derived substances, remain to be ascertained. Most important is the fact that currently there are no standardized and validated animal models for predicting pseudoallergic reactions (227).

Animal models

Guinea pigs have been used for years in studies of systemic anaphylaxis. However, variations in predictability and sensitivity limit their value (228,229). Passive cutaneous anaphylaxis is another guinea pig model, but it is no more sensitive than systemic anaphylaxis (228). Respiratory sensitization, resulting in IgE-mediated immediate hypersensitivity has been investigated in mice and guinea pigs (230,231). Most often highly reactive chemicals have been used, and the models are of limited value in testing antimicrobial drugs.

Contact sensitizers have been studied in guinea pigs and mice, and it has been stated that "these models can reasonably identify the majority of human contact sensitizers" (227).

The best approach to induce a specific immune response against substances of low molecular weights is to use hapten-carrier conjugates. This method is of value in assessing the potential for cross-reactivity between closely related compounds, such as beta-lactam antibiotics (232).

It is obvious that the development of new animal models, for example transgenic and knock-out mice, should create new possibilities for predicting the sensitizing potential of new antimicrobials. The sad fact that hypersensitivity reactions are among the most commonly occurring adverse effects when antibiotics are used underlines the urgent need for research efforts in academia and industry (227).

Incidence

The true incidence of immunologically mediated reactions to beta-lactam antibiotics is hard to evaluate. This is mainly because of problems associated with the case definition of hypersensitivity reactions. The pathogenetic mechanism for a significant number of reactions presumed to be immunological in nature has not yet been conclusively determined. Furthermore, studies that address the incidences of adverse reactions face the problem of dealing with heterogeneous patient populations, treated with different types of beta-lactams, and administered by diverse routes in various dosages. The issue can be illustrated by reviewing data derived from four pharmacoepidemiological studies.

1. The International Rheumatic Fever Study, a prospective multicenter study that recorded allergic reactions, defined as hypotension, dyspnea, pruritus, urticaria, angioedema, arthralgia, and maculopapular rash in 1790 patients treated with monthly intramuscular benzathine penicillin for prophylaxis of rheumatic fever (32 430 injections during 2736 patient years). There was a 3.2% case incidence of allergic reactions and a 0.2% case incidence of anaphylaxis (12/100 000 injections), including one death (0.05%, equivalent to 3.1/100 000 injections) (233).
2. A large national study by venereal disease clinics in the USA, including four cooperative surveys conducted at 5-year intervals (1954, 1959, 1964, and 1969). The study included data from 94 655 patients unselected with regard to a history of penicillin allergy. The frequency of anaphylaxis was 0.055%, including one death (234).
3. A retrospective analysis of allergic reactions (drug-induced fever and rash) in 90 adults with cystic fibrosis, of whom 26 developed probable allergic reactions to parenteral beta-lactams. There was drug-induced fever in 54 and skin reactions in 28 of 897 treatment courses (6 and 3.1% respectively). There was one case of non-fatal anaphylaxis. The numbers of allergic reactions per number of patients receiving specific antibiotics were: carbenicillin 4/56, mezlocillin 7/42, piperacillin 11/31, ticarcillin 1/20, cefazolin 0/24, ceftazidime 1/35, imipenem + cilastatin 4/16, and nafcillin 3/36 (17).
4. The Boston Collaborative Drug Surveillance Program. In this classic study in in-patients during 1966–82, beta-lactams headed the list of drugs causing skin reactions, presumably allergic. The overall reaction rate (the number of drug-related skin reactions per 1000 treated patients) was 51 for amoxicillin, 42 for ampicillin, 29 for semisynthetic penicillins, 16 for penicillin G, and 13 for cephalosporins (18,193).

These four sets of data illustrate a spectrum of diverse settings of beta-lactam administration: single-dose parenteral use (in venereal disease clinics), intermittent parenteral use (in rheumatic fever), and continuous high-dose parenteral use (in cystic fibrosis). Factors other than route of administration and dosing, such as drug history, underlying disease, co-administered drugs, and the risk profile of a particular compound, will be important in assessing the risk of giving a beta-lactam to a particular patient, as discussed in more detail below.

Table 1 contains a list of presumably immunologically mediated effects of beta-lactams, according to their estimated frequencies. The mechanisms of most of these reactions are not completely understood, which implies that some of the entities listed may be due to non-immunological mechanisms. The frequencies of the

© 2006 Elsevier B.V. All rights reserved.

various adverse effects vary among different beta-lactams and depend on additional factors, discussed below. A compilation of reported frequencies of occurrence related to different compounds has been published and was used and extended to prepare Table 1 (194).

Presentation

The requirement for sensitization explains why a drug may be administered for a variable length of time without adverse effects. Once the organism is sensitized, the manifestation of hypersensitivity will depend on the route and dose of the allergen as well as the type of effector mechanism involved, preformed IgE being the most rapid, others evolving more slowly, typically over days. Generally much less drug is required to trigger a hypersensitivity reaction in a sensitized subject than for induction. Anaphylactic reactions have been described after ingestion of meat from penicillin-fed animals or after sexual intercourse in a penicillin-sensitive patient (269,270).

The time for sensitization to occur is often difficult to establish in a patient who develops symptoms during continuous therapy. A classification scheme that distinguishes between immediate, accelerated, and late reactions is of limited clinical use, since it will only allow distinction between IgE-mediated reactions (that is, rapid reactions) and non-IgE-mediated reactions (that is, more slowly evolving reactions) in the setting of re-exposure of a sensitized subject (80).

In contrast to hypersensitivity, other adverse reactions do not require sensitization and require similar doses of drug for recurrence. A special case is a syndrome (Hoigné's syndrome) that resembles an immediate allergic reaction combined with hallucinations, aggressive behavior, anxiety, and auditory and visual disturbances, which has been described after intramuscular procaine penicillin and benzathine penicillin. It is probably due to accidental intravascular injection and results from microembolism of the penicillin depot formulation (271–275).

Susceptibility factors

Several factors that influence hypersensitivity have been recognized and reviewed (276).

Patient-related factors

Patient-related factors include an increased incidence of allergic reactions to beta-lactams in patients with systemic lupus erythematosus (277) but not with atopic diseases (278). Genetic factors that influence drug metabolism and excretion, as well as the underlying disease of the patient and host immune reactivity, are likely to modulate the risk and severity of hypersensitivity reactions.

Table 1 Presumably immunologically mediated adverse reactions to beta-lactams

Adverse reaction	References
Expected in one or more of 100 treatment courses	
Maculopapular rash[a]	(193,194,235)
Expected once in 100–1000 treatment courses	
Urticaria, angioedema	(80,194,235,236)
Drug fever[b]	(17,237)
Eosinophilia[c]	(238–240)
Expected once in 1000–10 000 treatment courses	
Anaphylactic shock	(210,241,242)
Bronchospasm and acute severe dyspnea	(243,244)
Thrombocytopenia	(91,245)
Serum sickness-like disease	(246–249)
Vasculitis	
Expected less than once in 10 000 treatment courses	
Hemolytic anemia	(81,82,250–253)
Vesicular and bullous skin reactions (including Stevens–Johnson syndrome and toxic epidermal necrolysis)	(254,260)
Erythema multiforme[d]	(257,261)
Erythema nodosum[e]	(257,261)
Interstitial nephritis[f]	(262)
Observed after occupational exposure	
Contact sensitivity	(219,263)
Anaphylaxis	(210)
Asthma, pneumonitis	(264–268)

[a] Occurs with all beta-lactams; more often with aminopenicillins, penicillinase-resistant penicillins, and anti-*Pseudomonas* penicillins
[b] Occurs with all beta-lactams; probably more often with piperacillin + tazobactam and aztreonam
[c] Occurs with all beta-lactams; probably more often with meticillin, nafcillin, oxacillin, second- and third-generation cephalosporins, aztreonam, and imipenem
[d] Occurs with all beta-lactams; probably more often with penicillins G and V, antipseudomonal penicillins, cefaclor, cefadroxil, cefalexin, loracarbef, aztreonam, and imipenem
[e] Occurs probably with all beta-lactams, but more often with penicillins G and V, cefuroxime, cefoperazone, cefaclor, and imipenem
[f] Occurs probably with all beta-lactams; well documented for methicillin

© 2006 Elsevier B.V. All rights reserved.

A history of a prior penicillin reaction increases the risk of a subsequent exposure. A classic study showed a frequency of allergic reactions to penicillin of 0.62% (155 of 24 906 treatment courses) in patients without a history of penicillin allergy compared with 13% (10 of 78 treatment courses) in patients with a history of penicillin allergy (234). Reaction rates are higher in patients with a history that suggests IgE-mediated reactions (279).

Patients with chronic lymphatic leukemia or with concurrent infection with Epstein–Barr virus or HIV have an increased frequency of ampicillin- and amoxicillin-associated rashes (280).

Drug-related factors

Drug dosage, mode of administration, and duration of treatment probably influence the frequency of allergic reactions. Topical administration has been associated with a high incidence of sensitization, in contrast to a low incidence with the oral route. For IgE-mediated reactions, a frequent and intermittent course of treatment is more likely to cause allergy than a prolonged course without a drug-free interval (208). High doses of parenteral beta-lactams are usually required for the induction of penicillin-induced hemolytic anemia (212). Similarly, it is likely that the high dosages of beta-lactams used in patients with cystic fibrosis result in a high incidence of drug fever (17).

Co-administration of beta-blockers has been associated with an increased risk of severe allergic drug reactions and reduces the effect of adrenaline in the immediate treatment of anaphylactic shock. The mechanism involves changes in the regulation of anaphylactic mediators (281).

Evidence that allopurinol potentiates skin reactions to ampicillin is controversial (192,282).

Long-Term Effects

Drug resistance

The introduction of penicillin G more than 50 years ago was one of the milestones in the treatment of infectious diseases, leading to a drastic reduction in mortality from severe infections (283–285). Two years later the emergence of the first penicillin-resistant *Staphylococcus aureus* rapidly cooled clinicians' enthusiasm. Since then microorganisms have developed various mechanisms to survive antibiotic pressure, including the following:

1. Modification of the targets of beta-lactam antibiotics, that is, the penicillin-binding proteins (286,287), resulting in a reduced affinity of the antibiotic.
2. The synthesis of new penicillin-binding proteins with very low affinity for the antibiotic, providing a high degree of resistance.
3. The production and secretion into the periplasmic space of beta-lactamases, that is, enzymes sharing structural analogies with the penicillin-binding proteins without fulfilling any function in the cell wall synthesis but hydrolysing and inactivating the beta-lactam ring. The genes encoding for these beta-lactamases are usually located on a plasmid but can also be anchored in the bacterial genome (288,289).
4. Structural modification of porines, proteins that form channels in the outer membrane of Gram-negative bacteria, preventing the antibiotics from reaching the penicillin-binding proteins by impairing their penetration through channels of the outer membrane (290,291).

All of these mechanisms are mainly based on interbacterial exchange of DNA or on point mutations (292), the predominant mechanisms for genetic exchange being transformation, transduction, and conjugation (293). Transformation is the simplest way to transfer DNA to another bacterium, provided that this is ready to accept foreign DNA (= competent bacteria). This mechanism of genetic transfer is mostly used by several human pathogens: *Streptococcus pneumoniae*, *Hemophilus influenzae*, *Neisseria meningitidis*, *Neisseria gonorrhoeae*, and *Bacillus subtilis*. The transduction needs a bacteriophage (a virus) as a vector to inject DNA into a bacterium. This elaborate system is limited by the restricted specificity of the vectors for few microorganisms. The most sophisticated system is conjugation. This mechanism was first observed in *E. coli* in 1952 by Hayes, who described the first transfer of genetic material (F-Factor, or fertility factor) by conjugation (294). Microorganisms use conjugation to transfer several types of genetic material, either extrachromosomal (that is, plasmids) or intrachromosomal (that is, transposons).

In summary, microorganisms can exchange and acquire genetic material in order to adapt to a changing environment, the antibiotic pressure. Furthermore, DNA exchange between prokaryotes and eukaryotic cells (yeasts) and some plants has been observed (295). A review has addressed in detail the problem of emergence and spread of resistance among clinical isolates (296). Here we shall only briefly discuss as examples the development of resistance by two major pathogens, *S. pneumoniae* and *S. aureus*.

One of the most striking features in microbiology is the rapid emergence and worldwide spread of penicillin-resistant *S. pneumoniae* (pneumococci), mainly due to the uncontrolled use of penicillin in certain countries (297). The first cases of penicillin-resistant pneumococci were reported in the 1960s in New Guinea and Australia. Penicillin-resistant pneumococci have now been registered in all continents. The highest rate was reported in 1989 in Hungary, amounting to 57% of all clinical isolates (298). Until now, pneumococci have not acquired the genes encoding for beta-lactamases. Accordingly, the underlying mechanism of penicillin resistance is structural modification of penicillin-binding proteins, leading to reduced affinity to the penicillin molecule (see above). These modifications of the penicillin-binding protein usually require several genetic steps. Moreover, horizontal transfer of pieces of penicillin-binding protein genes has been described between *Streptococcus mitis* and *Streptococcus pneumoniae* (299). Such modifications of penicillin-binding proteins lead to reduced affinity of these enzymes for their natural substrates (disaccharide-pentapeptides) (300) and eventually to the synthesis of a structurally different cell wall harboring more branched peptides. This is the biological price that pneumococci pay to survive antibiotic pressure (301). Usually in an

© 2006 Elsevier B.V. All rights reserved.

epidemic area a few clones of penicillin-resistant pneumococci are responsible for the majority of the registered cases (302). Furthermore, DNA polymorphism analysis has shown that isolates have been imported from one continent to another, causing new epidemics (303–306).

Another major pathogen *S. aureus* has developed two different mechanisms of resistance:

- synthesis of beta-lactamase (nowadays more than 80% of *S. aureus* secrete beta-lactamase).
- the emergence of so-called methicillin-resistant *S. aureus* (MRSA), which can grow even in the presence of high concentrations of methicillin (up to 800 μg/ml).

The unique feature of MRSA is based on the acquisition of a low-affinity penicillin-binding protein for beta-lactam antibiotic molecules (the penicillin-binding protein 2A), which allows the bacteria to carry on synthesis of its cell wall, whereas the other penicillin-binding proteins are already inactivated by the high concentration of methicillin or other beta-lactamase-resistant beta-lactam antibiotics.

The origin of the penicillin-binding protein 2A is a matter of debate. Until now the only antibiotics that inhibit MRSA are the glycopeptides, such as vancomycin. A nightmare scenario would be the transfer of vancomycin resistance from enterococci to MRSA, which would cause a major epidemiological and therapeutic problem in the treatment of staphylococcal infections. There have been a few cases of vancomycin-resistant coagulase-negative *S. aureus* (307,308), but none of vancomycin-resistant MRSA, although transfer of vancomycin resistance to staphylococci has been achieved experimentally (309).

The continuous spread of resistance among clinical isolates, especially of multiresistant microorganisms represents a unique challenge in the treatment of infectious diseases. The detection of asymptomatic carriers of pneumococci, especially young children in day care centers, makes early detection even more difficult (310). Uncontrolled use of antibiotics in agriculture selects multiresistant fecal flora in animals, and meat can be contaminated by imperfect processing.

The problem of increasing resistance of micro-organisms is a major worldwide issue that necessitates close collaboration of clinicians, epidemiologists, and basic research laboratories. Newer and fast diagnostic tools (such as the polymerase chain reaction), routinely introduced into clinical laboratories, and better understanding at the molecular level of mechanisms of resistance of microorganisms are key prerequisites for the prevention of further spread of resistant microorganisms. Additional measures, for example broad use of vaccines and restrictions on antibiotic use imposed by health authorities, will require global cooperation and will have to be addressed by international organizations such as the WHO.

Second-Generation Effects

Teratogenicity

Since the days of the thalidomide disaster about 40 years ago, resulting in the birth of some thousands of malformed babies, it has been well recognized that drugs taken by pregnant mothers can have severe adverse effects on their unborn children. A consequence of the thalidomide disaster was worldwide awareness that drugs can cause congenital malformations and the necessity to investigate this possibility in animals. Since thalidomide, around 30 drugs have been proven to be teratogenic, not all of which are currently in clinical use (311). For most drugs, however, safety in pregnancy has still to be established. With the risk of teratogenicity and dysmorphogenesis ever present, clinicians are in general very cautious in prescribing drugs for pregnant women. Despite this, over 60% of pregnant women consume therapeutic agents not directly related to their pregnancy, and it has been estimated that about 5% of birth defects are caused by maternal drug therapy (312).

Even if a drug is generally recognized as being safe after animal experiments, it is wise to be suspicious when giving it to a pregnant woman. One major obstacle in evaluating safety in humans is the sample size required to reach sound conclusions. For example, in Europe, neural tube defects and cleft lips both occur with a prevalence of around seven per 10 000 live births (313). It has been calculated that for an uncommon drug exposure (that is, a frequency of under one per 1000 pregnant women and a background malformation prevalence of 0.001), one would have to monitor more than 1 000 000 births in order to detect a teratogenic effect, even though the relative risk associated with the drug might be as high as 20 (that is, a 20-fold increased risk of a particular malformation). In contrast, for formulations that are commonly used in pregnancy (for example by 2% of women, as was the case with thalidomide) and that are associated with an extremely high relative risk (such as 175), 1000 births would be sufficient to detect the teratogenic potential, even when the background prevalence of the malformation was as low as 0.0024 (314).

Another issue that has to be taken into consideration is the temporal relation between drug exposure and the effect on the embryo or fetus (315). Exposure to harmful drugs in the 2 weeks after conception usually leads to abortion, which may not be noticed. In the next 6–7 weeks the embryo is assumed to be extremely sensitive to teratogens (316). However, different organs and systems may be susceptible to teratogens at different times during this period. Therefore, in order to link drug use during pregnancy to a congenital malformation, drug intake must have taken place when the organ or organ system was sensitive to its harmful effects (315). It goes without saying that exact information on the timing of exposure is crucial.

In an ideal world, no drug would become available before it had been thoroughly tested for safety and effectiveness in a randomized, double-blind, placebo-controlled trial in pregnant women (317). However, because of ethical concerns about the welfare of the mother and fetus, pregnant women are traditionally excluded from drug trials. Therefore, usage is most often based on indirect measures of safety, such as in vitro studies and animal models. However, the thalidomide affair reminds us of the potential inadequacy of animal models.

In reality, most information about the safety of antimicrobial drugs in pregnancy comes from a history of long-term use with no reported adverse outcomes. As has been emphasized (317) most practitioners are happy

© 2006 Elsevier B.V. All rights reserved.

to prescribe penicillin and its derivatives although there are no data from formal trials. However, there are data that show that penicillin V is safe during pregnancy (318). The study took place in Hungary between 1980 and 1996. The case group consisted of 22 865 malformed infants or fetuses, of whom 173 (0.8%) had mothers who had taken penicillin V during pregnancy. Two control neonates without malformations were matched with every case according to sex, week of birth, and the district of the parent's residence. Of the 38 151 infants in the control group, 218 had been treated with penicillin V. This difference was explained mainly by recall bias and confounders, because there was no difference in the adjusted odds ratio for medically documented phenoxymethylpenicillin treatment during the second and third months of gestation, that is, during the critical period for most major congenital abnormalities in case-matched control pairs. Thus, treatment with oral phenoxymethylpenicillin during pregnancy presents very little, if any, teratogenic risk.

There have also been two studies of the teratogenic potential of other penicillins. In the first study, in 791 women who had redeemed a prescription for pivampicillin during their first pregnancy, birth outcomes (malformations, pre-term delivery, and low birth weight) were matched with similar outcomes in 7472 reference pregnancies in which the mother had not redeemed any prescription for pivampicillin during pregnancy (319). There were no significant effects of pivampicillin. In the second study, in 78 women who took cefuroxime axetil during pregnancy, none of the 13 women who were treated in the first trimester gave birth to a malformed child, but one baby with hip dysplasia was found among 20 babies from mothers treated in their second trimester, and there was one case of hypospadias and one of imperforate anus in 47 children of mothers treated in the third trimester (320). The authors correctly concluded that the number of patients who had taken cefuroxime in the first trimester of pregnancy was small, and that cefuroxime should be used with caution in the early months of pregnancy.

Susceptibility Factors

Renal disease

Renal insufficiency is a risk factor for the toxic effects of the beta-lactams (321,322), including neurotoxic reactions (323), inhibition of platelet aggregation (324), and to some extent interaction with vitamin K-dependent synthesis of coagulation factors (325).

Drug–Drug Interactions

Antacids

Antacids increase gastric pH and can result in impaired dissolution of some cephalosporins (326–328).

Anticoagulants

Some beta-lactam antibiotics impair coagulation by inhibiting hepatic and intestinal vitamin K production and impairing platelet function.

- A patient suffered significant postoperative bleeding 4 days after dental surgery in a patient taking amoxicillin, despite the use of a tranexamic acid (4.8%) mouth rinse to control hemostasis (329).

Interactions with drugs that affect coagulation and platelet function must therefore be borne in mind.

- A 58-year-old woman developed a raised INR and microscopic hematuria while taking warfarin and co-amoxiclav (330). This was attributed to an interaction of the two drugs.

In contrast, some penicillinase-resistant penicillins (dicloxacillin, nafcillin) provoke resistance to warfarin, lasting for up to 3 weeks after withdrawal of the antibiotic (331,332).

- A patient experienced the effects of interactions of warfarin with nafcillin and dicloxacillin (333). During co-administration of nafcillin, warfarin doses were increased to as much as 4.5 times the previous amounts needed to provide adequate anticoagulation. During co-administration of dicloxacillin, warfarin doses gradually fell, but still stabilized at a higher maintenance dose than before.
- A 41-year-old man taking warfarin 22 mg/week with a prothrombin time of 20.7 seconds was given dicloxacillin 500 mg qds for 10 days (331). The prothrombin time and S- and R-warfarin concentrations fell by 17, 25, and 20% respectively after 5 days. In a retrospective review of seven other patients, the mean prothrombin time fell by 17% (range 11–26%) within 4 days of starting dicloxacillin.

This type of interaction may be due to induction of warfarin metabolism.

Digoxin

In 10% of patients taking digoxin, there is inactivation of up to 40% of the drug before absorption, by intestinal *Eubacterium lentum*. This can be reversed by antibiotics (334,335). The lack of effects of some beta-lactam antibiotics on serum digoxin concentrations in one study (336) might have been due to the small sample size or resistance of the bacteria.

Nifedipine

An active dipeptide transport system that depends on hydrogen ions takes up non-ester amino-beta-lactams (penicillin, amoxicillin, and oral first-generation cephalosporins) (337–339) and specific cephalosporins that lack the alpha-amino group (cefixime, ceftibuten, cefdinir, cefprozil) (340,341). Nifedipine increases amoxicillin and cefixime absorption, probably by stimulating the dipeptide transport system, since the serum concentrations of passively absorbed drugs and intestinal blood flow did not change (342–344).

Oral contraceptive steroids

There have been anecdotal reports that oral antibiotics reduced the efficacy of oral contraceptives. The proposed mechanism is that the antibiotics reduce the amount of gut bacteria that normally deconjugate excreted estrogens

© 2006 Elsevier B.V. All rights reserved.

prior to reabsorption. However, in small formal studies this effect has not been confirmed (345–347). It is nevertheless possible that this is the mechanism, but that it occurs in too few women to be detected in small formal studies.

As early as 1971, it was observed that there was an increased incidence of intermenstrual bleeding in women who were reliably taking oral contraceptives and rifampicin for tuberculosis (348). Subsequent studies showed that pregnancy was a possible adverse effect of the combined use of antibiotics and oral contraceptives, the most commonly involved antimicrobial drugs being ampicillin, co-trimoxazole, and tetracyclines (349). In an analysis based on reports to the Committee on Safety of Medicines in the UK between 1968 and 1984, 63 pregnancies were identified in women taking this combination of drugs (345). Tetracyclines and penicillin were the drugs most often involved. However, the question of under-reporting was underlined. Over the years, there have been a few reports of the possibility of ineffectiveness of oral contraceptives during the use of antimicrobial drugs.

- A healthy 21-year-old woman, using an oral contraceptive, became pregnant while taking minocycline 100 mg/day for acne (350).

At least three different mechanisms have been proposed.

1. Antibiotics, for example rifampicin (SEDA-8, 256), interfere with the hepatic metabolism of the compounds in oral contraceptives.
2. Antibiotics increase gastric emptying and small intestinal motility. This in turn alters gastrointestinal absorption (and reabsorption) of oral contraceptives (probably both estrogens and progestogens). Increased gastrointestinal motility has been best studied in relation to macrolide antibiotics (SEDA-18, 269). However, there is no evidence of reduced efficacy of oral contraceptives through an effect of macrolides on gastrointestinal motility, which is in any case an unlikely mechanism.
3. Antibiotics interfere with the normal flora in the gastrointestinal tract, thereby also interfering with the normal enterohepatic circulation of the compounds that are included in oral contraceptives. This is a complex story. Oral contraceptives contain estrogens and progestogens. There are several different derivatives in each group and the amounts of each compound vary from formulation to formulation. However, most (if not all) of the compounds have an enterohepatic circulation—they are excreted into the bile, usually as conjugates, and are reabsorbed from the intestinal tract. The efficacy of their absorption and reabsorption depends on physicochemical factors in the gut (such as pH, conjugated versus unconjugated compounds, and adsorption to microbes and dietary constituents). In addition to this basic physiological circulation, intestinal microbes interact with the compounds, most often by splitting conjugates, but also by acting on double bonds, hydroxyl groups, and keto groups, present in the original compounds. These derivatives may have different absorption rates from the original ones. Partly because of their complexity, these microbial interactions have been very little studied. However, it is well known that microbes interfere with the enterohepatic circulation of other molecules with similar structures, such as androgens (SEDA-13, 215) (SEDA-16, 262) and bile acids (351). A similar effect can take place in patients with gastrointestinal bacterial infections. In addition, and at least from a theoretical point of view, an effect on this enterohepatic circulation may also occur in individuals with a high load of living microbes, as is the case when ingesting probiotics (products that contain live bacteria such as Bifidobacterium and Lactobacillus). This possibility has not been adequately addressed by any of the companies that sell tons of probiotics to fertile women taking oral contraceptives.

Given the problems of under-reporting, the lack of proper investigations, and the possibility of an unwanted pregnancy, the concern can be reduced to a practical one: what should women be told? An excellent recommendation has been published in the UK (352): "Your doctor has prescribed antibiotics, which are necessary to treat [your] infection. However, the antibiotics can interfere with the pill and make it less effective. This means that you may not be protected from pregnancy if you have sex, even though you are taking the pill. You are advised that you should take precautions, that is use of a condom, during the time you are taking the antibiotics, and for 7 days after completing the course of antibiotics ···" For the time being, this is the best advice. However, more investigations in this important field are needed.

Phenobarbital

There was an unexpectedly high frequency of adverse effects in a pediatric intensive care unit with the combination of high-dose phenobarbital and beta-lactam antibiotics, mainly cefotaxime (353). The reactions, which mostly affected the skin and blood, were only rarely reproduced by a single component, suggesting an interaction. However, these findings have not been confirmed, and their impact is unclear.

Probenecid

Probenecid inhibits the tubular resorption of anions and inhibits the renal excretion of most beta-lactam antibiotics (354,355).

Vecuronium

There are various conflicting reports about acute interactions of beta-lactam antibiotics, especially acylaminopenicillins (apalcillin, azlocillin, mezlocillin, piperacillin), with vecuronium, leading to prolongation of muscle blockade. Reports of clinically relevant effects (356–358) conflict with reports of no effect (359).

Food–Drug Interactions

Co-administration of acid-labile beta-lactams, such as penicillin and ampicillin, with food reduces their systemic availability by lowering gastric pH and delaying gastric emptying (360).

Food increases the systemic availability of some cephalosporin prodrug esters, possibly by improving dissolution or blocking premature hydrolysis (361,362).

© 2006 Elsevier B.V. All rights reserved.

Interference with Diagnostic Tests

Aminoglycosides

Plasma aminoglycoside concentrations can be falsely low because they are inactivated by penicillins and cephalosporins. This effect occurred in plasma stored for 24 hours or longer before measurement (363–365).

Coombs' test

There are often false-positive antiglobulin tests by non-immunologically bound serum proteins, especially with cephalosporins, clavulanic acid, and imipenem + cilastin. This is a source of difficulty in cross-matching blood products.

Glycosuria

Urine samples containing beta-lactams should be tested for glucose by the glucose oxidase method, since falsely high values are observed with the copper reduction method (366,367).

Ciclosporin measurement

A retrospective study found an increased risk of ciclosporin-associated early nephrotoxicity in nafcillin-treated patients, despite the fact that ciclosporin concentrations were not different from controls (368). Possible interference of nafcillin with ciclosporin measurement, giving rise to falsely low concentrations, was considered as a possible explanation.

Beta-lactamase inhibitors

General Information

Beta-lactamases are genetically and structurally closely related to penicillin-binding proteins. Their production by bacteria is a major mechanism of resistance to the action of beta-lactam antibiotics. Drugs have therefore been developed that inhibit beta-lactamase, as a way of overcoming this resistance (SEDA-20, 229). They are beta-lactam compounds with particularly high affinities for beta-lactamases (1,2), which therefore act as competitive inhibitors of beta-lactamases. Beta-lactamase inhibitors have no important antimicrobial activity and are only given in combination with an antimicrobial beta-lactam.

The following beta-lactamase inhibitors are in use:

- clavulanic acid (rINN), produced naturally by *Streptomyces clavuligerus*, used in combination with amoxicillin or ticarcillin; the combination clavulanic acid + amoxicillin is also called co-amoxiclav (BAN);
- sulbactam (rINN), a halogenated derivative of penicillanic acid, used in combination with ampicillin or cefoperazone;
- tazobactam (rINN), a halogenated derivative of penicillanic acid, used in combination with piperacillin.

In order to improve absorption, sulbactam has also been bound to ampicillin in the single molecule sultamicillin, which is hydrolysed to the active components after absorption.

An inherent obstacle in evaluating the adverse effects of beta-lactamase inhibitors is that they are only co-administered with antimicrobial beta-lactams, the doses of which are usually several times higher. For the most part, combinations of beta-lactam antibiotics with beta-lactamase inhibitors produce the adverse effects of the individual drugs. However, it is not always possible to say whether an adverse effect is due to one drug alone or to the combination. For example, cholestatic hepatitis occurs more often with co-amoxiclav than with ampicillin alone; however, this could be because it is primarily due to clavulanic acid or because the combination somehow increases the risk.

Organs and Systems

Respiratory

Interstitial pneumonitis has been attributed to ampicillin + sulbactam in two Japanese patients (3).

Psychological, psychiatric

Behavioral changes occurred in four children aged 1.5–10.5 years, taking co-amoxiclav (4).

Hematologic

Parallel to a well-known phenomenon seen with cephalosporins, clavulanic acid can be associated with a positive direct antiglobulin test. In three patients antibiotic courses, including intravenous ticarcillin + clavulanic acid, were associated with positive direct antiglobulin tests in over 50% of cases (5–7). Corresponding observations were made in patients taking ampicillin + sulbactam (8). In vitro studies showed that clavulanic acid and sulbactam caused non-immunological absorption of plasma proteins on to the erythrocyte surface (5,9). There seems to be no clinical impact of this phenomenon, but it can interfere with cross-matching of blood products or with the investigation of true hemolysis.

Reversible bone marrow suppression after high-dose piperacillin + tazobactam was seen in an underweight woman and was thought to be a dose-dependent and piperacillin-related effect (10).

Gastrointestinal

Two cases of hemorrhagic colitis, apparently not related to *Clostridium difficile*, have been reported after co-amoxiclav (11,12). However, the same type of colitis has repeatedly been observed with aminopenicillins alone (12).

Co-amoxiclav often causes diarrhea and other gastrointestinal problems. Oral administration was associated with motor disturbances of the small intestine (13).

Liver

Cholestatic hepatitis

DoTS classification

Dose-relation: hypersusceptibility effect
Time-course: immediate
Susceptibility factors: genetic (DRB1*1501*DRB5-DRB5*0101-DQB1*0602 haplotypes); age over 55 years; male sex; duration of treatment

Co-amoxiclav can cause cholestatic hepatitis. The first report appeared in 1988 (14), since when several hundreds of cases have been reported, for example to health authorities (15), and over 100 cases have been described in detail (16–31). Clavulanic acid is instrumental, either alone or in combination with amoxicillin, since the risk of acute liver injury is much smaller with amoxicillin alone (32).

The relative contributions of amoxicillin and clavulanate to co-amoxiclav-induced hepatotoxicity are incompletely understood. In patients with co-amoxiclav hepatotoxicity, previous use of amoxicillin and rechallenge with amoxicillin were both uneventful, pointing to clavulanic acid as the more likely culprit (16). In a report from the UK, the incidence of liver injury with amoxicillin alone was 0.3 per 10 000 prescriptions versus 1.7 with co-amoxiclav (32). The risk increased after multiple use and with increasing age to 1 per 1000 prescriptions of co-amoxiclav. The main message is that the combination should be used with caution in elderly patients. A patient who has had documented hepatotoxicity related to co-amoxiclav should be well informed about this adverse drug reaction and any future use should be prohibited.

Ticarcillin + clavulanic acid, which is only used intravenously, has also been reported to induce a similar syndrome (33,34) and can also aggravate pre-existing hepatitis (35). One cholestatic reaction has been reported with intravenous sulbactam + ampicillin (36).

The importance of taking a careful history in patients in whom drug-related hepatitis is suspected has been underlined (37).

Incidence

Considering the large number of patients who take this very widely used combination, the risk of hepatitis was initially estimated to be very low, probably below 1/100 000 (23). Newer data, however, have suggested a risk of 1/10 000 or higher (32). In a retrospective cohort study of family practitioners' records, with a high proportion of mild cases, there was a rate of 1 per 4449 prescriptions (32). If this is the case, it is wise to reserve co-amoxiclav (and maybe also ticarcillin + clavulanate) for use in infections caused by strains producing beta-lactamases that can destroy amoxicillin (or ticarcillin).

The syndrome is practically unknown in children; only one pediatric case has been reported so far, in a 4-year-old boy with spherocytosis (16) and causality was disputed (17).

Presentation

The hepatitis usually develops acutely, although an interval of up to 4 weeks between the end of treatment and the first signs of hepatitis is frequent and can prevent rapid diagnosis. Although the clinical effects can be impressive, the condition is usually reversible within 4–6 weeks.

- A 40-year-old woman with a history of chronic sinusitis and asthma developed nausea, vomiting, abdominal pain, and diarrhea (38). Six weeks before, she had taken a 10-day course of co-amoxiclav for acute sinusitis. Her transaminase activities were markedly increased, as was total bilirubin. All drugs were withdrawn, her symptoms progressively improved, and she was discharged without a clearly identified cause of her illness. Liver function tests normalized completely within a few weeks. Two months later she had another episode of acute sinusitis and was again given co-amoxiclav. A few days later she developed nausea, vomiting, a skin rash, abdominal pain, and reduced appetite. Her alanine transaminase activity was 199 U/l (0–65), aspartate transaminase 99 U/l (0–60), and alkaline phosphatase 362 U/l (50–180). The antibiotic was withdrawn, and she completely recovered in 2 weeks and had normal liver function tests over the next several months.
- A 33-month-old boy took co-amoxiclav (dose not stated) for 10 days for otitis media (39). He had taken it twice before. One day after completing the course he developed a rash over his entire body, followed 3 days later by lethargy, jaundice, pale stools, and pruritus. The jaundice persisted, the liver was markedly enlarged, and all liver function tests were abnormal. Tests for known viral and metabolic causes of cholestasis were negative. A percutaneous liver biopsy showed centrilobular cholestasis "consistent with a drug reaction." He was given ursodeoxycholic acid (30 mg/kg/day) and vitamins A, D, and K; later prednisolone was added. However, his jaundice persisted, as did severe pruritus. He also developed extensive xanthomatosis and failure to grow. A liver transplantation was successfully performed 8 months after the onset of symptoms. His explanted liver had features of biliary cirrhosis, with ductular proliferation and ductopenia.

One fatal outcome was described in a patient who was also taking ethinylestradiol, which can itself cause cholestasis (40).

In isolated cases, Stevens–Johnson syndrome together with cholestasis and bone marrow aplasia have been associated with either amoxicillin alone (41) or with co-amoxiclav (42).

Histological features

Liver biopsy shows predominantly centrilobular or panlobular cholestasis, and occasionally granulomatous hepatitis (43).

Mechanism

The mechanism of the syndrome and its possible relation to the liver injury that other beta-lactams, particularly isoxazolylpenicillins, can cause are unclear. A slight eosinophilia has been seen in many cases (26,43,44) and some of the sporadic cases of rechallenge were positive (16). However, there is no other evidence supporting an

© 2006 Elsevier B.V. All rights reserved.

immunoallergic basis. Hepatic accumulation or biliary secretion of clavulanic acid or its metabolites have not been demonstrated (45).

Two other theories have been proposed (46). One is based on the metabolic formation of neo-antigens, and subsequent recognition of these antigens as foreign by the immune system. This "immune allergic hypothesis" is supported by the strong association with an HLA class II haplotype. The authors argued that "HLA class II molecules are required for antigen presentation to CD4-positive T cells. HLA alleles may differ by a little as a single codon, and one amino acid residue difference at a critical site in the resulting polypeptide may be functionally significant, determining not only the affinity with which a given antigen is presented but also the interaction of the HLA peptide complex with the T cell receptor." Their other theory was that the liver disease may arise through linkage with another gene on chromosome 6p. This "linked-gene" hypothesis, they proposed, may explain why jaundice is rare after treatment with co-amoxiclav, although this particular HLA haplotype is common in Northern Europe, where co-amoxiclav is commonly prescribed.

Whatever the mechanisms might be, at present it is reasonable to look on clavulanate as the main contributor to the development of hepatotoxicity with co-amoxiclav. Hepatotoxicity has also been reported with clavulanate plus ticarcillin (34). So far, however, there has been no genetic evaluation of patients with hepatotoxic reactions after therapy with clavulanate and ticarcillin.

Susceptibility factors

Increasing age (over 55 years), male sex, and duration of treatment are risk factors (26,32,47), while drug dose and route of administration, other medications, previous drug allergies, or prior use of co-amoxiclav were not significantly associated with the reaction.

The importance of HLA antigens in the pathogenesis of some liver diseases (autoimmune hepatitis, primary biliary cirrhosis, primary cholangitis) is also reasonably well established (48), and there is a significant association between co-amoxiclav-induced liver damage and an HLA haplotype (49,50). HLA-class antigens have been investigated in 35 patients with biopsy-documented liver damage due to co-amoxiclav and 300 controls (volunteer bone marrow donors) (46). HLA-A and HLA-B were typed using alloantisera and HLA-DBR and HLA-DWB were typed by PCR. The patients with hepatitis were characterized by a higher frequency of the DRB1*1501*DRB5-DRB5*0101-DQB1*0602 haplotype (57 versus 12% in controls). Patients with that haplotype tended to have a cholestatic rather than a hepatocellular type of hepatitis. However, these data also suggest that other factors must act concurrently. These factors may involve heterogeneity of the formed antigens and/or polymorphism of the T cell receptor. A reaction to (unknown) metabolites of clavulanic acid also has to be kept in mind. The authors suggested that "metabolic factors may play a greater role in the pathogenesis of hepatocellular cases, whereas immunological factors may be more involved in the pathogenesis of cholestatic ones." This HLA association has been confirmed in a study in which there was an increased frequency of homozygous status for this haplotype (51). This might reflect population differences and the small sample size in both studies (46). It is reasonable to assume that HLA characterization will be implemented in a future diagnostic armamentarium.

Urinary tract

The combination of piperacillin + tazobactam was thought to have caused acute interstitial nephritis in a 51-year-old woman (52). It remains open whether the combination or one of the components was the culprit.

Immunologic

Clavulanic acid has a very low immunogenic and allergenic potential in animals. The possible impact of its co-administration with other beta-lactam antibiotics is unknown (53). Two patients with IgE-mediated hypersensitivity to oral co-amoxiclav and positive skin tests for clavulanic acid, but not for penicillins, both tolerated oral amoxicillin. One patient was also challenged with clavulanic acid and developed urticaria, conjunctivitis, and bronchial obstruction (54). Since co-amoxiclav has been widely used since its introduction in 1981, the frequency of hypersensitivity reactions is low. The clinical data available on sulbactam and tazobactam are still limited and do not allow an assessment of the frequency and pattern of associated hypersensitivity reactions (55).

Body temperature

A woman immediately developed hyperpyrexia up to 40°C after a first dose of intravenous ampicillin + sulbactam, having previously tolerated ampicillin alone for 10 days. Hyperpyrexia was repeatedly observed after six more doses of sulbactam (56).

Interference with Diagnostic Tests

Leukocyte dipstick test

Clavulanic acid caused false-positive dipstick tests for leukocytes; sulbactam and tazobactam did not (57).

Bethanechol

General Information

Bethanechol is a quaternary ammonium compound that shares both the muscarinic and nicotinic actions of acetylcholine but it is much more slowly deactivated. It has been used to treat clomipramine-induced orgasmic dysfunction (1).

Organs and Systems

Nervous system

An acute dystonic reaction to bethanecol has been reported in a 10-month-old boy (SEDA-12, 124). This reaction was unexpected since bethanecol does not normally penetrate the blood–brain barrier; the authors assumed that the barrier may not be impenetrable to the drug in young infants.

During a controlled clinical trial of intraventricular bethanecol in patients with Alzheimer's disease, reversible drug-induced parkinsonism was observed in one patient (SEDA-15, 5). The frequent co-existence of Alzheimer's disease and Parkinson's disease presents potential problems for therapy and adverse effects when the cholinergic system is manipulated.

Bevantolol

See also Beta-adrenoceptor antagonists

General Information

Bevantolol, a hydrophilic cardioselective beta-blocker with membrane-stabilizing activity, may have a higher incidence of fatigue, headache, and dizziness than atenolol or propranolol (1,2).

Biguanides

General Information

Biguanides (1) and metformin (2–4) have been reviewed. Metformin (rINN) is the only biguanide commonly used; buformin (rINN) and phenformin (rINN) have been withdrawn in many countries (SEDA-4, 306) because of dangerous adverse effects. However, they are still available in a few countries, and with increasing travel, adverse effects of drugs no longer available in one country can occur if the drug is obtained elsewhere.

The biguanides have a special affinity for the mitochondrial membrane, which causes an alteration in electron transport and results in reduced oxygen consumption. Inhibition of the active transport of glucose in the intestinal mucosa, absent activation of glucose transporters, inhibition of gluconeogenesis, and inhibition of fatty

© 2006 Elsevier B.V. All rights reserved.

acid oxidation and of lipid synthesis are the effects that are considered to cause lowering of the blood glucose and improving blood lipids in diabetes mellitus. The blood glucose lowering effect of metformin was comparable to that of sulfonylureas, according to a meta-analysis, but body weight increases with sulfonylureas and falls with metformin, leading to a mean weight change difference of 2.9 kg (5).

Most (70–90%) of a dose of metformin is eliminated via the kidneys with a half-life of 9 hours (6). In contrast, phenformin is mostly eliminated by metabolism; its half-life is about 11 hours (7).

Observational studies

In a large American study in 3234 non-diabetic people with a raised fasting blood glucose and a raised blood glucose 2 hours after a glucose load, diabetes occurred in 7.8 cases per 100 participants per year after a mean treatment period of 2.8 years with metformin 850 mg bd; there were 11 cases per 100 participants per year after placebo and 4.8 cases per 100 participants per year after a life-style intervention program (8). Gastrointestinal symptoms were most frequent in those who took metformin. In a later study, glucose tolerance tests were performed after a 14-day washout period of metformin and placebo in the patients who had not developed diabetes (9). Diabetes was more frequently diagnosed in the metformin group, but when the diabetes conversions during treatment and washout were combined, diabetes was still significantly less common in the metformin group.

Comparative studies

Metformin and troglitazone have been compared in 21 patients with type 2 diabetes unresponsive to glibenclamide 10 mg bd (10). Metformin stabilized weight and reduced adipocyte size, leptin concentrations, and glucose transport. GLUT1 and GLUT4 in isolated adipocytes were not changed. Insulin-stimulated whole-body glucose disposal rate increased by 20%. Troglitazone caused increases in body weight, adipocyte size, leptin concentrations, and basal and insulin-stimulated glucose transport. GLUT4 protein expression was increased two-fold and insulin-stimulated whole-body glucose disposal rate increased by 44%.

Placebo-controlled studies

In a placebo-controlled study in 40 patients with impaired glucose tolerance metformin 500 mg bd for 6 months increased insulin-stimulated glucose metabolism by 20% with minimal improvement in glucose tolerance; this effect was maintained after 12 months (11).

In 82 children aged 10–16 years with type 2 diabetes, metformin lowered HbA_{1c} and fasting blood glucose compared with placebo (12). More patients who took placebo had to drop out because more medication was necessary. Most of the adverse events (abdominal pain, diarrhea, nausea, vomiting) occurred during metformin treatment.

Combinations of oral hypoglycemic drugs

The different mechanisms of action of the various classes of hypoglycemic drugs makes combined therapy feasible: the sulfonylureas and meglitinides stimulate insulin production by different mechanisms, the biguanides reduce glucose production by the liver and excretion from the liver, acarbose reduces the absorption of glucose from the gut, and the thiazolidinediones reduce insulin resistance in fat. It is not necessary to wait until the maximal dose of one drug has been reached before starting another. However, sulfonylureas and meglitinides should no longer be used when endogenous insulin production is minimal. Combinations of insulin with sulfonylureas or meglitinides should only be used while the patient is changing to insulin, except when long-acting insulin is given at night in order to give the islets a rest and to stimulate daytime insulin secretion.

This subject has been reviewed in relation to combined oral therapy. In a systematic review of 63 studies with a duration of at least 3 months and involving at least 10 patients at the end of the study, and in which HbA_{1c} was reported, five different classes of oral drugs were almost equally effective in lowering blood glucose concentrations (13). HbA_{1c} was reduced by about 1–2% in all cases. Combination therapy gave additive effects. However, long-term vascular risk reduction was demonstrated only with sulfonylureas and metformin.

In a placebo-controlled study in 116 patients who responded insufficiently to metformin 2.5 g/day, rosiglitazone 2 or 4 mg bd was added for 26 weeks (14). HbA_{1c} and fasting plasma glucose improved and hemoglobin fell. Edema was reported in 5.2% of the patients who took rosiglitazone and two patients withdrew because of headache.

Biguanides + meglitinides

Patients with type 2 diabetes with unsatisfactory control after taking metformin for 6 months were randomized to metformin alone, repaglinide alone, or metformin + repaglinide (each 27 patients) (15). Combined therapy reduced HbA_{1c} after 3 months by 1.4% and fasting glucose by 2.2 mmol/l. Repaglinide alone or in combination with metformin increased insulin concentrations. The most common adverse effects were hypoglycemia, diarrhea, and headache. Gastrointestinal adverse effects were common in those taking metformin alone, and body weight increased in both groups taking repaglinide.

In 12 patients with type 2 diabetes, a combination of nateglinide 120 mg or placebo with metformin 500 mg before each meal on two separate days was well tolerated (16). One patient taking nateglinide had a headache. One patient was withdrawn because of a myocardial infarction and had multivessel coronary artery disease on catheterization.

In a prospective, randomized, double-blind, placebo-controlled study for 24 weeks, 701 patients took nateglinide 120 mg before the three main meals, or metformin 500 mg tds, or the combination of the two, or placebo (17). The most frequent adverse effect was hypoglycemia, and it was most common in the combination group. There were no differences between those who took nateglinide only or metformin only and there were no episodes of serious hypoglycemia. Diarrhea was more frequent in those taking metformin or the combination, but infection, nausea, headache, and abdominal pain were comparable in the two groups.

© 2006 Elsevier B.V. All rights reserved.

Of 82 patients insufficiently controlled by metformin, 27 continued to take metformin with placebo, 28 took titrated repaglinide with placebo, and 27 took metformin with titrated repaglinide for 4–5 months (18). There were no serious adverse effects. Nine patients taking metformin + repaglinide reported 30 hypoglycemic events and three patients taking repaglinide reported 9 events.

Insulin + biguanides

Metformin was given as an adjunct to insulin in a double-blind, placebo-controlled study in 28 adolescents needing more than 1 U/kg/day (19). The dose of metformin was 1000 mg/day when body weight was under 50 kg, 1500 mg/day when it was 50–75 kg, and 2000 mg/day when it was over 75 kg. Metformin lowered insulin requirements. The number of episodes of hypoglycemia increased compared with placebo. There was gastrointestinal discomfort in six patients taking metformin and five taking placebo.

A comparable placebo-controlled study was reported in 353 patients with type 2 diabetes for 48 weeks. All were taking insulin, and HbA_{1c} fell in those who also took metformin. Body weight was reduced by 0.4 kg by metformin and increased by 1.2 kg by placebo. Symptomatic episodes of hypoglycemia were more common with metformin. There were mild transient gastrointestinal complaints in 56 and 13% respectively (20).

Insulin plus metformin (27 patients, 2000 mg/day) or troglitazone (30 patients, 600 mg/day) in patients with type 2 diabetes using at least 30 U/day was compared with insulin alone (30 patients) for 4 months (21). Body weight increased in the insulin and the insulin plus troglitazone groups. In the insulin plus metformin group there were significantly more gastrointestinal adverse effects but less hypoglycemia than the other groups.

In 80 patients taking metformin 850 or 1000 mg tds plus NPH insulin at bedtime, metformin was withdrawn and repaglinide 4 mg tds added in half of the patients for 16 weeks (22). In the repaglinide group the dose of insulin increased slightly and weight gain was 1.8 kg more. Mild hypoglycemia occurred more often in the metformin group; nightly episodes of hypoglycemia occurred only with repaglinide. One patient taking repaglinide had a myocardial infarction, and one had three separate hospitalizations for chest pain (myocardial infarction was excluded). No specific data were presented about gastrointestinal adverse effects or infections.

Contraindications

Contraindications to treatment with biguanides are:

1. impaired renal function (serum creatinine may not be a sufficient indicator; creatinine clearance must be estimated)
2. an increased risk of impaired renal function in intercurrent diseases with fever, congestive heart failure, or infections of the urinary tract, during treatment with diuretics, intravenous pyelography, or severe dieting
3. states associated with tissue hypoxia (respiratory insufficiency, heart insufficiency, anemia, and peripheral vascular disease)
4. hepatitis and hepatic cirrhosis
5. excessive use of alcohol
6. wasting diseases
7. preoperatively and postoperatively.

In general, biguanides should not be used in people aged over 75 years (23).

Of 308 patients 73% had contraindications, risk factors, or intercurrent illnesses necessitating withdrawal of metformin (24): 19% had renal impairment, 25% heart failure, 6.5% respiratory insufficiency, and 1.3% hepatic impairment; 51% had advanced coronary heart disease, 9.8% atrial fibrillation, 3.3% chronic alcohol abuse, 2% advanced peripheral arterial disease, and 0.7% were pregnant.

Four fatal cases in 18 months in a community hospital were reported; three had clear contraindications (25): a 45-year-old woman with liver cirrhosis, a 64-year-old man with coronary artery disease, and a 65-year-old man with peripheral arterial disease and asthma; a 74-year-old man had renal insufficiency.

In a retrospective study of 1874 patients with type 2 diabetes taking metformin, 25% had contraindications, including acute myocardial infarction, cardiac failure, renal impairment, and chronic liver disease (26). However, contraindications often did not lead to withdrawal of metformin: in 621 episodes, only 10% stopped taking it. Only 25 and 18% stopped taking metformin when they developed renal impairment or myocardial infarction, respectively. One patient developed lactic acidosis, but this may have been a consequence of myocardial infarction.

Organs and Systems

Cardiovascular

The cardiovascular effects of metformin have been reviewed (27). Metformin reduces blood pressure and has a beneficial effect on blood lipid concentrations.

In a retrospective study, cardiovascular deaths in patients using a sulfonylurea only ($n = 741$) were compared with deaths in patients taking a sulfonylurea + metformin ($n = 169$) (28). In patients taking the combination the adjusted odds ratios (95% CI) were:

- overall mortality 1.63 (1.27, 2.09);
- mortality from ischemic heart disease 1.73 (1.17, 2.55);
- stroke 2.33 (1.17, 4.63).

The patients taking the combination were younger, had had diabetes for longer, were more obese, and had higher blood glucose concentrations.

Metabolism

Biguanides cause hypoglycemia in 0.24 cases per 100 patient-years and it is more common when they are used in combination with a sulfonylurea (29). In 102 consecutive patients with drug-induced hospital-related hypoglycemic coma, 13 were taking metformin + glibenclamide and 3 were taking metformin + insulin (30).

Lactic acidosis

DoTS classification

Adverse effect: Lactic acidosis due to biguanides
Dose-relation: toxic effect
Time-course: time-independent
Susceptibility factors: genetic (slow phenformin metabolizers); age; disease (impaired liver, kidney, or cardiac function, alcoholism)

Biguanides can cause lactic acidosis, which is fatal in 50% of cases (31).

- A 65-year-old man with a creatinine clearance of 67 ml/minute taking metformin 850 mg bd developed lactic acidosis (lactate 25 mmol/l, pH 7.13, bicarbonate 5 mmol/l) (32). Despite the relatively small dosage of metformin, he had unexplained very high metformin concentrations (61 μg/ml).

A possible explanation for the high metformin concentration in this case was that an unknown substance related to intestinal inclusion inhibited its tubular excretion. Other cases involving metformin have included the following:

- a 62-year-old woman: pH 6.60, blood lactate 45 mmol/l, creatinine 133 μmol/l (33);
- a 72-year-old woman: pH 6.84, creatinine 125 μmol/l (34);
- a 75-year-old woman: pH 6.73, lactate 18 mmol/l (34);
- a patient with creatinine 91 μmol/l, creatinine clearance 52 ml/minute, metformin concentration 61 μg/ml (target under 5 μg/ml) (35);
- a 52-year-old woman, a chronic alcohol user: pH 6.74, lactate over 30 mmol/l, creatinine 710 μmol/l (36);
- an 83-year-old woman with mild renal insufficiency (37).

All survived, but all needed hemodialysis. In all cases there were contraindications to metformin.

Five patients with metformin-associated severe lactic acidosis, seen between 1 September 1998 and 31 May 2001, have been reported (38). Two had attempted suicide. All had severe metabolic acidosis with a high anion gap and raised blood lactate concentrations. Four developed profound hypotension and three had acute respiratory failure. Three had normal preceding renal function. Three required conventional hemodialysis and two continuous renal replacement therapy.

Cases also continue to be reported with buformin and phenformin (39).

- A 67-year-old man who had taken phenformin and glibenclamide for 2 years became lethargic and confused (40). His pH was 6.91, serum lactate 25 mmol/l and later 30 mmol/l, and blood glucose very low (0.5 mmol/l), possibly because of vomiting, anorexia, and glibenclamide. Hemodialysis was advised but not performed, since he recovered spontaneously.

Incidence

In patients taking metformin, lactic acidosis is rare (3 per 100 000 patient-years) and is most often seen when contraindications to metformin (impaired kidney or liver function, alcoholism, circulatory problems, old age) are neglected or not detected (41). Although the relative risk of lactic acidosis with metformin is significantly lower than with phenformin or buformin (42), it has been repeatedly reported (SEDA-6, 371) (43), even in the absence of known contraindications (44).

Experience with metformin in a large American health organization in 9875 patients has been presented (45). There was one probable case of lactic acidosis in an 82-year-old woman who developed renal impairment while taking metformin 500 mg/day.

In 11 797 patients (22 296 person-years) in Saskatchewan who took metformin from 1980–95 there were 9 cases of lactic acidosis per 100 000 patient-years (46), a much lower incidence than the estimated rate of 40–64 cases for phenformin.

The lower frequency of lactic acidosis during treatment with metformin compared with other biguanides may be caused by its short non-polar hydrophobic side chains substituted with two CH_3 groups. This has a lower affinity for hydrophobic structures, such as phospholipids in mitochondrial and cellular membranes, than the longer monosubstituted side-chains of the other biguanides (41).

Mechanism and susceptibility factors

Biguanides in high doses inhibit the oxidation of carbohydrate substrates by affecting mitochondrial function. Anoxidative carbohydrate metabolism stimulates the production of lactate. High lactate production leads to lactic acidosis (type B) with a low pH (<6.95). Hyperlactatemia was common in patients taking buformin, even without alcoholism or impaired liver, kidney, or cardiac function (47).

In reaction to a report of lactic acidosis at a therapeutic metformin concentration (SEDA-22, 476), in which a mitochondrial defect was supposed to have increased susceptibility to metformin, it has been observed that diabetes itself may dispose to hyperlactatemia (48). Others (49) have taken issue with the opinion (SEDA-22, 476) that the association of lactic acidosis with metformin may be coincidental, as lactic acidosis can also emerge during critical illnesses (type A lactic acidosis, caused by circulatory insufficiency). However, patients with type B lactic acidosis, with high biguanide concentrations, will also develop circulatory insufficiency after some hours.

The main susceptibility factor for lactic acidosis due to metformin is renal insufficiency (33). In patients taking phenformin, poor oxidative metabolism may contribute (50).

All patients admitted to a hospital during 6 months who had taken at least one dose of metformin were retrospectively evaluated for susceptibility factors for metformin-associated lactic acidosis (8). There were 263 hospitalizations in 204 patients. In 71 admissions there was at least one contraindication, such as renal or liver disease, renal dysfunction, congestive cardiac failure, metabolic acidosis, or an intravenous iodinated contrast medium given within 48 hours of metformin. In 29 (41%) metformin was continued despite the contraindication. The most frequent contraindication was a raised serum creatinine, but in only eight of the 32 admissions was metformin withdrawn. Of nine patients using metformin who died (not necessarily directly related to metformin), six had an absolute contraindication. In two patients who

© 2006 Elsevier B.V. All rights reserved.

died and in one who survived, blood lactate was increased and this was temporally related to the use of metformin.

Whether metformin in therapeutic doses can cause lactic acidosis in the absence of renal insufficiency has been investigated by studying case histories of metformin-associated lactic acidosis in various databases published from May 1995 to January 2000 (51). Overdoses and lactic acidosis caused by contrast media were excluded. There were 21 reports of 26 cases, of which five did not comply with the criteria (lactate over 5 mmol/l, pH 7.35 or less). Plasma metformin concentration was measured in only four cases. The authors distinguished between lactic acidosis precipitated by metformin, which was defined as occurring without accumulation of metformin, and lactic acidosis that occurred during primary acute or chronic renal insufficiency, with accumulation of metformin. In the first group, six of the eight patients died. In the second group, notwithstanding a mean lactate concentration of nearly 15 mmol/l, only one of the 12 patients died, having refused dialysis. They concluded that there is no relation between the use of metformin and lactic acidosis, except when metformin accumulates. This has been illustrated by the case of a 76-year-old woman taking 850 mg metformin bd who developed lactic acidosis due to metformin accumulation during deteriorating kidney function (52).

Drugs that can precipitate lactic acidosis in patients taking metformin include ACE inhibitors, thiazide diuretics, NSAIDs, and drugs such as furosemide, nifedipine, cimetidine, amiloride, triamterene, trimethoprim, and digoxin, which are all secreted in the renal tubules, compete with metformin, and can contribute to increased plasma metformin concentrations (53).

The need to follow recommended guidelines strictly in order to avoid lactic acidosis in patients taking metformin has been emphasized (54).

Presentation

The early symptoms of lactic acidosis are nausea, vomiting, and diarrhea; since these are common adverse effects of biguanides, a careful watch should be kept for their sudden onset or aggravation, which might point to lactic acidosis (55).

In retrospective studies, neither the degree of hyperlactatemia nor accumulation of metformin had prognostic significance, but mortality was linked to the underlying disease (56,57).

Management

The best therapy of metformin-induced lactic acidosis is immediate hemodialysis, but metformin in the tissues continues to produce lactate while the drug is being removed during dialysis. Sodium bicarbonate is not very effective and can paradoxically lower the pH and cause hypernatremia and fluid overload. Tracheal intubation and mechanical ventilation may be necessary (53). Theophylline and dichloroacetate have also been used. Theophylline stimulates oxygen exchange in the lungs. Dichloroacetate activates pyruvate dehydrogenase, inhibiting lactate formation, but it is neurotoxic, can cause cataract, and is mutagenic (SEDA-7, 410).

The results of hemodialysis in biguanide-induced lactic acidosis are variable. Metformin and buformin are dialysable, but phenformin is poorly eliminated. Successful continuous venovenous hemofiltration has been reported (58).

- A 68-year-old woman with type 2 diabetes and hypertension took phenformin 90 mg/day and glibenclamide 6 mg/day. She developed a urinary tract infection and oliguria followed by respiratory distress and mental confusion without neurological defects. Her pH was 6.84, serum lactate 28 mmol/l, creatinine 186 μmol/l, and glucose 10.4 mmol/l, and there were no ketone bodies. She received assisted ventilation, bicarbonate, dopamine + obutamine, glucose + insulin, and antibiotics. Her serum lactate increased to 44 mmol/l and continuous venovenous hemofiltration was started. After 5 days her lactate concentration was in the reference range (0.5–2.2 mmol/l). The serum phenformin concentration was almost 600 ng/ml (10 times the therapeutic value).

Nutrition

Vitamin B_{12} deficiency can be caused by metformin.

- A 63-year-old man with type 2 diabetes, who had taken metformin for at least 5 years, had a low serum vitamin B_{12} concentration (110 pg/ml; reference range 200–230) and a normal serum folate (59). There were no autoantibodies. A Schilling test showed malabsorption of vitamin B_{12}. Metformin was withdrawn and 2 months later a Schilling test showed no malabsorption.
- This case prompted a report of 10 metformin-associated patients with cobalamin deficiency among 162 patients with vitamin B_{12} concentrations below 200 pg/ml (60). They had taken a mean dose of metformin of 2015 mg/day for an average of 8.9 years. The mean vitamin B_{12} concentration was 140 pg/ml. All had normal serum folate and creatinine concentrations and no antibodies to intrinsic factor. In one patient there was malabsorption.

Hematologic

Megaloblastic anemia is rare with metformin, but vitamin B_{12} concentrations can be reduced by metformin and phenformin (61) because of reduced absorption, and pre-existing deficiency can be exacerbated (41).

Metformin can occasionally cause a hemolytic anemia.

- A 68-year-old woman of North African Jewish descent with a raised HbA_{1c} was given metformin 850 mg tds and repaglinide 1 mg tds, and 14 days later developed extreme weakness and anemia, her hemoglobin having fallen from 12 to 8 g/dl within 1 week (62). Her reticulocyte count was 11%, with polychromasia. The bilirubin rose to 35 μmol/l (27 μmol/l direct). The haptoglobin concentration was low and a direct Coombs' test was negative. Metformin was withdrawn. Two units of erythrocytes were transfused and the hemoglobin rose to 11 g/dl and remained stable. Glucose-6-phosphate dehydrogenase (G6PD) activity was significantly reduced. There were no other precipitating factors for hemolysis due to G6PD deficiency.

It is unclear whether metformin caused hemolysis directly in this case or via G6PD deficiency. Two other patients have been reported with normal G6PD activity (63,64); one had a positive Coombs' test (64).

© 2006 Elsevier B.V. All rights reserved.

Gastrointestinal

Abdominal discomfort is frequent with metformin (15–25%), and nausea, vomiting, and diarrhea occur even in the absence of lactic acidosis. Other effects include flatulence, abdominal bloating, anorexia, and a metallic taste. Anorexia and weight loss are often seen at the beginning of treatment. Phenformin can cause hemorrhagic gastritis (65).

The gastrointestinal adverse effects of metformin can be reduced by giving the metformin during or immediately after meals, starting with a low dose and increasing it gradually (41).

In 43 patients with poorly controlled type 2 diabetes using insulin, the addition of metformin improved HbA_{1c} and reduced the dose of insulin (66). Seven patients in the metformin group and four in the placebo group had nausea; nine versus four had diarrhea.

- Three patients who had taken metformin for more than 2 years developed diarrhea (67). After withdrawal of metformin the diarrhea resolved within 1 month. A fourth patient developed diarrhea after taking metformin for 4 months, which stopped after withdrawal; rechallenge with metformin 8 months later led to recurrence. Three of these patients had bowel disease (diverticulosis, irritable bowel syndrome, and diabetic neuropathy).
- A 49-year-old woman developed chronic diarrhea after using metformin 850 mg tds and insulin for 5 years (68). After 5 months, metformin was withdrawn and the diarrhea resolved within 3 days. On rechallenge the diarrhea returned.
- A 44-year-old non-diabetic man took metformin 1700 mg/day for some weeks for obesity (69). He developed severe gastrointestinal hemorrhage needing blood transfusion. A bleeding Meckel's diverticulum was removed and he had no further hemorrhage. Coagulation studies, to investigate whether reduced platelet aggregation or altered coagulation factors (increased tissue plasminogen activator (tPA) or reduced tPA-Ag, or PAI-1) could have contributed, were not done.

Liver

Metformin can cause hepatitis (70).

- A 52-year-old woman took glipizide and enalapril and then, because of persistent hyperglycemia, metformin 1000 mg/day (71). Her liver enzymes were normal, and after 2 weeks the dosage of metformin was increased to 2000 mg/day. Two weeks later she became icteric and her bilirubin and liver enzymes were increased. Serological studies were negative. All drugs were withdrawn. A liver biopsy was consistent with toxic hepatitis. She had normal liver enzymes after a month.

Hepatitis after sulfonylureas is known, and this patient had taken glipizide for several years. The combination of glipizide and metformin may have been to blame.

- A 75-year-old man taking insulin about 40 U/day was given metformin 500 mg bd (72). He also used enteric-coated aspirin, diltiazem XR, ibuprofen, and lovastatin. Two months later his liver enzymes were raised, but he felt well. Hepatitis antibodies were negative. After withdrawal of metformin his liver enzymes became normal. He agreed to restart metformin. His liver enzymes remained normal, but he finally preferred insulin monotherapy.

It is not clear what caused the hepatitis in this case, although it seems that metformin was not to blame.

- A 64-year-old man developed cholestatic jaundice 2 weeks after starting to take metformin 500 mg bd (73). It resolved slowly over several months after withdrawal.

Pancreas

Phenformin can cause pancreatitis (74).

Skin

Urticaria and rashes are seen occasionally with metformin. Lichen ruber planus has been reported (75).

Immunologic

Leukocytoclastic vasculitis and pneumonitis have been attributed to metformin (76,77).

Death

In 2275 diabetic patients aged 45–74 years compared with 9047 non-diabetics with proven coronary artery disease, 32% of those taking metformin and 44% of those taking combined metformin and glibenclamide died during 7.7 years (78). After 4 years the risks of death with metformin alone and combined therapy were equal, but after 7 years combined therapy had a worse prognosis.

Second-Generation Effects

Lactation

Metformin is increasingly being used in the polycystic ovarian syndrome and therefore in lactating women. In seven breastfeeding mothers taking a median dose of 1500 mg/day, the mean relative infant dose transferred in the milk was 0.28% (79). Serum metformin concentrations were very low or undetectable in infants and they appeared to be healthy. A specific warning was given for children with impaired renal function (prematurity, renal insufficiency).

Susceptibility Factors

Age

The effect of age on the response to metformin has been studied in 174 patients aged over 70 years, not well-controlled on glibenclamide 7.5 mg/day or gliclazide 120 mg/day (80). They were given either maximal doses of a sulfonylurea (glibenclamide 15 mg/day or gliclazide 240 mg/day) or a sulfonylurea + metformin (1700 mg/day). Renal function and liver function were normal. There were nine cases of non-severe hypoglycemia in the first group. In the second group there were two cases of hypoglycemia after delayed meals and 35% had transient mild gastrointestinal discomfort. There were no increases in lactic acid. Lipid

© 2006 Elsevier B.V. All rights reserved.

concentrations were a little lower in the second group. The authors concluded that age as such is not a contraindication to metformin, provided that contraindications, such as renal impairment, are absent and that blood glucose is measured regularly.

Drug Administration

Drug overdose

The regional poison centers certified by the American Association of Poison Control have reported 55 cases of metformin ingestion by children (81). Unintentional ingestion of 1700 mg of metformin did not pose health risks. In 21 children tested for blood glucose, lactate, or electrolytes, there was no evidence of lactic acidosis. Plasma metformin concentrations were not determined.

- A 37-year-old woman purposely took metformin 10 g (82). She did not develop hypoglycemia, but the serum lactate increased to 3.2 mmol/l (reference range under 2.1 mmol/l) and she became nauseated. She recovered.
- A healthy 21-year-old woman took metformin 45 g (53×850 mg) in a suicide attempt and developed acute pancreatitis with metabolic acidosis (pH 6.96), hypoglycemia (1.3 mmol/l), and an anion gap of 37 mmol/l (83). She was given 290 g of dextrose, and her blood glucose rose to 25 mmol/l. Other laboratory tests were normal. When later measured, serum amylase was 121 U/l, urinary amylase 97 U/l (both twice the upper limit of the reference range), and serum lipase 724 U/l (5–6 times raised). A CT scan with contrast showed stage B acute pancreatitis. Serum amylase and serum lipase rose to 368 and 1900 U/l respectively. She recovered after 8 days. A CT scan 1 month later was normal. Lactic acid and metformin were not determined. The use of alcohol or other drugs that can cause pancreatitis could not be established. Gallstones and hyperlipidemia were not present. The initial hypoglycemia could have been a direct effect of metformin; hyperglycemia is more often seen during lactic acidosis.
- A non-diabetic 25-year-old woman died after 2 days of lactic acidosis and multiple organ failure, having taken an unknown amount of her father's metformin (38,84).
- A 58-year-old woman with type 2 diabetes took an overdose of metform in 55 g plus 100 mg of glibenclamide and 3.1 g of acarbose (38,84). She developed lactic acidosis and survived with hemodialysis.

When a patient in coma has an unexplained anion gap, a suicide attempt with metformin should be considered.

Drug–Drug Interactions

Alpha-glucosidase inhibitors

Metformin can be effectively combined with miglitol (SEDA-25, 514) but metformin may accumulate in the gastrointestinal wall, and the combination of metformin with acarbose or miglitol may reduce the absorption of metformin (85,86).

Cephalexin

In a double-blind, randomized, crossover study in 12 healthy volunteers, cefalexin 500 mg increased the C_{max} and AUC of a single dose of metformin 500 mg by 34 and 24% respectively and reduced its renal clearance to 14% (87). The authors suggested that cefalexin inhibits the renal tubular secretion of metformin.

Contrast media for radiological investigations

Radiocontrast media can induce acute renal insufficiency in patients taking metformin (88,89). Metformin should be withdrawn 2 days before an iodinated contrast medium is given (SEDA-21, 445) and the following protocol has been suggested (90):

- take a blood sample for creatinine baseline estimation before giving a contrast medium;
- withdraw metformin 48 hours before the investigation;
- if the urine output is normal for 48 hours after the radiological procedure the patient can resume metformin;
- when it is discovered after a procedure that the preinvestigation creatinine was raised (since the procedure may be carried out before the creatinine is known), the patient's physician should be contacted and the creatinine must be measured again within 48 hours.

Since January 1998 the package insert approved by the FDA has stated: "Glucophage (metformin) should be discontinued at the time of or prior to the procedure and withheld for 48 hours subsequent to the procedure and reinstituted only after renal function has been re-evaluated and found to be normal" (91).

Multiple drugs

The combination of metformin with other drugs that can lower the blood glucose concentration can result in severe hypoglycemia.

- A 79-year-old woman was admitted to hospital stuporose and unresponsive (92). She had taken metformin 850 mg bd for 14 days, during which time she complained of loss of appetite and consumed little starch. On that morning she had had nausea and dizziness. Her blood glucose was 2.0 mmol/l and her serum potassium 3.3 mmol/l. A CT scan of the head was normal.

The combination of metformin, which itself does not cause hypoglycemia, with an ACE inhibitor, nitrofurantoin, and an NSAID, which all have glucose-lowering effects, and poor food intake may have led to hypoglycemia in this case.

NSAIDs

Drug interactions can precipitate metformin-induced lactic acidosis, as has been reported after the addition of indometacin (93).

- A 57-year-old woman, who had taken metformin 500 mg bd for 15 years, took indometacin 50 mg qds for 2 months. She developed oliguria and acidosis (pH 6.82, serum lactate 21 mmol/l, creatinine 480 μmol/l). After stopping metformin and indometacin she

© 2006 Elsevier B.V. All rights reserved.

improved and left hospital with stable impaired kidney function.

The authors reported that two other cases of metformin-associated lactic acidosis with concurrent NSAID therapy have been reported to the Committee on Safety of Medicines in the UK. Indometacin can impair kidney function and may have done so in this case. Phenformin can cause tubular damage and oliguria in animals (94) and so it is conceivable that metformin-induced renal damage may also have contributed.

Phenprocoumon

The clearance of phenprocoumon was increased by metformin, perhaps because of increased liver blood flow (95).

Rosiglitazone

In 16 male volunteers aged 22–55 years, rosiglitazone 2 mg bd had no effect on the steady-state pharmacokinetics of oral metformin 500 mg bd; there were no clinically significant episodes of hypoglycemia and blood lactic acid concentrations did not increase (96).

Warfarin

Potentiation of the anticoagulant action of warfarin by phenformin has been reported (97).

Bile acids

General Information

The bile acids are used in the long-term treatment of cholesterol gallstones. Ursodeoxycholic acid is the 7-epimer of chenodeoxycholic acid. Tauroursodeoxycholic acid is a derivative of ursodeoxycholic acid.

Observational studies

In a retrospective review of medical records over 12 months, ursodeoxycholic acid (20 mg/kg/day) reduced serum bilirubin concentrations in four of five children with cholestasis and hyperbilirubinemia (1). No adverse effects were reported.

Placebo-controlled studies

In a randomized placebo-controlled study in 219 patients with histology-proven chronic hepatitis (44 HbsAg-positive and 149 anti-HCV antibody-positive) and persistently raised transaminases, oral ursodeoxycholic acid 300 mg bd for 6 months produced significant improvement in clinical and biochemical markers (2). Apart from diarrhea, which was reported by a few patients, it was well tolerated.

The combinations of oral ursodeoxycholic acid 13–15 mg/kg/day plus interferon (3 MU three times a week) and interferon plus placebo for 6 months have been compared in a randomized, placebo-controlled study in 91 patients with chronic hepatitis C resistant to interferon (3). Combined interferon plus ursodeoxycholic acid was more effective than interferon alone in terms of normalizing alanine transaminase at 6 months (but not at 12 months), but not in terms of virological response. The frequency of adverse effects was similar in the two groups. Diarrhea, which was reported by a few patients, was the only adverse effect attributable to ursodeoxycholic acid.

The long-term effects of ursodeoxycholic acid 14–16 mg/kg/day has been investigated in a double-blind, placebo-controlled, multicenter trial in 192 patients with primary biliary cirrhosis (4). Ursodeoxycholic acid was associated with significant improvement in liver function tests and liver histology, but it did not affect the time to death or liver transplantation. Adverse effects were mild: abdominal pain, flatulence, and diarrhea were reported in nine patients taking ursodeoxycholic acid and six taking placebo.

High-dose ursodeoxycholic acid (20 mg/kg/day) has been compared with placebo in the treatment of primary sclerosing cholangitis in a 2-year double-blind preliminary study in 26 patients (5). High-dose ursodeoxycholic acid did not influence symptoms, but

© 2006 Elsevier B.V. All rights reserved.

resulted in significant improvement in liver biochemistry and a significant reduction in the progression of cholangiographic appearances and liver fibrosis, as assessed by disease staging. No significant adverse effects were reported.

Ursodeoxycholic acid 250 mg tds plus ofloxacin 200 mg bd has been compared with ursodeoxycholic acid alone in the prevention of occlusion of biliary stents in a randomized trial in 52 patients with inoperable obstructive jaundice (6). Combination treatment was not superior to ursodeoxycholic acid alone. There was no significant difference in the frequency of adverse events between the two groups.

General adverse effects

Mild diarrhea and slightly raised serum transaminases are very common with chenodeoxycholic acid, while ursodeoxycholic acid seldom causes significant diarrhea or hypertransaminasemia. This difference is puzzling, since ursodeoxycholic acid, like chenodeoxycholate, is metabolized to lithocholate, and some if not all animal studies have shown evidence of hepatotoxicity. One undesirable property of ursodeoxycholic acid is that occasionally treatment is followed by the development of resistant (and radio opaque) coatings to gallstones, thus retarding or preventing further dissolution. Neither hypersensitivity nor tumor-inducing effects reactions have been reported.

Experience with tauroursodeoxycholic acid is limited. It is less effective than ursodeoxycholic acid and causes more adverse effects. Two patients who took tauroursodeoxycholic acid for primary biliary cirrhosis developed severe right upper quadrant pain, and rechallenge with tauroursodeoxycholic acid was positive (7).

Organs and Systems

Metabolism

Although most studies have shown no consistent effects of chenodeoxycholic acid on serum cholesterol concentrations, in the National Cooperative Gallstone Study there was a 10% increase over a 2-year period in treated people compared with a 5% rise in controls (8). Low-density lipoprotein concentrations rose in association; other varieties were unaffected.

Gastrointestinal

About half of all patients given the usual dose of chenodeoxycholic acid, 15 mg/kg/day, develop diarrhea, because the unabsorbed bile acid causes water to be secreted into the large bowel (9). The symptoms remit with dosage reduction and may not recur if the dose is then slowly increased again. It is best avoided in inflammatory bowel disease.

Liver

Serum transaminases tend to double or triple in the early weeks of treatment with chenodeoxycholic acid in about one-third of patients (10). There is a hypothesis that this is due to impaired lithocholate sulfation. Lithocholic acid is formed by the 7-dehydroxylation of chenodeoxycholic acid and is ordinarily inactivated by sulfation. However, hypertransaminasemia has been detected in nearly 75% of people with a low sulfation capacity (this capacity being bimodally distributed) and in less than one in 10 of those with a high capacity. All the same, chenodeoxycholic acid is substantially, if not totally, devoid of serious hepatotoxic actions. Liver biopsy has shown no significant changes; minor changes can include fatty change and lipofuscin accumulation.

Skin

- Lichenoid skin eruptions have been reported in a 1-month-old infant with neonatal hepatitis 3 weeks after the administration of ursodeoxycholic acid (11). There was complete resolution after withdrawal of ursodeoxycholic acid and treatment with glucocorticoids.
- Lichenoid eruptions have been reported in a 61-year-old man with gallstones who took ursodeoxycholic acid 600 mg/day for a few weeks (12). The eruption improved on withdrawal, but recurred when ursodeoxycholic acid was reintroduced 3 months later.

Lichen planus developed in one patient taking a combination of chenodeoxycholic and ursodeoxycholic acid (SEDA-17, 428).

Second-Generation Effects

Teratogenicity

The clinical and biological effects and safety of ursodeoxycholic acid in intrahepatic cholestasis of pregnancy have been reported in 19 patients, 14 of whom had clinical improvement, with reduction or disappearance of pruritus, and 11 of whom had an improvement in biochemical liver function tests (13). The only birth defect reported was pyloric stenosis in a boy whose mother had taken ursodeoxycholic acid for 10 days at 34 weeks gestation.

Bimatoprost

See also Prostaglandins

General Information

Bimatoprost is an analogue of $PGF_{2\alpha}$, used to treat glaucoma. It is believed to lower intraocular pressure by increasing the outflow of aqueous humor through both the trabecular meshwork and uveoscleral routes.

Organs and Systems

Sensory systems

Bimatoprost can cause gradual darkening of the color of the eyes and the eyelid skin, increased thickness, numbers and darkness of eyelashes, conjunctival hyperemia, and ocular pruritus (1). Darkening of the iris occurs in 1.1% of patients (2).

Hair

Eyelash growth was reported in 36–48% of patients after 6 months of using bimatoprost (2).

Biotin

See also Vitamins

General Information

Biotin is a water-soluble vitamin of the B complex (vitamin B_{10}, also called vitamin H), and is found in many foods, especially eggs and liver. Biotin is involved in the action of four carboxylases:

- acetyl-CoA carboxylase, which catalyses the binding of bicarbonate to acetyl-CoA to form malonyl-CoA in the synthesis of fatty acids
- pyruvate carboxylase, which is involved in gluconeogenesis
- methylcrotonyl-CoA carboxylase, which catalyses an essential step in the metabolism of leucine
- propionyl-CoA carboxylase, which catalyses essential steps in the metabolism of amino acids, cholesterol, and fatty acids.

Although biotin has been proposed as a treatment for diabetes mellitus, brittle nails, and hair loss, there is little good evidence of its efficacy in these conditions. It has also been used as a skin-conditioning agent in many cosmetic products in concentrations of 0.0001–0.6% (1).

Organs and Systems

Cardiovascular

Eosinophilic pleural effusion with eosinophilic pericardial tamponade has been attributed to concomitant use of pantothenic acid and biotin (2).

- A 76-year-old woman developed chest pain and difficulty in breathing. She had no history of allergy and had been taking biotin 10 mg/day and pantothenic acid 300 mg/day for 2 months for alopecia. Chest X-rays showed pleural effusions and cardiac enlargement. Blood tests showed an inflammatory syndrome, with an erythrocyte sedimentation rate of 51 mm/hour and an eosinophil count of $1.2–1.5 \times 10^9$/l. Pericardiotomy showed an eosinophilic infiltrate. There was no evidence of vasculitis. Serological studies were negative for antinuclear antibodies, rheumatoid factor, viruses, bacteria, and Lyme disease. Stool examination and parasitological serologies were negative. A malignant tumor was excluded by mammography, thoracoscopy, and a CT scan. Myelography, a biopsy specimen of the iliac crest bone, and the concentrations of IgE,

lysozyme, and vitamin B_{12} were also normal. A week after withdrawal of pantothenic acid and biotin she improved dramatically and her eosinophilia resolved.

Biperiden

See also Anticholinergic drugs

General Information

Biperiden is given orally in doses rising from 2 to 6 mg/day, more being given in individual cases. Of the anticholinergic effects that biperiden can cause, drowsiness seems to be one of the most prominent, and it should not be given to patients who have to drive motor vehicles. A dose of 12 mg has been reported to precipitate involuntary movements in some cases of parkinsonism (SEDA-1, 120).

Organs and Systems

Skin

Contact dermatitis has been attributed to biperiden (1).

Long-Term Effects

Drug withdrawal

Insomnia occurred after biperiden withdrawal in two patients with schizophrenia (2).

Drug-Drug Interactions

Haloperidol

In eight healthy men volunteers biperiden 2 mg reduced the serum haloperidol concentrations increased by carteolol 10 mg (3).

Bismuth

General Information

Bismuth is a brittle reddish-white metallic element (symbol Bi; atomic no. 83). It enjoyed great popularity up to the early 20th century, and thereafter continued to be used in the form of insoluble bismuth compounds, used for their supposed effects on the gastric wall as antacids, protective coatings, or inhibitors of proteolytic activity. The use of bismuth was particularly heavy in Australia, where bismuth subgallate was commonly used in postcolectomy or postileostomy patients, and in France, where bismuth subnitrate and other salts were widely self-administered for both gastric and intestinal conditions.

Bismuth salts are still in use. Tripotassium dicitratobismuthate and bicitropeptide (a bismuth-peptide complex) are used in the eradication of *Helicobacter pylori* in combination with antibiotics (SEDA-21, 233) (1–4), and ranitidine bismuth citrate is used to treat peptic ulcer (5). Bismuth salicylates are used in other intestinal diseases, such as microscopic colitis (6,7) and collagenous colitis (8). Bismuth subnitrate plus iodoform is used to pack surgical cavities. Bismuth oxide and bismuth subgallate are found in some topical formulations that are used for treating hemorrhoids. Bismuth is also used topically as a bacteriostatic.

Bismuth compounds are also used as hemostatic compounds (9). A uniform technique of tonsillectomy, including the use of bismuth subgallate and re-assessment of the tonsillar fossae after a 3-minute observation period, reduced the incidence of primary tonsillar hemorrhage in a retrospective study of 705 children (10). However, in a randomized study of 204 patients the evidence for the use of bismuth subgallate as a hemostatic agent in tonsillectomy was weak (11). Bismuth iodoform paraffin paste is commonly used in ear, nose, and throat surgery and in oral and maxillofacial surgery. A new area for the use of bismuth compounds may be in oncology as anticancer agents (12).

Due to the formation of an insoluble bismuth chloride complex in the gastric juice after oral administration of bismuth salts, the diffusion of the bismuth ion into the circulation is delayed. During treatment with tripotassium dicitratobismuthate, plasma concentrations of bismuth rise to 10–20 μmol/l which are not regarded as toxic. From experience over somewhat more than 20 years it would seem that the inherent risks of bismuth intoxication are relatively small if these compounds are used within the recommended ranges of dosage and length of treatment. However, they too can be abused, resulting in renal tubular damage (SEDA-18, 241) and attention has been drawn to the possible risks resulting from the ready absorption of citrate (13).

© 2006 Elsevier B.V. All rights reserved.

Placebo-controlled studies

Data from 20 clinical studies in 5000 patients who had taken ranitidine bismuth citrate (200, 400, or 800 mg bd) have been reported (14). The incidence of adverse events was not different from that associated with placebo and was independent of dose. The most common events (>1% of patients) were upper respiratory tract infections, constipation, diarrhea, nausea, vomiting, dizziness, and headache, the last being the only event reported by over 2% of the patients. Adverse events considered by the clinical investigator to be adverse reactions occurred with a similar frequency amongst patients given ranitidine bismuth citrate (8%), ranitidine hydrochloride (6%), and placebo (6%). The incidence of adverse reactions was greater when amoxicillin (11%) or clarithromycin (20%) were co-prescribed.

Organs and Systems

Respiratory

There has been a single report of a lung disorder with cough, which was traced to intravenous injection of a so-called "health tonic" containing bismuth, which had resulted in bismuth-containing subpleural opacities in the lungs (15).

Two cases of respiratory complications following the use of bismuth gallate have been reported (9).

- A 19-month-old boy with reactive airways disease had a tonsillectomy and adenoidectomy and bismuth-coated sponges were used for hemostasis. Excessive bleeding was not reported. In the recovery room he developed difficulty in breathing, and required oxygen followed by bronchodilators and deep suctioning. A chest X-ray showed speckled opacities throughout the lung fields and in the oropharynx and nasopharynx, probably due to aspiration of bismuth particles. He went on to develop a pneumonitis.
- An 8-year-old girl with asthma underwent tonsillectomy and adenoidectomy; hemostasis was performed with bismuth–adrenaline paste. A small amount of bismuth was noted in the endotracheal tube before extubation, and in the recovery room she developed respiratory difficulty associated with nasal flaring and sternal retraction. A chest X-ray showed aspirated radio-opaque material outlining the tracheobronchial tree and early pulmonary infiltrates.

Both patients had a history of refractory airway disease that put them at risk of respiratory complications after bismuth aspiration. Fortunately neither developed any serious respiratory compromise immediately after aspiration or required intubation.

Nervous system

From 1973 onward many cases of an encephalopathy were reported among bismuth users. By 1979, 945 cases had been recorded in France alone, 72 of them fatal; the worldwide total exceeded 1000 cases. Bismuth encephalopathy is characterized by ataxia, confusion, speech disorder, and myoclonus. The subgallate and oxychloride have been implicated, as has the subcitrate when used in a patient with impaired bismuth clearance. The chelate tripotassium dicitratobismuthate, which contains very small amounts of bismuth, appears to be safe in this respect for normal use, as does the occasional use of more traditional bismuth products for conditions such as travelers' diarrhea. Use of bismuth subnitrate ("Roter" tablets) does not seem to lead to metal absorption (16), but such absorption does occur from bismuth salicylate (17).

- A 49-year-old woman with chronic gastric ulcers and 5 years of bismuth abuse developed bismuth encephalopathy, with progressive dementia, dysarthria, and myoclonic jerks 1 week after increasing the dosage of bismuth (18). Electroencephalography showed generalized spike-wave complexes, suggesting that the myoclonus was epileptic in nature. Bismuth was withdrawn and she was given valproate, which reduced the frequency of the myoclonic jerks. Administration of the chelator dimercaptopropane sulfonic acid (DMPS) enhanced bismuth elimination but aggravated the clinical symptoms and it was therefore withdrawn. She slowly recovered.
- An 86-year-old woman underwent partial maxillectomy for squamous cell carcinoma of the right alveolus and hard palate, and the maxillary antrum was packed with a length of bismuth iodoform paraffin paste (19). Postoperatively she developed delirium and by day 5 was exhausted, light-headed, and unsteady. She became increasingly aggressive and by day 11 was eating very little and having fainting episodes. Worsening confusion and some paranoid ideation was apparent and tremor was pronounced, but there were no focal neurological signs. The bismuth iodoform paraffin pack was removed on day 14 and 7 days later she had improved and was very cooperative and alert when she was discharged 5 days later. The bismuth serum concentration on day 14 was 146 nmol/l (reference range 0–4 nmol/l) and on day 22 was 81 nmol/l. The original peak bismuth concentration was extrapolated to over 300 nmol/l.

Three phases of the encephalopathy that bismuth can cause can be distinguished (SEDA-4 167) (20):

1. *Prodromal phase* This is characterized by such vague complaints as weakness, mental slowness, short memory, reduced working capacity, insomnia, headache, and anxiety. These symptoms can easily be dismissed as non-specific, and can persist for more than 2 years before further signs develop. In general, however, the course is gradually progressive toward the symptoms of the next phase.
2. *Acute phase* Sudden deterioration to an acute encephalopathy occurs over a period ranging from several hours to 1–2 days. Patients develop dysarthria, severe locomotor disturbances such as ataxia, difficulty in walking, intention tremor, myoclonic jerks (especially of the upper limbs, face, and trunk), incontinence due to loss of sphincter control, hyper-reflexia, and sometimes generalized convulsions. The patient may be confused, disoriented, and agitated. Excitation, hallucinations, delirium, and fluctuations of mental alertness, ranging from dizziness to loss of consciousness and coma, can occur. In about 7–9% of cases the outcome is fatal,

© 2006 Elsevier B.V. All rights reserved.

owing to bronchopulmonary, cardiovascular, thromboembolic, or infectious complications.

3. *Recovery phase* After withdrawal of bismuth, the toxic symptoms usually abate rapidly, although physical and psychological weakness, depressive mood, memory impairment, intellectual deterioration, sleep disturbances, headache, and other symptoms occasionally persist for several months, and in isolated cases for more than a year. Exceptionally, psychic and intellectual capacity remain permanently impaired.

The reason for the suddenness of the outbreak of bismuth encephalopathy in the 1970s after the drug had been used for so many years is uncertain. A major French epidemiological study undertaken at the time (SEDA-6, 217) failed to detect any clear link to particular dosage habits, topographical factors, or drug interactions. Unknown environmental factors may have altered either the effects of bismuth itself or the sensitivity of the brain. It was later suggested that a change in intestinal flora converted bismuth salts into more soluble neurotoxic compounds (21), although it is not clear why this should have happened during the 1970s. Since measures were taken to counter the traditional use of bismuth, only very occasional new cases of encephalopathy have been reported since then. It is currently unresolved whether the lower doses of bismuth in gastric powders, antacids, astringents, demulcents, purgatives, and antidiarrheal formulations that are still in use are in the long run innocuous; if an unknown environmental factor did indeed lead to toxic manifestations with the older products, it might similarly modify the effects of others; watchfulness is therefore essential. In fact, one suspects something of a renaissance of bismuth encephalopathy in the 1990s; in 1993 cases were reported from several countries, associated inter alia with abuse of bismuth subsalicylate (Pepto-Bismol) (22) and the use of bismuth subgallate (23).

As late as 1994 a toxic encephalopathy, relapsing but reversible, was reported in a woman who had received a large dose of bismuth when bismuth iodoform paraffin paste was inserted extradurally (24). Elsewhere neurotoxicity has been reported (SEDA-19, 446).

Mouth and teeth

A black tongue was reportedly caused by exogenous pigment in chewable bismuth subsalicylate tablets.

- A 51-year-old white woman developed black discoloration of her tongue (25). The black substance was easily removed by scraping the surface of the tongue. She denied using tobacco products or alcohol. Her medications included alprazolam, montelukast, amitriptyline, hydroxychloroquine, triamcinolone acetonide, omeprazole, cisapride, and calcium carbonate. She had recently started to chew three to six bismuth subsalicylate tablets daily. She was advised to stop using bismuth subsalicylate and to brush her tongue with a soft-bristled toothbrush. The discoloration improved within a couple of hours and eventually disappeared completely. She continued to take hydroxychloroquine, a known cause of oral mucosal pigmentation.

Gastrointestinal

The results of a comparative trial suggested that the adverse reactions most commonly encountered during courses of treatment including bismuth and designed to eliminate *H. pylori* are vomiting, diarrhea, abdominal pain, headache, and a metallic taste in the mouth (SEDA-22, 393) (26).

Constipation is an occasional adverse effect of bismuth therapy. The feces are grey or black, and can be mistaken for melena (27).

Biliary tract

- Acute cholecystitis caused by non-O1 *Vibrio cholerae* has been described in a 55-year-old healthy traveler immediately after a vacation in Cancun, Mexico (28). During his vacation he had taken the Pepto-Bismol brand of bismuth subsalicylate 30 ml tds as prophylaxis against traveler's diarrhea. At surgery his gall bladder was acalculous, inflamed, distended, and nearly ruptured. Pathogenetic factors may have included the use of bismuth subsalicylate, distension of the gall bladder from illness-induced fasting, and bacterial toxins in the gall bladder.

The authors implied that bismuth subsalicylate could have prevented the secretory diarrhea that is seen in many infections with non-O1 *V. cholerae*. Diarrhea would result in evacuation of many organisms from the small bowel. Bismuth subsalicylate might have impaired this mechanism and increased the number of organisms with access to the common bile duct at the ampulla of Vater.

Urinary tract

Some reviewers have claimed that bismuth can cause reversible acute renal insufficiency, but if this indeed occurs it must be excessively rare; it might be part of a nephrotic syndrome.

Skin

- A man who had taken bismuth subsalicylate after heavy meals once or twice a month for the previous 4 years developed crops of small, black, carbon-like particles (size range 0.2–0.5 mm) on the skin (29). The palms and soles were not involved. These particles appeared at intervals of 15–30 days and persisted for 2 or 3 days if not removed by soap and water. They were located in follicular orifices and caused no symptoms; they tested positive for bismuth. The condition receded completely after bismuth was withdrawn (30).

Musculoskeletal

Osteoarthropathy was an associated feature in some 3% of patients with bismuth encephalopathy. However, at least one case is on record in which a bismuth osteoarthropathy developed without any manifestation of encephalopathy (31). The symptoms mainly involve one or both shoulders, of which painful restriction of movement is usually the first sign in the postacute phase of bismuth encephalopathy. This can persist for several months after bismuth has been withdrawn. X-ray examination shows an

© 2006 Elsevier B.V. All rights reserved.

osteolytic deforming glenohumeral osteoarthropathy with necrosis of the humeral head. Unilateral or bilateral fractures can occur. The lesions described can regress without sequelae over several months and osteonecrosis can also proceed to complete lysis of the humeral head.

The fact that much bismuth is ordinarily stored in the skeleton may be relevant in the etiology of bismuth osteoarthropathy. In two reported cases a differing type of osteopathy occurred, associated with different localization of the pathological lesions and with unusually high bismuth concentrations in the bone: both patients had received bismuth injections for syphilis many months or even years before (SEDA-4, 169).

Immunologic

Sensitization to bismuth derivatives has been reported but is rare.

- A 33-year-old woman with atopic hand eczema and allergic rhinitis was given Noviform, an eye ointment containing bibrocathol (bismuth oxide and tetrabromocathechol), for periorbital dermatitis and noticed an exacerbation of her dermatitis (32). A patch test was positive for bismuth oxide.

Anaphylaxis to bismuth subsalicylate (Pepto-Bismol) has been observed (33).

- A 25-year-old man with symptoms of acute gastroenteritis took Pepto-Bismol, a total of eight caplets over 6 hours. About 30 minutes after the last dose, he developed generalized acute urticaria. He had previously tolerated Pepto-Bismol well, but had presumably become sensitized. He was successfully treated with intravenous fluids and histamine H_1 receptor antagonists.

Second-Generation Effects

Teratogenicity

Very little is known about the use of bismuth in pregnancy, but in documented cases mothers affected with bismuth encephalopathy during pregnancy gave birth to healthy infants.

Susceptibility Factors

Renal disease

Bismuth is predominantly excreted via the kidney and would be expected to accumulate in patients with renal insufficiency. It is not impossible that combined exposure to bismuth and other metals could render the patient more susceptible to bismuth toxicity; the parallels between the complications seen here and with other light metals (zinc, aluminium) are striking.

Drug Administration

Drug administration route

Severe systemic intoxication in the past has been observed after incautious use of bismuth salts on extensive wound areas.

Drug overdose

Renal damage has been reported in cases of bismuth overdose.

- A 17-year-old girl took 25 tablets of bismuth subcitrate 300 mg (total 7.5 g) in a suicide attempt and developed severe renal insufficiency (34). Renal biopsy showed evidence of acute tubular necrosis, with epithelial flattening, lumen widening, and atrophic changes in the convoluted tubules and mononuclear cell infiltration and edema in the interstitium. She was managed with hemodialysis and recovered.
- A 22-year-old woman took 5.4 g of colloidal bismuth subcitrate in a suicide attempt and developed Fanconi's syndrome and acute renal insufficiency (35). She received hemodialysis and intravenous sodium 2,3-mercapto-1-propanesulfonate 60 hours after intoxication. Her serum bismuth concentrations fell from 640 to 15 μg/l within 6 days, her renal function improved, and her tonsillar ulceration healed. Hemodialysis was discontinued on day 14. She had normal renal function 6 weeks later.
- Reversible bismuth nephrotoxicity was reported in a 16-year-old girl who had nausea, vomiting, and dizziness for 4–5 days and oliguria for 2 days (36). She had taken an overdose of tripotassium dicitratobismuthate tablets containing a total amount of 3.0–4.5 g of bismuth. Blood urea and serum creatinine were increased and there was proteinuria and erythrocytes in the urine. Acute tubular necrosis was observed on biopsy.

Bisoprolol

See also Beta-adrenoceptor antagonists

General Information

Bisoprolol is a highly selective $beta_1$-adrenoceptor antagonist. Its adverse effects profile is similar to that of atenolol (1), and despite theoretical benefits there is no convincing clinical evidence that bisoprolol has an advantage (2).

Organs and Systems

Metabolism

Bisoprolol can increase serum triglycerides and reduce HDL cholesterol (3).

Bisphosphonates

General Information

The development of bisphosphonates for clinical purposes began with the discovery that inorganic pyrophosphate is present in blood and urine and inhibits the precipitation of calcium and phosphate (1). Derivatives of pyrophosphate had been widely used for industrial purposes, because they inhibit the precipitation of calcium carbonate. Their principal use was as antiscaling additives in washing powders, water, and oil brines, to prevent deposition of calcium carbonate scale. It was then found that pyrophosphate binds strongly to calcium phosphate, prevents both the formation and dissolution of calcium phosphate crystals, and inhibits calcification in vitro. The bisphosphonates are used to treat bone diseases characterized by increased osteoclastic bone resorption (2). Long-term administration of low doses of oral bisphosphonates is considered to be valuable in patients with postmenopausal osteoporosis (3,4).

Adverse effects of the bisphosphonates include low-grade transient fever and headache; other effects are asymptomatic hypocalcemia, hypophosphatemia, and hypomagnesemia (5–7).

Alendronate

Alendronate is an aminobisphosphonate with general properties similar to those of the other bisphosphonates. It inhibits bone resorption and is used in osteoporosis and Paget's disease of bone. It has also been used in the treatment of bone metastases and hypercalcemia of malignancy.

Clodronate

Clodronate is a bisphosphonate that has demonstrated efficacy in patients with a variety of disorders of enhanced bone resorption, including Paget's disease, osteolytic bone metastases, and hypercalcemia of malignancy (8,9). In preclinical studies, clodronate prevented bone loss during immobilization (10).

Etidronate

Etidronate, an alkylbisphosphonate, was the first to be introduced for the management of bone resorption disorders. Subsequently, a cyclic regimen of etidronate followed by calcium supplementation was established in the treatment of osteoporosis.

Pamidronate

Pamidronate in the disodium form, a second-generation bisphosphonate, has an intermediate antiresorptive activity; its continuous administration produces rapid suppression of bone resorption. Unlike etidronate, it does not impair bone mineralization at therapeutic dosages in patients with Paget's disease. Pamidronate inhibits osteoclast activity primarily by binding with hydroxyapatite crystals in the bone matrix, preventing the attachment of osteoclast precursor cells. Other mechanisms of action of matrix-bound pamidronate may include direct inhibition of mature osteoclast function, promotion of osteoclast apoptosis, and interference with osteoblast-mediated osteoclast activation. In patients with osteoporosis, pamidronate increased bone mineral density by 6.8% over 2.2 years (11). The frequently observed adverse effects with pamidronate therapy were gastrointestinal: gastritis due to either a local reaction when a high concentration of the drug stays in the mucus or by chelation with calcium ions (12).

Residronate

Residronate is a pyridinylbisphosphonate with potent antiresorptive properties. In animal studies it was about 1000 times more potent than etidronate and 3-5 times more potent than alendronate (13), which enables the use of a lower dose and a shorter treatment regimen, with consequent potential minimization of adverse effects. In a randomized, double-blind, multicenter study of the efficacy, safety, and tolerability of residronate in 62 patients taking oral residronate for Paget's disease of bone, adverse effects were recorded in 29 patients (14). Twelve had upper gastrointestinal adverse events, of which three were moderate to severe. Four other patients withdrew because of adverse events, but one only was considered to be possibly drug-related (mild colitis). There was a transient reduction in serum calcium and phosphorus concentrations, greatest at 1 month after the start of treatment, and followed by a gradual return toward baseline concentrations.

Comparative studies

In 72 postmenopausal women (mean age 65 years) with established osteoporosis who took elemental calcium 1.0 g/day and vitamin D 400 U/day, etidronate and hormones were compared (15). The Hormone Replacement Therapy (HRT) group ($n = 18$) took cyclical estrogen and progesterone; the etidronate group ($n = 17$) took intermittent cyclical etidronate; and the combined therapy group ($n = 19$) took both HRT and etidronate. Three patients in the HRT group and two patients in the combined therapy group withdrew owing to estrogen-related adverse effects. One patient each from the control group and the etidronate group withdrew because of inability to tolerate the medications. Two patients each from the control and combined therapy groups, and one from the etidronate group withdrew owing to other medical problems. There was one death due to myocardial infarction in the etidronate group, and one patient in the control group was lost to follow-up. Six patients complained of nausea after etidronate, but symptoms improved with time.

In 32 women treated for postmenopausal osteoporosis for 2 years with either pamidronate or with oral fluoride, adverse effects were a transient fever with influenza-like symptoms in five patients after the first infusion of pamidronate, and rigors and mild phlebitis in one patient (16).

Placebo-controlled studies

Of 300 patients, 221 (111 pamidronate, 110 placebo) withdrew prematurely (17). The majority of withdrawals

© 2006 Elsevier B.V. All rights reserved.

($n = 115$) were due to disease progression or death due to multiple myeloma. The number of patients who withdrew because of adverse experiences ($n = 30$) was small in both groups, and no deaths occurred due to the treatment. Adverse gastrointestinal events were reported in patients who received both pamidronate and placebo, but although the rates were not significantly different in the two groups, there were more cases of nausea, dysphagia/dyspepsia, and gastrointestinal ulceration in the pamidronate group.

In a long-term follow-up of two randomized, placebo-controlled trials of pamidronate in women with breast carcinoma and osteolytic bone metastases, adverse events caused premature withdrawal of therapy in 22% of 367 patients taking pamidronate 90 mg/day and 20% of 38 patients taking placebo (18).

- A 75-year-old woman was withdrawn after developing an allergic reaction in her left eye possibly related to pamidronate.
- Another patient discontinued pamidronate after an episode of symptomatic hypocalcemia.
- Two other serious and unexpected adverse events occurred in patients taking pamidronate.
- A 45-year-old woman who had been taking placebo developed an interstitial pulmonary infiltrate and dyspnea 4 days after taking pamidronate on a compassionate basis after completing the study.
- An 83-year-old woman developed increased weakness, fatigue, and dyspnea 3 weeks after her last dose of pamidronate.

These adverse events were both assessed by the treating physician as being possibly related to pamidronate. Fatigue related to the study drug was reported slightly more often by patients taking pamidronate (40%) than those taking placebo (29%). Fever related to the study drug was reported in 14% of pamidronate patients and in 5% of placebo patients.

The effect of oral pamidronate on bone mineral density and its adverse effect profile has been investigated in a double-blind, placebo-controlled study in 122 patients aged 55–75 years with established vertebral osteoporosis (19). The patients took disodium pamidronate 300 mg/day for 4 weeks every 16 weeks (group A), 150 mg/day for 4 weeks every 8 weeks (group B), or placebo (group C). All also took calcium 500 mg/day and vitamin D 400 IU/day. In groups A and B there were significant reductions in serum osteocalcin and urinary deoxypuridinoline and an excess of gastrointestinal adverse effects, particularly in group A. The authors concluded that intermittent pamidronate therapy can prevent bone loss in both the lumbar spine and femoral neck in patients with established vertebral osteoporosis, although the 300 mg dose did not appear suitable for clinical use because of gastrointestinal adverse effects.

Organs and Systems

Neuromuscular function

The efficacy and safety of amidronate in recalcitrant reflex sympathetic dystrophy have been assessed in 10 women and 13.men, mean age 44 years (20). Amidronate was given intravenously in a dose of 1 mg/kg/day for 1–3 days. There were adverse events in 14 patients: transient fever ($n = 6$), venous inflammation ($n = 2$), transient symptomless hypocalcemia ($n = 3$), nausea ($n = 1$), lymphopenia ($n = 1$), transient hypertension ($n = 1$).

Sensory systems

Eyes

Adverse effects with various forms of pamidronate included 23 cases of suspected ocular adverse drug reactions associated with the use of intravenous pamidronate disodium (21). Bilateral anterior uveitis occurred 24–48 hours after administration in six cases; three reports involved unilateral episcleritis, occurring 1–6 days after administration; and 13 patients complained of non-specific transient conjunctivitis 6–8 hours after administration.

The first case of uveitis due to pamidronate was reported in 1993 (22). A review of reports published as of 1994 (21) found 23 cases, including 7 cases of anterior uveitis, 3 of episcleritis or scleritis, and 13 of non-specific transient conjunctivitis. Since then, other cases of anterior uveitis have been reported (23,24).

Of 16 cases of pamidronate-induced anterior uveitis (23,24), 11 were bilateral and 5 unilateral. In most cases, the onset was within 24–48 hours of initiation of the pamidronate infusion, although in one patient the interval was 17 days. The severity, when specified, ranged from mild to severe. Treatment was by watchful waiting in two patients, oral glucocorticoid therapy or hospital admission in four, and topical glucocorticoids with or without cycloplegic agents in nine. The time to recovery, when specified, ranged from a few days to a month. The cumulative pamidronate dose was 30–240 mg.

Ears

Serious adverse effects of aminobisphosphonates were reported in otospongiosis. Of two patients with stapedial otosclerosis and sensorineural hearing loss one developed total bilateral deafness and the other retained minimal auditory function in the low frequencies (25). It was recommended that sensorineural deafness in selected patients with otosclerosis should be treated with sodium fluoride, and that patients with Paget's disease treated with aminobisphosphonates should be closely monitored and the drug discontinued immediately if hearing deteriorates. Elsewhere, ototoxicity has been reported (SEDA-20, 440).

Psychological, psychiatric

Olfactory hallucinations have been attributed to etidronate (26).

Endocrine

A patient who was receiving disodium pamidronate developed gynecomastia, and of another 13 patients, two more men had gynecomastia and one woman had tender swollen breasts (27).

© 2006 Elsevier B.V. All rights reserved.

Mineral balance

Pamidronate can cause asymptomatic hypocalcemia (SEDA-20, 440). In a study of the use of pamidronate to treat immobilization hypercalcemia after acute spinal cord injury in nine patients, one patient had transient drug-related fever and four had asymptomatic hypocalcemia (28).

- A 39-year-old normocalcemic patient with subclinical hypoparathyroidism and bone metastases from breast carcinoma was given pamidronate 60 mg parenterally and developed hypocalcemia (1.42 mmol/l) and carpopedal spasm (29). Hypocalcemia due to latent hypoparathyroidism had been compensated by extensive osteolysis due to bone metastases.

Gastrointestinal

The aminobisphosphonates cause severe gastrointestinal adverse effects: of greatest concern is their capacity to cause esophageal lesions. A report identified three patients with severe esophagitis from alendronate (30). Four episodes of esophagitis occurred in 49 patients in a study of a new timed-release formulation of pamidronate (31). Severe esophagitis or esophageal ulceration have been reported in seven patients taking bisphosphonates (six alendronate and one etidronate); the lesions healed on withdrawal (32).

In 57 patients with advanced prostate cancer resistant to first-line hormonal therapy treated with estramustine and clodronate, the main adverse effect was nausea (33). Therapeutic efficacy was small. Reasons for premature withdrawal of clodronate in one study included refusal to continue treatment (five patients) and progressive disease of the bone (four patients) (34). One patient refused to take clodronate from the start; seven discontinued clodronate after a median of 13 (range 0.2–23) months because of adverse events. In five patients the cause was nausea, combined with vomiting in four and diarrhea in one. After 0.9, 1.0, and 1.3 months the dosage of clodronate was reduced to 800 mg/day in three patients (one had nausea, another dyspepsia, and a third had uncharacteristic sensations in the skeleton).

The safety of cyclic etidronate has been evaluated in 550 general practices in the UK in 7977 patients taking cyclic etidronate (7244 women) (35). The findings were consistent with the conclusions of several reviews of the safety and tolerability of cyclic etidronate (36,37). The most common adverse effects reported in these reviews were minor gastrointestinal events, such as diarrhea, nausea, and flatulence. Etidronate has not been associated with an increased incidence of serious gastrointestinal adverse events.

Liver

Although adverse events associated with bisphosphonates are usually gastrointestinal, raised transaminases (aspartate transaminase and alanine transaminase) have also been described in many cases. However, the frequency of such changes has been poorly investigated. The Probone study was a phase II trial in 610 osteopenic women randomized for 3 years to receive placebo or clodronate 65, 400, 800 mg/day, or 400 mg/day for 15 days out of 90 (intermittent group) (38). During the first study year, gastrointestinal adverse events were reported by 20–26% of the patients in the five study groups, but there were no differences between groups. The high-dose clodronate groups (400 and 800 mg/day) had no more hepatic adverse effects than the low-dose groups, and there were no serious adverse effects on the liver. However, these higher doses of clodronate caused a significant mean increase in alanine transaminase of 5.4–5.8 IU compared with placebo. In volunteers with initially normal transaminase activity, the risk ratio for an increase to above normal was 1.8 with clodronate 400 mg/day and 2.5 with clodronate 800 mg/day. In these groups, aspartate transaminase and alanine transaminase, respectively, rose above the top of the reference ranges in 12 and 18% of the volunteers. The respective percentages in the placebo group were 6.2 and 7.2%. All bilirubin concentrations were normal. The authors concluded that oral clodronate may increase the activity of serum transaminases, and that these enzymes most likely come from the liver.

Skin

Necrobiotic palisading granuloma has been attributed to intravenous disodium clodronate (39).

Musculoskeletal

Of 12 patients given pamidronate (seven men, mean age 25 years) with either corticosteroid-induced or postmenopausal osteoporosis, none of whom had undergone transplantation, nine reported severe bone pain, starting at about 12 hours after the infusion and lasting for up to 3 days (40). The bone pain typically started in the spine then migrated to the ribs and finally to the lower limbs. The pain was excruciating in seven patients, rendering them bed-bound and making sputum expectoration and physiotherapy difficult. Paracetamol and diclofenac were unsuccessful in preventing or relieving pain. Two of the nine patients also had febrile reactions and one developed phlebitis around the infusion site. None of the controls developed bone pain. The high incidence of bone pain after intravenous pamidronate may be a novel drug reaction specific to cystic fibrosis. The pain may be related to the abrupt reduction in bone turnover anticipated after intravenous pamidronate.

Body temperature

In a study of the use of pamidronate to treat immobilization hypercalcemia after acute spinal cord injury in nine patients, one patient had transient drug-related fever and four had asymptomatic hypocalcemia (29).

Susceptibility Factors

Age

Caution should be exercised when using pamidronate in children, since there may be an immediate calcium-lowering effect and persistence of hypocalcemia, hypomagnesemia, and hypophosphatemia, particularly when

© 2006 Elsevier B.V. All rights reserved.

high doses (for example 30 mg) are given intravenously (41). The authors recommended that children be given doses of 15–20 mg.

Drug Administration

Drug administration route

Intermittent intravenous clodronate is effective in preventing and treating postmenopausal bone loss (42). In Italy, it is also available for intramuscular administration, which might be an acceptable alternative for some patients. However, intramuscular injection caused substantial pain at the site of injection, which led to withdrawal in almost 50% of the patients who received a weekly dose (43). These results suggest that intermittent intramuscular clodronate can improve skeletal bone density in osteoporotic postmenopausal women, but in situ pain may limit its extensive use.

Bithionol

General Information

Bithionol is a chlorinated bisphenol with antihelminthic properties. It is active against most trematodes and has been recommended as preferable to praziquantel in fascioliasis and paragonimiasis, proving both effective and well tolerated. Bithionol also has antibacterial properties and was for this reason included for a time in cosmetic formulations. However, when given topically it caused photosensitivity reactions, and this form of application has been abandoned.

Organs and Systems

Gastrointestinal

An Egyptian report in 1991 on the use of bithionol in fascioliasis in doses of 30 mg/kg every other day for five doses noted that unpleasant symptoms were common, but some or most of them were certainly due to the underlying disease and actually abated with treatment (1). The only symptom the incidence of which actually increased as a result of treatment was diarrhea, which occurred in 12 of 14 users; one patient also developed urticaria with pruritus.

Liver

The effects of bithionol on the liver have been examined in an Egyptian study in 1990 (2). The pathology of human fascioliasis was studied before and after bithionol treatment using light and transmission electron microscopy. Fine needle biopsies were taken from five patients with established fascioliasis, before and after drug administration. By light microscopy the pathology of human fascioliasis was similar to that reported in experimental fascioliasis. The ultrastructural picture showed bile ductule hyperplasia, fibrosis of portal tracts, widening of the interhepatic spaces by many microvilli, and dilated Disse spaces with collagen fibers. Bile ductule hyperplasia may be the initial factor in fibrinogenesis, which subsequently enhances the development of microvilli on the surfaces of hepatocytes. Both light and electron microscopy showed regression of the picture of fascioliasis to normal after bithionol treatment, with no sign of adverse effects on the liver.

Bitoscanate

General Information

Bitoscanate (phenylene 1,4-diisothiocyanate) enjoyed some clinical interest in the treatment of hookworm infection in around 1975 (1), but it proved highly dangerous, and deaths have occurred with as little as 300 mg. Most of the publicity that it has had in recent years relates to its listing as an "extremely hazardous substance," and the US Office of Homeland Security has actually regarded it as a possible tool for bioterrorism.

Bleomycin

See also Cytostatic and immunosuppressant drugs

General Information

Bleomycin is a cytostatic drug that causes double-strand breaks in DNA. It has been used to treat Hodgkin's disease and a variety of solid cancers. It is often used in combination with other anticancer drugs, for example in the regimens known as ABVD (doxorubicin + bleomycin + vinblastine + dacarbazine) and BEP (bleomycin + etoposide + cisplatin). It has also been injected intrapleurally in the management of malignant effusions.

Organs and Systems

Respiratory

Bleomycin can cause diffuse interstitial pneumonitis, with significant mortality. Bleomycin is more slowly degraded in the lungs than in other tissues, such as the bone marrow or liver, because of lower bleomycin hydrolase activity. The mechanisms of lung damage include the formation of highly reactive oxygen species; lipid peroxidation of cell membranes has been suggested, but not confirmed (1). Others have suggested a role for angiotensin-converting enzyme in production of the lung damage (2), but the data are unconvincing.

Because this is a severe adverse effect it is generally recommended that a total dose of more than 400 mg of bleomycin should be avoided in patients with normal renal function. In those over 70 years of age reduced creatinine clearance makes dosage reduction necessary.

Estimates of the incidence of bleomycin pulmonary toxicity range from 11 to 23% (3). Of 99 patients previously treated with bleomycin together with other cytostatic drugs for testicular tumors, 16 developed abnormal lung function tests; amongst those who received more than 500 mg of bleomycin cumulatively, 75% had abnormal lung function tests, Raynaud's phenomenon, or both (4). Rapid progression to fatal pulmonary fibrosis has been documented previously and, in all but one instance, there had been previous or concurrent chest radiotherapy. Two cases have been reported of rapidly progressive fatal pulmonary fibrosis in patients receiving bleomycin who had had no previous lung disease, and who had not undergone radiotherapy to the chest (5). Lung toxicity can occur at low cumulative doses of bleomycin during concurrent treatment with cyclophosphamide (which independently causes pulmonary toxicity). In 19 patients (6) there was a high (26%) incidence of fatal pulmonary toxicity in patients receiving the combination of these two drugs, which warrants special caution.

Transient but significant reductions in pulmonary function tests have been reported within 8–12 months in 35 children treated with polychemotherapy who had received a cumulative dose of 120 mg/m^2 up to 12 years after diagnosis (7). However, there were no long-term abnormalities.

In 194 patients there was a fatality rate of 2.8% from pulmonary toxicity. The incidence of fatal pulmonary toxicity increased with each decade of life above 30 and the lower the glomerular filtration rate at the time of administration the greater the death rate; the death rate may exceed 10% in those over 40 years of age (8).

Bleomycin is also associated with a hypersensitivity pneumonitis. This should be considered when interpreting cytological swabs in patients treated with the drug, since the acute cytological changes can be misinterpreted (9).

A syndrome of acute chest pain occurring during bleomycin infusion has been described in 10 patients with features that could not be ascribed to pulmonary fibrosis, hypersensitivity pneumonitis, or cardiovascular toxicity (10). The pain was sudden in onset and occurred during the first or second course, usually on the second or third day. There was retrosternal pressure or pleuritic pain, in some cases severe enough to require narcotic analgesics. Stopping or slowing the infusion produced marked improvement. In two of seven patients who received a subsequent course of treatment, the pain recurred. One patient had dyspnea and two developed an erythematous rash. One had a pleural friction rub and one a pericardial friction rub. There was fever during five episodes. There were no other physical abnormalities. There were electrocardiographic changes suggestive of pericarditis in two patients; one patient developed transient blunting of a costophrenic angle on a chest X-ray, and another a transient and small retrocardiac pulmonary infiltrate. The pain resolved spontaneously with analgesics, and there were no long-term pulmonary or cardiac sequelae. Possible underlying mechanisms include pleuropericarditis due to serosal inflammation or vascular pathology.

Severe morbidity has been reported after the use of regimens containing bleomycin: 10% of patients developed adult respiratory distress syndrome and a further 9% needed prolonged ventilation (11). The authors thought that these rates were higher than expected and attributed this to a combination of the toxic effects of bleomycin on the lung and a large retroperitoneal and/or pulmonary tumor burden.

Skin

Bleomycin can occasionally cause scleroderma-like changes in the skin (12,13), an effect that may be enhanced by radiotherapy (14).

Body temperature

When bleomycin is used as a sclerosing agent in adults, a dose of up to 1 mg/kg is generally instilled into the chest through a thoracostomy tube. Bleomycin 60 mg intrapleurally caused a fever over 39°C in two of 21 patients with malignant pleural effusions; it settled without treatment and was not associated with local discomfort (15).

Drug Administration

Drug administration route

Several antineoplastic agents have been introduced into the pleural space to achieve pleurodesis, but the largest reported experience is with bleomycin. Intrapleural bleomycin has an efficacy similar to that of tetracycline and doxycycline (16). About 45% of a dose of bleomycin is

© 2006 Elsevier B.V. All rights reserved.

absorbed systemically, but significant adverse events are uncommon (17). Chest pain is reported in about 28% of patients, fever in 24%, and nausea in about 11% (18). A randomized comparison of bleomycin with tetracycline in 85 patients with malignant pleural effusions showed that toxicity, predominantly in the form of chest pain and fever, was similar with the two drugs (7–17%) (19). Nearly half the patients (34) died within 90 days owing to disease progression. However, one patient died within 2 days of intrapleural bleomycin, and the investigators could not exclude a contribution from the bleomycin. In another comparison of bleomycin with doxycycline there was fever in 13%, chest pain in 11%, and chills in 4% of patients treated with bleomycin (20).

Blood cell transfusion and bone marrow transplantation

General Information

The most common adverse effect of routine blood transfusion is an incompatibility reaction. Massive blood transfusions can cause other adverse effects (1). Human error resulting in blood group mismatching is the leading cause of transfusion-related fatalities (2,3). Although there have been major achievements in transfusion medicine to improve the safety of blood and blood products, the risks of transfusion reactions and of the transmission of infectious agents have not been eliminated. Treatment of patients with blood or blood-derived components has therefore been the subject of great public concern, mostly because of the tragic consequences of transfusion-transmitted human immunodeficiency virus (HIV).

Most patients do not react adversely to blood products. However, some have mild to severe effects immediately or delayed for 48 hours. Information on adverse reactions to blood products collected by the New Zealand Centre for Adverse Reactions Monitoring enables the identification of unusual or unpredictable adverse reactions; risk factors such as concomitant medications, underlying diseases, rate of administration; and batch problems (4).

Minimizing the risks of blood transfusion

Because of the possible complications of blood transfusion, it is constantly emphasized that unnecessary transfusions should be avoided. In most cases therapy with blood or blood components is solely a replacement therapy and should therefore be used only when a distinct deficiency of some blood component has been demonstrated; "component blood therapy" is usually preferable to

© 2006 Elsevier B.V. All rights reserved.

whole blood therapy, providing more specific treatment. Also, the use of autologous transfusions, although not always feasible, seems to be a strategy that might reduce complication rates (5).

In order to reduce risks to a minimum and at the same time ensure that blood products are of high quality, three measures must be enforced.

1. Proper selection of blood donors (6).
2. Screening of individual donations (7).
3. The use of production methods specifically aimed at minimizing the risks of transmitting infectious diseases (8).

Blood donor selection

Blood donors should be non-remunerated and voluntary, and their health should be checked at regular intervals. A scheme for donor selection may include permanent exclusion criteria, such as previous episodes of jaundice (including laboratory evidence of current or previous infectious hepatitis, especially hepatitis B or C), syphilis or malaria, the presence of anti-HIV antibodies, so-called risk conduct, such as homosexual or bisexual behavior, or treatment with non-recombinant growth hormone. Time-limited exclusion criteria relating to current health status should also be used; these may also include such temporary risk factors as the taking of certain kinds of medicine, a recent blood transfusion, vaccination with live vaccines, a recent pregnancy, and travel to certain geographical areas, for example regions with malaria or a high prevalence of HIV.

In most countries, people with a history of jaundice are excluded from the donor population. However, there is a substantial geographic variation in the prevalence and detection rate of hepatitis B surface antigen (HBsAg) and antibodies to hepatitis C virus (HCV) in donors (9,10). In addition, the type of donor involved influences the risk: commercial (paid) donors carry a much higher hepatitis risk than non-remunerated voluntary donors (11,12).

With respect to the risk of transmission of variant Creutzfeldt–Jakob disease by blood, some countries exclude from donation donors who lived in the UK for more than 6 months between 1980 and 1996 (13).

Laboratory screening of individual donations

Individual portions of donated blood should be tested for infectious risk whenever possible. The series of assays currently performed in most countries comprises tests for antibodies against HIV-I/-II, HCV, and HTLV-I/II, HBsAg, and a test for syphilis. However, screening for syphilis is no longer mandatory in all countries, as cost-benefit analysis has shown it to be of little value, at least with voluntary non-remunerated donors.

Now that hepatitis C can be tested for, the so-called surrogate tests such as alanine transaminase and antibodies to hepatitis B core antigen (HBcAb) are no longer carried out in all countries, and their relevance has been questioned (14).

Serological screening of every blood or plasma donation must be performed using the most sensitive techniques available. Screening may be unreliable in cases of HBsAg at low titers, as evidence has accumulated that blood that is HBsAg negative but strongly positive for HBcAg antibody may be infectious (15,16). However, routine screening for HBcAg antibodies is at present impracticable. There may also be a delay of 1–10 months before antibodies appear in patients infected with HIV or HCV.

In order to increase the sensitivity of screening, so as to minimize the so-called window period during which serological markers will not detect the infectivity marker, methods of detecting nucleic acids from, for example, the virus particle have been developed. Hepatitis C virus nucleic acid testing is obligatory in Europe, the USA, and Japan, and in many countries nucleic acid testing for other viruses has also been implemented. There is nevertheless no doubt that in future PCR-based methods will further increase the safety of blood and blood products.

Preparation of safe plasma-derived products

Infectivity can be reduced by introducing good manufacturing practice (GMP), both in blood banks and in plasma fractionation units. The sterility of the final products is checked and virus inactivation measures (for example heat treatment and/or chemical inactivation) are taken whenever appropriate. At present, virus inactivation procedures are most relevant to non-cellular products, although leukodepletion procedures using filtration have been used for infectious agents that are almost exclusively intracellular.

The virucidal methods currently in use (17) are based on different rationales. Heat treatment can involve heating solutions, heating lyophilized products, or heating in vapor under pressure, where the actual temperature, duration, and addition of stabilizers vary for the individual products (18,19). Chemical treatment of products with a mixture of an organic solvent and a detergent (S/D treatment) is highly effective against lipid-enveloped viruses (20,21). Other methods of removing or inactivating viruses use nanofiltration (22) or treatment with a combination of a colored photosensitizer and light (23).

Use of autologous blood transfusion

In some countries there has been a marked increase in the use of autologous blood transfusion, since it is known that blood-borne viruses, such as HIV, can be transmitted by allogeneic blood transfusion (24).

In 1997, 66 185 units of autologous blood (200 ml) were collected in Japan, 81% using preoperative collection and storage and 19% by perioperative hemodilution or blood salvage (24). The total volume of autologous blood collected accounted for 1.1% of the total number of units of whole blood donated in the same year. Of the autologous blood donated before surgery, 78% was used, while more than 70% of the blood that was collected by hemodilution, intraoperative salvage, and postoperative salvage was used. During whole blood donations adverse reactions were reported in 1.6% of cases, and ranged from mild reactions (for example dizziness) to severe reactions, such as angina and asthma. With respect to storage and transfusion, 288 errors or problems were reported, with a frequency of 1 per 455 units during production/storage, 1 per 213 transfusion problems/errors, 1 per 23 hemodilution procedures, and 1 per 54 salvage procedures. In 3.7% of the patients

© 2006 Elsevier B.V. All rights reserved.

hypotension occurred during hemodilution. Clotting in blood units (0.9%) and bacterial contamination (0.4%) were the most frequent problems associated with blood salvage.

Adverse effects of massive blood transfusions

Patients who receive massive transfusions are either extremely ill and suffering from prolonged shock or are undergoing major surgery (for example organ transplantation). Patients who receive massive transfusions are exposed to several risks resulting from the addition of anticoagulant, from transfusion of cold blood, and from biochemical, hematological, and other changes in the blood during storage. The complications lead in turn to metabolic disturbances and impaired hemostasis in proportion to the transfused volume.

Acidosis

Since stored blood has a relatively low pH, transfusion can cause acidosis. Prompt and appropriate restoration of the patient's blood volume is most important, to maintain sufficient tissue and organ perfusion and to correct or avoid acidosis.

Ammonia and phosphate

Concentrations of ammonia and inorganic phosphates rise significantly during blood storage, but caution is needed only when old blood is given to patients with liver failure.

Circulatory overload

Circulatory overload with symptoms of congestive heart failure and pulmonary edema can complicate transfusion in patients with poor cardiac reserve.

Citrate toxicity

The citrate in preserved blood can cause a dangerous fall in the ionized calcium concentration in the recipient's plasma in cases of rapid and massive transfusion. The most significant warning sign of citrate intoxication is an increase in the peripheral or central venous pressure, which should be monitored during massive transfusions. An adequate intravenous dose of calcium gluconate or chloride is a reliable means of correcting dangerous hypocalcemia (25).

Coagulation factors

To correct coagulation factor deficiencies, 1–2 units of fresh frozen plasma are recommended after every 10 units of stored blood. As far as the storage lability of coagulation factors is concerned, mild falls in factors V and VIII, and occasionally fibrinogen, occur in the recipient. It must be emphasized, however, that significant coagulation disorders including disseminated intravascular coagulation (DIC) appear almost routinely during prolonged hypovolemia (26).

Hemoglobin oxygen-carrying capacity

The progressive increase in oxygen affinity of stored erythrocytes caused by a fall in the 2,3-diphosphoglycerate concentration is clinically relevant only under extreme conditions. The abnormally increased oxygen affinity of the hemoglobin is reversible in vivo within 24 hours. It is possible to restore the oxygen transport function of hemoglobin by addition of purine nucleotides to old blood (27).

Hemosiderosis

Patients who have received about 100 units of erythrocytes inevitably develop siderosis of the organs and tissues as a consequence of transfusion-induced iron overload (28). Deposition of iron results in functional damage to the heart, liver, spleen, endocrine glands, and other organs, and is often fatal. The clinical signs of iron toxicity in children are retarded growth, splenomegaly, cardiomyopathy, and endocrinopathies. Examination of the serum ferritin concentration and transferrin saturation is useful for the diagnosis of iron overload. Subcutaneous infusion of deferoxamine provides effective and relatively safe treatment by increasing iron excretion. Furthermore, ascorbic acid significantly enhances urinary iron excretion (29). Iron accumulation can be significantly reduced by transfusing young erythrocytes, since the intervals between transfusions can be extended (30,31).

Hypothermia

Transfusion of refrigerated blood, especially during massive transfusions or during exchange transfusions, can induce hypothermia, with a danger of cardiac arrest. If several units of blood are to be rapidly administered, they should be warmed, but not overheated, before transfusion (32).

Platelets

Thrombocytopenia is a well-known consequence of hemodilution. It also occurs in blood transfusions, in which thrombocytopenia constitutes a more frequent clinical problem than abnormalities of coagulation (33). If the platelet count falls below $40 \times 10^9/1$, platelet concentrates should be transfused.

In one study changes in hemostasis in surgical patients undergoing massive transfusion occurred in 93% of patients (34). The platelet count was most frequently abnormal. Well-defined hemostatic disorders, for example DIC, were detected in 48% of patients. It was suggested that the laboratory abnormalities were induced by massive transfusion. Laboratory monitoring and therapeutic measures directed at any underlying disease have been recommended.

Potassium

Hyperkalemia is an infrequent problem associated with the massive transfusion of old blood. Potassium intoxication threatens only patients with raised potassium concentrations before transfusion, for example in the crush syndrome, renal insufficiency, and extensive burns.

Cord blood

Umbilical cord blood is an alternative source of hemopoietic stem cells rather than bone marrow, especially for patients who lack an HLA-matched donor (35). Umbilical cord blood contains significantly more early and committed progenitor cells and has been used in patients with malignant and non-malignant hematological diseases. One of the advantages of cord blood is that it

© 2006 Elsevier B.V. All rights reserved.

can be collected and stored in large scale in liquid nitrogen below –190°C. As the number of hemopoietic cells in umbilical cord blood is limited, current experience with this type of transplantation is predominantly restricted to children, although adults have been successfully treated with umbilical cord blood transplantation (35).

In almost all patients who receive a hemopoietic stem cell transplant, fever and neutropenia will develop (36). The median duration of fever in those given cord blood is substantially longer (27 days) than in those given allogeneic bone marrow (15 days), allogeneic peripheral blood stem cells (10 days), or autologous peripheral blood stem cells (6 days). In patients with a long period of fever, the time to engraftment and the period of neutropenia are longer. Therefore, aggressive prevention of infection will be necessary in these patients.

Exchange transfusion

Favorable results of exchange transfusion in a variety of diseases in adults, for example sickle cell disease, severe clotting disorders, hepatic failure, and acute hemolytic transfusion reactions, have been published (1). Today, however, machine apheresis procedures are more effective and safer for patients requiring exchange of cellular elements or plasma. Exchange transfusion is the most effective therapeutic procedure in the treatment of hemolytic disease of the newborn. Bilirubin removal prevents damage to the central nervous system caused by hyperbilirubinemia. In addition, sensitized erythrocytes are replaced by normally surviving cells and anemia is corrected.

The risks of exchange transfusion are essentially the same as those described above for massive transfusions, and their magnitude depends on the health of the newborn infant and its gestational age and weight. The transfused blood should be as fresh as possible and should not have been stored for more than 4–5 days. It must be free from antigens that react with antibodies in the maternal plasma. Technical errors involving perforation of the umbilical vein, wrong placement of the cannula, or air embolism are fortunately only rare complications.

Platelet transfusion

Severe thrombocytopenia is most often observed in connection with cancer chemotherapy. The availability of platelet concentrates has improved the therapeutic possibilities. Platelet concentrates are obtained by the differential centrifugation of several units of fresh blood or by apheresis from single donors using a blood cell separator. The quality of platelet concentrates obtained by apheresis deteriorates rapidly after storage for more than 24 hours. Of all blood components, platelet concentrates are the most vulnerable to bacterial contamination.

PlPlA1-negative platelets are used to treat neonatal alloimmune thrombocytopenic purpura, a rare, transient, but severe thrombocytopenia in the newborn due to platelet destruction by maternal antibody (1). The mother is usually a PlPlA1-negative person who has produced anti-PlPlA1 as a result of previous blood transfusions or pregnancy. The antibody crosses the placenta and destroys the PlPlA1-positive platelets of the neonate.

Leukocyte transfusion

Centrifugal blood cell separators and techniques for filtration leukapheresis or reversible leukoadhesion can provide a therapeutically adequate dose of granulocytes from a single donor (37), and cells separated in this way are clinically effective. Granulocyte transfusions are indicated in severely granulocytopenic febrile patients with septicemia who are not responding to antibiotics. At least 2×10^{10} granulocytes per day are considered to constitute an adequate granulocyte transfusion, but larger numbers are probably required in some cases.

Complications after granulocyte transfusions occur in about 15–20% of the recipients (38), most frequently in patients given granulocytes prepared by filtration leukapheresis. The complications are predominantly severe febrile reactions, the transmission of cytomegalovirus infection, and graft-versus-host disease. Of particular importance are respiratory reactions with pulmonary edema, which mostly occur in allo-immunized recipients. Leukocyte aggregation may be the cause, with sequestration microemboli and fluid overflow, but other causes have also been suspected. Reactions appear to be more common in patients with sepsis.

Since granulocytes prepared by centrifugation are markedly contaminated with erythrocytes, the ABO compatibility between donor and recipient will be important unless the erythrocytes can be removed before use. Some reactions, particularly allergic and febrile complications, are associated with the presence of macromolecular agents (hydroxyethyl starch, modified gelatin, dextran), used to increase the yield of centrifugal techniques. ABO incompatibility does not alter the in vivo fate of granulocytes (39).

Antibodies to "passenger B lymphocytes" can pose problems after transplantation. When kidneys from a rhesus-negative cadaveric donor, whose serum contained anti-Rho (D), were transplanted into two rhesus-positive patients, anti-Rho (D) was detected in their serum and on their erythrocytes 3.5 weeks after transplantation (40). One patient had hemolysis. The antibodies persisted for nearly 6 months, despite graft rejection and nephrectomy in one case. These antibodies presumably arose from passenger B lymphocytes in the grafts from the rhesus-immunized donor.

Leukodepleted blood products

As in several other countries, the Health Council of the Netherlands has prepared recommendations on the need for routine leukodepletion by filtration of blood. The presence of leukocytes in blood products has no beneficial effect for the recipient, except in special cases, such as patients undergoing organ transplantation (41). Apart from preventing the adverse effects associated with leukocyte transfusion, it has been postulated that the risk of transmission of new variant Creutzfeldt–Jakob disease can be prevented by using leukodepleted blood products.

The disadvantages of leukodepletion are hypotension and adult respiratory distress syndrome (42).

Red eye syndrome, which is characterized by conjunctivitis, headache, and muscle aches, with spontaneous resolution, was caused by a specific filter that is not being used any more (41).

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Cardiovascular

Bone marrow for transplantation is usually kept cryopreserved in dimethylsulfoxide (DMSO), and residual DMSO may be responsible for toxic reactions: in one report, all of a series of 10 patients had falls in heart rate and blood pressure (43). However, other factors, such as cell lysis or rapid intravenous infusion of large volumes, may be responsible.

Respiratory

Transfusion-related acute lung injury is an infrequent but life-threatening complication, clinically indistinguishable from adult respiratory distress syndrome (ARDS). It can occur after the administration of whole blood, erythrocytes, fresh frozen plasma, or cryoprecipitate, all of which contain variable amounts of plasma. In transfusion-related acute lung injury the symptoms of ARDS (dyspnea, pulmonary edema, severe hypoxia, fever, and hypotension) occur within 1–6 hours from the start of transfusion and usually subside within 1–4 days (44). These symptoms can vary from mild to severe and they lead to death in 5–10% of cases. The reaction may be more frequent than reported because confounding factors can mask the symptoms (45).

Transfusion-related acute lung injury has been associated with the presence of granulocyte antibodies, HLA antibodies, or biologically active lipids in the plasma. These agents activate granulocytes and endothelial cells and cause release of inflammatory mediators, which cause increased vascular permeability, fever, and hypotension (44). HLA class II antibodies can provoke transfusion-related acute lung injury, as observed in a 19-year-old woman, who developed transfusion-related acute lung injury after treatment with fresh-frozen plasma (46). Probably, monocytes are then involved in the pathogenesis of the acute lung injury (47).

Most of the fatal cases of transfusion-related acute lung injury have involved transfusions of fresh frozen plasma; whole blood, packed erythrocytes, cryoprecipitate, platelet concentrates, apheresis platelets, and occasionally intravenous immunoglobulin have also been implicated. The donors most often involved in fatal injury have been multiparous women who were antihuman lymphocyte antigen-positive or antigranulocyte antibody-positive; one or both of these antibody types have been found in 89% of reported cases. The factors that predispose to transfusion-related acute lung injury include surgery, active infection, massive transfusion, and cytokine therapy, which activate pulmonary endothelium and primes the patient's leukocytes. It has been hypothesized that transfusion-related acute lung injury results from a combination of two independent insults, the patient's clinical state and the presence of antileukocyte antibodies.

The FDA has issued a Dear Colleague letter, outlining the risk of transfusion-related acute lung injury with the use of blood products, particularly those that contain plasma (48). The agency has noted that since the first report of fatal transfusion-related acute lung injury in 1992, 45 more reports have been received by the Center for Biologics Evaluation and Research. Transfusion-related acute lung injury is now believed to be the third commonest cause of infusion-related deaths. The number of non-fatal cases of transfusion-related acute lung injury associated with blood products is also on the increase, but this may be due to better recognition and reporting.

A patient with acute myeloid leukemia developed pulmonary alveolar proteinosis during the period of leukopenia following an unrelated umbilical cord blood transplantation (49).

Hematologic

Hemolytic post-transfusion reactions (50) are most often caused by clerical and administrative errors involving misidentification (incorrect labeling of blood samples, erroneous identification of patients) rather than by mistakes in the laboratory (2,51). However, scrupulous care is demanded at all stages; in a review of hemolytic and other transfusion reactions, the importance of competent handling of whole blood and red cell suspensions (including the avoidance of freezing or osmotic damage) has been stressed (52).

Hemolysis mediated by immune reactions is usually avoided by routine antibody screening and cross-matching methods. Improved pre-transfusion testing has resulted in a significant decrease in the incidence of hemolytic transfusion reactions, although there are examples of transfusion reactions having occurred where no antibody was detectable either before or after transfusion (53).

Acute post-transfusion hemolytic reactions

Acute hemolytic post-transfusion reaction with measurable destruction of the donor's or recipient's erythrocytes due to incompatibility of antigens and antibodies is followed by hemoglobinemia. Hemoglobinemia occurs when the combined hemoglobin-binding capacity of the haptoglobins and hemopexin in plasma is saturated. The severity of the reaction depends on the nature of the antigen and antibody, on the binding strength of the antibody, and on the volume of transfused incompatible blood.

A severe acute hemolytic reaction immediately or soon after the transfusion of incompatible blood is characterized by classical symptoms: a feeling of heat along the vein into which the blood is being transfused, a sensation of severe pain in the lumbar region, substernal tightness, dyspnea, nausea, a fall in blood pressure, tachycardia, circulatory collapse, hemoglobinemia, hemoglobinuria, and jaundice. It is fatal in about 50% of cases, either because of hemolytic shock or hemorrhage due to intravascular coagulation, or because of acute renal insufficiency. Sometimes the clinical symptoms are poorly manifested, so that only fever with or without chills may be noted, or they are masked by signs of the primary disease, so that the reaction is not recognized. Especially in an anesthetized patient the only symptom of intravascular destruction of erythrocytes may be unexpected profuse bleeding from the operation wound and hypotension (54).

The overwhelming majority of such reactions (about 80%) are due to ABO incompatibility. Acute post-transfusion reactions can also occur in the presence of an irregular antibody in the recipient's plasma, usually

© 2006 Elsevier B.V. All rights reserved.

directed against antigens of the Rh system, which can sometimes be difficult to detect; such antibodies cause hemolytic reactions only exceptionally, although several cases have been extensively described (55–59).

Delayed post-transfusion hemolytic reactions

When the signs and symptoms of a hemolytic transfusion reaction occur more than 24 hours after transfusion, the reaction is classified as a delayed reaction (60–62). It is estimated that up to 0.025% of recipients may well be at risk of delayed transfusion reactions (1); however, in one study only 1 in 10 668 transfused units cause delayed hemolysis. The severity of this type of reaction varies widely. Many of these reactions are so mild that they remain unnoticed; only a few are severe or fatal. Almost all patients with this type of complication have a history of previous transfusion and/or pregnancy, which has made sensitization possible. The symptoms comprise fever, chills, anemia, hemoglobinemia, hemoglobinuria, and reticulocytosis. Renal insufficiency can occur and the direct antiglobulin test is positive.

Delayed reactions are difficult to prevent. Incompatibility may not be demonstrable before transfusion, and at the time of the reaction the relevant antibodies may not be detectable. Post-transfusion blood samples must therefore be subjected to repeated serological testing. Delayed reactions usually occur as a result of a secondary anamnestic response within 3–21 days after the transfusion of apparently compatible blood, at a time when the antibody concentration has risen sufficiently to bring about hemolysis of the donor's erythrocytes. A primary immune response can also evoke this kind of reaction (61).

Reports of delayed transfusion reactions continue to appear and confirm the difficulty of diagnosis. Many allo-antibodies responsible for delayed reactions of various severity have been demonstrated (61,63–69). The specificities include the usual Kidd and Rh antigens/antibodies and anti-S. Delayed reactions to the Kell antigens, for example Js(a,b), have been reported (68,69), and anti-FF(b) has also been found to cause a delayed reaction (63). A delayed reaction may occur because of anti-A1 production from the group O graft and the reduction of suppressor cell activity by immunosuppressive agents (70). In sickle cell patients a more severe delayed transfusion reaction can be misdiagnosed as sickle cell crisis (71,72). This occurs particularly in patients with U variants (73).

A method for predicting the safety of transfusion is based on the use of cells labeled with radioactive chromium (74). After the administration of several milliliters of the labeled blood, the survival of erythrocytes in the recipient's circulation is examined: poor survival in vivo indicates that transfusion with these erythrocytes will be hazardous (75,76). There are two types of survival curve for incompatible erythrocytes. A curve described by a single exponential function is seen with most potent IgG antibodies that do not bind complement, including anti-D, anti-C, and anti-K, antibodies. Clearance described by more than one exponential is observed with complement-binding antibodies (77). In the latter there is a slowing of erythrocyte destruction 5–20 minutes after injection into the circulation, probably due to acquired resistance to complement activation.

The interpretation of delayed transfusion reactions can be difficult, as the occurrence of low-grade warm acquired hemolytic anemia can resemble this form of transfusion reaction (78). Careful elution of antibody, its identification, and elucidation of its relation to the transfused erythrocytes are required to establish the nature of the reaction. If the indirect antiglobulin test is negative, autoimmune hemolysis is the likely pathogenic mechanism (79).

Hemolytic reactions after transplantation

Acquired hemolytic reactions due to anti-A or anti-B can be caused by group O allografts in renal transplantation (80–83) and can be prevented by prophylactic irradiation of the kidney (84). Cases of immune hemolytic anemia have also been attributed to donor-derived red cell antibodies after allogeneic bone marrow transplantation (85,86).

Prevention of microaggregate formation

In preserved blood, microaggregates are formed during storage. Such microaggregates are identified as cellular (platelet conglomerates, leukocyte ghosts, and platelet ghosts with fibrin co-aggregates) or proteinaceous material. Blood filters with small pore sizes seem to be effective in preventing such adverse effects as febrile non-hemolytic transfusion reactions, in preventing or delaying the development of leukocyte antibodies, and in reducing the risk of respiratory distress syndrome by removing intact or disintegrating cells, debris, and microaggregates (87).

Immunologic

Sensitization to HLA antigens

Sensitization to HLA antigens (88) is undesirable in patients awaiting organ transplantation and in patients who need long-term platelet transfusion. The success of protocols based on the use of leukocyte-depleted and frozen erythrocytes may be limited, since HLA antigens may be expressed on erythrocytes. In one study the erythrocytes of 50% of blood donors contained HLA-A, HLA-B, and HLA-C antibodies (but not antibodies to class II antigens or to leukocyte-specific antigens) (89). Neither storage at 4°C for 21 days nor cryopreservation affected the expression of these antigens. The immunogenicity of HLA antigens on red cells is unknown.

Reactions due to passive transfer of allo-antibodies

Passive transfer of allo-antibodies present in donor plasma can also cause hemolytic transfusion reactions. Low-titer erythrocyte antibodies in donor blood are considered to be relatively harmless, especially when plasma-reduced or concentrated erythrocytes are transfused in a recipient whose cells carry the relevant antigen. A complication of this type provoked by high-titer anti-E antibody has been described (90). Likewise, a hemolytic transfusion reaction occurred in a Kell-negative adult when anti-Kell contained in the plasma of a unit of whole blood reacted with Kell-positive cells transfused 4 weeks before (91).

© 2006 Elsevier B.V. All rights reserved.

Graft-versus-host disease

Graft-versus-host disease is a serious, potentially fatal complication of allogeneic bone marrow transplantation (92–94). It is caused by engrafted allogeneic immunocompetent T lymphocytes (passenger lymphocytes), which proliferate and react against the recipient. Graft-versus-host disease has been reported after the administration of various types of blood preparations (95), whole blood used for exchange transfusion (96), packed erythrocytes, granulocytes (97–99), and platelets (94).

Graft-versus-host disease is characterized by activated T helper cells (TH) and cytotoxic T lymphocytes (TTC) (100). Skin lesions show a reduction in antigen-presenting Langerhans cells and TTH cells and an increase in TTH/T suppressor (TTS) cells (101); these changes parallel others elsewhere in the body. Following the transfusion of blood components containing lymphocytes, graft-versus-host disease may also develop in severely immunocompromised patients, for example in patients with immunodeficiency syndrome or patients undergoing massive chemotherapy. The smallest number of lymphocytes capable of inducing graft-versus-host disease is not known, but it is known that 1 unit of blood contains a sufficient number of lymphocytes to produce graft-versus-host disease in severely immunocompromised adult patients. The finding that graft-versus-host disease is encountered more often in neonates than in adults may be explained by the immaturity of the immune defence system of neonates.

The common features of graft-versus-host disease are severe itching and persistent diarrhea. Treatment with prednisolone and, if necessary, antilymphocyte antibodies, and/or ciclosporin can help. Hepatic involvement can be mild but can progress to liver failure in spite of optimal treatment (102). Oral complications may be related to graft-versus-host disease but can also result from intensive chemotherapy/irradiation or intensive antibiotic treatment (103).

To minimize the risk of graft-versus-host disease, one can inhibit the proliferative capacity of the donor's immunocompetent lymphocytes by irradiating lymphocyte-containing blood products. A dose of 1500–3000 rads is used. A newer strategy, which seems promising, uses murine monoclonal antibodies to a pan-T cell antigen (for example CD3) to remove mature T lymphocytes from bone marrow grafts, and transplant recipients have greatly benefited from prophylactic ciclosporin (104). T cell depletion does not seem to impair (and may actually enhance) functional recovery of B cells after bone marrow transplantation (105).

The post-marrow transplantation period is followed by a period of profound immunosuppression, often complicated by life-threatening infections, for example caused by CMV (106,107).

Reactions to platelets

The major risks associated with platelet transfusion are allo-immunization and infection. Platelets rarely cause graft-versus-host disease (108,109). Allo-antibodies, especially anti-HLA antibodies, appear to be the major source of complications in patients given repeated platelet transfusions. These antibodies cause febrile reactions, but they can also be responsible for partial or complete refractoriness to platelet transfusions. It has been estimated that more than 50% of recipients become alloimmunized within 4–6 weeks after repeated platelet transfusions prepared from random donors (110,111), although there is some evidence that this problem may have been overestimated (112).

Platelet concentrates contain a considerable number of leukocytes and it is not clear whether allo-antibody formation is caused by the platelets themselves or by these contaminating leukocytes (112). There is in fact evidence that leukocyte-free platelets could prevent refractoriness to platelet transfusion (113), and also that induction of anti-HLA antibodies is reduced (114). It has also been found that that the use of HLA-matched platelets almost entirely avoids alloimmunization (114). There was severe but transient thrombocytopenia after the infusion of whole blood from a donor who was subsequently found to have a high-titer platelet-specific antibody (anti-PlA1) (115); this, however, is very rare.

Post-transfusion thrombocytopenic purpura is a rare immunological complication that develops about a week after transfusion of blood containing platelets (116–118). Most patients have been women aged 40–80 with a history of transfusions or pregnancy. The incriminated antibody in the patient's sera reacts with the recipient's own platelets. The thrombocytopenia and purpura usually last for up to 3 weeks, as the antibody disappears and the platelet count progressively rises. The responsible antibody is usually PlA1, and the patient's platelets are PlA1-negative. The precise mechanism causing this platelet destruction is uncertain, but the transient presence of an autoantibody (119) or adsorption of PlPlA1 antigen on to PlPlA1-negative platelets (120) has been suggested. There seems to be a linkage to HLA-DR3 and DRw52 (121). Anti-PlPlA2 is only seldom implicated in post-transfusion thrombocytopenia (122,123). This complication can be treated with plasma exchange, high doses of glucocorticoids, or intravenous gammaglobulin (124).

Reactions to leukocytes

Multitransfused patients often develop non-hemolytic febrile transfusion reactions. They are caused by antibodies to allo-antigens on leukocytes. The minimum number of leukocytes required to stimulate antibody production is unknown, but it is believed that these reactions occur when more than 0.5×10^9 leukocytes are transfused (125). The allo-antigens responsible for the reactions usually belong either to the HLA system, or to the granulocyte-specific antigens (126).

Allo-antibodies to these antigens can give rise to neonatal neutropenia, febrile transfusion reactions, or a poor response to granulocyte transfusions (127). The febrile reactions are usually mild, but pulmonary manifestations may be more severe. Respiratory distress may develop soon after starting the transfusion or within 24 hours. The radiologically evident pulmonary infiltrates may be associated with leukocyte aggregates and leukocyte antigen-antibody complexes. Recovery is usual.

Immune reactions to leukocytes after blood transfusion in sensitized recipients can be prevented by removing

© 2006 Elsevier B.V. All rights reserved.

leukocytes from blood and packed erythrocytes (128–131). Numerous procedures for removing leukocytes have been described (132,133), including filtration through cotton wool and other more sophisticated filtering media. A reduction in leukocyte content of at least 80% must be achieved.

Reactions to cord blood

Compared with stem cells purified from bone marrow, there is no risk to donors in giving cord blood. The risk of graft-versus-host disease in recipients is lower, and the ability to reconstitute hemopoiesis and immunity after transplant is improved (35,134).

- In a 23-year-old man with severe aplastic anemia, graft-versus-host disease, characterized by localized erythematous plaques and papules, developed 10 months after transplantation of unrelated cord blood stem cells, but required no therapy (35). Microsatellite DNA fingerprinting indicated a stable and persistent donor–recipient mixed chimerism, whilst the circulating erythrocytes remained of host origin.

It has been suggested that the increased degree of tolerance of cord blood stem cells will yield a lower graft-versus-tumor effect (35), which might be associated with an increased risk of relapse of the malignancy (134). Unlike sibling marrow transplants, in which additional infusions of donor lymphocytes may be successful in inciting a graft-versus-tumor effect and salvaging relapses, there are no additional cellular therapy options for patients receiving unrelated cord units (135). However, interleukin-2 has antitumor activity and can augment cytotoxic effects after cord blood transplantation (134,135).

Susceptibility Factors

Oncology patients treated with intensive chemotherapy are usually immunosuppressed and in one study the overall incidence of reactions to blood transfusion was 0.3% of all transfused units, which is significantly lower than expected (136). Febrile non-hemolytic reactions and allergic urticarial reactions were the most frequent, and the number of delayed hemolytic post-transfusion reactions was much lower than in non-oncology patients. This probably reflects a relative inability of oncology patients to produce allo-antibodies against blood group antigens.

Drug Administration

Drug contamination

Immunological reactions due to contaminants

Allergic reactions to potentially allergenic drugs may explain some transfusion reactions that cannot be explained by the results of routine tests. In many countries donors are asked to volunteer their history of drug intake during the previous 24 hours, so that donation can if necessary be delayed. Nevertheless, in Canadian donors who had not admitted to drug intake 6–7% of the blood samples taken were found to have detectable concentrations of acetylsalicylic acid and paracetamol (137). Such drugs would be potentially capable of causing untoward reactions in the recipients. The presence of drugs in donor blood can also damage some blood components, especially platelets.

Infection risk

Transmission of infectious disease by blood and blood products has remained a serious issue, especially after the unfortunate occurrence in some countries of large-scale transmission of HIV infection by blood or blood products.

It is, however, important to consider two circumstances separately: on the one hand the risk of transmitting disease with whole blood or cellular blood components under conditions where virus inactivation or virus removal methods are scarcely available, and on the other hand the far lesser risk of transmitting disease with plasma or plasma-derived products prepared in those centers where effective virus inactivation procedures can be applied to the product.

Bacteria

Transmission of bacterial infection by transfusion to recipients of blood or blood components is a dreaded complication, but is rare when modern methods (that is closed systems) are used for the collection and preparation of blood components. Since the introduction of closed systems for blood collection and of stringent regulations regarding the storage of blood at 4°C, contamination of erythrocyte products has become very uncommon. However, platelets stored at room temperature are a potential source of bacterial infection, and there have been many reports of septic episodes associated with both erythrocyte and platelet concentrate transfusions (138). These reports suggest that such reactions may occur as often as 1 per 4000 platelet transfusions or even more often (139,140). In one study, bacterial isolates from contaminated platelets included *Staphylococcus epidermidis*, *Staphylococcus aureus*, and *Bacillus cereus* (141).

Bacterial infections transmitted by contaminated erythrocyte concentrates have been caused mainly by *Yersinia enterocolitica*. This enteric organism is capable of efficient proliferation and even selective growth at refrigeration temperatures. Of the 182 reports of transfusion-related fatalities which the US FDA received between 1986 and 1991, 29 (16%) were due to bacterial contamination, and 8 of these were caused by contamination with *Yersinia enterocolitica* (142).

Spirochetes

Syphilis is one of the oldest recognized infectious risks of blood transfusion, and blood donors have been routinely screened for syphilis by serological tests for more than 50 years. In recent times, transfusion-transmitted syphilis has become extraordinarily rare, with only very few cases reported. The general use of refrigerated blood reduces the risk of transmission as *Treponema pallidum* loses its viability within a few days in whole blood stored at 4°C.

Viruses

The occurrence of viral hepatitis (143) and acquired immune deficiency syndrome (AIDS) after treatment with blood or blood products (6,144) underlines the importance of being aware of the risk of transmission of infections through blood products. More recently, human T cell lymphotropic viruses HTLV-I and HTLV-II and the parvoviruses have been recognized as blood-borne viruses that may compromise the safety of blood products. Cytomegalovirus may also be infective, especially in immunocompromised recipients.

Cytomegalovirus (CMV)

Up to about 70% of donors in Western countries are cytomegalovirus antibody positive (145) and about 10% have cytomegalovirus-infected leukocytes. In developing countries the percentage may be greater than 95%. Transfusion from such donors, especially leukocyte transfusions and massive transfusions of fresh blood, can result in a mild illness, with fever, splenomegaly, moderate rises in transaminases, atypical lymphoid cells in peripheral blood, and sometimes other symptoms. The syndrome usually appears about 4 weeks after transfusion and persists for 1–6 weeks. In immunocompetent individuals, infection with cytomegalovirus is transient and without serious consequences. Immunocompromised patients are at risk of serious, even fatal infections (146). Those at highest risk are premature low birth-weight neonates and bone marrow transplant recipients. Blood and platelets that have been screened for CMV-Ab are indicated in premature neonates and in CMV-Ab-negative recipients of seronegative bone marrow transplants. The use of seronegative donors has significantly reduced the risk of transfusion-induced cytomegalovirus infection in neonates (147–149). Emerging evidence suggests that leukodepletion may be effective in preventing transmission of cytomegalovirus by transfusion (150–152). The effect of leukodepletion suggests that the infective form of cytomegalovirus is intracellular.

Hepatitis viruses

Hepatitis transmitted by blood or blood products can be caused by several viruses. Hepatitis B virus (HBV) and hepatitis C virus (HCV), together with serologically unidentified hepatitis viruses that cause non-A, non-B, non-C hepatitis are leading pathological agents. Less important are hepatitis A virus (153,154), cytomegalovirus, Epstein–Barr virus, *Herpes simplex* virus, and other viruses that may cause liver damage.

Transmission of viral hepatitis continues to be a serious problem related to the transfusion of whole blood, cellular blood components, and to a lesser degree plasma-derived products (8,155). It is difficult and probably impossible to obtain complete data on the true incidence of hepatitis transmitted by blood or blood products: the incubation time is long, mild anicteric cases are not recognized, and systematic follow-up studies of transfused patients are difficult and expensive (156). In addition, the epidemiology of viral hepatitis is different in different regions.

Hepatitis A virus (HAV) Only a few reports on hepatitis A virus transmission have appeared (153,154). In 1992 an outbreak of icteric hepatitis A involving at least 83 patients with hemophilia A in Italy, Belgium, Ireland, and Germany was documented; all had been treated with a high purity factor VIII concentrate produced by one manufacturer (157,158); there was icterus in 93% and a diagnosis of hepatitis A was based on the presence of IgM anti-HA. The original source of contamination was not definitively established, but it is possible that the virus did not originate from the plasma donors.

Hepatitis B virus (HBV) Since the detection of HBsAg by Blumberg and the introduction of HBsAg screening for donors of blood and plasma in all developed countries, hepatitis B virus transmission through the use of blood and blood products has been effectively prevented. Estimates of the risk of infection, based on the sensitivities of current tests for HBsAg and for anti-HBcAg, are in the order of 1 in 200 000 per unit (159).

Passive immunization of the recipient at the time of potential exposure to hepatitis B virus is available. Prophylactic or post-exposure administration of hepatitis B immunoglobulin (HBIG) is of value in the prevention of hepatitis B. Addition of anti-hepatitis-B immunoglobulin to factor concentrates appears to abolish hepatitis B virus infectivity (160,161). Hepatitis B immunization has been used effectively in controlled trials (162,163). The prophylactic effectiveness of the vaccine administered immediately after exposure to hepatitis B virus has not been established (164).

Hepatitis C virus (HCV) Hepatitis caused by hepatitis C virus was one form of non-A, non-B hepatitis until 1989, when a test became available that identified 50–70% of acute, self-limiting cases and more than 80% of chronic cases of transfusion-related non-A, non-B hepatitis (165). In the USA 80–90% of post-transfusion hepatitis were of the non-A, non-B type (166). Post-transfusional non-A, non-B hepatitis is in general less severe than hepatitis B, and is asymptomatic and anicteric in about 60–80% of cases. However, there is evidence that non-A, non-B hepatitis tends to progress to chronic liver disease (167,168).

The test for hepatitis C was originally based on a recombinant antigen (selected from a cDNA expression library prepared from DNA) and RNA (from plasma taken from a chimpanzee infected with non-A, non-B hepatitis originating from a patient with transfusion-mediated, non-A, non-B hepatitis) (169). Although the infectious virus particle has not yet been isolated, isolation of the genome of hepatitis C virus, expression of viral proteins and synthesis of antigenic peptides of hepatitis C virus have now permitted highly sensitive tests, based on multiple antigens from the virus.

The incidence of hepatitis C among donors varies considerably (from 0.2 to 3%); among US blood donors the prevalence was 0.36% in unpaid voluntary donors, whereas it was 10% in commercial plasma donors (11). In another study, the per unit risk of hepatitis C virus infection was 0.45% before testing had been introduced, 0.19% after the introduction of so-called surrogate tests

© 2006 Elsevier B.V. All rights reserved.

(alanine transaminase, anti-HBcAg), and only 0.03% after the additional implementation of anti-hepatitis C virus tests (170). Now that second- or third-generation tests are available, the risk of transmitting hepatitis C virus infection is probably as low as 1 in 6000 (171).

The availability of the hepatitis C antibody test has also emphasized the relation between chronic hepatitis C, liver cirrhosis, and hepatocellular carcinoma: in Japan, 58 patients with chronic hepatitis C were followed for 7 years; 10 of them developed hepatocellular carcinoma, 14 developed cirrhosis, 30 continued with chronic hepatitis, and in 4 there was improvement of their hepatitis (172).

Hepatitis delta When they occur with any frequency, hepatitis delta infections pose a problem, since the hepatitis tends to be more severe than hepatitis B infection alone and is more likely to progress to chronic hepatitis. Hepatitis delta virus is a defective RNA virus that can replicate only in the presence of hepatitis B virus. It has a unique hybrid structure consisting of a delta inner core encapsulated by the surface antigen of hepatitis B virus. Delta superinfection can transform asymptomatic or mild chronic hepatitis B infection to severe progressive active hepatitis and cirrhosis, and contributes substantially to fulminant hepatitis B (173,174).

Parvoviruses

Parvovirus B19 is transmissible by blood and blood products. In most cases B19 infection is of little consequence to the recipient. However, maternal infection can have serious effects on the fetus, and patients with hemolytic anemia or HIV infection may suffer an aplastic crisis as a result of B19 infection. B19 is an essentially epidemic infection and is transmitted only during the preacute phase. The virus is not lipid enveloped and is therefore not inactivated by solvent detergent treatment. Furthermore, it is highly heat-resistant. The risk of infection is generally thought to be low, perhaps in the order of 1 in 10 000 to 1 in 50 000, although a much higher frequency has been suggested by studies based on PCR (175,176).

Retroviruses

HIV-1 In the late 1970s, the human immunodeficiency virus (HIV) was spreading silently and was still undetected. By 1981, when AIDS was first recognized, cases had already occurred in several countries, but the worldwide spread of HIV infection was only fully realized in the mid-1980s. A still pertinent review dating from that period discussed transfusion-associated AIDS in great depth and also highlighted the fact that the scope of the problem widened with the recognition of other pathogenic retroviruses, such as HIV-2, HTLV-I, and HTLV-II (144). HIV can be transmitted by blood and blood products, and in most countries donated blood and plasma have been screened for the presence of HIV-1 antibodies since 1985, and subsequently for HIV-2 antibodies as well; HIV-positive units have been discarded. The overall level of HIV prevalence in blood donors fell from 0.035% in mid-1985 to 0.012% by mid-1987, primarily as a result of donor education and self-exclusion, and by eliminating seropositive donors from the donor pool (177). The prevalence of HIV positivity among donors now seems to be around 1–2 per 400 000 in countries with blood donation systems based on non-remunerated voluntary donors.

Before the screening of blood and plasma and before virus inactivation procedures were applied to coagulation factor products (for example factor VIII and factor IX), many hemophiliacs who were treated with substitution therapy were exposed to infection with HIV. In the USA about 70% of tested persons with hemophilia A (factor VIII deficiency) and 35% with hemophilia B (factor IX deficiency) were HIV-seropositive (177).

Up to 1987, 4% of all reported patients with AIDS in 28 European countries were likely to have been infected by blood transfusion. In these countries the percentages of patients with hemophilia or other coagulation disorders that develop AIDS were similar up to 1987 (178).

Transfusion of HIV-infected blood is likely to remain a public health problem, especially in parts of Africa (Central, Eastern, and Southern), Asia, and parts of the Caribbean. Non-sterile needles, syringes, and other skin-piercing instruments also play a role in HIV transmission.

People who have been infected do not develop antibodies for some weeks or months, and HIV infection of a minute number of transfusion recipients must therefore still be expected. Several recipients are reported to have seroconverted after transfusion of blood from donors who were anti-HIV negative at the time of donation (179). This window period has been estimated to last for an average of 45 days and it is probably less than 150 days in 90% of cases (180). The HIV antibody tests in current use are more sensitive and can detect seroconversion 5–15 days earlier than the tests used in the late 1980s (181). Since the frequency of positive tests among donors continues to fall, the actual risk of HIV infection should now be significantly less than the 1990 estimate.

HIV-2 HIV-2, which is closely related to HIV-1, was first reported to be associated with AIDS in 1986 in West Africa, where it is believed to be endemic. Several cases of HIV-2 infection have been reported among Europeans and West Africans residing in Europe and in the USA. The spectrum of disease and modes of transmission of HIV-2 seem to be similar to those of HIV-1 (182). However, there have been only relatively few reports of HIV-2 transmission in blood. The anti-HIV-1 EIA tests currently used for screening blood donors are estimated to detect from 42 to 92% of HIV-2 infections (183). Anti-HIV-2 assays are available and are used routinely in blood donor screening.

HTLV-1 and HTLV-2 The human T cell lymphotropic virus type I (HTLV-I) is endemic in some areas of Japan, the Caribbean, and Africa, and has been associated with adult T cell leukemia. In Japan, seroconversion has been observed when anti-HTLV-I-negative patients were transfused with seropositive blood or blood components; in one study the conversion rate was 62% (177). However, no case of transfusion-associated adult T cell leukemia has been reported to date (184,185). HTLV-II was originally isolated from a patient with hairy cell leukemia, but

© 2006 Elsevier B.V. All rights reserved.

the association has not been confirmed. For both HTLV-I and HTLV-II, their natural history, their prevalence rates in blood donors, and their possible clinical consequences need to be studied further (186). In the USA the current risk of post-transfusion HTLV infection appears to be approximately 1 in 70 000 per unit (187). The risk factors for HTLV-I infection in donors are largely geographic, whereas HTLV-II infection is primarily associated with drug abuse (177). Some 97% of individuals with anti-HTLV-I show virus within their lymphocytes (179), but seroconversion has not been observed after transfusion of fresh frozen plasma or plasma-derived products from seropositive donors (177,178).

West Nile virus

A Georgia woman who died after an automobile crash was given multiple blood transfusions before she died (188). Blood samples taken at arrival in the emergency department were negative for West Nile virus, while blood samples that were taken after she had received several transfusions were positive. This finding raised concerns about transmission of West Nile virus via blood. One out of five people infected with West Nile virus will develop a mild febrile illness, lasting 3–6 days; one out of 150 people will develop meningitis or encephalitis. The West Nile virus circulates in the blood of an infected person for only a few days or weeks. Therefore, the risk of transmission of West Nile virus from transfusion of blood components is low (189).

Protozoa

Chagas' disease

In endemic areas (Central and South America), infection caused by *Trypanosoma cruzi* can be transmitted by blood. The total number of infected immigrants living in the USA has been estimated at about 50 000, and these carriers pose a risk as evidenced by reported transfusion-associated cases.

Malaria

Transfusion-induced malaria may be a life-threatening complication, especially in patients who have been repeatedly transfused, treated with immunosuppressive drugs, or splenectomized (190). The disease is readily transmitted from asymptomatic donors with latent infection. Means of preventing and treating transfusion-transmitted malaria are well defined in current literature (191,192). To prevent malaria transmission, donors from malaria-endemic areas are now only accepted after spending 3 years in a malaria-free area; this interval may well be too short.

Prion diseases

Creutzfeldt–Jakob disease (CJD), Gerstmann–Sträussler–Scheinker syndrome, fatal familial insomnia, and kuru are fatal diseases of the central nervous system, known as transmissible subacute spongiform encephalopathies (193). Creutzfeldt–Jakob disease is the most common of these and has an incidence of 1:1 000 000 in most countries. About 10% of those involved have a familial disposition, but most cases occur sporadically. There are similar diseases in sheep (scrapie), cattle (bovine spongiform encephalopathy), and other animal species. The cause of the disease was first believed to be a "slow virus," but more and more evidence points to a protein (prion) as the causative agent (194). It appears that a normally occurring protein, located primarily in neuronal cells, changes its conformation and thereby becomes diseased. This diseased protein induces the same conformational change in otherwise healthy proteins. The diseased protein is highly resistant to proteases and accumulates intracellularly and extracellularly, thereby causing the disease.

A few cases of Creutzfeldt–Jakob disease have been transmitted by corneal transplantation, dural transplantation, surgical equipment, and human growth hormone extracted from human pituitary glands (195). This has of course raised concern that Creutzfeldt–Jakob disease might prove to be transmissible by blood and blood products (196). The concern has been further accentuated by recent fears of transmission bovine spongiform encephalopathy through food consumption by humans. Some manufacturers of plasma products have reacted by recalling products from the market (197).

To date studies have shown that patients who develop Creutzfeldt–Jakob disease do not have a history of a higher rate of transfusion or treatment with blood products. Likewise, those who have received blood from donors who subsequently prove to have Creutzfeldt–Jakob disease do not acquire an increased risk. Furthermore, animal experiments have shown that blood and blood products are very low risk materials in transfer experiments from diseased to healthy animals. All the same, certain authorities are now considering the exclusion of donors from families with known cases of classic Creutzfeldt–Jakob disease.

However, the emergence of variant Creutzfeldt–Jakob disease (vCJD) in the UK and France has raised concern about a new "theoretical" risk of infection in patients treated with blood and blood products (198). Animal experiments in which blood from sheep infected with bovine spongiform encephalopathy and natural scrapie-infected sheep into scrapie-free recipient animals have suggested disease transmission by the blood transfusion route in 2 of 24 sheep with bovine spongiform encephalopathy and in 4 of 21 sheep with scrapie (199). Many European countries have incorporated leukodepletion of all blood products, as leukocytes are believed to play a key role in the pathogenesis of variant Creutzfeldt–Jakob disease (198). In some countries, people who have lived in the UK for a period longer than 6 months between 1980 and 1996 are excluded from blood donation (13). Furthermore, it has been shown that various steps used in the manufacture of plasma-derived products also contribute to reduced infectivity by bovine spongiform encephalopathy (198).

Other Environmental Interactions

Interactions of transfusion with transplantation can occur (200). Blood transfusions, and especially donor-specific transfusions, given before kidney transplantation have beneficial effects on graft survival; the mechanism for this is not known (201–203). By contrast, pre-transplant transfusions in bone marrow recipients with aplastic anemia cause major complications, and can be responsible for graft rejection and marrow transplantation failure (204).

© 2006 Elsevier B.V. All rights reserved.

Immunosuppressed patients with, for example, hematological malignancies are less likely to become sensitized to the histocompatibility antigens to which they are exposed by transfusion; restriction of transfusion in the pre-transplant period is therefore not necessary.

Blood donation

General Information

Among the various adverse effects of blood donation, vasovagal syncope and convulsive reactions are of concern to collection centers, as they may alarm potential first-time donors. First-time donors have a higher frequency of these reactions (1.7%) than repeat donors (0.2%), and donors who have such reactions donate fewer times than those without reactions (1). Donors who react are generally of lower weight and have slightly lower blood pressure than those who do not. Of the relevant social and psychological factors that have been studied, the ingestion of caffeinated beverages and shortening the duration between registration and time of phlebotomy are associated with a reduced risk of reactions (1).

Apheresis procedures are considered to be relatively safe when performed by experienced personnel. However, they are not without dangers, and there are some health risks to both patients and donors. Not unexpectedly, the risks are greater with therapeutic plasmapheresis on account of the underlying disease, with an estimated 3 deaths per 10 000 procedures (2).

Organs and Systems

Cardiovascular

Bruising in the antecubital fossa is one of the commonest adverse effects of blood donation. The common practice of flexing the arm over a cotton wool ball or swab can aggravate bleeding, and direct compression over the puncture site and elevation of the extended arm is recommended (3).

Hematologic

The only significant drawback to repeated whole blood donation is the risk of iron deficiency. In a study in 948 menstruating and 141 non-menstruating female blood donors, menstruating donors had lower mean serum ferritin concentrations than non-menstruating donors. First-time donors had a mean ferritin concentration of 24 μg/ml and regular donors 19 μg/ml. The frequency of donations was more predictive of ferritin concentrations than the number of donations (4). The authors concluded that female donors, especially those who donate three or more times a year, should have their iron status checked at appropriate intervals and should receive iron supplements.

Immunologic

Although no important adverse effects are associated specifically with multiple blood donations, depressed cell-mediated immunity and reduced lymphocyte proliferation responses have been reported in the past (5). This fear has been allayed, for example, by a 1992 study in 27 donors who had regularly given whole blood for at least 4 years; there were no abnormalities in lymphocyte subsets, neutrophil and monocyte receptors, or molecules important for host defences (6). In 25 volunteer donors undergoing regular platelet apheresis by a discontinuous process a large number of T4 and T8 lymphocytes, a moderate number of B lymphocytes, and a smaller number of monocytes were removed (7).

Frequent donations involving apheresis procedures have been reported to cause allergic reactions (urticaria, flushing, wheezing, chest pain, and in a few cases hypotension), probably due to exposure to ethylene oxide (8). Ethylene oxide is often used for sterilizing the polyvinyl chloride tubing, and similar allergic reactions in patients undergoing chronic hemodialysis have been attributed to sensitization to the ethylene oxide used for sterilizing the dialyser. One study has shown significant concentrations of IgE antibodies to ethylene dioxide in the sera of 78% of donors with allergic reactions but in only 12% of control sera.

Susceptibility Factors

Age

It has commonly been thought that donation of blood by older people might involve health risks for themselves, and in many countries healthy potential blood donors are therefore ineligible after the age of 60. However, in a study of the growing demographic group above this age, the adverse effects were no greater than in a control group of donors aged 50–65 years when the standard volume of blood (450 ml) was taken (9).

Blood glucose meters

General Information

There are various makes of meters used for measuring the blood glucose concentration. On occasion, some have been found to give false readings.

In early June 1998, the manufacturers of SureStep blood glucose meters (LifeScan) announced that they were going to replace some of the meters used by diabetics to test their blood sugar concentration because they were giving confusing error readings. SureStep home blood glucose meters manufactured before August 1997 may have been giving an error message ("Er-1") instead of "HI" (high) when a blood sugar concentration was very high—500 mg/dl (28 mmol/l) or greater. Such a concentration is potentially dangerous if not recognized and treated, and could result in hospitalization or death. The FDA had received reports of two deaths in people whose glucose was very high but who repeatedly got error message readings from the SureStep blood glucose meters and delayed seeking medical care. The FDA was concerned that some diabetics, wholesalers, and distributors who purchase these meters might not realize that this product replacement procedure concerns a potentially serious malfunction (1). The FDA classified LifeScan's recall as a Class I recall, that is a situation in which there is a reasonable probability that the use of the product will cause serious adverse health consequences or death.

People using the affected SureStep meters needed to know that an "Er-1" message might actually mean a very high concentration of blood glucose instead of an error. If users got an "Er-1" message, they needed to use the visual color change indicator to see if their blood glucose was too high. They had to compare the blue dot on the test strip to the color chart on the test strip bottle. If the dot on the strip was as dark as or darker than the color chart, it indicated a very high blood glucose, and they were advised to contact a health professional immediately.

People with diabetes who use the SureStep brand glucose meters were advised not to stop testing their blood glucose concentrations. They could continue to test with these meters as long as they knew that an "Er-1" message could actually mean a very high concentration. It was considered far more dangerous not to check blood glucose than to use a blood glucose meter that might give an unclear error message at high glucose concentrations.

Factors that alter measurements

High altitude

Sports like hiking and skiing at moderate high altitude make glucose estimation mandatory for people with diabetes. Changes in temperature, PaO_2, and humidity can result in errors in blood glucose determination. When tested at 3000 m (10 000 feet) the glucose meter Elite (Bayer Diagnostics) had a tendency to overestimate glucose concentrations, while the Life Scan One Touch II had a tendency to underestimate them (2). The bias was not clinically meaningful, although some care may be necessary when low or intermediate blood glucose concentrations are measured with the Glucometer Elite.

Icodextrin

Icodextrin in the dialysis fluid in continuous ambulatory peritoneal dialysis can contribute to overestimation of blood glucose (SEDA-26, 461). In a comparison of a meter using the glucose oxidation method and a meter using the glucose dehydrogenase method, only the former gave results that were comparable with the laboratory method (3). The authors concluded that meters must be cross-checked with the laboratory before they can be used to measure blood glucose in patients in contact with icodextrin.

Site of blood withdrawal

The site of blood withdrawal can give different values during acute monitoring of glucose (SEDA-26, 461). Blood was tested before and 60, 90, 120, 150, and 180 minutes after a meal from the finger tips, the arms, and the thighs with the One-Touch Ultra Blood Glucose Monitoring System (LifeScan) and an extra finger prick using a blood monitoring system. When the blood glucose concentration was rising, only the finger prick gave accurate results; the readings from the other sites were lower (even after extensive rubbing) (4).

In patients with diabetes given a 75 g oral glucose load followed by a rapid-acting insulin, producing a wide range of blood glucose concentrations, of three different devices for blood glucose estimation, only finger-prick estimations followed the changes in blood glucose (5), although patients preferred other sites for testing (6).

A subcutaneous continuous glucose monitoring system was used for 24 hours in seven strictly regulated adolescents and young adults. For comparison, blood was drawn from an intravenous cannula and determined in the laboratory, and capillary samples were measured on a glucose meter. During the night-time the readings on the continuous glucose monitoring system were on average 38% lower than the other measurements, indicating a high number of false (asymptomatic) attacks of hypoglycemia (7).

Organs and Systems

Immunologic

Finger sepsis aggressive enough to cause osteomyelitis has been reported in two women, one aged 61 years with *Staphylococcus aureus*, *Staphylococcus agalactiae*, and *Enterococcus faecalis*, and another aged 57 years with a beta-hemolytic staphylococcus, *Candida non-albicans*, and unidentified anaerobic bacteria. Antibiotic treatment and local drainage were unsuccessful and the third phalanx had to be amputated. Both patients had poorly controlled diabetes (HbA_{1c} 14% and 12% respectively); they had estimated their blood glucose six times a week using an automatic lancet without changing their disposable needle (8).

Boraginaceae

See also Herbal medicines

General Information

The genera in the family of Boraginaceae (Table 1) include bluebells, borage, comfrey, and forget-me-nots.

Cynoglossum officinale

Cynoglossum officinale (hound's tongue) contains alkaloids with curare-like activity as well as hepatotoxic and carcinogenic pyrrolizidine alkaloids, which are covered in a separate monograph.

Symphytum officinale

Symphytum officinale (black wort, boneset, bruise wort, comfrey, knitback, knitbone, slippery root) contains pyrrolizidine alkaloids, such as lasiocarpine and symphytine, and their N-oxides, and has repeatedly been associated with hepatotoxicity.

Comfrey products have been withdrawn from the market in several countries, including the USA and the UK. The German Federal Health Office has restricted the availability of botanical medicines containing unsaturated pyrrolizidine alkaloids (1,2). Herbal medicines that provide more than 1 mg internally or more than 100 mg externally per day, when used as directed, are not permitted; herbal medicines that provide 0.1–1 mg internally or 10–100 mg externally per day, when used as directed, may be applied only for a maximum of 6 weeks per year, and they should not be used during pregnancy or lactation.

Adverse effects

Symphytum officinale contains pyrrolizidine alkaloids, which are the subject of a separate monograph. Certain representatives of this class and the plants in which they occur are hepatotoxic, as well as mutagenic and carcinogenic. They can produce veno-occlusive disease of the liver with clinical features like abdominal pain with ascites, hepatomegaly, splenomegaly, anorexia, nausea, vomiting, and diarrhea. Sometimes there is also damage to the lungs.

Liver

The main type of liver damage caused by *S. officinale* is veno-occlusive disease, a non-thrombotic obliteration of small hepatic veins leading to cirrhosis and eventually liver failure (3). Patients can present with acute or chronic signs; portal hypertension, hepatomegaly, and abdominal pain are the main features.

Table 1 The genera of Boraginaceae

Alkanna (alkanna)
Amsinckia (fiddleneck)
Anchusa (bugloss)
Antiphytum (saucerflower)
Argusia (sea rosemary)
Asperugo (German-madwort)
Borago (borage)
Bothriospermum (bothriospermum)
Bourreria (strongbark)
Brunnera (brunnera)
Buglossoides (buglossoides)
Carmona (scorpionbush)
Cordia (cordia)
Cryptantha (cryptantha)
Cynoglossum (hound's tongue)
Dasynotus (whitethroat)
Echium (vipersbugloss)
Ehretia (ehretia)
Eritrichium (alpine forget-me-not)
Hackelia (stickseed)
Harpagonella (grapplinghook)
Heliotropium (heliotrope)
Lappula (stickseed)
Lithospermum (stoneseed)
Macromeria (giant-trumpets)
Mertensia (bluebells)
Myosotis (forget-me-not)
Myosotidium (giant forget-me-not)
Nonea (monkswort)
Omphalodes (navelwort)
Onosmodium (marbleseed)
Onosma (onosma)
Pectocarya (combseed)
Pentaglottis (pentaglottis)
Plagiobothrys (popcorn flower)
Pulmonaria (lungwort)
Rochefortia (rochefortia)
Symphytum (comfrey)
Tiquilia (crinklemat)
Tournefortia (soldierbush)

© 2006 Elsevier B.V. All rights reserved.

- A 23-year-old man who had taken comfrey leaves presented with hepatic veno-occlusive disease and severe portal hypertension and subsequently died from liver failure (4). Light microscopy and hepatic angiography showed occlusion of sublobular veins and small venous radicles of the liver, associated with widespread hemorrhagic necrosis of hepatocytes.

Other reports of hepatotoxicity due to *S. officinale* have appeared (5–7).

However, the author of a review of the toxicity of *S. officinale* pointed out that since 1990 no cases of adverse events have been reported and stated that comfrey has a history of effective therapeutic use in humans and that it "might not be as dangerous to humans as current restrictions indicate" (8).

Fetotoxicity

It is prudent to avoid exposing unborn or suckling children to herbal remedies containing pyrrolizidine alkaloids. Animal studies have shown that transplacental passage and transfer to breast milk are possible, and there is a human case on record of fatal neonatal liver injury, in which the mother had used a herbal cough tea containing pyrrolizidine alkaloids throughout her pregnancy.

Heliotropium species

Heliotropium species contain various pyrrolizidine alkaloids (which are covered in a separate monograph).

Adverse effects

It is prudent to avoid exposure of unborn or suckling children to herbal remedies containing pyrrolizidine alkaloids. Animal studies have shown that transplacental passage and transfer to breast milk can occur, and fatal neonatal liver damage has been reported, when the mother used an herbal cough tea containing pyrrolizidine alkaloids throughout her pregnancy.

The German Federal Health Office has restricted the availability of botanical medicines containing unsaturated pyrrolizidine alkaloids (1,2). Herbal medicines that provide over 1 mg/day internally or over 100 mg/day externally are not permitted; herbal medicines that provide 0.1–1 mg/day internally or 10–100 mg/day may be applied only for a maximum of 6 weeks per year, and they should not be used during pregnancy or lactation.

Boric acid

See also Disinfectants and antiseptics

General Information

In the past, boric acid was falsely considered to be relatively non-toxic, and had an unwarranted reputation as a germicide. However, it is only bacteriostatic, even in a saturated aqueous solution, and can cause adverse reactions. Boric acid has often proved poisonous, either by ingestion or after local use. Cases from the world literature have been reviewed (1,2). In 172 cases of boric acid intoxication, including 83 deaths, 37 deaths occurred after external use, including 23 children with nappy rash. From 1974 to 1984, the Poison Centre in Paris recorded 134 cases of intoxication with boric acid or borates, 88 of which were accidental and 31 iatrogenic.

Boric acid penetrates even intact skin, but it is readily absorbed through inflamed or otherwise damaged skin and through mucous membranes. After the application of wet compresses of boric acid to intact and eczematous skin in 21 patients over several days, blood concentrations of boric acid were generally not raised (3). One patient, however, did have a significant rise in blood boric acid concentration, which the authors ascribed to pre-existing kidney insufficiency.

Prolonged absorption of boric acid causes anorexia, weight loss, vomiting, mild diarrhea, skin rash, diffuse alopecia, convulsions, and anemia.

On account of the high toxicity and limited therapeutic value of boric acid, the borates have been abandoned as obsolete in many countries.

Organs and Systems

Skin

The skin, which is unlikely to react unfavorably to topical boric acid, can react strongly if it is absorbed systemically; resultant redness can mimic scarlet fever, and psoriasiform lesions, bullae, and alopecia can occur.

Drug Administration

Drug overdose

In acute intoxication, symptoms develop progressively, typically beginning with persistent vomiting and diarrhea (mucous and blood, with a bluish-green color). Shortly after the onset of the gastrointestinal symptoms, in some cases even earlier, a rash appears (with macules and/or papules), beginning on the abdomen, genitalia,

© 2006 Elsevier B.V. All rights reserved.

and head, and rapidly spreading, followed by excoriation and intensive desquamation after 1–2 days. Mucous membranes are often involved, especially in young infants, in whom the mouth, pharynx, and conjunctivae are often inflamed. Later, there are central nervous system symptoms, with headache and mental confusion followed by convulsions. In children there is meningism and twitching of the facial muscles and limbs followed by convulsions. Acute tubular necrosis can occur, with oliguria or anuria, hypernatremia, hyperchloremia and hyperkalemia, proteinuria, erythrocyturia, and cylindruria. Finally, hyperthermia, a fall in blood pressure, tachycardia, and shock occur.

Fourteen cases of acute boric acid ingestion were reported in New York City over 30 months. In these patients excretion of urinary riboflavin (vitamin B_2) was determined, and in about two-thirds it was significantly increased. This is not surprising, since riboflavin and boric acid are known to form a water-soluble complex. The range of lethal doses is 1–3 g for babies, 5 g for infants, and 15–20 g for adults.

- Severe acute boric acid poisoning occurred in a 3-year-old boy after the application of a boric acid-containing talcum powder (4).
- A similar case occurred in a 27-day-old baby girl (5).
- Generalized erythema and skin desquamation, fever convulsions, and diarrhea followed repeated boric acid application to a denuded umbilical stump (6).
- Fatal intoxication has followed prostatectomy and subsequent bladder irrigation with 3% boric acid (7).

Of 172 published cases of boric acid intoxication, 83 proved fatal; the series included 37 deaths after external use of boric acid, 23 of these being children who had developed diaper rashes. The actual number of cases, mostly unpublished, must have been much greater: from 1974 to March 1984, 134 cases of intoxication by boric acid or borates were recorded in France alone, 88 being accidental and 31 associated with medicinal use.

Bornaprine

See also Adrenoceptor agonists

General Information

Bornaprine, a synthetic quaternary ammonium compound, has been used as an anticholinergic drug in treating Parkinson's disease (1). Its adverse effects are those characteristic of the anticholinergic drugs.

Bosentan

See also Endothelin receptor antagonists

General Information

Bosentan is an endothelin-A and endothelin-B receptor antagonist. It is effective in pulmonary arterial hypertension (1,2) and has been marketed for this indication. The studies showed an improvement in exercise capacity and dyspnea and an increased time to clinical worsening. Efficacy in pulmonary hypertension has also been reported in an open study with a selective endothelin-A receptor antagonist (3).

The effects of bosentan (62.5 mg bd for 4 weeks followed by either 125 or 250 mg bd for a minimum of 12 weeks) have been studied in a double-blind, placebo-controlled trial in 213 patients with pulmonary arterial hypertension (2). The patients who took bosentan had improved exercise capacity, less dyspnea, and delayed worsening. There were similar results in 32 patients who took bosentan for a minimum of 12 weeks (62.5 mg bd for 4 weeks then 125 mg bd) (4). Bosentan significantly reduced pulmonary vascular resistance. The number and nature of adverse events were similar with bosentan and placebo.

Organs and Systems

Cardiovascular

In a dose-finding study with bosentan (100, 500, 1000, and 2000 mg/day) in 293 hypertensive patients (5) there were statistically significant falls in diastolic blood pressure with the 500 and 2000 mg/day doses. The effects were similar to that of enalapril 20 mg/day. The lowering of blood pressure was not associated with any changes in heart rate, plasma noradrenaline concentrations, plasma renin activity, or angiotensin II concentrations.

In the ENABLE (Endothelin Antagonist Bosentan for Lowering Cardiac Events in Heart Failure) placebo-controlled study the effects of low-dose bosentan (125 mg bd) were evaluated in 1613 patients with severe heart failure

© 2006 Elsevier B.V. All rights reserved.

(left ventricular ejection fraction < 35%, New York Heart Association classes IIIb-IV) (6). The primary endpoint of all-cause mortality or hospitalization for heart failure was reached in 321 of 808 patients who took placebo and 312 of 805 who took bosentan. Treatment with bosentan conferred an early risk of worsening heart failure necessitating hospitalization, because of fluid retention. These results throw doubt on the potential benefits of non-specific endothelin receptor blockade in heart failure. Preliminary data suggest that in heart failure selective endothelin-A receptor antagonists (BQ-123, sitaxsentan) may be more beneficial than non-selective antagonists, especially when there is associated pulmonary hypertension (7).

Liver

The major safety issue that has emerged with bosentan, the endothelin receptor antagonist that has been most extensively studied in man, has been dose-dependent reversible impairment of hepatic function (3% with 125 mg, 7% with 250 mg), manifesting as raised transaminases (2). The effect of bosentan on hepatocanalicular bile-salt transport has been studied in rats in conjunction with a re-examination of the safety database from two clinical trials (in hypertension and congestive cardiac failure) and measurement of bile-salt concentrations in stored blood samples from these trials (8). Hepatic injury was defined as a three-fold increase in alanine transaminase activity. In the hypertension trial there were no cases of hepatic injury with placebo or enalapril. With bosentan, the frequencies were 2, 4, 11, and 8% at dosages of 100, 500, 1000, and 2000 mg/day respectively. There was a dose-dependent increase in bile-salt concentrations. In the study in patients with heart failure (New York Heart Association classes III/IV), liver injury occurred in 4% of 126 patients taking placebo and 18% of 244 patients taking bosentan 500 mg bd. A subgroup analysis showed a higher incidence of hepatic injury in patients taking concomitant bosentan and glibenclamide. Patients with hepatic injury had raised bile-salt concentrations.

In rats, intravenous bosentan produced a dose-dependent increase in plasma bile salts. The effect was potentiated when glibenclamide was co-administered. In vitro studies in rat canalicular liver plasma membranes confirmed inhibition of bile-salt transport. Three bosentan metabolites were also investigated. The M2 metabolite was more potent than bosentan, whereas the M1 and M3 metabolites produced less inhibition of bile acid transport than bosentan. The effects of bosentan and its main metabolites, both of which are eliminated in the bile, on biliary secretion have been studied in rats with biliary fistulae and with or without a genetic defect in mrp2 (9). Intravenous bosentan 0.1–10 mg/kg caused a dose-dependent increase in biliary bilirubin excretion, and doses of 10 mg/kg or over caused a sustained increase in canalicular salt-independent bile flow, combined with significant increases in the concentrations and output of glutathione and of bicarbonate in the bile. Phospholipid and cholesterol secretion were profoundly inhibited and uncoupled from bile-salt secretion. In mrp2-deficient rats, the choleretic effect of bosentan was markedly reduced. Thus, bosentan alters canalicular bile formation mostly via mrp2-mediated mechanisms. Intermittent uncoupling of lipid from bile-salt secretion may contribute to its hepatic adverse effects.

These data suggest that bosentan causes cholestatic liver injury due to inhibition of bile-salt efflux and damage due to intracellular accumulation of bile salts.

Long-Term Effects

Drug tolerance

Despite short-term benefits of bosentan in systemic hypertension and congestive heart failure, it increases plasma concentrations of endothelin-1, probably by inhibiting its clearance via endothelin-B receptors. This may mean that its effectiveness is reduced during long-term therapy (7).

Susceptibility Factors

Renal disease

The effects of severe renal insufficiency on the pharmacokinetics and metabolism of bosentan 125 mg have been studied in an open, parallel-group study in eight patients with creatinine clearances 17–27 ml/minute and in eight healthy subjects (creatinine clearances 99–135 ml/minute) (10). The pharmacokinetics of bosentan did not differ significantly, although the concentrations of the three CYP2C9- and CYP3A4-derived metabolites increased about two-fold in the patients with renal insufficiency. It is not necessary to adjust the dosage of bosentan in patients with any grade of renal insufficiency.

Botulinum toxin

General Information

Botulinum toxin is one of several toxins produced by the bacterium *Clostridium botulinum*. The toxin binds with high affinity to peripheral cholinergic nerve endings, such as those at the neuromuscular junction and in the autonomic nervous system, preventing the release of the neurotransmitter acetylcholine (1). This action at the neuromuscular junction can cause weakness and even paralysis of the muscles supplied by the affected nerves. Sprouting of the terminal nerves eventually results in re-innervation of the muscles and return of function. Doses are measured in mouse units (MU), 1 MU being the LD_{50} in Swiss–Webster mice.

Botulinum toxin is used in the treatment of excessive muscle contraction disorders (dystonias), such as strabismus, blepharospasm, focal dystonias, and spasticity. One of its uses is in the removal of facial wrinkles by paralysing mimic muscles. It can reduce sweat production by blocking cholinergic innervation of eccrine sweat glands.

Therapeutic studies

For blepharospasm, injections of about 12.5–25 MU are made into the periocular muscles of each eye. When so used, adverse effects are seen in 20–50% of treatments. They consist of mild ptosis, increased or reduced tear function, diplopia, and ectropion. These effects are transient, most lasting about 2 weeks, and generally well tolerated. Occasionally ptosis is so severe as to be inconvenient for the patient. The blepharospasm is relieved for 2–4 months. Systemic effects have not been reported (2).

In the treatment of spastic torticollis there is a tendency to use larger doses (up to 1000 MU) injected into the neck muscles, and weakness of the pharyngeal muscles, resulting in dysphagia and paralysis of the vocal cords, has been reported. Difficulty in swallowing and deepening of the voice were found in up to 30% of cases in one series, resolving after 2–3 weeks (3). In one case there was severe dysphagia 2 days after an injection, with unilateral vocal cord paralysis a week later; swallowing was normal again after 6 weeks (4). The possibility of appreciable effects from this neurotoxin at more distant neuromuscular junctions and the development of antibodies are potential dangers here.

Treatment of spasmodic torticollis with botulinum toxin has been reviewed retrospectively in 107 patients (SEDA-17, 45). It was efficacious in 93% but adverse effects occurred in 84%. Initially, 500 MU were injected into each muscle, but the incidence of adverse effects led to a reduction in dosage, 200–500 MU being injected depending on the muscle used and on neck thickness. The median dose per treatment was 1000 (range 200–1600) MU on the first visit and 800 MU subsequently. Dysphagia occurred after 44% of the treatments. This was severe in 2% of treatments, allowing only sips of fluid and necessitating hospitalization for two patients because of dehydration. Two patients developed stridor, two had substantial weight loss, and one developed pneumonia as a result of aspiration. According to the authors, the risk of dysphagia is 40% if a sternomastoid is injected and 25% if it is not. The risks of moderate or severe dysphagia are 7% and under 1% respectively. The authors estimated that there is a 3% chance of antibody production with reduced responsiveness during the first 15 months of treatment. They recommended antibody testing for patients who have initial but not subsequent improvement after repeated injections of botulinum toxin. The problem of immunological resistance to the effects of botulinum toxin associated with repeat injections has been reviewed elsewhere (5).

In a multicenter, randomized, placebo-controlled trial in 145 patients with axillary hyperhidrosis, refractory to treatment with topical aluminium chloride, both 100 and 200 MU of botulinum toxin reduced sweat production by about 80% (6). After 24 weeks, sweat production in the treated axillae was about 45% of baseline. Temporary adverse events during the first 14 weeks included headache, soreness of the muscles of the shoulder girdle, axillary itching, and increased facial sweating.

A multicenter, double-blind, randomized, placebo-controlled study in 320 patients with untreated hyperhidrosis showed a more than 50% reduction in sweat production at 4 and 16 weeks after treatment respectively in 94 and 82% of patients treated with botulinum toxin (50 MU per axilla) and in 36 and 21% of placebo-treated patients (7). The major treatment-related adverse effect was an increase in sweating in non-axillary sites after treatment. Open treatment with botulinum toxin A was offered to patients in whom sweat production was at least 50% of baseline values (8). Of 207 study subjects, 39% had one treatment, 45% had two treatments and 15% had three treatments. Response rates 4 weeks after treatment were 96, 91, and 83% after the first, second, and third treatments respectively. In one of 207 patients there was possible transient seroconversion from negative to positive for neutralizing antibodies to botulinum toxin, and subsequent treatment with botulinum toxin resulted in complete disappearance of axillary sweating 7 days after injection.

The long-term effectiveness of high-dose botulinum toxin (200 MU per axilla) has been evaluated in an open study in patients with axillary hyperhidrosis unresponsive to previous therapies (9). In 34 patients follow-up was for at least 12 months. Four relapsed within 12 months and two relapsed after 16 and 19 months. Mild pain and a burning

© 2006 Elsevier B.V. All rights reserved.

sensation, sometimes lasting up to 1 hour after injection, were the most frequent adverse effects. No compensatory hyperhidrosis at other body sites was reported.

Organs and Systems

Nervous system

Five cases of severe headache refractory to oral analgesics have been reported in patients treated with 10–38 MU of botulinum toxin for glabella frown lines ($n = 4$) and in a patient treated with 120 MU for palmar hyperhidrosis (10). The headache lasted for 8 days to 4 weeks, did not respond to oral prednisolone, and in some patients was accompanied by photophobia, ear tenderness, or nasal congestion. Two patients had had a similar headache after a previous treatment with botulinum toxin and in another patient a similar headache occurred after the next treatment. None of the patients had a history of severe headaches.

Neuromuscular function

Muscle weakness after botulinum toxin injection is usually due to local spread of the agent. Asymptomatic systemic effects have been detected in patients with cervical dystonia after repeated botulinum toxin injections, when muscle biopsies from the vastus lateralis muscle were examined (11). However, generalized neuromuscular symptoms are rare. Patients with a reduced margin of safety with regard to neuromuscular transmission might be considered prone to systemic effects, but even in patients with myasthenia gravis symptoms distal from the injection site have been reported only occasionally (12). However, generalized muscle weakness can occur if higher doses of botulinum toxin are used, and a recent report has illustrated that this may happen in patients after many uneventful treatment sessions (13). Electrophysiological findings in these patients were suggestive of mild botulism, with doses of botulinum toxin of 600–900 units. Two similar cases had been reported previously (12). Therefore, constant long-term monitoring of patients is recommended, even if they have been receiving injections for many years without adverse effects.

Generalized muscular weakness associated with signs of systemic cholinergic autonomic impairment has been reported.

- A 25-year-old woman was treated with botulinum toxin for hyperhidrosis of the axillae and hands in one session with a total amount of 1400 MU. Six days later she complained of diffuse weakness, diplopia, mild bilateral ptosis, severe weakness in the fingers, and reduced lacrimation, salivary production, and sweating (14). She recovered completely within 2 months.

Permanent extraocular muscle damage has been reported (15).

- A 70-year-old man had increasing difficulty in maintaining binocular vision while reading. There was imbalance of his extraocular muscle activity. Botulinum toxin 2.5 MU was therefore injected into the left inferior rectus muscle under electromyography control using a 27-gauge needle. At the next visit 1 month later he complained of diplopia in all directions of gaze, in keeping with a left inferior rectus muscle palsy. Over the next 10 months there was no improvement. Magnetic resonance imaging then showed atrophy of the left inferior rectus muscle. Inferior transposition of the medial and lateral recti muscles was performed, which produced satisfactory alignment.

Botulinum-induced atrophy of extraocular muscles of the eye cannot be excluded in this case. This mechanism is supported by the observation that botulinum toxin can cause histological changes in the extraocular muscles in adult monkeys (16). The authors of the present report also suggested that intramuscular hematoma or direct damage to the nerve to the muscle may have been responsible. So far, permanent extraocular muscle damage after botulinum toxin injection seems to be rare. If additional cases are reported, patients should be informed about this possible complication before treatment.

Susceptibility Factors

In the presence of neuromuscular disorders, such as myasthenia gravis or Lambert–Eaton syndrome, botulinum toxin-induced inhibition of acetylcholine release can cause generalized weakness (17). Therefore, botulinum toxin should, if at all, be used with extreme caution in patients with neuromuscular disease, who have a reduced margin of safety with regard to neuromuscular transmission.

- An 80-year-old woman had severe difficulty in swallowing and flaccid paralysis of her cervical muscles starting 4 days after the periocular injection of botulinum toxin 120 MU for blepharospasm (12). She also developed bilateral facial nerve paralysis and slurred speech and could not fully close her eyes. Barium swallow and fluoroscopy showed signs of aspiration. The serum concentration of antiacetylcholine receptor antibodies was 6.9 units (reference range 0–0.7 units). Mestinone and prednisone improved her symptoms. She had been treated with botulinum toxin on 18 occasions over the previous 13 years without any untoward effects.

While the exact cause of muscle weakness was unclear, this case argues against the use of botulinum toxin in patients with myasthenic syndromes. When the margin of safety is reduced with regard to neuromuscular transmission, botulinum toxin can result in increased morbidity or even mortality. Generalized muscle weakness after botulinum toxin has also been reported in patients with other neuromuscular disorders (18). In addition, it should be remembered that both dysphagia and muscle weakness can occur after botulinum toxin injection, even in patients who do not suffer from generalized neuromuscular disorders (19).

Generalized weakness has been reported after botulinum toxin treatment in a patient with amyotrophic lateral sclerosis (18).

Drug Administration

Drug formulations

Pain due to injection of botulinum toxin has been reported to be less severe with botulinum toxin reconstituted in preservative-containing saline 0.9% (benzyl

© 2006 Elsevier B.V. All rights reserved.

alcohol 0.9% w/v) than with botulinum toxin reconstituted in preservative-free saline 0.9% in patients with glabella-frown lines (20).

Drug–Drug Interactions

Neuromuscular blocking drugs

As botulinum toxin inhibits acetylcholine release it can interfere with neuromuscular blocking agents (21). It has been suggested that each dose of botulinum toxin may have two effects: first, a direct increase in sensitivity to neuromuscular blocking agents; second, compensatory synaptic remodeling resulting in reduced sensitivity (21). Thus, the effects of neuromuscular blocking agents on neuromuscular transmission cannot be predicted in patients receiving botulinum toxin.

Bovine serum albumin (BSA)

General Information

Bovine serum albumin is often used as protein supplement in cell culture media, and residual bovine serum albumin in some formulations has occasionally caused adverse effects. Symptoms are usually mild, such as itching and urticaria. An anaphylactic reaction has been described in a patient undergoing bone marrow transplantation after the bone marrow cells had been kept in bovine serum albumin. As a component of sperm processing media, bovine serum albumin has caused adverse effects after intrauterine insemination (1). The risk of transmission of nvCJD by recombinant proteins is unknown, as cell cultures used for manufacturing them often contain bovine serum albumin (2).

Tropidocarpum (tropidocarpum)
Warea (pineland cress)

Several of the Brassicaceae contain allyl isothiocyanate, which is a potent irritant and has mutagenic activity in bacteria and fetotoxic and carcinogenic effects in rats. However, as allyl isothiocyanate also occurs in ordinary mustard, it would not be realistic to ban all botanical drugs that contain it, since they commonly provide no more than a normal daily dose of mustard (for example 5 mg of allyl isothiocyanate per 5 g of mustard).

Armoracia rusticana

Armoracia rusticana (horseradish) contains 0.05–0.2% of essential oils of which 85% is allyl isothiocyanate.

Adverse effects

Abdominal discomfort and convulsive syncope occurred after the ingestion of raw horseradish that had not been properly aired before use (1).

© 2006 Elsevier B.V. All rights reserved.

Brassica nigra

Brassica nigra (black mustard) contains allyl isothiocyanate. External application of preparations from black mustard has declined because of skin irritation (see *Sinapis* species).

Raphanus sativus

The root of *Raphanus sativus* var. niger (black radish) contains 0.0025% of essential oil with glycosides yielding allyl isothiocyanate and butyl isothiocyanate.

Adverse effects

The consumption of several roots of *Raphanus sativus* can produce miosis, pain, vomiting, slowed respiration, stupor, and albuminuria.

Allergic contact dermatitis has been attributed to radish (2).

Sinapis species

The *Sinapis* genus contains several different types of mustard species, including *Sinapis alba* (white mustard) and *Sinapis arvensis* (charlock mustard). Mustard has traditionally been used in heated compresses (sinapisms) to draw blood away from underlying infections and to act as a counterirritant. This can cause direct skin damage.

- A 50-year-old woman experienced a second-degree burn after applying a heated mustard compress to her chest to relieve pulmonary congestion associated with a recent episode of pneumonia (3). The injury resulted in permanent hyperpigmentation and hypertrophic scarring.

Brequinar

General Information

Brequinar (DUP 785, NSC 368390) is a quinoline carboxylic acid derivative that inhibits pyrimidine synthesis by inhibiting dihydro-orotate dehydrogenase. It was originally developed as an anticancer drug, but has also been investigated for its immunosuppressant activity after transplantation. Some data suggest that that the immunosuppressant activity of brequinar may be partly due to inhibition of tyrosine phosphorylation in lymphocytes (1).

© 2006 Elsevier B.V. All rights reserved.

Significant adverse effects of brequinar include thrombocytopenia, maculopapular dermatitis, mucositis, and gastrointestinal disorders (2).

Susceptibility Factors

In patients with renal, hepatic, and cardiac transplants the clearance of a single oral dose of brequinar was lower than expected from previous studies (3), perhaps due to an interaction with ciclosporin, as has been shown in rats (4). Overall safety results suggest that brequinar is well tolerated in stable transplant recipients (3).

Drug–Drug Interactions

Cisplatin

Brequinar was synergistic with cisplatin in preclinical models. However, co-administration of brequinar with cisplatin does not affect the pharmacokinetics of either drug (5).

Bretylium

See also Antidysrhythmic drugs

General Information

Bretylium, originally introduced as a hypotensive agent but no longer used as such, has not been extensively used as an antidysrhythmic drug. Its clinical pharmacology, uses, efficacy, and adverse effects have been reviewed (1–4). Adverse effects have reportedly caused the need for withdrawal in about 7% of patients (3).

Organs and Systems

Cardiovascular

Postural hypotension is common, and a significant fall in arterial pressure can occur, even in patients who are supine (5).

Occasionally bretylium causes a transient rise in blood pressure after intravenous administration, due to release of noradrenaline from sympathetic nerve endings.

Ventricular tachydysrhythmias have been reported occasionally (6).

Mouth and teeth

Long-term treatment with bretylium can cause parotid pain and swelling and pain in the tongue (7).

Body temperature

Intravenous bretylium can cause severe hyperthermia (8,9).

Drug Administration

Drug administration route

Bretylium is poorly absorbed and is therefore given parenterally. Despite its poor systemic availability, bretylium was available for some years and was often combined with a tricyclic antidepressant. After intravenous administration bretylium can cause hypotension, nausea, vomiting, and diarrhea. Bretylium should be infused over 30–60 minutes to minimize these effects.

Brimonidine

General Information

Brimonidine is a highly selective potent alpha$_2$-adrenoceptor agonist, which is distinguished from clonidine by a chemical modification that reduces its ability to cross the blood–brain barrier. Like apraclonidine, brimonidine has been used to treat glaucoma. However, unlike apraclonidine, it both reduces aqueous humor production and increases aqueous outflow through the uveoscleral pathway.

The most common adverse effects of brimonidine are dry mouth, fatigue/drowsiness, and blurring of vision, which occurred significantly more often with brimonidine 0.5% than 0.2% (1,2). It can also cause allergic conjunctivitis and ocular pruritus (3). Brimonidine causes fewer adverse effects than apraclonidine, and, because it is a highly selective alpha$_2$-adrenoceptor agonist, does not cause mydriasis, lid retraction, or conjunctival blanching/rebound hyperemia (4). It is less polar than apraclonidine and is therefore more likely to cross the blood–brain barrier. However, symptoms of fatigue can occur.

Organs and Systems

Sensory systems

In a comparison with timolol, brimonidine had similar efficacy but produced more ocular allergic reactions, oral dryness, and conjunctival follicles (5). In a comparison with betaxolol 0.25% suspension, brimonidine 0.2% solution was more effective, but with a similar overall incidence of adverse effects (6).

Susceptibility Factors

Age

Brimonidine should be avoided in children, because apnea and hypotension occur.

- A 1-month-old infant with Peters anomaly had recurrent episodes of unresponsiveness, hypotension, hypotonia, and bradycardia (7). Extensive medical evaluation showed that these episodes were caused by the ophthalmic use of brimonidine.

Brofaromine

See also Monoamine oxidase inhibitors

General Information

Brofaromine is a selective inhibitor of monoamine oxidase (MAO) type A. In an open study in endogenous depression, adverse effects were reported in nine of 51 patients; these included dry mouth, dizziness, tremor, hypomania, anxiety, and memory problems (SEDA-17, 16).

A randomized comparison of brofaromine with imipramine in inpatients with major depression showed that brofaromine was as effective as imipramine in the treatment of major depression but had a different adverse effects profile (1). Brofaromine was more likely to cause sleep disturbances but lacked the anticholinergic and certain cardiovascular adverse effects of imipramine.

Reference

1 Volz HP, Gleiter CH, Moller HJ. Brofaromine versus imipramine in in-patients with major depression—a controlled trial. J Affect Disord 1997;44(2–3):91–9.

Bromazepam

See also Benzodiazepines

General Information

Bromazepam, a moderately short-acting benzodiazepine (half-life about 12 hours), has been used in the treatment of anxiety states and has the usual effects of benzodiazepines, for example amnesia and depressed psychomotor performance, although it causes less depression than lorazepam (SED-12, 98).

Organs and Systems

Nervous system

The mechanism of rare extrapyramidal effects with bromazepam is unexplained (SEDA-18, 44).

Long-Term Effects

Drug withdrawal

Catatonia has been described as an effect of bromazepam withdrawal (1).

- A 51-year-old man who had been taking bromazepam for 9 years in a dosage that he had gradually increased to 18 mg/day abruptly stopped taking it. He initially developed psychotic symptoms and on day 5 after withdrawal became mute and was posturing. A provisional diagnosis of a catatonic syndrome was made, and he was given oral lorazepam 3 mg and risperidone 4 mg. It was later concluded that the catatonia had most probably been due to benzodiazepine withdrawal; the risperidone was withdrawn, and diazepam was substituted for lorazepam and slowly tapered. He had no recurrence of catatonic or psychotic symptoms and his fatigue improved.

Withdrawal-induced seizures have been described in a woman taking various benzodiazepines (2).

- A 43-year-old woman had had insomnia since she was a child. At the age of 15, benzodiazepine therapy improved her sleeping, but when she gradually stopped taking benzodiazepines the insomnia returned after a few days. At the age of 26 she was abusing several benzodiazepines, including diazepam and flunitrazepam. At the age of 30 she was taking high doses of bromazepam every evening before going to sleep. After 1 month, she abruptly stopped taking bromazepam and during withdrawal had an epileptic seizure. During the next few years, she had periods of relative well-being, but also two further periods of benzodiazepine abuse, both resulting in seizures after withdrawal. She later had withdrawal seizures with zolpidem.

Drug Administration

Drug overdose

A fatal overdose of bromazepam has been reported (3).

- A 42-year-old woman with a history of depression was found unconscious, lying near her car. The lower part of her body was undressed and there were multiple purple spots and excoriations on her body, suggesting a sexual assault. She was hypothermic (core temperature 28.4°C). Her plasma bromazepam concentration was 7.7 mg/l, the highest concentration reported in a case of fatal intoxication.

© 2006 Elsevier B.V. All rights reserved.

Drug–Drug Interactions

Fluconazole

The interaction of bromazepam with fluconazole has been studied in 12 healthy men in a randomized, double-blind, four-way crossover study (4). The subjects took a single oral or rectal dose of bromazepam (3 mg) after pretreatment for 4 days with oral fluconazole 100 mg/day or placebo. Pharmacodynamic effects of bromazepam were assessed using self-rated drowsiness, the continuous number addition test, and electroencephalography. After rectal administration there was a higher AUC (1.7-fold) and a higher C_{max} (1.6-fold) than after oral administration; there were electroencephalographic effects and subjective drowsiness after rectal bromazepam, and the electroencephalographic effects correlated closely with mean plasma bromazepam concentrations. However, fluconazole caused no significant changes in the pharmacokinetics or pharmacodynamics of oral or rectal bromazepam.

Bromfenac sodium

See also Non-steroidal anti-inflammatory drugs

General Information

Bromfenac sodium (2-amino-3-(4-bromo-benzoyl)-benzeneacetic acid sodium salt sesquihydrate) has a safety profile apparently similar to that of other NSAIDs (SEDA-17, 109) (SEDA-21, 104). It was approved by the FDA in 1997 for short-term management of acute pain, but was withdrawn by the manufacturers in 1998.

Organs and Systems

Liver

In June 1998 bromfenac was withdrawn from the market because of postmarketing reports of severe hepatic failure, resulting in four deaths and eight liver transplants (SEDA-22, 115). Descriptions of some cases have appeared (1–4).

Bromhexine

General Information

Bromhexine is taken orally or by aerosol and reduces sputum viscosity as measured ex vivo. Although it is still used empirically by some physicians, there have been no controlled studies showing a significant improvement in clinical status or lung function. Administration by inhalation aerosol or nasal spray produces a local expectorant/mucolytic effect (1). Inhaled bromhexine (Paxirasol) reduces the amount of sputum, but does not reduce symptoms (SEDA-17, 208).

Organs and Systems

Gastrointestinal

Bromhexine can cause gastrointestinal intolerance and impair the mucous barrier in the stomach; it has been suggested it should not be given to patients with gastric ulceration. Reactivation of ulcers has been reported in a few patients, but hematemesis, melena, or other complications have not been described (2).

Drug–Drug Interactions

Antibiotics

Bromhexine increases the concentration of amoxicillin in the sputum (SEDA-17, 208) and promotes the diffusion of antibiotics into lung tissue (1).

Bromocriptine

General Information

Bromocriptine is an ergot derivative. High doses (for example 30–75 mg/day orally) are used in Parkinson's disease; low doses (2.5–5.0 mg/day) are used for prostatic tumors and to suppress lactation. The adverse reactions are dose-dependent and, so far as is known, reversible, but they are frequent, being experienced in up to 50% of cases. At any dose, nausea, vomiting, and postural hypotension are problematic in some patients, especially those who take high doses from the start. The gastrointestinal symptoms tend to abate as treatment is continued, but other symptoms, for example peripheral circulatory disturbances, can occur later. Psychic and psychiatric changes can be troublesome in a proportion of patients on high doses. Constipation tends to be a frequent and persistent complication.

Organs and Systems

Cardiovascular

Occasionally, patients taking low doses have postural hypotension, leading to dizziness or syncope. Raynaud's syndrome, with blanching of the extremities in response to cold, is rare. At high doses some 30% suffer a peripheral cold reaction of this type, which may not become manifest for a time, while leg cramps occur in some 10% of cases. Under 10% of patients have flushing or erythromelalgia, and hypotension occurs in some 5%. Occasional cases of bradycardia or acute left ventricular failure have been described. Patients with angina pectoris can experience aggravation of their symptoms (SED-12, 317). Even acute myocardial infarction after coronary spasm has been reported (SEDA-12, 123) (SED-12, 317).

Bromocriptine has been associated with myocardial infarction, presumably because of coronary artery spasm.

- A 29-year-old woman took bromocriptine 5 mg/day postpartum to suppress lactation (1). Four days later she developed an acute anterior myocardial infarction. Angiography showed dissection of the left main and anterior descending arteries, with occlusion of the latter. She recovered after emergency arterial grafting.
- A 21-year-old woman had an inferior myocardial infarction, in the absence of cardiovascular risks and with normal coronary arteries on angiography (2). She made a good recovery, but with some persistent posterior-wall akinesia.

In another similar case the myocardial infarction proved fatal (3).

- A 30-year-old woman collapsed and died after a first dose of bromocriptine 2.5 mg. She had severe atheroma narrowing the right coronary artery proximal to the site of thrombosis. The only obvious risk factor was heavy smoking, 30 cigarettes per day.
- A 38-year-old woman had an acute occlusion of the right popliteal artery, which gradually resolved without surgical intervention after treatment with vasodilators, anticoagulants, and antiplatelet drugs (none of which were specified) (2). Her serum cholesterol concentration was 8 mmol/l, but she had no other risk factors.

Myocardial infarction occurred postpartum in two women taking bromocriptine (4).

- A 33-year-old woman taking bromocriptine 5 mg/day for suppression of lactation was given ergotamine 2.25 mg for acute migraine, having taken ergotamine intermittently for over 20 years. She had a myocardial infarction involving the left anterior descending coronary artery, without apparent pre-existing atherosclerosis. She made a good recovery following thrombolysis.
- A 29-year-old woman taking bromocriptine 5 mg/day postpartum had a dissection of the left anterior descending coronary artery and needed emergency bypass grafting. She made a good recovery.

These cases emphasize the potential danger of these drugs, even in young and apparently healthy individuals, although in the first case the use of two ergot derivatives simultaneously may have been ill-advised.

Edema can occur with this and other dopamine receptor agonists, the association easily being overlooked (SEDA-18, 159).

Fibrotic complications can extend to the heart, resulting in constrictive pericarditis.

Respiratory

Pulmonary reactions are rare. Pleural thickening and effusions and pleuropulmonary fibrosis have been observed in a few cases (SEDA-11, 130).

Ear, nose, throat

Nasal congestion can uncommonly occur with bromocriptine (5).

Nervous system

The high doses used in Parkinson's disease are perhaps slightly less well tolerated than equieffective doses of levodopa.

Dyskinesias can occur with bromocriptine but less often than with equieffective doses of levodopa (6).

Bromocriptine has been used successfully in patients with unilateral motor neglect, usually after a stroke.

- A 58-year-old man had a right middle cerebral artery infarction leading to, among many other neurological deficits, left-sided neglect (7). When he took bromocriptine 20 mg/day this abnormality worsened and then improved again on withdrawal.

The authors suggested that this may have been due to damage to the right putamen, while bromocriptine could still activate the striatum on the left, aggravating the hemispheric bias.

In the USA, bromocriptine has not been licensed for the suppression of lactation since 1994. Up to that time there had been no reports of intracranial hemorrhage associated with bromocriptine, but since the withdrawal

© 2006 Elsevier B.V. All rights reserved.

of the license for this indication there have been 15 case reports of this disastrous adverse effect.

- Three women aged 22, 24, and 40 years took bromocriptine 2.5 mg bd for 2–5 days postpartum and complained of headache; two lost consciousness (8). One subsequently died and another had a residual neurological deficit. In all three cases intracerebral hemorrhage, confirmed by CT or MRI scans, occurred on the sixth day of administration. Maximal recorded blood pressures were 200/100, 173/120, and 180/118 mmHg.

Three cases of contractures of the extremities were possibly caused by bromocriptine (SEDA-14, 119).

Occasionally, paresthesia and bad dreams have been described.

When the manufacturers examined reports from physicians on adverse effects from bromocriptine in inhibition of lactation, there were 38 cases of seizures (9).

A cerebral angiopathy postpartum was also described (10).

Cerebrospinal fluid rhinorrhea has been described as an interesting but highly unusual sequel of bromocriptine administration (SEDA-8, 143). The reverse effect, air aspiration through a sellar-pharyngeal leak, has also been encountered (SEDA-9, 126).

Sensory systems

In one series, three of 18 patients developed blurred vision during high-dose treatment of Parkinson's disease (SEDA-3, 124). Diplopia has been incidentally reported. In three patients with chronic hepatic encephalopathy, reversible ototoxicity developed after the administration of bromocriptine (11).

Psychological, psychiatric

Up to 10% of patients have to be withdrawn from treatment because of psychiatric symptoms. Bromocriptine-induced psychosis is well known and particular caution is warranted in patients with a family history of mental disorders (12). Even very low doses of bromocriptine can cause psychotic reactions (SEDA-9, 126) (SEDA-10, 117), and well-recognized problems include confusion, hallucinations, delusions, and paranoia.

Endocrine

Inappropriate secretion of ADH has been described in a single patient (13).

Hematologic

One case of leukopenia and thrombocytopenia has been described (14).

Gastrointestinal

Nausea and vomiting are common with bromocriptine (15).

Liver

In one series, six of 18 patients taking high doses for Parkinson's disease developed isolated and asymptomatic increases in serum transaminases (SED-12, 317). Other patients have also had this reaction, which is reversible (SEDA-17, 168).

Skin

- A 28-year-old woman taking bromocriptine 5 mg/day for a microprolactinoma developed numerous nodular skin lesions (16). Skin biopsy showed a polyclonal proliferation of both B and T lymphocytes in a follicular pattern, and a diagnosis of cutaneous pseudolymphoma was made. The lesions disappeared within 8 weeks of withdrawal.

Alopecia, reversible after drug withdrawal, has been reported as a rare effect of bromocriptine (SEDA-18, 159).

Hair

Treatment with bromocriptine has very rarely been associated with reversible alopecia (17).

Serosae

Retroperitoneal fibrosis (SEDA-12, 123) (18) and pulmonary fibrosis (SEDA-11, 130) during treatment with high doses of bromocriptine have been observed. The drug's structural relation to methysergide clearly has to be kept in mind. Pleural thickening and effusions can be present in up to 6% of patients treated with bromocriptine for Parkinson's disease, and this is related to duration of exposure and cumulative dose (19). The author recommended drug withdrawal in these patients. However, withdrawal does not always lead to complete resolution of the lesions (20).

- A 63-year-old woman with Parkinson's disease developed bilateral pleural thickening and effusions with interstitial shadowing in the lungs 4 years after starting treatment with bromocriptine. After replacement of the drug by levodopa there was gradual improvement, but some pleural thickening remained nearly 3 years later.

Constrictive pericarditis has also been reported.

- Constrictive pericarditis occurred in two men aged 63 and 69 years treated respectively with bromocriptine 40 mg/day for 4 years and 30 mg/day for 2 years (21). Pericardiectomy was performed in both cases, but bromocriptine was not suspected at that time. In one case the drug was continued until a pleural effusion occurred 7 months later; in the other withdrawal of bromocriptine was prompted by an episode of confusion just before pericardiectomy.

Sexual function

Increased sexual drive in patients with Parkinson's disease is common, but bromocriptine can also cause impotence, which can respond to dosage reduction (SEDA-13, 111).

Immunologic

- An allergic reaction was attributed to bromocriptine in a 26-year-old woman with a prolactin-secreting microadenoma (22).

© 2006 Elsevier B.V. All rights reserved.

Long-Term Effects

Mutagenicity

No chromosomal changes were found in 19 children born after bromocriptine-induced ovulation (23).

Tumorigenicity

In rats (but not in mice) high doses of bromocriptine induced malignant uterine tumors within 2 years (SEDA-3, 122). Tumor induction has not been seen in man, but enlargement of a non-invasive pituitary tumor has been observed on more than one occasion.

Second-Generation Effects

Fertility

Sudden induction of fertility in sterile women can occasionally be an embarrassing adverse reaction if the drug is being used for other purposes, for example Parkinson's disease.

Fetotoxicity

Because of its use in the treatment of female infertility, which inevitably involves early exposure of some embryos, the safety of bromocriptine in early pregnancy has been systematically evaluated in a large multicenter study with prolonged follow-up (SEDA-13, 112). There was no evidence that this use of bromocriptine was associated with an increased risk of spontaneous abortion, multiple pregnancy, or the occurrence of congenital malformations; nor did exposure in utero seem to have any adverse effects on postnatal development. Cervical incompetence may be a problem at the time of delivery, but this may well be due to a long history of infertility rather than to the drug itself.

Lactation

Bromocriptine suppresses lactation and the infant should not be breast-fed from the moment treatment is begun. If bromocriptine is deliberately (and successfully) used to suppress lactation, breast tenderness and milk leakage can ensue. It has been suggested that the use of bromocriptine for this purpose raises the risk of postpartum seizures, but the evidence is equivocal (SEDA-17, 146).

Susceptibility Factors

If bromocriptine is to be used to treat infertility, the presence of a pituitary adenoma must be excluded, since this can otherwise undergo suprasellar extension during pregnancy. Because of its adverse reactions profile, bromocriptine is better avoided in patients with cardiac disease or peripheral vascular disease. Acromegaly in patients with a history of gastrointestinal ulceration or bleeding should not be treated with bromocriptine; generally, however, it seems to be rather better tolerated by patients with acromegaly, as well as by postmenopausal women and patients with a raised serum prolactin concentration than by other patients.

It is thought that bromocriptine may aggravate hypertension of pregnancy (SEDA-15, 2); this has led to hesitation over the continued use of bromocriptine for suppression of lactation, especially in patients with a history of pregnancy-induced hypertension.

Cocaine abusers, it is thought, may develop cerebrovascular and cardiovascular disorders if they take bromocriptine (24,25).

Drug Administration

Drug administration route

Intravaginal administration, sometimes used to reduce gastric adverse effects, has caused a vaginal burning sensation in a few patients (26).

Drug–Drug Interactions

Griseofulvin

The response to bromocriptine, at least in acromegaly, can be blocked by griseofulvin (27).

Pseudoephedrine

Psychosis has been described in a 19-year-old postpartum woman who took bromocriptine and pseudoephedrine (28).

Sympathicomimetic drugs

Dangerous hypertensive reactions can result from interactions with the sympathicomimetic drugs isometheptene and phenylpropanolamine (SEDA-17, 168).

Tamoxifen

Tamoxifen can resolve some of bromocriptine's adverse effects, offering the possibility of bromocriptine treatment to patients who cannot otherwise tolerate it (SEDA-8, 144).

Brompheniramine

See also Antihistamines

General Information

Brompheniramine is a first-generation antihistamine, an alkylamine derivative, with antimuscarinic and moderate sedative actions.

Long-Term Effects

Drug withdrawal

Withdrawal symptoms resembling cholinergic rebound (nausea, tremor, and sweating) have been described after long-term brompheniramine treatment (1).

Reference

Bropirimine

General Information

Oral bropirimine is an immunostimulant that has been used in the management of transitional cell carcinoma of the bladder and upper urinary tract. It is supposedly an interferon inducer. In clinical trials, bropirimine produced mild adverse effects in about 30% of patients. Nausea or vomiting were the most common (21% of patients), and headache, transient liver enzyme rises, skin rash, and arthralgia were observed in 5–14% (1). Tachycardia or chest pain occurred in 5%. Adverse effects required drug withdrawal in 15% of patients (2).

Oral bropirimine (3 g/day thrice weekly for 1 year) has been compared with weekly intravesical Bacillus Calmette-Guérin (2 cycles of 6 weeks) in 55 patients with newly diagnosed bladder carcinoma (3). Whereas the response to treatment was not significantly different between the two groups, adverse effects resulted in more withdrawals with BCG than bropirimine (14 versus 4%). Bropirimine produced more frequent systemic reactions (in particular diarrhea, fever, flu-like syndrome, headache, nausea/vomiting) but less frequent and less severe local complications.

Bryostatins

General Information

Bryostatins are naturally occurring antineoplastic macrocyclic lactones derived from the marine invertebrate *Bugula neritina*, different varieties being isolated from different populations of the same species. More than 13 structurally related compounds have been isolated (1,2), and there is a variety of synthetic analogues (3). The bryostatins modulate the activity of protein kinase C.

Bryostatin 1 binds to the regulatory domain of protein kinase C; short-term exposure promotes activation of protein kinase C, whereas prolonged exposure promotes significant down-regulation (4). In preclinical and phase I clinical studies it had promising antitumor and immunomodulating effects. It amplifies expansion of myeloid and erythroid progenitor cells stimulated by the cytokines GM-CSF, M-CSF, and IL-3. Similarly, it induces the production of peripheral blood mononuclear cells with enhanced lymphokine-activated killer cell activity and proliferation in the presence of IL-2 (5).

In a phase II study, 17 patients with progressive indolent non-Hodgkin's lymphoma, previously treated with chemotherapy, received bryostatin 1 (5). Phlebitis was initially due to the 60% ethanol formulation used for administration, and the subsequent use of another formulation (60% polyethylene glycol, 30% ethanol, 10% Tween 80) reduced the incidence. In one patient, bryostatin 1 was withdrawn because of grade 2 thrombocytopenia. The dose-limiting adverse effect was myalgia, which occurred in eight patients.

Other adverse effects include fatigue, nausea, headache, vomiting, dyspnea, ataxia, anorexia, anemia, and lymphopenia (6–8).

In a phase-II study, 14 patients with metastatic cervical cancer or recurrent disease not eligible for surgery or radiation received bryostatin 1 50–65 $\mu g/m^2$ + cisplatin 50 mg/m^2. The most common adverse effects were myalgia, anemia, and nausea or vomiting; one patient had a hypersensitivity reaction and one developed grade 3 nephrotoxicity (9).

Organs and Systems

Skin

Adverse effects of bryostatin 1 on the skin reported during phase I and II studies were alopecia, mucositis, non-specific rashes, bronzing, and hyperpigmentation in sun-exposed areas; a morbilliform eruption has also been reported (10).

Musculoskeletal

In a phase-I trial of bryostatin 1 as a 24-hour continuous infusion followed by bolus vincristine in 24 patients with refractory B cell malignancies other than acute leukemias, the dose-limiting adverse effect was myalgia (11).

Bucillamine

General Information

Bucillamine (mercaptomethylpropanoylcysteine) is chemically related to penicillamine and is also used in rheumatoid arthritis. Most of the information on bucillamine comes from Japan, its country of origin (1).

The patterns of adverse reactions to sulfhydryl compounds that are used in rheumatoid arthritis (bucillamine, pyritinol, and tiopronin) show remarkable similarities to those of penicillamine (SED-12, 548) (2).

Organs and Systems

Respiratory

In 10 patients with bucillamine-associated interstitial pneumonitis, the HLA antigen DR4 was present in all 10 and a positive lymphocyte stimulation test was found in three of the six patients tested (3).

Nervous system

Myasthenia gravis has been reported during the use of bucillamine (4). However, since the disease persisted after withdrawal, the role of the drug was uncertain.

Sensory systems

A change in taste has been attributed to bucillamine in a single case, without further specification (1).

Hematologic

Among 36 Korean patients with rheumatoid arthritis agranulocytosis with high fever developed in one after 3-week use of bucillamine (dose not specified) (5).

Gastrointestinal

Stomatitis, nausea, anorexia, and epigastric discomfort are common during the use of bucillamine (5).

Hemorrhagic gastritis has been reported in a single case, without further specification (1).

Liver

Increased aminotransferase activities were found in about 5% of patients using bucillamine for rheumatoid arthritis (1,5).

Urinary tract

Proteinuria occurs in about 7% of patients using bucillamine (1). Less often, nephrotic syndrome can develop (5–9). Microscopically there is membranous glomerulonephritis, with diffuse fine granular precipitation of IgG and C3 around the capillary walls, electron-dense deposits at the subepithelial side of the basement membrane and effacement of foot processes.

Skin

Bucillamine causes skin reactions in about 5% of patients (10). Rashes and pruritus are frequent and eosinophilia can occur (1,5).

Bullous pemphigoid has been attributed to bucillamine 200 mg/day (10). The mouth, pharynx, larynx, and conjunctiva were involved, as well as the skin on the chest, abdomen, and axilla. Indirect immunofluorescence showed circulating antibodies against the basement membrane.

There have been reports of bucillamine-associated pemphigus.

- A 57-year-old woman developed a generalized itchy rash 9 months after she started to take bucillamine (11). A skin biopsy showed spongiosis, lymphocytic infiltration in the epidermis, and intercellular deposition of IgG.
- Another patient had a pemphigus foliaceus-like eruption on three different occasions, in association with penicillamine, auranofin, and bucillamine (12).

A patient taking bucillamine developed an eruption that had features of both pemphigus foliaceus and pemphigus vulgaris and was associated with glomerulonephritis (13).

- A 62-year-old man with rheumatoid arthritis developed a rash on the neck, chest, and legs after taking oral bucillamine (dose not specified) for 6 months. The lesions were of two different types: small pigmented, vesicular, erythematous macules, similar to those of pemphigus foliaceus, and skin erosions, as seen in pemphigus vulgaris. There was no mucosal involvement. Serology was positive for antinuclear antibodies (1:320, nucleolar type). A biopsy showed acantholysis in the granular, spinous, and suprabasal layers. Direct immunofluorescence showed intercellular deposits of IgG and C3 throughout the epidermis, but not in the basement membrane. Indirect immunofluorescence of donor skin showed IgG reactivity in the nuclei of keratinocytes. An enzyme-linked immunoadsorbent assay (ELISA), using baculovirus-expressed recombinant desmogleins as antigen, was positive and indifferent to circulating anti-Dsg1 and anti-Dsg3 antibodies. This patient also had the nephrotic syndrome (proteinuria 8.7 g/day, total serum protein 59 g/l, serum total cholesterol 10.2 mmol/l), probably also due to bucillamine. A renal biopsy was consistent with membranous glomerulonephritis. The skin lesions improved within 1 month of bucillamine withdrawal, but full recovery of both cutaneous and renal injury was achieved only after the use of prednisone, 40 mg/day for 2 weeks.

In 13 patients with the peculiar yellow nail syndrome, bucillamine was the suspected cause in 7 (14).

Reproductive system

Gigantism of the breasts, probably induced by bucillamine, has been reported (15).

- After attempts with chrysotherapy and lobenzarit, a 24-year-old woman was given bucillamine 300 mg/day and a glucocorticoid, predonine, for rheumatoid arthritis. After 10 months she noticed bilateral breast

© 2006 Elsevier B.V. All rights reserved.

enlargement, which over 6 months progressed to extreme proportions, the left breast ultimately reaching as far as her pubis. The skin of the breasts was thin and erythematous, with marked dilatation of the superficial veins. The nipple areola complexes were elongated and poorly defined from the surrounding skin. There were no abnormalities of prolactin, sex hormones, growth hormone, or TSH (but the values were not stated). Bilateral total mastectomy was performed and the nipple-areola complexes were removed from the resected tissue and grafted on to the breasts after insertion of a tissue expander. The breast tissue removed from the right side weighed 5 kg and that from the left side 7 kg. Histologically there was increased fibrosis and duct dilatation and no malignancy.

This effect, attributed here to bucillamine, is a rare but well-established adverse effect of penicillamine. Although the patient had also taken isoniazid for pulmonary tuberculosis, that was unlikely to have played a part, since the breast enlargement started earlier and progressed after the isoniazid had been withdrawn.

Bucloxic acid

See also Non-steroidal anti-inflammatory drugs

General Information

Bucloxic acid is an NSAID that is not widely used. The usual symptoms of gastrotoxicity, nephrotoxicity, and increased blood pressure have been reported, but the major adverse effects involve skin and allergic reactions. Quincke's edema has been observed (SED-9, 152) (1) (SEDA-1, 93).

Reference

Bucricaine

See also Local anesthetics

General Information

Bucricaine (centbucridine) is a quinolone derivative with local anesthetic activity.

Nausea, vomiting, bradycardia, backache, shivering, and hypotension can occur with a similar incidence to that of lidocaine (SED-12, 256) (1). It has been suggested that bucricaine is more potent than lidocaine and has few cardiovascular and nervous system adverse effects in animals, at high doses. One study in humans suggested that bucricaine may be associated with fewer cardiovascular adverse effects than lidocaine, but there are insufficient data to confirm this impression (2).

Bufexamac

See also Non-steroidal anti-inflammatory drugs

General Information

Bufexamac is intended for topical use as a cream (using iontophoresis, ultrasound, and massage). Local intolerance causes burning and irritation, attributable to components of the cream. Urticaria, folliculitis, and pyoderma can occur when occlusive dressings are used. The course of contact allergy by bufexamac was particularly protracted and refractory in most of the 24 patients observed in one hospital in 1983–1987 (1). An erythema multiforme-like rash associated with contact dermatitis has been reported (SEDA-18, 103). In children, long-term topical use of bufexamac was well tolerated with few mild local adverse effects (SEDA-20, 91).

Reference

1. Geier J, Fuchs T. Kontaktallergien durch Bufexamac. [Contact allergies caused by bufexamac.] Med Klin (Munich) 1989;84(7):333–8.

Buflomedil

General Information

Buflomedil hydrochloride is a vasoactive drug with a variety of actions. It is an alpha-adrenoceptor antagonist and a weak calcium channel blocker. It inhibits platelet aggregation and improves erythrocyte deformability. However, its mechanism of action in peripheral vascular disease is not known.

Buflomedil has generally been well tolerated by most patients in clinical trials (1). The most frequently reported adverse effects include flushing, headache, vertigo, gastrointestinal discomfort, and dizziness. These rarely require drug withdrawal. In controlled trials, adverse effects have occurred in 20% of patients assigned to buflomedil and 18% of those assigned to placebo; only gastrointestinal discomfort occurred more frequently in buflomedil-treated patients (3.4 versus 2%) (2).

Organs and Systems

Nervous system

Extrapyramidal symptoms have been reported in a few frail elderly women (SEDA-13, 169). A few cases of myoclonic encephalopathy have been observed at therapeutic dosages; old people, patients of low body weight, and patients with renal insufficiency due to dehydration appear to be especially vulnerable (SEDA-9, 189) (SEDA-10, 172) (SEDA-11, 179).

Psychological, psychiatric

Depression has been reported in a few frail elderly women taking buflomedil (SEDA-13, 169).

Immunologic

An anaphylactic reaction to buflomedil has been reported (3).

- A 53-year-old woman with Raynaud's phenomenon developed an urticarial rash, pruritus, and hypotension 10 minutes after the parenteral administration of buflomedil. She received corticosteroids and recovered within 6 hours. When she later underwent skin tests with buflomedil, there was an immediate positive reaction, suggesting a type I hypersensitivity mechanism.

Drug Administration

Drug overdose

Buflomedil is generally considered to be innocuous at therapeutic dosages. Acute toxicity is due to accidental or intentional overdosage. Overdosage causes generalized seizures and cardiac conduction abnormalities, eventually leading to cardiac arrest (SEDA-21, 215).

Three cases of self-poisoning with buflomedil have been reported (4–6); two were fatal.

- A 15-year-old girl took 24 tablets of buflomedil (300 mg) and had a plasma concentration of 93.7 μg/ml. She was deeply comatose and in a convulsive state. Shortly after, she developed cardiac arrest from which she did not recover despite initially successful resuscitation.
- A young girl took a single dose of buflomedil 7.5 g and a young man 18 g. Coma with convulsions occurred in both, soon followed by rhythm and conduction disturbances. Intensive resuscitation attempts could not prevent a fatal outcome in the girl.

Chronic overdose can also lead to convulsions (7).

- A 75-year-old woman had fever and convulsions. She had diabetes mellitus and angina pectoris and took buflomedil for peripheral arterial disease. No cause for her symptoms was found, but she had a high plasma concentration of buflomedil (6.3 μg/ml, usual target range 4–4.5 μg/ml). The drug was withdrawn and the symptoms did not recur. On questioning, it appeared that she had mistakenly forgotten to abandon her old commercial formulation when her pharmacist proposed a cheaper, new, generic brand, but took both at the correctly prescribed dose.

Bumadizone

See also Non-steroidal anti-inflammatory drugs

General Information

Bumadizone is an NSAID that is metabolized to phenylbutazone and oxyphenbutazone.

In a study in 647 patients, about 15% had adverse effects (gastrointestinal, fluid retention, and hypersensitivity); treatment was stopped in 7% (1).

Bumetanide

See also Diuretics

General Information

Bumetanide is very similar in most respects to furosemide, although it is more potent mole for mole. An oral dose of 1–4 mg often suffices for ordinary use compared with 40–160 mg of furosemide.

Most of the adverse effects of bumetanide are the same as those of furosemide. However, it is less ototoxic and can cause muscle cramps, which furosemide does not.

Organs and Systems

Respiratory

Bumetanide has been implicated in the development of pulmonary fibrosis (SEDA-16, 223), but causality could not be determined with certainty.

Sensory systems

One advantage of bumetanide is that it is less ototoxic than furosemide (1–3). It is sensible to prefer bumetanide to furosemide in patients with hearing problems or who concurrently need ototoxic drugs, such as an aminoglycoside antibiotic.

Metabolism

It has been suggested that bumetanide has a smaller effect on blood glucose than furosemide does, but that is not at all clear.

Gastrointestinal

Very high doses of bumetanide used for renal insufficiency have sometimes produced colic (SED-10, 376).

Pancreas

A patient in whom pancreatitis was induced by both furosemide and bumetanide has been documented (SEDA-14, 184).

Skin

Bullous pemphigoid induced by bumetanide has been reported (4).

- A 67-year-old man presented with an acute bullous eruption 6 weeks after starting bumetanide. He had numerous large tense bullae on erythematous skin, with superficial ulceration on the thighs, arms, and anterior trunk. Pruritus was severe. Routine laboratory tests were normal, except for blood eosinophilia. Biopsy of a blister showed subepidermal bullae associated with dermal infiltrates of neutrophils and eosinophils. Direct immunofluorescence showed continuous linear deposits of C3 and IgG at the basement membrane zone, confirmed by immunoelectron microscopy. Circulating IgG antibasement membrane antibodies were localized in the roof of the blister. Compete clinical healing and normalization of immunology occurred within 2 months of withdrawal of bumetanide.

Pseudoporphyria (SEDA-16, 222) and Stevens–Johnson syndrome have also been reported (SED-10, 376).

Musculoskeletal

Various musculoskeletal symptoms have been reported with bumetanide, including pain, cramping, and weakness (SEDA-22, 236). The symptoms are usually mild and self-limiting, with an incidence of less than 2%, but disabling reactions have occurred after oral administration and intravenous injection, and severity correlates with dose. The onset is usually 2–4 hours after dosing; the onset may be slower during infusion.

Bupivacaine

See also Local anesthetics

General Information

Bupivacaine is a long-acting aminoamide local anesthetic with significantly more systemic toxicity than lidocaine.

Organs and Systems

Cardiovascular

Bupivacaine-induced cardiotoxicity, notably after epidural use, is a matter of concern and controversy (1–3). The risk can be greatly reduced or eliminated by careful dosage and/or the use of lower concentrations (SEDA-12, 108) (1).

All studies of the cardiotoxic effects of local anesthetics on the isolated heart published from 1981 to 2001 have been reviewed (4). Thirteen studies were identified, all of which studied bupivacaine, either alone or compared with other local anesthetics. The general conclusions were:

- Highly lipid-soluble, extensively protein-bound, highly potent local anesthetics, such as tetracaine, bupivacaine, and etidocaine, are much more cardiotoxic than less lipid-soluble, protein-bound, and potent local anesthetics, such as lidocaine and prilocaine.
- Bupivacaine has a potent depressant effect on electrical conduction in the heart, primarily via an action on voltage-gated sodium channels that govern the initial rapid depolarization of the cardiac action potential.
- The *S*(−) isomer of bupivacaine is less cardiotoxic than the *R*(+) form.
- Bupivacaine predisposes the heart to re-entrant dysrhythmias.
- The actions of bupivacaine on channels other than voltage-gated sodium channels probably contribute to the dose-dependent cardiotoxic effects of bupivacaine.

The recommended safe upper dose limit for bupivacaine is commonly 2–2.5 mg/kg. However, some authors recommend a lower dose of 1.25 mg/kg as the safe upper limit in dental practice (SEDA-20, 128) (5).

Hyperkalemia, acidosis, severe hypoxia, and myocardial ischemia increase the cardiovascular depressive effects of bupivacaine.

There has been a report of T wave changes on the electrocardiogram during caudal administration of local anesthetics (6).

- A 4.2 kg 2-month-old baby was given a caudal injection under general anesthesia for an inguinal hernia repair. A mixture of 1% lidocaine 2 ml and 0.25% bupivacaine 2 ml was injected. Every 1 ml was preceded by an aspiration test and followed by observation for 20 seconds for electrocardiographic changes. On administration of the third 1 ml dose, there was a significant increase in T wave amplitude. The aspiration test was repeated and was positive for blood. The caudal injection was stopped and the electrocardiogram returned to normal after 35 seconds. The patient remained cardiovascularly stable with no postoperative sequelae.

Previous reports have suggested that an increase in T wave amplitude could result from inadvertent intravascular administration of adrenaline-containing local anesthetics. This is the first case report of local anesthetics alone causing significant T wave changes.

Bradycardia has been reported very occasionally (7).

Bupivacaine can cause ventricular extra beats (8). Ventricular dysrhythmias and seizures were reported in a patient who received 0.5% bupivacaine 30 ml with adrenaline 5 micrograms/ml for lumbar plexus block, after a negative aspiration test (9). The patient developed ventricular fibrillation and required advanced cardiac life support for 1 hour, including 15 defibrillations, and adrenaline 40 mg before sinus rhythm could be restored. There were no neurological sequelae.

Infusions of 0.25% bupivacaine into pig coronary arteries caused ventricular fibrillation at lower rates of infusion than 0.25% bupivacaine with 1% lidocaine (10). The lidocaine/bupivacaine mixture did not have a greater myocardial depressant effect than bupivacaine alone. The authors suggested that when regional anesthesia requires high doses of local anesthetics, bupivacaine should not be used alone but in a mixture with lidocaine, and that lidocaine should be useful in the management of bupivacaine-induced ventricular fibrillation.

An animal study of the mechanism of bupivacaine-induced dysrhythmias has shown that bupivacaine facilitates early after-depolarization in rabbit sinoatrial nodal cells by blocking the delayed rectifier potassium current (11).

Inadvertent administration of bupivacaine can lead to fatal cardiovascular collapse that may be refractory to conventional resuscitation. A study in rats has suggested that in addition to its direct cardiotoxic effect, bupivacaine may have a toxic action on the brainstem, and that cardiovascular collapse may result from dysfunction of vital cardiorespiratory control systems (12).

Nervous system

Neurological symptoms subsequent to unrecognized intravascular injection are the major complications of bupivacaine: tinnitus, muscle twitching, nystagmus, and convulsions can occur. The use of vasoconstrictors is probably not advisable, as they prolong the duration of action of local anesthetics. Whether the addition of hyperbaric glucose to 0.5% bupivacaine for spinal anesthesia alters the incidence of pain from an orthopedic tourniquet is disputed; some findings suggest that it aggravates the problem (SED-12, 256) (13).

- A 13-year-old girl developed tonic-clonic seizures followed by ventricular fibrillation after subcutaneous infiltration of extensive skin abrasions with 30 mg (0.5 mg/kg) of bupivacaine over about 1 hour. She was successfully resuscitated with cardiopulmonary resuscitation and intubation, intravenous diazepam, adrenaline, and sodium bicarbonate (14).

The authors noted that although the anticonvulsant effect of diazepam is significant, some animal studies have shown that diazepam can prolong the half-life of bupivacaine. They stressed the difficulty in treating bupivacaine-induced dysrhythmias and suggested the use of phenytoin

© 2006 Elsevier B.V. All rights reserved.

as a first-line agent in their management. However, this advice is based on only two case reports.

In seven children (aged 36–52 weeks) given caudal anesthesia with bupivacaine 3.1 mg/kg + adrenaline 5 micrograms/ml, there were significant electroencephalographic signs of central nervous system toxicity in six, and two had clinical signs of possible epileptic activity. The authors stopped the study early because of the high incidence of adverse effects. They felt that these were due to the fact that no sedative or anesthetic drugs that could have masked or alleviated local anesthetic toxicity were given, and also that infants have low concentrations of alpha$_1$ acid glycoprotein, leading to increased unbound plasma concentrations (15). However, it should be noted that 2 mg/kg is the usual upper dose limit recommended for bupivacaine. It is hardly surprising that such a high proportion of those studied showed evidence of systemic toxicity after the administration of a much higher dose of bupivacaine to such small children by a route that is known to result in rapid absorption of local anesthetic into the systemic circulation.

Reactions to local anesthetics often occur as a result of inadvertent overdose or accidental intravenous injection.

- A 53-year-old woman received postoperative epidural analgesia by nurse-administered bolus doses after a total knee replacement (16). She received her first epidural bolus of 0.25% bupivacaine 6 ml with morphine 2 mg 2 hours after the operation, with good effect. Six hours later she was accidentally given a second top-up dose intravenously. She became distressed and complained of tinnitus, palpitation, and dizziness. She was able to cooperate and was in sinus rhythm with a tachycardia of 120/minute. She was observed overnight on ICU and made a full recovery.

Despite correct epidural placement, this complication arose as a result of human error, and the authors believed that the low concentration and volume of the top-up had protected the patient from more serious sequelae.

Musculoskeletal

Muscular atrophy after intramuscular injection has been documented (17).

Immunologic

A non-IgE-mediated allergic reaction to bupivacaine has been reported (SEDA-21, 136).

- A 69-year-old woman with a history of bronchospasm after NSAID administration had heavy feelings in her arms and itchy eyes, without any change in hemodynamics, 30 minutes after an intradermal injection of bupivacaine. The same symptoms occurred during subsequent retesting 1 month later, with the addition of coughing and sneezing.

Second-Generation Effects

Pregnancy

Cardiotoxicity due to bupivacaine is more likely in pregnancy (18).

When epidural anesthesia was used for cesarean section, bupivacaine (with oxytocin) produced a higher frequency of neonatal jaundice than similar treatment using lidocaine (SEDA-14, 111).

Fetotoxicity

Adverse effects of bupivacaine on the fetus are uncommon (19), but fetal bradycardia has very occasionally been reported (20).

Susceptibility Factors

Genetic factors

Isovaleric acidemia (an autosomal recessive disorder of leucine metabolism causing episodes of acidosis during catabolic stress) and carnitine deficiency have been associated with a lowered threshold for bupivacaine-induced dysrhythmias (SEDA-22, 142).

Age

In the elderly, some local anesthetics (including lidocaine and bupivacaine) have longer durations of action (18).

Drug Administration

Drug formulations

A formulation of bupivacaine called Regibloc (bupivacaine HCl; Intramed, South Africa) was the only common factor in a series of serious complications after regional anesthesia (21).

- Three consecutive patients had prolonged blockade after retrobulbar block. One had not resolved after 3 months and three others had prolonged mydriasis for 2 weeks.
- Severe neuralgia developed in eight patients after interscalene blocks lasting 6–12 weeks.
- A 36-year-old woman developed supraclavicular skin necrosis, followed by sloughing of subcutaneous tissue down to the first rib, including the dorsal roots of the brachial plexus, after receiving an interscalene block followed by an infusion; 5 months later she still had complete sensory and motor paralysis of the C5 nerve root requiring nerve grafting.
- Skin sloughing after a penile ring-block required plastic reconstruction.
- A 16-year-old girl had a median nerve block followed by an area of skin and fat necrosis at the site of injection and a middle-aged patient received an interscalene block resulting in subsequent fat necrosis at the injection site.

No further complications were encountered after the authors changed to another formulation of bupivacaine and stopped using Regibloc.

Drug–Drug Interactions

Calcium channel blockers

Calcium channel blockers in combination with bupivacaine produce significant negative inotropic effects on the heart in animals, possibly due to reduced protein

© 2006 Elsevier B.V. All rights reserved.

binding of the local anesthetic, as well as a generalized myocardial depressant effect (22,23).

However, bupivacaine cardiotoxicity was reduced in rats by pretreatment with low doses of calcium channel blockers (24). In vivo, the LD_{50} for bupivacaine was increased from 3.08 to 3.58 mg/kg after pretreatment with verapamil 150 micrograms/kg, and to 3.50 mg/kg after nimodipine 200 micrograms/kg. Of the rats that died, only one developed cardiac arrest first, whilst the majority developed respiratory arrest. In vitro, bupivacaine alone dose-dependently reduced heart rate, contractile force, and coronary perfusion pressure. Dysrhythmias were also noted: bradycardias, ventricular extra beats, and ventricular tachycardia were the most common. Verapamil made no difference to these adverse effects, but nimodipine significantly reduced the negative chronotropic and dysrhythmogenic effects of bupivacaine. These results, although interesting, cannot be used to reach any clinical conclusions, particularly as the mechanism of interaction between bupivacaine and calcium channel blockers has yet to be elucidated.

Clonidine

The analgesic efficacy of the addition of clonidine to an epidural solution of bupivacaine plus fentanyl has been subjected to a randomized, double-blind study in 61 parturients who received bupivacaine plus fentanyl with or without clonidine (median dose 28 micrograms/hour). There was no difference between the groups in pruritus or nausea score, but those given clonidine had less shivering and better analgesia (25).

In another randomized, double-blind study, a combination of clonidine and neostigmine was added to intrathecal bupivacaine plus fentanyl in 45 parturients (26). The combination increased the duration of labor analgesia by 83%, but was associated with significantly more nausea. However, the results were equivocal, and larger studies are needed.

Clonidine inhibits the hepatic metabolism of bupivacaine in mice (27).

Desipramine

Desipramine displaces bupivacaine from plasma proteins (28).

Mepivacaine

Bupivacaine displaces mepivacaine from protein binding sites on $alpha_1$ acid glycoprotein in vitro (29).

Pethidine

Pethidine displaces bupivacaine from plasma proteins (28). However, this interaction is probably not of clinical importance (30).

Phenytoin

Phenytoin displaces bupivacaine from plasma proteins (28).

Quinidine

Quinidine displaces bupivacaine from plasma proteins (28).

Buprenorphine

See also Opioid analgesics

General Information

Buprenorphine is a partial agonist at OP_3 (μ) opioid receptors and an antagonist at OP_2 (κ) receptors.

In a double-blind, randomized study of three groups of 18 patients having abdominal surgery who received single doses of either intramuscular pethidine 75 mg, with sublingual buprenorphine 400 μg, or buprenorphine 300 μg alone, sedation and nausea were the most common adverse effects in all three groups. Patients who received sublingual buprenorphine were significantly less sedated in the immediate postoperative period (1).

In a 3-day randomized, placebo-controlled study, 40 patients with acute pancreatitis or acute-on-chronic pancreatitis were given either buprenorphine 2.4 mg/day or procaine hydrochloride 2 g/day by constant intravenous infusion (2). The patients who received buprenorphine had significantly lower pain scores than those given procaine and were significantly less likely to demand additional analgesia. The adverse effect profiles were similar in the two groups, with the exception of a significantly higher rate of sedation in those who were given buprenorphine. The authors suggested that intravenous buprenorphine is more effective and safer than procaine in acute pancreatitis.

Buprenorphine has been suggested to be useful for the treatment of cocaine and opiate dependence. In a study designed to assess its safety for this purpose (SEDA-18, 85) there were no adverse effects or serious interactions with a single dose of intravenous morphine or cocaine during daily maintenance on buprenorphine.

Organs and Systems

Cardiovascular

- A 27-year-old man injected a 2 mg suspension of crushed oral buprenorphine into his left ulnar artery, leading to acute ischemia of the hand; he was successfully treated with iloprost and dextran-40 (3).
- A 22-year-old man snorted an 8 mg crushed tablet of buprenorphine and 2 hours later had crushing chest pain, which resolved within a few minutes (4). The symptom recurred 3 weeks later after another inhalation of buprenorphine. An electrocardiogram suggested an acute anterior myocardial infarction caused by buprenorphine-induced coronary artery spasm.

Respiratory

Respiratory depression can occur with buprenorphine. It is not often a clinical problem, except in older and weaker subjects, in whom it can be fatal (5). When it occurs it is often prolonged and can be particularly difficult to reverse (SEDA-16, 87). Norbuprenorphine, a metabolite of buprenorphine via CYP3A4 causes dose-dependent respiratory depression, perhaps mediated by opioid receptors in the lung rather than the brain, and is 10 times more potent than buprenorphine (SEDA-22, 103).

Non-cardiogenic pulmonary edema has been reported after a single dose of buprenorphine (SEDA-19, 89).

Nervous system

Sedation and nausea are relatively frequent. When buprenorphine is used for patient-controlled analgesia, minor dysphoria or euphoria has been reported (SEDA-16, 88).

In one of three patients receiving epidural buprenorphine for the relief of pain from head and neck cancers, it was discontinued because of severe dizziness (SEDA-17, 87).

© 2006 Elsevier B.V. All rights reserved.

Mouth and teeth

There have been reports of facial and lingual ulcers, the ulceration following repeated injection of buprenorphine into the left superior cervical ganglion for trigeminal neuralgia (6) and the use of sublingual buprenorphine (7).

Gastrointestinal

Impaired gastric emptying and delayed absorption after sublingual buprenorphine have also been reported (SEDA-17, 87).

Liver

- A 33-year-old man developed severe hepatitis after an oral overdose of buprenorphine tablets 112 mg over 48 hours (8). He presented with an acute confusional state, including disorientation in time and space. The condition led to anuria and hepatorenal insufficiency. He was successfully treated with hemodialysis.

With increasing use of buprenorphine in the treatment of opioid dependence, it has been confirmed that the use of buprenorphine in opioid-dependent individuals with a history of hepatitis causes significant increases in aspartate transaminase and alanine transaminase activities (9). Liver enzymes should be monitored before giving buprenorphine to patients with hepatitis.

Four former opiate-dependent individuals with confirmed hepatitis C virus were given substitution therapy with sublingual buprenorphine. After injecting buprenorphine together with their sublingual doses, they had a marked increase in serum aspartate transaminase activity (13–50 times the upper limit of the reference range), resulting in jaundice (10). Another patient who was positive for hepatitis C and HIV developed jaundice, with panlobular liver necrosis and microvesicular steatosis, after using sublingual buprenorphine and small doses of paracetamol and aspirin (10).

Intravenous buprenorphine abuse precipitated acute-on-chronic hepatitis in a 25-year-old woman who was hepatitis C positive with a history of chronic diamorphine dependence (11).

Skin

There have been reports of severe pruritus with buprenorphine (12).

Immunologic

There have been reports of anaphylactic reactions with buprenorphine (13).

Death

Two series of 39 and 78 deaths attributed to buprenorphine have respectively been reported in Strasbourg and 13 other French forensic centers between 1996 and 2000 (14). The risks incurred by the misuse of buprenorphine seem to arise through a combination of (a) the concomitant use of other psychotropic drugs (especially benzodiazepines and neuroleptic drugs) and (b) the improper use of tablets for intravenous administration and/or massive oral doses. The total recorded number of buprenorphine-related deaths is largely underestimated, because the very low concentrations require sensitive immunoassay techniques, making them difficult to detect; furthermore different cut-off points are used by different forensic pathology laboratories in diagnosing drug-related deaths.

Long-Term Effects

Drug abuse

Abuse of buprenorphine has been reported in many countries and it is now widely dealt with under psychotropic drug legislation.

Although sublingual buprenorphine has been used in the management of heroin addiction (SEDA-16, 88), widespread abuse of buprenorphine by addicts is known (SEDA-16, 88), including the snorting of crushed sublingual tablets (SEDA-16, 88).

Buprenorphine is increasingly being used as a substitute for other opioids in the treatment of opioid abuse and is generally considered to be safe because of the ceiling effect. One report from Vienna described 50 opioid-dependent subjects who received gradual (10-day) detoxification with buprenorphine, contacting the outpatient clinic daily, so that buprenorphine could be administered according to their clinical need in a free dosage scheme (15). The mean daily dosage was 2.3 mg on day 1 and the highest mean daily dose was administered on day 2, followed by daily reduction over the study period. There was 70% compliance with the regimen and withdrawal symptoms during the study period were described as moderate.

Less satisfactory outcomes have been reported from France (16–18), where acute poisoning during buprenorphine substitution has been described in three series of patients. The first included 29 opiate addicts taking high-dosage sublingual buprenorphine with non-fatal poisoning and the second included 20 addicts who died (16). Blood concentrations of buprenorphine in the first group were low (1.0–2.3 ng/ml, mean 1.4 ng/ml), but there was concomitant intake of psychotropic medication, especially benzodiazepines, in 18 cases. Blood concentrations of buprenorphine in the fatal cases were 1.1–29 (mean 8.4) ng/ml, while concentrations of its primary metabolite, norbuprenorphine, were 0.2–13 (mean 2.6) ng/ml, within or slightly over the target range. Extensive tissue distribution buprenorphine was reported (myocardium, kidney, brain, and liver) but the highest concentrations of buprenorphine and norbuprenorphine were found in the bile, and the authors suggested that this may be the sample of choice for postmortem screening. Buprenorphine was also identified in eight of 11 hair samples assayed. Intravenous injection of crushed tablets and the concomitant use of benzodiazepines were identified as the major risk factors in the fatal cases (17).

Drug dependence

Sublingual buprenorphine is an alternative to methadone in treating opiate dependence, but its opioid agonist effects pose the risk of intravenous abuse and subsequent dependence. This abuse potential may be limited by using a combination of buprenorphine with naloxone, which will precipitate opiate withdrawal when given

© 2006 Elsevier B.V. All rights reserved.

intravenously but not sublingually. The effects of three combinations of intravenous buprenorphine and naloxone on agonist effects and withdrawal signs and symptoms in 12 opiate-dependent patients have been described (19). After stabilization with morphine 60 mg intramuscularly the patients were challenged with intravenous doses of buprenorphine 2 mg, either alone or in combination with naloxone in ratios of 2:1, 4:1, and 8:1, with morphine alone (15 mg), or with placebo. In those given the combination there was a naloxone dose-dependent increase in opiate withdrawal signs and a reduction in the pleasurable effects that might induce abuse liability. The authors suggested that the combination of buprenorphine with naloxone in a ratio of 2:1 or 4:1 can be useful in the treatment of opiate dependence.

There have been three studies of the use of buprenorphine to treat opiate dependence.

The authors of a randomized, multicenter, placebo-controlled, double-blind study of 72 opioid-dependent individuals, who were given either buprenorphine 8 mg/day or methadone 60 mg/day for 6 months, claimed that there were no significant differences in adverse effects during induction or maintenance (20). Buprenorphine provided an alternative to methadone, with equal improvement in quality of life, psychopathology, and compliance. The results of this study should be interpreted with care, because of the unusual experimental design, which did not reflect practices in ordinary methadone maintenance programs. However, similar observations were observed during an open, flexible-dose study involving inpatient induction and outpatient maintenance in 15 opioid-dependent pregnant women (21). Sublingual buprenorphine (1–10 mg/day) was well accepted by the women, and there was a low incidence of neonatal abstinence syndrome. Further controlled and larger studies need to be done to substantiate these observations.

In a double-blind, randomized comparison of sublingual buprenorphine tablets with oral methadone in a 6-week trial in 58 patients using a flexible dosing procedure the retention rate was significantly better in those using methadone (90 versus 50%) (22). Those who completed the study had a similar number of opioid-positive urine samples, with a mean stabilization dose of 11 mg/day of buprenorphine and 70 mg/day of methadone. This study had several limitations: 6 weeks is too short a period to determine any intermediate or long-term treatment outcomes, the sample size was too small, and the comparison of non-equivalent doses makes interpretation difficult.

Drug withdrawal

The effects of buprenorphine (sublingually or by injection) in an opioid-dependent population have been studied (23,24). There was benefit in using buprenorphine to counteract opioid withdrawal effects in patients with chronic heroin use and subsequent dependence. However, the results are limited and the benefits short-term if psychosocial support is not in place as part of an overall treatment package before buprenorphine is prescribed (25).

- A 35-year-old man with a 10-year history of heroin use was given sublingual buprenorphine 24 mg/day (26). Although it was dispensed daily by a pharmacist, he was not adequately supervised: he saved the buprenorphine tablets and continued to use heroin. He then took buprenorphine 40 mg and stopped using heroin; he immediately developed opioid withdrawal symptoms. In an attempt to relieve these symptoms, he took a further 40 or 45 mg buprenorphine in 24 hours. He subsequently came to a drug treatment clinic, where he was given another 16 mg of buprenorphine, with no effect. After 3 days, he was transferred to methadone and his withdrawal symptoms resolved.

In this case buprenorphine precipitated opioid withdrawal symptoms after heroin use. This highlights the importance of regular monitoring and supervision of community-dispensed buprenorphine.

Second-Generation Effects

Fetotoxicity

It is inadvisable to use buprenorphine during labor, as its effects on the fetus cannot be reversed.

Drug Administration

Drug formulations

A sublingual formulation that combines buprenorphine and naloxone is thought to be ideal for reducing parental buprenorphine abuse. In a small pilot study in nine opioid-dependent individuals already stabilized on buprenorphine 8 mg/day, naloxone 0, 4, or 8 mg was added (27). The addition of naloxone did not precipitate opiate withdrawal.

A transdermal therapeutic system (TTS) for rate-controlled delivery of buprenorphine is available in three strengths, with release rates of 35, 52.5, and 70 μg/hour for 72 hours. This is equivalent to daily doses of 0.8, 1.2, and 1.6 mg respectively. In a double-blind, randomized, controlled study using one of three dosage strengths of buprenorphine TTS in 445 patients with chronic pain the adverse effects were mild and typical of the opioid analgesics; they included nausea (17%), vomiting (9.3%), dizziness (6.8%), tiredness (5.6%), constipation (5.3%), and sweating (3.7%) (28). There was erythema in 25% and pruritus in 22%. More than half of the cases of erythema and one-third of the cases of pruritus resolved within 24 hours. In a single-blind, randomized study sublingual buprenorphine 0.2 mg provided an effective and convenient alternative in the treatment of acute renal colic compared with pethidine 50 mg intramuscularly (29). There was a slightly but non-significantly higher incidence of nausea, vomiting, and dizziness in those given buprenorphine.

Drug dosage regimens

Two doses (8 and 16 mg) of sublingual buprenorphine have been compared in a 6-week double-blind, placebo-controlled inpatient study of the reinforcing effects of intravenous diamorphine (30). Only eight diamorphine-dependent men were recruited and the authors could only postulate that doses over 16 mg might be more effective in blocking the reinforcing effects of diamorphine.

© 2006 Elsevier B.V. All rights reserved.

Drug administration route

Adverse effects after parenteral, sublingual, and rectal use have included hypotension, bradycardia, reduced systolic blood pressure, reduced stroke volume, nausea, sweating, vomiting, vertigo, sedation, and a reduction in respiratory rate (31). In some intravenous studies nausea and vomiting have occurred in as many as 20%. Hypotension occurs in 1–5% of patients, and hypertension, tachycardia, or bradycardia in under 1%.

Drug–Drug Interactions

Benzodiazepines

Six deaths linked to misuse of buprenorphine plus benzodiazepine combinations have been described (18). The authors emphasized that blood concentrations of buprenorphine were in the target range in three subjects, although higher in three others. Exhaustive screening detected no traces of opiates in postmortem blood, but all subjects had target range concentrations of both desmethyldiazepam and 7-aminoflunitrazepam. The risk of high-dose substitution therapy (2–8 mg), if physicians do not comply with correct practices for the prescription, and use of buprenorphine were emphasized, particularly when there is a large population of patients being treated, as there was in France in 1997 (34 000 patients).

HIV-1 protease inhibitors

The metabolism of buprenorphine is inhibited by the HIV-1 protease inhibitors (32).

Naloxone

Naloxone is of limited use in reversing the effects of buprenorphine, because of its relative inability to displace it from opioid receptors. Naloxone 1 mg had little effect on the respiratory depression caused by buprenorphine 300 μg/70 kg, although both 5 and 10 μg produced consistent reversal, which was more complete with the larger dose (33). Insignificant effects on circulation and respiration have been reported at lower doses of buprenorphine (4.5–10 μg/kg) (34).

Opioid agonists

Under some conditions the antagonist action of buprenorphine can jeopardize the effect of subsequently administered pure opioid agonists, by blocking OP_3 (μ) opioid receptors so effectively that normal doses of the opioid agonist are ineffective, necessitating the administration of a higher dose, with the attendant risk of respiratory depression, from which deaths have been reported (SEDA-13, 60). Fortunately such instances appear to be rare.

Buspirone

General Information

Buspirone, an azapirone drug, similar to its analogues ipsaperone and tandospirone, is chemically and pharmacologically dissimilar to the benzodiazepines and is useful in both generalized anxiety and depression (1). In contrast to benzodiazepines, buspirone has an antidepressant-like therapeutic latency (2), and for this reason it needs to be given with considerable education and encouragement. It is effective in children with anxiety disorders (SEDA-19, 36) and as an antidepressant adjuvant in refractory depression with (3) and without (4) obsessive-compulsive symptoms. Buspirone is also effective in treating anxious alcoholics, and in patients with agitation or aggression associated with organic brain disease (5).

Originally thought to act through a dopaminergic mechanism, buspirone is now regarded as acting as a 5-HT_{1A} receptor (partial) agonist (6) and produces dose-related adverse effects similar to those of the SSRIs (nausea, headache, insomnia, dizziness, and sexual dysfunction) (SEDA-22, 39) (7). Like them, it interacts with monoamine oxidase inhibitors and can produce the serotonin syndrome (8). An uncommon association with extrapyramidal movement disorders (SEDA-17, 46) (SEDA-18, 45) may reflect its structural relation to some dopamine receptor antagonists.

Compared with benzodiazepines, buspirone causes less sedation and memory impairment (9), has little interaction with alcohol (2,10), and is essentially devoid of problems of abuse, disinhibition, tolerance, and dependence.

These advantages are important in treating particular groups of patients, including patients with brain injury, elderly people, forensic populations, and the medically ill (11,12). On the other hand, over 50% of patients with cerebellar ataxia reported significant adverse effects, as described above (SEDA-21, 39).

Buspirone may also have advantages in treating individuals who are susceptible to problems with alcohol (13) or other hypnosedatives (10), although habitual users of benzodiazepines are often unwilling to persist with buspirone long enough for it to have a therapeutic effect (2).

Unlike carbamazepine or tricyclic antidepressants, buspirone is not helpful in the management of benzodiazepine withdrawal (14).

The safety results from two comparisons of buspirone 15 mg bd and buspirone 10 mg tds in patients with persistent anxiety have been subjected to meta-analysis (15). The incidences of adverse events were similar, except for a significantly higher incidence of bouts of palpitation in patients taking buspirone bd (5%) compared with tds (1%). The most frequently reported adverse events with both regimens were dizziness, headache, and nausea. There were no appreciable differences between treatments in vital signs, physical examination, electrocardiography, or clinical laboratory results. A change to twice-daily dosing with buspirone may offer convenience and

© 2006 Elsevier B.V. All rights reserved.

possibly greater adherence to therapy in patients with persistent anxiety, without compromising the safety and tolerability profile of the drug.

The effects of hydroxyzine 50 mg/day, buspirone 20 mg/day, and placebo have been studied in 244 patients with generalized anxiety disorder in a double-blind placebo-controlled study (16). Hydroxyzine ($n = 81$) was considerably better than placebo ($n = 81$), and buspirone ($n = 82$) was intermediate. The main adverse effects were headache and migraine with buspirone (6.1 versus 4.9% with hydroxyzine and 1.2% with placebo). Somnolence occurred in 9.9% with hydroxyzine, 4.9% with buspirone, and none with placebo. Dizziness occurred in 6.1% with buspirone, none with hydroxyzine, and 2.5% with placebo.

In a 21-day, open, multicenter, dose-escalation study, 13 children and 12 adolescents with anxiety disorder and 14 healthy adults took buspirone 5–30 mg bd titrated over 3 weeks (17). Buspirone was generally safe and well-tolerated at doses up to 30 mg in adolescents and adults and in most of the children. The most common adverse events in children and adolescents were light-headedness (68%), headache (48%), and dyspepsia (20%); two children withdrew from the study at the higher doses (15 mg and 30 mg bd) owing to adverse effects. In adults, the most common adverse event was somnolence (21%); mild light-headedness, nausea, and diarrhea were also reported.

Organs and Systems

Respiratory

Because of its virtual absence of respiratory depressant effects compared with benzodiazepines (18), buspirone may be especially useful in treating anxious patients with lung disease (19).

Nervous system

The efficacy and safety of buspirone have been evaluated in the management of anxiety and irritability in 22 children with pervasive developmental disorders. One child developed abnormal involuntary movements of the mouth, cheeks, and tongue after having taken buspirone 20 mg/day for 10 months. No other drugs were prescribed. The abnormal movements disappeared completely within 2 weeks of withdrawal of buspirone. Other adverse effects in other children were minimal and included initial sedation, slight agitation, and initial nausea (20).

Long-Term Effects

Drug abuse

Despite continuing scrutiny, buspirone has shown little, if any, abuse potential (7).

Drug Administration

Drug formulations

Because of their short half-lives, buspirone and its analogues are problematic to administer (6). A single dose of buspirone ER (extended-release) 30 mg has been compared with two doses of buspirone IR (immediate-release) 15 mg given 12 hours apart to assess differences in tolerability in an open, crossover, randomized study in 18 healthy men (21). Blood samples were obtained at 22 times. Seven subjects reported a total of 13 adverse events during the study, but none of the events recorded was unexpected. All were mild and resolved by the end of the study without medical intervention. Three adverse events (rhinitis, headache, and light-headedness) were categorized as unrelated to the study drug. The other 10 adverse events included drowsiness, dizziness, depression, tinnitus, and increased blood pressure. There were no significant differences between the two formulations.

Drug–Drug Interactions

Calcium channel blockers

In a randomized placebo-controlled trial, the possible interactions of buspirone with verapamil and diltiazem were investigated. Both verapamil and diltiazem considerably increased plasma buspirone concentrations, probably by inhibiting CYP3A4. Thus, enhanced effects and adverse effects of buspirone are possible when it is used with verapamil, diltiazem, or other inhibitors of CYP3A4 (22).

Erythromycin

Erythromycin, an inhibitor of CYP3A, can increase buspirone concentrations (SEDA-22, 39).

Fluvoxamine

The effects of fluvoxamine on the pharmacokinetics and pharmacodynamics of buspirone have been investigated in 10 healthy volunteers. Fluvoxamine moderately increased plasma buspirone concentrations and reduced the production of the active metabolite of buspirone. The mechanism of this interaction is probably inhibition of CYP3A4. However, this pharmacokinetic interaction was not associated with impaired psychomotor performance and is probably of limited clinical significance (23).

Grapefruit juice

In a randomized, two-phase crossover study, the effects of grapefruit juice on the pharmacokinetics and pharmacodynamics of oral buspirone were investigated in 10 healthy volunteers. Grapefruit juice increased the mean peak plasma concentration of buspirone 4.3-fold (24). Large amounts of grapefruit juice should be avoided in patients taking buspirone.

Haloperidol

Buspirone increases haloperidol concentrations in some patients (SEDA-21, 39).

Itraconazole

Itraconazole, an inhibitor of CYP3A, can increase buspirone concentrations (SEDA-22, 39).

© 2006 Elsevier B.V. All rights reserved.

Monoamine oxidase inhibitors

Buspirone interacts with monoamine inhibitors and can cause the serotonin syndrome (8).

Rifampicin

The effects of rifampicin on the pharmacokinetics and pharmacodynamics of buspirone were investigated in 10 young healthy volunteers. There was a significant reduction in the effects of buspirone in three of the six psychomotor tests used after rifampicin pretreatment. The interaction between rifampicin and buspirone is probably mostly due to increased CYP3A4 activity. Buspirone will most likely have a greatly reduced anxiolytic effect when it is used together with rifampicin or other potent inducers of CYP3A4, such as phenytoin and carbamazepine (25).

Sertraline

Serotonin syndrome has been attributed to the combination of buspirone and sertraline.

- A 49-year-old man had major adverse effects 11 days after taking a combination of sertraline, buspirone, and loxapine (26). The adverse effects were characteristic of the serotonin syndrome, which is characterized by a constellation of symptoms, including hypomania, agitation, seizures, confusion, restlessness, hyper-reflexia, tremor, myoclonus, ataxia, incoordination, anxiety, double vision, fever, shivering, variable effects on blood pressure, nausea and vomiting, sweating, and diarrhea.

St John's wort

Clinicians should inform their patients about the risks associated with taking St John's wort if they are taking psychotropic drugs that can cause the serotonin syndrome.

- A 27-year-old married woman developed symptoms of generalized anxiety disorder and was given buspirone 30 mg/day (27). During treatment she felt depressed and decided to take St John's wort. Two months later she started to have nervousness, aggressiveness, hyperactivity, insomnia, blurred vision, and very short periods of confusion and disorientation. The symptoms were consistent with serotonin syndrome. St John's wort was withdrawn and her symptoms resolved after 1 week.

Buspirone is a partial agonist at $5HT_{1A}$ receptors; St John's wort is a non-selective inhibitor of 5HT reuptake and also upregulates postsynaptic $5HT_{1A}$ and $5HT_{2A}$ receptors; it therefore causes overstimulation of $5HT_{1A}$ receptors, leading to the serotonin syndrome.

Busulfan

See also Cytostatic and immunosuppressant drugs

General Information

Busulfan is an alkylating agent that is used to treat myeloproliferative disorders and to produce myeloablation before bone marrow or stem cell transplantation. Busulfan is metabolized by hepatic glutathione *S*-transferase, the activity of which correlates negatively with busulfan maximum and minimum concentrations and positively with busulfan clearance (1).

General adverse effects

Leukemic patients receiving marrow from HLA-identical sibling donors were randomized to either oral busulfan 16 mg/kg ($n = 88$) or total body irradiation ($n = 79$), plus cyclophosphamide 120 mg/kg (2). Over 5–9 years the following adverse effects occurred in the two groups:

- obstructive bronchiolitis (26 versus 5%).
- cataracts (6 versus 2%).
- veno-occlusive disease of the liver (12 versus 1%).
- complete or partial alopecia (28 versus 6%).
- hemorrhagic cystitis (32 versus 10%).
- acute graft-versus-host disease (cumulative incidence at 7 years, 59 versus 47%); death from graft-versus-host disease was more common with busulfan (22 versus 3%).

Organs and Systems

Cardiovascular

Pericardial fibrosis has been reported after busulfan treatment in a man with chronic myeloid leukemia (3). Endocardial fibrosis has also been reported (4).

Respiratory

Busulfan can cause interstitial fibrosing lung disease ("busulfan lung") with an estimated incidence of 6% (5). It begins gradually, causes dyspnea and cough, and is often accompanied by skin pigmentation. It usually occurs after prolonged treatment (on average 41 months, cumulative dose 2900 mg). The respiratory function pattern is characterized by reduced lung volumes with hypoxemia and hypocapnic respiratory failure. Radiology shows interstitial and predominantly basal shadows.

Various authors have discussed the differences in busulfan-induced idiopathic pneumonia syndrome, as a result of either chronic low-dose or short-course high-dose therapy. One group found that chronic low-dose therapy (even at cumulative doses of busulfan of up to 3 g) caused different lung damage from the clinical characteristics, radiological, and pathological features of the idiopathic pneumonia syndrome (6).

Three patients with busulfan-induced interstitial pneumonitis each had circulating immune complexes and alveolitis, and histology demonstrated consistent abnormalities of type I pneumocytes and depletion of type II pneumocytes (7).

Nervous system

Busulfan can cause generalized seizures (8).

High concentrations of busulfan in the cerebrospinal fluid have been correlated with development of myoclonic epilepsy and/or other electroencephalographic changes after high-dose busulfan conditioning regimens for acute leukemia (9).

- A 21-year-old woman with acute lymphoblastic leukemia underwent bone marrow transplantation after a conditioning regimen consisting of busulfan and cyclophosphamide (10). The day after starting busulfan, she had a generalized tonic-clonic seizure and electroencephalography showed diffuse polyspikes and spike-and-wave discharges, with persistent abnormalities (slowing of background activity intermixed with diffuse slow waves and isolated delta and theta bursts) for about 20 days and complete normalization 1 month after the seizure.

Phenytoin and benzodiazepines have been successfully used to prevent seizures during busulfan therapy; benzodiazepines may be preferable, because phenytoin can induce the metabolism of busulfan, reducing its efficacy. In 29 children undergoing hemopoietic stem cell transplantation who received high-dose busulfan, intravenous or oral lorazepam (median dose 0.022 mg/kg) before each dose of busulfan and for 24 hours after the last dose was used as seizure prophylaxis; drowsiness was the only significant adverse effect and there were no seizures (11). There were no tonic-clonic or myoclonic seizures in a prospective study in 16 patients with leukemia receiving busulfan before autologous bone marrow transplantation who were given phenobarbital and clonazepam, despite electroencephalographic changes in two patients after busulfan (12).

Sensory systems

Cataract due to busulfan has been reported after long-term administration (SEDA-1, 341) (13).

- A 42-year-old Japanese woman received busulfan 212 mg/day for only 4 days and developed reduced visual acuity and blurred vision in both eyes; she had a posterior polar subcapsular opacity in the lenses in both eyes (14).

© 2006 Elsevier B.V. All rights reserved.

- A 49-year-old man with chronic myelogenous leukemia developed dense posterior subcapsular cataracts and punctate cortical opacities after taking busulfan for 5 years (15). Ultrastructural examination showed cortical liquefaction, with Morgagnian droplets involving primarily the region from the equator to the posterior subcapsular space, crystalloid rays, and abundant degenerate lens fiber membranes.

Hematologic

Aplastic anemia developed in 84 patients with chronic myeloid leukemia receiving busulfan; three patients died (16). The time interval until pancytopenia was detected varied considerably, ranging between 6 and 126 months. The effect did not correlate with the initial doses of busulfan.

Colony-stimulating factors have been used to treat and prevent the adverse hematological effects of busulfan (17,18).

- In a 91-year-old woman with essential thrombocythemia and marked bone marrow suppression induced by long-term busulfan, G-CSF and M-CSF increased the neutrophil and platelet counts but only transiently; there was transient eosinophilia after withdrawal of M-CSF (19).
- A 63-year-old woman with thrombocythemia was given busulfan 2 mg/day and later developed pancytopenia (20). She was given metenolone acetate 15 mg/day and G-CSF 300 μg/day, and frequent blood transfusions without effect. She was then given metenolone acetate, G-CSF 600 μg/day, and erythropoietin 24 000 units twice a week, and her pancytopenia gradually improved over several months.

One patient with busulfan-induced pancytopenia and recurrent thrombocytopenic bleeding was successfully treated prophylactically with random-donor platelet transfusions and later with HLA-matched platelets from a sibling (21).

- A patient with polycythemia vera who had undergone splenectomy received six courses of busulfan for recurrent thrombocytosis over 19 years (22). Severe pancytopenia followed and persisted for 4 months. There was marked erythroid hyperplasia in the bone marrow, with striking dyserythropoiesis, PAS-positive erythrocyte precursors, moderate numbers of circulating normoblasts, and evidence of chronic and acute hemolysis.

Of 39 patients taking busulfan 16 mg/kg/day and cyclophosphamide 120 mg/kg/day for leukemias, who received non-T cell depleted, HLA-matched sibling or unrelated donor marrow transplants 2 days after the end of chemotherapy followed by ciclosporin and methylprednisolone given to prevent graft-versus-host disease, 11 developed eosinophilia, of whom only 2 were still taking methylprednisolone (23). At the onset of eosinophilia, five of these 11 patients had graft-versus-host disease that worsened within 2 months. In the other six patients, graft-versus-host disease was not present initially but developed in all cases at a median of 4 months after the onset of eosinophilia.

Liver

In 66 patients who received busulfan in combination with cyclophosphamide, etoposide, and/or cytarabine in preparation for bone marrow transplantation, there was a higher incidence of veno-occlusive disease of the liver (sinusoidal obstruction syndrome) in those who received busulfan + cyclophosphamide (four of 10) than in those who received busulfan + cyclophosphamide + cytarabine (one of 18) or busulfan + cyclophosphamide + etoposide (seven of 38) (24). The risk of veno-occlusive disease was higher in those whose busulfan AUC was over 1500 minute.μmol/l (relative risk = 11). Other pharmacokinetic parameters, age, sex, type of bone marrow transplantation, previous therapy, or pretransplant liver function tests were not predictive of veno-occlusive disease.

In 30 patients who received oral busulfan 1 mg/kg, all six of those who developed hepatic veno-occlusive disease had a busulfan AUC greater than the mean, and five had an AUC that was greater than 1 standard deviation above the mean; veno-occlusive disease correlated with an increased AUC (25).

- Intrahepatic cholestasis has been attributed to busulfan in a 57-year-old man with chronic megakaryocytic granulocytic myelosis (26).
- Cholestatic hepatitis occurred in a 61-year-old man with chronic myelocytic leukemia who had taken busulfan for 8 years (27). He presented with fever, abdominal pain, and raised liver enzymes. A liver biopsy showed cellular cholestasis with focal liver cell necrosis accompanied by a mild inflammatory infiltrate. When busulfan was withdrawn, his liver enzymes normalized and his fever resolved.

Urinary tract

Busulfan can rarely cause hemorrhagic cystitis (28,29).

Skin

Busulfan can cause hyperpigmentation (30,31), often in combination with interstitial lung disease (5).

Hair

Of 65 patients who survived for at least 6 months after bone marrow transplantation, 31 had some degree of alopecia and 19 had extensive alopecia (32). The mean minimum busulfan concentration was 656 ng/ml in patients who developed alopecia, compared with 507 ng/ml in those who did not. Patients with more extensive alopecia had higher busulfan concentrations. In multivariate analysis, alopecia was associated with busulfan concentrations higher than the median (OR = 3.43; 95% CI = 3.04, 3.88), allogeneic transplantation (OR = 2.56; CI = 2.28, 2.88), and female sex (OR = 1.96; CI = 1.73, 2.88). There was no association between alopecia and chronic graft-versus-host disease.

Reproductive system

Busulfan can cause ovarian failure.

- A 26-year-old woman with chronic myeloid leukemia developed busulfan-induced ovarian failure, with amenorrhea, climacteric symptoms, raised plasma concentrations of luteinizing and follicle-stimulating

© 2006 Elsevier B.V. All rights reserved.

hormones, and low 17 beta-estradiol concentrations (33). However, 1 year later she became pregnant, the busulfan was stopped, and amniocentesis showed a normal karyotype. The remainder of the pregnancy was unremarkable and ended with the normal delivery of a healthy child.

Of 21 girls aged 11–21 years who had received high-dose chemotherapy and autologous bone marrow transplantation without total body irradiation for malignant tumors 1.2–13 years before (median 7 years), 10 were given busulfan 600 mg/m^2 and melphalan (140 mg/m^2) with or without cyclophosphamide (3.6 g/m^2) (34). Eleven others did not receive busulfan. Twelve girls (57%) had clinical and hormonal evidence of ovarian failure. Among nine others who had had normal puberty, six had normal gonadotropin concentrations, one had raised gonadotropin concentrations, and two had gonadotropin concentrations at the upper limit of the reference range. All 10 girls who received busulfan developed severe persistent ovarian failure.

Second-Generation Effects

Teratogenicity

Retinal degeneration and microphthalmia have been described in the infants of women who have taken busulfan during pregnancy (35).

- Myeloschisis occurred in a 6-week-old human embryo whose 39-year-old mother had taken busulfan before and during the early stages of gestation for chronic lymphatic leukemia (36). Histology showed reduced mesenchymal elements together with somite disorganization in the affected area of the embryo.

Drug Administration

Drug overdose

A 4.6 kg infant with Wiskott–Aldrich syndrome received an accidental overdose of busulfan during preparation for allogeneic stem cell transplantation (37). Hemodialysis was immediately performed and resulted in accelerated clearance of busulfan. There were no acute neurological or hepatic adverse effects, and after cough and by rales for 2 months pulmonary symptoms resolved. There was stable partial donor chimerism after transplantation, but the patient was well 12 months later.

Drug–Drug Interactions

Cyclophosphamide

In bone marrow transplant recipients, prior administration of busulfan, which itself causes hemorrhagic cystitis, can increase the risk of cyclophosphamide-induced damage (38).

Busulfan reduces the clearance of cyclophosphamide to its active metabolite 4-hydroperoxycyclophosphamide (39). The first dose of high-dose cyclophosphamide should therefore be delayed for at least 24 hours after the last dose of busulfan.

Itraconazole

In 13 patients given bone marrow transplantation, the clearance of busulfan was reduced by an average of 20% in patients taking itraconazole compared with control patients and patients taking fluconazole (40).

Metronidazole

In 24 patients with graft-versus-host disease, metronidazole significantly increased busulfan plasma concentrations from 452 to 807 ng/ml (41). The authors concluded that metronidazole should not be administered simultaneously with busulfan, because of the risk of severe toxicity and/or mortality.

Phenytoin

In 17 patients given busulfan during conditioning before bone marrow transplantation, phenytoin increased the clearance of busulfan and shortened its half-life; diazepam did not have the same effect (42). There were reductions in the steady-state concentrations of busulfan in four of seven patients who took phenytoin and in only one of eight patients who took diazepam. This effect of phenytoin is probably due to induction of glutathione transferase.

Butibufen

See also Non-steroidal anti-inflammatory drugs

General Information

Experience with the NSAID butibufen is limited. Only gastrointestinal adverse effects have been described (1).

Reference

1. Aparicio L. Butibufen. Drugs Today 1979;15:43.

Butorphanol

See also Opioid analgesics

General Information

Butorphanol is a synthetic 14-hydroxymorphinan analogue with a low dependence potential and a low propensity to cause opioid adverse effects (1). It is a synthetic OP_2 (κ) receptor agonist and OP_3 (μ) receptor antagonist.

General adverse reactions

In some patients, effective doses cause troublesome effects. For example, in a randomized study of patients with sickle-cell crisis who received either butorphanol 2 mg intramuscularly or morphine 6 mg intramuscularly, adverse effects occurred in 23 and 13% respectively (2). On the other hand, a wide range of doses (4–48 mg/day) over 1 month failed to produce scores indicative of euphoric effects, and the withdrawal syndrome resembled a cyclazocine rather than a morphine abstinence effect (1).

Organs and Systems

Cardiovascular

Although cardiovascular toxicity with butorphanol is slight, raised pulmonary wedge pressure has occurred at cardiac catheterization (1).

Respiratory

Respiratory depression occurs minimally at doses of 2–4 mg (1).

Biliary tract

Butorphanol is generally believed to have a much smaller effect on biliary pressure than morphine, fentanyl, or pethidine, but 2 mg has caused biliary spasm (3).

Musculoskeletal

Fibrous myopathy has been reported in a 40-year-old woman who injected butorphanol intramuscularly (SEDA-17, 87).

Second-Generation Effects

Fetotoxicity

Two cases of sinusoidal fetal heart rhythm have been reported in which there was a significant temporal relation between the administration of butorphanol and the onset of the abnormal heart rhythm (4). In both instances the pattern reverted to normal after further analgesia was given.

Drug Administration

Drug administration route

Butorphanol has been used for epidural anesthesia in obstetric practice without adversely affecting the neonate, and no patients had pruritus (SEDA-16, 88).

As butorphanol is not orally active, reports of its transnasal administration are of interest. The most common adverse effects of transnasal butorphanol were dizziness, nausea and/or vomiting, headache, and drowsiness (SEDA-20, 83). Increased cardiac workload can also occur.

After cesarean section, transnasal butorphanol did not work quite as quickly as intravenous butorphanol. The effect lasted longer but the adverse effects were similar (SEDA-16, 88).

Butriptyline

See also Tricyclic antidepressants

General Information

Butriptyline is the isobutyl side-chain homolog of amitriptyline. Its adverse effects, reported in two open studies, were no different from those of other tricyclic antidepressants (1,2).

References

Butylated hydroxytoluene

General Information

Butylated hydroxytoluene is an additive used as an antioxidant in foods, such as packet cake mixes, potato crisps, salted peanuts, and dehydrated mashed potatoes. Its safety, and that of a number of other food additives, has been critically reviewed in a Danish study (1).

Organs and Systems

Immunologic

It is impossible to decide from experimental findings in animals what the result will be of prolonged human exposure to low concentrations of such substances. Butylated hydroxytoluene causes various allergies; symptoms of hay fever and asthma have been reported.

Chewing gum should be considered as a possible cause of unexplained food allergy.

- Butylated hydroxytoluene in chewing gum caused disseminated urticarial eruption in a young woman (2). An adverse drug reaction was ruled out, and the only recent dietary change had been regular use of chewing-gum containing butylated hydroxytoluene. The skin lesions showed signs of vasculitis, with a perivascular cellular infiltrate, heavy extravascular deposition of fibrinogen, and intraendothelial deposits of IgM, C'9, C3, and C9. She stopped using the gum and within a week the eruption had subsided. An oral provocation test confirmed that butylated hydroxytoluene was responsible, the cutaneous signs returning within several hours of rechallenge.

Long-Term Effects

Tumorigenicity

Although it has been suggested that butylated hydroxytoluene induces tumors in rats, others have suggested that it may protect tissues against the carcinogenic effects of many different substances.

C1 esterase inhibitor concentrate

General Information

Hereditary angioedema, which is characterized by episodic bouts of swelling of submucosal and subcutaneous tissue, is due to a hereditary abnormality of C1 esterase inhibitor, either a deficiency of the normal enzyme or more rarely the presence of an abnormal enzyme. If C1 esterase inhibitor deficiency can be demonstrated, infusion of concentrated C1 esterase inhibitor is effective in treating the attack. In three studies, no adverse effects were recorded (1–3).

Organs and Systems

Immunologic

Allergic reactions to C1 esterase inhibitor concentrate have been observed, including possible exacerbation of angioedema (4).

Infection risk

The use of C1 esterase inhibitor concentrate has been associated with transmission of hepatitis C, but this can be prevented by heat treatment (5).

Cabergoline

General Information

Cabergoline is an ergoline derivative that has been used in patients with hyperprolactinemia (SEDA-15, 133), but is used nowadays in patients with Parkinson's disease. Its adverse effects include nausea, hypotension, headache, gastric pain, dizziness, and weakness, which as a rule resolve over time.

It is almost universally accepted that directly acting dopamine receptor agonists have less efficacy than levodopa, although the reasons are not clear. Neurologists from London have sought to question this assumption by using cabergoline ($n = 11$) and pergolide ($n = 7$) at considerably higher doses than recommended (1). The actual mean doses were 8.8 and 9.4 mg/day, compared with recommended maxima of 6 and 5 mg/day respectively. The high doses were tolerated by the patients for 2.3–2.5 years; mild dyskinesias ($n = 7$), ankle edema ($n = 3$), and hallucinations ($n = 1$) were the only reported adverse effects. The authors concluded that the therapeutic window for these drugs is apparently much greater than is generally accepted, and that higher doses can be given safely with potentially enhanced efficacy.

Organs and Systems

Respiratory

- Interstitial pneumonitis occurred in a 65-year-old man who had taken cabergoline in a low dose (1 mg/day) for 4 months (2). He was given no specific therapy, but withdrawal of the drug resulted in clinical recovery after 3 weeks and radiological resolution within 2 months.

Nervous system

When cabergoline is used in patients with Parkinson's disease, the same spectrum of dyskinesias and psychiatric complications as with bromocriptine is observed (3).

The successful use of ergot derivatives to shrink macroprolactinomas can have unwanted neurological consequences, and this has been described in two case reports.

Three Italian men aged 39, 42, and 53 years with invasive prolactinomas took cabergoline 1.0–3.0 mg/week and all developed CSF rhinorrhea after 2–7 months (4). This was clearly a consequence of loss of the "stopper" effect of the tumor, owing to shrinkage, and in each case was successfully treated by endoscopic trans-sphenoidal surgery.

- A 42-year-old Spanish man took cabergoline (up to 3 mg/day) for a large prolactinoma causing hypopituitarism and symptomatic chiasmal compression (5). After 18 months there was only a minimal tumor remnant on the floor of the sella turcica, but there was chiasmal herniation. However, there were no clinical effects of this, and in particular the visual fields were normal.

Serosae

Some patients who developed retroperitoneal or pleural fibrosis from bromocriptine experienced aggravation of the condition when they switched to cabergoline. Cabergoline may share this risk with bromocriptine (SEDA-17, 169).

- A 76-year-old man taking cabergoline 10 mg/day developed constrictive pericarditis after 11 months (6). He required pericardiectomy, but cabergoline was continued and a few months later he was found to have pleuropulmonary fibrosis, which did not resolve on drug withdrawal.

Cadmium

General Information

Cadmium is a bluish-white metallic element (symbol Cd; atomic no. 48). It is found as cadmium sulfate in a mineral called greenockite.

Cadmium is an environmental and occupational pollutant that is associated with nephrotoxicity (1) and bone toxicity (2); even low concentrations can impair renal function and/or increase bone fragility. Cadmium is also an adulterant in infant formulas and weaning foods.

Cadmium concentrations were determined in 59 baby food samples, including milk-based cereals and milk-based and soya-based formulas, recommended from 0–18 months of age. The mean weekly intake of dietary cadmium was estimated to be 0.1–3.1 μg/kg. Exposure to dietary cadmium from weaning diets can be up to 12 times higher in children fed infant formulas than in breast-fed children (3).

Caffeine

General Information

Caffeine is a methylxanthine used to stimulate the central nervous system in combating fatigue and drowsiness. Caffeine stimulates the central nervous system, skeletal muscle contraction and gastric secretion. It acts to a lesser extent on the kidney, producing a diuresis. Most of its adverse effects result from accentuated pharmacological actions, including those described above, and they may become especially evident in pathologically or genetically predisposed individuals. Differences in the activity of *N*-acetylases in the liver, secondary to genetic polymorphism lead to differential susceptibility to caffeine (xanthine toxicity) (1). A certain degree of tolerance develops to some of the pharmacological actions of caffeine, but there is little or no tolerance to its central stimulatory effects; however, some kind of psychic habituation can develop after prolonged consumption.

The term "caffeinism" refers to a state of acute or chronic toxicity resulting from the ingestion of high doses of caffeine. An average intake of 500–600 mg/day of caffeine (about 7–9 cups of tea or 4–7 cups of coffee) is currently regarded as representing a significant health risk. The symptoms of caffeinism include behavioral, psychophysiological, and affective manifestations. They include restlessness, anxiety, irritability, agitation, muscle tremor, insomnia, headache, sensory disturbances, diuresis, cardiovascular symptoms, and gastrointestinal complaints (SEDA-10, 5). At very high doses caffeine can even produce epileptiform convulsions. Acute overdosage can occur and produce severe CNS excitation in sensitive individuals and small children (SEDA-15, 1). Tonic-clonic seizures have been reported postpartum. Maternal use of caffeine in pregnancy can cause dysrhythmias in the neonate (SEDA-14, 1). Because of a significant abuse potential and potential toxicity, formulations that contain a high content of caffeine have been made available by prescription only in some European countries.

Workers in the coffee industry often develop allergic reactions, in the form of dermatitis, rhinitis, and bronchial asthma, on exposure to dust in the process of stripping the chaff from raw beans before roasting (2). This may or may not be a reaction to caffeine itself.

The ability of caffeine to catalyse the formation of *N*-nitrosamine in the digestive tract has raised the question of its being carcinogenic (see "Pancreas" below). Caffeine has been associated with fibrocystic breast disease (3). However, a study of benign proliferative endothelial disorder of the breast did not show any association with methylxanthine consumption (SEDA-15, 1).

Organs and Systems

Cardiovascular

There is debate over the association between caffeine intake and cardiovascular disease. Increases in mean blood pressure, blood glucose and free fatty acid concentrations, and urinary catecholamine excretion have been

found after acute ingestion of 150 mg of caffeine (SEDA-4, 4). While not particularly potent, caffeine appears to produce cardiac dysrhythmias, including ventricular tachycardia. Furthermore, in non-smokers, daily consumption of five cups of percolated coffee per day (about 680 mg of caffeine) was associated with a modestly increased risk of having a cardiac arrest without a prior history of cardiovascular disease (4). In patients with pre-existing heart disease, caffeine lowers the effective and functional refractory period of the atrioventricular node (SEDA-4, 5). A two-fold increased risk of myocardial infarction has been suggested for women who drink six or more cups of coffee a day (5), and in two studies, men who drank five or more cups of coffee a day had an approximately two-fold increase in the risk of myocardial infarction (6) or coronary artery disease (7). However, prospective studies of the relation between caffeine consumption and an increased risk of coronary artery disease (or stroke) have been negative (SEDA-15, 1) or inconclusive (8,9), as has been the association between the consumption of coffee and serum cholesterol concentration assessed in 24 cross-sectional epidemiological studies (SEDA-15, 1). However, a Finnish study did show a positive-dose relation with serum cholesterol after adjustment for confounding variables, in men but not in women. It has also been suggested that the relation is seen only with boiled and not instant or filter coffee.

Guaraná is produced from the guaraná plant (*Paullina cupana*), the seeds of which contain 3.6–5.8% caffeine.

- A 25-year-old woman, who had pre-existing mitral valve prolapse and a history of having had bouts of palpitation with caffeine, developed intractable ventricular fibrillation after consuming a "natural energy" guaraná health drink containing a high concentration of caffeine (10). At autopsy, she was found to have sclerosis and myxoid changes in the mitral valve leaflets. The caffeine concentration in her aortic blood was 19 μg/ml.

This case highlights the need for more careful regulation of "natural" products, including warning patients with underlying health problems, and clear labeling to document the presence of any constituents with potentially adverse effects. It also shows the need for medical practitioners to be familiar with the more widely used "natural remedies" and their toxicological profiles. Following the death of this patient, the Western Australian Coroner recommended that Race 2005 Energy Blast should be removed from the local market, and the product was recalled nationally in August 1999.

Nervous system

Insomnia, anxiety, tachycardia, and tremor are among the symptoms most commonly reported with caffeine (11). Tenseness and irritability also occur and, with high intake, symptoms resembling those of anxiety neurosis (12). A case of "caffeine psychosis" has also been reported (13). Dose–response associations have not been particularly well studied, but some are known (SEDA-7, 6). Paradoxically, six cases have been reported of pathological sleepiness induced by caffeine (14). Tonic-clonic seizures occurred postpartum in a woman who had received 500 mg of caffeine sodium benzoate for headache after lumbar puncture; a prolonged half-life was implicated (SEDA-17, 1).

Consumption of methylxanthine-containing products can aggravate the neurological symptoms associated with the glucose transporter type 1 (Glut 1 deficiency syndrome). The human erythrocyte and the brain glucose transporters are identical, and the erythrocyte transporter has been used in four patients with individual mutations in the Glut 1 gene to demonstrate that caffeine and theophylline inhibit glucose transport (15). The Glut 1 deficiency syndrome represents impaired glucose transport across the blood–brain barrier caused by partial Glut 1 deficiency, which results in hypoglycorrhachia, seizures, and developmental delay. Identifying potential inhibitors of Glut 1 is essential in preventing further impairment of glucose transport in these patients. In addition to phosphodiesterase inhibition and adenosine A_1 receptor antagonism by methylxanthines, it is likely that inhibition of glucose transport also contributes to the convulsive effects of methylxanthines in high doses.

Psychological, psychiatric

Red Bull, a mixture of caffeine, taurine, and inositol, a widely consumed "power drink," affects mental performance and mood.

- A 36-year-old man with bipolar-I disorder had a second manic episode, after having been in remission for 5 years while taking lithium to maintain a serum lithium concentration of 0.8–1.1 mmol/l (16). One week before this episode, he drank three cans of Red Bull at night, as he needed less sleep; 3 days later he drank three more cans. After 4 days he was feeling euphoric, hyperactive, and insomniac. He gradually became more hyperactive and had increased libido and irritability. He took no more Red Bull and improved within 7 days.

Based on this report, the authors suggested that stimulant beverages that contain caffeine might cause cognitive and behavioral changes, especially in vulnerable patients with bipolar illness.

Metabolism

The major metabolic effects of caffeine are increase in free fatty acids and blood glucose concentration (17,18).

Electrolyte balance

Hypokalemia and myopathy are known effects of caffeine toxicity, and severe hypokalemia and fatigue and hypokalemia with myopathy have been described before (19).

Gastrointestinal

Large doses of caffeine can cause nausea and vomiting. Caffeine is a potent stimulant of hydrochloric acid secretion (20) and has been incriminated in exacerbating duodenal ulcers. However, decaffeinated coffee has also been reported to be as potent as instant coffee in stimulating gastric acid secretion (20).

© 2006 Elsevier B.V. All rights reserved.

Pancreas

A relation between coffee consumption and pancreatic cancer was originally reported in a case-control study (SEDA-7, 8), with an unexpected increase in pancreatic cancer in coffee drinkers (relative risk in men 2.6). The same group studied differences in mortality from pancreatic cancer in different countries in relation to differences in coffee consumption and found a significant relation between increases in coffee consumption and increases in mortality from pancreatic cancer. However, the data on which the findings were based were crude.

Although the results of published epidemiological studies are compatible with a small effect of coffee consumption on pancreatic carcinogenesis, the interpretation of these findings is not clear, because of the possibility of residual confounding and other sources of bias (21). In two large cohort studies of 1 907 222 person-years of follow-up, there were 288 cases of pancreatic cancer with no evidence of an association between coffee and pancreatic cancer (22). Furthermore, there is no association between folate intake, caffeine consumption, and the risk of pancreatic cancer (23).

The relation between coffee drinking and the presence of the K-*ras* mutation in patients with exocrine pancreas cancer has been investigated in Spain in 121 cases in which tissue specimens were available (24). In exocrine pancreatic cancer, the K-*ras* gene may be activated less often among regular coffee drinkers, suggesting that caffeine, or other compounds present in coffee, or other factors with which coffee drinking is associated, may modulate K-*ras* activation. While the results of this study may have mechanistic and pathogenic relevance, they have no clinical or health policy implications.

Urinary tract

Large doses of caffeine cause diuresis. Daily consumption of caffeine citrate increased the mean urinary excretion rate of tubular cells and erythrocytes in volunteers (25). The nephrotoxicity of analgesic antipyretic drug combinations may result from a combined effect, in which aspirin, phenacetin, and caffeine all play a role (SEDA-4, 5). In 10 asymptomatic women and 20 women with confirmed detrusor instability, caffeine caused a significant increase in detrusor pressure on bladder filling in the latter, but no difference in volume at first contraction, height of contraction, or bladder capacity (26).

As up to 10% of about 42 000 dialysis patients have suffered from renal insufficiency due to analgesic nephropathy (in the postphenacetin era), German nephrologists have demanded that medications that contain fixed combinations of analgesics (paracetamol, aspirin, or propyphenazone plus caffeine) be withdrawn from the market, following the example of their US colleagues in the National Kidney Foundation (27).

Skin

Urticaria as an allergic response to caffeine has been reported (SEDA-4, 5).

Musculoskeletal

Caffeine toxicity is an uncommon cause of myopathy, but a history of excessive dietary and pharmaceutical consumption of caffeine should be sought in any patient with unexplained myopathy, particularly if there is concomitant hypokalemia (28).

- A 21-year-old woman with a 12-month history of progressive muscle weakness, nausea, vomiting, diarrhea, and weight loss had significant worsening of muscle weakness over 2 weeks, associated with exercise-induced muscle stiffness and pain. She had severe hypokalemia and metabolic acidosis. For the past 1–2 years she had been consuming about 8 liters of cola every day. She stopped drinking cola and took potassium supplements, after which her hypokalemia and muscle weakness resolved and the serum creatine kinase activity fell. Based on the concentration of caffeine in the cola, it was estimated that she had been consuming at least 1 g/day of caffeine for more than 12 months.

Long-Term Effects

Drug abuse

Abuse of analgesic combinations has been thought to be especially facilitated if they contain caffeine or codeine, reinforcing abuse. However, this has not been confirmed in an expert review, in which it was concluded that the available evidence does not support the claim that analgesics co-formulated with caffeine, in the absence of phenacetin, stimulate or sustain overuse (29). Caffeine has a synergistic effectiveness with analgesics, but although it can cause dependence, the risk is low. Withdrawal is not likely to cause increased need of analgesics. However, there is strong dependence behavior in patients using formulations containing phenacetin, antipyretics/analgesics, and caffeine. This finding may have led to the impression that caffeine stimulates overuse of analgesics.

Drug withdrawal

Restlessness, irritability, and headache are withdrawal effects attributable to caffeine. These and other symptoms can occur with lower doses of caffeine than generally supposed (30). The caffeine withdrawal headache may be responsible for the widespread practice of taking caffeine-containing analgesics habitually, since a withdrawal headache could create a vicious cycle of drug use (SEDA-5, 6).

Tumorigenicity

A possible association between the use of methylxanthine consumption and the occurrence of fibrocystic breast disease has been suggested (SEDA-6, 8) (3). It was concluded that in women who are predisposed to fibrocystic disease, methylxanthines are factors in its development. The mechanism of this effect might be an inhibitory action on the activity of cyclic AMP and cyclic GMP phosphodiesterases.

© 2006 Elsevier B.V. All rights reserved.

Second-Generation Effects

Fertility

It has been suggested that the use of caffeine to improve the mobility of human sperm used in artificial insemination may be very risky, owing to the potential for chromosome damage and also possible damage to the fertilized ovum (SEDA-5, 32).

Another study suggested that a high daily intake of caffeine may predispose women to reproductive difficulties (SEDA-9, 2). Although delayed mitosis and excessive chromatid breaks have been noted in human lymphocytic cultures to which caffeine was added (31), the rapid and almost complete metabolism of caffeine in man may protect against the various deleterious effects found in human cell culture studies and animal studies.

Epidemiological studies requiring further verification have suggested a relation between caffeine intake and reduced fertility, even at a consumption as low as the caffeine equivalent of more than one cup of brewed coffee a day (SEDA-14, 1). A more recent study has suggested that this reduction in fertility is limited to non-smokers; possible acceleration of caffeine metabolism in smokers has been offered as a possible explanation for the apparent effect of smoking (32).

Fetotoxicity

In two studies (SEDA-6, 9), there was a relation between caffeine consumption and fetotoxicity. In one, a high rate of spontaneous abortions, stillbirths, and prematurity at birth was associated with ingestion of more than 600 mg of caffeine per day by either the mother or the father. In the other, a daily intake of more than eight cups of coffee by the mother increased the frequency of congenital malformations.

Concern about the possible harmful effects of caffeine on the outcome of pregnancy has evolved mainly from studies of animals which have shown a reduction in intrauterine fetal growth. However, the implications of these data for men are unclear, because of the differences in mode of exposure to caffeine, the amounts consumed, and caffeine metabolism. The possible effects of caffeine intake on the human fetus have been reviewed (SEDA-7, 8); the conclusion was that the scientific data currently available could not answer the question. In an analysis of interview and medical record data in 12 205 non-asthmatic women to evaluate the relation between coffee consumption and adverse outcomes in pregnancy, the findings were negative.

In eight pregnant women at 32–36 weeks of gestation, two cups of caffeinated or decaffeinated coffee were associated with an increase in the incidence of fetal breathing activity, and the caffeinated coffee was associated with a significant fall in baseline fetal heart rate (33). Three cases of fetal dysrhythmias resulting from excessive intake of caffeine by the mother during pregnancy have been reported (SEDA-14, 1).

Some studies have reported that a caffeine consumption of over 150 mg/day during pregnancy may be associated with a small but statistically significant increase in the risks of spontaneous abortion and low birth weight, although the authors could not rule out contributions of maternal age, smoking, ethanol use, or other confounders (34). Careful evaluation of these confounders may at least partly resolve the controversy surrounding possible adverse effects of caffeine on pregnancy outcome.

Whether the consumption of caffeine during pregnancy increases the risk of spontaneous abortion is controversial. In a nested case-control study, 591 women who had a spontaneous abortion before 140 days of gestation were compared with 2558 matched women from the same clinic who gave birth to live infants at 28 weeks' gestation and who had serum drawn on the same day of gestation as the women who had abortions (35). The women were enrolled in the Collaborative Perinatal Project from 1959 to 1966, and the serum paraxanthine concentration was measured 30 years later. Moderate consumption of caffeine was unlikely to increase the risk of spontaneous abortion; only extremely high serum paraxanthine concentrations were associated with spontaneous abortion.

Lactation

The relation between serum and breast milk concentrations of caffeine has been studied (SEDA-6, 8). Caffeine accumulation in the infant would depend on the average concentration in maternal serum and breast milk over time, the volume of milk ingested, and particularly the infant's clearance rate of caffeine.

Susceptibility Factors

Age

Infants

Xanthines have been given to infants at the risk of sudden infant death syndrome or idiopathic apnea of prematurity (see monograph on Theophylline). About 50% of 30 infants treated with caffeine (and 12 of 18 infants treated with theophylline) had significant increases in episodes of gastroesophageal reflux (36). The authors stressed that screening for reflux should precede the administration of caffeine (and theophylline) to infants at the risk of sudden infant death syndrome. As expected, the frequency of adverse effects such as tachycardia and gastroesophageal reflux is lower with lower doses of caffeine; for example 2.5 mg/kg qds (SEDA-17, 1).

Children

In healthy boys, there were increases in subjective anxiety in long-term low-caffeine users, and withdrawal symptoms in high-caffeine users. No beneficial effects of caffeine use were found (37). It has been recommended that children should take caffeine only in analgesic products and in a dose related to their age (SEDA-5, 6).

Other features of the patient

In patients who are susceptible to cardiac dysrhythmias, restriction of caffeine may be indicated. Caffeine can also add to the rise in renin and noradrenaline that occur in hepatic cirrhosis and can also considerably aggravate diarrhea in patients with irritable bowel syndrome (SEDA-15, 1).

© 2006 Elsevier B.V. All rights reserved.

Drug Administration

Drug overdose

Excessive amounts (1 g or more) of caffeine can cause untoward central nervous effects, including psychotic organic brain syndrome (SEDA-5, 6).

Oral route

Oral doses that cause death are said to range from 3 to 50 g of caffeine, but death from excessive caffeine ingestion is rare, perhaps owing to its emetic effect. Death may be due to cardiovascular shock, but chronic potentially lethal toxicity, even for heavy coffee or tea drinkers, is very unlikely since 60–100 cups a day would be required.

Intravenous route

In two instances in which caffeine was given intravenously, convulsions and death were recorded at doses of 400 mg and 3.2 g (38).

The elimination of caffeine has been described in a neonate weighing 1860 g, born at 31 weeks of gestation, after the accidental administration of 160 mg/kg. The first serum concentration was 218 mg/l at 36.5 hours after dosing. The half-life was 81 hours, the clearance 0.01 l/hour (0.17 ml/minute), and the volume of distribution 1.17 liters. Toxic manifestations were hypertonia, sweating, tachycardia, cardiac failure, pulmonary edema, and metabolic disturbances such as metabolic acidosis, hyperglycemia, and raised creatine kinase activity. An unusual feature of this infant's illness was gastric dilatation. These signs resolved by day 7 at a serum concentration of 60–70 mg/l (39).

Confirmed reports of caffeine overdose are rare. Postmortem concentrations of caffeine measured in femoral blood were 220 and 190 mg/l in two adults who took unknown doses (40). In view of the extensive use of caffeine, the authors emphasized the forensic importance of measuring caffeine.

Drug–Drug Interactions

General

A comprehensive textbook has listed more than 40 drugs that interact with caffeine (41). See also the monograph on Theophylline.

Caffeine has been included in a wide variety of fixed drug combinations (for example, with non-steroidal anti-inflammatory drugs or antihistamines). The purpose of including caffeine is to increase systemic availability (for example, antipyrine), to counteract adverse effects of the other drug (for example, sedation induced by antihistamines), or to provide additional therapeutic efficacy (aspirin). The use of combination formulations complicates evaluation of caffeine's adverse effects.

Aspirin

In a comparison of a caffeine-free formulation containing aspirin 650 mg plus citric acid 60 mg and a formulation containing aspirin 650 mg plus caffeine citrate 120 mg (equivalent to 60 mg of anhydrous caffeine), caffeine significantly increased the rate of appearance as well as the maximum concentration of the salicylate in plasma by about 31 and 15% respectively; the AUC of salicylate was also significantly higher (42). The authors concluded that caffeine can increase the systemic availability of aspirin in man without any other effects on the salicylate disposition.

However, in a systematic review and meta-analysis of published randomized controlled trials, it was found that caffeine did not enhance the analgesic effect of aspirin (43).

Benzodiazepines

Caffeine and other central stimulants can reverse daytime sedation from benzodiazepine use. There was a positive effect of caffeine 250 mg on early morning performance after placebo, and flurazepam 30 mg given the night before (44,45), particularly in terms of subjective assessment of mood and sleepiness. However, one cannot assume that the alerting effect of caffeine necessarily reverses the amnestic, disinhibiting, or insight-impairing effects of benzodiazepines. Indeed, caffeine may actually worsen learning and performance already impaired by lorazepam (46).

Carbamazepine

In five children, due to receive carbamazepine for epilepsy, the caffeine breath test was carried out before the administration of carbamazepine 200–600 mg and after a minimum of 2–3 weeks therapy (47). The results suggested that carbamazepine induces the metabolism of caffeine by CYP1A2.

Clozapine

In an open, randomized, crossover study in 12 non-smoking healthy volunteers, caffeine 400–1000 mg/day reduced clozapine clearance, probably by inhibiting CYP1A2 (48). Differences in habitual caffeine intake can, therefore, explain some of the large variability in the kinetics of clozapine (49), and should be taken into consideration when clozapine is used. An earlier case report (50) also suggested that caffeine increases plasma concentrations of clozapine, causing toxic symptoms.

In seven schizophrenic patients taking clozapine monotherapy, caffeine was withdrawn for 5 days; clozapine plasma concentrations fell by 50% (51). The authors suggested that schizophrenic patients treated with clozapine should have their caffeine intake supervised, and that monitoring of concentrations of clozapine and its metabolite may be warranted.

Ephedrine

Even low doses of caffeine can, in sensitive patients, cause tremor, insomnia, and anxiety, and such problems are much more marked if ephedrine is given together with caffeine, as it sometimes is for appetite control (SEDA-17, 161).

Idrocilamide

The pharmacokinetics of caffeine is greatly altered by concomitant administration of the myorelaxant, idrocilamide, which inhibits the biotransformation of caffeine and prolongs its half-life nine-fold (SEDA-5, 7). Consequently, when idrocilamide is prescribed, partial

© 2006 Elsevier B.V. All rights reserved.

or total abstinence from caffeine-containing products should be enforced.

Lithium

Caffeine increases renal lithium clearance, and it is conceivable that drastic curtailment of caffeine intake could result in an increase in serum lithium concentration.

Mexiletine

Mexiletine reduces the clearance of theophylline, and this combination has been reported to cause ventricular tachycardia (52). A similar interaction with caffeine has been reported (53).

Neuroleptic drugs

Caffeine can alter the plasma concentrations of neuroleptic drugs (SEDA-5, 6).

Excess caffeine can stimulate the CNS, which can worsen psychosis and thus interfere with the effects of neuroleptic drugs (54). Neuroleptic drugs can precipitate from solution when mixed with coffee or tea (55), but the clinical significance of this interaction is unknown (56).

Oral contraceptives

The clearance of both theophylline and caffeine is reduced in oral contraceptive users, and their half-lives are increased, probably because of inhibition of hepatic metabolism by cytochrome P450 isozymes (57). Again, caution in dosage is advisable.

Phenylpropanolamine

Phenylpropanolamine, which is available over the counter for weight loss, inhibits caffeine metabolism, leading to excessive stimulation; for example, manic psychosis (SEDA-17, 1).

Interference with Diagnostic Tests

Dexamethasone suppression test

A false-positive dexamethasone-suppression test has been associated with ingestion of caffeine equivalent to 4–5 cups of coffee (58).

Calcipotriol

General Information

Topical calcipotriol (a vitamin D analogue) is an effective and safe treatment for mild to moderate psoriasis vulgaris. Its mode of action is identical to that of 1,25-dihydroxycolecalciferol (calcitriol).

Organs and Systems

Nervous system

Calcipotriol can cause headache (SEDA-20, 157).

Mineral balance

With the use of doses larger than the recommended maximum of 100 g/week, a few reports have documented hypercalcemia and hypercalciuria (SEDA-18, 176) (SEDA-22, 172) (1,2). However, hypercalcemia has also been reported in a few patients using no more than the recommended doses (3,4). Calcipotriol exerts its effects on systemic calcium homeostasis by increasing intestinal absorption of calcium and probably phosphate. This results in suppression of parathyroid hormone and 1,25-dihydroxycolecalciferol (5).

Skin

At recommended doses, the adverse effects of calcipotriol are limited to skin reactions. Lesional and perilesional

© 2006 Elsevier B.V. All rights reserved.

irritation occurs in about 20% of patients (6). Contact dermatitis is rare. Photosensitization can occur when calcipotriol is used in patients undergoing UVB phototherapy.

Contamination of the facial skin can result in frank irritant contact dermatitis. Allergic contact dermatitis has been observed in some patients (7–10).

Hyperpigmentation due to local application of vitamin D in combination with photochemotherapy has been described. Calcipotriol may have the same potential.

- In one case, there was profound hyperpigmentation during UVB 311 nm phototherapy in combination with local calcipotriol, applied after the UVB irradiation (11). Calcipotriol-treated areas, and not the surrounding normal skin, started to show increased pigmentation after six sessions of irradiation, stabilized during therapy, and slightly decreased in intensity during the 6 months after photochemotherapy had ended. No photoallergy tests were performed.

Calcipotriol can occasionally convert psoriasis vulgaris into pustular psoriasis (SEDA-19, 165).

Immunologic

Contact allergic reactions to calcipotriol are rare. In one case patch tests with Psorcutan Salbe and calcipotriol (its active ingredient) were both positive (10).

Calcitetracemate

General Information

The use of calcitetracemate in the treatment of lead poisoning has been described (1). Between 1993 and 2000, 45 adult patients consulted the Poison Centre of Marseilles, France after lead exposure (9 women, 36 men, average age 44, range 22–76 years). In 22 patients, a calcitetracemate provocation test was negative. Six patients with a positive test refused to be treated; the other 16 were treated with a total of 58 courses of calcitetracemate by infusion 500 mg bd for 5 days. The mean blood lead concentration in these 16 patients was 566, range 320–943 ng/ml; the mean urinary lead excretion was 3011, range 789–7229 μg/day. The mean amount of lead eliminated in the urine during chelation therapy was 30 912 μg. In 12 patients in whom lead exposure ended after the diagnosis of lead poisoning, chelation therapy reduced the blood lead concentration by 69%. In four patients in whom exposure continued during treatment, the blood lead concentration fell by only 7%. In the 16 treated patients, there was clinical improvement and no adverse effects of chelation therapy.

Drug Administration

Drug administration route

Lead poisoning in a six-week-old child was treated by adding disodium calcitetracemate to the peritoneal dialysis fluid (2).

Calcitonin

General Information

Calcitonin inhibits osteoclastic bone resorption, increases the urinary excretion of calcium and phosphate, and reduces serum calcium. It is established in the treatment of disorders of high bone turnover, including Paget's disease and postmenopausal osteoporosis, but is less effective than the bisphosphonates. Calcitonin is less effective than other therapeutic measures in the treatment of acute hypercalcemia. Long-term administration of calcitonin reduces morbidity in cases of osteogenesis imperfecta

© 2006 Elsevier B.V. All rights reserved.

and algoneurodystrophy (SEDA-13, 1307) (1,2). The role of calcitonin in treating acute pain due to osteoporotic crush fractures has been reviewed, but the mechanism of its analgesic effect is not known (3).

When used continuously in high doses, the therapeutic effect of calcitonin is sustained for only a few months, probably because of down-regulation of osteoclast receptors. The duration of the response to calcitonin can be extended by periodically interrupting treatment. A number of regimens, ranging from cycles of a few days to several months, are effective both as prophylaxis in healthy postmenopausal women and in women with established osteoporosis; however, the risk of fractures is not reduced (4). Calcitonin also has a potent analgesic effect independent of its effect on bone, possibly mediated through endogenous opioids (5). It appears to be more effective when given intranasally than subcutaneously for this indication.

Salmon- and eel-derived calcitonins are more potent than the human and porcine forms. Intranasal calcitonin has a systemic availability of only 3% of the subcutaneous form but is associated with fewer adverse effects, probably because of lower systemic availability. Antibodies against calcitonin are often found after prolonged treatment, more commonly with salmon (30–69%) or eel calcitonin than with human calcitonin. Antibodies do not usually affect the clinical effect of calcitonin and have not been reported to cause any harm to the patient. Antibody-mediated resistance is exceptional.

The adverse effects of calcitonin, although common, are usually mild and are dose-related in the therapeutic range. They include gastrointestinal effects (nausea, cramps, and vomiting), dizziness and flushing, and local reactions either at the injection site (rash, pruritus) or in the nose (rhinitis, dryness, sneezing, and rarely epistaxis). In 40 patients there was nausea and dizziness in 37% of those given rectal salmon calcitonin compared with 6% of those given placebo (6).

Observational studies

The usefulness of intranasally administered salmon calcitonin for 2 years has been evaluated in 44 glucocorticoid-dependent asthmatics (SEDA-19, 378) (7). All were taking calcium supplements (1000 mg/day), but one group also took calcitonin 100 IU every other day. Calcitonin increased spinal bone mass during the first year of treatment, and maintained bone mass in a steady state during the second year. However, the rate of vertebral fractures was similar in the two groups. The addition of salmon calcitonin did not increase the efficacy of calcium plus vitamin D in the prevention of bone loss in 48 newly diagnosed patients taking glucocorticoids for giant cell arteritis and polymyalgia rheumatica in a double-blind, randomized, placebo-controlled trial (SEDA-21, 418) (8).

Placebo-controlled studies

Salmon calcitonin nasal spray prevented bone loss in the lumbar spine of 31 patients treated with prednisone for polymyalgia rheumatica (SEDA-22, 448) (9). They were randomized to salmon calcitonin nasal spray 200 IU/day or matched placebo for 1 year. Both groups were treated with calcium supplements if their dietary intake was below 800 mg/day. With calcitonin the mean bone mineral density in the lumbar spine fell by 1.3% and with placebo by 5% after 1 year. There were no differences in the hip, including the femoral neck and trochanter, or in total body bone density.

Organs and Systems

Cardiovascular

Flushing occurs soon after administration of calcitonin in up to 20% of patients and usually settles within several minutes (10).

Respiratory

When salmon calcitonin 100 IU was given intravenously to 18 patients with atopic asthma in a randomized, double-blind, crossover study, to assess any potential anti-inflammatory effect, it significantly reduced FEV1 and FVC, but the effect lasted less than 1 hour (11). Three subjects had dyspnea that did not require specific treatment.

Ear, nose, throat

In a randomized, placebo-controlled trial 22% of 1255 postmenopausal women taking calcitonin compared with 15% of women taking placebo had rhinitis (nasal congestion, discharge, or sneezing) (12). Almost all cases were of mild to moderate severity.

Gastrointestinal

Nausea is common with calcitonin, and vomiting or diarrhea occur more rarely. These symptoms usually settle without treatment if the drug is continued and may also be reduced by giving the dose at bedtime.

In 46 patients with Paget's disease given synthetic salmon thyrocalcitonin 80 IU/day for 3 months, there were hot flushes in 35% and nausea in 24%; in only one case was it necessary to stop treatment because of intractable diarrhea (13).

Urinary tract

In postmenopausal osteoporosis treatment with calcitriol plus etidronate or calcitonin produced improvement in spinal bone mineral density, but a high rate of nephrotoxic adverse events (14).

Skin

Rash and pruritus can occur at the site of subcutaneous injections of calcitonin (15).

Immunologic

Calcitonin allergy is very rare.

- A 60-year-old woman tolerated daily intranasal calcitonin for 6 months of the year for 4 years (16). She developed nasal watering, nasal and ocular pruritus, and sweating immediately after the administration of nasal calcitonin when she restarted after a 6-month break. These symptoms recurred 2 years later, with abdominal pain and hypotension, after 10 months of

© 2006 Elsevier B.V. All rights reserved.

intramuscular calcitonin, and were again reproduced by a lower dose intramuscularly.

- A 65-year-old woman, who had previously tolerated calcitonin nasal spray, developed eye and nose congestion, an itchy nose, and sneezing minutes after using intranasal salmon calcitonin (17). She was later given intramuscular salmon calcitonin and developed generalized urticaria and nasal itching within minutes. Skin testing was positive with eel and salmon calcitonins but not human calcitonin, and she was treated with human calcitonin without adverse effects.

Drug Administration

Drug formulations

Intranasal calcitonin is associated with fewer adverse effects than parenteral formulations, probably because of low systemic availability. However, a meta-analysis has confirmed that adverse events are poorly reported in clinical trials (18). The pooled relative risk for rhinitis from four trials ($n = 1663$) was 1.72, but this did not reach statistical significance.

Drug–Drug Interactions

Lithium

In four women serum lithium concentrations fell significantly within 3 days of starting calcitonin (19) because of increased renal clearance of lithium (19,20). Serum lithium concentrations should therefore be monitored in patients who start to take calcitonin.

Calcium carbimide

General Information

Calcium carbimide has effects and uses similar to those of disulfiram, and has been used in the treatment of chronic alcoholism (1). Its alternative name, cyanamide, has also been used to designate carbimide, which is used in veterinary medicine.

Organs and Systems

Hematologic

Calcium carbimide has been linked to granulocytopenia (2) (SEDA-22, 525).

Liver

Calcium carbimide has been linked to liver damage (3) (SED-12, 1244), but caution is needed in attributing liver damage in alcoholic patients to drugs.

Skin

Calcium carbimide has been linked to skin reactions (4).

- A 37-year-old man developed itchy erythema on his trunk and legs after taking calcium carbimide (dose not specified) for 3 days. He had an eosinophilia of 22%. Patch-testing with calcium carbimide was positive. The eruption subsided after withdrawal.
- A 60-year-old man developed keratotic erythema on his trunk and extremities after taking calcium carbimide (dose not specified) for 1 month. Patch-testing with calcium carbimide was positive. The eruption subsided after withdrawal, but itch and redness persisted for 9 months.

Calcium channel blockers

See also Individual agents

General Information

The calcium channel blockers block the movement of calcium across L-type calcium channels. The main drugs that share this action are verapamil (a phenylalkylamine), diltiazem (a benzthiazepine), and the dihydropyridines, which include amlodipine, darodipine, felodipine, isradipine, lacidipine, lercanidipine, manidipine, nicardipine, nifedipine, nimodipine, nisoldipine, and nitrendipine. Other agents, for example prenylamine and lidoflazine, are now rarely used, and perhexiline, having failed to reach the market at all in some countries, was withdrawn in the UK after continuing concerns about its safety (1). Mibefradil blocks T type calcium channels; it was withdrawn within 1 year of marketing because of multiple drug interactions, emphasizing the need for rigorous drug assessment before release and the importance of postmarketing surveillance of new drugs (2).

Although they are chemically heterogeneous, many adverse effects are common to all calcium channel blockers, predictable from their pharmacological actions. Calcium plays a role in the functions of contraction and conduction in the heart and in the smooth muscle of arteries; drugs that interfere with its availability (of which there are many, the calcium channel blockers being the most specific) will therefore act in all these tissues. A few idiosyncratic and hypersensitivity reactions have also been reported with individual calcium channel blockers.

The properties of these drugs vary widely (3). Nifedipine is said to have little negative inotropic effect and no effect on the atrioventricular node; verapamil is a potent cardiac depressant, with a marked effect on the atrioventricular node; and diltiazem has less cardiac depressant effect but inhibits atrioventricular nodal activity.

Controversy has surrounded the use of calcium channel blockers in the treatment of hypertension (4) and ischemic heart disease (5), with evidence for an association with unfavorable coronary outcomes compared with other therapies. Most of the evidence comes from the use of short-acting formulations, especially short-acting nifedipine. The hypothesis put forward to explain these findings was that short-acting formulations cause reflex activation of the sympathetic nervous system (6). Further observational studies showed that these drugs were also associated with gastrointestinal hemorrhage (7) and cancer (8). Claims of conflicts of interests amongst authors were published (9), often amid heated debate. Further evidence against the short-acting calcium channel blockers in hypertension has been forthcoming (10,11) and a worse than expected outcome with respect to coronary outcomes in diabetic patients has fuelled the debate (12). Further evidence of gastrointestinal bleeding has been published (13), but there is evidence against a link with cancer (14). All these scares have undoubtedly reduced the standing of this class of drugs in the eyes of physicians.

© 2006 Elsevier B.V. All rights reserved.

That calcium channel blockers are effective in relieving the symptoms of angina pectoris is beyond doubt. However, the Angina and Silent Ischemia Study (15), in which nifedipine, diltiazem, and propranolol were compared with placebo in a crossover study, produced conflicting results. Only diltiazem improved treadmill exercise time and only propranolol convincingly reduced the number of silent ischemic episodes during ambulatory monitoring. These findings are hard to explain (16). Beta-blockers may be cardioprotective and therefore preferable to calcium channel blockers (17). The clinically significant deterioration seen in patients with impaired left ventricular function taking calcium channel blockers is important, as many patients with angina have previously had a myocardial infarction or have poor left ventricular function. Calcium channel blockers cannot be assumed to be safe second-line drugs for angina in patients with poor cardiac reserve, although newer agents may prove to be safer (18).

Calcium channel blockers are very effective in controlling variant angina, and are often used during coronary angioplasty and after coronary artery surgery. They are also useful in patients who are intolerant of beta-blockers (19), or who have a poor response to nitrates, or who have concurrent hypertension.

General adverse effects

Throbbing headache, facial warmth and flushing, and dizziness are minor complaints associated with the use of calcium channel blockers; these effects are believed to be caused by inhibitory actions on smooth muscle (20). Palpitation, muscle cramps, and pedal edema also occur (21–27). Dizziness, facial flushing, leg edema, postural hypotension, and constipation have been reported in up to one-third of patients. They are rarely severe and often abate on continued therapy. More serious adverse effects, mainly those affecting cardiac conduction, are much less common, and only rarely is withdrawal necessary.

Organs and Systems

Cardiovascular

Cardiac failure

Although acute hemodynamic studies have suggested that calcium channel blockers can be beneficial in cardiac failure (28), long-term treatment has been associated with clinical deterioration. Calcium channel blockers should therefore be prescribed with caution for patients with impaired cardiac function, who should be regularly reassessed; treatment should be withdrawn if the signs or symptoms of cardiac failure appear. In some cases heart failure is predictable, as in the case of a patient with aortic stenosis who developed left ventricular failure after treatment with nifedipine (29). Increased sympathetic activity can also compensate for the myocardial suppressant effects of calcium channel blockers, and the combination of these drugs (particularly verapamil) with beta-adrenoceptor antagonists has therefore given cause for concern in the past, although this combination is now considered relatively safe for the majority of patients with normal cardiac function (30–32).

Myocardial ischemia

There have been many studies of the efficacy of calcium channel blockers in early and late intervention in myocardial infarction (33). These studies have failed to show convincing benefits. Indeed, in the nifedipine intervention studies there was a consistent trend towards higher mortality in the treated patients than in those taking placebo. A study in which patients were randomized to placebo or nifedipine within 48 hours of admission was terminated after 1358 patients had been recruited, because mortality at 6 months was 15.4% on nifedipine and 13.3% on placebo (34).

It has been argued that dihydropyridine calcium channel blockers, which increase heart rate, can all increase the risk of death and reinfarction (35,36). Early beneficial results with diltiazem in patients with non-Q-wave infarction (37) were not confirmed in the Multicenter Diltiazem Postinfarction Trial (38). In patients with pulmonary congestion, diltiazem was associated with an increase in cardiac events, and there was a similar result in patients with low ejection fractions. However, verapamil does appear to reduce reinfarction (39), a benefit that is more marked in those without heart failure (40). Nifedipine may also have a detrimental effect in unstable angina; it certainly appears to offer no benefit (41).

A retrospective case-control study (4) has sparked controversy concerning the use of short-acting calcium channel blockers in treating hypertension. The study involved 623 cases of fatal and non-fatal myocardial infarction over a period of 8 years, and 2032 age- and sex-matched controls. The risk of myocardial infarction in patients taking calcium channel blockers was 16 per 1000, compared with 10 per 1000 in patients taking beta-blockers or thiazides. However, this result may have been an example of confounding by indication, since patients exposed to calcium channel blockers will have been more likely to have had peripheral vascular disease, lung disease (a low forced expiratory volume being a risk factor for cardiovascular disease), higher serum cholesterol concentrations, and diabetes mellitus. Careful statistical analysis was carried out in an attempt to control for some of the confounding factors, but such confounding can only be properly controlled for in a randomized study. A meta-analysis of 16 randomized secondary prevention studies in patients with coronary heart disease showed that the use of short-acting nifedipine is associated with an increased mortality in a dose-related manner (dose, risk: 30–50 mg, 1.06; 60 mg, 1.18; 80 mg, 2.83) (5). However, the event rates in this study were relatively small. A prospective cohort study in 906 elderly hypertensive patients showed that short-acting nifedipine is associated with a relative mortality risk of 1.7 compared with beta-blockers (42). After the publication of these studies, the FDA recommended that short-acting nifedipine should no longer be used in hypertension or unstable angina (43).

Disturbances of cardiac rhythm

Calcium channel blockers differ in their effects on the myocardial conduction system. Both verapamil and diltiazem have significant inhibitory effects on both sinoatrial and atrioventricular nodal function, whereas nifedipine has little or no effect. Nevertheless, nifedipine can on occasion cause troublesome bradydysrhythmias (44,45).

© 2006 Elsevier B.V. All rights reserved.

Severe conduction disturbances can also occur if calcium channel blockers are used in hypertrophic cardiomyopathy (46), but these drugs are used in this condition (47).

Hypotension

There are many case reports of symptomatic hypotension, usually in hypertensive patients treated with large dosages of calcium channel blockers (48,49) or in patients with myocardial infarction (50). These may represent injudicious prescribing rather than true adverse drug effects. In the DAVIT II study, 1.9% of the verapamil-treated group versus 1.6% of the placebo-treated group developed hypotension or dizziness (40); the frequency of hypotension in a randomized study of diltiazem after infarction was 0.6% in the drug-treated group and 0.2% in the placebo-treated group (37).

Respiratory

Adverse respiratory effects are uncommon with calcium channel blockers. However, three cases of acute bronchospasm accompanied by urticaria and pruritus have been reported in patients taking verapamil (51), and a patient with Duchenne-type muscular dystrophy developed respiratory failure during intravenous verapamil therapy for supraventricular tachycardia (52). Recurrent exacerbations of asthma occurred in a 66-year-old lady with hypertension and bronchial asthma given modified-release verapamil (53).

In pulmonary hypertension, both verapamil and nifedipine increase mean right atrial pressure in association with hypotension, chest pain, dyspnea, and hypoxemia; the severe hemodynamic upset resulted in cardiac arrest in two patients after verapamil and death in another after nifedipine (54). A patient with pulmonary hypertension also developed pulmonary edema whilst taking nifedipine (55) and another seems to have developed this as an allergic reaction (56).

Nervous system

Calcium channel blockers can cause parkinsonism. Of 32 patients with this complication, only three had made a full recovery 18 months after withdrawal; patients under 73 years of age tended to have a better prognosis (57). It is not known if these patients would have developed parkinsonism in any case, and whether the drugs merely act as precipitants.

Calcium channel blockers can worsen myasthenic syndromes. Myasthenia gravis can deteriorate with oral verapamil (58). A patient with Lambert–Eaton syndrome and a small-cell carcinoma of the lung developed respiratory failure within hours of starting treatment with verapamil for atrial flutter, and required assisted ventilation (59). Only after verapamil had been withdrawn did breathing improve. Verapamil affects calcium channels in nerve membranes in animals, but the experimental concentrations used exceeded those found in clinical practice (59). Thus, the evidence for a drug-related effect is circumstantial. In another case, diltiazem triggered Lambert–Eaton syndrome, which improved with drug withdrawal (60).

Sensory systems

Eyes

Painful eyes occurred in 14% of patients taking nifedipine compared with 9% in captopril-treated patients in a postmarketing surveillance study (61). The mechanism is unknown but is not via ocular vasodilatation (62).

Taste

Transient disturbances of taste and smell, without other signs of neurological deficit, have been reported after nifedipine and diltiazem. The time to the onset of symptoms after nifedipine varied from days to months, and symptoms regressed within 24 hours of withdrawal (63). With diltiazem the effect gradually abated over 10 weeks, despite continuation of therapy (64).

Psychological, psychiatric

A patient taking diltiazem developed the signs and symptoms of mania (65) and another developed mania with psychotic features (66). There have also been reports that nifedipine can cause agitation, tremor, belligerence, and depression (67), and that verapamil can cause toxic delirium (68). Nightmares and visual hallucinations have been associated with nifedipine (69). Depression has been reported as a possible adverse effect of nifedipine (70).

Some reports have suggested that calcium channel blockers may be associated with an increased incidence of depression or suicide. However, there is a paucity of evidence from large-scale studies. A study of the rates of depression with calcium channel blockers, using data from prescription event monitoring, involved gathering information on symptoms or events in large cohorts of patients after the prescription of lisinopril, enalapril, nicardipine, and diltiazem by general practitioners (71). The crude overall rates of depression during treatment were 1.89, 1.92, and 1.62 per 1000 patient-months for the ACE inhibitors, diltiazem, and nicardipine respectively. Using the ACE inhibitors as the reference group, the rate ratios for depression were 1.07 (95% CI = 0.82, 1.40) and 0.86 (0.69, 1.08) for diltiazem and nicardipine respectively. This study does not support the hypothesis that calcium channel blockers are associated with depression.

Endocrine

In six hypertensive patients given nitrendipine 20 mg/day for 30 days, there was inhibition of aldosterone response but no significant change in ACTH secretion in response to corticotrophin-releasing hormone (72).

The calcium-dependent pathway of aldosterone synthesis in the zona glomerulosa is blocked by calcium channel blockers, producing a negative feedback increase in the pituitary secretion of ACTH, which in turn causes hyperplasia of the zona glomerulosa. This leads to increased production of androgenic steroid intermediate products and subsequently testosterone, which acts on gingival cells and matrix, giving rise to gingival hyperplasia (see the section on Mouth and teeth).

Metabolism

Calcium transport is essential for insulin secretion, which is therefore inhibited by calcium channel blockers (73).

© 2006 Elsevier B.V. All rights reserved.

Despite this, calcium channel blockers generally have minimal effects on glucose tolerance in both healthy and diabetic subjects. Oral glucose tolerance is not affected by verapamil, and basal blood glucose concentrations were not altered during long-term verapamil administration (74). Similarly, neither nifedipine nor nicardipine produced significant hyperglycemic effects in either diabetic or non-diabetic patients (75–77). In 117 hypertensive patients nifedipine caused a significant rise in mean random blood glucose of only 0.3 mmol/l (78), an effect that was clearly of no clinical relevance. In the Treatment of Mild Hypertension Study, 4 years of monotherapy with amlodipine maleate caused no change compared with placebo in the serum glucose of 114 hypertensive patients (79). In a review (80) it was concluded that in usual dosages calcium channel blockers do not alter glucose handling. However, in a few patients diabetes appeared de novo or worsened considerably on starting nifedipine (78,81), so there may be a small risk in some individuals.

Fluid balance

Edema of the legs is a well-recognized reaction to nifedipine and also occurs with verapamil, diltiazem, and the long-acting dihydropyridines (82,83), suggesting that this is a class effect of calcium channel blockers.

Hematologic

Calcium channel blockers rarely cause hematological effects. A hemorrhagic diathesis, including impaired platelet function, develops in chronic renal insufficiency, in which calcium channel blockers are used widely as antihypertensive agents. In 156 patients with moderate to severe chronic renal insufficiency not on hemodialysis calcium channel blockers prolonged the bleeding time (OR = 3.52; 95% CI = 1.01, 12.3) (84). However, despite this effect, there were no clinically serious hemorrhagic events during the study. Among those taking calcium channel blockers, 21 patients with prolonged bleeding times were randomly assigned to two groups; in one group treatment was withdrawn and bleeding time shortened; in those who continued to take the treatment the bleeding time was unchanged.

Nifedipine has been reported to cause agranulocytosis (85) and leukopenia was attributed to diltiazem; the latter patient had scleroderma, active rheumatoid disease, and pulmonary fibrosis, but the white cell count fell after 3 weeks of diltiazem, recovered on withdrawal, and fell on rechallenge (86). Diltiazem has also been reported to cause immune thrombocytopenia in a 68-year-old man with angina (87).

Mouth and teeth

Gingival hyperplasia, similar to that seen with phenytoin and ciclosporin, is a rare but well-recognized adverse effect of nifedipine (88). It has also been reported in patients taking felodipine (89,90), nitrendipine (SEDA-16, 200), and verapamil (91), suggesting that this adverse effect is a class effect. Only one case of gingival hyperplasia related to calcium channel blockers was reported to the Norwegian Adverse Drug Reaction Committee up to 1991, despite their widespread use (92). However, subclinical gingival hyperplasia on tissue histology was found in 83 and 74% of patients taking nifedipine and diltiazem respectively (93). The reaction generally occurs within a few months of starting treatment, and in some cases drug withdrawal produces marked regression of clinical hyperplasia. The mechanism of this adverse effect is unclear, but has been proposed to involve a hormonal imbalance in the hypothalamic–pituitary–adrenal axis (94).

Periodontal disease has been assessed in 911 patients taking calcium channel blockers, of whom 442 were taking nifedipine, 181 amlodipine, and 186 diltiazem, and in 102 control subjects (95). There was significant gingival overgrowth in 6.3% of the subjects taking nifedipine, while the prevalence induced by amlodipine or diltiazem was not significantly different than in the controls. The severity of overgrowth in the nifedipine group was related to the amount of gingival inflammation and also to sex, men being three times as likely to develop overgrowth than women.

Gastrointestinal

Because of effects on smooth muscle, the calcium channel blockers (particularly verapamil (96) but also diltiazem) can cause constipation. This may be due to colonic motor activity inhibition (97). Gastroesophageal reflux can also occur, and the calcium channel blockers should be avoided in patients with symptoms suggestive of reflux esophagitis (98). Calcium channel blockers (verapamil, diltiazem, and nifedipine) can also be associated with an increased incidence of gastrointestinal bleeding, as reported in a prospective cohort study in 1636 older hypertensives, with a relative risk of 1.86 (95% CI = 1.22, 2.82) compared with beta-blockers (7). However, this finding was not confirmed in other retrospective studies (13,99,100).

Liver

Mild hepatic reactions have been observed in association with verapamil, nifedipine (101–104), and diltiazem (105,106). In some cases fever, chills, and sweating have been associated with right upper quadrant pain, hepatomegaly, and mild increases in serum bilirubin and transaminase activity; in others, patients have remained asymptomatic. One patient had granulomatous hepatitis with diltiazem (107); another had a periportal infiltrate rich in eosinophils while taking verapamil (108). The increase in liver enzyme activities is generally transient, although mild persistent abnormalities have been seen. Occasionally, extreme increases in hepatic enzyme activities have been reported (85,105). Their frequency appears to be low, and since the symptoms and signs are mild they could easily be overlooked.

Skin

Apart from minor flushing and leg erythema associated with edema, skin reactions with calcium channel blockers are infrequent; the frequency has been estimated at 1.3% for diltiazem (109).

© 2006 Elsevier B.V. All rights reserved.

An erythematous rash with painful edema has been described with nifedipine (110) and also with diltiazem, but without the edematous element (109).

Mild erythema multiforme and Stevens–Johnson syndrome have been reported as probable reactions to diltiazem (85) and long-acting nifedipine (111).

Nifedipine, verapamil, and diltiazem have all been implicated as possible causes of erythema multiforme and its variants, Stevens–Johnson syndrome and toxic epidermal necrolysis, and/or exfoliative dermatitis from FDA data (112).

Psoriasiform eruptions have been reported in patients taking verapamil and nicardipine (SEDA-16, 199).

Photo-induced annular or papulosquamous eruptions due to subacute cutaneous lupus erythematosus with positive antinuclear, anti-Ro, and anti-La antibodies have been reported with verapamil, nifedipine, and diltiazem (113).

Reproductive system

Calcium channel blockers can occasionally cause menorrhagia (114) and gynecomastia (115).

Immunologic

Verapamil, nifedipine, and diltiazem have all been associated with allergic reactions, including skin eruptions and effects on liver and kidney function. Nifedipine has also been reported to cause a febrile reaction (116), and diltiazem was associated with fever, lymphadenopathy, hepatosplenomegaly, an erythematous maculopapular rash, and eosinophilia in a 50-year-old man (117).

Long-Term Effects

Drug withdrawal

The possibility of a calcium antagonist withdrawal syndrome has been raised (118–127), as it has been reported that withdrawal of verapamil, nifedipine, and diltiazem can worsen angina or even cause myocardial infarction. However, in a randomized, double-blind study of withdrawal of nifedipine in 81 patients before coronary artery bypass surgery, angina at rest occurred only in patients who had experienced similar symptoms previously, and there were no early untoward effects of drug withdrawal (120). If a withdrawal syndrome does exist, it could be due to rebound coronary vasospasm, but the present weight of evidence suggests that withdrawal results in no more than the loss of a useful therapeutic effect or the unmasking of progressive disease (127).

Tumorigenicity

A retrospective cohort study in 5052 elderly subjects, of whom 451 were taking verapamil, diltiazem, or nifedipine, showed that these drugs were associated with a cancer risk of 1.72 (95% CI = 1.27, 2.34), and there was a significant dose–response relation (8). A small risk of cancer (RR = 1.27; 95% CI = 0.98, 1.63) with calcium channel blockers was reported in a nested case-control retrospective study involving 446 cases of cancers in hypertensive patients (128). However, the authors concluded that this finding may have been spurious, as there was no relation between the cancer risk and the duration of drug use. Another study did not show any excess cancer risk with short-acting nifedipine after myocardial infarction in patients followed up for 10 years, although there were only 22 cancer deaths in 2607 patients (129). Neither did the much larger Bezafibrate Infarction Prevention (BIP) Study, which reported cancer incidence data in 11 575 patients followed for a mean period of 5.2 years, with 246 incident cancer cases, 129 among users (2.3%) and 117 (2.1%) among non-users of calcium channel blockers (130). Others also failed to find a positive link between calcium channel blockers and cancer (14,131). However, elderly women taking estrogens and short-acting calcium channel blockers had a significantly increased risk of breast carcinoma (hazard ratio = 8.48; 95% CI = 2.99, 24) (132). This controversy can perhaps only be resolved by prospective studies with longer follow-up periods (133), although ideal studies are unlikely ever to be conducted.

Second-Generation Effects

Pregnancy

The calcium channel blockers have had very limited use in pregnancy. The absence of reports of fetal deaths, malformations, or other maternal or neonatal adverse effects cannot therefore be construed as indicating safety. However, a comparison of nifedipine and hydralazine in 54 patients with severe pre-eclampsia showed that nifedipine is more effective, allowing delivery of more mature infants (134).

- Modified-release nifedipine 40 mg tds caused marked hypotension when used to delay preterm labor in a previously healthy 29-year-old woman who started contracting at 29 weeks; the hypotension may have precipitated an uncomplicated non-Q-wave myocardial infarction (135).

When nifedipine is combined with intravenous magnesium to delay preterm labor, colonic pseudo-obstruction can occur (136).

Lactation

Both verapamil (137) and diltiazem (138) are excreted in breast milk, but the risk to the suckling infant is unclear.

Susceptibility Factors

Patients with impaired function of the sinus node or impaired atrioventricular conduction can develop sinus bradycardia, sinus arrest, heart block, hypotension and shock, and even asystole, with verapamil (139) or diltiazem. These drugs should not be given to patients with aberrant conduction pathways associated with broad-complex tachydysrhythmias, and they can cause severe conduction disturbances in hypertrophic cardiomyopathy.

Similarly, verapamil should be used with caution in patients with heart failure, and both diltiazem and nifedipine can cause problems in patients with poor cardiac reserve. However, the PRAISE study (18) suggested that amlodipine may be used safely, even in the presence of severe heart failure optimally treated with diuretics,

© 2006 Elsevier B.V. All rights reserved.

digoxin, and ACE inhibitors. In this study, amlodipine significantly reduced cardiac mortality by more than a third in non-ischemic dilated cardiomyopathy, without significantly affecting mortality in ischemic cardiomyopathy (140).

Calcium antagonists should be avoided when possible in the peri-infarction period.

The use of calcium channel blockers in patients with pulmonary hypertension has been associated with cardiac arrest and sudden death.

Caution should be exercised in using verapamil in patients with hepatic cirrhosis, as its metabolism is reduced, leading to high plasma concentrations and potential toxicity (SEDA-16, 198). Similarly, lower starting and maintenance doses of other calcium channel blockers should be used in the presence of liver impairment. This also applies to patients with chronic renal insufficiency, especially those taking the modified-release formulation of verapamil (SEDA-17, 238).

Drug Administration

Drug overdose

The treatment of overdosage with calcium channel blockers has been reviewed (141); other reports have reviewed poisoning with verapamil (142–144), and other calcium channel blockers (145,146).

The features appear to be arterial hypotension, bradycardia due to sinus node depression and atrioventricular block, and congestive cardiac failure and angina (147–149). Although the therapeutic effects are different according to the drug, in overdosage the effects are similar (145). Severe metabolic acidosis (usually lactic acidosis) and generalized convulsions can also occur (150) and hypoglycemia has been reported (151). Non-cardiogenic pulmonary edema has been reported with diltiazem (152) and verapamil (153). Several deaths have occurred with verapamil.

- An overdose of nifedipine 280 mg produced marked vasodilatation in a young patient with advanced renal insufficiency; it was successfully treated with intravenous calcium (154).

Treatment consists of gastric lavage, activated charcoal, and cathartics. Contrary to popular belief, significant overdosage of immediate-release verapamil can be associated with delayed absorption, as suggested by a case report, the authors of which suggested the use of repeated doses of activated charcoal (142). In severe cases total gut lavage should be considered. Intravenous calcium gluconate (155), glucagon (156), pressor amines (isoprenaline, adrenaline, or dobutamine), artificial ventilation, and cardiac pacing may all be required. Hemoperfusion does not appear to influence the clinical course, but 4-aminopyridine reversed the features of a modest accidental overdose of verapamil in a patient on maintenance hemodialysis (157). The rationale for the use of aminopyridine, an antagonist of non-depolarizing neuromuscular blocking agents, supported by prior animal experiments, was the enhancement of transmembrane calcium flux and the facilitation of synaptic transmission. This is of potential value, in view of the apparent unresponsiveness of some patients to supportive measures.

Five cases of overdose of calcium channel blockers have been reported (158):

- a 34-year-old woman who took amlodipine 0.86 mg/kg;
- a 48-year-old man who took an unknown amount of modified-release diltiazem;
- a 5-month-old girl inadvertently given nifedipine 20 mg;
- a 14-year-old girl who took modified-release verapamil 30 mg/kg;
- a 31-year-old man who took modified-release verapamil 71 mg/kg.

All were successfully treated with hyperinsulinemia/euglycemia therapy. The authors described the mechanism of action of this form of therapy, which is mainly related to improvement in cardiac contractility and peripheral vascular resistance and reversal of acidosis. They proposed indications and dosing for this therapy consisting in most cases of intravenous glucose with an intravenous bolus dose of insulin 1 U/kg followed by an infusion of 0.5–1 U/kg/hour until the systolic blood pressure is over 100 mm/Hg and the heart rate over 50/minute. Hyperinsulinemia/euglycemia therapy is currently reserved as an adjunct to conventional therapy and is recommended only after an inadequate response to fluid resuscitation, high-dose calcium salts, and pressor agents.

Drug–Drug Interactions

Beta-adrenoceptor antagonists

The greatest potential for serious mishap arises from interactions between calcium channel blockers (especially verapamil and related compounds) and beta-adrenoceptor antagonists (159,160). This combination can cause severe hypotension and cardiac failure, particularly in patients with poor myocardial function (161–163). The major risk appears to be associated with the intravenous administration of verapamil to patients who are already taking a beta-blocker (164), but a drug-like tiapamil, which closely resembles verapamil in its pharmacological profile, might be expected to carry a similar risk (165). Conversely, intravenous diltiazem does not produce deleterious hemodynamic effects in patients taking long-term propranolol (166). However, there have been instances when the combination of diltiazem with metoprolol caused sinus arrest and atrioventricular block (167).

The concurrent use of oral calcium channel blockers and beta-adrenoceptor antagonists in the management of angina pectoris or hypertension is less likely to result in heart block or other serious adverse effects (168), and these two drug groups are commonly used together. However, caution is still advised, and nifedipine or other dihydropyridine derivatives would be preferred in this type of combination (26,169,170). Nevertheless, the combination of nifedipine with atenolol in patients with stable intermittent claudication resulted in a reduction in walking distance and skin temperature, whereas either drug alone produced benefits (171).

Carbamazepine

A pharmacokinetic interaction has been described between carbamazepine and the calcium channel blockers

© 2006 Elsevier B.V. All rights reserved.

verapamil (172) and diltiazem (173). With both drugs, inhibition of the hepatic metabolism of carbamazepine resulted in increased serum carbamazepine concentrations and neurotoxicity, with dizziness, nausea, ataxia, and diplopia. Adding nifedipine to carbamazepine was not associated with alterations in steady-state carbamazepine concentrations (173).

Cardiac glycosides

Calcium channel blockers interact with cardiac glycosides. The main mechanism is inhibition of digoxin renal tubular secretion by inhibition of P glycoprotein. In a review of the interactions of calcium channel blockers with digoxin, in which their clinical relevance was assessed, it was concluded that serious consequences can be prevented by careful monitoring, especially in patients whose serum digoxin concentration is already near the upper end of the therapeutic range (174).

Verapamil suppresses renal digoxin elimination acutely, but this suppression disappears over a few weeks (175). However, inhibition of the extrarenal clearance of digoxin persists, and the result of this complex interaction is an increase in steady-state plasma digoxin concentrations of less than 100%. Patients taking both drugs should be carefully monitored. However, the pharmacodynamic effects of digoxin are apparently reduced by verapamil (176), so that dosage adjustment may be unnecessary. Cardiovascular collapse and/or asystole has followed the use of intravenous verapamil in patients taking oral digoxin alone (177) or in combination with quinidine, propranolol, or disopyramide (165).

The interaction of digoxin with nifedipine increases plasma digoxin concentrations by only about 15% (178,179) and is less important.

Diltiazem increases digoxin concentrations by 20–50% (180,181).

Interactions of digoxin with nitrendipine (182) and bepridil (183) have also been described.

Verapamil and diltiazem, but not nifedipine, increase steady-state plasma digitoxin concentrations (184).

Ciclosporin

Calcium channel blockers are given to transplant patients for their protective effect against ciclosporin-induced nephrotoxicity and to optimize ciclosporin immunosuppression in order to reduce early rejection of renal grafts. Nifedipine has been used to treat ciclosporin-induced hypertension, although amlodipine may be just as effective (185).

However, some calcium channel blockers have pharmacokinetic interactions: diltiazem, verapamil, nicardipine, and amlodipine increase ciclosporin concentrations, whereas nifedipine, felodipine, and isradipine do not (SED-14, 604) (SEDA-21, 210) (SEDA-21, 212) (SEDA-22, 216). Two confirmations of these observations have been published. In a retrospective study of 103 transplant patients verapamil and diltiazem, but not nifedipine or isradipine, caused a significant increase in plasma ciclosporin concentrations (186). The effect of verapamil and diltiazem on ciclosporin concentrations was independent of dosage. In a crossover comparison between verapamil, felodipine, and isradipine in 22 renal transplant recipients, verapamil interacted pharmacokinetically with ciclosporin but felodipine and isradipine did not (187).

Nine kidney transplant recipients had an increase in trough whole blood ciclosporin concentrations of 24–341% after introduction of nicardipine (188). A similar interaction has been reported with diltiazem (189) and verapamil (190).

Cimetidine

The histamine H_2 receptor antagonist cimetidine increases plasma concentrations of nifedipine and delays its elimination by inhibition of hepatic mono-oxygenases. Maximum plasma nifedipine concentrations and AUC can be increased by as much as 80%, and this results in a significant increase in the antihypertensive and antianginal effects of nifedipine and also toxicity (191,192).

Cimetidine also increases plasma concentrations of nitrendipine and nisoldipine (182,193).

Ranitidine, which inhibits the microsomal mono-oxygenase system only slightly, does not alter plasma dihydropyridine concentrations to the same extent (194).

Combinations of calcium channel blockers

Paralytic ileus has been attributed to the combined use of diltiazem and nifedipine (195).

- A 62-year-old man with chest pain underwent cardiac catheterization. The diagnosis was vasospastic angina and he was given nifedipine 20 mg bd; when his angina attacks persisted he was also given oral diltiazem 100 mg bd. After 2 days, although his angina was well controlled, abdominal distension and vomiting occurred, and an X-ray suggested intestinal ileus. The drugs were withdrawn and the ileus resolved. It recurred when the treatment was resumed and gradually resolved again after withdrawal.

The disorder was suspected to be due to enhanced pharmacodynamic effects caused by the combination of the two calcium channel blockers. However, plasma concentrations of nifedipine have also been reported to increase about three-fold when it is combined with diltiazem (196).

Dantrolene

Dantrolene interacts with verapamil and with diltiazem, causing myocardial depression and cardiogenic shock (SEDA-16, 199).

Grapefruit juice

The ability of grapefruit to increase the plasma concentrations of some drugs was accidentally discovered when grapefruit juice was used as a blinding agent in a drug interaction study of felodipine and alcohol (197). It was noticed that plasma concentrations of felodipine were much higher when the drug was taken with grapefruit juice than those previously reported for the dose of drug administered. In other studies concurrent administration of grapefruit juice and felodipine increased the AUC, causing increased heart rate, and reduced diastolic blood pressure (198), or caused increased blood pressure and heart rate, headaches, flushing, and light-headedness (199). Grapefruit increases plasma concentrations of

© 2006 Elsevier B.V. All rights reserved.

nifedipine (200) and nisoldipine (201) by increasing their systemic availability (202); with nisoldipine or nitrendipine there was an increase in heart rate.

Prazosin

An interaction of prazosin with nifedipine or verapamil resulted in acute hypotension (203,204). The mechanism appears to be partly kinetic (the systemic availability of prazosin increasing by 60%) and partly dynamic.

Theophylline

Theophylline toxicity has been reported in several patients, apparently stabilized on theophylline, after the introduction of verapamil (205) or nifedipine (206).

Calcium dobesilate

General Information

Calcium dobesilate is an antioxidant that has been used to treat diabetic retinopathy, in which it slows progression of the disease during long-term oral treatment by reducing microvascular permeability, leading to improved visual acuity (1). It not only acts as an antioxidant but also stimulates endothelial production of nitric oxide.

In early studies the most common adverse effects of calcium dobesilate after oral administration were gastrointestinal disturbances and, occasionally, nervousness and fever (SEDA-3, 181) (SEDA-16, 204).

In a systematic review of the published literature from 1970 to 2003, a postmarketing surveillance report covering the period 1974–1998, and periodic safety update reports covering the period 1995–2003 from the French regulatory authorities pharmacovigilance database, the following adverse effects were reported: fever (26%), gastrointestinal disorders (12.5%), skin reactions (8.2%), arthralgia (4.3%), and agranulocytosis (4.3%) (2).

Organs and Systems

Hematologic

Agranulocytosis associated with calcium dobesilate has occasionally been reported (3). Although the risk has been calculated at 121 cases per million per year from case-control and case-population studies (4), there have been many fewer spontaneous reports than are consistent with this relatively high figure, and the true incidence is unknown (5).

Drug Administration

Drug administration route

Intramuscular calcium dobesilate can be painful (SEDA-3, 181).

© 2006 Elsevier B.V. All rights reserved.

Calcium salts

General Information

Calcium is a soft grayish-white metallic element, one of the alkaline earth metals (symbol Ca; atomic no. 20). It is found in sources such as lewisite (calcium antimonate), colemanite and pandermite (calcium borates); ankerite, aragonite, calcite, chalk, dolomite, and stromatolite (calcium carbonates); hydrophilite (calcium chloride); powellite (calcium molybdate); whewellite (calcium oxalate); autunite (calcium phosphate); anorthite, apophyllite, chabazite, datolite, epidote, eudialite, feldspar, gyrolite, hornblende, margarite, melilite, monticellite, nephrite, pectolite, phillipsite, piedmontite, prehnite, scapolite, scawtite, scolecite, thaumasite, titanite, vesuvianite, wollastonite, and zeolite (calcium silicates); glauberite, gypsum, and polyhalite (calcium sulfates); perovskite (calcium titanate); and scheelite (calcium tungstate). Calcium phosphate is a major constituent of bones (apatite).

Uses

Salts of calcium are used as a source of calcium:

- to treat hypocalcaemia (for example calcium gluconate);
- to treat hyperphosphatemia (for example calcium acetate, calcium carbonate);
- to treat hyperkalemia (calcium polystyrene sulfonate; see monograph on Polystyrene sulfonates);
- to treat and prevent osteomalacia and osteoporosis (in combination with vitamin D or a bisphosphonate);
- as antacids (for example calcium hydroxide and calcium carbonate).

However, although calcium salts can produce short-term relief from dyspepsia, calcium ions stimulate antral gastrin release, and hence gastric acid secretion, making them unsuitable for long-term treatment of peptic disorders (1).

Other uses of calcium salts incidental to the calcium they contain include:

- in wound dressings (calcium alginate);
- to prevent methotrexate toxicity (calcium folinate and levofolinate);
- in lead poisoning (sodium calcium edetate).

Organs and Systems

Mineral balance

In one study of the use of calcium carbonate as a phosphate binder in patients on chronic hemodialysis, there was a low incidence of hypercalcemia at daily doses below 6 g (2), whereas in another report on 26 dialysis patients who used calcium carbonate for 3 years, 42% developed new calcification (3).

Calcium edetate can cause mild transient hypercalcemia (4) and hypercalciuria (5).

Acid–base balance

Long-term use of calcium salts can cause the milk-alkali syndrome and alkalosis in conjunction with hypercalcemia and renal insufficiency (6). It presents acutely with headache, nausea, irritability, and weakness, or chronically with uremia, alkalosis, and hypercalcemia. Sustained high dosage and/or concurrent renal disease are common antecedents (7).

Gastrointestinal

There is an unsubstantiated belief that calcium-containing antacids cause a rebound increase in gastric acid secretion that is more intense than with other antacids. This was thought to be due to absorption of calcium, the resultant hypercalcemia leading to increased acid secretion. This has been investigated in two trials. One (8) was an open, randomized, crossover study in 12 healthy volunteers who were given calcium carbonate and magnesium carbonate (Rennie) and hydrotalcite (Talcid). The other (9) was a double-blind, crossover trial in 12 healthy volunteers who were given placebo, Maalox liquid, and Rennie liquid. All the antacids had similar efficacy and there was no evidence of acid rebound with calcium carbonate.

Urinary tract

In general, there is an increased risk of nephrolithiasis with prolonged high calcium intake. Studies aimed at determining whether high calcium intake increases the risk of nephrolithiasis have shown that in patients at risk of nephrolithiasis or with a history of nephrolithiasis, calcium can be safely given for osteoporosis, provided there is careful monitoring (10,11).

In a French analysis of 22 510 urinary calculi performed by infrared spectroscopy, drug-induced urolithiasis was divided into two categories: first, stones with drugs physically embedded ($n = 238$; 1.0%), notably indinavir monohydrate ($n = 126$; 53%), followed by triamterene ($n = 43$; 18%), sulfonamides ($n = 29$; 12%), and amorphous silica ($n = 24$; 10%); secondly, metabolic nephrolithiasis induced by drugs ($n = 140$; 0.6%), involving mainly calcium/vitamin D supplementation ($n = 56$; 40%) and carbonic anhydrase inhibitors ($n = 33$; 24%) (12). Drug-induced stones are responsible for about 1.6% of all calculi in France. Physical analysis and a thorough drug history are important elements in the diagnosis.

Second-Generation Effects

Pregnancy

In a pregnant woman, calcium-containing antacids raised the calcium concentration to the point where hemodialysis was required (SEDA-17, 413).

Lobelia inflata

Lobelia inflata (Indian tobacco) contains lobeline and other pyridine alkaloids. It has been used as an emetic, antidepressant, respiratory stimulant, an aid to smoking cessation, and a treatment for metamfetamine abuse (1).

Adverse effects

Lobeline has peripheral effects similar to those of nicotine, whereas its central activity may be different. It has been associated with nausea, vomiting, headache, tremors, and dizziness. Symptoms caused by overdosage include profuse sweating, paresis, tachycardia, hypertension, Cheyne-Stokes respiration, hypothermia, coma, and death. Large doses are convulsant.

Camphor

General Information

The symptoms of systemic camphor poisoning have been reviewed (1).

Organs and Systems

Nervous system

Systemic nervous system adverse reactions after cutaneous contact with camphor have been reported (2).

- A 15-month-old child had crawled through spirits of camphor containing 10% camphor. Over the next 48 hours he became progressively ataxic and had several brief generalized motor seizures. The seizures persisted for 2 days despite appropriate therapy. Over 15 days he slowly improved; recovery in motor and mental function was eventually complete. The child had no further seizures until 1 year later, when a camphorated vaporizer containing 4.81% camphor was administered by the mother. During inhalation there was a brief major motor seizure.

Breathing difficulties, convulsions, and coma have been reported after repeated topical application of camphor-containing agents (3).

Skin

- A woman developed severe eczema of the ears, neck, and upper chest after having applied Earex ear drops. Patch tests with rectified camphor oil were positive on days 2 and 4 (4).

Candesartan cilexetil

See also Angiotensin II receptor antagonists

General Information

Candesartan cilexetil is the prodrug of candesartan, an angiotensin II type 1 (AT_1) receptor antagonist. Absorbed candesartan cilexetil is completely metabolized to candesartan. Candesartan has a half-life of about 9 hours (slightly longer in elderly people).

© 2006 Elsevier B.V. All rights reserved.

In an open study of 4531 hypertensive patients, the total incidence of adverse effects of candesartan was 6.1% (1). Individual adverse effects did not occur in more than 0.8% and were mainly dizziness and headache.

Susceptibility Factors

Renal disease

In patients undergoing chronic hemodialysis, the safety profile did not differ from that reported in other populations, except for some rare cases of hypotension during hemodialysis. Hemodialysis does not affect the kinetics of candesartan. Because of the variability of oral clearance and the pronounced influence of hemodialysis-induced volume contraction on the hemodynamic effects of candesartan, careful monitoring is recommended (2).

Cannabaceae

See also Herbal medicines

General Information

The family of Cannabaceae contains two genera:

1. *Cannabis* (hemp)
2. *Humulus* (hop).

The cannabinoids are covered in a separate monograph.

Humulus lupulus

Humulus lupulus (hop) contains a variety of sesquiterpenoids, diterpenoids, and triterpenoids, phytoestrogens, and the flavonoid xanthohumol, which has some in vitro anti-HIV activity (1). Apart from their use in brewing beer, hops have been used for sedative purposes, but evidence of efficacy is poor.

Adverse effects

Hop farmers are exposed to air that can contain dust, endotoxin, and micro-organisms. In one study of 19 farms in Poland Gram-positive bacteria formed 22–96% of the total count; among them, corynebacteria and endospore-forming bacilli were prevalent (2). Fungi constituted 3.7–65% of the total count; the dominant species were *Penicillium citrinum*, *Alternaria alternata*, and *Cladosporium epiphyllum*. Thermophilic actinomycetes and Gram-negative bacteria were detected in the air of only 10 and six farms respectively. The concentrations of endotoxin were 313–6250 μg/g. The hop growers seem to be exposed to lower concentrations of dust, micro-organisms, and endotoxin than other branches of agriculture, which the authors partly attributed to antimicrobial properties of *H. lupulus*.

Eight of twenty-three hops farmers, who had been exposed to organic dust from *H. lupulus*, reported symptoms of chronic bronchitis and five reported work-related symptoms, including dry cough and dyspnea (3).

After 30 years of working with hop without any health problems a 46-year-old farmer developed erythema of the face, neck, and upper chest, edema of the eyelids, conjunctivitis, and dermatitis of the hands (4). Her symptoms were provoked by both fresh and dried hops, appeared after half-an-hour of working, and persisted over 1–2 days. Skin tests yielded the following results: hop leaves (saline extract)—prick positive, patch negative; hop leaves (glycerol extract)—prick positive, patch negative; hop cones (saline extract)—prick positive, patch negative; hop cones (glycerol extract)—prick negative, patch positive after 48 and 72 hours. Despite discontinuing work, the patient had several relapses attributed to other sources of hop allergens: a beauty cream, a herbal sedative, and her husband, also a hop farmer.

Systemic urticaria has been reported in patients who had been exposed to *H. lupulus* (5), in one case with arthralgia and fever (6).

Flavonoids in hops that persist in beer can inhibit certain isoforms of cytochrome P450 in vitro (7). At a concentration of 10 μmol/l xanthohumol almost completely inhibited CYP1A1 and other hop flavonoids inhibited it by 27–91%. At a concentration of 10 μmol/l xanthohumol completely inhibited CYP1B1 and other hop flavonoids inhibited it by 2–99%. The most effective inhibitors of CYP1A2 were the two prenylated flavonoids, 8-prenylnaringenin and isoxanthohumol, which produced over 90% inhibition in concentrations of 10 μmol/l. However, the flavonoids were poor inhibitors of CYP2E1 and CYP3A4 and so in vivo drug interactions are unlikely to be of importance.

Cannabinoids

General Information

Cannabis is the abbreviated name for the hemp plant *Cannabis sativa*. The common names for cannabis include marijuana, grass, and weed. Other names for cannabis refer to particular strains; they include bhang and ganja. The most potent forms of cannabis come from the flowering tops of the plants or from the dried resinous exudate of the leaves, and are referred to as hashish or hash.

Cannabis is one of the oldest and most widely used drugs in the world. In different Western countries the possible therapeutic use of cannabinoids as antiemetics in patients with cancer or in patients with multiple sclerosis has become an issue, because of the prohibition of cannabis, and has polarized opinion about the seriousness of its adverse effects (1,2).

Pharmacology

The primary active component of cannabis is Δ9-tetrahydrocannabinol (THC), which is responsible for the greater part of the pharmacological effects of the cannabis complex. Δ8-THC is also active. However, the cannabis plant contains more than 400 chemicals, of which some 60 are chemically related to Δ9-THC, and it is evident that the exact proportions in which these are present can vary considerably, depending on the way in which the material has been harvested and prepared. In man, Δ9-THC is rapidly converted to 11-hydroxy-Δ9-THC (3), a metabolite that is active in the central nervous system. A specific receptor for the cannabinols has been identified; it is a member of the G-protein-linked family of receptors (4). The cannabinoid receptor is linked to the inhibitory G-protein, which is linked to adenyl cyclase in an inhibitory fashion (5). The cannabinoid receptor is found in highest concentrations in the basal ganglia, the hippocampus, and the cerebellum, with lower concentrations in the cerebral cortex.

When cannabis is smoked, usually in a cigarette with tobacco, the euphoric and relaxant effects occur within minutes, reach a maximum in about 30 minutes, and last up to 4 hours. Some of the motor and cognitive effects can persist for 5–12 hours. Cannabis can also be taken orally, in foods such as cakes (for example "space cake") or sweetmeats (for example hashish fudge) (6).

Many variables affect the psychoactive properties of cannabis, including the potency of the cannabis used, the route of administration, the smoking technique, the dose, the setting, the user's past experience, the user's expectations, and the user's biological vulnerability to the effects of the drug.

Animal and in vitro toxicology

Δ9-tetrahydrocannabinol, the active component in herbal cannabis, is very safe. Laboratory animals (rats, mice, dogs, monkeys) can tolerate doses of up to 1000 mg/kg, equivalent to some 5000 times the human intoxicant dose. Despite the widespread illicit use of cannabis, there are very few, if any, instances of deaths from overdose (7).

Long-term toxicology studies with THC were carried out by the National Institute of Mental Health in the late 1960s (8). These included a 90-day study with a 30-day recovery period in both rats and monkeys and involved not only Δ9-THC but also Δ8-THC and a crude extract of marijuana. Doses of cannabis or cannabinoids in the range 50–500 mg/kg caused reduced food intake and lower body weight. All three substances initially depressed behavior, but later the animals became more active and were irritable or aggressive. At the end of the study the weights of the ovaries, uterus, prostate, and spleen were reduced and the weight of the adrenal glands was increased. The behavioral and organ changes were similar in monkeys, but less severe than those seen in rats. Further studies were carried out to assess the damage that might be done to the developing fetus by exposure to cannabis or cannabinoids during pregnancy. Treatment of pregnant rabbits with THC at doses up to 5 mg/kg had no effect on birth weight and did not cause any abnormalities in the offspring (8).

A similarly detailed toxicology study was carried out with THC by the National Institute of Environmental Health Sciences in the USA, in response to a request from the National Cancer Institute (9). Rats and mice were given THC up to 500 mg/kg five times a week for 13 weeks; some were followed for a period of recovery over 9 weeks. By the end of the study more than half of the rats treated with the highest dose (500 mg/kg) had died, but all of the remaining animals appeared to be healthy, although in both species the higher doses caused lethargy and increased aggressiveness. The THC-treated animals ate less food and their body weights were consequently significantly lower than those of untreated controls at the end of the treatment period, but returned to normal during recovery. During this period the animals were sensitive to touch and some had convulsions. There was a trend towards reduced uterine and testicular weights.

In further studies rats were treated with doses of THC up to 50 mg/kg and mice with up to 500 mg/kg 5 times a week for 2 years in a standard carcinogenicity test (9). After 2 years, more treated animals had survived than controls, probably because the treated animals ate less and had lower body weights. The treated animals also had a significantly lower incidence of the various cancers normally seen in aged rodents in testes, pancreas, pituitary gland, mammary glands, liver, and uterus. Although there was an increased incidence of precancerous changes in the thyroid gland in both species and in the mouse ovary after one dose (125 mg/kg), these changes were not dose-related. The conclusion was that there was "no evidence of carcinogenic activity of THC at doses up to 50 mg/kg." This was also supported by the failure to detect any genetic toxicity in other tests designed to identify drugs capable of causing chromosomal damage. For example, THC was negative in the so-called "Ames test,"

© 2006 Elsevier B.V. All rights reserved.

in which bacteria are exposed to very high concentrations of a drug to see whether it causes mutations. In another test, hamster ovary cells were exposed to high concentrations of the drug in tissue culture; there were no effects on cell division that might suggest chromosomal damage.

By any standards, THC must be considered to be very safe, both acutely and during long-term exposure. This probably partly reflects the fact that cannabinoid receptors are virtually absent from those regions at the base of the brain that are responsible for such vital functions as breathing and blood pressure control. The available animal data are more than adequate to justify its approval as a human medicine, and indeed it has been approved by the FDA for certain limited therapeutic indications (generic name = dronabinol) (7).

Respiratory

There have been several attempts to address this question by exposing laboratory animals to cannabis smoke. After such exposure on a daily basis for periods of up to 30 months, extensive damage has been observed in the lungs of rats (10), dogs (11), and monkeys (12), but it is very difficult to extrapolate these findings to man, as it is difficult or impossible to imitate human exposure to cannabis smoke in any animal model.

Nervous system

Animal studies on neurotoxicity have yielded conflicting results. Treatment of rats with high doses of THC given orally for 3 months (13) or subcutaneously for 8 months (14) produced neural damage in the hippocampal CA3 zone, with shrunken neurons, reduced synaptic density, and loss of cells. But in perhaps the most severe test of all, rats and mice treated on 5 days each week for 2 years had no histopathological changes in the brain, even after 50 mg/kg/day (rats) or 250 mg/kg/day (mice) (9). Although claims were made that exposure of a small number of rhesus monkeys to cannabis smoke led to ultrastructural changes in the septum and hippocampus (15,16), subsequent larger-scale studies failed to show any cannabis-induced histopathology in monkey brain (17).

Studies of the effects of cannabinoids on neurons in vitro have also yielded inconsistent results. Exposure of rat cortical neurons to THC shortened their survival: twice as many cells were dead after exposure to THC 5 μmol/l for 2 hours than in control cultures (18). Concentrations of THC as low as 0.1 μmol/l had a significant effect. The effects of THC were accompanied by release of cytochrome c, activation of caspase-3, and DNA fragmentation, suggesting an apoptotic mechanism. All of the effects of THC could be blocked by the antagonist AM-251 or by pertussis toxin, suggesting that they were mediated through CB1 receptors. Toxic effects of THC have also been reported in hippocampal neurons in culture, with 50% cell death after exposure to THC 10 μmol/l for 2 hours or 1 μmol/l for 5 days (19). The antagonist rimonabant blocked these effects, but pertussis toxin did not. The authors proposed a toxic mechanism involving arachidonic acid release and the formation of free radicals. On the other hand, other authors have failed to observe any damage in rat cortical neurons exposed for up to 15 days to THC 1 mmol/l, although they found that this concentration killed rat C6 glioma cells, human astrocytoma U373MG cells, and mouse neuroblastoma N18TG12 cells (20). In a remarkable study, injection of THC into solid tumors of C6 glioma in rodent brain led to increased survival times, and there was complete eradication of the tumors in 20–35% of the treated animals (21). A stable analogue of anandamide also produced a drastic reduction in the tumor volume of a rat thyroid epithelial cell line transformed by K-ras oncogene, implanted in nude mice (22). The antiproliferative effect of cannabinoids has suggested a potential use for such drugs in cancer treatment (23).

Some authors have reported neuroprotective actions of cannabinoids. WIN55,212-2 reduced cerebral damage in rat hippocampus or cerebral cortex after global ischemia or focal ischemia in vivo (24). The endocannabinoid 2AG protected against damage elicited by closed head injury in mouse brain, and the protective effects were blocked by rimonabant (25). THC had a similar effect in vivo in protecting against damage elicited by ouabain (26). Rat hippocampal neurons in tissue culture were protected against glutamate-mediated damage by low concentrations of WIN55,212-2 or CP-55940, and these effects were mediated through CB1 receptors (27). But not all of these effects seem to require mediation by cannabinoid receptors. The protective effects of WIN55,212-2 did not require either CB1 or CB2 cannabinoid receptors in cortical neurons exposed to hypoxia (24), and there were similar findings for the protective actions of anandamide and 2-AG in cortical neuronal cultures (28). Both THC and cannabidiol, which is not active at cannabinoid receptors, protected rat cortical neurons against glutamate toxicity (29) and these effects were also independent of CB1 receptors. The authors suggested that the protective effects of THC might be due to the antioxidant properties of these polyphenolic molecules, which have redox potentials higher than those of known antioxidants (for example ascorbic acid).

Pregnancy

In animals, THC can cause spontaneous abortion, low birth weight, and physical deformities (30). However, these were only seen after treatment with extremely high doses of THC (50–150 times higher than human doses), and only in rodents and not in monkeys.

Tolerance and dependence

Many animal studies have shown that tolerance develops to most of the behavioral and physiological effects of THC (31). Dependence on cannabinoids in animals is clearly observable, because of the availability of CB_1 receptor antagonists, which can be used to precipitate withdrawal. Thus, a behavioral withdrawal syndrome was precipitated by rimonabant in rats treated for only 4 days with THC in doses as low as 0.5–4.0 mg/kg/day (32). The syndrome included scratching, face rubbing, licking, wet dog shakes, arched back, and ptosis, many of the signs that are seen in rats undergoing opiate withdrawal. Similar withdrawal signs occurred when rats treated chronically with the synthetic cannabinoid CP-55940 were given rimonabant (33). Rimonabant-induced withdrawal after 2 weeks of treatment of rats with the cannabinoid HU-120 was accompanied by a marked increase in release of the stress-related neuropeptide corticotropin-releasing factor in the

© 2006 Elsevier B.V. All rights reserved.

amygdala, a result that also occurred in animals undergoing heroin withdrawal (34). An electrophysiological study showed that precipitated withdrawal was also associated with reduced firing of dopamine neurons in the ventral tegmental area of rat brain (35).

These data clearly show that chronic administration of cannabinoids leads to adaptive changes in the brain, some of which are similar to those seen with other drugs of dependence. The ability of THC to cause selective release of dopamine from the nucleus accumbens (36) also suggests some similarity between THC and other drugs in this category.

Furthermore, although many earlier attempts to obtain reliable self-administration behavior with THC were unsuccessful (31), some success has been obtained recently. Squirrel monkeys were trained to self-administer low doses of THC (2 μg/kg per injection), but only after the animals had first been trained to self-administer cocaine (37). THC is difficult to administer intravenously, but these authors succeeded, perhaps in part because they used doses comparable to those to which human cannabis users are exposed, and because the potent synthetic cannabinoids are far more water-soluble than THC, which makes intravenous administration easier. Mice could be trained to self-administer intravenous WIN55212-2, but CB_1 receptor knockout animals could not (38).

Another way of demonstrating the rewarding effects of drugs in animals is the conditioned place preference paradigm, in which an animal learns to approach an environment in which it has previously received a rewarding stimulus. Rats had a positive THC place preference after doses as low as 1 mg/kg (39).

Some studies have suggested that there may be links between the development of dependence to cannabinoids and to opiates (40). Some of the behavioral signs of rimonabant-induced withdrawal in THC-treated rats can be mimicked by the opiate antagonist naloxone (41). Conversely, the withdrawal syndrome precipitated by naloxone in morphine-dependent mice can be partly relieved by THC (42) or endocannabinoids (43). Rats treated chronically with the cannabinoid WIN55212-2 became sensitized to the behavioral effects of heroin (44). Such interactions can also be demonstrated acutely. Synergy between cannabinoids and opiate analgesics has been described above. THC also facilitated the antinociceptive effects of RB 101, an inhibitor of enkephalin inactivation, and acute administration of THC caused increased release of Met-enkephalin into microdialysis probes placed into the rat nucleus accumbens (45).

The availability of receptor knockout animals has also helped to illustrate cannabinoid–opioid interactions. CB_1 receptor knockout mice had greatly reduced morphine self-administration behavior and less severe naloxone-induced withdrawal signs than wild type animals, although the antinociceptive actions of morphine were unaffected in the knockout animals (38). The rimonabant–precipitated withdrawal syndrome in THC-treated mice was significantly attenuated in animals with knockout of the pro-enkephalin gene (46). Knockout of the μ opioid (OP_3) receptor also reduced rimonabant-induced withdrawal signs in THC-treated mice, and there was an attenuated naloxone withdrawal syndrome in morphine-dependent CB_1 knockout mice (47,48).

These findings clearly point to interactions between the endogenous cannabinoid and opioid systems in the CNS, although the neuronal circuitry involved is unknown. Whether this is relevant to the so-called "gateway" theory is unclear. In the US National Household Survey of Drug Abuse, respondents aged 22 years or over who had started to use cannabis before the age of 21 years were 24 times more likely than non-cannabis users to begin using hard drugs (49). However, in the same survey the proportion of cannabis users who progressed to heroin or cocaine use was very small (2% or less). Mathematical modeling using the Monte Carlo method suggested that the association between cannabis use and hard drug use need not be causal, but could relate to some common predisposing factor, for example "drug-use propensity" (50).

Tumorigenicity

THC does not appear to be carcinogenic, but there is plenty of evidence that the tar derived from cannabis smoke is. Bacteria exposed to cannabis tar develop mutations in the standard Ames test for carcinogenicity (51), and hamster lung cells in tissue culture develop accelerated malignant transformations within 3–6 months of exposure to tobacco or cannabis smoke (52).

General adverse effects

A review has summarized the evidence related to the adverse effects of acute and chronic use of cannabis (53). The effects of acute usage include anxiety, impaired attention, and increased risk of psychotic symptoms. Probable risks of chronic cannabis consumption include bronchitis and subtle impairments of attention and memory.

The adverse effects of cannabis can be considered under two main headings, reflecting psychoactive and autonomic effects, in addition to which there are direct toxic effects. The most frequently reported psychoactive effects include enhanced sensory perception (for example a heightened appreciation of color and sound). Cannabis intoxication commonly heightens the user's sensitivity to other external stimuli as well, but subjectively slows the appreciation of time. In high doses, users may also experience depersonalization and derealization. Various forms of psychomotor performance, including driving, are significantly impaired for 8–12 hours after using cannabis. The most serious possible consequence of cannabis use is a road accident if a user drives while intoxicated.

Adverse reactions have been reported at relatively low doses and principally affect the psyche, leading to anxiety states, panic reactions, restlessness, hallucinations, fear, confusion, and rarely toxic psychosis. These effects appear to be reversible (54). Ingestion of cake with cannabis by people who seldom use or have never used cannabis before can result in mental changes, including confusion, anxiety, loss of logical thinking, fits of laughter, hallucinations, hypertension, and/or paranoid psychosis, which can last as long as 8 hours.

The autonomic effects of cannabis lead to tachycardia, peripheral vasodilatation, conjunctival congestion, hyperthermia, bronchodilatation, dry mouth, nystagmus, tremor, ataxia, hypotension, nausea, and vomiting, that is a spectrum of effects that closely resembles the consequences

© 2006 Elsevier B.V. All rights reserved.

of overdosage with anticholinergic agents. Some individuals have sleep disturbances. Increased appetite and dry mouth are other common effects of cannabis intoxication.

Hypersensitivity reactions are rare, but a few have been reported after inhalation. Delayed hypersensitivity reactions, particularly affecting vascular tissue, have been recorded with chronic systemic administration. Tumor-inducing effects are difficult to attribute to cannabis alone. Animal studies have shown neoplastic pulmonary lesions superimposed on chronic inflammation, but such pathology may be primarily associated with the "tar" produced by burning marijuana. The most serious potential adverse effects of cannabis use come from the inhalation of the same carcinogenic hydrocarbons that are present in tobacco, and some data suggest that heavy cannabis users are at risk of chronic respiratory diseases and lung cancer.

The effects of oral cannabinoids (dronabinol or *Cannabis sativa* plant extract) in relieving pain and muscle spasticity have been studied in 16 patients with multiple sclerosis (mean age 46 years, mean duration of disease 15 years) in a double-blind, placebo-controlled, crossover study (55). The initial dose was 2.5 mg bd, increasing to 5 mg bd after 2 weeks if the dose was well tolerated. The plant extract was more likely to cause adverse events; five patients had increased spasticity and one rated an adverse event of acute psychosis as severe. All physical measures were in the reference ranges. There were no significant differences in any measure of efficacy score that would indicate a therapeutic benefit of cannabinoids. This study is the largest and longest of its kind, but the authors acknowledged some possible shortcomings. The route of administration could affect subjective ratings, since the gastrointestinal tract is a much slower and more inefficient route than the lungs. Another possibility is that the dose was too small to have the desired therapeutic effects.

Organs and Systems

Cardiovascular

Marijuana has several effects on the cardiovascular system, and can increase resting heart rate and supine blood pressure and cause postural hypotension. It is associated with an increase in myocardial oxygen demand and a decrease in oxygen supply. Peripheral vasodilatation, with increased blood flow, orthostatic hypotension, and tachycardia, can occur with normal recreational doses of cannabis. High doses of THC taken intravenously have often been associated with ventricular extra beats, a shortened PR interval, and reduced T wave amplitude, to which tolerance readily develops and which are reversible on withdrawal. While the other cardiovascular effects tend to decrease in chronic smokers, the degree of tachycardia continues to be exaggerated with exercise, as shown by bicycle ergometry.

Marijuana use is most popular among young adults (18–25 years old). However, with a generation of post-1960s smokers growing older, the use of marijuana in the age group that is prone to coronary artery disease has increased. The cardiovascular effects may present a risk to those with cardiovascular disorders, but in adults with normal cardiovascular function there is no evidence of permanent damage associated with marijuana (54,56,57), and it is not known whether marijuana can precipitate myocardial infarction, although mixed use of tobacco and cannabis make the evaluation of the effects of cannabis very difficult.

Ischemic heart disease

Investigators in the Determinants of Myocardial Infarction Onset Study recently reported that smoking marijuana is a rare trigger of acute myocardial infarction (58). Interviews of 3882 patients (1258 women) were conducted on an average of 4 days after infarction. Reported use of marijuana in the hour preceding the first symptoms of myocardial infarction was compared with use in matched controls. Among the patients, 124 reported smoking marijuana in the previous year, 37 within 24 hours, and 9 within 1 hour of cardiac symptoms. The risk of myocardial infarction was increased 4.8 times over baseline in the 60 minutes after marijuana use and then fell rapidly. The authors emphasized that in a majority of cases, the mechanism that triggered the onset of myocardial infarction involved a ruptured atherosclerotic plaque secondary to hemodynamic stress. It was not clear whether marijuana has direct or indirect hemodynamic effects sufficient to cause plaque rupture.

Cardiac dysrhythmias

Paroxysmal atrial fibrillation has been reported in two cases after marijuana use (59).

- A healthy 32-year-old doctor, who smoked marijuana 1–2 times a month, had paroxysmal tachycardia for several months. An electrocardiogram was normal and a Holter recording showed sinus rhythm with isolated supraventricular extra beats. He was treated with propranolol. He later secretly smoked marijuana while undergoing another Holter recording, which showed numerous episodes of paroxysmal atrial tachycardia and atrial fibrillation lasting up to 2 minutes. He abstained from marijuana for 12 months and maintained stable sinus rhythm.
- A 24-year-old woman briefly lost consciousness and had nausea and vomiting several minutes after smoking marijuana. She had hyporeflexia, atrial fibrillation (maximum 140/minute with a pulse deficit), and a blood pressure of 130/80 mmHg. Echocardiography was unremarkable. Within 12 hours, after metoprolol, propafenone, and intravenous hydration with electrolytes, sinus rhythm was restored.

The authors discussed the possibility that Δ9-THC, the active ingredient of marijuana, can cause intra-atrial re-entry by several mechanisms and thereby precipitate atrial fibrillation.

Sustained atrial fibrillation has also been attributed to marijuana (60).

- A 14-year-old African-American man with no cardiac history had palpitation and dizziness, resulting in a fall, within 1 hour of smoking marijuana. After vomiting several times he had a new sensation of skipped heartbeats. The only remarkable finding was a flow murmur. The electrocardiogram showed atrial fibrillation. Echocardiography was normal. Serum and urine

© 2006 Elsevier B.V. All rights reserved.

toxicology showed cannabis. He was given digoxin, and about 12 hours later his cardiac rhythm converted to sinus rhythm. Digoxin was withdrawn. He abstained from marijuana over the next year and was symptom free.

The authors noted that marijuana's catecholaminergic properties can affect autonomic control, vasomotor reflexes, and conduction-enhancement of perinodal fibers in cardiac muscle, and thus lead to an event such as this.

Arteritis

A case of progressive arteritis associated with cannabis use has been reported (61).

- A 38-year-old Afro-Caribbean man was admitted after 3 months of severe constant ischemic pain and numbness affecting the right foot. The pain was worse at night. He also had intermittent claudication after walking 100 yards. He had a chronic history of smoking cannabis about 1 ounce/day, mixed with tobacco in the early years of usage. However, at the time of admission, he had not used tobacco in any form for over 10 years. He had patchy necrosis and ulceration of the toes and impalpable pulses in the right foot. The serum cotinine concentrations were consistent with those found in non-smokers of tobacco. Angiography of his leg was highly suggestive of Buerger's disease (thromboangiitis obliterans).

Remarkably, this patient, despite having abstained from tobacco for more than 10 years, developed a progressive arteritis leading to ischemic changes. While arterial pathology with cannabis has been reported before, it has been difficult to dissociate the effects of other drugs.

Respiratory

Acute inhalation of marijuana or THC causes bronchodilatation, but with chronic use resistance in the bronchioles increases (62,63). Prolonged use of cannabis by inhalation can cause chronic inflammatory changes in the bronchial tree, in part related to the inhalants that accompany the smoke. In some cases attacks of asthma and glottal and uvular angioedema can occur. Reduced respiratory gas exchange has been reported in long-term smokers, and under experimental conditions THC can depress respiratory function slightly and act as a respiratory irritant. In fact, chronic marijuana cigarette smoking and chronic tobacco cigarette smoking produce very similar changes, but these occur after smoking fewer cigarettes when marijuana is smoked, compared with tobacco-smoking. With marijuana inhalation, when a filter is never used, inhalation is deeper and the smoke is held in the lungs for longer than when smoking commercially produced tobacco-based cigarettes (64). There is therefore a greater build-up of carbon monoxide, reduction in carboxyhemoglobin saturation, and alveolar cellular irritation with depression of macrophages (SEDA-13, 25). Pneumothorax, pneumopericardium, and pneumomediastinum have been reported when positive pulmonary pressure is applied or a Valsalva maneuver used, as often happens (65,66).

A possible role of marijuana use in the formation of large lung bullae has been discussed (67). Four men, who smoked both tobacco and marijuana, developed large, multiple, bilateral, peripheral bullae at their lung apices, with normal parenchymal tissue elsewhere. Three patients with large bullae in the upper lung lobe have been reported (68). All had been heavy marijuana smokers over 10–24 years. However, they all had at least nine pack-years of cigarette exposure and so marijuana may not have been the only cause of their lung bullae. Nevertheless, the authors recommended that all those who present with upper lung bullae should be screened for cannabis use.

While Δ9-THC may not contribute directly to lung bullae, it is possible that the respiratory dynamics of smoking the drug explains it. Typically, a draw on a marijuana joint has, on average, a depth of inspiration that is one-third greater, a volume two-thirds greater, and a breath-holding time four times longer than a draw on a cigarette. The marijuana joint lacks a filter tip, and the practice of smoking "leads to a fourfold greater delivery of tar and a five times greater increase in carboxyhemoglobin per cigarette smoked" (62). Smoking three to four joints of marijuana per day is reported to produce a symptom profile and damage to the respiratory airways similar to that caused by smoking 20 tobacco cigarettes daily.

Nervous system

Marijuana can interact with the neurotransmitter dopamine, and the effects of marijuana on the brain in schizophrenia have been studied by single photon emission computerized tomography (SPECT) (69).

A 38-year-old man with schizophrenia secretively smoked marijuana during a neuroimaging study. A comparison of two sets of images, before and after marijuana inhalation, showed a 20% reduction in the striatal dopamine D_2 receptor binding ratio, suggestive of increased synaptic dopaminergic activity.

On the basis of this in vivo SPECT study, the authors speculated that marijuana may interact with dopaminergic systems in brain reward pathways.

Sensory systems

Eyes

No consistent effects of cannabinoids on the eyes have been reported, apart from a reduction in intraocular pressure (70). The initial reduction in intraocular pressure is followed by a rebound increase associated with increased prostaglandin concentrations.

Ears

The effect of THC, 7.5 mg and 15 mg, on auditory functioning has been investigated in eight men in a double-blind, randomized, placebo-controlled, crossover trial (71). Blood concentrations of THC were measured for up to 48 hours after ingestion, and audiometric tests were carried out at 2 hours. There were no significant differences across treatments, suggesting that cannabis does not affect the basic unit of auditory perception.

Psychological, psychiatric

The psychological effects of cannabis vary with personal and social factors. However, some guidance to the essential

© 2006 Elsevier B.V. All rights reserved.

effects of the drug can be derived from investigations with THC and marijuana in non-user volunteers. Blood concentrations of THC over 75 μg/ml under these conditions are associated with euphoria, and somewhat higher concentrations with dissociation of events and memory and impairment of psychomotor tasks lasting over 24 hours (54).

Through random urine testing of draftees to the Italian army, 133 marijuana users were identified, tested, and interviewed (72). Among these marijuana users, 83% of those with cannabis dependence, 46% with cannabis abuse, and 29% of occasional users had at least one DSM-IIIR psychiatric diagnosis. With greater cannabis use, the risk of associated psychiatric disabilities tended to increase progressively.

Occasional and regular users can suffer panic attacks, paranoia, hallucinations, or feelings of unreality (depersonalization and derealization).

Psychosis

The causal relation between cannabis abuse and schizophrenia is controversial. Cannabis abuse, and particularly heavy abuse, can exacerbate symptoms of schizophrenia and can be considered as a risk factor eliciting relapse in schizophrenia (74). Chronic cannabis use can precipitate schizophrenia in vulnerable individuals (75).

Four cases in which psychosis developed after relatively small amounts of marijuana were smoked for the first time have been reported (76). All required hospitalization and neuroleptic drug treatment. Each had a mother with manic disorder and two had psychotic features. The authors noted that marijuana is a dopamine receptor agonist, and mania may be associated with excessive dopaminergic neurotransmission. The use of marijuana may precipitate psychosis or mania in subjects who are genetically vulnerable to major mental illness.

Marijuana abuse and its possible associated risks in reinforcing further use, causing dependence, and producing withdrawal symptoms among adolescents with conduct symptoms and substance use disorders has been investigated in 165 men and 64 women selected and then interviewed from a group of 255 consecutive admissions to a university-based adolescent substance abuse treatment program (77). All had DSM-IIIR substance dependence, 82% had conduct disorder, 18% had major depression, and 15% had attention-deficit/hyperactivity disorder. Most (79%) met the criteria for cannabis dependence. Two-thirds of the cannabis-dependent individuals admitted serious drug-related problems and reported associated drug withdrawal symptoms according to the Comprehensive Addiction Severity Index in adolescents (CASI). For the majority, progression from first to regular cannabis use was as rapid as tobacco progression and more rapid than that of alcohol.

Cognitive effects

Long-term heavy use of cannabis impairs mental performance, causes defects in memory (especially short-term memory), and leads to impairment of memory, attention, and organization and integration of complex information (78). Adolescents with pre-existing disabilities in learning and cognition have experienced serious aggravation of their problem from regular use of cannabis (79).

The effects of chronic marijuana smoking on human brain function and cognition have been further investigated (62). Normalized regional brain blood flow and regional brain metabolism, measured using PET scanning with ^{15}O, were compared in 17 frequent marijuana users and 12 non-users. Testing was performed after at least 26 hours of monitored abstinence in all subjects. Marijuana users had hypoactivity or reduced brain blood flow in a large region of the posterior cerebellum compared with controls. This is consistent with what was reported in the only previous PET study of chronic marijuana use (80). The cerebellum is hypothesized to have input to aspects of cognition, specifically timing, the processing of sensory information, and attention and prediction of real-time events. Users often report that marijuana smoking is followed by alterations in the sense of time and less efficient cognitive processing.

The safety and possible benefits of long-term marijuana use have been studied in four seriously ill patients in the Missoula Chronic Clinical Cannabis Use Study with a quality-controlled sample of marijuana (73). They were evaluated using an extensive neurocognitive battery.

- A 62-year-old woman with congenital cataracts smoked marijuana illicitly for 12 years (current use 3–4 g/day smoked and 3–4 g/day orally). She had mild-to-moderate difficulty with attention and concentration and minimal-to-mild difficulty with acquisition and storage of very complex new verbal material. Her executive functioning was not affected.
- A 50-year-old man with hereditary osteo-onychodysplasia had smoked marijuana since 1974 to alleviate muscle spasms and pain (current use 7 g/day of 3.75% THC). He had mild-to-moderate impairment of attention and concentration and reduced ability to acquire new verbal material. He scored poorly on the California Verbal Learning Test (CVLT), a measure of short-term memory recall, and had difficulty with motor tasks.
- A 48-year-old man with multiple congenital cartilaginous exostoses had smoked marijuana since the late 1970s (current use 9 g/day of 2.7% THC). His neurocognitive scores suggest mild difficulty in sustaining attention and a minimal-to-mild deficit in the acquisition of new verbal material.
- A 45-year-old woman with multiple sclerosis had smoked cannabis since 1990 to control pain and muscle spasms (current use marijuana cigarettes containing 3.5% THC 10/day). She had impairment of concentration, learning, and memory efficiency. Her ability to acquire new verbal information was also impaired.

The authors attributed these cognitive deficits not to marijuana use but rather to the patients' illnesses, arguing that it is difficult for patients with painful debilitating diseases to concentrate on neurocognitive tasks. Any abnormalities in MRI imaging and electroencephalography were attributed to age-related brain deterioration. There were no significant abnormalities of respiratory function, apart from a "slight downward trend in FEV_1 and FEV_1/FVC ratios, and perhaps an increase in FVC" in three patients, interpretation of these findings being complicated by concomitant tobacco smoking. One patient had mild polycythemia and a raised white cell count. None had abnormal endocrine tests. This was a comprehensive study of the long-term effects of cannabis,

© 2006 Elsevier B.V. All rights reserved.

but concomitant illnesses and use of tobacco made the results difficult to interpret.

Concerns have been raised about the possible adverse effects of acute as well as chronic medicinal and recreational use of cannabis on cognition and the body (81). The author, while acknowledging the therapeutic role of cannabinoids in the management of pain and other conditions, expressed concern that in recent years the prevalence of recreational cannabis use (especially in the young) and the potency of the available products have markedly increased in the UK.

An unusual account of transient amnesia after marijuana use has been reported from Europe (82).

- A 40-year-old healthy man with a long history of cannabis use was hospitalized with an acute memory disturbance after smoking for several hours a strong type of marijuana called "superskunk." After smoking, he had difficulty recollecting recent events and would ask the same questions repeatedly. While his routine laboratory results were within the reference ranges, his urine and blood toxic screens had very high concentrations of cannabinoids (and no other drugs). He was alert and oriented to his name, address, date, and place of birth, but could not recall his marital status, whether he had children, or the nature of his job. He was disoriented in time. He performed normally in tests of general cognitive functioning (for example Raven's matrices, word fluency, Rey's complex figurecopy) and short-term memory (for example digit span, verbal cues), but showed severe impairment in verbal and non-verbal long-term components of anterograde memory tests. He had a severe retrograde memory defect mainly affecting autobiographical memory, with a temporal gradient such that remote facts were preserved. These memory impairments lasted 4 days and then rapidly improved, leaving amnesia for the acute episode. Electroencephalography during the amnestic episode was normal, except for brief trains of irregular slow activity in the frontal areas bilaterally. A SPECT scan of his brain was normal. A week later, repeat neuropsychological examination showed normal memory and a normal electroencephalogram and MRI scan of the brain with enhancement. One year later, he had stopped using marijuana and had no further amnestic episodes.

The authors found similarities between the memory disorder seen here and transient global amnesia, which consists of anterograde amnesia and a variably graded retrograde amnesia. Such amnesia has been previously reported with a number of substances and medications, but not with marijuana. The authors stated that although memory impairment has been reported with marijuana before, it has never involved retrieval of already learned material. They wondered if the memory impairment was due to marijuana-induced changes in cerebral blood flow and ischemia through vasospasm. However, their SPECT data did not support this theory. They considered the possibility that cannabinoid receptors, which are dense in the hippocampus, could have been occupied by marijuana, resulting in such memory loss. They cautioned that the effects of marijuana on memory may be more severe than previously thought.

Endocrine

In animals (particularly monkeys), cannabis depresses ovarian and testicular function. In man, chronic use has been associated with reduced serum FSH and LH concentrations in a few people, often accompanied by reduced serum testosterone, oligospermia, reduced sperm motility, and gynecomastia (83). There is no evidence of impairment of male fertility; no studies have been carried out on female fertility. There is evidence of slightly shortened gestation periods in chronic users (84). There are variable non-specific effects on serum prolactin and growth hormone and a rise in plasma cortisol concentrations has been recorded in one study.

Hematologic

Of the hematological changes very occasionally noted, polycythemia appears to be secondary to reduced pulmonary oxygen exchange (see the Respiratory section in this monograph).

Immunologic

Tetrahydrocannabinol depresses lymphocyte and macrophage activity in cell cultures, while in rats in vivo it directly suppresses natural killer cell activity and impairs T lymphocyte transformation by phytohemagglutinin in concentrations of cannabinoids achievable with the usual doses (85). Variable results have been obtained in man in tests of circulating T cells and hormonal immunity (86).

In animals and man, chronic use often suppresses the immune system's response to inhaled bacterial or fungal material. In this connection it is relevant to note that a contaminant mould (*Aspergillus*) found in cannabis can predispose immunocompromised cannabis smokers to infection. It has been suggested that baking the cannabis (at 300°F for 15 minutes) before smoking will kill the fungus and reduce the potential risk (87).

The effects of marijuana on immune function have been reviewed (88). The studies suggest that marijuana affects immune cell function of T and B lymphocytes, natural killer cells, and macrophages. In addition, cannabis appears to modulate host resistance, especially the secondary immune response to various infectious agents, both viral and bacterial. Lastly, marijuana may also affect the cytokine network, influencing the production and function of acute-phase and immune cytokines and modulating network cells, such as macrophages and T helper cells. Under some conditions, marijuana may be immunomodulatory and promote disease.

A severe allergic reaction after intravenous marijuana has been reported (89).

- A 25-year-old man with intermittent metamfetamine use developed facial edema, pruritus, and dyspnea 45 minutes after injecting a mixture of crushed marijuana leaves and heated water. He was anxious, and had tachypnea, respiratory stridor, wheezing, edema of the face and oral mucosa, and truncal urticaria. There was mild pre-renal uremia and urine toxicology was positive for metamfetamine and marijuana. Skin testing was not done. With appropriate medical intervention there was resolution of symptoms within a day.

© 2006 Elsevier B.V. All rights reserved.

The authors noted that marijuana may have contaminants, including *Aspergillus*, *Salmonella*, herbicides, and mercury, which can trigger allergic reactions.

Long-Term Effects

Drug tolerance

Tolerance develops with heavy chronic use in individuals who report problems in controlling their use and who continue to use cannabis despite adverse personal consequences (53).

Drug withdrawal

Withdrawal symptoms occur after chronic heavy use (53). Abrupt withdrawal of high-level use of cannabinoids causes irritability, restlessness, and insomnia, with a rebound increase in REM sleep, tremor, and anorexia lasting up to a week (90–92). Occasional use does not appear to be associated with major consequences.

Second-Generation Effects

Pregnancy

Behavioral anomalies have been identified in the offspring of monkeys and women exposed to cannabis during pregnancy (93,94). These include reduced visual responses, increased auditory responses, and reduced quietude. Most of the effects resolved within 4–5 weeks postpartum and there were no abnormalities at 1 year.

Teratogenicity

In animals, THC crosses the placenta and is excreted in breast milk. There is conflicting evidence concerning teratogenicity in animals, but no definitive evidence in man. However, there have been many anecdotal reports of abnormalities. Although these were without consistent characteristics, the descriptions would readily fit the fetal alcohol syndrome (95–98) and clinical evaluation of the use of cannabis during pregnancy is complicated by the frequent concomitant use of alcohol and tobacco.

Fetotoxicity

The effect of maternal and prenatal marijuana exposure on offspring from birth to adolescence is being investigated (99). The Ottawa Prenatal Prospective Study (OPPS), a longitudinal project begun in 1978, recently reported its findings in 146 low-risk, middle-class children aged 9–12 years. Their performances on neurobehavioral tasks that focus on visuoperceptual abilities (ranging from basic skills to those requiring integration and cognitive manipulation of such skills) were analysed. Performance outcomes were different in children with prenatal exposure to cigarette smoking and those with prenatal exposure to marijuana. Maternal cigarette smoking affected fundamental visuoperceptual functioning. Prenatal marijuana use had a negative effect on performance in visual problem-solving, which requires integration, analysis, and synthesis. In a second prospective study, the effects of prenatal marijuana exposure and child behavior problems were studied in 763 subjects aged 10 years (100). Prenatal maternal marijuana exposure was associated with increased hyperactivity, impulsivity, and inattention in the children. There was also increased delinquency and externalizing problems. The authors suggested a possible pathway between prenatal marijuana exposure and delinquency, which may be mediated by the effects of marijuana exposure on symptoms of inattention.

Susceptibility Factors

Age

Children

In young children, accidental ingestion leads to the rapid onset of drowsiness, hypotonia, dilated pupils, and coma. Fortunately, gradual recovery occurs spontaneously, barring accidents. Passive inhalation of marijuana in infants can have serious consequences.

- A 9-month-old girl presented with extreme lethargy and a modified Glasgow coma scale of 10, after having been exposed to cigarette and cannabis smoke at the home of her teenage sister's friend (101). The physical examination and laboratory results were unremarkable. Cannabinoids were detected in a urine screen.

While chronic adult users can display apathy and impaired concentration, these effects are possibly in part associated with other factors. No permanent organic brain damage has been demonstrated (101,102).

Other features of the patient

People with pre-existing coronary artery disease may have an increased incidence of attacks of angina (103). In individuals who are vulnerable to schizophrenia, cannabis can precipitate psychoses or aggravate schizophrenia. The control of epilepsy may be impaired. Users undergoing anesthesia may react unexpectedly and may have enhanced nervous system depression. Because of impairment of judgement and psychomotor performance, users should not drive or operate machinery for at least 24 hours after administration.

Drug–Drug Interactions

Alcohol

Additive psychoactive effects sought by users may be achieved by combinations of cannabis and alcohol, but at the same time the ability of THC to induce microsomal enzymes will increase the rate of metabolism of alcohol and so reduce the additive effects (90).

Anticholinergic drugs

The anticholinergic effects of cannabis (90) may result in interactions with other drugs with anticholinergic effects, such as some antidysrhythmic drugs.

Barbiturates, short-acting

Additive psychoactive effects sought by users may be achieved by combinations of cannabis and short-acting

© 2006 Elsevier B.V. All rights reserved.

barbiturates, but at the same time the ability of THC to induce microsomal enzymes will increase the rate of metabolism of barbiturates and so reduce the additive effects (90).

Disulfiram

Concurrent administration with disulfiram is associated with hypomania (104).

Lysergic acid diethylamide

"Flashbacks," or the return of hallucinogenic effects, occur in almost a quarter of those who have used LSD, particularly if they have also used other CNS stimulants, such as alcohol or marijuana. They can experience distortions of perception of objects, space, or time, which intrude without warning into reality, resulting in delusions, panic, and unusual images. A "trailing phenomenon" has also been reported, in which the visual perception of objects is reduced to a series of interrupted pictures rather than a constant view. The frequency of these events may slowly abate over several years, but in a significant number their incidence later increases (105,106).

Psychotropic drugs

Cannabis alters the effects of psychotropic drugs, such as opioids, anticholinergic drugs, and antidepressants, although variably and unpredictably (90).

Sildenafil

Myocardial infarction has been attributed to the combination of cannabis and sildenafil.

- A 41-year-old man developed chest tightness radiating down both arms (107). He had taken sildenafil and cannabis recreationally the night before. His vital signs were normal and he had no signs of heart failure. However, electrocardiography showed an inferior evolving non-Q-wave myocardial infarct and his creatine kinase activity was raised (431 U/l).

Cannabis inhibits CYP3A4, which is primarily responsible for the metabolism of sildenafil, increased concentrations of which may have caused this cardiac event.

Capparaceae

See also Herbal medicines

General Information

The genera in the family of Capparaceae (Table 1) include caper and stinkweed.

Capparis spinosa

The leaf and fruit of *Capparis spinosa* (caper plant) both contain isothiocyanates, in addition to the flavonoid rutinoside and the quaternary alkaloid stachydrine.

Adverse effects

Allergic contact dermatitis can follow the application of *C. spinosa* in the form of wet compresses (1).

Table 1 The genera of Capparaceae

Atamisquea (atamisquea)
Capparis (caper)
Cleome (spiderflower)
Cleomella (stinkweed)
Forchhammeria (forchhammeria)
Koeberlinia (allthorn)
Morisonia (morisonia)
Oxystylis (oxystylis)
Polanisia (clammyweed)
Wislizenia (wislizenia)

Capreomycin

See also Antituberculosis drugs

General Information

Capreomycin has been abandoned for the treatment of tuberculosis and replaced by first-choice drugs. In rare cases, it has been administered in infections with non-tuberculous mycobacteria when there is multiple drug resistance to the first-line antituberculosis drugs (1).

Organs and Systems

Electrolyte balance

Marked renal loss of sodium, chloride, potassium, and magnesium with progressive metabolic alkalosis and hyper-reninemia have been reported (2).

Urinary tract

A Bartter-like syndrome has been reported in a 25-year-old man taking prolonged capreomycin for drug-resistant pulmonary tuberculosis (2).

Drug–Drug Interactions

Streptomycin

Capreomycin should never be combined with streptomycin or other aminoglycosides because of nephrotoxicity and ototoxicity (3).

Captopril

See also Angiotensin converting enzyme inhibitors

General Information

Captopril is a sulfhydryl-containing ACE inhibitor used in the management of hypertension and heart failure, after myocardial infarction, and in diabetic nephropathy.

Organs and Systems

Respiratory

Two cases of alveolitis have been reported with captopril, one associated with eosinophilia (1) and the other with a lymphocytic pulmonary infiltrate (2).

Sensory systems

A report from the Australian Drug Evaluation Committee has confirmed that dysgeusia (taste disturbance and taste loss) is more likely to complicate treatment with captopril than with other ACE inhibitors; captopril accounted for more than half the cases of taste loss (3). Taste loss was dose-related, in that more than 90% of reports detailed a daily dose of 50 mg or more. Most cases recovered on withdrawal, although the sense of taste had not returned 7 months after withdrawal in one case, and in two of the reports there was associated anosmia. Although there was no significant difference between captopril and lisinopril

© 2006 Elsevier B.V. All rights reserved.

(4), it appears that captopril, presumably via its sulfhydryl group, is more likely to provoke dysgeusia.

Hematologic

Anecdotal reports of a bone-marrow suppressant effect of captopril have been published, but not since 1989. Cases of neutropenia and agranulocytosis (5–8) have also been reported, although in some of these there were complicating issues, making a clear association difficult to establish. Usually the incidence is higher in patients with renal insufficiency or collagen vascular disease. In few cases the white cell count returned to normal when captopril was withdrawn. Although agranulocytosis has been attributed to the presence of the sulfhydryl group in captopril, it has also been reported with enalapril (9).

Agranulocytosis has also been reported in association with toxic epidermal necrolysis (10).

- A 59-year-old woman with long-standing hypertension took captopril 200 mg bd plus hydrochlorothiazide 50 mg od and 3 days later developed nausea, vomiting, malaise, and a severe, pruritic, erythematous rash, with severe dehydration and orthostatic hypotension. The diuretic was withdrawn and intravenous fluids and diphenhydramine were given. She recovered within 1 week and remained asymptomatic for 4 weeks. She then developed fever, malaise, a new rash, orthostatic hypotension, and diffuse erythroderma. Her posterior pharynx was erythematous. She had neutropenia (900×10^6/l) and captopril was withdrawn. She was treated empirically with antibiotics and intravenous fluids and subcutaneous granulocyte colony-stimulating factor (G-CSF) for 5 days. The erythroderma progressed to large coalescing blisters, which then ruptured, producing large areas of weeping skin over all her limbs. The bone-marrow and skin recovered fully within 2 weeks.

Autoimmune thrombocytopenia, gradually reversible on withdrawal of captopril, was reported in three patients taking captopril (11).

Pancreas

Two new cases of pancreatitis with captopril have been reported (12,13). It has been suggested that early detection of raised serum amylase and lipase activities can prevent the development of full-blown pancreatitis (13).

Urinary tract

Acute renal insufficiency with tubular necrosis has been described (14). It occurred within 24 hours of the first dose of captopril and required hemodialysis for 8 weeks. The diagnosis of ischemic tubular necrosis was confirmed by renal biopsy. Few previous cases of ACE inhibitor-induced nephropathy have been documented by renal biopsy.

Immunologic

Lupus–like syndrome has been reported with captopril (15). The authors believed their patient to be the fifth such published case.

- A 54-year-old Caucasian man presented with a 4-week history of chills, fever, malaise, and generalized arthralgia. Following an aortic valve replacement, he had taken aspirin, coumadin, and captopril 25 mg tds for 1 year. He was febrile (temperature 39.4°C), normotensive, with diffuse livedo reticularis, and the physical signs of aortic valve disease. Infective endocarditis was ruled out by appropriate investigations. He had a raised erythrocyte sedimentation rate (142 mm/hour) and a positive antinuclear antibody test (FANA 1:2560) with a negative antinative DNA test. Captopril was withdrawn and he was given prednisone for 5 days. His symptoms resolved rapidly and the livedo reticularis cleared within 2 days. The FANA and ESR returned to normal and remained so at follow-up 6 months later.

During early drug development, the occurrence of antinuclear antibodies in 10 of 37 patients taking high doses of captopril was described (16).

Drug–Drug Interactions

General anesthesia

The hazards of general anesthesia in the presence of ACE inhibitors have been recognized and reviewed (17). It has generally been accepted that ACE inhibitors should be continued up to the time of surgery. Patients should be monitored aggressively and hemodynamic instability treated appropriately.

- An 86-year-old man, who was taking captopril 25 mg bd and bendroflumethiazide 25 mg/day for hypertension, had a transurethral resection of the prostate under spinal anesthesia, and developed profound bradycardia and hypotension with disturbances of consciousness during transfer to the recovery room (18). Initial treatment with atropine produced rapid improvement in cardiovascular and cerebral function. A further hypotensive episode, without bradycardia, occurred about 1 hour later, but responded rapidly to methoxamine. He made a full recovery overnight.

The authors suggested that the concomitant administration of captopril may have contributed to the adverse effect, since the renin–angiotensin system is important in maintaining blood pressure during anesthesia. Because of a protective effect of angiotensin II in the presence of sympathetic blockade by presynaptic stimulation of adrenergic neurons, the authors hypothesized that hypotension and bradycardia in this patient may have been magnified by suppression of the renin–angiotensin system, resulting in an enhanced negative Bainbridge effect.

Iron and other transition metals

Captopril has been reported to react with iron and other transition metals. This interaction has been investigated in vivo in seven healthy adults (19). Co-administration of ferrous sulfate and captopril resulted in a 37% decrease in the AUC of unconjugated captopril, with no significant changes in C_{max} or t_{max}. The plasma AUC of total captopril was not altered. The authors suggested that the interaction may be specific to captopril among ACE inhibitors, because it contains a sulfhydryl group. Therefore, if iron salts were to be taken by a patient requiring an ACE inhibitor, an agent other than captopril might be considered.

Interference with Diagnostic Tests

Legal reaction

Like other sulfhydryl-containing compounds, captopril can cause false-positive ketonuria when assessed with the Legal reaction (sodium nitroprusside reacting with acetoacetic acid and possibly with acetone). It has therefore been suggested that in patients with diabetes taking such drugs ketonuria should be assessed with the Acetest (20). Alternatively, a blood ketone test with Acetest and/or enzymatic detection of beta-hydroxybutyric acid can be performed for confirmation.

Carbachol

General Information

Carbachol is a quaternary ammonium compound that shares both the muscarinic and nicotinic actions of acetylcholine but is much more slowly deactivated. Carbachol has been used topically in ophthalmology and systemically (subcutaneously, for example in doses of 2 mg/day) for urinary retention. Severe cholinergic effects can result. In one instance they primarily involved the gastrointestinal tract and the patient died of esophageal rupture (1). In other cases patients have experienced extreme bradycardia with hypotension, requiring treatment with intravenous atropine. As carbachol is not destroyed by cholinesterase, a cumulative effect is possible in patients who receive regular doses at short intervals; in one case, hypotension only developed on the third treatment day (2).

Carbamazepine

See also Antiepileptic drugs

General Information

Carbamazepine is usually regarded as the drug of choice for partial seizures (with or without secondary generalization) and it can also be valuable in preventing primary generalized tonic-clonic seizures.

© 2006 Elsevier B.V. All rights reserved.

General adverse reactions

Cerebellovestibular and oculomotor dysfunction (with dizziness, diplopia, nystagmus, ataxia), fatigue, and sedation (usually transient) are relatively common. Nausea, vomiting, cognitive dysfunction, headache, myoclonus (including non-epileptic myoclonus), exacerbation of seizures, movement disorders, behavioral or psychiatric disturbances, hyponatremia, and altered cardiac conduction are less common.

Hypersusceptibility reactions

Hypersusceptibility reactions to carbamazepine are relatively common and range from cutaneous reactions (including Stevens–Johnson syndrome and toxic epidermal necrolysis, severe forms of erythema multiforme) to systemic reactions with fever, lymphadenopathy, and/or involvement of the bone marrow, the liver, the heart, the gastrointestinal system, the lungs, and other organs.

In ten children with chorea (eight girls and two boys; aged 7–16 years), nine with rheumatic fever, carbamazepine (4–10 mg/kg/day; plasma concentrations 12–34 μmol/l) produced improvement within 2–14 days (1). The chorea disappeared within 2–12 weeks. There were no adverse effects.

Organs and Systems

Cardiovascular

Carbamazepine can depress the cardiac conducting system (SEDA-16, 71). There have been a few reports of reversible atrioventricular block (SED-12, 130) (2–4), and asystole has been described in a patient with Guillain–Barré syndrome (SEDA-18, 62).

In one patient carbamazepine caused pacemaker failure until the pacemaker was adjusted, no doubt because of its effects on cardiac conduction (SEDA-18, 62).

Three cases of carbamazepine-induced Stokes–Adams attacks caused by intermittent total atrioventricular block, sinoatrial block with functional escape rhythm, and intermittent asystole have been described; it was suggested that cardiac conduction should be assessed if syncope or changes in seizure type occur in patients taking carbamazepine (5).

Bradydysrhythmias of different types and severity have also been reported, especially in the elderly, but they do not seem to be common.

There has been a report of carbamazepine-induced hypertension (6).

- A 33-year-old man with complex partial seizures was switched from phenytoin to carbamazepine. His blood pressure was 118/70, but 4 months later, while he was taking carbamazepine 600 mg bd, his blood pressure was 150/112 and 1 month later 142/110. He was taking no medications beside carbamazepine. Secondary causes of hypertension were ruled out. Carbamazepine was withdrawn and gabapentin prescribed. One month later his blood pressure was normal, and it remained so at subsequent follow-up appointments over the next 2 years.

A case of congestive heart failure possibly caused by carbamazepine has been described (SED-12, 130) (7), but there have been no subsequent reports.

Potentially fatal eosinophilic myocarditis may be a manifestation of carbamazepine hypersensitivity (SEDA-22, 86).

Four additional cases of carbamazepine-induced sinus node dysfunction ($n = 3$) and atrioventricular block ($n = 1$) were described in elderly Japanese women taking 200–600 mg/day. In two of the three patients rechallenged, sinus arrest recurred within 48 hours (8).

In 12 patients in whom carbamazepine was withdrawn, power-spectrum analysis of RR interval variability was used to investigate changes in sympathetic/parasympathetic autonomic equilibrium (9). Abrupt withdrawal of carbamazepine altered the sympathovagal balance during non-REM sleep, shifting the sympathovagal balance toward sympathetic predominance. However, analysis of the before and after withdrawal cardiac Holter recordings showed no serious cardiac dysrhythmias in any patient.

Respiratory

Acute hypersensitivity reactions involving the lung or the bronchi have been reported, but are rare (SEDA-16, 71) (SEDA-18, 62).

Nervous system

Most central nervous system adverse effects are mild, transient, and reversible on dosage adjustment. Those reported more commonly (in 10–50% of patients, depending on dosage and assessment method) include somnolence, which is usually transient, diplopia, nystagmus, dizziness, fatigue, headache, ataxia, and cognitive dysfunction. These effects may be intermittent and related to high peak concentrations of the drug. Dividing the total daily dose or switching to a modified-release formulation can minimize these effects (SEDA-19, 64). Patients with MRI evidence of cerebellar atrophy may be more prone to nystagmus, dizziness, and ataxia when they take carbamazepine (SEDA-21, 69).

Carbamazepine can precipitate or aggravate myoclonic, atonic, and absence seizures, especially in children and adolescents with a history of bilaterally synchronous spike-and-wave discharges in the electroencephalogram; both generalized and partial seizures can be worsened (10). In children, the new appearance of generalized paroxysmal discharges after treatment may be predictive of seizure exacerbation or suboptimal control (11). Tonic seizures are occasionally aggravated by carbamazepine (SEDA-22, 85). Non-epileptic myoclonus occurs rarely.

A mild reduction in motor and sensory conduction velocities, possibly related to folate deficiency, has been found in patients taking long-term treatment (SED-13, 146) (12), but symptoms of peripheral neuropathy are uncommon.

Asterixis, dystonias, and dyskinesias (including motor tics, orofacial and lingual dyskinesias, and oculogyric crises) are uncommon, as are auditory disturbances (SED-13, 146) (13–15), (SEDA-20, 60) (SEDA-21, 69).

Neuroleptic malignant syndrome occurred in a middle-aged man who had previously experienced the same

© 2006 Elsevier B.V. All rights reserved.

reaction to tiotixene (SEDA-17, 72). A 54-year-old man who had been taking neuroleptic drugs for about 30 years developed neuroleptic malignant syndrome within 3 days of taking add-on carbamazepine (400 mg/day) (16). It was speculated that the pathogenesis could have involved rebound cholinergic activity after a reduction in plasma neuroleptic drug concentrations by carbamazepine.

Aseptic meningitis reversible on drug withdrawal has been described at least three times (17).

Retrospective studies have suggested that antiepileptic drugs can be associated with peripheral nerve dysfunction. This has been prospectively studied in 81 patients (aged 13–67 years) without polyneuropathy who took sodium valproate ($n = 44$) or carbamazepine ($n = 37$) as monotherapy in standard daily doses (18). After 2 years one patient had clinical signs of polyneuropathy and six had symptoms of polyneuropathy, but electrophysiology did not show significant changes or trends. Only one patient had abnormal electrophysiological findings, which were only subclinical, and eight patients had abnormal values at two subsequent visits. There were no consistent patterns, and the data were unaffected when the drugs were examined separately or when patients were grouped according to whether or not they had symptoms of polyneuropathy. The authors concluded that previously untreated young to middle-aged patients who take valproic acid or carbamazepine for 2 years are not at risk of polyneuropathy.

Combined phonic and motor tics occurred in a 7-year-old boy with Down's syndrome when he took carbamazepine 19 mg/kg for suspected focal epilepsy (19). Carbamazepine concentrations were within the usual target range. The symptoms resolved completely after withdrawal.

Carbamazepine can cause altered visual evoked potentials and brainstem evoked potentials (20). In 100 epileptic patients aged 8–18 years taking carbamazepine in a modified-release formulation, interpeak latencies of I-III and III-V of brainstem evoked potentials were significantly delayed and N75/P100 and P100/N145 amplitudes in the visual evoked potentials were reduced.

Relatively low doses of carbamazepine (300–600 mg/day) have been reported to cause serious worsening of disability in five patients with multiple sclerosis (21). The authors suggested that this effect was due to blockade of sodium channels by carbamazepine.

Sensory systems

There was abnormal color perception in 28% of 18 patients taking carbamazepine monotherapy; in one case there was an abnormality in the blue-yellow (tritan) axis (22). In the same patients carbamazepine had no effect on contrast sensitivity or glare sensitivity (23).

Auditory disturbance is rarely associated with carbamazepine.

- A 25-year-old woman had falsely higher pitch perception after starting carbamazepine for schizoaffective disorder (24). Her serum carbamazepine concentration was in the usual target range. The symptom resolved on withdrawal.

Psychological, psychiatric

Behavioral and psychiatric disturbances are less common with carbamazepine than with other anticonvulsants.

- A 9-year-old boy with seizures developed intermittent complex visual hallucinations during therapy with fosphenytoin and, on a separate occasion, carbamazepine (25).

In 10 children with rolandic epilepsy, carbamazepine impaired memory and possibly visual search tasks (26). Evaluation of individual data suggested that some children were especially vulnerable to the adverse effects of carbamazepine on cognition. The authors did not comment on the fact that rolandic epilepsy is regarded as a syndrome for which treatment in most cases is not indicated.

The cognitive effects of carbamazepine and gabapentin have been compared in a double-blind, crossover, randomized study in 34 healthy elderly adults, of whom 19 withdrew (15 while taking carbamazepine, probably because of excessively rapid dosage titration) (27). The primary outcome measures were standardized neuropsychological and mood state tests, yielding 17 variables. Each subject had cognitive testing at baseline (before drug treatment), at the end of the first drug phase, the end of the second drug phase, and 4 weeks after completion of the second drug phase. Adverse events were frequently reported with both anticonvulsants, although they were more common with carbamazepine. There were significant differences between carbamazepine and gabapentin for only one of 11 cognitive variables, with better attention/vigilance for gabapentin, although the effect was modest. Both carbamazepine and gabapentin can cause mild cognitive deficits in elderly subjects, and gabapentin has a slightly better profile.

Endocrine

Carbamazepine therapy in eight women was associated with increased serum concentrations of sex hormone binding globulin (SHBG) and a reduced serum ratio of 17-α-estradiol and estradiol to SHBG. Of 56 women who had been taking carbamazepine for over 5 years, 14 had menstrual disturbances, which tended to be associated with raised SHBG and reduced serum concentrations of 17-α-estradiol (28). Carbamazepine may also reduce serum LH, progesterone, dehydroepiandrosterone, and the free androgen index (29,30), and some of these changes may be associated with anovulatory cycles and menstrual irregularities.

Men taking carbamazepine had mean low serum concentrations of dehydroepiandrosterone and a high SHBG concentration. Moreover, 18% of men taking carbamazepine for epilepsy reported reduced libido, impaired potency, or both.

Metabolism

Changes in body weight have been evaluated in 349 patients taking carbamazepine, phenytoin, or tiagabine. Carbamazepine add-on therapy caused significant mean weight gain of 1.5% (31). Tiagabide add-on therapy

© 2006 Elsevier B.V. All rights reserved.

caused no significant weight change when added to either phenytoin or carbamazepine.

Some antiepileptic drugs have been associated with low serum and erythrocyte folate concentrations and high total plasma homocysteine concentrations in some patients. The concentrations of folate and homocysteine have been measured in 42 patients taking carbamazepine and 42 matched healthy controls (32). Patients taking carbamazepine had significantly lower serum and erythrocyte folate concentrations. There was hyperhomocystinemia (over 15 μmol/l) in 24% of the patients and 5% of the controls.

Nutrition

Concentrations of plasma homocysteine, plasma pyridoxal 5′-phosphate (active vitamin B6), serum folate, erythrocyte folate, and serum vitamin B12 have been measured both during fasting and after methionine in 60 epileptic patients (aged 14–18 years) and 63 sex- and age-matched controls before therapy and after 1 year of therapy with valproate or carbamazepine (33). After 1 year the patients who took valproate and carbamazepine had significantly increased plasma homocysteine concentrations compared with both baseline and control values and there was a significant fall in serum folate and plasma pyridoxal 5′-phosphate. Serum vitamin B12 and erythrocyte folate were unchanged.

The genetic determinants of this effect on homocysteine have been determined in 136 epileptic children taking carbamazepine or valproate as monotherapy (34). Nutritional determinants (folate and vitamins B6 and B12) and genetic determinants (MTHFR 677CT) of plasma homocysteine were studied in a random sample of 59 of those children. Total homocysteine concentrations were significantly increased and folate and vitamin B6 concentrations were significantly reduced. Carbamazepine lowered folate concentrations in association with hyperhomocysteinemia, which seemed to be related to the homozygous MTHFR 677CT mutation. Valproate, although also associated with hyperhomocysteinemia, only reduced vitamin B6 concentrations, independent of the MTHFR genotype.

Electrolyte balance

Carbamazepine can cause hyponatremia due to stimulation of antidiuretic hormone secretion (35,36). In a boy who developed hyponatremia it also seems to have caused fluid retention and cardiomegaly (SEDA-18, 62).

Symptomatic cases are relatively rare, but two cases have been reported (37).

- A 72-year-old woman developed somnolence and continuous sharp waves over the left hemisphere when carbamazepine was added to primidone and a diuretic. Her serum sodium concentration was initially 130 mmol/l and fell further to 100 mmol/l.
- In a 65-year-woman, carbamazepine-induced hyponatremia (127–130 mmol/l) led to serial tonic-clonic seizures, somnolence, confusion, and an electroencephalographic misdiagnosis of non-convulsive status.

Both patients recovered with normalization of the serum sodium when the carbamazepine dose was tapered.

In 117 patients with chronic epilepsy taking carbamazepine in residential care the retrospective prevalence of hyponatremia was 42% compared with 9.4% in controls (38). Higher doses and serum concentrations of carbamazepine were associated with a higher risk of hyponatremia.

Hematologic

In view of the very low incidence of serious blood dyscrasias, such as pancytopenia and agranulocytosis, indiscriminate continuous hematological monitoring is of little value (SED-13, 145) (39). Leukopenia occurs in up to 21% of patients, usually during the first 3 months of treatment, with a higher risk in those with a low or low-normal pretreatment white blood cell count. Although it may reverse during continuation of treatment (SED-12, 131) (40), (SEDA-20, 60), high-risk cases should be monitored. Bone-marrow aspirates need not be performed routinely in patients with chronic leukopenia and continuation of treatment is probably safe, although caution is required if the neutrophil count is consistently below 1.0×10^9/l (SEDA-19, 66). Other authors have recommended a reduction in dose or withdrawal of treatment if white cell counts are below 3.0×10^9/l or if neutrophil counts are below 1.0×10^9/l.

Some 15 cases of thrombocytopenia, reversible after withdrawal of carbamazepine, have been published (SED-13, 147) (41,42). There have also been single case reports of reticulocytosis (SED-13, 147) (43), leukopenia with thrombocytopenia with Henoch-Schönlein purpura (SEDA-18, 63), hemolytic anemia, and pure red cell aplasia (SED-13, 147) (44).

Serious blood dyscrasias from carbamazepine can be accompanied or preceded by a rash.

- A 66-year-old man had severe leukopenia a few days after a generalized rash appeared on the 36th day after he started to take carbamazepine (45).
- A 69-year-old woman had severe leukopenia and thrombocytopenia about a month after the onset of a rash and 2 months after she started to take carbamazepine (45).

In both patients, the abnormalities resolved after withdrawal, except for the platelet count, which increased but did not fully normalize over 6 weeks. This report suggests that patients developing a rash on carbamazepine should be monitored for the possible risk of associated blood dyscrasias.

Increased concentrations of PIVKA-II (prothrombin-induced by vitamin K absence for factor II) were found in four of six samples of cord blood collected at parturition from the placenta in 12 mothers exposed to carbamazepine during pregnancy (46). Prothrombin concentrations were also reduced in the whole group. High PIVKA-II concentrations were also recorded in cord blood from a newborn exposed prenatally to phenytoin and vigabatrin, but not in two exposed to phenytoin alone and one exposed to valproate alone. These results are consistent with evidence that enzyme-inducing anticonvulsants, particularly carbamazepine, interfere with vitamin K metabolism during pregnancy and can result in bleeding disorders in the newborn. Administration of vitamin K is recommended in these newborns at time of birth or in the mother toward the end of pregnancy. The authors also discussed the possibility that vitamin K supplementation in early pregnancy might reduce the risk of fetal

© 2006 Elsevier B.V. All rights reserved.

facial dysmorphisms caused by enzyme-inducing anticonvulsants.

Gastrointestinal

Nausea, vomiting, and gastric intolerance are relatively uncommon and mild. However, there have been reports of severe diarrhea requiring drug withdrawal. Eosinophilic colitis (47) and lymphocytic colitis (SEDA-22, 85) are rare reactions.

A report of two cases has suggested that carbamazepine can cause colitis as part of the anticonvulsant hypersensitivity syndrome (48).

- A 47-year-old man developed fever, lymphadenopathy, flu-like symptoms, facial edema, a skin rash, and diarrhea after taking carbamazepine 200 mg/day for 3 weeks. Laparotomy because of severe abdominal pain 2 weeks later showed severe colitis with perforations.
- A 41-year-old woman had diarrhea, fever, and a skin rash after taking carbamazepine 300 mg/day for 4 weeks. Colitis was confirmed at colonic biopsy.

Both patients also had raised liver enzymes, peripheral eosinophilia, and eosinophils in the colonic infiltrate. Persistent recovery occurred after carbamazepine was withdrawn.

Lymphocytic colitis has been attributed to carbamazepine in a 77-year-old man, who had taken it for 6 months (49).

Liver

There have been several reports of fatal hepatic failure (SED-12, 132) (50), granulomatous hepatitis (SED-12, 132) (51–53), cholestatic hepatitis (SEDA-16, 71), and cholangitis ascribed to carbamazepine. Most acute hepatotoxic reactions caused by carbamazepine are accompanied by fever, rash, eosinophilia, and other signs of hypersensitivity, although they have also occurred without rash and eosinophilia (SEDA-19, 66).

Urinary tract

Carbamazepine-induced renal insufficiency has been described, but has not been firmly documented (SEDA-18, 63). Two diabetic patients who developed urinary retention on low doses (400–600 mg/day) were confirmed by rechallenge; there have been earlier reports, and pre-existing autonomic dysfunction may be a predisposing factor (54).

Skin

A skin rash occurs in 5–20% of patients started on carbamazepine, and is a common cause of early drug withdrawal. The rash is usually erythematous or maculopapular and may accompany systemic manifestations of hypersensitivity. Exfoliative dermatitis, Stevens–Johnson syndrome, and toxic epidermal necrolysis are relatively rare (SED-13, 148) (55,56).

There has been one case of toxic pustuloderma and two cases of lichenoid eruption attributed to carbamazepine (SEDA-16, 71) (SED-13, 148) (57–59). Patch testing for carbamazepine allergy tends to be positive only in some cases (60,61). A desensitization procedure, using gradually increasing dosages of carbamazepine over 6 weeks, has been described (SEDA-18, 64).

- A 58-year-old man developed stomatitis and widespread edematous erythema with papules and pustules after taking a combination of carbamazepine and paracetamol for 2 days, a most unusual treatment for headache and fever (62). The stomatitis improved but the eruption persisted for 2 months and was diagnosed as eosinophilic pustular folliculitis, a disorder that is rarely drug-induced. Recovery was achieved with glucocorticoid therapy.

A role of carbamazepine was suggested by reoccurrence of eosinophilic folliculitis after patch testing and low-dose (2 mg) oral rechallenge.

- A 17-year-old girl developed Stevens–Johnson syndrome after using carbamazepine 400 mg/day for 2 weeks (63). She was treated with intravenous immunoglobulin and intravenous methylprednisolone and recovered completely.

Immunologic

Hypersensitivity reactions are relatively common with carbamazepine. Most affect the skin, but systemic reactions with fever, lymphadenopathy, and/or involvement of the bone-marrow, the liver, the heart, the gastrointestinal system, the lungs, and other organs have been described. Severe serum sickness associated with immunoblastic lymphadenopathy has been reported in one case (SED-13, 148) (64). Occasional cases of systemic lupus erythematosus have occurred within the first few months, although an unusual case with onset after 8 years has been described (SEDA-22, 83).

- A 44-year-old woman, who was allergic to phenytoin, developed fever, lymphadenopathy, pneumonitis, hepatitis, and a morbilliform eruption after taking carbamazepine for 1 month (65). A skin biopsy of the dermis showed atypical lymphocytes that were CD3+, CD30+, and L26–. She improved quickly after carbamazepine was withdrawn.

This seems to have been the first report of carbamazepine-induced histological features of cutaneous pseudolymphoma, including CD30+ cells.

Cervical lymphadenopathy, fever, and a maculopapular skin rash developed in a 17-year-old boy after he had taken carbamazepine for 3 weeks (up to 600 mg/day) (66). Lymph node biopsies showed features typical of Kikuchi disease, a rare and self-limited immune-mediated lymphadenopathy that affects mostly the cervical region. The condition cleared rapidly after withdrawal.

- A 40-year-old man who had taken carbamazepine since childhood suffered for over 10 years from a lupus-like illness with hypocomplementemia, pancytopenia, and splenomegaly (67). He later developed cryoglobulinemia with membranoproliferative glomerulonephritis and raised ANA and pANCA titers. A causative role of carbamazepine in the latter syndrome was suggested by the observation that after withdrawal the antibodies fell and cryoglobulinemia resolved.

The carbamazepine hypersensitivity syndrome has been reviewed (68). Some of the following cases are examples of the different manifestations of this syndrome.

© 2006 Elsevier B.V. All rights reserved.

- A 12-year-old boy developed a maculopapular rash on two occasions after taking carbamazepine (69). A patch test was positive, but an in vitro lymphocyte transformation test was negative. However, T cells incubated with carbamazepine produced an excess of interferon-gamma.

The author proposed that this had been a delayed hypersensitivity response, perhaps mediated by a reactive metabolite.

- A 45-year-old man developed acute cardiac tamponade due to systemic lupus erythematosus associated with carbamazepine, which he had taken for 8 months (70).
- An 11-year-old girl developed a skin rash, fever, lymphadenopathy, and arthralgia after taking carbamazepine (plasma concentration 21 μmol/l) for 3 weeks (71). She had a lymphocytosis, mild thrombocytopenia, marked eosinophilia, and high transaminases. She was given betamethasone, and carbamazepine was gradually withdrawn. The fever and rash gradually abated and all the laboratory tests normalized by 2 weeks after the disappearance of the skin rash.

Long-Term Effects

Tumorigenicity

Carbamazepine and phenytoin have previously been associated with lymphoproliferative disorders, including dermatopathic lymphadenitis, atypical lymphoid proliferation, and cutaneous pseudolymphoma. In most reported cases, regression follows withdrawal of treatment with the causative drug. However, rarely true lymphoma can develop.

- A 13-year-old girl who had taken carbamazepine for about 8 months developed multiple painless reddish skin nodules, which grew and quickly ulcerated (72). The nodules were on the neck, trunk, and arms and varied in size. Neither lymphadenopathy nor splenomegaly was detected. Histology showed a CD30, primary, cutaneous, anaplastic, large-cell lymphoma. Carbamazepine was withdrawn, she received radiotherapy, and the lesions regressed. At 3 years after diagnosis she was still in complete remission.

Second-Generation Effects

Teratogenicity

Data from various studies in 1255 patients exposed to carbamazepine have been analysed to evaluate its potential teratogenicity (73). There was an increased rate of congenital anomalies, mainly neural tube defects, cardiovascular and urinary tract anomalies, and cleft palate. The combination of carbamazepine with other antiepileptic drugs was more teratogenic than carbamazepine monotherapy. Because this study was retrospective, the conclusions should not be seen as definitive.

There is an association of carbamazepine with cardiac malformations.

The Israeli Teratogen Information Service has prospectively followed 210 pregnancies with exposure to carbamazepine in the first trimester (74). The outcomes were compared with those in two overlapping groups of matched controls ($n = 629$) who had been exposed to non-teratogens. There was a two-fold increase in the rate of major congenital anomalies in the women who had used carbamazepine (12/160 on carbamazepine versus 18/560 controls; RR = 2.24; 95% CI = 1.10, 4.56) and a reduction in birth weight of about 250 g after in utero exposure to carbamazepine. There were no neural tube defects. These results are to be interpreted with caution, as they were obtained from a questionnaire in 87% of cases.

Fetotoxicity

Increased concentrations of PIVKA-II (prothrombin-induced by vitamin K absence for factor II) were found in four of six samples of cord blood collected at parturition from the placenta in 12 mothers exposed to carbamazepine during pregnancy (46). Prothrombin concentrations were also reduced in the whole group. High PIVKA-II concentrations were also recorded in cord blood from a newborn exposed prenatally to phenytoin and vigabatrin, but not in two exposed to phenytoin alone and one exposed to valproate alone. These results are consistent with evidence that enzyme-inducing anticonvulsants, particularly carbamazepine, interfere with vitamin K metabolism during pregnancy and can cause bleeding disorders in the newborn. Administration of vitamin K is recommended in these newborns at time of birth or in the mother toward the end of pregnancy. The authors also discussed the possibility that vitamin K supplementation in early pregnancy might reduce the risk of fetal facial dysmorphisms caused by enzyme-inducing anticonvulsants.

Lactation

In seven lactating women the mean concentrations of carbamazepine in milk and plasma samples were 15 and 26 μmol/l respectively; the concentrations of carbamazepine 10,11-epoxide were 5 and 8 μmol/l respectively (75). The mean milk/plasma ratios were 0.64 and 0.79 respectively. The amounts of carbamazepine and carbamazepine 10,11-epoxide that a breast-feeding child is likely to consume are thus very small.

Susceptibility Factors

Age

The elderly appear to be at increased risk of blood dyscrasias and liver reactions (39). Age above 55 years was associated with a greater risk of toxicity after rapid switch-over to a carbamazepine dosage designed to yield a plasma concentration of 10 μg/ml (76). Moderately severe to severe adverse effects in the 11 patients in either subgroup included sedation, ataxia, and confusion.

Hepatic disease

Because of the reactions described above, and because carbamazepine is mostly metabolized in the liver, it should be used with caution in patients with hepatic disorders.

© 2006 Elsevier B.V. All rights reserved.

Other features of the patient

Because of the reactions described above, carbamazepine should be used with caution in patients with cardiac disorders.

Alcohol abusers may represent a high-risk group for serious skin reactions (SED-13, 145) (39).

Carbamazepine is porphyrogenic (SED-12, 131) (77), (SED-13, 147) (78), and should not be used in patients with acute intermittent porphyria.

The presence of a static encephalopathy (defined as focal or diffuse structural brain lesions associated with mild to moderately severe cognitive dysfunction) was associated with a greater risk of toxicity after rapid switch-over to a carbamazepine dosage designed to yield a plasma concentration of 10 μg/ml (76). Moderately severe to severe adverse effects in the 11 patients in either subgroup included sedation, ataxia, and confusion.

Drug Administration

Drug formulations

When 14 patients taking a brand-named modified-release formulation of carbamazepine were switched to a generic modified-release formulation, nine developed adverse effects such as dizziness, nausea, ataxia, diplopia, and nystagmus, despite the fact that the two formulations met pharmacokinetic criteria for bioequivalence (79). Mean AUC and C_{max} values were about 10% higher with the generic formulation. The authors suggested that standard bioequivalence criteria (90% confidence limits of 80–125% for AUC and 70–143% for C_{max}) may be too broad for carbamazepine, which has a relatively narrow therapeutic ratio. While this may be correct, the findings could have been biased by the lack of a control group, lack of randomization in the sequence of the two treatments, and the use of a non-blinded design.

The suitability of a modified-release formulation of carbamazepine (Carbatrol) for administration through feeding tubes in six children has been assessed (80). Carbatrol was administered as follows: first, the tube was flushed with 10 ml of water, then the granular contents of a capsule of Carbatrol were added to 15 ml of water and administered via the tube; this was followed by an additional flush with 10 ml of water. Two of the six children had to be withdrawn from the study because of frequent tube occlusions, attributed to the Carbatrol granules.

Drug dosage regimens

The relations between plasma concentrations of carbamazepine and its two major metabolites, carbamazepine-10,11-epoxide and carbamazepine-10,11-diol, and antimanic efficacy and adverse effects in patients with schizoaffective disorder have been studied in 10 patients (81). There were positive relations between plasma concentrations of the epoxide and the degree of clinical improvement and adverse effects, but not with plasma concentrations of carbamazepine or its diol.

Drug overdose

Acute interstitial pneumonia or diffuse alveolar damage in the context of other manifestations of overdose has been described (SEDA-22, 84).

There was impaired neuromuscular transmission at high frequency repetitive nerve stimulation in two children who presented in coma with diffuse hypotonia and areflexia after carbamazepine overdose (82). Both recovered with supportive care.

Acute massive carbamazepine intoxication has been reported in a 27-year-old man (83). The plasma concentration was 147 μmol/l. He had a sinus tachycardia and a leukocytosis.

In 14 children under the age of 5 years with peak serum carbamazepine concentrations of 76–134 μmol/l after acute accidental overdose there was nystagmus in 12, drowsiness in 10, ataxia in four, and mild tachycardia in two (84). None died.

Three drug dispensing errors causing carbamazepine overdose have been reported (85). In each case carbamazepine was given instead of another drug with a similar name—Tegretol instead of Trental (pentoxifylline, two cases) and carbamazepine–Neuroxpharm instead of piracetam–Neuraxpharm. All three developed mild cerebellar symptoms and all had high carbamazepine concentrations (50–55 μmol/l).

The postmortem blood concentration of carbamazepine has been reported in a case of suicide attributed to "mixed drug toxicity" with carbamazepine, lamotrigine, paroxetine, and thioridazine (86). It was 76 μmol/l.

Drug–Drug Interactions

General

Carbamazepine is an enzyme inducer, and its own metabolism can be induced or inhibited by other drugs, particularly those affecting cytochrome CYP3A4.

Antiretroviral protease inhibitors

Some antiretroviral protease inhibitors inhibit CYP3A4, which is mostly responsible for the metabolism of carbamazepine.

- Failure of antiretroviral drug therapy has been attributed to an interaction of carbamazepine with indinavir in a 48-year-old man taking indinavir, zidovudine, and lamivudine; his HIV-RNA viral load became undetectable after less than 2 months and he developed a Herpes zoster infection (87). Lower doses of carbamazepine are also required during co-administration of ritonavir, as has been shown in two recent cases.
- Within 4 days of the introduction of ritonavir in a 49-year-old woman taking carbamazepine 600 mg/day the serum carbamazepine concentration rose from 29 to 84 μmol/l and ataxia occurred (88). The dosage of carbamazepine was reduced to 300 mg/day and the serum concentration fell but then rose again. Finally, a serum carbamazepine concentration in the target range was achieved with a dosage of 100 mg/day.

© 2006 Elsevier B.V. All rights reserved.

- The serum carbamazepine concentration rose from 27 to 76 μmol/l after ritonavir was introduced in a 36-year-old man (89). Dizziness and a gait disorder resolved when carbamazepine was withdrawn. The serum phenytoin concentration was unaffected by ritonavir.

Clobazam

Negative myoclonus and more typical signs of carbamazepine intoxication (fatigue, ataxia, clumsiness) occurred in a 66-year-old man after he took add-on clobazam (10 mg/day) for 4 weeks (90). Plasma concentrations of carbamazepine (58 μmol/l) and carbamazepine-10, 11-epoxide (19 μmol/l) were higher than before clobazam therapy, and his symptoms resolved quickly when carbamazepine dosage was reduced and clobazam was withdrawn. The interaction was confirmed on rechallenge; however, it does not occur in most patients.

Coumarin anticoagulants

Carbamazepine reduces the effects of coumarin anticoagulants (SED-14, 1185) (91,92), including phenprocoumon (SEDA-22, 86), by inducing cytochrome P450 enzymes, and another case has been reported (93).

- A 53-year-old woman taking phenprocoumon had a large reduction in prothrombin time when carbamazepine was added. After withdrawal of carbamazepine, the prothrombin time returned to target values. Valproate had no effect on phenprocoumon.

Dextropropoxyphene

Dextropropoxyphene inhibits the oxidative metabolism of carbamazepine, leading to clinically significant rises in carbamazepine concentrations (94).

Fluconazole

In a 33-year-old man stabilized on carbamazepine, the addition of fluconazole (150 mg/day) led to severe carbamazepine toxicity associated with high carbamazepine concentrations (104 μmol/l) (95). The condition cleared after withdrawal of both drugs, and carbamazepine was then readministered without recurrence of toxicity. This interaction is likely to be mediated by inhibition of the CYP3A4-mediated metabolism of carbamazepine by fluconazole.

Grapefruit juice

In 10 patients grapefruit juice 300 ml taken with the morning dose of carbamazepine resulted in an approximate 50% increase of plasma carbamazepine concentrations (96). The interaction was ascribed to inhibition of cytochrome CYP3A4 by components of the juice.

Inhibitors of epoxide hydrolase

Clinically significant interactions can be caused by inhibitors of epoxide hydrolase, such as valpromide and valnoctamide, which increase the serum concentrations of the active metabolite carbamazepine-10,11-epoxide.

Lamotrigine

In dogs concurrent administration of lamotrigine had no significant effect on the pharmacokinetics of carbamazepine or the plasma concentration ratio of carbamazepine epoxide to carbamazepine (97).

In a retrospective study, in which 376 samples from 222 patients were analysed, carbamazepine reduced lamotrigine concentrations by 54% (98).

Lithium

A 42-year-old woman developed sinus node dysfunction during lithium toxicity (serum concentration 3.4 mmol/l) (99). The authors suggested that concomitant carbamazepine therapy (serum concentration 22 μmol/l) had exacerbated the effect of lithium on the sinus node.

Mianserin

In 12 patients, carbamazepine (400 mg/day for 4 weeks) markedly reduced the plasma concentrations of concomitantly administered mianserin, probably through enzyme induction (100). The concentration of *S*-mianserin, the more potent of the enantiomers of mianserin, fell by 45%, while the plasma concentrations of desmethylmianserin changed only slightly. These data suggest that patients co-medicated with carbamazepine may require higher dosages of mianserin.

Monoamine oxidase inhibitors

Carbamazepine is contraindicated in patients taking monoamine oxidase inhibitors (101,102). The combination can cause sudden high body temperature, extremely high blood pressure, and severe convulsions; at least 14 days should be allowed between stopping treatment with one medicine and starting the other.

Nefazodone

The pharmacokinetic interaction of nefazodone 200 mg bd with steady-state carbamazepine has been investigated in 12 healthy men (103). Nefazodone increased the steady-state plasma AUC of carbamazepine by 23% and reduced the AUC of active carbamazepine-10,11-epoxide by 20%. The steady-state AUC of nefazodone fell 14-fold and the AUCs of its metabolites (hydroxynefazodone, metachlorophenylpiperazine, and triazoledione) also fell significantly. Thus nefazodone had a small inhibitory effect on carbamazepine metabolism, while carbamazepine greatly increased the metabolism of nefazodone.

Olanzapine

In 11 healthy volunteers carbamazepine (400 mg/day for 2 weeks) reduces by about 30% the AUC of olanzapine, presumably by induction of olanzapine metabolism (104). Although the interaction was considered of little relevance, it cannot be excluded that some patients on carbamazepine may require higher olanzapine dosages than usual.

© 2006 Elsevier B.V. All rights reserved.

Rifampicin

Serum carbamazepine concentrations were reduced in a 44-year-old woman who also took rifampicin (105), presumably through induction of metabolism.

Risperidone

Risperidone significantly increases serum carbamazepine concentrations (106) and carbamazepine significantly reduces serum risperidone concentrations (107). The clinical relevance of these changes is uncertain.

Steady-state plasma concentrations of risperidone and 9-hydroxyrisperidone have been measured in 23 patients taking risperidone alone and in 11 patients co-medicated with carbamazepine (108). Carbamazepine markedly reduced the concentrations of both compounds, although the difference was significant only for the metabolite.

Sertraline

Loss of antidepressant activity of sertraline can occur at usual therapeutic doses when depressed patients have also taken drugs that induce CYP3A4, including carbamazepine, as has been reported in two cases, a 33-year-old woman and a 25-year-old man (109).

St. John's wort

St. John's wort contains an enzyme inducer that can reduce the plasma concentrations of drugs that are substrates of CYP3A4, such as indinavir and ciclosporin. However, in eight healthy volunteers aged 24–43 years, St. John's wort 300 mg/day (0.3% hypericin standardized tablet) for 14 days had no effect on the pharmacokinetics of carbamazepine (110).

Trazodone

In one case trazodone increased serum carbamazepine concentrations by about 30% (111). However, only one sample was taken after adding trazodone, and the rise in carbamazepine concentration might have been caused by random fluctuation.

Ziprasidone

In 25 healthy subjects, carbamazepine (up to 400 mg/day for 25 days) reduced the steady-state AUC of ziprasidone (40 mg/day) by about 35%, presumably through induction of the CYP3A4-mediated metabolism of the neuroleptic drug (112). Although the interaction was considered clinically insignificant, the dosage of carbamazepine was relatively low and a greater effect might occur at higher dosages.

The effect of steady-state carbamazepine administration on the steady-state pharmacokinetics of ziprasidone has been studied in 25 healthy young adults, in a randomized, placebo-controlled study (112). Carbamazepine caused small reductions in ziprasidone $AUC_{0\rightarrow12}$ and C_{max} (36% and 27% respectively). The authors concluded that carbamazepine had increased ziprasidone clearance by induction of CYP3A4.

Diagnosis of Adverse Drug Reactions

The usual target range for plasma carbamazepine concentrations is 17–42 μmol/l (4–10 μg/ml).

Carbapenems

See also Beta-lactam antibiotics

General Information

Carbapenems differ from penicillins and cephalosporins by a methylene substitution for sulfur in the five-membered beta-ring structure. Imipenem and meropenem belong to this class of compounds.

In the last 25 years, various natural carbapenems have been discovered (1). However, their potential is limited by chemical instability. Imipenem (*N*-formimidoylthienamycin), the first carbapenem in use, is therefore a stabilized synthetic compound. To overcome a second difficulty, namely inactivation by a kidney dehydropeptidase, imipenem has to be combined with cilastatin, a competitive inhibitor of that enzyme. Meropenem has better stability in the presence of renal dehydropeptidase I (2). The antibacterial spectrum of carbapenems is among the broadest of all beta-lactam antibiotics, and they have good stability against many beta-lactamases.

General adverse reactions

The safety profile of the carbapenems is comparable to that of other beta-lactam antibiotics, in particular with regard to laboratory abnormalities, the most common ones being those related to liver function (3,4). In patients with pre-existing nervous system disease or who take dosages above the recommended limits (for example in renal impairment) seizures appear to be more common with imipenem + cilastatin.

Organs and Systems

Nervous system

Seizures associated with imipenem + cilastatin have repeatedly been reported (5–7). As with other beta-lactam antibiotics, it is difficult to assess clearly the cause of a seizure in patients with a cluster of other predisposing factors for neurotoxicity (8) and hence to reach clear estimates of frequency. In a review of 1754 patients there was a similar incidence of seizures with imipenem + cilastatin as with other antibiotic regimens usually containing another beta-lactam (9). In rabbits imipenem + cilastatin and another carbapenems were more neurotoxic than benzylpenicillin (10). In mice, ataxia and seizures were seen, with much lower blood concentrations of imipenem than cefotaxime or benzylpenicillin (1900 μg/ml versus 3400 μg/ml and 5800 μg/ml) (11). In mice imipenem also lowered the convulsive threshold of pentetrazol (pentylenetetrazole) more than cefazolin or two other carbapenems (12). Cilastatin alone was not proconvulsant, but it increased the effects of co-administered imipenem.

Imipenem is a more common cause of seizures than other beta-lactam antibiotics, particularly when high doses are given (13–15). In one study, seven of 21 children developed seizure activity while receiving imipenem + cilastatin for bacterial meningitis, a recognized risk factor (13). However, computer-assisted monitoring of imipenem + cilastatin dosages in relation to renal function resulted in a reduced incidence of seizures (16).

In animals, meropenem (17) and other carbapenems (18,19) were less epileptogenic than imipenem. In 403 children there was no meropenem-associated neurotoxicity (20) and meropenem was well tolerated in children with bacterial meningitis (21). In summary, a larger dose range of meropenem than imipenem appears to be tolerated, but when strictly observing known risk factors for seizure propensity the difference between the two compounds is very small (22,23).

Sensory systems

Taste alterations were seen in some early patients who were treated with carbapenems (24); these observations have not subsequently been confirmed.

© 2006 Elsevier B.V. All rights reserved.

Hematologic

As with some cephalosporins and clavulanic acid, the Coombs' test was positive in a number of patients taking carbapenems, but without hemolysis (25).

Mouth and teeth

Yellowish-brown staining of the teeth was related to imipenem in several cases (26,27). Staining was mostly removable with dental assistance.

Urinary tract

In animals, the tubular toxicity of imipenem was completely prevented by cilastatin. Accordingly, definite nephrotoxicity of this combination has not been documented in patients (25) or in healthy volunteers (28). The cilastatin component may even reduce the nephrotoxic effects of ciclosporin after kidney transplantation (29) or bone marrow transplantation (30).

Skin

Of all the drugs that have been implicated in drug-induced toxic epidermal necrolysis, antimicrobial drugs account for 29–42% (now more than 100 in number) (31,32), and almost all antimicrobial drugs have been implicated, including meropenem (33).

- A 75-year-old woman developed acute pneumonia. She was first given oral co-amoxiclav, fluconazole, and ciprofloxacin for 10 days, followed by cefotaxime and amikacin, both intravenously. Six days later, she developed a progressive erythematous rash, soon involving 40% of her body surface. The antibiotics were withdrawn and she was rehydrated and given intravenous immunoglobulins 0.75 g/kg for 5 days, but not systemic glucocorticoids. She then developed severe septic shock because of a combination of two very resistant bacterial strains and was given meropenem 1 g and teicoplanin 800 mg bd. However, within 2 days her skin lesions recurred, extending to previously uninvolved skin areas and including over 60% of her body. A biopsy showed typical features of toxic epidermal necrolysis. Meropenem was withdrawn and replaced by aztreonam. However, she died 5 days later.

Imipenem, which is related to meropenem, has also been reported to cause toxic epidermal necrolysis (34). The authors stated that to the best of their knowledge, this was the first report of a possible cross-reaction between two classes of antibiotics in causing toxic epidermal necrolysis. The time between first administration and the occurrence of epidermal necrolysis is considerably shorter in recurrence or provocation testing (35,36). They also claimed that it is likely that the beta-lactam ring is responsible for this hypersensitivity reaction, citing the evidence that the patient had been given amoxicillin 15 days before the cephalosporin, and that could have served as the sensitizing event. They did not discuss whether aztreonam, a monobactam, also could have caused a cross-reaction; however, it has been involved in two cases of fatal toxic epidermal necrolysis (37).

A pustular rash, as repeatedly observed with cephalosporins, has been described in one case (38). The frequencies of rash, urticaria, and pruritus were similar to those seen with other beta-lactam antibiotics (25).

Meropenem can cause occupational allergic contact dermatitis (39).

- A 45-year-old nurse presented with a 6-month history of recurrent periorbital erythema with itching and runny eyes. Each episode lasted about 5–6 days and settled on withdrawal from her place at work, where she handled a large number of drugs, including meropenem. She was patch-tested with the European standard series, and was negative to all except meropenem. She had complete remission after quitting her workplace.

The authors assumed that the localization to the periorbital region was due to involuntary contact with her hands or airborne contact.

Immunologic

There was a high degree of cross-reactivity between imipenem determinants, analogous to the penicillin determinants in penicillin-allergic patients. Nine of twenty patients with positive penicillin skin tests had positive skin reactions to analogous imipenem determinants (40). In view of this appreciable cross-reactivity, imipenem should not be given to patients with penicillin allergy.

Immediate hypersensitivity related to imipenem has been reported in a patient allergic to penicillin and aztreonam (41).

Drug–Drug Interactions

Ciclosporin

The addition of imipenem + cilastatin to long-term ciclosporin provoked seizures in patients without a corresponding history (42). In general, nervous system toxicity occurred shortly after the start of the antibiotic therapy and drug concentrations were stable, suggesting a synergistic effect.

Ciclosporin-induced acute nephrotoxicity was reduced by cilastatin, an inhibitor of active tubular resorption (30,43). Reduced renal parenchymal accumulation of the drug may account for this effect. Serum ciclosporin concentrations were unchanged or insignificantly reduced. A similar protective effect against tacrolimus is possible, but unproven (44).

GABA receptor antagonists

Carbapenems (imipenem more than meropenem) are believed to increase central nervous system excitation by inhibition of GABA binding to receptors. Combinations with other GABA inhibiting drugs such as theophylline or quinolones have been reported to provoke seizures (45,46).

Valproic acid

Two carbapenems, meropenem and panipenem + betamipron, reduced serum valproic acid concentrations, and increased the risk of seizures (47,48). The mechanism of the interaction was unclear. Accelerated

© 2006 Elsevier B.V. All rights reserved.

renal elimination of valproic acid is probable, since the almost immediate fall in serum drug concentrations and low protein binding of carbapenems argue against enzyme induction or protein binding displacement (49).

Interference with Diagnostic Tests

Leukocyte urine dipstick test

Imipenem caused positive dipstick tests for leukocytes in patients with agranulocytosis and normal urinary sediments. This phenomenon was reproducible in vitro with imipenem, meropenem, and clavulanic acid. Sulbactam, tazobactam, three penicillins, three cephalosporins, and the basic structures of penicillins, cephalosporins, and monobactams tested negative (50).

Carbenoxolone

General Information

Liquorice owes its ulcer-healing properties to glycyrrhizin and glycyrrhizic acid; carbenoxolone is related to the latter. All these substances have unwanted mineralocorticoid-like effects. Deglycyrrhizinated liquorice and lauryl glycyrrhetinic acid, which are also used in some countries for their ulcer-healing effects, do not have mineralocorticoid-like effects. It should be noted that liquorice is sometimes present in laxatives, for example those prepared by herbalists, and that hyperaldosteronism can occur unexpectedly in such cases when liquorice consumption has gone unrecognized (SEDA-16, 425). For example, hypokalemia and hypertension has been associated with the use of liquorice flavored chewing gum (1).

Organs and Systems

Endocrine

- Hyperprolactinemia occurred in a woman with secondary amenorrhea and hypertension who was taking large amounts of liquorice; all the abnormalities reversed on withdrawal (2).

This effect could have reflected involvement of prolactin in adrenal steroidogenesis or salt and water homeostasis.

Electrolyte balance

The mineralocorticoid properties of carbenoxolone are probably exerted by displacement of aldosterone from non-specific receptor sites in cells, thus making it more available to affect mineral metabolism. What this means in practice is that in normal doses carbenoxolone can cause salt and water retention, with occasional hypokalemia. These effects are common but usually mild; they are detected more often during treatment if patients are weighed, their blood pressure measured, and serum potassium concentrations checked. Those who take prolonged courses, elderly patients, and those with hepatic, cardiac, or renal impairment are at special risk; severe effects, with serious hypertension, heart failure, and hypokalemia of sufficient degree to induce myopathy and tubular necrosis, can usually be ascribed to ill-advised treatment of people in whom carbenoxolone is contraindicated, to its use in elderly patients, or to prolonged intake without supervision.

Liquorice-induced pseudohyperaldosteronism can cause hypokalemic myopathy (3).

- A 65-year-old man, diabetic and alcoholic, developed pseudohyperaldosteronism with hypokalemia, myopathy, and a reversible dilated cardiomyopathy associated with a small dose of liquorice-containing stomachics (0.06 of liquorice extract in total granules of 3 g/day) over a few years for gastritis and a total of 800 mg of glycyrrhizin intravenously over 2 months for worsening liver dysfunction.

© 2006 Elsevier B.V. All rights reserved.

Drug–Drug Interactions

Amiloride

Amiloride inhibits the ulcer-healing action of carbenoxolone (SEDA-6, 317).

Antihypertensive drugs

Because of its mineralocorticoid fluid-retaining properties, carbenoxolone opposes the therapeutic effects of diuretics and other drugs used to treat hypertension.

Spironolactone

Spironolactone inhibits the ulcer-healing action of carbenoxolone (SEDA-6, 317).

Carbocisteine

General Information

Carbocisteine is a mucolytic that is administered orally or from a metered dose inhaler. Its adverse effects include headache, nausea, vomiting, gastric discomfort and bleeding, diarrhea, and skin rash. It has, however, been shown to be an effective mucolytic which is generally well tolerated with few adverse effects (SEDA-17, 208).

The place of mucolytic drugs in respiratory disease has recently been reviewed (1). The authors suggested that they have been inappropriately used in the past. As mucolytic agents do not improve lung function tests in COPD, the European Respiratory Society and the American Thoracic Society guidelines discourage their use in the treatment of COPD. Future trials should evaluate clinical symptoms and quality of life as well as lung function tests. Mucolytic agents should be evaluated earlier in the natural history of COPD, when mucus hypersecretion is the major feature and before lung function has deteriorated.

Carbon dioxide

General Information

Alternatives to iodinated X-ray contrast agents have been sought for cases in which they are contraindicated. One such agent is carbon dioxide (CO_2), a highly soluble gas, which is therefore relatively safe to inject into the circulation, where it displaces blood and reduces X-ray absorption, acting as a negative contrast agent (SEDA-20, 423) (1). No complication of any kind was reported with the use carbon dioxide in aortography or peripheral angiography (SEDA-20, 423).

In a UK study the safety and diagnostic efficacy of carbon dioxide as an arterial contrast agent have been investigated in 63 patients (36 men and 27 women, aged 46–86 years) who underwent angiographic examinations with carbon dioxide via an automated injector and iodinated contrast medium (2). There were adverse effects in 15 patients, including nausea ($n = 4$), abdominal pain ($n = 8$), and leg and groin pain ($n = 8$). All the symptoms were directly related to the injection of carbon dioxide and resolved within 1–2 minutes of injection. No arteriogram had to be abandoned because of adverse effects, and the incidence of adverse reactions was less with selective studies. Although it has been reported that carbon dioxide is well tolerated, with minimal discomfort, in this study there was a variety of mild to severe unpleasant symptoms, but no serious complications. The abdominal symptoms were related to the passage of a large volume of carbon dioxide into the mesenteric vessels. The catheter was above the mesenteric vessels in most of the patients with abdominal symptoms. These symptoms can be reduced by placing the tip of the catheter in non-selective studies at the aortic bifurcation to reduce the amount of carbon dioxide that passes into the superior or inferior mesenteric arteries. The symptoms are also reduced by injecting smaller volumes. The authors concluded that when iodinated contrast media are contraindicated carbon dioxide provides a diagnostic alternative.

The safety of carbon dioxide in vena cavography has been investigated in 119 patients (aged 17–89 years, 65 men). Patients with intracardiac shunts, severe pulmonary compromise, or non-dialysis-dependent renal insufficiency were excluded. Two patients developed mild adverse effects: one had nausea that resolved spontaneously and the other vomited several minutes after the administration of carbon dioxide but needed no treatment. The diagnostic quality of the venography was comparable to that with iodinated contrast media. The authors concluded that carbon dioxide cavography is well tolerated and is especially valuable in patients with a history of a reaction to iodinated contrast material or renal insufficiency.

Carbonic anhydrase inhibitors

General Information

The carbonic anhydrase inhibitors, of which acetazolamide (rINN), a non-competitive inhibitor, is the prototype, are not suitable for normal diuretic use, because tolerance soon develops. However, they are well suited to brief intermittent use, particularly in the relief of glaucoma and in the prevention of acute mountain sickness. Acetazolamide and methazolamide (rINN) should be used with caution in the long-term control of glaucoma because of its serious systemic adverse effects. However, brinzolamide (rINN) and dorzolamide (rINN) are available for long-term topical administration.

The safety profile and efficacy of 2% dorzolamide hydrochloride (Trusopt) eye-drops have been evaluated. It was as effective as pilocarpine 2% and its ocular hypotensive efficacy was comparable with that of betaxolol 0.5%. The patients reported less interference with quality of life with dorzolamide than pilocarpine, particularly in regard to limitations in their ability to drive, read, and perform moderate activities. Long-term use was not associated with important electrolyte disturbances or the systemic effects commonly observed with oral carbonic anhydrase inhibitors (1–3).

In a 3-month prospective study of the adverse effects and efficacy of topical dorzolamide in 39 patients intolerant of systemic carbonic anhydrase inhibitors, the effect on mean intraocular pressure was similar to that of acetazolamide, and health assessment scores improved significantly in seven of the eight categories of the SF-36 health assessment questionnaire used to evaluate changes in well-being and quality of life (4). There were no adverse effects with the switch in medication.

General adverse effects

The incidence and severity of many adverse reactions to carbonic anhydrase inhibitors are dose-related and the problems usually abate when the dose is reduced or the drug is withdrawn. Symptoms of depression, confusion, fatigue, impotence, irritability, malaise, nervousness, and weight loss are often present to some extent in patients on long-term acetazolamide or methazolamide therapy. These symptoms may be related to systemic metabolic acidosis (due to renal excretion of bicarbonate), which is often accompanied by a reduction in serum potassium concentration (5). Gastrointestinal intolerance, manifested as abdominal cramping, dyspepsia, and nausea, with or without diarrhea, is another common problem. Carbonic anhydrase inhibitors reduce the urinary excretion of citrate and uric acid, which may lead to renal calculi and gouty arthritis. Pulmonary edema, taste disorders, and alopecia have also been reported. The most serious adverse effect of carbonic anhydrase inhibitors is bone-marrow depression.

Organs and Systems

Cardiovascular

Anaphylactic shock has been reported after a single oral dose of acetazolamide (6).

- A 70-year-old man was given acetazolamide 250 mg to control postoperative intravascular pressure 5 hours after cataract removal under local anesthetic. Thirty minutes later he complained of nausea, became cyanotic, and had an acute respiratory arrest. His systolic blood pressure was 70 mmHg, his heart rate was 180/minute, and there was tachypnea (40 breaths/minute). Arterial gases confirmed hypoxemia (PaO_2 6.34 kPa, 47 mmHg). Pulmonary embolism and high-pressure pulmonary edema were excluded by perfusion lung scanning and right-sided heart catheterization. Management was with ventilatory support, vasopressors, intravenous hydrocortisone, and diphenhydramine. Clinical improvement occurred over 12 hours. After stabilization, sulfonamide hypersensitivity was confirmed by skin testing, suggesting cross-sensitivity with a sulfonamide derivative (acetazolamide).

Physicians should be aware of the risk of anaphylaxis to acetazolamide, particularly in patients with a history of allergy to sulfonamides.

Nervous system

A case of possible Gerstmann syndrome has been attributed to acetazolamide (7).

- A 60-year-old woman became acutely confused 2 days after the removal of a cataract. She had long-standing diabetes mellitus, hypertension, and ischemic heart disease. There had been a minor stroke with complete recovery 2 years before. Her medication included aspirin, indapamide, enalapril, and oral hypoglycaemic agents. Acetazolamide 500 mg bd was added shortly after her eye operation. Neurological examination showed finger agnosia, nominal and receptive dysphasia, acalculia, astereognosis, and left–right disorientation. Other systems were normal. Withdrawal of acetazolamide resulted in rapid improvement with no residual neurological signs two days after admission.

Acetazolamide toxicity was suspected, because of the temporal association between drug treatment and the onset of the neurological symptoms, together with metabolic acidosis. Gerstmann syndrome is usually due to an acute stroke. Although a brain CT scan was negative, such an event was likely in this patient, who had a history of cerebrovascular disease and multiple risk factors, and a causal relation to acetazolamide must be considered tenuous.

Sensory systems

Eyes

In a multicenter, double-blind, prospective, parallel-group comparison of brinzolamide 1.0% bd or tds, dorzolamide 2.0% tds, and timolol 0.5% bd in 572 patients with

© 2006 Elsevier B.V. All rights reserved.

primary open-angle glaucoma or ocular hypertension, the three drugs were equally effective (8). Brinzolamide 1.0% caused less ocular discomfort (burning and stinging) (bd 1.8%; tds 3.0%) than dorzolamide (16%).

- A 68-year-old woman developed bilateral marginal keratitis 2 weeks after starting to use dorzolamide eye-drops (9). One week after withdrawal she was asymptomatic, with complete resolution of her corneal infiltrates.

In this case the allergic reaction was caused by dorzolamide hydrochloride and not the preservative, benzalkonium chloride, since therapy was uneventfully continued with timolol maleate, which also contains benzalkonium chloride as a preservative. This is the first report of this phenomenon with a carbonic anhydrase inhibitor.

Taste

Acetazolamide can cause altered taste perception of carbonated drinks. The mechanism is unknown, but carbonic drinks may be a source of high concentrations of carbonic acid, which are reduced by carbonic anhydrase activity (SEDA-15, 219).

Endocrine

Thyrotoxic periodic paralysis occurs only occasionally in Caucasians, but for unknown reasons it can be worsened by acetazolamide (SEDA-15, 219).

Electrolyte balance

The carbonic anhydrase inhibitors are the most kaliuretic of all diuretics and can cause severe hypokalemia during the first few days of administration. However, hypokalemia is not a problem during long-term administration, because of compensatory potassium retention secondary to acidosis (10).

- A 46-year-old man with hypokalemic periodic paralysis and diabetes mellitus had worse muscle weakness after taking acetazolamide, possibly because of reduced muscle uptake of potassium (11).

Acid–base balance

Acetazolamide can produce severe lactic acidosis, with an increased lactate:pyruvate ratio, ketosis with a low beta-hydroxybutyrate:acetoacetate ratio, and a urinary organic acid profile consistent with pyruvate carboxylase deficiency. The acquired enzymatic injury that results from inhibition of mitochondrial carbonic anhydrase V, which provides bicarbonate to pyruvate carboxylase, can damage the tricarboxylic acid cycle.

Four preterm neonates with posthemorrhagic ventricular dilatation developed severe metabolic acidosis after being given acetazolamide (12). The acidosis suddenly disappeared after a transfusion of packed erythrocytes, which was attributed to the citrate contained in the blood.

Acetazolamide can cause a metabolic acidosis in 50% of elderly patients (SEDA-11, 199); occasionally (particularly if salicylates are being given or renal function is poor) the acidosis can be severe. It does this by inhibiting renal bicarbonate reabsorption. This effect is of particular use in treating patients with chronic respiratory acidosis with superimposed metabolic alkalosis. Life-threatening metabolic acidosis is rarely observed in the absence of renal insufficiency and/or diabetes mellitus. In three patients with central nervous system pathology alone conventional doses of acetazolamide resulted in severe metabolic acidosis (13). After withdrawal it took up to 48 hours for the metabolic acidosis and accompanying hyperventilation to resolve.

Metabolic acidosis has also been described with the topical carbonic anhydrase inhibitor dorzolamide.

- A 5-day-old boy, weighing 2.3 kg, developed a metabolic acidosis after receiving topical dorzolamide for 1 week for bilateral Peter's anomaly (a congenital corneal disorder characterized by a central leukoma and adhesions at the periphery of the corneal opacity) (14). The maximum base deficit was 20.2 mmol/l. On withdrawal of topical dorzolamide his acidosis resolved within 1 day.

Factors that may have contributed to this metabolic acidosis included low birth weight, renal tubular immaturity, and impaired renal function, which may have resulted in systemic accumulation with repetitive dosing. This case stresses the fact that topical medications can cause systemic effects if a sufficient amount of drug is absorbed in a susceptible subject.

Hematologic

Aplastic anemia occurs in about one in 18 000 patient-years of exposure to oral carbonic anhydrase inhibitors. Most cases occur within the first 6 months, and peak at 2–3 months.

Eleven cases of acetazolamide-associated aplastic anemia were reported in Sweden during a 17-year period (15). The median dose was 500 mg/day and the median duration of therapy was 3 (2–71) months. Ten of the eleven patients died within 8 weeks of diagnosis. The relative risk of aplastic anemia with acetazolamide was 13.3 (95% CI = 6.8, 25) and the estimated frequency was 1 in 18 000. These findings suggest that acetazolamide is associated with a substantially increased risk of aplastic anemia.

However, the National Registry of Drug-Induced Ocular Side Effects has not received a report of blood dyscrasias in patients who have taken oral carbonic anhydrase inhibitors for less than 2 weeks (16). Since there is generally some time before abnormal blood counts progress to bone-marrow failure, seeking a symptomless "early window" is precisely the point of routine hematological screening; thus, patients taking long-term oral carbonic anhydrase inhibitors should have erythrocyte, leukocyte, and platelet counts bimonthly during the first 6 months of therapy and then every 6 months thereafter. Routine hematological surveillance should always be accompanied by patient education about warning signs and symptoms of progressive marrow failure.

Urinary tract

In a French analysis of 22 510 urinary calculi performed by infrared spectroscopy, drug-induced urolithiasis was divided into two categories: first, stones with drugs

© 2006 Elsevier B.V. All rights reserved.

physically embedded ($n = 238$; 1.0%), notably indinavir monohydrate ($n = 126$; 53%), followed by triamterene ($n = 43$; 18%), sulfonamides ($n = 29$; 12%), and amorphous silica ($n = 24$; 10%); secondly, metabolic nephrolithiasis induced by drugs ($n = 140$; 0.6%), involving mainly calcium/vitamin D supplementation ($n = 56$; 40%) and carbonic anhydrase inhibitors ($n = 33$; 24%) (17). Drug-induced stones are responsible for about 1.6% of all calculi in France. Physical analysis and a thorough drug history are important elements in the diagnosis.

Skin

Two Japanese-American women developed clinical features that satisfied the criteria for Stevens–Johnson syndrome during methazolamide treatment (18). Methazolamide is a sulfonamide, the most common group of drugs associated with Stevens–Johnson syndrome.

Topical dorzolamide caused severe periorbital dermatitis after an average exposure time of 20 weeks in 14 patients (19). Although dermatitis due to dorzolamide can resolve when it is withdrawn, this does not always occur, and in some patients all topical medications containing benzalkonium chloride must be withdrawn. Allergic contact blepharoconjunctivitis has also been reported with dorzolamide in a 72-year-old man (20).

Musculoskeletal

Chronic acetazolamide therapy is associated with greater spinal bone mineral density. This is probably the result of metabolic acidosis; urine calcium is increased and serum phosphate reduced. Osteomalacia has been reported during long-term therapy in combination with barbiturates in two patients.

Immunologic

Fatal anaphylactic shock with massive pulmonary edema has been reported in a 66-year-old woman who was taking acetazolamide for glaucoma (21). She had a history of sulfonamide allergy, and acetazolamide is a sulfonamide derivative. Sulfonamide allergy should be regarded as a contraindication to acetazolamide.

- Non-fatal anaphylactic shock with acute pulmonary edema has been reported in a 79-year-old woman after a first dose of acetazolamide (22). There was no history of sulfonamide allergy and she had been taking hydrochlorothiazide for some time.

Anaphylactic shock with acetazolamide should be recognized to occur as a first-dose phenomenon with no prior demonstrable sulfonamide allergy.

Long-Term Effects

Drug tolerance

Acetazolamide alkalinizes the urine and increases its volume. Urinary sodium, potassium, and bicarbonate concentrations rise, and chloride concentration falls. These effects are due to inhibition of carbonic anhydrase in the nephron, mainly in the proximal convoluted tubule, which reduces the number of protons available for Na/H antiporter exchange. Consequently, the concentration of bicarbonate in extracellular fluids falls, causing a metabolic acidosis, which itself limits the diuretic response to acetazolamide. Thus, the initial kaliuretic effect is lost within a few weeks.

Second-Generation Effects

Teratogenicity

Possible teratogenicity due to acetazolamide resulted in one case of congenital glaucoma, microphthalmia, and patent ductus arteriosus and one case of sacrococcygeal teratoma. One child was born with acidosis, hypercalcemia, and hypomagnesemia; these features resolved rapidly, but at 8 months there was mild hypotonicity of the legs. It has been suggested that acetazolamide should be avoided in the first trimester of pregnancy (SEDA-21, 228).

Fetotoxicity

The use of acetazolamide in pregnancy is ill-advised.

- Renal tubular acidosis occurred in a preterm boy shortly after birth (23). His mother had taken oral acetazolamide during pregnancy for glaucoma. When renal tubular acidosis developed, acetazolamide was detected in his serum, demonstrating transplacental passage of acetazolamide.

Susceptibility Factors

Carbonic anhydrase inhibitors should be used with caution in patients with respiratory acidosis or those with severe loss of respiratory capacity, and in patients with diabetes mellitus. They are contraindicated in patients with hepatic disease or insufficiency, reduced serum concentrations of sodium or potassium, adrenocortical insufficiency, hyperchloremic acidosis, or severe renal disease or dysfunction. They should also be avoided in patients taking salicylates.

Drug Administration

Drug administration route

Brinzolamide eye-drops can cause transient blurred vision (24).

Dorzolamide eye-drops can cause irreversible corneal edema in glaucoma patients with endothelial compromise (25).

Drug overdose

Overdosage with acetazolamide can destroy the gastric mucosal barrier, by interfering with prostaglandin and bicarbonate release, and can cause thrombocytopenia by bone marrow suppression, eventually leading to hemorrhagic gastritis. Although acetazolamide binds strongly to plasma proteins, and clearance by hemodialysis is generally poor, this approach and hemoperfusion (without heparin) appears to be effective (SEDA-22, 236).

© 2006 Elsevier B.V. All rights reserved.

Acetazolamide overdose has been reported in a child.

- A 12-month-old girl, weighing 10 kg, developed metabolic acidosis after taking 500–1250 mg of acetazolamide (26). The maximum base deficit recorded was 11.6. She was treated with sodium bicarbonate and recovered completely.

Accidental poisoning with acetazolamide should be included in the differential diagnosis of metabolic acidosis.

Drug–Drug Interactions

Furosemide

Acetazolamide inhibits cerebrospinal fluid production, and its effects are augmented by furosemide, suggesting a role for this combination in infants with ventricular dilatation resulting from severe periventricular hemorrhage. The International Posthaemorrhagic Ventricular Drug Trial Group has reported the results of a randomized, controlled trial of standard therapy alone or with the addition of acetazolamide plus furosemide in the first 151 of 177 randomized patients (27). The addition of acetazolamide plus furosemide was not only ineffective but also worsened the already poor outcome in these infants. At 1 year, death and the need for shunt placement were substantially commoner in the diuretic-treated group. There were adverse events (for example acidosis, nausea, anorexia, and diarrhea) in 37% of those given acetazolamide plus furosemide; in addition, 27% developed nephrocalcinosis (SEDA-21, 228). Altered cerebral blood flow due to acetazolamide may have caused additional brain injury.

In a commentary on this trial (28) it was pointed out that the use of acetazolamide alone or with furosemide in the treatment of posthemorrhagic hydrocephalus is another example of the use of untried therapy in neonatal care. The safety and efficacy of acetazolamide in children has never been established.

Salicylate

Two elderly patients developed lethargy, confusion, and incontinence, attributed to an interaction between acetazolamide and salicylate (29). Salicylate may reduce acetazolamide clearance by inhibiting its renal tubular secretion. Analgesic doses of salicylates should probably be avoided in elderly patients taking acetazolamide.

- A 50-year-old woman with chronic renal insufficiency treated with acetazolamide for simple glaucoma developed confusion, cerebellar ataxia, and metabolic acidosis 2 weeks after starting to take aspirin for acute pericarditis (30). A diagnosis of salicylism was made despite low serum salicylate concentrations.

The authors suggested that acetazolamide-induced acidosis increases the concentration of the unionized form of salicylate, which crosses membranes more rapidly, and hence explains the cerebral toxicity associated with low serum concentrations of salicylate. However, an increase in the plasma or erythrocyte concentrations of acetazolamide (not measured) is a much more convincing explanation for this patient's symptoms.

Other Environmental Interactions

Ketogenic diet

A ketogenic diet is sometimes used to control intractable seizures. Acetazolamide should be discontinued before starting the diet, because of the potential risk of severe secondary metabolic acidosis (31). Acetazolamide can be reintroduced once the acid–base status of the patient has stabilized.

Interference with Diagnostic Tests

HPLC assays for theophyline

Acetazolamide interferes with certain HPLC assays for theophylline, leading to spuriously increased theophylline concentrations (SEDA-21, 228).

Carboprost

See also Prostaglandins

General Information

Carboprost is a 15-methylated analogue of $PGF_{2\alpha}$. It is used in termination of pregnancy, in the management of labor, and to treat postpartum hemorrhage and uterine atony.

Organs and Systems

Respiratory

Pulmonary edema has been attributed to carboprost (1).

- An 18-year-old woman at 37 weeks gestation was given prostaglandin E_2 gel for cervical ripening followed by oxytocin. After delivery by cesarean section uterine atony, which did not respond to oxytocin and methylergometrine maleate, was treated with intramyometrial 15-methyl-prostaglandin $F_{2\alpha}$ 0.25 mg. After 5 minutes, her SpO_2 fell to 89 and she had dyspnea and sinus tachycardia due to acute pulmonary edema.

Gastrointestinal

Vomiting is a common adverse effect of $PGF_{2\alpha}$ (2).

Reproductive system

Uterine rupture has been reported after intramuscular injection of carboprost to terminate a mid-trimester pregnancy (3).

Drug Administration

Drug overdose

A neonate was accidentally given a large dose of carboprost and recovered (4).

- A full-term neonate was accidentally given carboprost 250 μg intramuscularly in an error for hepatitis vaccine. Within 15 minutes, he became tachypneic and hypertensive and then developed bronchospasm and dystonic movements and/or seizure activity in the arms. He was hyperthermic and had diarrhea. He recovered within 18 hours.

Cardiac glycosides

General Information

Many aspects of the pharmacology, clinical pharmacology, and adverse effects and interactions of cardiac glycosides have been reviewed (1–12).

Note on nomenclature

The most commonly used cardiac glycosides, digoxin and digitoxin, are derived from foxgloves, respectively *Digitalis lanata* and *Digitalis purpurea*. For this reason they are generally known as "digitalis." Most other cardiac glycosides, such as ouabain and proscillaridin, do not come from foxgloves but are nevertheless also commonly called "digitalis." Thus, the terms "cardiac glycoside" and "digitalis" are used interchangeably.

The cardiac glycosides that have been used therapeutically are listed in Table 1.

Mechanisms of digitalis toxicity

There is a large amount of evidence that the mechanisms of action of cardiac glycosides are mediated directly or indirectly by inhibition of the sodium/potassium pump enzyme, Na/K-ATPase (13). Their toxic effects on the myocardium may be due to excessive inhibition of cardiac Na/K-ATPase, although there is also evidence that effects on the nervous input to the heart may be involved (14), and it is not clear to what extent such an effect is mediated by inhibition of Na/K-ATPase. However, color vision disturbances associated with cardiac glycosides are due to inhibition of Na/K-ATPase (15).

Table 1 Cardiac glycosides that have been used therapeutically

Drug	Source	Main route of elimination
Acetyldigoxin	Semisynthetic derivative of digoxin	Renal
Digitoxin	*Digitalis purpurea*	Hepatic
Digoxin	*Digitalis lanata*	Renal
Gitoformate	*Digitalis purpurea*	Hepatic
Gitoxin	*Digitalis purpurea*	Hepatic
Lanatoside C	*Digitalis lanata*	Renal
Metildigoxin (betamethyldigoxin)	Semisynthetic derivative of digoxin	Hepatic/ renal
Ouabain (strophanthin-g)	*Strophanthus gratus, Acokanthera schimperi, Acokanthera ouabaio*	Renal
Peruvoside	*Nerium peruviana*	Hepatic
Proscillaridin	*Drimia maritima*	Hepatic
Strophanthin-k	*Strophanthus kombe*	Renal

Epidemiology of digitalis toxicity

Digitalis toxicity is common, since all cardiac glycosides have a low therapeutic index. Estimates vary widely from study to study, but in large prospective studies of hospital inpatients the frequency of digitalis toxicity has been as high as 29% (16). In outpatients the figure may be as high as 16% (7). The lower frequency in outpatients may be due partly to poor compliance and partly to digitalis toxicity being a reason for admission to hospital, thus increasing the numbers of toxic inpatients. The risk of toxicity may be lower with digitoxin than with digoxin (4), but when toxicity occurs it lasts longer, because of the very long half-life of digitoxin.

The overall mortality from digitalis toxicity also varies widely, having been reported as low as 4% and as high as 36% (7). However, it varies with dysrhythmias, and for paroxysmal supraventricular tachycardia with block may be as high as 50% (7).

In a study of serum digoxin concentrations in 1433 patients admitted to hospital, 115 had a raised concentration (17). Of the 82 in whom the blood sample had been taken at an appropriate time, 59 had electrocardiographic or clinical features of digoxin toxicity. The patients whose serum digoxin concentrations were over 3.2 nmol/l (2.5 ng/ml) were slightly older (78 versus 73 years) and had higher serum creatinine concentrations (273 versus 123 μmol/l) than those whose plasma concentrations were below 3.1 nmol/l. Of 47 patients with raised digoxin concentrations on admission, 21 were admitted because of digoxin toxicity, and impaired or worsening renal function contributed to high concentrations in 37 patients. A drug interaction was a contributory factor in 10 cases. These results suggest that digoxin toxicity is still very common and confirms the increased risk in elderly patients, patients with renal impairment, and patients taking drugs that may interact with digoxin. Serum potassium concentrations were not reported in this study.

In another study of this sort, serum digoxin concentrations were measured in 2009 patients (18). The concentration was over 2.6 nmol/l in 320 cases (9.3%) but in 51 of those the sample had been drawn too soon after the dose. When other results were omitted in cases in which the sampling time was not known, there were 138 evaluable patients, of whom 83 had clinical evidence of digoxin toxicity, an overall incidence of 4.1%. The authors concluded that digoxin toxicity was less common in their series than has previously been reported. There were no differences between the groups in serum potassium, calcium, or magnesium concentrations, but the serum creatinine concentration was significantly higher in those who had definite and possible toxicity. The mean age of the patients was 69 years. It is likely that the differences across studies of this sort are largely due to differences in renal function and age in the population being studied.

In a multicenter survey, conducted between 1988 and 1997, of 28 411 patients aged 70 (s.d. 16) years admitted to

© 2006 Elsevier B.V. All rights reserved.

81 hospitals throughout Italy, 1704 had adverse drug reactions (19). In 964 cases (3.4% of all admissions), adverse reactions were considered to be the cause of admission. Of these, 187 were regarded as severe. Gastrointestinal complaints (19%) were the most common, followed by metabolic and hemorrhagic complications (9%). The drugs most often responsible were diuretics, calcium channel blockers, non-steroidal anti-inflammatory drugs, and digoxin. Female sex (OR = 1.30; 95% CI = 1.10, 1.54), alcohol use (OR = 1.39; 95% CI = 1.20, 1.60), and number of drugs (OR = 1.24; 95% CI = 1.20, 1.27) were independent predictors of admission for adverse reactions. For severe adverse reactions, age (for age 65–79, OR = 1.50; 95% CI = 1.01, 2.23; for age 80 and over, OR = 1.53; 95% CI = 1.00, 2.33), co-morbidity (OR = 1.12; 95% CI = 1.05, 1.20 for each point on the Charlson Comorbidity Index), and number of drugs (OR = 1.18; 95% CI = 1.11, 1.25) were predisposing factors. Of the 28 411 patients, about 6700 were taking digoxin, and they suffered 82 adverse effects, either gastrointestinal ($n = 28$) or unspecified dysrhythmias ($n = 44$), or presumably both (data not given); of those, 11 were graded as severe (two gastrointestinal and nine dysrhythmias).

Of 603 adults aged 79 years, of whom 59% were women and 18% African-American, 376 patients (62%) were discharged taking digoxin, and 223 (37%) had no indication for its use, based on the absence of left ventricular systolic dysfunction or atrial fibrillation (20). After adjustment for various factors, prior digoxin use (OR = 11; 95% CI = 5.7, 23) and pulse over 100/minute (OR = 2.33; 95% CI = 1.1, 4.9) were associated with inappropriate digoxin use. Unfortunately, the authors did not report the frequency of adverse effects, and it is not therefore clear whether patients in whom digoxin is used inappropriately are more or less likely to suffer adverse reactions.

General adverse effects

The adverse effects of cardiac glycosides can be cardiac or non-cardiac. They mostly occur through toxicity and are time-independent (DoTS classification); susceptibility factors include electrolyte abnormalities (particularly hypokalemia), renal insufficiency, and age.

Frequent non-cardiac reactions include gastrointestinal effects (anorexia, nausea, vomiting, and diarrhea), central nervous system effects (drowsiness, dizziness, confusion, delirium), and less commonly visual effects (color vision abnormalities, photophobia, and blurred vision). Hypersensitivity reactions are rare and include thrombocytopenia and skin rashes. Tumor-inducing effects have not been reported.

Frequent cardiac adverse effects include heart block and ectopic dysrhythmias (ventricular extra beats, other ventricular tachydysrhythmias, and paroxysmal supraventricular tachycardia). The combination of heart block with an ectopic dysrhythmia, for example paroxysmal supraventricular tachycardia with block, is particularly suggestive of toxicity due to cardiac glycosides. Any other dysrhythmia can occasionally be caused by cardiac glycosides.

Of 332 residents of a nursing home, 52 had to be admitted to hospital because of adverse drug reactions (21). The drugs most commonly associated with adverse effects were non-steroidal anti-inflammatory drugs ($n = 30$), psychotropic drugs ($n = 14$), and digoxin ($n = 5$).

Individual cardiac glycosides

There are major pharmacokinetic differences among the different cardiac glycosides, the principal difference being between those that are mainly excreted via the kidneys (for example digoxin, metildigoxin, beta-acetyldigoxin, ouabain, and k-strophanthin) and those that are mainly excreted via hepatic metabolism (including digitoxin, gitoxin, pengitoxin (16-acetyldigoxin), and gitoformate).

It has also been suggested that there may be some pharmacodynamic differences among different cardiac glycosides (22), but these may at least partly be determined by differences in tissue distribution.

It is debatable whether any of these differences makes any particular cardiac glycoside preferable to another. The most strongly argued case is that digitoxin is preferable to digoxin in patients with renal insufficiency, since digitoxin is metabolized and digoxin is excreted by the kidneys. However, digitoxin has a much longer duration of action, and if toxicity occurs it will take longer to resolve. Furthermore, determining the effective dose of digitoxin is much more difficult, since there is great interindividual variability in the extent to which digitoxin is metabolized, and hepatic metabolic function cannot be directly measured. Although digoxin excretion also varies from patient to patient, it can at least be gauged by measurement of creatinine clearance. The arguments for and against these preferences have been outlined (4,23) and it is probably best to choose a particular drug according to individual patient requirements.

Herbal formulations

Numerous plants worldwide contain cardiac glycosides that have been used both therapeutically as herbal formulations and for the purposes of self-poisoning. Details are given in Table 2.

- A 59-year-old man developed third-degree atrioventricular block after using an extract of *Nerium oleander* transdermally to treat psoriasis (24). A fatality due to drinking a herbal tea prepared from *N. oleander* leaves, erroneously believed to be eucalyptus leaves, has been reported (25).

Poisoning from ingestion of the seeds of *Thevetia peruviana* (yellow oleander) can be treated with oral multiple-dose activated charcoal (26).

In a Turkish case, the ingestion of two bulbs or *Urginea maritima* as a folk remedy for arthritic pains was sufficient to result in fatal poisoning (27).

Organs and Systems

Cardiovascular

Cardiac dysrhythmias and heart block

Percentage incidence figures for digitalis-induced dysrhythmias were given by Chung in his review of 726 patients (5). The commonest dysrhythmias are ventricular extra beats (54% of all dysrhythmias), coupled ventricular

Table 2 Some plants that contain cardiac glycosides

Plant	Common name(s)	Cardiac glycoside(s)	Comments
Adonis vernalis	False hellebore, pheasant's eye	Adonitoxin, strophanthidin	
Antiaris toxicaria	Upas tree	Antiarin	A Javanese tree of the mulberry family, used as an arrow poison
Convallaria majalis	Lily of the valley	Convallamarin	
Erysimum helveticum	Wallflower	Helveticoside	
Helleborus niger	Black hellebore, Christmas rose	Helleborcin	Also called melampodium after the Greek physician Melampus, who used it as a purgative
Nerium oleander	Pink oleander	Neriifolin	
Periploca graeca	Silk vine	Periplocin	
Tanghinia venenifera	Ordeal tree	Tanghinin	At one time used in Madagascar to test the guilt of someone suspected of a crime
Thevetia peruviana	Yellow oleander	Peruvoside, thevetins	Seeds widely used for self-poisoning in Southern India and Sri Lanka
Urginea (Scilla) maritima	Squill	Proscillaridin	Squill was a common remedy for dropsy in ancient times and up to the 19th century

extra beats (25%), and supraventricular tachycardia (33%). Sinus tachycardia was not common (3.4%). Atrial fibrillation (1.7%) or atrial flutter (1.8%) can cause difficulty in diagnosis, since digitalis is often used to treat those dysrhythmias.

Atrioventricular block was common (42%): first-degree, 14%; second-degree, 17%; and complete, 11%). However, first-degree heart block (that is prolongation of the PR interval) without higher degrees of atrioventricular nodal block can occur in the absence of digitalis intoxication.

Digitalis-induced dysrhythmias can be classified according to their sites of origin in the sinus node, the atria and atrioventricular node, and the ventricles.

Sinoatrial node

Digitalis can cause sinus bradycardia as a toxic effect, although patients with sinus bradycardia at rest often have no other evidence of digitalis toxicity, and this effect may simply represent increased vagal tone (28). Digitalis inhibits conduction through the sinoatrial node and has been reported to cause a syndrome mimicking that of the sick sinus syndrome (29–31); however, it is not clear whether or not it can impair sinus node function in patients who have previously normal sinoatrial nodes (32,33). Digitalis can certainly worsen sinus node function that has been otherwise impaired, for example by hyperthyroidism (34) or endotracheal suction (35).

Atria and atrioventricular node

Digitalis can cause supraventricular extra beats or tachycardia. The combination of such dysrhythmias with atrioventricular block is particularly suggestive of digitalis toxicity and carries a high mortality rate (3,36). Rarely atrial fibrillation (37) and atrial flutter (38) may be attributed to digitalis toxicity. The frequency of atrioventricular nodal block is mentioned above.

Paroxysmal atrial tachycardia with Wenckebach (Mobitz type I) atrioventricular block has been reported in a patient with a serum digoxin concentration of 3.2 ng/ml (39) and in a patient who in error took three times the recommended dose (40).

Ventricles

Ventricular extra beats, including coupled beats (that is ventricular bigeminy), are the most common cardiac effects of digitalis toxicity, although they are not specific. In more severe cases ventricular tachycardia, bidirectional tachycardia, and ventricular fibrillation can occur. There have also been reports of accelerated idioventricular rhythm (41,42).

Digoxin can cause ventricular fibrillation in children with Wolff–Parkinson–White syndrome (43,44).

- A male infant, whose narrow-complex tachycardia at birth had responded to adenosine, was treated with digoxin and 1 week later, during transesophageal electrophysiology with isoprenaline, developed coarse ventricular fibrillation after the induction of a supraventricular tachycardia (45). The serum digoxin concentration was not measured. The isoprenaline was withdrawn and the dysrhythmia resolved spontaneously at 160 seconds.

The effects of digoxin, isoprenaline, and transesophageal stimulation may have combined in this case to cause ventricular fibrillation.

Effects of digitalis on the electrocardiogram

Digitalis can prolong the PR interval and cause shortening of the QT interval, depression of the ST segment, and asymmetrical T wave inversion. These effects are non-specific and can occur in the absence of toxicity. However, there is evidence that the effects on the ST segment and T wave may be more common in patients with co-existing ischemic heart disease (46). Digitalis can also rarely cause both left (47) and right (48) bundle branch block.

The electrocardiographic effects of cardiac glycoside toxicity in 688 patients have been reviewed in the context of three cases of digoxin toxicity (49). The three cases featured bidirectional tachycardia in a 50-year-old man with a plasma digoxin concentration of 3.7 ng/ml, junctional tachycardia in a 59-year-old man with a plasma digoxin concentration of 4.3 ng/ml, and complete heart block in a 90-year-old woman whose postmortem digoxin concentration was 5.0 ng/ml.

© 2006 Elsevier B.V. All rights reserved.

Heart failure

In toxic doses digitalis impairs myocardial contractility and can cause or worsen heart failure. In one series of 148 patients with digitalis intoxication, worsening heart failure was diagnosed in 7.5% (50). In some cases worsening heart failure may be attributable to a cardiac dysrhythmia (51).

Vasoconstrictor and hypertensive effects

Giving a cardiac glycoside rapidly intravenously causes a transient increase in blood pressure, which has been attributed to an increase in peripheral resistance (52). However, digitalis does not seem to increase blood pressure during long-term treatment.

Myocardial ischemia

Subacute digitalis intoxication in dogs causes myocardial damage (53), and after intravenous administration there is increased creatine kinase activity in the plasma in man (54), suggesting ischemic damage.

There has been a report of coronary vasoconstriction in patients who were given acetyldigoxin 0.8 mg intravenously at angiography (55). Pretreatment with nisoldipine 10 mg, 2 hours before angiography, prevented the digoxin-induced vasoconstriction. These patients all had pre-existing coronary artery disease, but the vasoconstrictor effect occurred in both normal and abnormal coronary segments. However, the effect on high-grade stenoses was more pronounced. There is other evidence that ischemic damage can occur in patients who have been given digoxin intravenously, including an increase in the activity of serum creatinine kinase (54) and impaired left ventricular function after acute myocardial infarction (56).

- A 26-year-old woman who had taken a herbal supplement for stress relief which contained *Scutellaria lateriflora*, *Pedicularis canadensis*, *Cimifuga racemosa*, *Humulus lupulus*, *Valeriana officinalis*, and *Capsicum annuum* developed chest pain of 7 hours duration (57). Her medical history was otherwise unremarkable. Examination of her heart showed no abnormality, but during monitoring her heart rate fell to 39/minute and her blood pressure to 59/36 mmHg. Her serum digoxin concentration was 0.9 ng/ml. The authors therefore concluded that the herbal remedy contained digoxin-like factors that had caused digitalis toxicity.

Long-term use and cardiovascular adverse effects of cardiac glycosides

There have been many studies of the long-term efficacy of digitalis in patients in heart failure in sinus rhythm and also in patients with atrial fibrillation. These have been reviewed (SEDA-4, 123) (SEDA-14, 145) (SEDA-18, 196). The following is a brief resumé.

Atrial fibrillation is not necessarily an indication for long-term therapy with digitalis. In patients with controlled atrial fibrillation whose plasma digitalis concentration is below the lower limit of the target range (0.8 ng/ml for digoxin and 10 ng/ml for digitoxin) withdrawal rarely if ever results in deterioration. However, in those who have plasma digitalis concentrations within the target range withdrawal should not be attempted, since the risk of worsening atrial fibrillation outweighs the risk of toxicity, if there is careful monitoring of the plasma concentration.

In patients with heart failure in sinus rhythm there is no way of predicting which patients will benefit from long-term therapy, but the following recommendations can be made:

1. If the plasma digitalis concentration is below the therapeutic range (0.8 ng/ml for digoxin and 10 ng/ml for digitoxin) withdrawal is very unlikely to produce deterioration.
2. If a patient's condition is stable, and the plasma digitalis concentration is in the therapeutic range, with little risk of toxicity, withdrawal is probably not worthwhile because of the risk of deterioration.
3. If there is an increased risk of toxicity (for example because of renal impairment or if potassium balance is difficult to maintain) careful withdrawal of digitalis may be worth attempting.
4. In patients who have evidence of poor left ventricular function it may be better to continue therapy, even if there is an increased risk of toxicity, since these patients are very likely to deteriorate following withdrawal. In these cases careful monitoring of therapy will help to reduce the risk of toxicity.

The long-term adverse cardiovascular effects of digitalis have been reviewed (SEDA-10, 142) (SEDA-11, 153) (SEDA-15, 165). Briefly, in a number of retrospective studies, although mortality in the digitalis-treated patients was generally higher than in those not treated with digitalis, the difference was reduced when allowance was made for other confounding factors, such as the degree of heart failure, a history of dysrhythmias, and the use of other drugs. There may also be a higher mortality rate in patients who take long-term digitalis therapy after coronary artery bypass graft surgery (58), in patients who have had a cardiac arrest (59), and in those without evidence of heart failure or atrial fibrillation (60). In the first two studies the risk was increased further among those who were taking digitalis with diuretics, and it may be that these effects are due to digitalis toxicity secondary to potassium depletion, although it may simply indicate a greater prevalence of hypertension or heart failure among those treated with digitalis and diuretics.

Despite these earlier results, in the Digitalis Investigation Group (DIG) study (61) digoxin had no overall impact on mortality in patients with heart failure in sinus rhythm and with left ventricular ejection fractions equal to or less than 0.45.

It produced a small reduction in hospitalizations due to heart failure (nine per 1000 patients-years) balanced by a significant increase in deaths from presumed dysrhythmias. Digitalis is therefore indicated for a small number of patients who have severe heart failure associated with sinus rhythm after treatment with diuretics, vasodilators, beta-blockers, and spironolactone. It remains the drug of first choice in patients with heart failure accompanied by fast atrial fibrillation, especially if due to myocardial or mitral valve disease. A trial of withdrawal of digitalis therapy can be considered in some cases (as noted in point 3 above).

Of course, there are alternatives to digitalis in the long-term treatment of heart failure in sinus rhythm. It is not

© 2006 Elsevier B.V. All rights reserved.

clear that any of these offers any particular advantage over digitalis in terms of therapeutic efficacy, although there may be fewer problems with toxicity. The comparative studies have been reviewed (SEDA-14, 141).

Sinus rhythm

The question of whether digoxin should be used to treat patients with mild to moderate heart failure in sinus rhythm, in the wake of randomized, controlled trials of its efficacy, including PROVED, RADIANCE, and DIG (SEDA-18, 196) (SEDA-20, 173), has been reviewed (62). The authors concluded that digoxin is effective in producing symptomatic improvement in patients with mild or moderate heart failure, but that because of concerns about its safety careful consideration must be taken in each case before using it.

Other positive inotropic drugs carry no extra benefit, and can increase mortality during long-term administration. There is no evidence that the combination of two drugs with positive inotropic actions is beneficial in chronic congestive heart failure. Vasodilators are as efficacious as digitalis, but there is a rationale for combining digitalis and a vasodilator, since by doing so it is possible to affect simultaneously the three important factors determining cardiac output (contractility, pre-load, and afterload). Furthermore, a vasodilator will oppose the small effect that digitalis has in increasing peripheral resistance, and which may reduce the beneficial effect of digitalis on cardiac output.

Of 2254 elderly patients, 724 were being treated with digoxin, of whom 187 had congestive heart failure, 90 had atrial fibrillation, and 447 were both free from heart failure and in sinus rhythm (60). Among those who did not have heart failure or atrial fibrillation, cardiovascular and total mortality were significantly higher among those taking digoxin. Digoxin was a predictor of mortality in those subjects. In addition, the incidence of non-fatal heart failure was higher among those taking digoxin. This is yet another non-randomized study purporting to show deleterious effects of digoxin during long-term use, in this case in patients in whom it was not indicated in the first place. Since similar non-randomized studies in patients with heart failure, which also showed deleterious effects (SEDA-20, 173), have since been contradicted by proper prospective randomized studies, this result should be ignored.

Atrial fibrillation

In uncomplicated atrial fibrillation a cardiac glycoside such as digoxin remains the drug of first choice. However, in those in whom digitalis is not completely effective or in whom symptoms (for example bouts of palpitation) persist despite adequate digitalization, a calcium antagonist, such as verapamil or diltiazem, can be added, or amiodarone used as an alternative. In patients with atrial fibrillation due to hyperthyroidism, a beta-adrenoceptor antagonist should be used in preference to digitalis, but digitalis can be added if there is an incomplete effect. In patients with atrial fibrillation secondary to an anomalous conduction pathway (for example Wolff–Parkinson–White syndrome), in most of whom digitalis is contraindicated, a calcium antagonist would be the treatment of choice. Paroxysmal atrial fibrillation generally does not respond to digitalis, and digitalis may in fact prolong the duration of a paroxysmal attack when it occurs. The treatment of paroxysmal atrial fibrillation is problematic, but many use amiodarone. Sotalol, propafenone, and flecainide are options, but there are doubts about the long-term safety of flecainide and sotalol, particularly in those who have had an acute myocardial infarction.

There has been a multicenter, randomized, placebo-controlled, double-blind comparison of aprindine and digoxin in the prevention of atrial fibrillation and its recurrence in 141 patients with symptomatic paroxysmal or persistent atrial fibrillation who had converted to sinus rhythm (63). They were randomized in equal numbers to aprindine 40 mg/day, digoxin 0.25 mg/day, or placebo, and were followed every 2 weeks for 6 months. After 6 months the Kaplan-Meier estimates of the numbers of patients who had no recurrences while taking aprindine, digoxin, and placebo were 33%, 29%, and 22% respectively. The rates of adverse events were similar in the three groups. This confirms that digoxin does not prevent relapse of symptomatic atrial fibrillation after conversion to sinus rhythm.

Cardioversion and digitalis

The presence of digitalis increases the risk of serious dysrhythmias after electrical cardioversion, even in the absence of frank toxicity (64). In order to minimize the risk of dysrhythmias in these circumstances digitalis should be withdrawn if possible a day or two before cardioversion and potassium depletion should be corrected. If cardioversion is required acutely, it has been recommended that low energies (for example 10 J) should be used initially (65).

Nervous system

Toxic effects of digitalis on the nervous system occur relatively often. Although in severe toxicity the incidence may be as high as 65% (66), in most series it has been below 25% (67).

Anorexia, nausea, and vomiting are mediated by the central nervous system. Other common nervous system effects of digitalis include confusion, dizziness, drowsiness, bad dreams, restlessness, nervousness, agitation, and amnesia.

Epilepsy occurs rarely and can be accompanied by electroencephalographic changes (68–70).

Other reported effects include transient global amnesia (71), trigeminal neuralgia (72,73), nightmares (74), organic brain syndrome (including impairment of long-term and short-term memory) (75), impairment of learning and memory (23), and a clinical syndrome resembling herpes encephalitis (76).

- Progressive stupor has been reported in an 85-year-old woman with mild renal insufficiency who was given digoxin 0.25 mg/day (77). The plasma digoxin concentration was 7.8 nmol/l. She recovered within 2 weeks after digoxin withdrawal, consistent with the likely half-life of digoxin. A 24-hour electrocardiogram showed one period of asystole for 4 seconds, but that is unlikely to have explained her symptoms.

© 2006 Elsevier B.V. All rights reserved.

Chorea has occasionally been reported in adults taking digitalis (SEDA-13, 138) (78), and also in a child (79).

- A 7-year-old girl with severe congenital heart disease who was given digoxin 0.125 mg bd developed chorea and had a serum digoxin concentration of 3.8 ng/ml. When digoxin was withheld and the serum concentration fell to 1.5 ng/ml her symptoms resolved. They recurred 4 days after rechallenge when her digoxin concentration was 2.5 mg/ml and again resolved after it had fallen to 1.3 mg/ml.

The authors hypothesized that digoxin caused chorea by virtue of an estrogenic effect in the basal ganglia, similar to the effect that is occasionally produced by oral contraceptives.

Sensory systems

Color vision abnormality is a well-known adverse effect of digitalis (SEDA-20, 173), and particularly occurs in patients with digitalis toxicity.

There have been two cases of digoxin-related visual disturbances in patients whose blood concentrations were in the usual target range (319).

- A 68-year-old woman had shimmering lights in her field of vision in both eyes when in sunlight, and a 63-year-old woman complained of blurring of vision in both eyes. The serum digoxin concentrations were 2.2 and 1.3 nmol/l (1.7 and 1.0 ng/ml) respectively. Withdrawal of digoxin caused resolution of their symptoms within 1–2 weeks.

Unfortunately the authors did not report serum electrolyte concentrations, and it is not clear in these cases whether the effect of digoxin was potentiated by potassium depletion.

In 30 patients (mean age 81 years) taking digoxin and an age-matched control group there was no correlation between color vision impairment and serum digoxin concentration (80). There was slight to moderate red-green impairment in 20–30% of those taking digoxin, depending on the test used; about 20% had a severe tritan defect. The authors suggested that color vision testing in elderly patients would have limited value in the detection of digitalis toxicity. However, this conclusion was based on using the digoxin concentration as a standard, while the point of pharmacodynamic tests, such as color vision measurement, is that they are supposed to reflect the effect of the drug better than the serum concentration.

Psychological, psychiatric

Acute psychosis and delirium can occur in digitalis toxicity, particularly in elderly people (81–83), and can be accompanied by visual or auditory hallucinations (84,85).

- Acute delirium occurred in a 61-year-old man whose serum digitoxin concentration was 44 ng/ml (86).

Digitalis toxicity can occasionally cause depression (87).

- A 77-year-old woman developed extreme fatigue, anorexia, psychomotor retardation, and social withdrawal 1 month after starting to take digoxin 0.5 mg/day for congestive heart failure (88). She did not respond to intravenous clomipramine 25 mg/day for 7 months. Her serum digoxin concentration was 3.2 ng/ml. Digoxin was withdrawn, and 12 days later, when her serum digoxin concentration was 0.5 ng/ml, she had improved, but was left with a memory disturbance, which was attributed to background dementia.

Endocrine

Digitalis has effects on sex hormones. It causes increased serum concentrations of follicle-stimulating hormone (FSH) and estrogen and reduced concentrations of luteinizing hormone (LH) and testosterone (89–92). These effects are probably not related to any direct estrogen-like structure of digitalis (despite structural similarities), but rather to an effect involving the synthesis or release of sex hormones. There are three possible clinical outcomes of these effects.

Gynecomastia in men and breast enlargement in women

Effects of cardiac glycosides in the breasts can be associated with demonstrable histological changes (93,94).

Stratification of the vaginal squamous epithelium in postmenopausal women

This can cause difficulty in the pathological interpretation of vaginal smears for cancer diagnosis (95).

A possible modifying effect on breast cancer

Digitalis can reduce the heterogeneity of breast cancer cell populations and reduce the rate of distant metastases (96). There is also evidence that the 5-year recurrence rate after mastectomy is lower in women who have been treated with digitalis (97). Early studies suggested that when breast tumors occurred in women with congestive heart failure taking cardiac glycosides, tumor size was significantly smaller and the tumor cells more homogeneous (SEDA-7, 194). It was originally thought that this action was due to an estrogen-like effect of cardiac glycosides, but more recent evidence suggests that it occurs because inhibition of the Na/K pump is involved in inhibiting proliferation and inducing apoptosis in various cell lines (98–101). Cardiac glycosides have different potencies in their effects on cell lines such as those of ovarian carcinoma and breast carcinoma (order of potency: proscillaridin A > digitoxin > digoxin > ouabain > lanatoside C) (102).

Metabolism

In three patients with diabetes mellitus, withdrawal of digoxin improved blood glucose control, implying that digoxin had impaired glucose tolerance (103). The authors conceded that the effect might have occurred coincidentally, but in one case glucose tolerance deteriorated again after rechallenge. Insulin increases the cellular uptake of glucose and stimulates the sodium/potassium pump, and it may be that inhibition of the sodium/potassium pump by digoxin has the opposite effect.

In 14 patients with morbid obesity, who were being given digoxin in the hope that reduced production of cerebrospinal fluid, with the consequent reduction in pressure, might be associated with weight reduction, the dosage of digoxin (Lanacrist 0.13 mg, equivalent to 0.065 mg of digoxin) was titrated to produce a minimum serum digoxin concentration of 1.0 nmol/l (104). One patient was already diabetic, and five developed fasting

© 2006 Elsevier B.V. All rights reserved.

blood glucose concentrations greater than 5.0 mmol/l on three consecutive occasions, with accompanying glycosuria. Another had fasting blood glucose concentrations of 6.0–8.5 mmol/l. There was a significant relation between the dose of digoxin and the risk of impaired glucose tolerance. However, the diabetes mellitus did not abate after digoxin withdrawal, and since all these patients were obese, the occurrence of diabetes was probably coincidental.

Hematologic

Thrombocytopenia has been reported in patients taking digitoxin, acetyldigoxin, and digoxin (105–108).

There have been rare reports of eosinophilia in patients taking cardiac glycosides (109).

Gastrointestinal

Gastrointestinal symptoms are common in digitalis toxicity. These include anorexia, nausea, and vomiting (110), probably as a result of stimulation of the chemoreceptor trigger zone in the brain.

Diarrhea occurs occasionally (111).

Dysphagia has been rarely reported (112,113).

Other rare events include intestinal ischemia (SEDA-17, 215) (114), and hemorrhagic intestinal necrosis (115).

- A 79-year old woman with a serum digoxin concentration of 4.9 ng/ml had a mesenteric infarction (116). At postmortem no other causes were discovered.

Intestinal ischemia responds to verapamil and to antidigoxin antibody (115).

Death

In a retrospective, non-randomized study of 484 patients, 90 of whom were taking digoxin, there was an increased death rate (RR = 2.12, CI = 1.21, 3.74) in those taking digoxin (117). In another non-randomized, retrospective analysis of the effects of digoxin in patients with acute myocardial infarction there was a higher rate of mortality in the 243 patients taking digoxin compared with the 1743 patients who were not (118). The results of these studies are reminiscent of the results of previous similar retrospective analyses. However, the prospective DIG study clearly showed no increase in mortality (SEDA-20, 173), and the results of these more recent non-randomized retrospective studies should be ignored.

In 345 patients with heart failure randomized to either digoxin ($n = 175$) or captopril ($n = 170$) and followed for a median of 4.5 years the death rate at 48 months was lower with captopril (21%) than with digoxin (32%), although this did not reach conventional significance (119). Since there was no placebo group for comparison it is not clear whether digoxin altered mortality in this study. Of the numerous adverse effects that were reported, the only one that differed between the two treatments was cough, which was significantly more frequent with captopril. In the absence of a placebo comparison it is impossible to say whether any of the other adverse effects were drug-related.

Despite the fact that the prospective study called DIG clearly showed that there was no increase in mortality in patients in taking long-term digoxin therapy (SEDA-20, 173), retrospective, non-randomized studies continue to be reported (SEDA-24, 201). In 180 patients with idiopathic dilated cardiomyopathy the overall mortality was 19% in those taking digoxin and 10% in those not taking digoxin (120). However, when the use of digoxin was adjusted for several predictive variables it no longer predicted cardiac death. This finding is reassuring, but results of studies like this, whatever their results, should be ignored, in view of the evidence that is currently available from the one large prospective, randomized study.

When interpreting the evidence presented in other accounts of the association between drug therapy and death it is important to remember that the current evidence suggests that digoxin does not cause excess mortality. For example, digoxin was the second most commonly encountered medication in an investigation of 2233 deaths reported to an American County Medical Examiner's office, with a medication history available in 775 cases (121). Furosemide was mentioned 181 times, digoxin 131 times, and glyceryl trinitrate 103 times. All other drugs were mentioned less than 100 times each. The authors suggested that the presence of digoxin at a death scene should suggest heart failure or a cardiac dysrhythmia, but they did not go further and stress that in such a case digoxin need not necessarily be implicated in the death. Postmortem diagnosis of digoxin toxicity is exceptionally difficult, but measurement of digoxin in the vitreous fluid can be helpful.

In a survey of 2 312 203 deaths in the USA in 1995, 206 (0.009%) were attributed to adverse drug reactions on death certificates (122). At the same time in the MedWatch program, 6894 deaths were reportedly attributed to adverse drug reactions, representing 6.3% of the 108 735 reports of adverse drug reactions. In the death certificate study 18 deaths were attributed to cardiac glycosides and in the MedWatch survey 15 deaths. This compares with figures of 289 and 782 from antimicrobial drugs, 449 and 280 from hormones, and 947 and 477 from drugs that affect the constituents of the blood (for example anticoagulants).

Sex-based differences in the effect of digoxin have been explored in a post-hoc analysis of the data from the DIG) study (SEDA-20, 173) (123). There was an absolute difference of 5.8% (95 CI = 0.5, 11) between men and women in the effect of digoxin on the case fatality rate from any cause. Women who were randomly assigned to digoxin had a significantly higher fatality rate than women who were randomly assigned to placebo (33 versus 29%), while the fatality rate was similar among men randomly assigned to digoxin or placebo (35% versus 37%). However, serum digoxin concentrations were higher in the women at 1 month, and this may have contributed to the increased risk of death (124).

In another post-hoc analysis of the data from the DIG study the patients who had been randomized to digoxin were divided into three groups, according to serum digoxin concentration, 0.5–0.8 ng/ml, 0.9–1.1 ng/ml, and 1.2 ng/ml and over (125). Higher concentrations were associated with higher all-cause fatality rates: 30%, 39%, and 48% respectively.

Both of these studies suggest that lower serum concentrations of digoxin (0.5–1.0 ng/ml) may be beneficial for

© 2006 Elsevier B.V. All rights reserved.

routine therapy of heart failure than have traditionally been recommended (0.8–2.0 ng/ml), and this has been discussed in a brief review (126).

Second-Generation Effects

Pregnancy

Digoxin has been used to cause fetal death before termination of pregnancy (127). However, in a double-blind study in 126 women who had terminations by dilatation and evacuation at 20–23 weeks gestation intra-amniotic injection of digoxin 1 mg did not alter blood loss or pain; nor did it reduce difficulties with or the complications of the procedure (128). Significantly more women vomited after intra-amniotic digoxin. Digoxin given by this route is slowly absorbed into the systemic circulation, with a peak plasma concentration of 0.8 ng/ml at 11 hours (129).

Fetotoxicity

Digoxin crosses the placenta and enters the neonatal circulation (130). It has therefore been used, for example, to improve fetal cardiac function (131). In normal circumstances there seem to be no adverse effects on the neonate, and neonatal plasma concentrations are below those generally considered to be therapeutic. There has been one report of fatal toxicity in the fetus of a woman who took an overdose of digitoxin (132).

Susceptibility Factors

Age

Elderly people

The risk of digoxin toxicity is increased in old people, partly because they have poor renal function and lower body weight, factors that tend to increase the concentration of drug at the active site during steady-state therapy, and partly because they are liable to electrolyte imbalances, such as hypokalemia, which tend to increase the response of the tissues to a given concentration. Other factors, such as altered Na/K pump activity, may also contribute to increased tissue sensitivity. This means that the serum digoxin concentration that is associated with an increased risk of toxicity is slightly lower in elderly people than in younger people, and this has been confirmed in a recent study of 899 patients taking digoxin for heart failure or atrial fibrillation (133). No patients with serum digoxin concentrations below 1.4 ng/ml had evidence of digoxin toxicity. All patients who had a concentration of 3.0 ng/ml or more had severe toxicity. However in the range 1.4–2.9 ng/ml there were patients with and without evidence of toxicity, and the overlap was age-dependent. In patients aged 51–60 there was more evidence of toxicity with concentrations of 2.4–2.9 ng/ml; in patients aged 61–70 the range was 1.8–2.9 ng/ml, in patients aged 71–80 it was 1.4–2.7 ng/ml, and in those aged over 80 it was 1.4–2.6 ng/ml. The authors therefore suggested that serum digoxin concentrations should be no greater than 1.4 ng/ml during routine steady-state therapy. The incidences of toxicity were 16% in patients over 70 years of age and 7.3% in the whole group. The risk of toxicity was increased in the presence of renal insufficiency.

Because digitoxin is metabolized rather than being renally eliminated, the effects of renal impairment in elderly patients may not be so important in precipitating digitoxin toxicity. In 80 patients hospitalized 147 times, toxicity with digitoxin occurred in 7.6% of 92 admissions and digoxin toxicity occurred in 18.3% of 55 admissions (134). On the basis of these results the authors suggested that digitoxin is safer than digoxin in elderly patients. This is an old debate, and there are arguments in favor of both digoxin and digitoxin (135). However, there is currently no information on the long-term toxicity of digitoxin, and in particular its effects on mortality in patients with heart failure. Neither the severity of toxicity nor its duration was reported in this study.

A retrospective Bayesian analysis in 60 patients confirmed that age is a major factor in digoxin toxicity (136). However, an analysis of the data from the DIG study (SEDA-20, 173) has shown that while mortality in heart failure increases with age, the actions of digoxin are independent of age (137).

Children

Matters are also more complicated in young people. The pharmacokinetics of cardiac glycosides are different (138): the apparent volume of distribution of digoxin is higher in neonates, infants, and older children than in adults, and renal digoxin clearance is lower in children under 4–6 months. However, there may also be increased resistance to the effects of digoxin in infants because of changes in digitalis tissue receptors (139). Seriously ill children of low birth weight may be particularly at risk, even when low dosages of digitalis are used (140).

The risk of digitalis toxicity during the therapeutic use of cardiac glycosides is similar in children to that in adults, ranging in 12 separate published series from 12 to 50% (median 21%) (141). The most common non-cardiac effects are vomiting and feeding problems, and the most common cardiac effects are conduction defects, particularly atrioventricular block and ectopic rhythms, although (as in adults) any dysrhythmia can occur.

The pharmacokinetics of digoxin have been studied in 181 neonates and children with and without congestive heart failure (142). The clearance rate was lower in premature neonates than in neonates born at full term. Children with congestive heart failure also had lower digoxin clearance.

A population pharmacokinetic study in 172 neonates and infants showed that the clearance of digoxin is affected significantly by total body weight, age, renal function, and congestive heart failure (143).

Other features of the patient

Several factors increase patient susceptibility to digitalis intoxication. They can be considered in two groups (144).

Factors that alter the amount of digitalis that accumulates in the body or the plasma concentration at a fixed dose (pharmacokinetic factors)

Pharmacokinetic factors affect different cardiac glycosides differently.

© 2006 Elsevier B.V. All rights reserved.

Altered tissue distribution
The apparent volume of distribution of digoxin is reduced in hypothyroidism (145) and in renal insufficiency (146). This leads to increased plasma concentrations after a loading dose and hence an increased risk of toxicity, but does not affect the plasma concentration at steady state. The opposite occurs in hyperthyroidism.

Altered renal elimination
The effects of renal insufficiency on the pharmacokinetics of cardiac glycosides have been reviewed (146). The most important effect of renal failure is a reduced rate of elimination of digoxin, leading to increased accumulation during steady-state treatment. The same applies to some other glycosides, including beta-methyldigoxin, beta-acetyldigoxin, ouabain, and k-strophanthin, but not to glycosides that are mostly metabolized, such as digitoxin, the proscillaridins, and peruvoside (4). Drug interactions can also lead to reduced digoxin renal elimination.

A retrospective Bayesian analysis in 60 patients confirmed that renal impairment is a major factor in digoxin toxicity (136).

A population pharmacokinetic study in 172 neonates and infants showed that the clearance of digoxin is affected significantly by renal function (143).

Altered non-renal elimination
See Drug–Drug Interactions.

Factors that alter the clinical response to digitalis at a fixed amount of digitalis in the body and a fixed plasma concentration (pharmacodynamic factors)
Pharmacodynamic factors affect all cardiac glycosides in the same way.

Electrolyte disturbances
Of electrolyte disturbances that alter the response to a cardiac glycoside, hypokalemia is the most important. It has been estimated that a fall in plasma potassium concentration from 3.5 to 3.0 mmol/l is associated with a 50% increase in sensitivity to digoxin (144). Total body potassium depletion, even in the absence of hypokalemia, has a similar effect (147).

There is evidence that hypomagnesemia has the same effect as hypokalemia (148).

Hypercalcemia has the same effect as hypokalemia; hypocalcemia has the opposite effect, that is it causes resistance to the effects of digitalis.

Hypoxia and acidosis increase the risk of digitalis intoxication.

Renal insufficiency
In addition to its effect in reducing the elimination of digoxin, renal insufficiency may be associated with an increased sensitivity to the actions of digitalis (149).

Thyroid disease
Apart from the pharmacokinetic differences in thyroid disease (mentioned above), there may also be changes in tissue responsiveness, with reduced sensitivity in hyperthyroidism and the reverse in hypothyroidism (145). The reasons for these changes are not known, but they may be related to differences in tissue Na/K-ATPase activity.

Cardiac disease
All cardiac glycosides are best avoided in patients with acute myocardial infarction, since they increase oxygen demand in ischemic tissue, increase peripheral vascular resistance, and carry an increased risk of dysrhythmias, especially in the presence of tissue hypoxia and acidosis. Furthermore, there is evidence that digitalis is of little value in patients with acute myocardial infarction and either left ventricular failure or cardiogenic shock (150). The evidence that mortality in patients who take digitalis after an acute myocardial infarction is increased is discussed in the section Death in this monograph.

Cardiac glycosides are contraindicated in conditions in which there is obstruction to ventricular outflow, for example hypertrophic obstructive cardiomyopathy, constrictive pericarditis, and cardiac tamponade. Acute myocarditis may also increase the risk of toxicity.

Direct current cardioversion increases the risk of digitalis-induced dysrhythmias, but digitalis treatment is not a contraindication to cardioversion (151).

Hypercalcemia
The effects of digitalis are enhanced in the presence of hypercalcemia.

- An 81-year-old woman with congestive heart failure and hypercalcemia secondary to squamous cell carcinoma of the bronchus developed first-degree heart block and symptomatic sinus pauses when her serum digoxin concentration was only 1.5 mg/ml (152).

Drug Administration

Drug contamination

Digoxin toxicity has been reported in two patients who took herbal remedies (153). *D. lanata* was found as a contaminant.

Drug administration route

Intramuscular injection of digitalis can be painful and can cause local muscle necrosis, sometimes with pyrexia (154). The systemic availability of digitalis after intramuscular injection is poor (155), and this route of administration should be avoided if possible.

Digoxin has a rapid onset of action after oral administration, and there is rarely any justification for giving digoxin intravenously. This route of administration should be restricted to those who have severe atrial fibrillation that requires rapid treatment and in whom cardioversion or other drug therapy is not possible or indicated. If digoxin is given intravenously it should be infused over at least half-an-hour, since there is a risk of hypertension if it is infused faster.

There has been a randomized, double-blind comparison of intravenous diltiazem and digoxin in 40 patients with atrial fibrillation and a ventricular rate of over 100/minute (156). One patient given intravenous digoxin had a burning sensation at the site of injection.

© 2006 Elsevier B.V. All rights reserved.

Drug overdose

The most important complication of overdosage of digitalis in all age groups is disturbance of cardiac conduction, but in addition any dysrhythmia can occur. Death can result from asystole or ventricular fibrillation. Hyperkalemia is common, and the higher the plasma potassium concentration the poorer the prognosis (157).

Other common effects of overdosage are nausea, vomiting, and central nervous system and visual disturbances (66).

- Accidental overdose of digoxin in a 22-month-old boy caused vomiting, lethargy, and dehydration. The plasma digoxin concentration was 12 mg/ml. There was a relative bradycardia of 90/minute and Mobitz type 1 second-degree heart block on the electrocardiogram (158).

The pharmacokinetics of digoxin are altered after overdosage, the half-life being reportedly rapid, but there is too little information to define the kinetics precisely (157).

- Plasma glycoside concentrations have been documented after an overdose with purple foxglove in a 36-year-old woman (159). Apart from gitaloxin, which peaked on the fifth day at 113 ng/ml, all the glycosides detected peaked on the first day (gitoxin 13 ng/ml, digitoxin 113 ng/ml, digitoxigenin 3.3 ng/ml, and digitoxigenin monodigitoxoside 8.9 ng/ml). There was a second peak of digitoxin at about 70 hours, and this is consistent with the known enterohepatic recirculation of digitoxin.

Treatment of toxicity and overdosage

The treatment of digitalis toxicity and overdose have been reviewed (SEDA-5, 172) (SEDA-12, 149). In summary, the following measures should be taken.

Remove digitalis from the stomach

If the patient is seen within 1 hour of overdosage try to remove whatever drug still remains in the stomach by gastric lavage, although the risk of dysrhythmias may be increased. There is no evidence that emesis is beneficial.

Give activated charcoal

The use of activated charcoal in the treatment of digitalis overdose has been reviewed (160). The rationale for its use is that after absorption into the systemic circulation digitoxin is secreted into the bile and digoxin (161) (and probably other cardiac glycosides) is secreted into the gut lumen by the action of the P glycoprotein. Activated charcoal in the gut binds this secreted digoxin and encourages further secretion. To be fully effective charcoal should be given at regular intervals (for example 50 g 4-hourly).

In pigs, repeated doses of activated charcoal reduced the half-life of intravenous digoxin significantly from 65 to 17 hours and increased the clearance from 2.3 to 7.1 ml/minute/kg (162).

There is evidence of the efficacy of charcoal in healthy volunteers. In six adult volunteers repeated doses of activated charcoal significantly reduced the half-life of digoxin from 23 to 17 hours without a significant increase in clearance; the half-life of digitoxin was also reduced from 110 to 51 hours, and this was accompanied by a significant increase in clearance from 0.24 to 0.47 l/hour (163). In a volunteer with chronic renal insufficiency charcoal reduced the digoxin half-life from 93 to 29 hours and increased the clearance from 3.6 to 10 l/hour (163). Similarly, during maintenance therapy in six individuals, daily activated charcoal significantly reduced the mean plasma digoxin concentration by 31% and serum digitoxin concentration by 18% (164). In 10 healthy volunteers given intravenous digoxin 10 μg/kg repeated doses of activated charcoal significantly increased the total body clearance from 12 to 18 l/hour and reduced the half-life from 37 to 22 hours (161).

There have also been reports of the value of multiple doses of activated charcoal in patients with digoxin and digitoxin poisoning. In 23 patients with plasma digoxin concentrations over 2.5 ng/ml multiple doses of activated charcoal increased the mean clearance of digoxin to 98 ml/minute compared with 55 ml/minute in 16 patients who were not treated, and reduced the half-life from 68 to 36 hours (165). Anecdotal reports have also appeared.

- In a 69-year-old man the plasma digoxin concentration of 8.3 ng/ml fell with a half-life of 14 hours (166).
- In a 71-year-old woman with chronic renal insufficiency and a plasma digoxin concentration of 9 ng/ml charcoal shortened the half-life from 7.3 to 1.4 days (167).
- In a 66-year-old man with chronic renal insufficiency whose serum digoxin concentration did not respond to daily hemodialysis, multiple doses of activated charcoal caused a rapid reduction in the serum concentration (168).
- In a patient with a peak plasma digoxin concentration of 264 ng/ml multiple doses of activated charcoal reduced the half-life of digitoxin from 162 hours to 18 hours (169).
- In a patient on hemodialysis, activated charcoal caused a fall in the plasma digoxin concentration with a half-life of 29 hours (170).
- In another patient there was convincing evidence of a change in the digoxin half-life after repeated doses of activated charcoal (166).
- In a 73-year-old woman who took 12.5 mg of digoxin, gastric lavage and activated charcoal tided the patient over until antibodies became available (171).

However, the best evidence of the usefulness of repeated oral doses of activated charcoal in cardiac glycoside poisoning comes from the results of a randomized, placebo-controlled study in 402 individuals who took overdoses of the seeds of the yellow oleander tree in Sri Lanka. Repeated doses of activated charcoal reduced mortality from 8.0% to 2.5% (26).

Thus, the use of repeated doses of activated charcoal in patients with digitalis toxicity is a cheap way of increasing the rate of cardiac glycoside clearance.

Colestyramine has been used for the same purpose. In two elderly patients with congestive heart failure and raised serum digoxin concentrations it enhanced the elimination of digoxin (172). In one case the half-life of digoxin was 20 hours and in the other 24 hours.

Correct electrolyte disturbances

Hypokalemia should be treated with potassium chloride.

© 2006 Elsevier B.V. All rights reserved.

Hyperkalemia carries a poor prognosis and is usually an indication for antidigoxin antibody. The suggestion that intravenous calcium should be used to treat the hyperkalemia that can occur in digitalis intoxication (173) has been challenged, on the grounds that it can increase the risk of cardiac dysrhythmias in such cases (174).

Give antidigoxin antibody

Antidigoxin antibody (Fab fragments) is the treatment of choice in patients with severe digitalis toxicity due to any cardiac glycoside. It is effective after self-poisoning with digitoxin, lanatoside C, and acylated forms of digoxin, as well as digoxin itself (175). It should be used when there are life-threatening dysrhythmias or heart block, and when the plasma potassium concentration is above 5.0 mmol/l or is rising, since hyperkalemia is evidence of serious toxicity and carries a poor prognosis. Evidence of the efficacy of antidigoxin Fab antibody fragments in reducing the risk of cardiac dysrhythmias in the treatment of intoxication due to oleander poisoning, previously only anecdotally reported (176,177), has come from a prospective study (178), although the study was too small to assess the effect on mortality. The role of antidigoxin antibody fragments in treating milder forms of digitalis toxicity has not been fully assessed.

In a systematic review of 250 publications no controlled, randomized trials were found, and the authors concluded that there was little or no scientific evidence of efficacy, because there are no randomized, controlled trials (179). However, this is one case in which the cumulative anecdotal evidence is overwhelmingly convincing, and there can be no doubt that antidigoxin antibodies are highly effective in the treatment of digoxin intoxication and of intoxication with other cardiac glycosides. The important question is whether there are cases in which the antibodies need not be used, and guidelines have yet to be developed.

- Overdose of digoxin in a neonate caused complete atrioventricular block and cardiogenic shock, which were completely reversed within 4 hours after administration of the first dose of antidigoxin antibody; a second dose was given 48 hours later, when first-degree atrioventricular block occurred (180).

However, it is not known whether antidigoxin antibody reduces mortality after digitalis poisoning; one randomized, controlled study (178) was too small to detect an effect on mortality after self-poisoning with seeds of the yellow oleander, which contains cardiac glycosides such as peruvoside. Another study that suggested reduced mortality (181) was confounded by being retrospective and inferential, based on changes in death rates as antibody was introduced and reintroduced; furthermore, the change in mortality that was attributed to the use of antibody occurred at the same time as multiple-dose activated charcoal was introduced, and that has definitively been shown to reduce mortality.

The dose of antidigoxin antibody should be based on the dose of digitalis taken and, when possible, the plasma digitalis concentration. The recommended doses for cases of poisoning with digoxin and digitoxin are given in Table 3. Although the clearance of the fragments is reduced in patients who also have severe renal impairment (182,183), there is no need to reduce the dose of antibody in such patients (184–187).

Different formulations of antidigoxin antibody are available. Digibind is an ovine antibody to digoxin, whose production is stimulated by the administration of digoxin conjugated to human albumin. In contrast, DigiFab, also ovine, is stimulated by injecting a conjugate of digoxin to keyhole-limpet hemocyanin (188). In 15 adults with digoxin toxicity who were given DigiFab, electrocardiographic abnormalities resolved within 4 hours in 10 patients and the signs of toxicity completely resolved within 4 hours in seven patients and within 20 hours in 14 patients. In one patient loss of the effect of digoxin resulted in pulmonary edema, pleural effusions, and renal insufficiency. The half-life of DigiFab is slightly shorter than that of Digibind (15 versus 23 hours), but their pharmacodynamic properties are similar. It is said that DigiFab may be preferred in patients who are allergic to sheep proteins, papain, chymopapain, or bromelains.

Antidigoxin antibody fragments cause adverse events in about 7% of cases. These include allergic responses, possible recurrence of digitalis toxicity after treatment, and some effects attributable to the withdrawal of digitalis, such as worsening of heart failure. In one series allergic reactions occurred in only six of 717 patients reviewed, and consisted of pruritic rash and flushing or facial swelling (189). The risk of an allergic reaction was increased in patients who had a history of previous allergy or asthma. Recurrence of digitalis toxicity after treatment was usually due to inadequate treatment with the antibody.

Plasma exchange has been used to enhance the rate of removal of antidigoxin antibody Fab fragments in a

Table 3 Methods for calculating the required dose of antidigoxin antibody fragments in cases of digoxin or digitoxin intoxication

Digoxin

(1) When the ingested dose is known:

(a) Tablets	dose in mg x 40
(b) Elixir	dose in mg x 48
(c) Capsules	dose in mg x 55
(d) Intravenous	dose in mg x 60

(2) When the plasma or serum concentration is known:
ng/ml x lean body weight x 0.34
or
nmol/l x lean body weight x 0.26

Example: Plasma digoxin concentration = 24 ng/ml in a 75 kg patient
Dose of antibody = 24 x 75 x 0.34 = 612 mg
Give 640 mg (for example 16 ampoules of Digibind)

Digitoxin

(1) When the ingested dose is known (all formulations):
Dose in mg x 60

(2) When the plasma or serum concentration is known:
ng/ml x lean body weight x 0.034
or
nmol/l x lean body weight x 0.026

Example: Plasma digitoxin concentration = 280 ng/ml in a 70 kg patient
Dose of antibody = 280 x 70 x 0.034 = 666 mg
Give 680 mg (for example 17 ampoules of Digibind)

© 2006 Elsevier B.V. All rights reserved.

46-year-old man with renal insufficiency (190). Removal of the digoxin-Fab complexes in this case prevented their subsequent dissociation and a further increase in the unbound concentration of digoxin. The authors proposed that plasma exchange is best used in these cases within the first 3 hours after the administration of antidigoxin antibodies.

Treat dysrhythmias

Cardiac dysrhythmias in digitalis overdose should be treated only if they are life-threatening. Phenytoin is probably the treatment of choice for ventricular tachydysrhythmias, but lidocaine or a beta-adrenoceptor antagonist, such as propranolol, are options. After an overdose of 300 tablets of digoxin (plasma digoxin concentration 50 ng/ml), recurrent ventricular fibrillation was successfully treated with bretylium tosylate (191). Sinus bradycardia may respond to atropine.

Treat or anticipate heart block

Heart block is the most serious consequence of digitalis poisoning and should be anticipated by the insertion of a temporary pacemaker. If this is postponed until heart block or dysrhythmias occur, there may be difficulty in inserting the pacemaker (because of ventricular excitability), and delay in treatment can be deleterious.

Other measures

Because digoxin has a large apparent volume of distribution, plasma exchange, hemodialysis, and hemoperfusion are not effective methods of removing digoxin from the body.

Hemoperfusion

Hemoperfusion has been used to treat digitalis overdose (SEDA-5, 174) but once a cardiac glycoside has been distributed to the body tissues hemoperfusion is unlikely to be of benefit. For digitoxin, which has a lower apparent volume of distribution than digoxin, charcoal hemoperfusion may be more valuable.

- In an 88-year-old woman whose serum digoxin concentration was 6.4 ng/ml, hemoperfusion with an adsorption column containing beta$_2$-microglobulin caused a fall in serum concentration from 6 ng/ml to 2.3 ng/ml, with improvement in gastrointestinal symptoms (192). The serum digoxin concentration then rose again to 3.5 ng/ml over the next 3 days, and a further hemoperfusion treatment reduced it to 1.7 ng/ml, after which the serum concentration gradually fell and the patient improved. Because of chronic renal insufficiency, she also had repeated hemodialyses on alternate days, which also contributed to the reduction in serum digoxin concentrations.

The clearance of digoxin was measured in eight patients receiving hemodialysis during the use of a beta$_2$-microglobulin column (193). After 240 minutes of hemoperfusion the serum digoxin concentration fell from 1.11 to 0.57 ng/ml and digoxin clearance was about 145 ml/minute. However, this clearance rate cannot have been the true total body clearance, since it merely reflected the change in plasma concentration during hemoperfusion, which would have been almost entirely due to removal of digoxin from the plasma only and not from the tissues. This method cannot be recommended as a substitute for the use of antidigoxin antibodies in the treatment of digitalis toxicity.

Hemofiltration

Hemofiltration has been used to treat digitalis poisoning (SEDA-12, 149), but there is no convincing evidence of its efficacy.

Exchange transfusion

There have been reports of the use of exchange transfusion to remove Fab antibody fragment-digoxin complexes in patients with acute anuric renal insufficiency (194).

- Plasma exchange was used to enhance the rate of removal of antidigoxin antibody Fab fragments in a 46-year-old man with renal insufficiency (190). Removal of the digoxin-Fab complexes in this case prevented their subsequent dissociation and a further increase in the unbound concentration of digoxin.

The authors proposed that plasma exchange is best used in these cases within the first 3 hours after the administration of antidigoxin antibodies.

- A 70-year-old man with alcoholic cirrhosis was given amiodarone and digoxin for atrial fibrillation after a hemicolectomy for adenocarcinoma (195). He developed acute renal insufficiency and digoxin toxicity, with a serum concentration of 4.4 ng/ml. A dose of Fab antidigoxin antibody fragments was followed 16 hours later by exchange transfusion and another dose was followed by two exchanges. He recovered slowly over the next few days. The total digoxin concentration (antibody bound and unbound) rose after the first dose of Fab fragments but did not fall until after the second plasma exchange (after the second dose of Fab fragments).

In this case digoxin was recovered from the plasma collection bags, but the total amount recovered seems to have been less than 100 μg, so the efficacy of plasma exchange was not clear.

Drug–Drug Interactions

General

Drug interactions with cardiac glycosides can be subdivided into six types, according to mechanism. Interactions with digoxin have been reviewed (SEDA-6, 173) (196–198). Drug interactions with digitoxin have been briefly reviewed in the context of its use in the treatment of congestive heart failure (199).

Absorption

Absorption interactions with digitalis are probably not of great clinical importance, since (a) the dosages of drugs that reduce the absorption of digitalis are usually larger than those used clinically, and (b) the major effect on absorption probably occurs only if the two drugs are taken together.

The effect of activated charcoal in reducing digitalis absorption is mentioned under the treatment of

© 2006 Elsevier B.V. All rights reserved.

poisoning, and binding resins such as colestyramine and colestipol have similar actions (200,201).

Certain combinations of cytotoxic drugs (cyclophosphamide, vincristine, and prednisone, with and without procarbazine) reduced plasma digoxin concentrations by about 50% during treatment with beta-acetyldigoxin, perhaps through impaired absorption of beta-acetyldigoxin (202); digitoxin was not affected (203).

Absorption interactions involving altered gastrointestinal motility have been described. These include interactions of digoxin with propantheline (204), metoclopramide (204), and cisapride (205). However, the clinical relevance of these interactions is unclear and they are probably unimportant.

Some antacids, such as magnesium trisilicate, reduce the absorption of digoxin slightly, but these interactions are probably of no clinical importance (206).

Protein-binding displacement

Interactions of this kind are of no importance for digoxin, which is only about 20% bound and has a high apparent volume of distribution.

An interaction of heparin with digitoxin has been described and ascribed to altered protein binding, secondary to changes in fatty acid concentrations, but the clinical relevance, for example in patients undergoing hemodialysis, is unclear (207).

Renal clearance

Digoxin is cleared by the kidneys by glomerular filtration and active secretion, and retained by passive reabsorption, the last two roughly balancing each other, so that clearance is usually proportional to creatinine clearance. A major mechanism for drug interactions with digoxin is inhibition of its renal tubular secretion by inhibition of P glycoprotein. This mechanism has been reviewed in relation to an in vitro tissue culture model, consisting of confluent polarized renal tubular cell monolayers (208). This model has confirmed the action of several drugs that can inhibit the renal tubular secretion of digoxin in this way, including amiodarone, ciclosporin, itraconazole and ketoconazole, mifepristone, propafenone, quinidine, spironolactone, verapamil, and vinblastine and vincristine.

In three large studies using either population pharmacokinetic analysis or Bayesian techniques, drugs that inhibit the transport of digoxin by inhibiting P glycoprotein significantly increased the serum digoxin concentration (143,209,210). These drugs included quinidine, spironolactone, and the calcium channel blockers diltiazem, nicardipine, nifedipine, and verapamil. The effects varied from about 22% to about 36%.

Vasodilators may increase the active secretion of digoxin, which is a high clearance process and is therefore affected by renal blood flow.

Uptake by the end-organ

The interaction of quinidine with digoxin involves displacement of digoxin from tissues.

Hyperkalemia, due to potassium chloride, potassium-retaining diuretics, ACE inhibitors, or angiotensin-receptor antagonists, reduces the apparent affinity of digitalis for Na/K-ATPase and thereby reduces its tissue binding.

Response of the end-organ

Interactions involving changes in the response of the end-organ to digitalis are the most common of all interactions with cardiac glycosides.

Potassium depletion, for example due to diuretics or corticosteroids, potentiates the effects of cardiac glycosides on the myocardium and may also have a small effect in reducing the renal tubular secretion of digoxin (211,212).

Magnesium depletion may have a similar effect (213), but the data are not as clear-cut as those for potassium.

Anecdotal reports suggest that intravenous infusion of calcium salts in patients taking digitalis can result in dangerous cardiac dysrhythmias. This may also be the basis of reports that edrophonium and suxamethonium enhance the actions of digitalis, since both of these drugs might cause altered disposition of calcium. Conversely, there is good anecdotal evidence that hypocalcemia causes reduced plasma responsiveness to digoxin (214).

Alpha-glucosidase inhibitors

Acarbose

In patients taking steady-state digoxin therapy the addition of acarbose reduced the plasma digoxin concentration (215,216). The association was confirmed in both cases by withdrawal of acarbose. The likely mechanism of this interaction is inhibition of the absorption of digoxin by acarbose, although the authors also suggested that acarbose might interfere with the hydrolysis of digoxin before absorption, thus altering the pattern of metabolites in the blood; however, this is a much less likely mechanism. The authors recommended that if acarbose be used in conjunction with digoxin, the doses should be separated by about 6 hours. This absorption interaction has previously been highlighted (217,218).

However, in a formal study of the pharmacokinetics of a single dose of digoxin 0.75 mg before and after the administration of acarbose 50 mg tds for 12 days in healthy volunteers, apart from a small increase in C_{max}, the pharmacokinetics of digoxin were unaffected by acarbose (219). It is not uncommon for anecdotal reports of a possible interaction to be unconfirmed by formal kinetic studies, and it is possible in such cases that there is a subset of patients who are susceptible to the interaction who have not been included in the formal study. In this case, for example, it may be that the interaction occurs in people with diabetes and not in healthy subjects. There may also be a difference in the effect of acarbose on a single dose of digoxin, compared with steady-state therapy. Advice that acarbose and digoxin should be administered 6 hours apart is still reasonable.

Voglibose

In eight healthy men voglibose, another inhibitor of alpha-glucosidase, had no effect on the pharmacokinetics of digoxin (220). This result suggests that inhibition of alpha-glucosidase is not the mechanism whereby acarbose alters the absorption of digoxin; however, acarbose also inhibits alpha-amylase and such inhibition cannot be ruled out as a mechanism of the interaction with acarbose, perhaps by altered gastrointestinal motility.

© 2006 Elsevier B.V. All rights reserved.

Amiodarone

Amiodarone inhibits the renal tubular secretion of digoxin (SEDA-22, 201) and it has also been suggested that it increases its absorption (SEDA-10, 144) (SEDA-12, 150). This interaction has also been reported with acetyldigoxin (SEDA-18, 198) (221).

Amiodarone also interacts with digitoxin (222). In two cases the half-life of digitoxin was prolonged, but there was no other information that suggested a mechanism. The author suggested that amiodarone might displace digitoxin from tissue sites, but that would have led to a shortening of the half-life rather than a prolongation. It seems more likely that amiodarone inhibits the clearance of digitoxin by inhibiting renal and gut P glycoprotein and perhaps by inhibiting its metabolism.

Antacids

Although digoxin is not extensively metabolized in most patients, it is metabolized before its absorption from the gut by two mechanisms, hydrolysis by gastric acid and hydrogenation by intestinal bacteria. In patients who have hypochlorhydria presystemic metabolism is reduced and increasing concentrations of digoxin are achieved systemically. This means that drugs that reduce gastric acid secretion, such as cimetidine, ranitidine, other histamine H_2 receptor antagonists, and omeprazole would be expected to increase the systemic availability of digoxin, and there is some supporting evidence (223,224), although this is not conclusive (SEDA-17, 216).

Antidysrhythmic drugs

Digoxin does not interact with a variety of antidysrhythmic drugs, including ajmaline, aprindine, lidocaine, lidoflazine (225), and moracizine (226). Other drugs that may have minor and clinically unimportant interactions include captopril, carvedilol, disopyramide, and flosequinan.

Antifungal imidazoles

Itraconazole increases steady-state serum digoxin concentrations, perhaps by inhibiting the renal tubular secretion of digoxin (SEDA-22, 202) (227–229). An alternative proposed mechanism is inhibition of CYP3A (SEDA-21, 196), and this has been reported in rats with ketoconazole (230), although an effect on P glycoprotein was also possible. Whatever the mechanism, ketoconazole increased the systemic availability of digoxin from 0.68 to 0.84 and reduced the mean absorption time from 1.1 hours to 0.3 hours. The increased systemic availability could have been explained by inhibition of CYP3A or P glycoprotein in the gut, but the increased rate of absorption could only be explained by inhibition of the P glycoprotein. Since the t_{max} was unaffected, the authors hypothesized that inhibition of P glycoprotein increased the absorption rate, which would have tended to reduce the t_{max}, while inhibition of CYP3A, which would have reduced the elimination rate of digoxin, would have tended to increase the t_{max}. Thus a combination of these two effects would have had no effect on t_{max}. It should be noted that CYP3A is an important route of metabolism of digoxin in rats, but not in man.

Digoxin toxicity sometimes accompanies this interaction.

- A 62-year-old woman who was taking digoxin took itraconazole 400 mg/day for 3 days developed nausea, anorexia, and lethargy; the symptoms improved within 48 hours after withdrawal of itraconazole (231). The serum digoxin concentrations were not reported.
- In a 75-year-old man who took itraconazole in a low dose (200 mg/day) the steady-state serum digoxin concentration only rose from 0.8 to 1.1 ng/ml after 8 days (232).
- Two renal transplant patients developed digoxin toxicity when they also took itraconazole (233).

Itraconazole increases the digoxin $AUC_{0–72}$ by about 50%, and reduces its renal clearance by about 20% (234). Apart from inhibition of the renal secretion of digoxin, which is probably mediated by inhibition of P glycoprotein, a study in guinea pigs also showed significantly reduced biliary excretion of digoxin by itraconazole, suggesting that the interaction between itraconazole and digoxin may be due not only to a reduction in renal clearance, but also to a reduction in the metabolic clearance of digoxin by itraconazole (235).

Argatroban

The thrombin inhibitor argatroban had no effect on the steady-state pharmacokinetics of oral digoxin 0.375 mg/day in 12 healthy volunteers; the argatroban was given as an intravenous infusion of 2 micrograms/kg/minute on days 11–15 (236).

Bosentan

In a randomized study in 18 young men, bosentan caused a small (12%) reduction in the AUC of digoxin, without changing either the C_{max} or the C_{min} (237). This was a steady-state study, with plasma concentration measurements for only 24 hours, and so the half-life of digoxin was not measured. Bosentan is an antagonist at endothelin type 1 receptors and could therefore have increased renal blood flow by pre- and postglomerular vasoconstriction, increasing the elimination of digoxin. Furthermore, bosentan is a substrate for P glycoprotein, which mediates the renal tubular secretion of digoxin, and may induce its expression, increasing digoxin renal clearance. However, whatever the mechanism of this putative interaction, it is clearly unlikely to be of clinical significance.

Calcium channel blockers

Calcium channel blockers have varying effects on the disposition of digoxin. The calcium channel blockers for which varying amounts of information are available include cinnarizine, diltiazem, felodipine, fendiline, gallopamil, isradipine, lidoflazine, mibefradil, nicardipine, nifedipine, nitrendipine, tiapamil, and verapamil (238).

Diltiazem

Studies of the effects of diltiazem on the pharmacokinetics of digoxin have yielded variable results. In one study, diltiazem reduced the steady-state total body clearance of beta-acetyldigoxin in 12 healthy men, perhaps because of reduced renal and non-renal clearances (SEDA-10, 145). In some studies diltiazem 120–240 mg/day increased steady-state plasma digoxin concentrations by about 20–40% (SEDA-14, 146) (239), although not in other

© 2006 Elsevier B.V. All rights reserved.

studies (SEDA-14, 146), and reduced the total body clearance of digoxin, with changes in both renal and non-renal clearances (SEDA-11, 154), although others did not find this (240). In at least one case digoxin toxicity was attributed to this interaction (SEDA-17, 216). In eight patients with chronic heart failure taking digoxin 0.25 mg/day, diltiazem 180 mg/day increased the AUC and mean steady-state serum concentrations of digoxin by 50% and reduced its total clearance (241).

Mibefradil

In 40 healthy subjects mibefradil 50 or 100 mg/day for 6 days had no significant effects on the steady-state pharmacokinetics of digoxin, apart from a very small increase in the C_{max} (242).

Tiapamil

Tiapamil reversed digoxin-induced splanchnic vasoconstriction in healthy men (243), but this has no direct effect on systemic hemodynamics.

Verapamil

Verapamil increases plasma digoxin concentrations at steady state by inhibiting the active tubular secretion and non-renal clearance of digoxin (244,245). There is only anecdotal evidence that this can result in digitalis toxicity (245,246).

Verapamil reversed digoxin-induced splanchnic vasoconstriction in healthy men (243), but this has no direct effect on systemic hemodynamics.

Captopril

There have been contradictory results in studies of the effects of captopril on digoxin pharmacokinetics. In some cases, captopril increased steady-state plasma digoxin concentrations (247), while in others there was no evidence of an interaction (248–251). In eight patients with NHYA Class IV congestive heart failure, captopril 12.5 mg tds for 1 week increased the peak digoxin concentration, reduced the time to peak, and increased the AUC during a single dosage interval at steady state; trough digoxin concentrations did not change (252). There are two possible explanations for these findings: that captopril reduced the clearance of digoxin or that it increased both the rate and extent of absorption of digoxin; unfortunately, the authors did not measure either the mean steady-state concentration or the half-life, which would have clarified this. On the whole, however, it is unlikely that this interaction is of any clinical significance, since in no study has there been evidence of digoxin toxicity during concomitant captopril therapy, and in one formal study (251) there was evidence of no pharmacodynamic interaction.

Cilomilast

In 12 healthy young adults the phosphodiesterase inhibitor cilomilast 15 mg bd for 5 days had no effect on the steady-state pharmacokinetics of digoxin, apart from a small reduction in the maximal concentration and a small increase in the time to peak (253). This was consistent with a small effect on the rate of digoxin absorption, which is unlikely to be of clinical significance. Digoxin had no effect on the disposition of cilomilast.

Cisapride

- In a 90-year-old woman the addition of cisapride 5 mg bd reduced the mean steady-state digoxin concentration from 0.9 ng/ml to 0.6 ng/ml and 5 mg tds reduced it to 0.4 ng/ml, with recurrence of her severe biventricular failure (254). When the doses of digoxin and cisapride were separated, the serum digoxin concentration rose again. The mechanism of this effect is thought to be increased gastrointestinal motility, although in this case the effect of separating the doses suggests that there might be a direct chemical interaction between the two drugs.

Citalopram

In 11 healthy adults citalopram 40 mg/day had no effect on the pharmacokinetics of a single oral dose of digoxin 1 mg (255). Digoxin did not affect citalopram pharmacokinetics.

Clopidogrel

In 12 healthy men steady-state clopidogrel 75 mg/day had no effect on the steady-state plasma concentrations of digoxin (256).

Dihydroergocriptine

The effect of dihydroergocriptine on the pharmacokinetics of a single oral dose of digoxin has been studied in 12 healthy men aged 23–39 years (257). There was no interaction.

Dofetilide

In 14 healthy men dofetilide 250 μg bd for 5 days had no effect on the pharmacokinetics of digoxin at a steady-state trough concentration of 1.0 ng/ml (258). However, in a placebo-controlled study in patients with atrial fibrillation or atrial flutter, conversion to sinus rhythm in patients given dofetilide was more likely if they were also given digoxin (259), so there may be a pharmacodynamic interaction.

Fondaparinux

Fondaparinux sodium, a selective inhibitor of coagulation factor Xa, is eliminated by the kidneys. In a randomized, crossover study in 24 healthy volunteers the pharmacokinetics and pharmacodynamics of digoxin 0.25 mg/day orally for 7 days were unaffected by fondaparinux sodium 10 mg/day subcutaneously for 7 days (260).

Hydralazine

The vasodilator hydralazine increases the renal clearance of digoxin, perhaps by increasing renal blood flow and therefore renal tubular secretion (261). This causes a small fall in plasma digoxin concentration the clinical significance of which is unclear.

© 2006 Elsevier B.V. All rights reserved.

Indometacin

Indometacin increased plasma digoxin concentrations in premature neonates with a patent ductus arteriosus (262), but a formal study in healthy adults showed no interaction (263). It may be that pre-existing impairment of renal function is required for this interaction, but this remains to be elucidated.

Levetiracetam

In 11 healthy adults in a double-blind, placebo-controlled study levetiracetam had no effect on the steady-state pharmacokinetics of digoxin or the actions of digoxin on the electrocardiogram (264).

Macrogol

Macrogol 20 g/day for 8 days caused a 30% reduction in the AUC and a 40% reduction in the C_{max} of a single dose of digoxin in 18 healthy volunteers; the t_{max} and half-life were not affected (265). This interaction was probably due to reduced absorption of digoxin, perhaps by a physicochemical interaction between the two compounds.

Macrolide antibiotics

Although digoxin is not extensively metabolized in the majority of patients, in some it is metabolized before its absorption from the gut, by two mechanisms: hydrolysis by gastric acid and hydrogenation by intestinal bacteria, mainly *Eubacterium lentum*. The macrolide antibiotics and tetracycline increase the systemic availability of digoxin, by inhibiting its breakdown by intestinal bacteria (266,267).

Macrolides have also been suggested to interact with digoxin by inhibiting P glycoprotein (SEDA-26, 200). However, in a study of this mechanism in nine healthy Japanese men, clarithromycin 200 mg bd and erythromycin 200 mg qds did not alter the plasma concentration versus time curve of a single intravenous dose of digoxin 0.5 mg, but increased its renal clearance (268). This contrasts with an observation of reduced renal clearance of digoxin in two patients taking clarithromycin (SEDA-23, 194). That inhibition of renal P glycoprotein may not reduce the renal clearance of digoxin has also been suggested by studies with talinolol (SEDA-25, 172) and atorvastatin (269). Other transport mechanisms for digoxin, including the organic anion-transporting polypeptides, have not been well studied and may play a role in digoxin disposition and hence drug interactions.

Azithromycin

- In a 31-month-old boy with Down's syndrome and Fallot's tetralogy during a 5-day course of azithromycin 5 mg/kg/day the serum digoxin concentration rose and the child had anorexia, diarrhea, and second-degree atrioventricular block with junctional extra beats (270).

The mechanism was not investigated.

Clarithromycin

- In a 72-year-old woman taking digoxin 0.25 mg/day, the addition of clarithromycin caused a rise in the serum digoxin concentration to 4.6 ng/ml (271).

In two other cases in which clarithromycin increased serum digoxin concentrations there was an associated reduction in the rate of renal digoxin clearance, which may be another mechanism for this interaction (272). The authors hypothesized that clarithromycin inhibited P glycoprotein. This was supported by the observation of a concentration-dependent effect of clarithromycin on in vitro transcellular transport of digoxin.

There is anecdotal evidence that this interaction may be clinically important. Digoxin toxicity occurred in a patient taking clarithromycin (273).

Erythromycin

- Digoxin toxicity occurred in a neonate who was also given erythromycin (274). She had bradycardia and coupled extra beats. Digoxin and erythromycin were withdrawn and she was given antidigoxin antibodies. Her plasma digoxin concentration, which had previously been 1.8 ng/ml, had risen to 8.0 ng/ml.

Meglitinides

In 12 healthy volunteers aged 19–36 years nateglinide had no effects on the pharmacokinetics of a single dose of digoxin (275). Similarly, in 14 healthy adults, repaglinide 2 mg three times had no effect on the steady-state pharmacokinetics of digoxin (276). These results suggest that the meglitinides do not affect P glycoprotein.

Nitrates

The effects of nitrates on the pharmacokinetics of digoxin are probably small.

In eight patients with chronic heart failure taking digoxin 0.25 mg/day, isosorbide dinitrate 10 mg tds caused only a small increase in C_{max} (15%) and had no effect on the mean steady-state serum concentration or AUC (241).

Nitroprusside increased the renal clearance of digoxin, perhaps by increasing renal blood flow and therefore renal tubular secretion (261). This caused a small fall in plasma digoxin concentration, the clinical significance of which is unclear.

Phenobarbital

The metabolism of digitoxin can be increased, with resulting increasing dosage requirements, by enzyme-inducing drugs (200). For example, phenobarbital 100 mg daily reduces steady-state serum digitoxin concentrations by 50%.

Propafenone

Propafenone causes a small increase in plasma digoxin concentrations by an unknown mechanism (277,278). Although this effect is perhaps not clinically significant, in patients with dysrhythmias it was accompanied by an increase in PR interval (214).

Quinidine

Digoxin

The quinidine–digoxin interaction has been reviewed (SEDA-6, 173) (SEDA-7, 195) (SEDA-9, 159) (SEDA-10, 145) (SEDA-15, 166) (SEDA-18, 198).

© 2006 Elsevier B.V. All rights reserved.

Although the major mechanism of the interaction is probably inhibition of the active tubular secretion of digoxin by quinidine, other mechanisms are involved, including reduced non-renal clearance and displacement of digoxin from the tissues. The reduction in non-renal clearance is at least partly due to a reduction in biliary clearance. This interaction affects most patients and on average causes a two-fold increase in steady-state plasma digoxin concentrations. Because both clearance and apparent volume of distribution are reduced, the half-life of digoxin is either unaffected or perhaps slightly prolonged.

In addition to the pharmacokinetic interaction, there may be a pharmacodynamic interaction, since there is some evidence that quinidine reduces the positive inotropic effect of digoxin on the heart, in addition to having a negative inotropic effect of its own. Thus, the outcome of the interaction is a 24-fold increased risk of digoxin toxicity and a reduction in its beneficial effect on the heart, at least in sinus rhythm. If the two drugs are used together, the initial digoxin dosage should be halved and adjusted subsequently on the basis of the patient's clinical condition and the plasma digoxin concentration.

Lanatoside C and metildigoxin are theoretically likely to be similarly affected by quinidine, and there is anecdotal evidence of this (279).

The pharmacokinetic interaction of quinidine with digoxin also occurs with quinine (280,281) and hydroxychloroquine (282). However, the effects of these drugs are smaller than those with quinidine. Quinine reduces the extrarenal clearance of digoxin, perhaps by altering its biliary secretion (283).

Digitoxin

In five healthy adults quinidine prolonged the half-life of a single dose of digitoxin from 174 to 261 hours and reduced its total body clearance from 1.54 to 1.09 ml/hour/kg and renal clearance from 0.65 to 0.46 ml/hour/kg. Digitoxin volume of distribution and protein binding were unaffected. Quinidine caused a rise in serum digitoxin concentrations (284).

In eight healthy subjects steady-state digitoxin plasma concentrations and renal excretion increased from 13.6 ng/ml and 16.1 μg/day before dosing to 19.7 ng/ml and 23.4 μg/day respectively during quinidine dosing for 32 days (285). Renal digitoxin clearance was not noticeably changed by quinidine, but total and extrarenal digitoxin clearances fell by 32% and 41% respectively. The half-life of digitoxin was prolonged from 150 to 203 hours. There were corresponding pharmacodynamic effects, as assessed by electrocardiography and systolic time intervals.

Quinolone antibiotics

The quinolone antimicrobial drugs gemifloxacin, levofloxacin, and sparfloxacin do not interact with digoxin.

In a crossover study in 14 healthy elderly individuals gemifloxacin 320 mg/day had no effect on the steady-state pharmacokinetics of digoxin (286).

Levofloxacin 500 mg bd for 6 days in 12 healthy volunteers did not interact with digoxin (287).

The interaction of sparfloxacin with digoxin, both at steady state, has been studied in a double-blind, placebo-controlled, crossover study in 24 healthy men aged 20–49 years. Sparfloxacin had no effect on the steady-state mean plasma concentration, C_{min}, t_{max}, or AUC of digoxin (288). Conversely digoxin did not alter the steady-state pharmacokinetics of sparfloxacin.

Rifampicin

The metabolism of digitoxin can be increased, with resulting increasing dosage requirements, by rifampicin (289).

Rifampicin also induces P glycoprotein and should therefore increase the clearance of digoxin by that mechanism. Some reports (290,291) have suggested that rifampicin reduces the steady-state concentration of digoxin. Another study in eight healthy men has shown that steady-state rifampicin significantly reduced the AUC of oral digoxin but had less of an effect on intravenous digoxin (292). The authors attributed this to induction of P glycoprotein in the intestine, with increased secretion of the drug into the gut lumen. Rifampicin has previously been reported to reduce steady-state plasma digitoxin concentrations, an effect that was attributed to induction of the metabolism of digitoxin to digoxin (289); however, in that study plasma digoxin concentrations were not measured separately, and it may be that rifampicin also increases the secretion of digitoxin into the gut lumen.

Ropinirole

In 10 patients with Parkinson's disease steady-state ropinirole treatment caused small reductions in the AUC and C_{max} of digoxin at steady state (10% and 25% respectively) (293). However, the C_{min} was unaffected and overall there was probably no significant effect of ropinirole on digoxin disposition.

Sevelamer

Sevelamer, a non-absorbed phosphate-binding polymer, in a dose of 2.4 g, had no effect on the pharmacokinetics of single doses of digoxin in 19 healthy volunteers (294).

Spironolactone

Spironolactone inhibits the active tubular secretion of digoxin by about 25% and in some cases digoxin dosages may have to be reduced (295).

St. John's wort (*Hypericum perforatum*)

St. John's wort (*Hypericum perforatum*) had no effect on the pharmacokinetics of digoxin after a single dose in 25 healthy volunteers, but during steady-state therapy it reduced the AUC of digoxin by 25% (296). There were also significant reductions in C_{max} and C_{min} (26% and 33% respectively). This effect was attributed to induction of P glycoprotein.

In Japan enough patients take St. John's wort with a cardiac glycoside to make this interaction potentially important; of 741 outpatients taking St. John's wort, 171 had been given a prescription for either digoxin or metildigoxin (297).

© 2006 Elsevier B.V. All rights reserved.

Statins

The effects of statins on the pharmacokinetics of digoxin have been variable. There is no simple explanation that reconciles the disparate findings.

- A 52-year-old man developed rhabdomyolysis while taking simvastatin, digoxin, ciclosporin, and verapamil (298). The authors proposed that this had been due in part to inhibition of the biliary secretion of simvastatin by digoxin; however, it is likely that the major mechanism of the interaction was inhibition of CYP3A4 by ciclosporin.

Atorvastatin

Atorvastatin 80 mg/day increased the AUC and C_{max} of digoxin 0.25 mg/day by 15% and 20% respectively during steady-state therapy, without affecting renal digoxin clearance (269).

Cerivastatin

In 20 healthy men, cerivastatin had no effect on the steady-state pharmacokinetics of digoxin (299). Digoxin had no significant effect on the pharmacokinetics of cerivastatin.

Fluvastatin

A single dose of fluvastatin increased the steady-state C_{max} of digoxin 0.125–0.5 mg/day by 11% and renal clearance by 15%, without changing AUC or t_{max} (300).

Rosuvastatin

Rosuvastatin 40 mg/day had no effect on the pharmacokinetics of a single oral dose of digoxin 0.5 mg in 18 healthy men (301).

Talinolol

The effects of talinolol on the pharmacokinetics of digoxin have been studied in 10 healthy volunteers aged 23–30 years in a crossover study (302). Oral talinolol 100 mg increased the AUC of digoxin significantly, but the renal clearance and half-life of digoxin were unchanged. Intravenous talinolol 30 mg had no effect on the pharmacokinetics of oral digoxin. The authors concluded that the change in AUC after oral talinolol was due to increased systemic availability of digoxin, through inhibition of intestinal P glycoprotein. They did not discuss the possibility that talinolol had also reduced the non-renal clearance of digoxin by inhibiting its biliary secretion, and indeed there was a small, albeit non-significant reduction in non-renal clearance of digoxin after both oral and intravenous talinolol. In contrast, digoxin did not affect the kinetics of talinolol.

Tamsulosin

The alpha$_1$-adrenoceptor antagonist tamsulosin 0.4 and 0.8 mg/day had no effect on the pharmacokinetics of a single intravenous dose of digoxin 0.5 mg in 10 healthy men (303).

Tegaserod

In 12 healthy subjects the 5-HT$_4$ receptor partial agonist tegaserod 6 mg bd for 3 days had a small effect on the pharmacokinetics of a single oral dose of digoxin 1 mg, reducing the mean AUC by 12% and the C_{max} by 15% (304). There was a small delay in the time to peak, which was not significant. These results suggest that tegaserod slightly reduces the systemic availability of digoxin, perhaps because it increases gastrointestinal motility, but that the effect is of no clinical significance.

Telmisartan

Multiple-dose telmisartan 120 mg/day administered with digoxin 0.25 mg/day resulted in higher serum digoxin concentrations (305). Digoxin AUC rose by 22% and C_{max} by 50%; the rise in C_{min} (13%) was not significant. These results suggest that telmisartan reduces the clearance of digoxin. The magnitude of this effect is comparable to that observed with calcium channel blockers, carvedilol, captopril, amiodarone, quinidine, and propafenone. Monitoring serum digoxin concentrations should be considered when patients first use telmisartan and when the dosage of telmisartan is changed.

Tetracycline

Although digoxin is not extensively metabolized in the majority of patients, in some it is metabolized before its absorption from the gut, by two mechanisms: hydrolysis by gastric acid and hydrogenation by intestinal bacteria, mainly *E. lentum*. Tetracycline increases the systemic availability of digoxin, by inhibiting its breakdown by intestinal bacteria (252).

Tiagabine

Tiagabine, which is principally metabolized by CYP3A, had no effect on the steady-state pharmacokinetics of digoxin in 13 healthy volunteers (306). This is evidence that CYP3A is not important in the metabolism of digoxin.

Warfarin

It has been claimed that digoxin potentiated the effects of warfarin in a 66-year-old man (307). However, the discussion of the possible mechanisms of this observation was flawed, and there is no reason to expect such an interaction, which probably does not occur (308).

Zaleplon

The effects of zaleplon on the pharmacokinetics and pharmacodynamics of steady-state digoxin have been studied in 20 healthy men aged 18–45 years (309). There was no interaction.

Interference with Diagnostic Tests

Digoxin radioimmunoassays

Spironolactone interferes with some digoxin radioimmunoassays, because it and its metabolites, such as canrenone and 7-alpha-thiomethylspironolactone, are

© 2006 Elsevier B.V. All rights reserved.

immunoreactive with some forms of antidigoxin antibody (310–312). However, in contrast to this there has been a recent report that canrenoate, the main metabolite of spironolactone, interfered with the immunoassay of digoxin (313). The effect was largest with the AxSym MEIA II assay, and there was also some interference with the EMIT assay. However, the TDx assay did not show any interference. Spironolactone also caused some interference in the AxSym assay but less than canrenoate. In this case the failure to measure high digoxin concentrations resulted in clinical toxicity in a 71-year-old man who was given 3.8 mg over 11 days.

In a study of the use of the TDx II assay in 80 children and adults, there was apparent digoxin immunoreactivity in 3.7% of healthy subjects ($n = 80$), 3.6% of pregnant women ($n = 28$), 10% of patients with renal transplants ($n = 31$), and 23% of immature infants ($n = 40$) (314).

In nine assays (AxSYM, IMx, TDx, Emit, Dimension, aca, TinaQuant, Elecsys, and Vitros) interference by spironolactone, canrenone, and three metabolites was sought in vitro, and all routine digoxin measurements using the AxSYM system over 16.5 months ($n = 3089$) were reviewed (315). There was a reduction in the expected concentrations by canrenone (3125 ng/ml) in the following assays: AxSYM (42% of expected), IMx (51%), and Dimension (78%). There was positive bias in aca (0.7 ng/ml), TDx (0.62 ng/ml), and Elecsys (>0.58 ng/ml). Of 669 routinely monitored patients, 25 had falsely low results and 19 of them actually had potentially toxic digoxin concentrations; this was attributable to concurrent therapy with spironolactone, canrenone, hydrocortisone, or prednisolone. However, standard doses of spironolactone (up to 50 mg/day) in patients with heart failure produced less than 11% inhibition.

Monitoring Therapy

The use of plasma digitalis concentrations in monitoring therapy has been reviewed (133,316).

In a retrospective analysis of 210 randomly selected digoxin plasma concentration determinations in inpatients, the indications were considered to have been inappropriate in 67, appropriate in 81, and unevaluable in 4 (317). Timing of the blood sample was wrong in 17 cases (samples should be taken at least 6 hours and preferably about 11 hours after the dose). Of the measurements whose indications were considered to have been inappropriate, most (52) were performed as part of "routine" monitoring.

The following are the main uses of plasma digitalis concentration measurements.

Individualizing therapy

In the absence of factors that alter the response to digitalis it may be worth measuring the plasma concentration during the initial stages of therapy to ensure that a reasonable concentration has been achieved (1.0–1.5 ng/ml for digoxin, 10–15 ng/ml for digitoxin). In cases where there is still a poor response to treatment it is justifiable to increase digitalis dosages cautiously, but the risk of toxicity starts to rise markedly at plasma concentrations above 2.0 and 20 ng/ml respectively. If there are subsequent changes in the patient's condition, for example renal impairment, then plasma concentration measurement may help in readjusting dosages.

Monitoring adherence

The commonest cause of a low plasma digitalis concentration in a patient taking a cardiac glycoside is poor adherence to therapy.

Making decisions about long-term therapy

If the plasma digitalis concentration is below the target range in a patient whose condition is stable (for example atrial fibrillation with a ventricular rate of 80/minute) digitalis can usually be withdrawn safely.

Diagnosis of toxicity

The underlying principles in using plasma digitalis concentrations to diagnose toxicity are as follows:

1. The plasma digitalis concentration must be considered in conjunction with other clinical information, that is symptoms, the signs of possible intoxication, the stability of the underlying condition, age, renal function, the dosage, and biochemical measurements such as the plasma potassium concentration.
2. At plasma digitalis concentrations above 3.0 ng/ml (digoxin) or 30 ng/ml (digitoxin) toxicity is highly likely. At concentrations below 1.5 or 15 ng/ml, respectively, toxicity is unlikely. However, toxicity can occur even with low concentrations and should be suspected particularly if there is hypokalemia.
3. Certain factors increase the risk of digitalis toxicity at a given plasma concentration (see Susceptibility Factors). These factors will alter the interpretation of the plasma digitalis concentration and should lower the threshold for suspicion.
4. When in doubt it is far better to withhold digitalis and monitor progress than to continue treatment, thereby running the risk of perpetuating toxicity.

In patients whose condition is satisfactory and stable and whose plasma digoxin concentration is low (below 0.8 ng/ml), withdrawal of digoxin is recommended and is highly unlikely to affect the patient's condition (discussed in the section Making decisions about long-term therapy). Probably the same applies for digitoxin at concentrations below 8.0 ng/ml, although that has not been demonstrated.

It has yet again been confirmed that the serum digoxin concentration distinguishes between patients with and without digoxin toxicity, but with considerable overlap (318). Of 99 patients, 41 with toxicity had mean serum digoxin concentrations of 3.1 ng/ml compared with 1.6 ng/ml in 58 non-toxic patients. However the digoxin concentration was below 2 ng/ml in 10 patients with toxicity and higher than 2 ng/ml in 16 patients without. There were no significant differences in serum electrolyte concentrations between the toxic and non-toxic patients, and the authors therefore concluded that such abnormalities are less important than they have usually been considered to be. However, this study does not demonstrate that at all; rather it shows that even if serum electrolyte concentrations are well controlled it may not be possible to avoid digitalis toxicity for other reasons. Indeed, in this study

© 2006 Elsevier B.V. All rights reserved.

the patients with toxicity had significantly worse renal function, which would have explained their increased risk.

Carisoprodol

General Information

Carisoprodol is a precursor of meprobamate, an oral anxiolytic with similarities to benzodiazepines. The spasmolytic effect of carisoprodol is thought to be due to interruption of neuronal communication within the reticular formation and spinal cord. Major adverse effects are sedation and drowsiness.

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Nervous system

In 104 cases carisoprodol and its metabolite meprobamate were detected in the blood of car drivers who were either involved in accidents or arrested for impaired driving (1). In many of these cases, either alcohol or other nervous system depressants were also found. In 21 cases carisoprodol/meprobamate were the only drugs detected. Symptoms and reported driving behavior were similar in all cases. Impairment of driving ability appeared to be possible at any concentration of these two drugs. However, the most severe driving impairment and most overt symptoms of intoxication were noted when the combined concentration of carisoprodol and meprobamate exceeded 10 mg/l.

Long-Term Effects

Drug dependence

Because of its relation to benzodiazepines, dependence on carisoprodol can be a problem. Among patients who had taken carisoprodol for 3 months or more, up to 40% had used it in amounts larger than prescribed, and up to 30% had used it for an effect other than that for which it was prescribed (2). A significant percentage of physicians were unaware of the potential of carisoprodol for abuse and of its metabolism to meprobamate. Patients with carisoprodol withdrawal can present with agitation, restlessness, hallucinations, seizures, anorexia, and vomiting.

Drug Administration

Drug overdose

Carisoprodol overdose is reportedly rarely fatal. However, a review of the deaths examined at the Jefferson County Medical Examiner Office from 1986 to 1997 revealed 24 cases of carisoprodol overdosage (3). In all 24 cases other co-intoxicants were involved. Since the mechanism of death was respiratory depression in 82% of the cases, the authors suggested that carisoprodol had contributed to the fatal outcome. Carisoprodol overdosage should be regarded as potentially fatal if other respiratory depressants add to its effect.

Carisoprodol intoxication can also be associated with symptoms of nervous system overactivity rather than depression. Agitation and myoclonic movement disorders have been observed (4).

As carisoprodol and its metabolite meprobamate are GABA receptor agonists, the use of the benzodiazepine receptor antagonist flumazenil might be considered in some cases of carisoprodol toxicity (5).

- A 51-year-old woman took 87 tablets of carisoprodol (350 mg each) over 13 days and developed lethargy and abnormal speech. She was confused and her Glasgow Coma Score was 9/15. Her pupils were small and reactive. Two boluses of naloxone 2 mg were administered with no effect. After flumazenil 0.2 mg she became more alert but was still mildly somnolent. After a second dose of flumazenil 0.2 mg all signs of intoxication were reversed within 2 minutes. Her blood concentrations at admission were 7.4 μg/ml for carisoprodol and 30.7 μg/ml for meprobamate.

This suggests that flumazenil may be an effective therapeutic option if carisoprodol intoxication results in nervous system depression. However, carisoprodol overdose can also produce myoclonic movements or agitation (4), in which case it is questionable if flumazenil should be used.

Carnidazole

General Information

Carnidazole is an imidazole derivative, less potent than most other similar compounds (1). In early studies, its adverse effects were mild; nausea and vomiting, abdominal discomfort, dry mouth, dizziness, headache, and tiredness were reported (SEDA-6, 264). Metronidazole-like adverse effects should be anticipated.

Antimicrob Agents chemother 1985;28(4):561–4.

Carprofen

See also Non-steroidal anti-inflammatory drugs

General Information

The main adverse effects of the NSAID carprofen are cutaneous and hepatic. Photoreactions are being increasingly reported and its chemical similarity to benoxaprofen is worth noting (SEDA-12, 84). The photosensitivity mechanism is either toxic or allergic.

© 2006 Elsevier B.V. All rights reserved.

Other cutaneous symptoms, such as burning, pruritus, dermatitis, and skin redness, have also been reported (1). In trials in the USA, 14% of 1500 patients had slight transient rises in liver function tests, the significance of which is unclear (SEDA-13, 79). Headache, dizziness, gastrointestinal discomfort, and dysuria have also been described (1). Asthma can be precipitated in aspirin-sensitive patients.

Susceptibility Factors

Other features of the patient

Although carprofen is reported to be well tolerated by patients with peptic ulcers taking ranitidine (2), it cannot be presumed to be without risk in patients with ulcer disease.

Carvedilol

See also Beta-adrenoceptor antagonists

General Information

Carvedilol is a highly lipophilic non-selective beta-adrenoceptor antagonist with alpha$_1$-blocking action, promoting peripheral vasodilatation. It also has free radical scavenging and antimitogenic effects.

The safety and tolerability profile of carvedilol in heart failure appears to be reassuring (1). In trials in patients with congestive heart failure, carvedilol was withdrawn in only about 5% (2). The most common adverse reactions were edema, dizziness, bradycardia, hypotension, nausea, diarrhea, and blurred vision. The rate of drug withdrawal was not different among patients under 65 years and among older ones.

The largest trial of carvedilol in patients with heart failure documented only a 5% withdrawal rate in 1197 patients during the open phase that preceded randomization. The major reasons for withdrawal were worsening heart failure (2%), dizziness (1.1%), bradycardia (0.2%), and death (0.5%). Overall, 78% of the patients who entered the trial and were randomized to carvedilol achieved the target dose of 50 mg/day, and withdrawal rates were comparable with carvedilol and placebo (11–14% over 6.5 months of treatment).

The issue of tolerability is particularly important in patients with severe heart failure (NYHA class IV). Unfortunately, so far all trials with carvedilol have failed to recruit a large number of such patients. A retrospective analysis of the tolerability profile of carvedilol in 63 patients with NYHA class IV heart failure showed that non-fatal adverse events while taking carvedilol were more frequent than in patients with class II-III heart failure (43 versus 24%) and more often resulted in permanent withdrawal of the drug (25 versus 13%) (3). However, 59% of the patients with class IV heart failure improved by one or more functional class after 3 months of treatment. The conclusion was that carvedilol is a useful adjunctive therapy for patients with NYHA class IV heart failure, but these patients require close observation during the start of treatment and titration of the dose.

In patients with heart failure, amiodarone is often required for the treatment of serious ventricular dysrhythmias. The beneficial effects of carvedilol on left ventricular remodeling, systolic function, and symptomatic status were not altered by amiodarone in 80 patients with heart failure. Adverse effects that necessitated withdrawal of carvedilol were no more frequent in patients taking amiodarone than in those taking carvedilol alone (26 versus 25%) (4).

In 10 patients with gastroesophageal varices, none having bled, treated with oral carvedilol 12.5 mg/day for 4 weeks, hemodynamic measurements were performed before the first administration and at 1 hour and 4 weeks after (5). After acute administration, the hepatic venous pressure gradient was significantly reduced by 23% (from 16.4 to 12.6 mmHg), with a significant reduction in heart rate. After 4 weeks, the hepatic venous pressure gradient was further significantly reduced to 9.3 mmHg. Carvedilol was well tolerated, and only one patient had asymptomatic hypotension. The results of this study suggest that low-dose carvedilol significantly reduces portal pressure without significantly systemic hemodynamic effects. The reduction in portal pressure with carvedilol was larger than that obtained with propranolol, encouraging specific trials of carvedilol for the primary prevention of variceal hemorrhage.

Organs and Systems

Cardiovascular

Since the adrenergic system is activated to support reduced contractility of the failing heart, the administration of a beta-blocker in a patient with heart failure can cause myocardial depression. This effect is more marked with non-selective first-generation beta-blockers, such as propranolol. Carvedilol has an acceptable tolerability profile, reducing after-load and thus counteracting the negative inotropic properties of adrenoceptor blockade. While these vasodilatory properties can play a favorable role at the start of treatment, it is less likely that vasodilatation can make a substantial contribution to the long-term effects of third-generation beta-blockers.

As with other alpha-blockers, postural hypotension is quite common with carvedilol, especially in elderly people (6). In a comparison of carvedilol with pindolol in elderly patients, postural hypotension occurred even with small doses of carvedilol (12.5 mg) (7). The authors concluded

© 2006 Elsevier B.V. All rights reserved.

that lower starting doses should be used in elderly people, in patients taking diuretics, and in patients with heart failure.

Liver

Liver function abnormalities in trials of carvedilol occurred in 1.1% of patients taking carvedilol compared with 0.9% in patients taking placebo (2). However, in all trials the patients with pre-existing liver disease were excluded, and so information on the effects of carvedilol in these patients is not available.

Urinary tract

Renal insufficiency can occur in patients with heart failure treated with carvedilol, usually when pre-existing renal insufficiency, low blood pressure, or diffuse vascular disease are present (2). Patients at high risk of renal dysfunction should be carefully monitored, particularly at the beginning of treatment, and the drug should be withdrawn in case renal function worsens.

Skin

- Stevens–Johnson syndrome occurred in a 71-year-old man with stable ischemic cardiomyopathy taking carvedilol (8).

Sexual function

In a comparison of carvedilol with valsartan in 160 patients with hypertension (mean age 46 years) each treatment was continued for 16 weeks, with crossover after 4 weeks of placebo (9). Blood pressure was significantly lowered by both drugs (48% normalization with valsartan and 45% with carvedilol). In the first month of treatment, sexual activity (assessed as the number of episodes of sexual intercourse per month) fell with both treatments compared with baseline, although the change was statistically significant only with carvedilol. After the first month of treatment, sexual activity further worsened with carvedilol, but it improved or recovered fully with valsartan. The results were confirmed by the crossover. This confirms that beta-blockers can cause chronic worsening of sexual function.

Drug Administration

Drug overdose

Overdosage of carvedilol results mainly in hypotension and bradycardia (2). For excessive bradycardia, atropine has been used successfully, while to support ventricular function intravenous glucagon, dobutamine, or isoprenaline have been recommended. For severe hypotension, adrenaline or noradrenaline can be given.

Catheters

General Information

Adverse effects can arise from physical effects of catheters used for intravenous, intra-arterial, urinary, or spinal access. Adverse reactions can also occur from the latex that some catheters contain or from the antiseptics with which they are sometimes combined.

Central venous catheters are reluctantly used as blood access for hemodialysis because of safety concerns and frequent complications, for example sepsis, thrombosis, and vessel stenosis. Nevertheless, 20% or more of all patients rely on atrial catheters for chronic dialysis because of lack of other access. Potentially fatal risks related to central venous catheters include air embolism (1), severe blood loss (2), and electric shock (3). These specific risks have been substantially eliminated by the inherent design and implantation of Dialock (Biolink Corporation, USA). Dialock is a subcutaneous device consisting of a titanium housing with two passages with integrated valves connected to two silicone catheters. The system is implanted subcutaneously below the clavicle. The tips of the catheters are placed in the right atrium. The port is accessed percutaneously with needle cannulas.

The results of a study of Dialock/CLS have been reported in 70 patients (29 men, 41 women; mean age at implantation 63 (range 30–88) years), of whom 42 had no infection (45 when infections occurring within 30 days after implantation were omitted) (4). Excluding these early events, 25 patients had a total of 30 infections. The majority (22 events in 20 patients) were pocket infections. The first seven of these pocket infections caused loss of the Dialock. After local treatment with gentamicin no further devices were lost through pocket infection. No infections were recorded during the last 3 months, although the expected rate calculated on the basis of

© 2006 Elsevier B.V. All rights reserved.

previous occurrences would have been about four. This may have been related to increased nursing care.

Fracture of a central venous catheter due to compression between the clavicle and the adjacent first rib has been reported (5). A "pinched-off sign" on X-ray indicates the need to remove the catheter, because of a significant risk of subsequent fracture, which has an incidence of 0.9%. Catheters lying anterior to the subclavian vein between the clavicle and the first rib are liable to be compressed and to fracture subsequently. This is a potentially life-threatening complication that can be averted by correct placing of the central venous catheter and by immediate chest radiography to search for evidence of catheter kinking or compression.

Totally implantable venous devices are being increasingly used in patients who require long-term continuous parenteral drug therapy, especially in cancer chemotherapy. Inevitably there have been complications, including catheter fracture, as a consequence of "pinched-off" syndrome (6).

- A 67-year-old woman was provided with a totally implantable venous device in the right subclavian vein by the Seldinger technique with a peel-away sheath. The device was used for a course of chemotherapy. After about 1 month there was subcutaneous extravasation of the drug. A chest X-ray showed that the silicone catheter had fractured below the clavicle and the distal portion of the catheter had embolized into the right atrium. The fragments were removed.

This "pinched-off" effect appears to be due to narrowing of the catheter as it passes over the first rib and beneath the clavicle, when using the Seldinger technique, but it is usually only observed after long-term use. The authors recommended that the cephalic cut-down (Seldinger) technique is best avoided.

Continuous venous access for extended periods is commonly required in patients with cancer for chemotherapy delivery. Transcutaneously tunnelled central venous lines provide one means for the administration of such therapy, although they account for significant costs and morbidity (7). In a prospective study, 923 central venous tunnelled catheters in 791 patients were evaluated for devise-specific events. The most important adverse events included 11 insertion complications. Subsequent to placement, a proven or suspected devise-specific complication occurred in 540 lines. For every 10 000 catheter days there were 17.6 episodes of infection, 8.1 thrombotic complications, 6.9 instances of catheter breakage, 3.5 accidental or inadvertent cases of catheter displacement, and 0.6 device leaks. The devices were in position for a median of 365 days, but the median duration of device-specific complications was 167 days, reflecting a highly significant device salvage rate after complications. The authors concluded that central lines can be placed safely for use in long-term administration of cancer chemotherapy. Factors determining outcome are related to where the device is placed as well as the patient's disease.

Migration of a catheter caused failure of parenteral nutrition in a baby (8).

- A premature small-for-dates girl (34 weeks gestation, birth weight 1000 g) received parenteral nutrition for necrotizing enterocolitis. On day 7, among several septic spots that developed on the skin, an abscess developed on the left shoulder and ruptured spontaneously, leaving a superficial ulcer with purulent discharge. This was cleaned daily with isotonic saline and covered with gauze. On day 11, the blood glucose fell to 1.3 mmol/l and 10% glucose was given. Four further episodes of hypoglycemia during the next 12 hours were similarly treated. Over the next 12 hours the baby became lethargic, hypothermic, and apneic. Her blood glucose remained low (0.9–1.6 mmol/l). Several hours later she became bradycardic and hypotensive. It was then noticed that her bed linen was wet, and some fluid was seen trickling from the ulcer on her shoulder. A chest X-ray showed that the catheter tip had migrated to the left cephalic vein adjacent to the site of the ulcer. Despite rigorous resuscitation she died.

The authors speculated that the catheter tip had spontaneously migrated because the ulcer on the left shoulder had eroded deeply to form a venocutaneous fistula with the left cephalic vein. Continuous leakage of parenteral nutrition fluid through the fistula was soaked up by the gauze pads used to cover the ulcer, preventing early recognition of the problem.

In a systematic review of randomized studies of the use of different catheter materials for umbilical catheterization in newborn infants of any birth weight or gestation, there were no significant differences between heparin-bonded polyurethane catheters and polyvinyl chloride (PVC) catheters (9).

Organs and Systems

Cardiovascular

A major complication of intravenous infusion is thrombophlebitis, which is a principle limitation of peripheral parenteral nutrition. Its precise pathogenesis is unclear, but venospasm has been proposed as the most likely cause. However, in a study with ultrasound techniques to monitor vein caliber, there was no evidence to support this hypothesis, although thrombophlebitis was observed (10). The author suggested that the initiating event may be venous endothelial trauma, caused by the venepuncture itself, abrasion at the catheter tip, or the delivery of the feeding solution.

Venous reactions could also theoretically be influenced by the composition of the fat emulsion, because long-chain triglycerides, in particular, generate prostaglandin synthesis which can in turn effect vein tolerance. This potentially important issue has been assessed in a randomized, comparative trial of peripheral parenteral nutrition regimens with fat emulsions containing either long-chain triglycerides alone or in equal proportions with medium-chain triglycerides (11). All other factors were standardized. Long-chain triglyceride-based fat emulsions significantly prolonged the life of the peripheral vein, compared with mixtures of medium-chain and long-chain triglycerides. The authors hypothesized that this effect was due to a reduced reaction of the venous epithelium to the irritating nutritional mixture.

Superior vena cava thrombosis has been described after frequent central venous catheterization and total parenteral nutrition, with eventual partial recovery (12).

© 2006 Elsevier B.V. All rights reserved.

The possible etiological factors included the catheter material, catheter-related sepsis, endothelial trauma, osmotic injury, and hypercoagulability. Although thrombosis of the great veins of the thorax is rare, it is life-threatening, characterized by swelling of the head, upper limbs, and torso, and on chest X-ray by mediastinal widening. Confirmation of thrombosis is best achieved by contrast venography or contrast-enhanced CT scan.

Cardiac tamponade is a serious complication of central venous catheterization. A classical case history has been described with detailed discussion of prevention and management (13). Most serious complications, including air embolism, pneumothorax, hemothorax, chylothorax, chylopericardium, rupture of the right atrium, ventricular dysrhythmias, and cardiac tamponade, are essentially mechanical injuries relating to catheter insertion. Cardiac tamponade can be caused by acute perforation of the superior vena cava during insertion. Alternatively, a delayed event may be due to catheter-related erosion of the vascular wall, either in the vena cava or in the ventricular wall. The consequences are impairment of diastolic filling and a dramatic decrease in cardiac output, with a very high death rate (about 70%).

- A 63-year-old man with cancer of the esophagus developed severe dysphagia. A central venous catheter was introduced for presurgical parenteral nutrition and 3 hours later he reported severe epigastric and retrosternal pain. His condition deteriorated rapidly, with loss of consciousness, a weak pulse, hypotension, distant heart sounds, and jugular venous distension. A chest X-ray showed an enlarged mediastinal shadow and an electrocardiogram showed reduced voltage. The catheter was promptly removed. An emergency laparotomy showed only hepatic engorgement and about 100 ml of ascites, but at thoracotomy the pericardial sac was distended by about 500 ml of clear fluid. There was no apparent injury to the right subclavian artery or evidence of pleural hemorrhage.

The authors concluded that the right ventricle had been perforated by the catheter and they pointed out that these events can be insidious, and can take several months before symptoms suddenly start, requiring quick diagnosis and immediate intervention. This includes immediate removal of the catheter and often also emergency surgical intervention.

Respiratory

Lung transplant patients appear to be at increased risk of air embolism from catheters perhaps because of the considerable negative intrathoracic pressure that can develop when the diseased lung is replaced with a normal lung. Lung transplant patients are often also emaciated and have little subcutaneous tissue, allowing for a short tract from the central venous line insertion site to the opening of the central vein.

- A 53-year-old woman developed a serious air embolism from the central venous catheter tract after lung transplantation, at the time of removal of the catheter (14).

The authors referred in their report to four other cases of air embolism in lung transplant patients.

Nervous system

Complications have been described after the insertion of 157 intrathecal catheters in 142 patients (15). In most cases problems were related to the placement procedure, with subsequent neurological complications. Clinically unsuspected degeneration of the posterior columns, perhaps related to intraspinal infusion of morphine or to a paraneoplastic effect, has been observed postmortem in two patients with implanted pumps (16).

Paraplegia has been reported 2 months after morphine infusion by intrathecal catheter (17). Another case of paraplegia was reported in a 73-year-old man with an intrathecal catheter and a spinal cord stimulator (18).

Fluid balance

Umbilical venous catheters are commonly used in neonatal care for drug administration and parenteral nutrition. However, many risks are associated with their use. Ascites associated with parenteral nutrition have been reported (19).

- A girl weighing 1488 g was born by emergency cesarean section at 28 weeks gestation. An umbilical venous catheter was inserted as sole venous access. An abdominal X-ray showed that the catheter was at the level of T11/T12 in the midline. Owing to complications with oral feeding, parenteral nutrition was begun on day 2. The baby developed necrotizing enterocolitis and had to be ventilated. An abdominal X-ray suggested abdominal ascites. A diagnostic paracentesis produced 90 ml of bloodstained opalescent fluid, which settled to show a white layer on the surface (presumed to be fat emulsion). Following this procedure, respiratory status improved. Ultrasound and aerated saline tests on the umbilical venous catheter suggested that it had not migrated to the peritoneal cavity. However, it was removed and the abdominal distension resolved. The baby was extubated 3 days later and subsequently thrived with no further abdominal problems.

Hematologic

Heparinization of the fluid infused through an umbilical arterial catheter with heparin 0.25 units/ml reduces the likelihood of catheter occlusion; heparinization of flushes without heparinizing the infusate is ineffective (20).

Immunologic

Anaphylaxis to a central venous catheter (ARROWg+ard Blue Catheter) coated with chlorhexidine and sulfadiazine has been reported in a 50-year-old man (21).

Infection risk

Systemic catheter-related infections and local infections at catheter exit sites have been studied in relation to 479 central venous catheters in a prospective study in 311 patients in a general hospital in Australia (22). Local infections developed in association with 54 catheters (11%) and systemic infections with 32 (6.7%). Local

© 2006 Elsevier B.V. All rights reserved.

infections predicted systemic infections, but the absence of a local infection did not exclude the possibility of systemic infection. Local complications included entry-site abscesses, cellulitis, and septic thrombophlebitis. Hemodialysis catheters were responsible for a higher rate of systemic infections than other types. Of all cases of bacteremia (33/160) detected in the hospital, 20% occurred in patients with a central venous catheter, and 24 of these (73%) were definitely or probably due to the catheter. The most common organism responsible was methicillin-resistant *Staphylococcus aureus*, and 40% of cases were due to catheter-related infection. Infection complications were few: three patients developed local abscesses, one developed endocarditis, and two died. In other surveys infective endocarditis has complicated 20% of systemic catheter-related infections, but it occurred only once in this study. It is possible that the short duration of this study (5 months) resulted in an underestimate of the real incidence of late complications of catheter-related infections. Innocuous in situ catheters can apparently be responsible for systemic infections. In other studies the risk of infection depended mainly on the duration of catheter therapy (23,24).

Catheter-related bacteremia due to *Pseudomonas paucimobilis* has been reported in two patients with cancer-associated neutropenia (25). This organism has rarely been implicated in community-acquired and nosocomial infections. Both patients had been undergoing intensive chemotherapy, and both required removal of the catheter to eradicate the infection.

There is some disagreement as to whether infectious complications differ with the use of different types of chronic central venous access devices in patients with cancer. In one study there was no significant difference in the risk of infection between subcutaneous ports and external catheters (26). However, this has been disputed by other workers, who found that in children with cancer there was a lower infection rate when subcutaneous ports were used compared with external catheters (27). The differences between the studies and the conclusions reached may be the result of their size and design, rather than real differences.

In 55 patients, continuous lumbar sympathetic blockade with local anesthetics administered via a catheter to treat sympathetic pain caused a psoas abscess in two patients, both of whom were treated with a continuous infusion of 0.25% bupivacaine (28). It was assumed that the catheter had been dislodged and that the drug had been injected into the psoas muscle or the psoas sheath. Another reason for this complication could have been local trauma due to a hematoma around the vertebrae during the insertion of the needle. The main drawbacks of the technique were the high incidences of infections and displacement of the catheters.

Infective endocarditis is a serious complication of centrally placed venous access devices. The successful treatment in situ of a large thrombus associated with the tip of the catheter has been described (29). The antibiotic regimen was gentamicin and vancomycin, both delivered via the venous access device; vancomycin was allowed to remain in situ between each 8-hourly dosing. This regimen successfully eradicated the thrombus within 3 weeks, without removal of the line.

In a prospective, double-blind study, the use of either vancomycin + heparin + ciprofloxacin or vancomycin + heparin flush solution, compared with heparin alone, significantly reduced the infective complications associated with tunnelled central venous lines in immunocompromised children. Neither antibiotic could be detected after flushing and there were no adverse events (30).

The incidence and types of complications related to central venous catheters in 71 patients with AIDS have been studied and compared with two control groups of patients without AIDS (65 immunocompromised patients and 14 immunocompetent patients receiving home total parenteral nutrition) (31). Three groups of patients requiring permanent venous access for administration of virustatics and/or total parenteral nutrition were investigated retrospectively. The Port-A-Cath system of implantation was used in all cases. Catheter-related mortality was low in all the groups (0–1%). Infectious complications could not be related to the degree of immunosuppression (CD4+ lymphocyte counts or white blood cell count). The incidence of both infectious and non-infectious complications was significantly higher in the immunocompetent subjects than in the others, probably because of the type of medium used and/or differences in handling of the catheter. The overall conclusions were that central venous catheters are safe and well tolerated by patients with AIDS and that they present no greater risk to them than they do to other categories of patients, regardless of degrees of immune competence. This conclusion should be regarded with some caution, given the retrospective nature of the study and the imbalance in the number of subjects studied in each category. However, it appears that totally implantable central venous catheters are safe and well tolerated by patients with AIDS, no differently to other immunocompromised patients and immunocompetent patients.

Total parenteral nutrition

Catheter sepsis rates in total parenteral nutrition are variable, depending on several patient factors. These include immunosuppression or associated critical illness, multiple intravascular catheters, and bacterial transfer from another source in the body. Catheter-related sepsis can present as fever, chills, change in mental status, hypotension, and leukocytosis. In patients with suspected catheter-related infection whose peripheral blood cultures do not grow the same organism as a culture drawn directly from the catheter, a guide wire exchange of the catheter may be effective. However, this is a surgical procedure which can become complicated by catheter malposition, air embolism, dislodgement of a septic thrombus, or cardiac dysrhythmias (32).

In a study of catheter infection in patients treated with total parenteral nutrition a distant septic focus was present in 165 of 244 patients (188 of 269 catheters: 70%). There was a colonization rate of 19% of the catheters of the patients with a distant septic focus, compared with 7.4% in patients without a distant septic focus. There was a high mortality rate in patients with a distant septic focus and a colonized catheter; sepsis was responsible for 33 of the 48 deaths (69%) in this group (33).

If a centrally placed venous catheter is required, tunnelling of the catheter under the skin from the entry point to the appropriate vein minimizes the risk of infection,

© 2006 Elsevier B.V. All rights reserved.

and the inclusion of an internal cuff on the catheter provides a more reliable subcutaneous anchor point. The purpose of the cuff is to fibrose to the wall of subcutaneous tissue, helping to prevent dislodgement of the catheter and reduce the risk that infection will migrate from the entrance site in the skin. Cuffed catheters can be composed of polyurethane or silicone. It has been suggested that the former is better, because they are theoretically less thrombogenic. However, in a prospective study there was no difference between the two types (34). Mean catheter lifespans were similar, as were complication rates (including sepsis, obstruction, dislodgement, and thrombosis). However, fractures were entirely associated with the detachable flow-control devise. The authors therefore concluded that there was little evidence to support the hypothesis that polyurethane catheters offer more security in long-term parenteral nutrition.

Catheter infections in recipients of parenteral nutrition are of particular concern in children and can result in line removal, deep vein thrombosis, or an increased risk of liver disease. The incidence of catheter-related infections in 47 children receiving long-term parenteral nutrition has been studied retrospectively, one goal being to identify potential risk factors (35). The children had 125 catheters and 207 catheter-years. The average infection rate was 2.1/1000 parenteral nutrition days. The only factor identified was that early onset of infection after starting parenteral nutrition appeared to predict a poor prognosis.

HIV-positive subjects are expected to be at even greater risk of line-related infection. A prospective study of 212 subjects with HIV infection with 327 central venous catheters has provided evidence of this enhanced risk (36). Over the period 1994–97, 33% were suspected as being infected, although only 61 episodes were diagnosed as catheter-related sepsis. Three variables affected the rate of sepsis: parenteral nutrition, low numbers of circulating CD+ cells, and a high Apache score.

General Information

The genera in the family of Celastraceae (Table 1) include bittersweet and khat.

Table 1 The genera of Celastraceae

Canotia (canotia)
Cassine (cassine)
Catha (khat)
Celastrus (bittersweet)
Crossopetalum (crossopetalum)
Euonymus (spindle tree)
Gyminda (false box)
Lophopyxis
Maytenus (mayten)
Mortonia (saddlebush)
Pachystima (pachystima)
Paxistima (paxistima)
Perrottetia (perrottetia)
Pristimera (pristimera)
Salacia
Schaefferia (schaefferia)
Torralbasia (torralbasia)
Tripterygium

Catha edulis

Chewing the leaves of *Catha edulis* (khat, qat) results in subjective mental stimulation, increased physical endurance, and increased self-esteem and social interaction. Until recently, this habit was confined to Arabian and East African countries, because only fresh leaves are active, but because of increased air transportation, khat is now also chewed in other parts of the world. Although cathine (norpseudoephedrine) is quantitatively the main alkaloid, the amphetamine-like euphorigenic and sympathomimetic cardiovascular effects of khat are primarily attributed to cathinone (1). In Yemen chewers of khat produced in fields where chemical pesticides are used regularly have more symptoms than chewers of khat produced in fields where chemical pesticides are rarely or never used (2).

The toxicologist Louis Lewin described the effects of chewing khat in his monograph *Phantastica* (1924): "The khat eater is happy when he hears everyone talk in turn and tries to contribute to this social entertainment. In this way the hours pass in a rapid and agreeable manner. Khat produces joyous excitation and gaiety. Desire for sleep is banished, energy is revived during the hot hours of the day, and the feeling of hunger on long marches is dispersed. Messengers and warriors use khat because it makes the ingestion of food unnecessary for several days."

Adverse effects

Tachycardia and increased blood pressure, irritability, psychosis, and psychic dependence have been described as acute adverse effects of khat.

The long term adverse effects were well described by Louis Lewin: "Those organs functions which are incessantly subjected to the influence of the drug finally flag or are diverted into another channel of activity ... The khat eater is seized with a restlessness which robs him of sleep. The excited cerebral hemispheres do not return to their normal state of repose, and in consequence the functions of the peripheral organs, especially those of the heart, suffer to such a degree that serious cardiac affectations have been ascertained in a great number of khat eaters. The disorders of the nervous system in many cases also give rise to troubles of general metabolism partly due to the chronic loss of appetite from the consumption of khat ... In Yemen it was openly stated that inveterate eaters of khat were indifferent to sexual excitation and desire, and did not marry at all, or for economic reasons waited until they had saved enough money. The lost of libido sexualis has been also observed in other inhabitants of these countries."

Cardiovascular

When 80 healthy volunteers chewed fresh khat leaves for 3 hours there were significant progressive rises in systolic and diastolic blood pressures and heart rate, without return to baseline 1 hour after chewing had ceased (3).

Of 247 chronic khat chewers 169 (62%) had hemorrhoids and 124 (45%) underwent hemorrhoidectomy; by comparison, of 200 non-khat chewers 8 (4%) had hemorrhoids and one underwent hemorrhoidectomy (4).

Nervous system
Of 19 khat users suspected of driving under the influence of drugs, three had impaired driving and 10 had marked impairment of psychophysical functions with effects on the nervous system (slow pupil reaction to light, dry mouth, increased heart rate), trembling, restlessness/nervousness, daze/apathy/dullness, and impaired attention, walking, and standing on one leg; however, the concentrations of the khat alkaloids assayed in blood did not correlate with the symptoms of impairment (5).

A leukoencephalopathy has been associated with khat (6).

Psychiatric
Khat has amphetamine-like effects and can cause psychoses (7–13), including mania (14) and hypnagogic hallucinations (15). Two men developed relapsing short-lasting psychotic episodes after chewing khat leaves; the psychotic symptoms disappeared without any treatment within 1 week (16).

In 800 Yemeni adults (aged 15–76 years) symptoms that might have been caused by the use of khat were elicited by face-to-face interviews; 90 items covered nine scales of the following domains: somatization, depression, anxiety, phobia, hostility, interpersonal sensitivity, obsessive-compulsive, hostility, interpersonal sensitivity, paranoia, and psychoticism (17). At least one life-time episode of khat use was reported in 82% of men and 43% of women. The incidence of adverse psychological symptoms was not greater in khat users, and there was a negative association between the use of khat and the incidence of phobic symptoms.

Psychological
In 25 daily khat-chewing flight attendants, 39 occasional khat-chewing flight attendants, and 24 non-khat-chewing aircrew members, memory function test scores were significantly lower in khat chewers than non-chewers and in regular chewers than occasional chewers (18).

Sensory systems
Bilateral optic atrophy occurred in two patients who were long-standing users of khat leaves and had chewed larger quantities than usual (19).

Metabolism
Chronic khat chewing increased plasma glucose and C-peptide concentrations in people with type 2 diabetes mellitus (20).

Mouth
In 20 volunteers who chewed khat regularly (10–160 g/day), there was an eight-fold increase in micronucleated buccal mucosa cells compared with 10 controls (21). Among heavy khat chewers, 81% of nuclei had a centromere signal, suggesting that khat is aneuploidogenic. The effects of khat, tobacco, and alcohol were additive. The highest frequency of abnormality occurred during the fourth week after consumption.

Of 2500 Yemeni citizens (mean age 27 years) 1528 (61%) were khat chewers; of them, 342 cases (22%) had oral keratotic white lesions at the site of khat chewing, while only 6 (0.6%) non-chewers had such lesions; the prevalence and severity of these lesions increased as duration and frequency of use increased (22).

However, in a case-control study in 85 khat-chewing Kenyans and 141 matched controls, smoking unprocessed tobacco (Kiraiku) and smoking cigarettes were the most significant factors for oral leukoplakia; traditional beer, khat, and chili peppers were not significantly associated with oral leukoplakia (23).

A 30-year-old immigrant from Somalia developed a plasma-cell gingivitis in the mandibular gums, probably caused by chewing khat (24).

Chewing khat can cause a generalized mousy brown pigmentation of the gums (25).

Gastrointestinal
In 12 healthy volunteers who chewed Khat leaves or lettuce for 2 hours gastric emptying was significantly prolonged by khat (26).

Chewing khat is said to be a risk factor of duodenal ulceration. (27).

Urinary tract
In 11 healthy men khat chewing produced a fall in average and maximum urine flow rate; this effect was inhibited by the alpha$_1$-adrenoceptor antagonist indoramin (28).

Sexual function
Chewing khat lowers libido and can also lead to erectile impotence after long-term use (29).

Fertility
In 65 Yemeni khat addicts (mean duration of addiction 25 years; mean age 40 years), semen volume, sperm count, sperm motility and motility index, and percentage of normal spermatozoa were lower than in 50 controls (30). There were significant negative correlations between the duration of khat consumption and all semen parameters. On electron microscopy, about 65% of the spermatozoa were deformed, with different patterns of deformation, including both the head and flagella in complete spermatozoa, aflagellate heads, headless flagella, and multiple heads and flagella. Deformed heads had aberrant nuclei with immature nuclear chromatin and polymorphic intranuclear inclusions; these were associated with acrosomal defects.

Fetotoxicity
In pregnant women, consumption of khat affects fetal growth by inhibiting placental blood flow (29), and birth weights are reduced (31). In 1141 consecutive deliveries in Yemen, non-users of khat ($n = 427$) had significantly fewer low birth-weight babies (less than 2500 g) than occasional users ($n = 223$) and regular users ($n = 391$) (32). Khat-chewing mothers were older, of greater parity, and had more surviving children than the non-chewers. Significantly more khat-chewers had concomitant diseases. There was no difference in rates of stillbirth or congenital malformations.

© 2006 Elsevier B.V. All rights reserved.

Lactation
Khat chewing by a breastfeeding mother can lead to the presence of cathine in the urine of the suckling child.

Drug interactions
The speed and extent of ampicillin systemic availability were reduced significantly by khat chewing in eight healthy adult Yemeni men, except when they took it 2 hours after the khat (33).

Euonymus species

The fruit of *Euonymus europaeus* (the European spindle tree) and the bark of *Euonymus atropurpureus* (Wahoo bark) have cathartic and emetic activity, due to sesquiterpenoids and cardiac glycosides that they contain.

Adverse effects
IgE-mediated type I allergy to *E. europaeus* wood has been described in a 44-year-old goldsmith who developed rhinitis and conjunctivitis after having worked with dust from the wood for 15 years (34).

Tripterygium wilfordii

Extracts from the root of *Tripterygium wilfordii* (Lei gong teng) are used in China for the treatment of various disorders, such as rheumatoid arthritis, ankylosing spondylitis, systemic lupus erythematosus, and glomerulonephritis. The potential benefits in such serious diseases should be carefully weighed against a substantial risk of adverse reactions, including gastrointestinal disturbances, skin rashes, amenorrhea, leukopenia, and thrombocytopenia (35).

Adverse effects
Cardiovascular

- A previously healthy young man developed profuse vomiting and diarrhea, leukopenia, renal insufficiency, profound hypotension, and shock after taking an extract of *T. wilfordii* (36). Serial electrocardiograms, cardiac enzymes, and echocardiography showed evidence of coexisting cardiac damage. He died of intractable shock 3 days later.

Gastrointestinal
In a double-blind, placebo-controlled study in 35 patients with long-standing rheumatoid arthritis in whom conventional therapy had failed, an extract of *T. wilfordii* was used in either a low-dose (180 mg/day) or a high-dose (360 mg/day) for 20 weeks, followed by an open extension period (37). Only 21 patients completed the study, of whom one in each group withdrew because of adverse events. The most common adverse effect of *T. wilfordii* was diarrhea, which caused one patient in the high-dose group to withdraw.

Reproductive system
In men, prolonged use of *T. wilfordii* can cause oligospermia and azoospermia, and a reduction in testicular size (38–40).

In 14 women with rheumatoid arthritis *T. wilfordii* caused amenorrhea associated with increased FSH and LH concentrations, which began to rise after 2–3 months and reached menopausal values after 4–5 months; estradiol concentrations began to fall after 3–4 months and reached very low concentrations at 5 months, suggesting an effect on the ovary (41).

Immunologic
The immunosuppressive properties of Lei gong teng can promote the development of infectious diseases (42).

Teratogenicity
A boy whose mother had taken *T. wilfordii* for rheumatoid arthritis early in her pregnancy was born with an occipital meningoencephalocele and cerebellar agenesis, which the authors attributed to the herb (43).

Celecoxib

See also COX-2 inhibitors

General Information

Celecoxib is a selective COX-2 inhibitor.

Organs and Systems

Psychological, psychiatric

A 78-year-old woman had auditory hallucinations while taking celecoxib for osteoarthritis (1). Her symptoms occurred after she had taken celecoxib 200 mg bd for 48 hours and progressed over the next 8 days. Celecoxib was withdrawn and her hallucinations gradually disappeared over the next 4 days. Rechallenge with a lower dose (100 mg bd) caused recurrence.

There have been two reports of visual hallucinations in patients taking celecoxib.

- A 79-year-old woman presented to her optometrist with a 2-day history of seeing orange spots in both visual fields 2 months after starting to take celecoxib 100 mg/day (2). Physical examination and a CT scan were normal. Celecoxib was withdrawn and her symptoms resolved within 3 days.
- An 81-year-old woman took celecoxib 100 mg/day, and over the next 2 weeks developed delirium and auditory and visual hallucinations (3). Celecoxib was withdrawn and her symptoms resolved over several days. She took a few doses of rofecoxib 12.5 mg/day 6 months later without any problem. She began to take rofecoxib regularly again 2 months later, and after 1 month developed agitation, confusion, and hallucinations. Physical examination suggested no cause of the delirium other than rofecoxib. A CT scan was negative. The rofecoxib was withdrawn, and over the next 2 days her symptoms resolved

© 2006 Elsevier B.V. All rights reserved.

Auditory hallucinations have been previously reported in a patient taking celecoxib (SEDA-25, 134) but are probably uncommon.

Hematologic

A report has raised the possibility that patients with a known prothrombotic state and raised platelet thromboxane A_2 production may be at high risk of thrombosis when selective COX-2 inhibitors are used (4).

Thrombosis occurred during celecoxib therapy (400 mg/day) in four women (aged 37–56 years) with connective tissue diseases and conditions that predisposed them to thrombosis, including Raynaud's phenomenon, raised anticardiolipin antibody titers, and a previous history of thrombosis. Peripheral artery thrombosis (three patients) and pulmonary embolism (one patient) were documented after starting celecoxib. Symptoms of thrombosis began to appear within 1 week of starting celecoxib in three patients and 2 months after starting celecoxib in the fourth patient.

A causal relation between celecoxib and these thrombotic events cannot be established with certainty on the basis of the available evidence. However, the temporal relation between the start of treatment and the thrombotic event was impressive, at least in three patients, and the findings were consistent with the hypothesis that thrombosis is an adverse consequence of reduced production of systemic prostaglandin I_2 brought about by COX-2 inhibition. Reduced synthesis of prostaglandin I_2 may act in concert with other thrombotic risk factors (such as those occurring in this series of patients) to precipitate acute vascular occlusion.

Gastrointestinal

Celecoxib reportedly exacerbated inflammatory bowel disease in two patients (5).

- An 80-year-old woman with ulcerative colitis started taking celecoxib for arthritic pain, and 3 days later developed abdominal pain and diarrhea. Celecoxib was withdrawn and her symptoms improved.
- A 35-year-old woman with ileal and perianal Crohn's disease took four doses of celecoxib for an orthopedic injury, and had rectal bleeding, severe abdominal pain, and worse diarrhea. Celecoxib was withdrawn and her symptoms returned to baseline within 5 days.

The possible association of NSAIDs with inflammatory bowel disease is a matter of controversy (SEDA-25, 131), and there is little clinical experience with the selective COX-2 inhibitors. Coxibs should not be prescribed for patients with chronic inflammatory bowel disease until more experience has accumulated.

Liver

A 67-year-old woman developed acute hepatocellular and cholestatic liver damage after taking celecoxib 100 mg/day for 1 week (6). Celecoxib was withdrawn and the liver function tests normalized within 2 weeks.

There have been three case reports of acute cholestatic hepatitis in patients taking celecoxib.

- A 55-year-old non-alcoholic obese woman, who was allergic to sulfa drugs, presented with a 5-day history of jaundice, malaise, and a pruritic rash that began 3 weeks after she started to take celecoxib 200 mg/day for radicular pain (7). There were marked increases in liver enzymes and bilirubin and a peripheral eosinophilia. Liver biopsy showed marked intrahepatocyte cholestasis with eosinophil-rich inflammation, consistent with a drug reaction. Her symptoms and laboratory abnormalities completely resolved after withdrawal of celecoxib but took a long time (4 months) to normalize.
- A 54-year-old woman took celecoxib 200 mg/day for sacroiliac pain (8). After 4 days her pain resolved, but she developed generalized pruritus, which resolved when celecoxib was withdrawn. A week later, the pain recurred and celecoxib was restarted; 2 days later she again developed pruritus associated with dark urine, and 5 days later jaundice and raised bilirubin and liver enzymes. Her eosinophil count was raised. On withdrawal of celecoxib her liver function tests improved and her symptoms resolved.
- A 49-year-old man with alcoholic cirrhosis developed jaundice, fatigue, and choluria after he started to take celecoxib 200 mg/day for musculoskeletal pain (9). There were increases in transaminases, alkaline phosphatase, and bilirubin (to 547 μmol/l). Liver biopsy showed cirrhosis and marked hepatocellular cholestasis. On withdrawal of celecoxib the bilirubin began to fall very slowly; 1 year later he was well, with a total bilirubin concentration of 44 μmol/l.

The histories, clinical findings, and laboratory tests in these cases all suggested celecoxib-induced acute cholestatic hepatitis. The first case suggested that a sulfonamide-like allergic reaction was the pathogenic mechanism, and the same mechanism cannot be excluded in the other two patients, as sulfonamide allergy is often ignored and is discovered only when an adverse reaction occurs. Celecoxib should not be given to patients who are allergic to sulfa drugs.

Urinary tract

As more experience accumulates it appears clear that COX-2 inhibitors have a nephrotoxic potential similar to that of the non-selective NSAIDs. Sixteen cases of tubulointerstitial nephritis were reported to the manufacturers of celecoxib between the time when it was launched in 1999 and July 2001, but the diagnosis was not confirmed in 12 of these cases (10). Most of these renal adverse reactions occur in patients with susceptibility factors associated with prostaglandin-dependent renal function (11–13).

Skin

Skin reactions, including rashes, urticaria, and other allergic reactions, are not uncommon, according to data reported to the Australian Adverse Reactions Advisory Committee (14) and other reports (15–17).

Stevens–Johnson syndrome occurred in a 58-year-old man taking celecoxib (18). He recovered promptly after withdrawal. The reaction recurred 1 month later, after one dose of celecoxib.

© 2006 Elsevier B.V. All rights reserved.

Sweet's syndrome can be associated with several drugs. A case involving celecoxib has been reported (19).

- A 57-year-old man developed the typical cutaneous erosions and plaques of Sweet's syndrome after taking celecoxib 100 mg bd for 1 week for bursitis. Celecoxib was withdrawn and the mucocutaneous lesions began to clear. However, the bursitis recurred and he restarted celecoxib. The cutaneous lesions worsened dramatically. After withdrawal of celecoxib for the second time the lesions cleared completely.

Drug–Drug Interactions

Clopidogrel

Co-administration of celecoxib and clopidogrel can increase the hemorrhagic potential of clopidogrel, possibly by a pharmacokinetic interaction involving CYP2C9 (20). However, this possibility requires confirmation, as serious, sometimes fatal, hemorrhage has been reported during the postmarketing use of clopidogrel alone (21).

Warfarin

Celecoxib can potentiate the anticoagulant effects of warfarin. Although concomitant administration of celecoxib and warfarin had no significant effect on prothrombin time or the steady-state pharmacokinetics of *S*-warfarin or *R*-warfarin in 24 healthy volunteers (22), serious bleeding complications have been reported to adverse drug reactions monitoring systems (23) and in journals (24–26). These data suggest that celecoxib potentiates the anticoagulant effects of warfarin in some patients. Patients taking warfarin must be fully monitored when celecoxib is adding, changed, or withdrawn.

Celiprolol

See also Beta-adrenoceptor antagonists

General Information

Celiprolol is a beta$_1$-selective antagonist with partial beta$_2$-agonist activity. In healthy volunteers it caused "particularly unpleasant" subjective adverse effects, including headache, sleepiness, and feeling cold and generally unwell (1). However, it has beneficial effects on lipids, reducing total cholesterol by 6% and low-density lipoproteins by 10% (SEDA-17, 235). Whether this translates into clinical benefit is not known, and celiprolol has no convincing advantages over other beta-blockers (2).

Organs and Systems

Respiratory

There has been a report of hypersensitivity pneumonitis secondary to celiprolol (3).

Cephalosporins

See also Beta-lactam antibiotics

General Information

The cephalosporins represent a family of beta-lactam antibiotics originally derived from the naturally occurring cephalosporin C. Isolation of the cephalosporin C nucleus, 7-aminocephalosporanic acid, made it possible to introduce new groups into this molecule to obtain the current variety of compounds (1). Cephalosporins vary widely in their antibacterial properties, beta-lactamase stability, and pharmacokinetic behavior, but there is as yet no unequivocal classification (2). For reasons more practical than pharmacological, cephalosporins are often classified into first-, second-, third- and fourth-generation compounds, as shown in Table 1.

General adverse effects

Reactions that parallel those observed with penicillins include local reactions to parenteral administration, epileptogenicity, effects on sodium and potassium balance, autoimmune hemolytic anemia, neutropenia, thrombocytopenia, and altered platelet function.

More specifically associated with cephalosporins are false-positive Coombs' tests (also seen with clavulanic acid and imipenem + cilastatin), impaired vitamin K-dependent clotting factor synthesis with cephalosporins that contain the *N*-methylthiotetrazole side chain, biliary sludge formation with ceftriaxone, tubular nephrotoxicity of some older compounds (cefaloridine, cefaloglycin, and cefalotin), and disulfiram-like interactions with alcohol. Anaphylactic shock and other IgE antibody-mediated reactions are rare, but analogous to those experienced with the penicillins. Sufficiently reliable tests to predict or prove these reactions are still lacking for the cephalosporins. Other hypersensitivity reactions include acute interstitial nephritis, the majority of drug-inducible mucocutaneous manifestations, and various combinations of symptoms often referred to as "serum sickness-like reactions."

Table 1 Some cephalosporins and cephamycins (all rINNs except where stated)

Orally active cephalosporins	Injectable cephalosporins
Cefaclor[2] (pINN)	Cefamandole[2] (pINN)
Cefadroxil[3] (pINN)	Cefazolin[3] (pINN)
Cefalexin[2] (pINN)	Cefotaxime[3]
Cefetamet[3]	Cefoxitin[2]
Cefixime[3]	Ceftazidime[3]
*Cefradine[1]	Ceftizoxime[3]
*Cefuroxime[2]	Ceftriaxone[3]
	Cefuroxime[2]
	Latamoxef[3] (pINN)

[1]First-generation drugs
[2]Second-generation drugs
[3]Third-generation drugs
*Can also be given by injection

Organs and Systems

Cardiovascular

In isolated cases, cefalotin (3) and cefaclor (4) have been suspected to cause hypersensitivity myocarditis.

Respiratory

Diffuse pulmonary inflammation, as documented by gallium scanning in one case, was possibly caused by ceftriaxone (5). Cefotiam and in another case cefotiam followed by ceftazidime have been suspected to have caused pulmonary hypersensitivity (6,7).

Cefotetan-induced hiccup recurred after each cefotetan infusion and disappeared immediately after withdrawal; it did not recur after administration of another antibiotic (8). Intractable hiccups in a boy were attributed to ceftriaxone-induced pseudolithiasis (9).

Nervous system
