To determine the frequency and types of malignancies that occur in children with end-stage renal insufficiency who required renal replacement therapy, data from 249 patients were analysed retrospectively (57). There were 22 malignancies in 21 patients; skin cancers accounted for 59% and non-Hodgkin's lymphomas for 23%. At 25 years after first renal replacement therapy, the probability of developing a malignancy was 17%. The incidence of cancers overall was 10-fold higher than in the general population. For cancers other than melanoma and non-Hodgkin's lymphoma, the standardized risks were 222 and 46 respectively. The use of more than 20 mg/kg cyclophosphamide was associated with an increased risk of malignancy. Six patients died as a result of their malignancy, accounting for 9.5% of overall mortality. The long-term risk of certain malignancies is significantly increased in children who have undergone renal replacement therapy, especially after treatment with cyclophosphamide.

Second-Generation Effects

Fertility

Cyclophosphamide, or testicular and cranial irradiation, in the treatment of childhood malignancies can lead to small testicular size and decreased sperm production in adulthood (58). Of 17 adult male survivors of childhood sarcomas treated before puberty with high-dose cyclophosphamide, only two had normal sperm counts, 10 had azoospermia, and five had oligospermia (34). The two patients with normal sperm counts had taken the lowest doses of cyclophosphamide.

Gonadal toxicity has been documented in both men and women receiving cyclophosphamide (4). In men, the incidence of transient or permanent oligospermia/azoospermia is 50–90%, and in prepubertal patients spermatogenesis will more readily return to normal than adults. In one study, testosterone prophylaxis given at the same time as cyclophosphamide reduced the incidence of disorders of spermatogenesis and accelerated spermatogenesis recovery after cyclophosphamide discontinuation, but few patients were evaluable (59).

Of 23 men treated with either cyclophosphamide or non-alkylating agent combinations, there was a dose-related disturbance of gonadotrophin secretion in the cyclophosphamide group (60). The chances of maintaining normal gonadal function after combined treatment of Hodgkin's disease are significantly greater among girls than boys at 9-year follow-up (61). Pre- and post-pubescent boys were affected by six cycles of MOPP, whether or not pelvic radiation was administered; on the other hand, in girls similarly treated, ovarian function was directly affected by the number of courses of chemotherapy and the ovarian radiation dose (62). In a study of male gonadal function at 9 years follow-up after regimens containing cyclophosphamide, mechlorethamine, vincristine, or procarbazine, there was azoospermia, whereas regimens containing dactinomycin and vinblastine did not have a toxic effect on spermatogenesis (63). Testicular volume and sperm count in 18 patients, 1–3 years after chemotherapy, showed that all those who had received chemotherapy that did not include cisplatin had normal testicular size and sperm counts, whereas of seven who had received cisplatin, six had small testes and azoospermia and one was oligozoospermic with normal-sized testes (64).

The risk of ovarian failure and infertility has been studied in 84 women with an underlying inflammatory disease receiving intravenous cyclophosphamide (65). The incidence of sustained amenorrhea was 22% and was independent of the underlying inflammatory disease. After treatment with cyclophosphamide following bone marrow transplantation, ovarian function can occasionally recover, resulting in a successful pregnancy up to 7 years after treatment (66). No specific factors correlated with recovery of normal ovarian function. However, recovery was rare if the patient had undergone concurrent total body irradiation (67).

Pregnancy

Cyclophosphamide crosses the placenta and reaches an amniotic fluid concentration of 25%. Six pregnancies occurred in women taking cyclophosphamide; three had induced abortions, one had a spontaneous abortion, and two had normal pregnancies. After withdrawal of cyclophosphamide, 16 women became pregnant; three had induced abortions for severe morphological anomalies, three had spontaneous miscarriages, and 10 delivered healthy infants. Contraception during intravenous cyclophosphamide therapy is recommended, and after withdrawal, pregnancy is possible, with a favourable outcome in two-thirds of cases.

Teratogenicity

The FDA has classified cyclophosphamide as a pregnancy risk factor D drug: it is teratogenic in animals, but population studies have not conclusively shown teratogenicity in humans. However, in a study of in utero first-trimester exposure to four doses of cyclophosphamide 20 mg/kg it was concluded that cyclophosphamide is a human teratogen, that there is a distinct embryopathic phenotype, and that there are serious doubts about the safety of cyclophosphamide in pregnancy (68). The congenital malformation rate has been estimated at 10–44% (69).

Reported congenital abnormalities are many and include facial and palate defects, skin and skeletal anomalies, and visceral malformations. Based on one case and a review of six previous reports of malformations after in utero exposure to cyclophosphamide in the first trimester, a distinct embryopathy due to cyclophosphamide has been suggested (68). The proposed phenotype included growth deficiency, developmental delay, craniosynostosis, blepharophimosis, flat nasal bridge, abnormal ears, and distal limb defects; chromosomes were normal.

In one case of first-trimester exposure to cyclophosphamide in a woman pregnant with twins, the male twin was born with multiple congenital abnormalities and developed papillary thyroid cancer at 11 years of age and stage III neuroblastoma at 14 years of age; the female twin was unaffected (70).

Most cases have been reported in patients with cancer who were also exposed to other antineoplastic drugs or to irradiation. The potential for congenital abnormalities in the offspring of men treated with cyclophosphamide is yet unknown.

Fetotoxicity

The effects of second- or third-trimester exposure to cyclophosphamide are poorly documented, although normal children have been described (71). However, in other cases growth retardation and neutropenia have been reported (72).

Drug Administration

Drug dosage regimens

In inflammatory or autoimmune diseases, both daily oral and cyclic pulse intravenous cyclophosphamide regimens are used, but it is unclear whether one route of administration should be preferred to another. The cumulative dose obtained in those given an intravenous pulse regimen is consistently lower than in those given daily oral administration, and the incidence of bladder cancer or infection is expected to be lower in the former. However, the choice of the maintenance regimen remains a dilemma as regards efficacy and toxicity (73). For example, in one study in 50 patients with Wegener's granulomatosis there was a similar overall incidence of adverse effects in patients treated with prednisone plus oral cyclophosphamide compared with those who received prednisone plus intravenous pulse cyclophosphamide (74). Patients in the oral group had a higher incidence of severe or fatal infectious complications, but a lower incidence of cumulative relapse rates at 4.5 years.

In 47 patients intravenous pulsed cyclophosphamide was as effective as daily oral cyclophosphamide, but caused fewer adverse effects (75). The patients were randomized to receive monthly intravenous pulses of cyclophosphamide (0.75 g/m^2, $n = 22$) or daily oral cyclophosphamide (2 mg/kg/day, $n = 25$) for at least 1 year. Both groups received glucocorticoids. Whereas efficacy end-points did not show significant differences between the two groups, leukopenia (18 versus 60%) and severe infections (14% with no deaths versus 40% with three deaths) were significantly less frequent with intravenous pulsed cyclophosphamide. As a result, the probability of freedom from adverse effects (no deaths, severe infections, leukopenia, or thrombocytopenia) over a 12-month period was only about 25% in the oral group, compared with 70% in the intravenous group. In addition, and based on the findings of a significantly lower serum follicle-stimulating hormone concentration at 3 and 6 months and a 57% reduction in the total dose in the intravenous pulse group, the intravenous pulse regimen was expected to produce fewer adverse gonadal effects and a reduced risk of malignancies.

Drug–Drug Interactions

Cisplatin

A 4-year follow-up of comparison of a combination of cyclophosphamide with either 50 mg/m^2 or 100 mg/m^2 of cisplatin in ovarian cancer has been reported (76). Peripheral neuropathy was dose-limiting and persistent. Ten of thirty-one patients had significant toxicity in the high-dose group compared with one of 24 in the low-dose group.

Fluconazole

Cyclophosphamide is a prodrug that requires cytochrome P_{450}-dependent hepatic activation to produce alkylating species and several inactive by-products. However, very few metabolic interactions involving cyclophosphamide have been reported. In a retrospective study of 22 children treated with cyclophosphamide for cancer or bone marrow transplantation, cyclophosphamide clearance was significantly lower in nine patients taking fluconazole compared with 13 patients not taking it (77). In vitro studies in human liver microsomes confirmed that the rate of 4-hydroxylation of cyclophosphamide was inhibited by fluconazole.

Prednisolone

Daily prednisolone significantly reduced the total clearance of cyclophosphamide and the peak concentration and AUC of 4-hydroxycyclophosphamide (78). It is not known whether this interaction has clinical consequences.

Cyclopropane

See also General anesthetics

General Information

Cyclopropane is an inhalational anesthetic gas. Its minimum alveolar concentration (MAC) is 9.2%. Because of the risk of explosion, it is usually administered by closed circuit (1).

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Cardiovascular

Cardiac dysrhythmias, which can be ventricular, can complicate the use of cyclopropane (2), and the risk is increased in patients who have also been given catecholamines (3).

Nervous system

Delirium can occur in patients given cyclopropane (4).

Gastrointestinal

Nausea and vomiting are fairly frequent after recovery from cyclopropane anesthesia (5,6).

Liver

Liver dysfunction due to cyclopropane, as judged by effects on indocyanine green clearance, has been reported (7).

Urinary tract

Cyclopropane has an antidiuretic effect that is partly reversed by alcohol (8).

Body temperature

There has been a report of malignant hyperthermia in a patient who was given cyclopropane during cesarean section (9), consistent with the in vitro effect of cyclopropane on caffeine-induced muscle contraction (10).

See also Antituberculosis drugs

General Information

Cycloserine is an aminoisoxazolidone that shows no cross-resistance with other tuberculostatic agents (1). Because of its high toxicity, it should only be used when microorganisms are resistant to other drugs (relapse or primary resistance). It is usually given orally.

Organs and Systems

Nervous system

Cycloserine can cause headache, somnolence, and tremor (2). In mice, L-cycloserine protects against auditory-invoked seizures by binding to pyridoxal phosphate in the presence of zinc ions (3). The addition of a fluoroquinolone can increase the risk of nervous system effects (4).

Psychological, psychiatric

Cycloserine can cause altered mood, cognitive deterioration, dysarthria, confusion, and even psychotic crises (2).

Susceptibility Factors

Renal disease

Cycloserine accumulates to toxic concentrations in patients with renal insufficiency (5).

Cyproheptadine

See also Antihistamines

General Information

Cyproheptadine is a first-generation antihistamine with antiserotoninergic effects (SEDA-12, 142). It has been used because of its appetite-stimulating capacity.

© 2006 Elsevier B.V. All rights reserved.

Drowsiness and other adverse effects common to the first-generation antihistamines are common.

Organs and Systems

Psychological, psychiatric

A central anticholinergic syndrome with psychotic symptoms in a 9-year-old boy on therapeutic doses has also been described (1).

Cyproheptadine (6 mg/day) was considered to be the most likely cause of aggressive behaviour in a 5-year-old boy (2).

Long-Term Effects

Drug dependence

A case of cyproheptadine dependence has been reported (SEDA-12, 142).

Drug Administration

Drug overdose

Cyproheptadine caused a reversible toxic psychosis in a patient with renal impairment and low body weight after an incidental overdose of 24 mg within 24 hours (SEDA-2, 150).

Cytarabine

See also Cytostatic and immunosuppressant drugs

General Information

Cytarabine is a pyrimidine nucleoside that is used to treat acute myelogenous leukemia and lymphocytic leukemias. It is activated intracellularly by deoxycytidine kinase to phosphorylated nucleotides that interfere with DNA synthesis in the S phase of the cell, and is rapidly deaminated intracellularly to the inactive metabolite uracil arabinoside.

Organs and Systems

Respiratory

Two cases of respiratory failure occurred during induction chemotherapy for acute myelomonocytic leukemia with cytarabine and all-*trans*-retinoic acid (1). The authors attributed this to a manifestation of the retinoic acid syndrome. Both patients developed acute respiratory failure with widespread pulmonary infiltrates about 60 hours after starting chemotherapy. Both were managed successfully using high-dose dexamethasone and ventilation.

Nervous system

Central nervous system disturbances, especially impaired cerebellar function, limit doses of cytarabine, and age is an important predictive factor. Of 418 patients who received 36–48 g/m^2 only 35 (8%) had severe cerebellar toxicity, which was irreversible or fatal in 4 (1%) (2). Patients over 50 years of age were significantly more likely to develop cerebellar problems than younger patients (26/137, 19%, compared with 9/281, 3%); a second course did not increase the incidence, implying that it is the individual rather than the cumulative dose that is important.

The cerebellar syndrome is the most common complication of high-dose cytarabine therapy. In a study of the cerebellar syndrome caused by cytarabine (3), in which it was found in seven of 30 patients treated, symptoms of toxicity appeared between the third and seventh days of chemotherapy, manifesting first as lethargy and confusion (3). Within the next 24 hours there were signs of cerebellar dysfunction, including dysarthria, ataxia, tremor, nystagmus, and dysmetria. In most patients in whom neurotoxicity developed, liver function worsened during chemotherapy. Abnormal liver function at the start of therapy and the development of neurotoxicity appear to be linked. The symptoms of neurotoxicity resolved within 4–49 days.

Aseptic meningitis can also occur in patients given cytarabine (4,5), and signs of cerebellar dysfunction after the administration of cytarabine 24 g/m^2 have been reported in association with aseptic meningitis (6).

Sensory systems

Keratoconjunctivitis is a complication of cytarabine therapy, with a reported incidence of 30–100% and commonly associated with high doses (3 g/m^2). Corneal and conjunctival toxicity have been described after therapy for 4 days with 235 mg (100 mg/m^2) daily (7).

Gastrointestinal

The addition of cytarabine 10 mg/m^2/day subcutaneously for 10 days to interferon monotherapy more than doubled the incidence of gastrointestinal toxicity in the treatment of chronic myeloid leukemia in 139 patients (8).

Skin

Acute, painful, swollen, and self-limiting erythema of the hands and soles has been reported after induction therapy for acute myeloid leukemia and attributed to cytarabine (9).

© 2006 Elsevier B.V. All rights reserved.

Immunologic

A hypersensitivity reaction has been ascribed to cytarabine (10).

Drug Administration

Drug administration route

The safe intrathecal administration of a long-acting formulation of cytarabine has been reported (11).

Drug–Drug Interactions

Daunorubicin

Hepatotoxicity, with either hyperbilirubinemia or increased alkaline phosphatase activity, occurred in five of 14 patients in a trial of cytarabine 200 mg/m^2/day for 9 days by continuous infusion and daunorubicin 70 mg/m^2/day for 3 days (12).

Cytostatic and immunosuppressant drugs

See also Individual agents *and* Alkylating cytostatic agents

General Information

Cytostatic drugs generally have both anticancer and immunosuppressive properties, while immunosuppressant drugs have more specific immunosuppressive effects, although this is a somewhat arbitrary distinction. The following list of drugs is based on the classification used in the *British National Formulary*. Monoclonal antibodies and corticosteroids are not included in this list.

A. Cytostatic drugs

1. Alkylating drugs
   Nitrosoureas: carmustine (BCNU), lomustine (CCNU), nimustine (ACNU), streptozocin.
   N-lost derivatives: chlormethine (mechlorethamine, mustine, nitrogen mustard), cyclophosphamide, estramustine.
   Others: busulfan, chlorambucil, dacarbazine, ifosfamide, melphalan, mitobronitol, mitomycin, procarbazine, thiotepa, temozolomide, treosulfan.
2. Antimetabolites
   Folic acid antagonists: methotrexate, raltitrexed.
   Purine derivatives: cladribine (2-chlorodeoxyadenosine), fludarabine, mercaptopurine, pentostatin (deoxycoformycin), tioguanine.
   Pyrimidine derivatives: capecitabine, cytarabine, fluorouracil (SEDA-23, 476), gemcitabine, tegafur.
3. Cytostatic antibiotics
   Anthracyclines (SEDA-25, 533): aclarubicin, daunorubicin, doxorubicin, epirubicin, idarubicin.
   Others: acivicin, amsacrine, bleomycin, dactinomycin (actinomycin D), mitoxantrone.
4. Photodynamic drugs: porfimer, temoporfin.
5. Platinum compounds (SEDA-26, 490): carboplatin, cisplatin, oxaliplatin.
6. Taxanes: docetaxel, paclitaxel (SEDA-21, 463).
7. Topoisomerase inhibitors (SEDA-27, 477)
   Inhibitors of topoisomerase type 1: irinotecan, topotecan.
   Inhibitors of topoisomerase type 2: etoposide, teniposide.
8. Vinca alkaloids (SEDA-28, 538): vinblastine, vincristine, vindesine, vinorelbine.
9. Others: bexarotene, bortezomib, colaspase and crisantaspase (asparaginases), hydroxycarbamide (hydroxyurea).

B. Immunosuppressant drugs

1. Antiproliferative immunosuppressants: azathioprine, mycophenolate mofetil.

© 2006 Elsevier B.V. All rights reserved.

2. Calcineurin inhibitors: ciclosporin, everolimus, pimecrolimus, sirolimus, tacrolimus, temsirolimus.

General adverse effects

There are several types of adverse effects that the cytostatic drugs have in common. These include hyperuricemia (as a result of tumor lysis syndrome), bone marrow suppression, oral mucositis, gastrointestinal discomfort, and alopecia. These are dealt with under the relevant headings below.

Individual drugs also have specific adverse effects. However, one of the difficulties in attributing adverse effects to individual cytostatic and immunosuppressant drugs is the common use of multidrug or multiintervention studies. A good example of this is the Phase I Study of Foscan-Mediated Photodynamic Therapy and Surgery in Patients with Mesothelioma, in which the authors could not separate the adverse effects, which included local effects, cardiotoxicity, and hepatotoxicity, according to causative drug or procedure (1).

Extravasation of cytostatic drugs

Extravasation is leakage of intravenous drugs from a vein into the surrounding tissues. This can cause local pain accompanied by burning or stinging, erythema, swelling, and tenderness. Not all cytostatic drugs are harmful to the tissues after extravasation. The different types of drugs are classified in Table 1.

The management of extravasation of cytostatic drugs has been reviewed (2–5) and guidelines have been suggested (http://www.ucht.n-i.nhs.uk/pubinfo/Extravasation_of_intravenous_drugs).

Local extravasation

- Stop administering the drug and explain to the patient that extravasation may have occurred.
- Put on gloves and goggles.
- Leave the cannula in place.
- Attach a 20 ml syringe and try to withdraw residual drug.
- Give specific antidotes for specific cytostatic drugs (Table 2).
- Remove the cannula.
- Do not apply pressure, which increases the area of extravasation.
- Apply a thermal pack (for vesicant, exfoliant, and irritant drugs only) (Table 2).
- Raise the limb for 48 hours for vesicant drugs.
- Review vesicant extravasation in 24 hours.
- Consult a plastic surgeon if necessary.

Extravasation from a central venous catheter

If the patient complains of altered sensation, pain, burning, or swelling at the central venous catheter site or in the ipsilateral chest, or if there is a change in intravenous flow rate, extravasation may have occurred.

- Stop administering the drug and explain to the patient that extravasation may have occurred.
- Put on gloves and goggles.
- Attach a 20 ml syringe and try to withdraw residual drug from the line.
- If the reason for extravasation is needle dislodgement, and if aspiration through the needle was unsuccessful, remove the needle and try to aspirate subcutaneously in the pocket and surrounding tissues.
- Give specific antidotes for specific cytostatic drugs (Table 2).
- If a needle is still in situ it should be removed after instillation of the antidote; the antidote can also be injected into the surrounding tissues if needed.
- Do not apply pressure, which increases the area of extravasation.
- Apply a thermal pack (for vesicant, exfoliant, and irritant drugs only) (Table 2).

Table 1 Classification of cytostatic drugs according to their ability to cause tissue damage after extravasation (from http://www.ucht.n-i.nhs.uk/pubinfo/Extravasation_of_intravenous_drugs)

Vesicants[a]	Exfoliants[b]	Irritants[c]	Inflammatory agents[d]	Neutral agents[e]
Amsacrine	Aclarubicin	Carboplatin	Etoposide phosphate	Asparaginase
Chlormethine	Carmustine	Daunorubicin liposomal	Fluorouracil	Bleomycin
Dactinomycin	Cisplatin	Doxorubicin liposomal	Methotrexate	Cladribine
Daunorubicin	Dacarbazine	Etoposide	Raltitrexed	Cyclophosphamide
Doxorubicin	Docetaxel	Irinotecan		Cytarabine
Epirubicin	Floxuridine	Teniposide		Fludarabine
Idarubicin	Mitoxantrone			Gemcitabine
Mitomycin	Oxaliplatin			Ifosfamide
Streptozocin	Paclitaxel			Interleukin-2
Vinca alkaloids	Topotecan			Melphalan
	Treosulfan			Pentostatin
				Thiotepa
				Interferon alfa

[a]Vesicants cause pain, inflammation, and blistering of the skin and underlying tissues, leading to tissue death and necrosis
[b]Exfoliants cause inflammation and shedding of the skin, but are less likely to cause tissue death
[c]Irritants cause inflammation and irritation, but rarely cause tissue damage
[d]Inflammatory agents cause mild to moderate inflammation and flare in local tissues
[e]Neutral agents do not cause inflammation or tissue damage

© 2006 Elsevier B.V. All rights reserved.

Table 2 Specific antidotes for cytostatic drugs after extravasation

Drug	Antidote	Instructions	Comments
Anthracyclines	Dimethylsulfoxide Dexrazoxane	Apply dimethylsulfoxide 99% topically Give intravenous dexrazoxane 1000 mg/m^2 on days 1 and 2 and 500 mg/m^2 on day 3; most effective if the first dose is given within 6 hours	Apply a cold pack for 15 minutes, four times a day. Inspect after 24 hours and 7 days. If there are signs of erythema or ulceration after 7 days, discuss with a plastic surgeon
Chlormethine	Sodium thiosulfate	Dilute 0.6 ml of sodium thiosulfate 50% with 9.4 ml of water for injection. Inject 4 ml through the cannula, then remove the cannula. Infiltrate with 0.2 ml subcutaneously over and around the affected area	Apply a cold pack for 15 minutes, four times a day. Inspect after 24 hours and 7 days. If there are signs of erythema or ulceration after 7 days, discuss with a plastic surgeon
Cisplatin[a,b]	Sodium thiosulfate	Dilute 0.6 ml of sodium thiosulfate 50% with 9.4 ml of water for injection. Inject 4 ml through the cannula, then remove the cannula. Infiltrate with 0.2 ml subcutaneously over and around the affected area	Apply a warm pack for 15 minutes, four times a day. Inspect after 24 hours and 7 days. If there are signs of erythema or ulceration after 7 days, discuss with a plastic surgeon
Vinca alkaloids	Hyaluronidase	Mix 1500 units of hyaluronidase with 1 ml of sodium chloride 0.9% for injection. Inject 0.5 ml through the cannula. Remove the cannula. Infiltrate with 0.2 ml subcutaneously over and around the affected area	Apply a warm pack for 15 minutes, four times a day. Inspect after 24 hours and 7 days. If there are signs of erythema or ulceration after 7 days, discuss with a plastic surgeon

[a]High concentration only
[b]Sodium thiosulfate should only be used if a large volume (greater than 20 ml) of concentrated cisplatin (that is a concentration over 0.5 mg/ml) has extravasated

- Review vesicant extravasation in 24 hours.
- Extravasation in the deep part of a central venous catheter will require referral to a plastic surgeon.

Review articles

Some review articles on the adverse effects of cytostatic drugs and related topics are listed in Table 3.

Organs and Systems

Nervous system

Neurological symptoms occur in more than 20% of patients with cancer and can be increased by cytostatic drugs. Acute and late neurotoxic syndromes involve a number of cytostatic agents (Table 4).

The late nervous system effects in survivors 7 years after treatment for childhood acute lymphoblastic leukemia include impaired concentration, attention, and memory (32).

The late effect of chemotherapy and radiotherapy for nervous system lymphoma has been studied in 15 patients; 10 had severe symptomatic diffuse changes in the white matter within 8 months of completing treatment (33).

Endocrine

Combined cytostatic drug therapy for Hodgkin's disease in childhood often results in abnormal endocrine function, particularly increases in follicle-stimulating hormone, prolactin, and thyroid-stimulating hormone (34).

Metabolism

Hyperglycemia was reported in 21 of 56 patients who received weekly paclitaxel with oral estramustine and carboplatin (4-weekly); under 10% required pharmacological intervention (35). There was mild hyperphosphatemia in 24.

There was fasting hypoglycemia in 19 of 35 children with acute lymphoblastic leukemia receiving maintenance therapy of daily oral mercaptopurine and weekly oral methotrexate; all the children improved on withdrawal of chemotherapy and 10 of 15 normalized (36).

There have been cases of acute tumor lysis syndrome in patients with melanoma (37) and light-chain amyloidosis (38). The authors reviewed the incidence of acute tumor lysis syndrome in these diseases, which are less typically associated with it.

Hematologic

The authors of a study in 101 patients concluded that in addition to the dose of chemotherapy and the administration of hemopoietic growth factors, poor performance status and a high concentration of soluble p75-R-TNF can predict the occurrence of chemotherapy-induced myelosuppression in lymphoma (39).

In 43 patients, raised plasma concentrations of FLT3-L (an fms-like tyrosine kinase) in patients who had previously received chemotherapy predicted the stage of recovery of the bone-marrow compartment (40). FLT3-L seems to identify the likelihood that the patient will have severe thrombocytopenia if additional cytostatic therapy is given. Knowledge of bone-marrow activity

should permit more aggressive therapy, by establishing the earliest possible time for dosing with any cytostatic agent for which myelosuppression is the dose-limiting toxic effect.

Mouth and teeth

Cytostatic drugs can cause oral mucositis, which characteristically affects the whole buccal mucosa (41). It is caused by damage to the oropharyngeal epithelium which has a rapid turnover. The oral mucosa can also be affected by infection. Susceptibility factors include age, nutritional status, tumor type, oral hygiene, and neutrophil count.

Oral mucositis causes pain, interferes with nutrition, and can lead to systemic infection and other complications that increase morbidity and mortality (42). Interventions that have been used to prevent oral mucositis or reduce its severity and sequelae include meticulous pretransplantation and continuing mouth care, calcium phosphate solution, treatment with near-infrared light and lower-energy laser light, interleukin-11, sucralfate, oral glutamine, rinsing with granulocyte-macrophage colony-stimulating factor, tretinoin, keratinocyte growth factor, and amifostine. However, very few interventions have been shown to be effective compared with placebo.

Table 4 Neurotoxic effects of cytostatic drugs

Drug	Neurotoxicity
Asparaginase	Acute encephalopathy
Bortezomib	Peripheral neuropathy
Busulfan	Seizures
Carmustine	Brain damage in conventional doses when combined with radiation
Chlorambucil	Disorientation, cognitive dysfunction
Chlormethine	Rare encephalopathy following high doses
Cisplatin	Peripheral neuropathy, deafness, cerebral cortical blindness, seizures
Cytarabine	Cerebellar ataxia in high doses
Fluorouracil	Cerebellar ataxia in high doses
Ifosfamide	Mild memory disturbances
Methotrexate	Acute meningitis; acute fatal cerebral dysfunction; chronic leukoencephalopathy
Oxaliplatin	Acute and chronic sensory neuropathy
Taxanes	Peripheral neuropathy
Vinblastine	Jaw pain, myopathy, inappropriate ADH secretion
Vincristine	Peripheral neuropathy, abdominal pain, constipation
Vindesine	Overdose or accidental intrathecal injection is usually fatal
Vinorelbine	Sensorimotor distal symmetrical axonal neuropathy

In a retrospective analysis over 13 years of cytostatic therapy for various conditions, six doses of etoposide each of 250 mg/m^2 caused grade 4 mucositis and 50% of patients who received epirubicin 120 mg/m^2 developed grade 2 or 3 mucositis (43). Severe stomatitis complicated epirubicin 1250 mg/m^2 (44).

A scoring system for mucositis has been proposed and validated (45) and multivariate analysis has been used to identify contributory factors (46). A diagnosis of leukemia, the use of total body irradiation or allogenic transplantation in treatment, or delayed neutrophil recovery were associated with an increased incidence of oral mucositis.

It has been proposed that a change in serum diamine oxidase activity is a very sensitive surrogate for early signs of upper gastrointestinal tract mucositis (47).

Gastrointestinal

Nausea and vomiting are common adverse effects of cytostatic drugs (48). They can be acute (occurring within 24 hours of therapy), delayed (persisting for 6–7 days after therapy), or anticipatory (occurring before chemotherapy) (49). Their treatment has been reviewed (50,51).

Diarrhea can also occur (52) and is particularly problematic with some drugs, such as irinotecan (53). Its management has been reviewed (54).

In a retrospective analysis over 13 years of cytostatic therapy for various conditions there were 12 cases in which chemotherapy had caused gastrointestinal perforation (43). Six doses of etoposide each of 250 mg/m^2 induced an advanced stage (grade 4) of mucositis. Fifty percent of patients receiving epirubicin 120 mg/m^2

© 2006 Elsevier B.V. All rights reserved.

developed grade 2 or 3 mucositis. Severe stomatitis complicated epirubicin 1250 mg/m^2 (44).

Increased intestinal permeability has been shown in children receiving low-dose methotrexate therapy (44).

Liver

Of 54 patients with non-small-cell lung cancers treated with a combination of gemcitabine 1000 mg/m^2 on days 1 and 8 and paclitaxel 200 mg/m^2 on day 1, six had abnormal but significantly raised transaminases (55). The authors believed that this was drug-induced, but could not rule out underlying liver disease.

Urinary tract

Hemolytic-uremic syndrome in association with thrombotic thrombocytopenic purpura has been reported in a patient receiving pentostatin (deoxycoformycin) after exposure to only 15 mg/m^2 given over 3 days (56).

Skin

There has been a report of six cases of a variant of the palmar-plantar erythrodysesthesia syndrome (hand-foot syndrome), in which patients who had previously reported the syndrome developed it again when they were treated with completely different chemotherapeutic drugs (57). The recall syndrome was of mild to moderate intensity, less severe than the primary syndrome, and self-limiting in all cases.

Four cases of hyperkeratotic seborrheic warts appearing over a 2-year period, 25 years after the patients had been started on azathioprine 2.5 mg/kg, have been reported (58).

Calciphylaxis is a rare, often fatal disease, characterized clinically by progressive cutaneous necrosis and ulceration and histologically by vascular calcification and thrombosis. It has been described in association with end-stage renal disease and hyperparathyroidism.

- A 64-year-old woman who 3 months before had finished a course of cyclophosphamide, doxorubicin, and fluorouracil chemotherapy for breast carcinoma developed calciphylaxis (59). She had no renal disease and had normal renal function and parathyroid hormone concentrations.

The authors speculated that the cause may have been chemotherapy-induced functional deficiency of protein C and protein S.

Musculoskeletal

Bone mineral density has been used to help predict which children who have had chemotherapy may subsequently develop osteoporosis (60).

Reproductive system

Gynecomastia is frequent in men with testicular tumors that produce large amounts of human chorionic gonadotrophin (HCG), and its appearance after completion of chemotherapy may indicate residual or recurrent disease. However, not uncommonly, gynecomastia is a harmless, although troubling, late adverse effect of chemotherapy. In 16 patients who developed gynecomastia 2–9 months after treatment, and who were in complete remission, estradiol concentrations were raised; follicle-stimulating hormone (FSH) produced a higher estradiol/testosterone ratio than similarly treated patients without gynecomastia (61). It is likely that this was due to increased secretion of testicular estrogen in response to a compensatory increase in pituitary gonadotrophins after cytostatic damage to Leydig cells and spermatogenesis.

The gonadal effects of MOPP (mechlorethamine + Oncovin (vincristine) + procarbazine + prednisone/prednisolone) and MVPP (mustine + vinblastine + procarbazine + prednisone/prednisolone) in patients with Hodgkin's disease have been described (SEDA-11, 397) (SEDA-11, 403). Similar studies have been conducted in patients treated with ABVD (adriamycin + bleomycin + vinblastine + dacarbazine) and COPP (cyclophosphamide + vincristine + procarbazine + prednisone) (62). The results suggested that all men have irreversible sterility with preservation of normal Leydig cell function after COPP, which is more spermatotoxic than MOPP and much more so than ABVD. Ovarian failure was age-related after COPP, occurring in 86% of those over 24 years of age at the time of therapy, compared with 28% in women patients less than 24 years old. In contrast to men, sterility in women was always associated with ovarian endocrine failure requiring estrogen replacement. Pregnancies and normal births did occur: 14 women became pregnant and five healthy children were born. It has been proposed that analogues of gonadotropin-releasing hormone preserve gonadal function during the administration of anticancer drugs to premenopausal women.

Infection risk

Infections are major causes of morbidity and mortality in the period after transplantation, whichever immunosuppressive regimen is used, in particular bacterial infections and viral infections (cytomegalovirus, *Herpes simplex* virus, Epstein–Barr virus), but also protozoal and fungal infections (63–65). Based on an analysis of medical and autopsy records, infections were the cause of death in 70% of transplant patients, with bacteria (50%) or fungi (29%) as the most common pathogens (66).

Long-Term Effects

Mutagenicity

An increased incidence of gene aberration is to be expected in the offspring of men being treated at the time of conception with chemotherapy for testicular tumors (67). Various drug regimens for Hodgkin's disease and high-grade non-Hodgkin's lymphoma produce different patterns of changes in sister chromatid exchange frequency, and the changes may reflect the potential of the drugs concerned to induce second malignancies (68).

Tumorigenicity

Malignant tumors have been documented with increasing frequency over the last 35 years as a long-term complication of cytostatic and immunosuppressant therapy.

© 2006 Elsevier B.V. All rights reserved.

Alkylating agents have been implicated in the causation of secondary tumors, including acute myeloid leukemia, myelodysplastic syndromes (69), solid tumors (70,71), Hodgkin's disease (72,73), ovarian cancer (74,75), and gastric cancer (69). Survival from the time of diagnosis of secondary malignancies is usually very short (69).

Risks in patients with Hodgkin's disease

The actuarial risks of developing secondary malignancies and/or myelodysplastic syndrome at 5, 10, and 15 years after treatment for Hodgkin's disease have been calculated (76).

In a multicenter, case-control study, the incidence of acute myeloid leukemia in treated Hodgkin's disease was 64 times higher than in the general population, the risk being greater in men. There was also a significant association between the development of acute myeloid leukemia in those patients and the use of extensive radiotherapy, vincristine + procarbazine, splenectomy, and the dose of chlormethine (73). The problem is thought to be the result of chromosomal aberrations developing in patients treated with alkylating agents (77), although there is no general agreement about this (75).

Among 679 patients receiving chemotherapy for advanced Hodgkin's disease, there were four deaths due to secondary malignancies (78). There were 75 deaths in all during 3 years, of which the vast majority were related to disseminated Hodgkin's disease.

The increased incidence of breast cancer after treatment of Hodgkin's disease may be related to supradiaphragmatic irradiation, but the risk was higher in patients with ovarian cancer, which is consistent with a common predisposition to breast and ovarian cancer. However, cytostatic drugs may have contributed to the risk.

Risks in patients with leukemias

The nucleoside analogues fludarabine, pentostatin, and cladribine have not traditionally been associated with secondary malignancies. Long-term follow-up for 5–7.5 years of 2014 patients who had received these agents for chronic lymphoid leukemia and hairy cell leukemia has been reviewed (79). Of 111 malignancies that were detected, the three most common were lymphoma ($n = 25$), prostate cancer ($n = 19$), and lung cancer ($n = 15$). While these incidences suggested significant additional risks beyond those in the normal population, the authors could not conclude beyond a reasonable doubt that the increased risks were greater than expected.

Chemotherapy-related myelodysplastic syndrome has been reported in association with adult T cell leukemia (80).

Risks in patients with Wilms' tumor

The National Wilms' Tumor Study Group has reported the incidence of second malignant neoplasms in 5278 patients treated over 22 years (81). There were 43 second malignant neoplasms, whereas only five were expected. Fifteen years after the diagnosis of Wilms' tumor, the cumulative incidence of a second malignant neoplasm was 1.6% and increasing steadily. Abdominal irradiation, given as part of the initial therapy, increased the risk, and doxorubicin potentiated the radiation effect. Among 234 patients who received doxorubicin and over 35 Gy of abdominal radiation, eight second malignant neoplasms were observed, whereas only 0.22 were expected. Treatment for relapse further increased the risk by a factor of 4–5.

Risks in patients with other tumors

Lymphoblastic leukemia has been described after treatment of a malignant germ cell tumor; it was suggested that this was related to the etoposide component of the treatment, and that development of secondary leukemia after etoposide may not be confined to the myeloid cell lineage (82).

A large international collaborative study by cancer registries has published the incidence of second malignancies following testicular cancer, ovarian cancer, and Hodgkin's disease (83): 3157 second cancers were observed among 133 411 patients diagnosed between 1945 and 1984. Patients with Hodgkin's disease were at particular risk, having an 80% excess of cancers. It confirms the high incidence of this complication noted in other reports involving smaller numbers of patients (84,85).

Other conclusions deriving from the international collaborative study (83) include the following:

- patients with testicular cancer had a 30% greater probability of developing cancers than the general population, and those with ovarian cancer 20%;
- leukemia, previously linked to alkylating agents, occurred in excess after testicular cancer, ovarian cancer, and Hodgkin's disease (relative risk 6.1), as did non-Hodgkin's lymphoma (relative risk 1.8) (the latter particularly after Hodgkin's disease);
- other cancers with significant excesses were lung cancer following Hodgkin's disease (relative risk 1.9), breast cancer following Hodgkin's disease (relative risk 1.4), and bladder cancer following ovarian cancer and Hodgkin's disease (relative risks 1.7 and 2.2 in women, respectively);
- a marked excess in incidence of secondary malignancies was found in the salivary gland, thyroid, bone, and connective tissue (there was a smaller excess for colorectal cancers following ovarian cancer).

It is likely that there is a casual relation between treatment of a first malignancy and development of a second. Alkylating agents are strongly implicated in the pathogenesis of the leukemias. Non-Hodgkin's lymphoma occurred after a 10-year latency in patients with ovarian cancer, suggesting a possible radiation effect, but early in patients with testicular tumors or Hodgkin's disease, possibly related to the immunosuppressive effect of cytostatic drugs. The excess of bladder cancers in patients with Hodgkin's disease and ovarian cancer may be related to radiotherapy (subdiaphragmatic in the former), and/or cyclophosphamide, which is widely used in the treatment of both and is a human bladder carcinogen.

Risks in transplant recipients

Although the risk of secondary malignancy clearly outweighs that of under-treatment in transplant patients,

increasing periods of survival extend the importance of this problem and the need for close monitoring. Considerable amounts of data are accumulating based on multicenter or single-center experience, but they reflect the use of various immunosuppressive regimens and prophylactic antiviral treatments, and use different approaches to the calculation of risk incidence. Estimates of risk therefore vary widely between studies and no direct comparison is as a rule possible. However, updated data from the Cincinnati Transplant Tumor Registry, published in 1993, have helped to define comprehensively the characteristics of neoplasms observed in organ transplant recipients (86). Skin and lip cancers were the most common, and non-Hodgkin's lymphomas represent the majority of lymphoproliferative disorders with an incidence some 30- to 50-fold higher than in controls. An excess of Kaposi's sarcomas, carcinomas of the vulva and perineum, hepatobiliary tumors, and various sarcomas is also reported. By contrast, the incidence of common neoplasms encountered in the general population is not increased. In renal transplant patients, the actuarial cumulative risk of cancer is 14–18% at 10 years and 40–50% at 20 years (87,88). Skin cancers accounted for about half of the cases.

There is controversy about which factors (duration of treatment, total dosage, the degree of immunosuppression, or the type of immunosuppressive regimen) are the most relevant to determining risk. Partial or complete regression of lymphoproliferative disorders and Kaposi's sarcomas after reduction of immunosuppressive therapy argues strongly for the role of the degree of immunosuppression (86). The incidence of cancer was also significantly higher in renal transplant patients receiving triple therapy regimens compared with double therapy (89). Similarly, aggressive immunosuppressive therapy may account for the higher incidence of lymphomas in cardiac versus renal allograft patients. In a large, multicenter study involving more than 52 000 kidney or heart transplant patients between 1983 and 1991, the rate of non-Hodgkin's lymphomas in the first year after transplantation was 0.2% in kidney recipients and 1.2% in heart recipients, and fell substantially thereafter (90). Initial immunosuppression with azathioprine and ciclosporin, and prophylactic treatment with antilymphocyte antibodies or muromonab was associated with a significantly increased incidence of non-Hodgkin's lymphomas compared with other immunosuppressive regimens, which confirmed the major role of the degree of immunosuppression. Other studies have confirmed that immunosuppression per se rather than a single agent is responsible for the increased risk of cancer (SEDA-20, 340). Finally, the most striking difference between conventional and modern immunosuppressive regimens, including ciclosporin, was the average time to the appearance of tumors, in particular skin cancers and lymphomas, which was shorter in ciclosporin-treated patients (91,92).

The risk of malignant disease in renal transplant recipients increases with time after the transplant. The commonest cancers in this setting are squamous carcinoma of the skin and lip, in situ carcinoma of the cervix, and non-Hodgkin's lymphoma. An increased incidence of hepatocellular carcinoma has been reported (93). In Australia and New Zealand tumors of the urogenital tract, especially of the kidney and bladder, are the commonest non-cutaneous tumors encountered in renal transplant recipients (94). Severe metaplastic and dysplastic changes, suggestive of premalignancy, have been found in the lining epithelium of collecting ducts and tubules of cadaveric renal transplants in two patients receiving azathioprine and prednisolone (95).

Second-Generation Effects

Fertility

A reduced chance of paternity has been reported in 67% of patients who had been treated with MOPP/ABVD for Hodgkin's disease. This included oligospermia, asthenozoospermia, and/or teratozoospermia. The recovery of spermatogenesis was documented in only 40% (97).

Teratogenicity

The outcomes of pregnancies after the use of immunosuppressive drugs, in particular in renal transplant patients, have been reported, and hundreds of pregnancies have been analysed (98). The largest experience is that derived from the National Transplantation Pregnancy Registry, which has been built up in the USA since 1991 (99). This registry has accumulated data on more than 900 pregnancies, of which 83% followed kidney transplantation. Overall, the immunosuppressive regimens commonly used in transplant patients (that is azathioprine-based or ciclosporin-based programmes) do not appear to increase the overall risk of congenital malformations or to produce a specific pattern of malformation. There was no difference in the rate of malformations when comparing ciclosporin to other immunosuppressive regimens or to the baseline risk of malformations (100,101). Ectopic pregnancies and miscarriages seemed to occur at a similar rate as in the general population. The most common complications were frequent prematurity and more frequent intrauterine growth retardation with low birth weight. Susceptibility factors associated with adverse pregnancy outcomes included a short interval between transplantation and pregnancy (less than 1–2 years), graft dysfunction before or during pregnancy, and hypertension (102). Possible long-term effects of in utero exposure to immunosuppressive drugs are still seldom investigated. There is no evidence that physical and mental development or renal function are altered in children. In one study, there were changes in T lymphocyte development in seven children born to mothers who had taken azathioprine or ciclosporin, but immune function assays were normal, suggesting that fetal immune system development is not affected (103).

Dabequine

General Information

Dabequine is a 4-aminoquinoline derivative, the adverse reaction pattern of which is unknown. The WHO Scientific Group's report concerning this drug dates from 1984 and there seems to be little or no later information on it in humans.

Dacarbazine and temozolomide

See also Cytostatic and immunosuppressant drugs

General Information

Dacarbazine is converted to an active metabolite that is thought to be an alkylating agent. It has been used to treat metastatic melanoma and, in combination regimens, soft-tissue sarcomas and Hodgkin's disease.

Temozolomide is structurally related to dacarbazine and is thought to act via the same active metabolite. It has been used to treat malignant gliomas and malignant melanoma.

Organs and Systems

Hematologic

- Temozolomide-related myelodysplastic syndrome has been reported in a 44-year-old woman with recurrent anaplastic astrocytoma in association with a cytogenetic deletion in chromosome 3 (1).

Liver

Hepatotoxicity has been reported with single-dose dacarbazine (2,3), presenting as acute liver necrosis with hepatic venous thrombosis, which can be fatal.

- Severe hepatic insufficiency in a 69-year-old man after two courses of dacarbazine, 250 mg/m^2/day for 5 days, was successfully treated with intravenous hydrocortisone 300 mg/m^2/day (4).

Fatal hepatotoxicity has also been associated with dacarbazine 500 mg/day for 5 days (5). The cause of this effect is unclear; an allergic hepatic vasculitis with thrombosis is possible.

Skin

Phototoxic reactions occurred in 10 patients with malignant melanoma when they were given dacarbazine (6). In five patients who were tested there was increased sensitivity to ultraviolet A; patch-testing in six showed no type IV allergies. In five patients oral temozolomide did not cause phototoxicity.

Daclizumab

See also Monoclonal antibodies

General Information

Daclizumab, a humanized antibody directed against the alfa chain of the interleukin-2 receptor, has been used for initial immunosuppression in transplant patients. In a phase III trial in 275 patients who received ciclosporin, glucocorticoids, and daclizumab or placebo, there were no specific adverse effects associated with daclizumab (1). In particular, the cytokine-release syndrome did not occur, and there was no difference in the incidence of fungal or cytomegalovirus infections between the two groups.

Organs and Systems

Immunologic

The efficacy of daclizumab in acute and chronic glucocorticoid-refractory graft-versus-host disease has been studied in 16 patients, of whom nine responded (2). However 14 developed infectious complications during treatment, with a high incidence of cytomegalovirus reactivation; there were three infection-related deaths.

Dactinomycin

See also Cytostatic and immunosuppressant drugs

General Information

Dactinomycin is used to treat cancers in children, in particular Wilms' tumor. It has similar adverse effects to doxorubicin.

Organs and Systems

Respiratory

Dactinomycin increases the pulmonary toxic effects of radiation by an estimated 30%, and reduces the radiation tolerance of the lung by at least 20% (1).

Liver

Several cases of hepatotoxicity have been reported in children receiving dactinomycin for Wilms' tumor (2–5). The hepatotoxicity of dactinomycin is dose- and schedule-related; mild hepatotoxicity is described in up to 12% of patients (6).

Five of 40 patients, who received a pulsed regimen of 60 μg/kg of dactinomycin every 3 weeks up to and including week 15, developed severe hepatotoxicity, with sharp rises in liver function test values, ascites, and liver enlargement. One child with complicating factors died and the others recovered. All five had possible contributing factors, such as repeated anesthesia (3).

Danaparoid sodium

General Information

Danaparoid is a low molecular heparinoid consisting of a mixture of sulfated glycosaminoglycans (heparan, dermatan, and chondroitin sulfates). It has an antithrombotic effect via antithrombin III-mediated inhibition of factor Xa and to a lesser extent through inhibition of factor IIa. The ratio of antifactor Xa to antifactor IIa is over 20.

Danaparoid is as effective as heparins in inhibiting the formation of thrombi. Its major advantage over low molecular weight heparins is its low rate of cross-reactivity with heparin-associated antibodies from patients with heparin-induced thrombocytopenia (1). It is therefore indicated in patients with heparin-associated thrombocytopenia who require further anticoagulation after withdrawal of heparin. However, it should not be used if there is in vitro cross-reactivity between heparin and danaparoid. Cross-reactivity is uncommon but can result in thrombotic complications, as reported in a case with a fatal outcome (2).

Organs and Systems

Hematologic

Severe bleeding is uncommon with danaparoid but was 3.1% in one series (3).

Immunologic

Delayed hypersensitivity reactions have been reported in patients given danaparoid (4).

Dantrolene

General Information

Dantrolene, a hydantoin derivative, is well established in clinical practice, being of greatest value for the reduction of clonus and involuntary muscle spasms (1,2). The recommended oral doses for the treatment of spastic conditions are 75–400 mg/day.

Dantrolene (1,2) is the agent of choice for treatment of malignant hyperthermia and greatly reduces the mortality to under 10% if given in time (3) together with general supportive measures.

Dantrolene differs from the centrally acting muscle relaxants in that its site of action is beyond the muscle cell membrane. It interferes with the excitation–contraction coupling mechanism of striated muscle, presumably

© 2006 Elsevier B.V. All rights reserved.

by inhibition of calcium release from the sarcoplasmic reticulum.

The most common adverse reactions, seen in up to 75% of patients, are weakness, fatigue, drowsiness, and dizziness. Nausea, vomiting, and diarrhea or constipation are also common, but all these adverse reactions tend to disappear as treatment continues. In general, by adjusting the dose a satisfactory effect can be achieved with acceptable adverse effects.

Rare, but occasionally very serious, adverse effects include hepatotoxicity, respiratory depression, seizures, pleuropericardial reaction, and lymphocytic lymphoma (SEDA-5, 137).

Organs and Systems

Respiratory

Muscle weakness associated with the oral prophylactic use of dantrolene in a patient with compromised respiratory function is reported to have exacerbated postoperative respiratory depression to such an extent that artificial ventilation was required (SEDA-14, 114) (4).

Pleuropericardial reactions, with sterile effusions and eosinophilia, have also rarely been reported in patients taking 225–400 mg/day for 3 months to 4 years (5). There is no proof of a causal relation, but the chemically related nitrofurantoin has also been associated with pulmonary reactions. Patients taking dantrolene should be screened periodically.

Nervous system

Numbness of the hands and feet has been reported (6); long-term use of the structurally related phenytoin has been incriminated in causing polyneuropathy.

Exacerbation or precipitation of seizures has been reported in children with cerebral palsy taking long-term treatment with high doses of dantrolene (4–12 mg/kg) (7).

Sensory systems

Deafness occurred after 5 days' treatment with dantrolene 25 mg/day in a patient who was also taking long-term baclofen and diazepam (8). This may have been coincidental, but the authors suggested that dantrolene may have caused the effect by interfering with the release of calcium from the sarcoplasmic reticulum. It is therefore interesting that one hypothesis that explains the ototoxicity of aminoglycoside antibiotics involves disturbance of calcium ion binding and phosphorylation processes (SED-11, 549).

Hematologic

Fatal lymphocytic lymphoma has been described during high-dose dantrolene therapy (600 mg/day over 3 years) (9). Although the association was only circumstantial, another hydantoin derivative, phenytoin, is known to cause pseudolymphoma.

Liver

Hepatotoxicity from dantrolene consists mainly of minor liver function disturbances (in 1% of patients), with symptoms in 0.35–0.5% and fatal hepatitis in 0.3% (10,11). The risk of severe liver damage is greater with doses above 300–400 mg/day, with prolonged treatment (more than 60 days), in women and in patients older than 35 years.

Reproductive system

Dantrolene may have contributed to uterine atony, with resulting excessive hemorrhage when given prophylactically after a cesarean section (12).

Drug–Drug Interactions

Calcium channel blockers

The combination of dantrolene with calcium channel blockers, such as verapamil, can result in severe cardiovascular depression and hyperkalemia (SEDA-12, 113) (13,14), so that extreme care is required.

Metoclopramide

The absorption of oral dantrolene can be significantly increased by metoclopramide (15). As the risk of hepatotoxicity has been related to the dosage of dantrolene, increased clinical surveillance is necessary to avoid toxicity of dantrolene during concurrent treatment with metoclopramide.

Dapsone and analogues

General Information

Dapsone is 4,4-diaminodiphenylsulfone (DDS, avlosulfone, disulfone) (SEDA-17, 352). It is a bacteriostatic antileprosy drug with a sulfonamide-like structure. The dosage should be 50–100 mg/day in adults (1). In children aged 3–5 years, the dosage should be reduced according to weight to, for example, 25 mg/day (2).

Studies of patients with borderline leprosy have suggested that dapsone has mild immunosuppressive effects (SEDA-18, 30). Thus, it has been given with some success to patients with dermatitis herpetiformis, subcorneal pustular dermatosis, bullous dermatoses, relapsing polychondritis, thrombocytopenic purpura (3), giant cell arteritis (4), rheumatoid arthritis, and systemic lupus erythematosus (5).

Dapsone is an alternative drug for *Pneumocystis jiroveci* pneumonia prophylaxis in individuals who cannot tolerate co-trimoxazole, and although this has become less of a problem since the advent of highly active antiretroviral drug therapy in countries able to afford these regimens, further data on the toxicity of dapsone in children are welcome. In a multicenter study from the USA daily and weekly dapsone regimens have been compared in 94 HIV-infected children, monitoring hematological and liver toxicity and the incidence of skin rashes, *P. jiroveci* pneumonia, or death (6). They concluded that the weekly regimen produced less hematological toxicity, but that this advantage was offset by a trend toward higher breakthrough rates of *P. jiroveci* pneumonia.

Dapsone analogues

The sulfone acedapsone (rINN) (4,4′-diacetyldiaminodiphenylsulfone, DADDS) is the diacetyl derivative of dapsone with a long half-life (7). However, its plasma concentrations are much lower than those of dapsone and it could enhance the emergence of resistant strains of *Mycobacterium leprae*. Its adverse effects are similar to those of dapsone, which it can replace if gastrointestinal symptoms become severe. It is available in an enteric-coated formulation, given in a dosage of 330 mg/day.

General adverse effects

The adverse effects of dapsone have been comprehensively reviewed (8). The most common untoward effect is hemolysis of varying degree; it is usually mild, except in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Methemoglobinemia and Heinz body formation also occur and methemoglobinemia can be a problem at doses over 200 mg/day. Agranulocytosis is rare but potentially fatal. Mild gastrointestinal complaints and neurological effects of dapsone are not uncommon. Under 0.5% of the patients taking prolonged dapsone therapy develop the dapsone syndrome (SEDA-16, 347). Other rare adverse effects include peripheral neuropathy, psychosis, hepatitis, nephritic syndrome, and renal papillary necrosis. Hypoalbuminemia has been seen after prolonged dapsone therapy of dermatitis herpetiformis (9). Erythema nodosum leprosum may be due to an immune complex mechanism; the antigen is provided by the bacteria and their degeneration products, possibly as a kind of Jarisch–Herxheimer reaction (10). Anaphylactic shock and tachycardia are rare. Rashes, serious cutaneous reactions, and erythema nodosum may have an immunological basis. Tumor-inducing effects have not been reported.

In France, dapsone is available in combination with ferrous oxalate as Disulone (Aventis), and in 1983–98, 249 adverse reactions were reported to French pharmacovigilance centers, mainly blood dyscrasias (often neutropenia and agranulocytosis, rarely hemolysis and anemia) (11). Five patients died; three of them had septicemia secondary to agranulocytosis. There were 29 cases of dapsone syndrome, 39 skin reactions, 27 cases of liver damage, and 27 cases of neurological and psychiatric adverse effects. Patients taking dapsone need to be under close medical supervision for early recognition of adverse reactions.

Organs and Systems

Cardiovascular

Signs of heart failure with edema, ascites, and severe hypoalbuminemia have been described in the treatment of dermatitis herpetiformis with dapsone (9).

Respiratory

Two cases of pulmonary eosinophilia attributed to dapsone were reported in 1998. Four cases had previously been reported, in which the fixed combination of dapsone and pyrimethamine (a malaria prophylactic) had been implicated, but only one previous report had implicated dapsone alone.

- A French woman with chronic urticaria (12) and an Indian man with lepromatous leprosy (13) developed fever, wheezing, and breathlessness. Both had peripheral eosinophilia and chest X-rays showed infiltrates. The woman's symptoms began 2 weeks after she started to take dapsone but recurred a few hours after a subsequent rechallenge. The man's symptoms occurred a few hours after each daily dose. Symptoms in both cases resolved within a few days of stopping dapsone.

Nervous system

Dapsone-induced neuropathy is not common (14), in spite of its widespread use in a variety of unrelated disorders. It has not been reported in patients with leprosy, but it would be easy to miss, since worsening neuropathy would readily be attributed to the underlying disease.

© 2006 Elsevier B.V. All rights reserved.

Neuropathy has not been reported in patients with leprosy taking the usually recommended dosage of 100 mg/day. Isolated cases of dapsone-induced peripheral neuropathy, including motor and minor sensory defects, have been published (15,16). The clinical characteristics include a motor neuropathy affecting the extremities with onset within 5 years after the start of dapsone therapy in doses of over 300 mg/day. Complete recovery from the neuropathy almost always occurs after the dose is reduced or the drug is withdrawn.

Infection with *M. leprae* affects the peripheral nerves and the dermis, causing an accumulation of macrophages and other immune cells at the infected site (17).

Sensory systems

Ocular toxicity is rare with dapsone. Reduced visual acuity has been described after overdosage (18).

Psychological, psychiatric

Dapsone-induced psychosis has rarely been reported (SEDA-15, 331) (19).

Hematologic

The most common adverse effect of dapsone therapy is hemolysis (SEDA-15, 331). In varying degrees, it develops in nearly all patients taking dapsone in dosages of 200–300 mg/day. Even with the usual dose of 100 mg/day in normal persons and 50 mg/day in patients with G6PD deficiency, there can be some degree of hemolysis (20,21). Red cell survival can be reduced by dapsone, depending on the dose of the sulfone and its oxidizing activity, but hemolytic anemia generally does not occur without a preexisting disorder of the erythrocytes or bone marrow. The hemolysis can be so severe that manifestations of hypoxia become striking (20).

- Mild hemolytic anemia occurred in a breast-fed infant and his mother, who had continuously been taking 100–150 mg/day; dapsone and its metabolite, monoacetyldapsone, were identified in the infant's serum (SEDA-8, 290).

Dapsone is an oxidant and can trigger methemoglobinemia and delayed sulfhemoglobinemia (SEDA-8, 289) (22). Methemoglobinemia remains subclinical in most cases. However, it can be accurately inferred by a discrepancy between the oxygen saturation measured by pulse oximetry and the concentration of oxygen in the arterial blood (22). Methemoglobinemia at concentrations over 10% produces a visible lavender-colored cyanosis, and concentrations over 35% result in weakness and shortness of breath. Methemoglobinemia can be minimized by the administration of an antioxidant, such as vitamin C or vitamin E (23). Methemoglobinemia disappears after withdrawal of dapsone (SEDA-10, 273).

- A patient who had been taking dapsone inappropriately instead of an antispasmodic that had been prescribed for a spinal condition, because of incorrect labeling in a pharmacy, developed methemoglobinemia (24). Methylene blue was given intravenously and may have contributed to the severe hemolysis that followed.

Agranulocytosis is a rare complication of dapsone treatment (25).

Liver

Jaundice and hepatitis can occur as part of the sulfone syndrome with dapsone (26). Previous liver damage can predispose to serious hepatic or other adverse effects.

Urinary tract

Renal insufficiency can be associated with severe hemolysis due to dapsone (27).

Skin

Pruritus and various forms of rash can occur with dapsone. In 17 cases of dapsone syndrome, the symptoms developed on average 27 days after the start of treatment. The skin lesions took the form of erythematous papules and plaques ($n = 13$), eczematous lesions ($n = 4$), and associated bullous lesions ($n = 2$) (28). The other manifestations were: fever ($n = 16$), pruritus ($n = 15$), lymphadenopathy ($n = 14$), hepatomegaly ($n = 10$), icterus and oral erosions ($n = 5$ each), photosensitivity ($n = 4$), and splenomegaly ($n = 2$).

Serious cutaneous reactions, such as exfoliative dermatitis, toxic epidermal necrolysis, and erythema multiforme bullosum are extremely rare. Erythema nodosum leprosum has been described during dapsone therapy, mostly in the lepromatous type of leprosy (10). If erythema nodosum develops before the start of therapy, the drug should be withheld until the reaction has disappeared. Severe erythema nodosum can be controlled by short-term glucocorticoid therapy. Desensitization to dapsone in patients with hypersensitivity reactions has been proposed (29).

Immunologic

The sulfones occasionally exacerbate lepromatous leprosy, the so-called sulfone syndrome or dapsone syndrome, which resembles acute infectious mononucleosis (SEDA-16, 347) (30), and can develop 3–6 weeks after the start of treatment in malnourished patients. It appears to be an allergic reaction. It includes fever, malaise, pruritus, exfoliative dermatitis, photosensitivity, polyarthritis (31), jaundice and even hepatic necrosis, hepatosplenomegaly, lymphadenopathy, methemoglobinemia, and anemia. The syndrome is accompanied by the formation of atypical T lymphocytes with markedly increased spontaneous thymidine uptake (SEDA-8, 289). The full syndrome is probably rare, but it is important to recognize its partial expression (5,32,33). It has been suggested that it has become more common since the introduction of multidrug therapy (34), especially with rifampicin plus dapsone. The syndrome usually resolves rapidly after withdrawal of dapsone and with glucocorticoid treatment (for example prednisolone 30–60 mg/day). However, it can also end in a fatal allergic reaction (SEDA-12, 259).

Anaphylactic shock and tachycardia are among the most severe allergic reactions to dapsone (34).

Second-Generation Effects

Pregnancy

The use of antileprosy drugs during pregnancy depends upon the severity of the disease and the relative need for treatment. Even though untoward effects on the fetus have not been reported, treatment of leprosy during pregnancy probably predisposes to erythema nodosum leprosum; if this occurs during pregnancy, clofazimine is considered the best drug available (35).

Lactation

Dapsone passes into the breast milk, with a milk to plasma AUC ratio of 0.22:0.45 (36). Assuming a daily milk ingestion of 1 liter by the infant, the maximum percentage of the maternal dose in milk was 14% over 9 days. Usually no adverse effects are noted in the newborn, unless there is G6PD deficiency.

Susceptibility Factors

Genetic factors

Glucose-6-phosphate dehydrogenase deficiency is a risk factor for hemolytic anemia (37–39).

To what extent phenotype (fast versus slow acetylators) affects the metabolism of dapsone is controversial. Since dapsone is acetylated in the liver, an effect might be anticipated (SEDA-4, 217) (40), but has not been demonstrated.

Hepatic disease

Previous liver damage predisposes to adverse effects during dapsone therapy (41).

Other features of the patient

Malnutrition predisposes to adverse effects during dapsone therapy (42).

Drug Administration

Drug administration route

Aqueous or oily suspensions of dapsone for intramuscular injection can be used to ensure adherence and to prevent resistance due to irregular drug intake. The therapeutic efficacy of intramuscular formulations lasts 3–4 weeks (43).

Drug overdose

Several reports of accidental poisoning with dapsone in children have appeared since the early 1980s. Two reports (44,45) have emphasized the persistence of the problem, although the number of childhood cases has fallen over the years. Poisoning with dapsone results in cyanosis due to methemoglobinemia, vomiting, mental confusion, tachycardia, and dyspnea. It has been suggested that treatment with multiple doses of activated charcoal may be sufficient for less severely poisoned children (methemoglobin concentration below 30%) and that a single dose of methylthioninium chloride (methylene blue) should be given to those with higher concentrations (45).

Drug–Drug Interactions

Clofazimine

In 28 patients with lepromatous leprosy, clofazimine did not influence the urinary excretion of dapsone, except in one case (46).

Rifamycins

When rifampicin was given, dapsone blood concentrations were lowered and urinary excretion was increased during the first 2 days; however, blood concentrations remained in the therapeutic range (47).

Daptomycin

General Information

Daptomycin is a novel lipopeptide antibiotic, an inhibitor of lipoteichoic acid synthesis, with potent bactericidal activity against most clinically important Gram-positive bacteria, including resistant strains (1,2).

When daptomycin 4 mg/kg was given intravenously to seven healthy men the mean peak concentrations in plasma and inflammatory fluid were 78 and 28 μg/ml respectively; the mean half-lives were 7.7 and 13 hours respectively; the overall penetration of total drug into the inflammatory fluid was 68% and the mean urinary recovery over 24 hours was 60% (3).

Organs and Systems

Musculoskeletal

Daptomycin may have adverse effects on skeletal muscle, since it increases serum creatine kinase activity. To find the dosing regimen that has the least effects on skeletal muscle, dogs were given repeated intravenous daptomycin every 24 hours or every 8 hours for 20 days (4). The results suggested that adverse effects on skeletal muscle are primarily related to dosing frequency but not peak plasma concentrations, and once-daily administration appeared

© 2006 Elsevier B.V. All rights reserved.

to minimize the potential for daptomycin-related skeletal-muscle effects, possibly by allowing more time between doses for repair of subclinical effects.

Long-Term Effects

Drug tolerance

The activity of daptomycin against both vancomycin-sensitive and vancomycin-resistant *Enterococcus faecalis* was greater than that of quinupristin + dalfopristin (5). Daptomycin was as active as quinupristin + dalfopristin but more active than linezolid. At concentrations four times the MIC, daptomycin and vancomycin achieved 99.9% killing of methicillin-resistant *Staphylococcus aureus* after 8 hours, which was greater than the killing seen with linezolid and quinupristin + dalfopristin. However, the antibacterial activity of daptomycin strongly depended on the calcium concentration of the medium.

Decamethonium

See also Neuromuscular blocking drugs

General Information

Decamethonium, a depolarizing neuromuscular blocker, is little used nowadays. A dose of 3 mg provides adequate relaxation for intra-abdominal surgery for about 15 minutes, supplements being required at intervals of 10–30 minutes. It is not as rapid in onset of action as suxamethonium. It is not hydrolysed by plasma cholinesterase, but is eliminated by the kidneys (1).

Tachyphylaxis occurs and a phase II block develops readily (2). In high doses, muscarinic actions can be seen and histamine release can occur.

Organs and Systems

Cardiovascular

Cardiovascular effects are less frequent than with suxamethonium; a reduction in heart rate sometimes occurs after a second dose.

Nervous system

Fasciculation occurs, with similar consequences to those described with suxamethonium.

Myotonia has been precipitated by decamethonium in patients with myotonia congenita and dystrophia myotonica (3).

Susceptibility Factors

Decamethonium depends on renal excretion for the termination of its effects and is therefore contraindicated in renal insufficiency (1).

The action of decamethonium is prolonged by hypothermia (4).

Drug–Drug Interactions

Hexafluorenium and decamethonium are antagonistic. Potentiation of decamethonium block has been reported with ketamine, and can occur with neostigmine.

Deferiprone

General Information

Deferiprone is an alpha-ketohydroxypyridine compound with metal-chelating properties (1). It is absorbed within minutes after oral administration and reaches maximum blood concentrations within 1 hour. It has a half-life of 1–2 hours, and is almost completely undetectable in blood within 5–7 hours after a single dose. Deferiprone is mostly metabolized to a glucuronide conjugate that reaches maximum blood concentrations within 1.0–1.5 hours. Deferiprone, its iron complex, and its glucuronide conjugate are detectable in the urine, and in most instances the total amount of all three accounts for almost 100% of the

© 2006 Elsevier B.V. All rights reserved.

Table 1 Metal stability constants of deferiprone, deferoxamine, and diethylenetriaminepentaacetic acid (DTPA)

Ion	Deferiprone	Deferoxamine	DTPA
Fe^{3+}	35.0	30.6	28.6
Cu^{2+}	19.6	14.0	21.0
Zn^{2+}	13.5	11.1	18.4
Ni^{2+}	12.1	10.0	20.2
Co^{3+}	11.7	11.0	19.0

dose. Deferiprone is not excreted in the feces. However, there is much interindividual variation in its metabolism. The order of metal binding by deferiprone at pH 7.4 is iron > copper > aluminium > zinc (1) (see Table 1).

Deferiprone has a concentration-dependent affinity for iron, with a higher binding constant than deferoxamine or diethylenetriaminepentaacetic acid (DTPA). However, it takes three molecules of deferiprone to bind one molecule of iron, whereas deferoxamine binds iron in a 1:1 ratio. For this reason, deferiprone must be present in very high concentrations, close to toxic concentrations, to be effective (2). Deferiprone dissociates from iron when its concentration in body fluids falls to the concentration achieved just a few hours after oral administration (3). Deferiprone is effective in excreting iron in iron storage diseases and aluminium in patients on hemodialysis (1).

Iron chelation treatment has dramatically improved the prognosis of patients with beta-thalassemia (4). Parenteral deferoxamine reduces tissue iron stores, prevents iron-induced organ damage, and reduces morbidity and mortality. However, the burden of prolonged subcutaneous portable pump infusions, adverse reactions, patient non-compliance, and high cost are limiting factors, which have stimulated the development of orally active compounds. Combinations of chemically different types of chelators, which have different iron-carrying capacities and access different iron compartments, may work synergistically and result in increased efficacy, whereas lower doses of individual drugs may be less toxic (5). Examples are parenteral deferoxamine with oral deferiprone or 2,3-dihydroxybenzoic acid (2,3-DHB), or oral deferiprone with oral *N,N′-bis*(2-hydroxybenzyl)ethylenediamine-*N,N′*-diacetic acid (HDEB). Iron bound to a "shuttle," an oral agent that mobilizes tissue iron, is exchanged in the blood stream with a "sink," such as parenteral deferoxamine, and excreted via the kidneys, while the shuttle is reused. Combinations of different iron chelators can enhance iron excretion, target specific iron compartments, minimize adverse effects, increase treatment options, improve adherence to therapy, and facilitate individualization of therapy. Increasing understanding of the kinetics of iron metabolism, iron overload, and the complexity of chelation should further improve therapeutic strategies.

Observational studies

Since the controversy about the safety of deferiprone (SEDA-18, 250), its position as a therapeutic agent has been clarified (1). In the absence of iron storage, deferoxamine is undoubtedly toxic. However, it has been accepted, in spite of serious toxicity, because of the great need of an effective iron chelator for oral use (SEDA-18, 250). In this context, two studies are important, because they cast doubt on the efficacy of deferiprone (6,7). In the first, a long-term study in 51 transfusion-dependent iron-overloaded patients, 19 withdrew because of adverse events: arthropathy (stiffness, crepitus, effusion; $n = 5$), gastrointestinal symptoms (severe nausea, anorexia, vomiting; $n = 5$), granulocytopenia ($n = 3$), renal insufficiency ($n = 1$), and tachycardia ($n = 1$) (6). In the second study, in 26 patients who continued to use the drug, there was generally no satisfactory reduction in iron stores. On the other hand, deferiprone caused fewer adverse effects and was more effective in patients who were previously well-chelated and had lower initial ferritin concentrations. Also, in the long run deferiprone did not adequately control the body iron burden. In addition, in this study the alarming suspicion was raised that deferiprone can paradoxically worsen hepatic fibrosis in patients with thalassemia major, based on hepatic biopsies in 19 patients (7).

In contrast, studies in Italy and the USA have reached more positive conclusions. Of 187 patients with thalassemia who were unable or unwilling to use deferoxamine, 162 completed 1 year of treatment with deferiprone (75 mg/kg/day) (8). One patient developed agranulocytosis and another nine had various degrees of neutropenia (altogether 5%). Other reasons for withdrawal were nausea and vomiting ($n = 4$; total frequency 24% of patients), thrombocytopenia below 100×10^9/l ($n = 2$), and a fall in serum alanine transaminase ($n = 2$). Arthralgia developed in 11 patients (6%). In 29 patients who had not adhered well to deferoxamine and who took deferiprone (70 mg/kg/day) with a minimum follow-up of 1 year, adverse effects were pain in the knees in three patients, reversible neutropenia in one, and gastric intolerance in one (9). A repeat liver biopsy in 20 patients showed a reduction in the grade of liver siderosis and of iron content in seven. Worsening of hepatic fibrosis was not mentioned.

In 11 Greek patients who took deferiprone 75–100 mg/kg/day for 6 months, there were no serious adverse events of any kind (10).

In a Lebanese study in 17 patients, mainly with thalassemia major, there were no serious adverse reactions to deferiprone 50–75 mg/kg/day (11). Joint pain, stiffness, or swelling occurred in six patients; the symptoms were severe in two and mild in four patients. Seven patients had nausea, especially in the first month of treatment, and two had a reduced appetite. Headache developed in four patients. Mouth ulcers, sore throat, bitter taste, and fatigue occurred in single cases. In one patient there was a weakly positive ANF after 6 months. There were no cases of granulocytopenia and in none of the patients did adverse effects require drug withdrawal. The authors suggested that environmental or hereditary factors might have influenced the results.

In a large-scale program for the controlled use of deferiprone, established in 1997 by the Italian Ministry of Health, 86 centers collected information about 532 patients (12). In 187 patients, 269 events led to interruption of treatment, often transient. Permanent withdrawal because of adverse events occurred in 47 patients (8.9%). Reasons for withdrawal of treatment in 64 patients included

© 2006 Elsevier B.V. All rights reserved.

non-compliance ($n = 30$), a serum ferritin concentration above 4000 ng/ml ($n = 14$), and a ferritin concentration below 500 ng/ml ($n = 3$). The most common adverse events were mild to severe granulocytopenia (4.3%), arthralgia (3.9%), gastrointestinal discomfort (3.2%), including nausea, vomiting, and abdominal pain, and transient increases in alanine transaminase activity (2.8%); however, the alanine transaminase results were not clearly presented in the report. Adverse events that were not established as adverse effects were urticaria, erythema, dermatitis, fever, flu-like symptoms, and "infectious episodes"; the authors did not comment on these.

Comparative studies

Deferiprone and deferoxamine have been compared in Lebanese patients, mainly with thalassemia major, of whom 17 used oral deferiprone 75 mg/kg/day and 40 received subcutaneous deferoxamine 20–50 mg/kg/day on 5 days a week; the patients were followed for 2 years (13). All those who took deferiprone did so because deferoxamine had not been suitable, due to either non-compliance or adverse reactions. One of those taking deferiprone withdrew for unknown reasons (and was excluded from the study). Deferiprone was commonly associated with orange discoloration of the urine. Six patients complained of joint pains, mainly in large joints (moderate to severe in two and mild in four), not requiring drug withdrawal. Seven patients reported nausea, four had headaches, two rashes, and two fatigue. Abdominal discomfort, mouth ulcers, and sore throat each occurred in one patient. Although two patients had transient falls in neutrophil count (to 1.3×10^9 and 1.44×10^9/l), presumably secondary to a viral infection, there were no cases of agranulocytosis.

Organs and Systems

Cardiovascular

Since circulating deferiprone-iron complexes can easily dissociate, deferiprone can redistribute iron in the body (14). Although this might theoretically lead to the precipitation or aggravation of heart failure (14), no such cases have as yet been reported.

Sensory systems

Eight patients with deferoxamine-related hearing loss were switched to deferiprone (dose not specified). In five there was deterioration in hearing (15).

Metal metabolism

Zinc deficiency was detected in 12 out of 84 patients, but withdrawal of deferoxamine was not needed (16). In another study, zinc excretion was moderately increased in three of 16 patients, and two had reduced serum zinc concentrations (17). None had clinical signs of zinc deficiency.

Hematologic

Agranulocytosis is a major limitation to the use of deferiprone and has an estimated frequency of 1.6% (16–21). Moderate leukopenia is more common.

Oxidation of deferiprone with hypochlorous acid, the major oxidant of neutrophil leukocytes, results in the formation of a chemically reactive species, consistent with the quinone metabolite of deferiprone. Deferiprone-related agranulocytosis presumably results from a T cell-mediated immunological reaction, induced by a reactive metabolite of deferiprone (18). In one case agranulocytosis and systemic vasculitis (with arthritis, palpable purpura of the legs, erythema of the palms and soles, and desquamation of the skin over the distal phalanges) occurred in association with deferiprone (22).

In 51 children with thalassemia studied in the All India Institute of Medical Sciences some degree of granulocytopenia developed in 12, 7 of whom were taking a low dose (50 mg/kg/day) and 5 a high dose (75 mg/kg/day) (23). Four had neutrophil counts well below 1×10^9/l; one developed a serious infection. Deferiprone was restarted in nine of the 12, leading to a relapse of granulocytopenia after 5 months in only one. The mechanism may be different for moderate and severe granulocytopenia. The authors suggested that the high prevalence of granulocytopenia in the Indian study could have been secondary to conditions such as poor transfusion schedules, poor nutritional status, higher serum ferritin concentrations, or genetic factors. In another study, five of 13 patients were re-challenged and granulocytopenia recurred (18).

In a large-scale program for the controlled use of deferiprone, established in 1997 by the Italian Ministry of Health, 86 centers collected information about 532 patients (12). Agranulocytosis developed in five patients, three of whom had previously had transient episodes of granulocytopenia, while using deferiprone; deferiprone was permanently withdrawn and all five recovered. There were episodes of less profound neutropenia in 18 other patients. In eight patients with neutropenia deferiprone was restarted; in one case agranulocytosis recurred and in three there was a relapse of less severe neutropenia; in the other four patients rechallenge was uneventful. Granulocytopenia occurred predominantly in patients with an intact spleen and in the younger age group (under 18 years); however, splenectomy was more frequent in the older patients. The risk of agranulocytosis is higher during the first months of exposure and probably falls with time.

In a patient with sickle cell anemia there was an increase in the frequency of sickle cell crises during the use of deferiprone (17).

Gastrointestinal

Nausea, occasionally with vomiting, occurred in six out of 20 children taking deferiprone (21). In another study, in 38 patients with transfusional iron overload, three withdrew because of severe nausea and another three had mild gastrointestinal complaints (17). The daily doses were 3–6 g (50–100 mg/kg).

Liver

In 84 patients receiving deferiprone, there were transient increases in liver enzymes in 44%, but persistent

© 2006 Elsevier B.V. All rights reserved.

liver dysfunction leading to withdrawal occurred in only one (16).

Deferiprone paradoxically worsened hepatic fibrosis in patients with thalassemia major, based on hepatic biopsies in 19 patients (7). On the other hand, in another study of 20 liver biopsies, worsening of hepatic fibrosis was not mentioned (9).

In view of the suspicion that deferiprone can cause hepatic fibrosis, experience at the Sydney Children's Hospital in Australia has been reviewed, encompassing two liver biopsies in 14 patients taking deferiprone and 22 receiving deferoxamine (SEDA-23, 240) (24). The liver iron concentrations in the two groups, both at initial biopsy and subsequent biopsy, were not significantly different. Fibrosis progressed in five of 14 deferiprone users and in eight of 22 deferoxamine users. Progression greater than 1 unit occurred in four of 14 deferiprone users and two of 22 deferoxamine users. In those with positive hepatitis C serology, fibrosis showed progression in one of three patients using deferiprone and two of nine deferoxamine users; these findings were not significantly different. Pericellular fibrosis and Councilman bodies were seen in some patients: four of 11 deferiprone users and one of 20 deferoxamine users, a significant difference. However, errors in the presentation of the data hindered interpretation of the findings.

A further study has provided some reassurance. Three pathologists evaluated 112 coded liver biopsies obtained from 56 patients before and after deferiprone treatment (median duration 3.5 years). They found no evidence that deferiprone had worsened hepatic fibrosis (25). In view of the history of this problem, it is worth noting that "The International Safety Monitoring Committee that commissioned this study [was] an independent body of scientists," and that "The members of the Safety Monitoring Committee and the authors [had] no financial interest in the development of deferiprone."

Skin

In 38 patients with transfusional iron overload, deferiprone had to be withdrawn in one case because of a rash (17). Another patient developed a systemic vasculitis with arthritis, palpable purpura of the legs, erythema of the palms and soles, and desquamation over the distal phalanges. This patient had also had agranulocytosis in association with deferiprone (22).

Musculoskeletal

Deferoxamine commonly causes arthropathy of the knees, hips, shoulders, wrists, and fingers (1,17,26–32). Symptoms range from pain to inflammation and restriction of movement. Knee radiographs in one patient showed thalassemic changes, joint effusions, and minor degenerative changes in the patellofemoral joint. Magnetic resonance imaging confirmed effusions, with no evidence of synovial hypertrophy or cartilage abnormalities. The synovial fluid was a sterile transudate without inflammatory cells and low concentrations of deferiprone uncomplexed to iron. Arthroscopy showed mild synovial hypertrophy and hyperplasia, with iron staining. Synovial biopsy showed mild synovial lining cell proliferation and extensive iron deposition, without evidence of an inflammatory or allergic reaction. Since circulating deferiprone-iron complexes can easily dissociate, iron redistribution might play a role in the development of arthropathy (14). High concentrations of iron relative to deferiprone were detected in synovial fluid, suggesting that iron is shifted by deferiprone from body stores to the joints and that incomplete complexation may result in the formation of catalytic iron.

A joint effusion developed in one of 14 children using deferiprone (24).

Immunologic

A few observations have suggested that deferiprone can cause a lupus-like syndrome, with antinuclear and antihistone antibodies (33,34), but this suspicion is still unproven (29,35).

Infection risk

- An 82-year-old woman with a myelodysplastic syndrome died of *Escherichia coli* septicemia after 5 months of treatment with deferiprone (17). There was no granulocytopenia.

Death

The preliminary results of adding deferiprone to conventional treatment in order to reduce mortality from acute *Plasmodium falciparum* malaria suggest benefit (36). In 24 patients who were given deferiprone there were two deaths, compared with four in the control group of 21 patients. One patient who was given deferiprone died of unexplained pneumonia.

Second-Generation Effects

Fetotoxicity

Deferiprone inhibits intracellular ribonucleotide reductase, a rate-limiting enzyme in DNA synthesis, and in animal experiments it is toxic to proliferating tissues, especially the bone marrow. It has a pattern of adverse effects similar to those of cytotoxic drugs and is teratogenic and embryotoxic in animals (14,37).

Deferoxamine

General Information

Deferoxamine is a polyhydroxamine acid with specific affinity for iron and, less strongly, aluminium. It is a naturally occurring siderophore produced by *Streptomyces pilosus*.

Uses

Deferoxamine is used in the treatment of acute iron poisoning and in iron storage diseases, notably beta-thalassemia (1). The usual regimen is 40 mg/kg/day as a subcutaneous infusion over 10–12 hours, starting at an early age (3 years). During erythrocyte transfusion,

© 2006 Elsevier B.V. All rights reserved.

deferoxamine 300 mg/kg can be given intravenously over 24 hours. Vitamin C 100 mg/day can also be given orally to facilitate mobilization of stored iron. With such a regimen the duration and quality of life in thalassemia can be greatly improved (2,3). Another indication for deferoxamine is aluminium storage in patients on hemodialysis.

Iron chelation treatment has dramatically improved the prognosis of patients with beta-thalassemia (4). Parenteral deferoxamine reduces tissue iron stores, prevents iron-induced organ damage, and reduces morbidity and mortality. However, the burden of prolonged subcutaneous portable pump infusions, adverse reactions, patient non-compliance, and high cost are limiting factors, which have stimulated the development of orally active compounds. Combinations of chemically different types of chelators, which have different iron-carrying capacities and access different iron compartments, may work synergistically and result in increased efficacy, whereas lower doses of individual drugs may be less toxic (5). Examples are parenteral deferoxamine with oral deferiprone or 2,3-dihydroxybenzoic acid (2,3-DHB), or oral deferiprone with oral *N,N′-bis*(2-hydroxybenzyl)ethylenediamine-*N,N′*-diacetic acid (HDEB). Iron bound to a "shuttle," an oral agent that mobilizes tissue iron, is exchanged in the blood stream with a "sink," such as parenteral deferoxamine, and excreted via the kidneys, while the shuttle is reused. Combinations of different iron chelators can enhance iron excretion, target specific iron compartments, minimize adverse effects, increase treatment options, improve adherence to therapy, and facilitate individualization of therapy. Increasing understanding of the kinetics of iron metabolism, iron overload, and the complexity of chelation should further improve therapeutic strategies.

Comparative studies

Deferiprone and deferoxamine have been compared in Lebanese patients, mainly with thalassemia major, of whom 17 used oral deferiprone, 75 mg/kg/day for 2 years, and 40 received subcutaneous deferoxamine 20–50 mg/kg/day on 5 days a week (6). Those who received deferoxamine had done so for 4–24 years and were followed for 2 years. Infusion site reactions occurred in 34 patients, including pain, tenderness, itching, burning, erythema, swelling, induration, and lipodystrophy. Five patients had disturbances of vision and hearing, three had growth retardation. Six patients had increased heart rates, four had dizziness, and one had leg cramps.

General adverse effects

Deferoxamine is only used parenterally. It is more toxic when used in patients with a low iron burden. After subcutaneous infusion many patients have some local irritation and swelling. Rapid intravenous injection can be followed by flushing, wheals, tachycardia, hypotension, acute adult respiratory distress, and renal insufficiency; shock or convulsions can also occur. Headache, blurred vision, dysuria, diarrhea, and leg or hand cramps have been reported. Intramuscular injection can be painful. Hypersensitivity reactions occasionally occur, with rash, fever, and edema; anaphylactic shock has been encountered (SEDA-7, 262) (7,8). As a test dose in patients with aluminium storage disease, a low dose (500 mg in 100 ml of 0.9% saline) is usually effective and safe (9). At the higher doses used in treatment, nausea, itching, dizziness, or more serious reactions can occur. When deferoxamine is given early in childhood, osteopathy and growth impairment can occur.

Withholding iron is an important protection strategy of the body against microbial and neoplastic cells, and cellular iron depletion plays a prominent role in cell-mediated immune defence (10). The use of deferoxamine is associated with an increased risk of life-threatening opportunistic infections, notably yersiniosis and mucormycosis; such infections can affect various organ systems and pose diagnostic problems. Hypersensitivity reactions can occur but are infrequent. Rare cases of anaphylactic shock, thrombocytopenia, and bone marrow failure have been described. Tumor-inducing effects have not been reported. Deferoxamine is teratogenic in animals.

Organs and Systems

Cardiovascular

Although rarely described, hypotension can be a significant problem in patients receiving deferoxamine, especially when it is given too rapidly by intravenous injection (11); it is possibly due to histamine release (12). Dose reduction alleviates the hypotension. Anaphylactic shock has only rarely been reported (SEDA-7, 262).

In a single report, soft-tissue swelling around the elbow and localized mild pitting edema were thought to have been induced by deferoxamine (13). Although the clinical features suggested a deep-vein thrombosis, this was ruled out by a phlebogram.

In iron storage disease, ascorbic acid should be given only after adequate serum concentrations of deferoxamine have been attained, in order to prevent serious cardiac arrhythmia (14). Opportunistic fungal infections associated with deferoxamine may also involve the heart muscle and usually have a fatal outcome (15–17).

There was severe phlebitis in cancer patients receiving deferoxamine (50 mg/kg/day by intravenous infusion over 72 hours) and iron sorbitol citrate in an attempt to enhance doxorubicin activity (18). Dilution of the drug in large volumes of saline did not prevent this adverse effect.

Respiratory

Deferoxamine by continuous infusion can cause life-threatening acute adult respiratory distress syndrome, with respiratory failure, hypoxia, pulmonary edema, low pulmonary compliance, and a reduced pulmonary capillary wedge pressure (19,20). Respiratory distress can start 32–72 hours after the infusion. Lung biopsy shows diffuse abnormalities with alveolar damage, interstitial fibrosis, and inflammatory infiltration with lymphocytes, eosinophils, mast cells, and some erythrocytes. It is therefore recommended that deferoxamine should not be given as a continuous infusion for more than 24 hours (21). Although the mechanism is unknown, it has been suggested that deferoxamine causes lung damage by paradoxically increasing the production of free radicals, as a result of extended exposure of the

© 2006 Elsevier B.V. All rights reserved.

lungs to ferrioxamine (21). However, others have emphasized that pulmonary endothelial cells are sensitive to macrophage-generated oxidants, and have proposed that in chelating, intracellular iron deferoxamine may acutely reduce the synthesis of catalase and heme, and that readily available extracellular heme subsequently enters cells, is broken down, and releases iron in the presence of low concentrations of catalase, which catalyses oxidant damage (22).

- In one patient, pulmonary symptoms occurred after 7 days of continuous deferoxamine infusion (dyspnea, tachypnea, tachycardia, pleuritic chest pain, and fever) and were diagnosed as pulmonary microemboli (23).

Respiratory distress and interstitial infiltrates have also been reported in children receiving deferoxamine for iron poisoning or refractory cancers (24,25).

Lung damage was attributed to high doses of deferoxamine in 17 patients with beta-thalassemia major who were given 33 courses by continuous intravenous infusion of 10 days duration in doses up to 10 mg/kg/hour (26). Respiratory dysfunction developed in two girls given the highest doses (aged 11 and 15 years). The symptoms were dyspnea, tachypnea, tachycardia, and low-grade fever. Arterial blood gas measurements showed hypoxemia and hypercapnia. Chest X-rays showed bilateral interstitial infiltrates. In one patient, mechanical ventilation was needed for 2 weeks and it took 8 months before pulmonary function returned to normal. In both patients deferoxamine was reintroduced later on without relapse.

The lungs can also be involved in deferoxamine-associated infections, such as systemic mucormycosis, which often runs a fatal course (16,17,27,28).

- Pneumonia during treatment with high doses of deferoxamine (2–2.5 g by continuous infusion) in a patient with thalassemia major was found to be caused by *Pneumocystis jiroveci* (29).

Nervous system

The use of deferoxamine to reduce aluminium overload in hemodialysis patients can exacerbate aluminium encephalopathy and precipitate dialysis dementia (30–34). Confusion, disorientation, agitation, aggression, abnormal behavior, speech arrest, myoclonus, hallucinations, and seizures can occur. Some patients are very sensitive to this effect, and a test dose of deferoxamine is advisable in order to ascertain whether aluminium is excessively mobilized (35).

Deferoxamine can modify the electroencephalogram, with progressive slowing and bilateral paroxysms (36).

Nausea and vomiting often develop in patients with rheumatoid arthritis after 4–12 days of treatment with deferoxamine, presumably as a result of chelation of iron from the central nervous system (37). Two patients who took the phenothiazine derivative prochlorperazine during treatment of rheumatoid arthritis with deferoxamine lost consciousness for 48–72 hours, possibly because this combination of drugs removed essential iron from the nervous system (38).

Headache, loss of vision, disturbed consciousness, and various other neurological symptoms can be alarming signs of deferoxamine-associated systemic mucormycosis with cerebral involvement, a condition that is usually fatal (15–17).

Sensorimotor neurotoxicity, with paresthesia, areflexia, reduced vibration and position sense, muscle weakness of the arms, and concomitant disturbances of vision and hearing, has been described in two thalassemia patients during the intravenous administration of high dosages of deferoxamine (120 mg/kg/day) (28).

Neurophysiological evaluation of 40 patients with beta-thalassemia major showed abnormal findings in brainstem-evoked potentials: auditory (25%), visual (15%), and somatosensory (7.5%); some had abnormal nerve conduction velocity (25%) and 15% had involvement of multiple neural pathways (39). Subclinical involvement of the auditory pathway was statistically associated with a higher mean daily dose of deferoxamine and a longer duration of treatment. Abnormalities of the somatosensory pathways were related to old age, a long duration of deferoxamine use, and low serum copper concentrations. Multiple neural pathway involvement was related to the duration of treatment. However, deferoxamine is only partly responsible for the subclinical abnormalities of neural pathways often found in patients with beta-thalassemia major.

Sensory systems

The reported frequency of sensorineural toxicity of deferoxamine varies. Some degree of visual and auditory toxicity can occur in about one-third of patients (40), and impairment of vision and hearing can occur simultaneously (41).

- A 25-year-old woman with beta-thalassemia, who had received subcutaneous deferoxamine 2 g/day (50 mg/kg) for 7 days a week for 3 years, developed visual loss. Her best-corrected visual acuity was 20/60 bilaterally. Automated perimetry showed bilateral central scotomata, and a Farnsworth Panel D-15 test showed an irregular pattern of errors. There were no lens opacities, and fundoscopy and fluorescein angiography were normal. Audiometry showed a bilateral high-frequency sensorineural deficit. Two days after withdrawal of deferoxamine and oral administration of zinc sulfate 20 mg/day, the central scotomata disappeared and her color vision and audiographic abnormalities reversed completely. The serum ferritin concentration was 656 ng/ml.

Since the serum ferritin concentration was relatively low, the original dose of deferoxamine may have been too high. Although zinc concentrations were not measured before treatment, the rapid and complete improvement in 48 hours after starting zinc sulfate suggested that deferoxamine-induced zinc deficiency may also have played a role.

Eyes

In aluminium-overloaded dialysis patients, acute visual impairment can occur after only the first or second intravenous test dose of 40 mg/kg deferoxamine (42–44). Visual symptoms are of retinal origin and include impairment of color vision, night blindness, and reduced visual acuity; serious and persistent visual loss can occur

© 2006 Elsevier B.V. All rights reserved.

(42,45–48). Color blindness is of the tritan type, involving the blue–yellow axis (49). A light- and electron-microscopic study showed loss of microvilli from the apical surface, patchy depigmentation, vacuolation of the cytoplasm, swelling and calcification of mitochondria, and thickening of Bruch's membrane (50). Optic neuritis and pigmentary retinal degeneration can develop (51–55).

In one prospective study in 17 patients with hemolytic anemia (aged 5–25 years) lens opacities were found in 41%, changes in the retinal pigment epithelium in 35%, tortuosity of retinal vessels in 24%, dilatation and sheathing of retinal vessels in 18%, defects in color vision in 29%, and abnormal dark adaptation in 18% (56). In many other studies much lower frequencies were found. Perhaps retinal injury is related to the depletion of metals such as zinc, copper, and/or iron (57). On the other hand, ocular and auditory disturbances are not infrequent in patients with thalassemia, iron storage diseases (58,59), or uremia (45), and may be coincidental in patients receiving deferoxamine (60).

The sensorineural toxicity of deferoxamine is much more pronounced in patients without iron storage disease (for example rheumatoid arthritis). Ocular toxicity was also apparent in cancer patients receiving deferoxamine and iron sorbitol citrate in an attempt to enhance doxorubicin activity (18). Careful estimation of the necessary doses of deferoxamine and regular ophthalmological monitoring can often prevent serious injury. Visual evoked potentials can be used to monitor patients receiving high doses of deferoxamine (61). It is of great diagnostic and prognostic importance to keep in mind that a sudden loss of vision or other neurological events in a patient receiving deferoxamine can also be the first sign of life-threatening cerebral mucormycosis (62).

Cataract has been observed in animals, but even after prolonged use of deferoxamine it has only rarely been reported in humans (63,64).

- Two patients with transfusion-related hemochromatosis, who received deferoxamine 9 g/week and 10 g/month to a total dose of 39 g, and one with hemodialysis-related aluminium storage, who received 9 g/week, experienced gradual loss of visual acuity (65). There was pigmentary mottling near the maculae and electroretinography was abnormal in the two patients studied.

Acute loss of visual acuity has been described after a single test dose of deferoxamine (66).

- A 58-year-old patient with proliferative glomerulonephritis suddenly suffered loss of visual acuity (320/200 in both eyes) and disturbance of color vision 2 hours after hemodialysis, during which deferoxamine 10 mg/kg had been given to test for aluminium storage. Computerized campimetry showed bilateral central scotomata. Recovery was good but slow: within 3 months visual acuity had increased to 20/30, but bilateral pigmentary macular changes persisted.

In a study in China, electroretinographic responses and dark adaptation visual thresholds showed subtle but significant retinal dysfunction in elderly chronically transfused patients with thalassemia receiving deferoxamine (67). The authors concluded that the findings suggested that iron accumulation and not deferoxamine toxicity played a major role in these patients.

Ears

Ototoxicity due to deferoxamine ranges from a subclinically abnormal audiogram, through mid- to high-frequency neurosensorial hearing loss of the cochlear type, to acute deafness (SED-12, 552) (46). The ototoxic effects of deferoxamine have been studied in 70 adult transfusion-dependent patients (40). Characteristically there was high-frequency sensorineural hearing loss; tinnitus was less frequent. In five of eight patients with deferoxamine-related hearing loss who were switched to deferiprone there was a deterioration of hearing (40).

There are two risk factors: a high total cumulative deferoxamine dose and a low serum ferritin concentration. In order to prevent deferoxamine ototoxicity, a therapeutic index has been proposed, defined as the daily dose of deferoxamine (in mg/kg/day) divided by the serum ferritin concentration (ng/ml) (SED-12, 552) (68). A therapeutic index of 0.027 is considered to be associated with a low risk of deterioration of hearing. Regular audiometric follow-up, with special attention to the frequencies of 3 and 6 kHz, can help to detect and prevent permanent hearing loss.

Of 75 adults with thalassemia major (age range 17–32 years) 50 had normal audiography (69). Of the other 25, 13 had a sensorineural deficit of 35 dB or less, with high frequency losses, and two had a deficit of 35–75 dB. There was no association between hearing loss and age, ferritin concentration, or therapeutic index. The authors concluded that their findings were not different from those in a healthy population of the same age and were not suggestive of an ototoxic effect of deferoxamine.

In an Iranian study, the incidence of sensorineural hearing impairment in 128 patients taking deferoxamine was assessed by otological examination and pure tone audiometry (70). Patients who received deferoxamine subcutaneously every other day were compared with those who received it for 6 days a week. In both groups the average daily dose was the same, 21–39 mg/kg/day, since the alternate-day group received double doses. Of the patients in the once-a-day group there was hearing loss at a frequency of 8000 Hz in the right ear in 28% and in the left ear in 23%. In the alternate-day group, hearing loss was more common: 45% and 42% respectively. It appears that the maximum plasma deferoxamine concentration is a determinant of sensorineural toxicity. There was no relation between ototoxicity and either the serum ferritin concentration (which was meticulously controlled) or the duration of deferoxamine treatment.

Mineral balance

The administration of deferoxamine to dialysis patients in order to chelate aluminium is often associated with asymptomatic hypocalcemia, which can in turn aggravate hyperparathyroidism (12). Deferoxamine-induced hypocalcemia can be corrected with supplements of vitamin D and calcium carbonate.

- In an 8-month-old child the administration of deferoxamine for chelation of aluminium, which had accumulated as a result of total parenteral nutrition, caused sustained hypocalcemia without concomitant hypercalciuria (71).

© 2006 Elsevier B.V. All rights reserved.

Presumably, the reduced calcium concentrations in this case reflected bone regeneration following the disappearance of aluminium from the bone.

Hematologic

Deferoxamine has a strong depressant effect on proliferation of bone marrow cultures in vitro (72). On the other hand, deferoxamine improves hemopoiesis in patients with anemia, for example in rheumatoid arthritis, hemolysis, or myelodysplastic syndromes, and reduces transfusion dependency (73–78). The mechanism is unknown, but increased erythropoietin responsiveness secondary to iron chelation may play a role (77).

In 11 hemodialysis patients who also received recombinant human erythropoietin for anemia secondary to renal failure, deferoxamine increased the proliferation of erythroid precursor cells and had a synergistic in vivo effect on erythropoietin (79,80).

When used in patients without iron overload, deferoxamine can cause iron deficiency (12). In 20 patients, there were falls in ferritin concentrations in six, requiring withdrawal of deferoxamine and parenteral administration of iron dextran (12). Monitoring ferritin concentrations is therefore recommended in patients receiving deferoxamine for aluminium overload. On the other hand, the administration of deferoxamine (500 mg/day by subcutaneous infusion) improves chronic anemia in patients with rheumatoid arthritis (77). This effect is thought to be achieved through increased erythropoietin responsiveness, secondary to iron chelation. Iron chelation with deferoxamine also improves hemopoiesis in patients with myelodysplastic syndromes and can reduce transfusion dependency (78). Exactly how deferoxamine works in these patients remains to be explained.

There have been rare reports of thrombocytopenia and aplastic anemia with pancytopenia, attributed to deferoxamine (81,82). Deferoxamine can accumulate in renal insufficiency if repeated doses are given, and it has been advised that platelet counts should be monitored in such patients (81).

Gastrointestinal

Gastrointestinal upsets are frequent after parenteral administration of deferoxamine (12). In addition to nausea, vomiting, and abdominal cramps, passage of black stools can occur, perhaps because of increased stool iron content. Nausea, anorexia, and vomiting often occur when deferoxamine is used in rheumatoid arthritis or Alzheimer's disease (32,83).

Urinary tract

The iron–deferoxamine complex gives the urine a reddish-brown color.

In 27 patients with thalassemia, subcutaneous deferoxamine caused a clinically significant reduction in renal glomerular filtration rate in 40% and a mild reduction in another 40% (84). In all cases of severe reductions the glomerular filtration rate tended to return to baseline on withdrawal of deferoxamine. There was also a significant increase in urine volume during deferoxamine therapy.

Deferoxamine has occasionally been reported to cause renal insufficiency (85,86) and adequate hydration and repeated measurements of renal function are recommended in patients receiving intravenous deferoxamine. Perhaps the inability to reabsorb sodium and to concentrate urine during administration of deferoxamine is due to a diuretic effect of ferrioxamine (87).

Skin

Subcutaneous deferoxamine often causes local irritation, pruritus, and swelling of the skin at infusion sites (11,88–90). Dilution of the deferoxamine solution reduces the frequency, and the addition of 1–2 mg hydrocortisone to the solution can alleviate the problem. Occasionally, severe local reactions with fever occur, leading to withdrawal (89). Disfiguring lumps can develop and can serve as foci for bacterial infection. Proper needle placement in deep subcutaneous sites and rotation of sites around the lower abdomen, thighs, buttocks, and arms usually allow sufficient time for one area to heal before it is used again.

Rapid intravenous infusion of deferoxamine (more than 25 mg/kg over 30 minutes) can cause vertigo, hypotension, diffuse erythema, and generalized pruritus (11). Such reactions reverse on withdrawal of the infusion, although occasionally a fluid bolus and/or an antihistamine may be needed to reverse the symptoms more rapidly. This reaction is considered to be due to histamine release and not to be immunological in nature; patients can be safely treated later at a lower rate of infusion.

- An edematous, erythematous, itchy rash developed on the legs of a 62-year-old woman within 48 hours after infusion of deferoxamine (91).
- Porphyria cutanea tarda-like skin lesions on the dorsum of the hands and forearms, worsening with sun exposure, has been described in association with penicillamine (12).

In another study, deferoxamine was used successfully as a treatment for hemodialysis-related porphyria cutanea tarda (92).

Skin lesions imitating vasculitis or cutaneous infarction can be the first manifestation of life-threatening mucormycosis (93,94).

Musculoskeletal

Bone dysplasia

In children, deferoxamine can cause bone dysplasia, especially when it is started at a young age (95–100). Injury to the metaphyseal growth plate cartilage affects the development of tubular bones and vertebrae. The lesions are reminiscent of scurvy, but the mechanism is uncertain. Perhaps a combination of mechanisms is involved, of which the most relevant seem to be defective function of iron-dependent enzymes and chelation of other metals, such as zinc, copper, and aluminium. Deferoxamine-induced bone dysplasia can cause reduced body height and spinal deformities. Metaphyseal changes can be detected at an early stage by serial radiography. When they are found, the nightly dose of deferoxamine should be reduced to the lowest dose that results in a negative iron balance, and growth rate should be carefully observed.

© 2006 Elsevier B.V. All rights reserved.

The issue of deferoxamine osteochondropathy is even more complex, because thalassemia itself is also associated with growth impairment and body disproportionality with truncal shortening, whether puberty is induced or spontaneous (101).

Presentation

Of 476 patients in a multicenter study 40% had a short trunk and 18% short stature; in 14% there was disproportion between the upper and lower body segments (102). Spinal growth deficit starts early in infancy and is progressive. Deferoxamine-induced bone dysplasia has been identified as a contributing factor, in addition to thalassemia, hypogonadism, and siderosis. In addition to a short trunk, platyspondylosis and signs of bone dysplasia are characteristic features of bone lesions due to deferoxamine (102). The same group studied three children with beta-thalassemia (one girl aged 7 and two boys aged 6 and 12) (103). The ages of first exposure to deferoxamine were 2.5, 2, and 1.5 years and the mean daily doses were 48, 49, and 55 mg/kg/day respectively (route not stated). All three had short stature, a short trunk, and reduced growth velocity. One had protrusion of the sternum and another had genu valgum. Radiographs of the spine and long bones showed various degrees of osteopenia, platyspondylosis, cupped metaphysis of the distal femur, and pseudocystic cavities with sclerotic borders at distal and proximal metaphyses of the tibia. A reduction in the dosage of deferoxamine was followed by improvement in the bone lesions and growth velocity but not height. The authors concluded that in all children receiving deferoxamine, regular radiological and growth evaluation is needed, in order to limit bone dysplasia and short stature.

Another patient had pain and swelling at the anterior ends of the eighth and ninth ribs (104). This patient had been treated with subcutaneous deferoxamine since the age of 3 years with 37–66 mg/kg/day for 6 days a week. Radiologically there were rickets-like "rosary" lesions of the costochondral junctions. The pain disappeared within a few days after withdrawal of deferoxamine and reappeared after readministration. The mechanism underlying rickets-like changes due to deferoxamine is not known.

In a long-term evaluation of 29 patients with transfusion-dependent thalassemia major there were deferoxamine-induced skeletal changes in 15 patients: metaphyseal and spinal changes in five and spinal changes alone in 10 (105). After a reduction in the dosage of deferoxamine, the metaphyseal changes regressed in two but progressed in three, whereas the spinal changes were unchanged or progressed. Two patients required surgical intervention for marked valgus knee deformities. Of a further 21 patients with growth retardation and skeletal dysplasia, secondary to deferoxamine, four underwent surgery to correct genu valgum (106). Bone histology showed abnormal chondrocytes, alteration of staining pattern of cartilage, irregular columnar cartilage, and lacunae in the cartilaginous tissue. Bone microfractures were sometimes present. Bone microstructure showed varying degrees of impaired mineralization and the hardness of bone tissue was reduced. Bone apatite was quantitatively reduced.

Two Chinese studies in 35 consecutive patients with thalassemia on a hypertransfusion scheme plus chelation therapy have confirmed that deferoxamine-induced bone dysplasia was associated with height reduction and occurred at doses below 50 mg/kg/day (107,108).

In the first study, the patients had radiography of the left hand for bone age determination, and 12 had deferoxamine-induced long bone dysplasia (107). There was irregularity at the physeal–metaphyseal junction of the distal ulna (the site most frequently affected) and radius; metaphyseal sclerosis was also common, especially of the ulna, but also of the radius, metacarpals, and phalanges. Radiolucent lesions occasionally accompanied metaphyseal sclerosis. In six patients with relatively mild lesions, the dysplastic changes had been missed or not mentioned.

In another study, probably in the same 35 patients, coronal T1-weighted MRI scanning of the femur was performed, and in 11 patients also of the patella (108). In the distal but not proximal femurs of 11 of the 35 patients the following abnormalities were seen (in decreasing frequency): blurred physeal–metaphyseal junction, distal metaphyseal areas of hyperintensity, physeal widening, metadiaphyseal lesions, and (in only two) patellar lesions. Patients with MRI evidence of bone dysplasia had a significantly greater reduction in height than patients without.

Of 180 thalassemic patients receiving chelation therapy with subcutaneous deferoxamine, five had deferoxamine-induced serious rickets-like lesions of the long bones; two more had vertebral compression without long bone involvement (109). A microstructural analysis was made of tibia biopsy specimens taken in six patients during orthopaedic surgery and a biopsy of the iliac crest in one. With microradiography and X-ray diffraction there was irregular and reduced mineralization in all seven patients, compared with autopsy bone tissue. Apparently the osteochondrodystrophic lesions in deferoxamine osteopathy are areas with poor mineralization. The bone tissue does not reach maturity, and reduced microhardness leads to an increased risk of microfractures.

In a separate study, apparently in the same seven patients, the histological findings were presented (110). All the bone specimens showed a similar pathological pattern, with irregular columnar cartilage, lacunae in the cartilaginous tissue, abnormal chondrocytes, and impaired mineralization. Microfractures were common and were a likely explanation for the pain experienced by the patients.

Of 41 patients in Hong Kong with transfusion-dependent homozygous beta-thalassemia, who received subcutaneous infusion of deferoxamine in doses not exceeding 50 mg/kg/day, 16 had radiographic evidence of deferoxamine-induced bone dysplasia (111). All 16 had metaphyseal sclerosis of long bones (arms, hands, legs, and/or ribs); three had irregular sclerosis at the costochondral junction; one had platyspondyly. There was osteoporosis (unrelated to deferoxamine), as indicated by thinning of the metacarpal cortex, in 17 patients, eight with and nine without deferoxamine dysplasia. Two patients had evidence of medullary expansion; however, they were from mainland China and had had irregular blood transfusions and no chelation therapy, and it was unrelated to deferoxamine.

Diagnosis

The use of sonography as a cheap and easy tool in the assessment of deferoxamine-induced bone dysplasia of the knee has been studied in 32 patients with thalassemia major (112). Characteristic lesions were notching at the metaphyseal corner, a blurred or irregular peripheral juxtaphyseal–metaphyseal contour, and widening of the peripheral juxtaphyseal–metaphyseal echogenic interface. There were 14 true positive results, 10 true negative, 7 false negative, and 1 false positive. Thus, sonography is specific but not sensitive in the diagnosis of deferoxamine-induced dysplasia. Because of its high specificity, low cost, and non-invasiveness, sonography may have a role in the longitudinal monitoring of deferoxamine-induced bone dysplasia.

Mechanism

The mechanism underlying the effect of deferoxamine on bone formation has not been identified. In one study in 21 thalassemic patients with growth retardation and skeletal dysplasia secondary to deferoxamine, there were reduced concentrations of growth hormone in 72% of patients with bone dysplasia, compared with 41% of patients without (106). Four patients with growth hormone deficiency were treated with human recombinant growth hormone. Growth velocity doubled in two patients and one patient had a partial response; the fourth patient did not respond. There was a fall in growth velocity after 1 year of treatment with growth hormone in the partial responder and in one of the responders.

Management

The following strategy may be helpful in preventing bone dysplasia during treatment with deferoxamine (105,106):

- Chelation therapy should be started after the age of 3 years and when iron accumulation has become established.
- The dosage of deferoxamine should be established on the basis of iron balance and dose–response curves.
- Deferoxamine dosages above 50 mg/kg/day subcutaneously should be avoided.
- The deferoxamine dosage should be reduced if serum ferritin values are consistently below 1500–1000 ng/ml, or if the patient has reduced growth velocity.
- It is important to detect bone changes as early as possible, since a timely reduction in deferoxamine dosage or a switch to deferiprone can prevent serious skeletal injury.

A change from deferoxamine to deferiprone led to general improvement in a 14-year-old boy with deferoxamine-induced osteochondropathy (113). Unfortunately, the patient's sitting height had deteriorated, illustrating the irreversibility of platyspondylosis.

Sexual function

Repeated monilial vaginitis was reported in patients receiving deferoxamine for dialysis-related aluminium overload (12).

Immunologic

Generalized hypersensitivity reactions and anaphylactic shock can occur but are infrequent. Hypersensitivity reactions to deferoxamine may require permanent withdrawal, worsening the prognosis in thalassemia. However, successful desensitization has been achieved in three patients with previous deferoxamine hypersensitivity, enabling continued administration of deferoxamine (8,114,115).

Infection risk

In many species, from mammals to microbes, iron is essential, and the extremely low free iron content of the blood is an important antimicrobial factor. Many microorganisms do not produce siderophores and are entirely dependent on the iron content of their direct environment; usually their inability to produce siderophores is associated with low infectivity. In the case of increased availability of iron, for example in iron storage diseases, patients may have increased susceptibility to infectious diseases (116–118). Furthermore, iron impairs granulocyte function (119,120) and monocytic function (94). An abundance of publications has shown that the use of deferoxamine in iron storage disease, dialysis patients, or acute iron poisoning (121) can promote the development of infections, notably with microorganisms that are iron-dependent and are known to be otherwise only slightly infective (SED-12, 553) (122–126). Besides providing iron to these microorganisms by acting as a siderophore, deferoxamine can deplete the pool of iron available to the macrophage cytotoxic system (127), and adversely influence the immune system (29,35).

Yersinia enterocolitica or *Yersinia pseudotuberculosis*, *Pneumocystis jiroveci* (29), *Staphylococcus aureus* (128), *Cunninghamella bertholletiae* (127), and *Rhizopus* spp. have been involved. The diagnosis of these spontaneously rare infections may be even more difficult, because the deferoxamine-associated form can have an unusual and atypical course.

Mucormycosis

Many reports of fatal cases of mucormycosis have underlined the danger of acquiring disseminated fungal infection in patients receiving deferoxamine (15–17,93,94,129–135). Boelaert and co-workers of the International Registry of Mucormycosis in Dialysis Patients (Algemeen Ziekenhuis Sint Jan, B-8000 Brugge, Belgium) collected data on a total of 62 cases of mucormycosis, of which 59 were studied in detail (136); 78% of these patients were receiving deferoxamine. The infection presented as disseminated mucormycosis in 44%, rhinocerebral in 31%, and other forms in 25%, and ran a fatal course in 52 patients (86%). The fungus (cultured in only 36%) was always *Rhizopus* (in spite of the fact that human mucormycosis can be caused by various other fungal genera (for example *Mucor*, *Absida*, and *Cunninghamella*). The finding that the species was *R. microsporus* in all identified cases is at variance with the usual predominance of *R. oryzae* in patients with diabetes mellitus. Patients using deferoxamine who present with fever, sinusitis, dry cough, hemoptysis (28), acute loss of vision (62), or neurological symptoms should undergo evaluation for mucormycosis.

© 2006 Elsevier B.V. All rights reserved.

Occasionally, such conditions can start with skin lesions imitating vasculitis (93) or cutaneous infarction (94), or present with cavernous sinus or carotid arterial thrombosis (131). Although mucormycosis often has a fatal course, it can have a favorable prognosis if diagnosed early and treated aggressively with surgery and antifungal drugs (28). Many patients have several risk factors for mucormycosis in addition to deferoxamine (for example hemochromatosis, diabetes mellitus, splenectomy, immune suppression) and the contribution of deferoxamine can be difficult to prove or quantify in individual cases.

Yersinia enterocolitica

Infections with *Y. enterocolitica*, a Gram-negative aerobic and facultatively anaerobic, non-spore-forming bacterium, can occur in immunocompromized patients, and enteritis and lymphadenopathy are characteristic. However, in deferoxamine-treated patients septicemia predominates, and peritonitis and intestinal perforation (123) have been reported; the fatality rate is high (119,121,126,137–143). In all patients receiving deferoxamine, children and adults, the appearance of fever and other non-specific signs of infection should be a reason to think of yersiniosis. Children with acute iron poisoning are also at risk. In view of the severity of *Yersinia* sepsis, the prophylactic use of antibiotics has been advised whenever deferoxamine is administered to children from areas with a high incidence of yersiniosis (121). There have been single case reports of neck abscess (*Salmonella choleraesuis*) and of osteomyelitis of the ilium (*S. aureus*) during the use of deferoxamine (144,145). In the latter case bacterial contamination was considered to have occurred during insertion of the needle or during the preparation or infusion of the deferoxamine solution.

Long-Term Effects

Tumorigenicity

Deferoxamine is used experimentally in a variety of diseases, including Kaposi's sarcoma, and in vitro tests have suggested that it inhibits the growth of sarcoma-derived cells (146). Unfortunately, the intralesional injection of deferoxamine led to paradoxical exacerbation of Kaposi's sarcoma of the skin and the development of numerous sarcomatous papules in the area of injection, whereas there were no changes in untreated lesions (147).

Second-Generation Effects

Teratogenicity

Deferoxamine is teratogenic in animals, but experience in humans is not so far suggestive of deferoxamine-related malformations (148–150).

Susceptibility Factors

Age

The administration of high subcutaneous doses of deferoxamine to young children with thalassemia before iron overload has been established and is associated with a significant reduction in mean body length (151,152). Impairment of growth is associated with a rickets-like syndrome and joint stiffness. Metabolic studies have shown reduced hair and leukocyte zinc concentrations and leukocyte alkaline phosphatase activity. Retardation of growth may be related to chelation of trace elements (for example zinc), to a direct toxic effect of unchelated deferoxamine by inhibiting critical iron-dependent enzymes, or to both. It is advised that in thalassemia major, treatment with deferoxamine be started only after iron accumulation is established, that is at around 3 years of age, after 20–30 blood transfusions, when ferritin concentrations are in the range 800–1000 ng/ml. Deferoxamine doses should be established on the basis of studies of iron balance and dose–response curves, and longitudinal growth monitoring is warranted.

Children are also susceptible to opportunistic infection, notably *Y. enterocolitica* sepsis (142). In 10 children receiving intravenous deferoxamine (25 mg/kg) there were unexpected infections in four; three had episodes of fever and *S. aureus* in blood cultures, and one had *Y. enterocolitica* sepsis (128). Because of the possibility of septicemic dissemination secondary to digestive *Y. enterocolitica* infection, the occurrence of febrile diarrhea in a child with thalassemia is a reason for immediate withdrawal of deferoxamine and the administration of antimicrobial therapy (co-trimoxazole) (142).

Other features of the patient

A possible relation has been suggested between toxicity and the ratio of metabolite B of deferoxamine to unmetabolized deferoxamine (SEDA-18, 250) and there is a relation between regular deferoxamine treatment in respect to the degree of iron overload, as defined by the therapeutic index, that is the daily dose of deferoxamine in mg/kg/day divided by the serum ferritin concentration in ng/ml (SED-13, 621), and the ratio of metabolite B to total deferoxamine (deferoxamine plus ferrioxamine) in the plasma or urine (153). This is consistent with the hypothesis that metabolite B of deferoxamine, which is a product of the intercellular metabolism of iron-free but not iron-bound deferoxamine, inversely reflects the availability of iron in the plasma compartment. In patients who receive a high amount of chelation (measured as mean daily dose of deferoxamine in mg/kg) in relation to iron stores (as reflected by serum ferritin in ng/ml), the proportion of iron-free deferoxamine that is available for metabolism is greater. Therefore, the proportion of metabolite B is higher in the urine or blood of patients who are relatively well chelated. These findings suggest that the ratio of metabolite B/ferrioxamine, expressed either as plasma AUCs or urine concentrations, reflects the availability of chelatable iron, and hence the risk from excess deferoxamine administration at the time the measurement is taken, but that there is unlikely to be an inherent qualitative difference in deferoxamine metabolism in at-risk patients. Further study is needed to determine whether this is of value in identifying patients with increased risk of adverse effects prospectively.

Drug Administration

Drug administration route

Intravenous deferoxamine can be indicated in gross iron overload, serious cardiomyopathy, or intolerance of or non-adherence to subcutaneous administration. The results of continuous 24-hour deferoxamine infusion via indwelling intravenous catheters in 17 patients (25 intravenous lines) have been presented (154). The doses of deferoxamine were calculated with reference to the serum ferritin concentration, with a view to maintaining the therapeutic index (mean daily dose in mg/kg divided by the serum ferritin concentration in ng/ml) below 0.025. The usual regimen was 6 or 7 days of continuous treatment. Only eight patients received mean daily deferoxamine doses exceeding 50 mg/kg at any time. The mean number of catheter days per patient was 697 and the median follow-up was 54 months (the longest study reported to date). The main catheter-related complications were infection (1.15 events per 1000 catheter days) and thromboembolism (0.48 events per 1000 catheter days). There were 10 episodes of bacteremic infection (with a variety of species) and 11 of port or exit-site infections (mainly coagulase-negative staphylococci). Line thrombosis occurred in four instances, pulmonary embolism in two, superior vena cava thrombosis in one, and internal jugular thrombosis in one. Since deferoxamine is a risk factor for acquiring bacterial and fungal infections (SED-14, 717), it is noteworthy that the observed rate of infection was similar to that in other patient groups. During this study, audiometric abnormalities were not observed. Only one of the 17 patients, while the therapeutic index was briefly exceeded (mean daily dose of deferoxamine 80 mg/kg), had manifestations of deferoxamine toxicity, with visual field and acuity defects (retinopathy). In this patient full resolution occurred over 9 months after dosage reduction.

The local tolerability of subcutaneous bolus injections of deferoxamine has been studied in 27 patients; deferoxamine was given 12-hourly into the abdominal wall on 5 days per week (30 mg/kg/day) (155). The patients had iron overload due to multiple transfusions and were treated for a mean period of 20 months. All had mild transient painless swelling during injection, disappearing within 10–15 minutes. Two also had pain at the injection site, with redness in one case.

Drug–Drug Interactions

Artemisinin derivatives

Co-administration of artemisinin derivatives, such as artesunate, with deferoxamine can be useful in patients with cerebral malaria, because of the combination of rapid parasite clearance by the former and central nervous system protection by the latter. Artesunate has been studied alone and in combination with deferoxamine in a single-blind comparison (156). Adverse effects were generally mild and there were no differences between the two regimens.

Ascorbic acid

There is a complex interaction between ascorbic acid, iron, and deferoxamine (157). Ascorbic acid appears to be essential for the mobilization of stored iron into a labile pool, available for chelation therapy. As a result, the administration of deferoxamine to patients with ascorbic acid deficiency will have a limited effect. On the other hand, ascorbic acid increases the toxic effects of iron, especially on the heart. In order to prevent serious cardiac dysrhythmias, ascorbic acid should only be given after deferoxamine infusion has been started and adequate serum concentrations of deferoxamine have been reached (SEDA-8, 239) (158). Ascorbic acid reduces ferric to ferrous iron, and it is the reduced iron that is responsible for the generation of highly reactive free radicals, causing tissue injury (157). Ascorbic acid up to 2 g/day stimulates deferoxamine-mediated urinary iron excretion, probably without adverse cardiac results (159). However, a report of the precipitation of cardiomyopathy with a dose of 1 g/day of ascorbic acid in a patient with hemochromatosis not receiving deferoxamine provides reason for caution in this respect (160). Interestingly, this patient later had a rapid beneficial response to deferoxamine on the heart, even before significant iron chelation could have been established. Presumably deferoxamine detoxifies iron by the inhibition of Fe^{2+}-induced hydroxyl radical generation and lipid peroxidation.

Methotrexate

In 21 children the liberation of "catalytic iron" in acute myeloid leukemia appeared to aggravate the adverse effects of high-dose methotrexate chemotherapy (161). This finding suggests that the toxicity of chemotherapy might be reduced by the co-administration of iron chelators.

Prochlorperazine

The combination of prochlorperazine and deferoxamine can cause loss of consciousness (38).

Interference with Diagnostic Tests

Iron-binding capacity

In the presence of deferoxamine, misinterpretation of the measurement of the iron-binding capacity can occur (125).

Radioactive ^{67}gallium scanning

Experience in a patient with a cerebral hemorrhage showed that chelation of gallium by deferoxamine can interfere with the diagnostic value of a ^{67}Ga scan (162).

Defibrotide

General Information

Defibrotide is a polydeoxyribonucleotide extracted from mammalian organ. Its antithrombotic activity is partly ascribed to enhancement of eicosanoid metabolism, in particular increased release of prostacyclin, with ensuing vasodilatation and inhibition of platelet aggregation. An additional mechanism is activation of the fibrinolytic system, primarily increased activation of tissue plasminogen in the vessel wall.

The antithrombotic potential of defibrotide has been reported in patients with hepatic veno-occlusive disease after stem cell transplantation. In a randomized, placebo-controlled trial in 310 patients with claudication there was significant improvement in walking distance with defibrotide, but no difference in efficacy between the two doses of the drug tested (800 and 1200 mg/day) (1). Twenty patients stopped taking the drug because of cardiovascular events, the preset endpoints of the study. Seven others stopped because of adverse drug reactions, mainly gastrointestinal intolerance and skin reactions. They were equally distributed among the placebo and the two defibrotide groups.

Delavirdine

See also Non-nucleoside reverse transcriptase inhibitors (NNRTIs)

General Information

Delavirdine is a non-nucleoside reverse transcriptase inhibitor, which is dosed three times daily. No food restrictions apply. It is metabolized mainly by CYP3A, and so interactions with other drugs that use this metabolic pathway can occur.

Organs and Systems

Skin

The most frequent adverse effect of delavirdine is a rash, which usually occurs during the first 3 months of therapy in up to 50% of individuals. It is usually mild and resolves spontaneously in most patients or can be treated successfully with a short course of antihistamines. Interruption of treatment is required in less than 4% of patients (1,2).

Immunologic

Severe hypersensitivity reactions, including anaphylaxis, can occur and may necessitate drug withdrawal (3).

Drug–Drug Interactions

Antacids

Antacids interfere with the absorption of delavirdine and should therefore not be given concomitantly (4).

© 2006 Elsevier B.V. All rights reserved.

Administration of antacids and buffered formulations of didanosine should be separated from that of delavirdine by at least 1 hour.

Didanosine

Didanosine interferes with the absorption of delavirdine and should therefore not be given concomitantly (5).

Enzyme inducers

Concomitant use of inducers of cytochrome P450, such as rifampicin, rifabutin, phenytoin, phenobarbital, or carbamazepine, should be avoided, since they significantly reduce delavirdine plasma concentrations (4).

HIV protease inhibitors

By inhibiting their metabolism, ritonavir potentiates the actions of other protease inhibitors. The addition of delavirdine instead of another NNRTI in three patients taking protease inhibitors plus ritonavir further increased the exposure to the protease inhibitors (6). Combining delavirdine with indinavir removes the food restrictions during indinavir administration (4). The superior virological response observed in antiretroviral regimens containing delavirdine and protease inhibitors has been attributed in part to the pharmacokinetic interaction.

Statins

- Rhabdomyolysis with acute renal insufficiency has been reported in a 63-year-old man who was taking atorvastatin 20 mg/day and delavirdine 400 mg 8-hourly (7).

The authors suggested that delavirdine had inhibited the metabolism of atorvastatin by inhibiting CYP3A4.

Desflurane

See also General anesthetics

General Information

Desflurane is identical in structure to isoflurane, except that it is halogenated completely with fluorine instead of fluorine and chlorine. Desflurane is a volatile anesthetic that combines low blood gas solubility with moderate potency and high volatility. Its pharmacology has been reviewed (1,2).

Compared with volatile anesthetics in current use, desflurane has the advantages of being practically inert and of having a low blood-gas partition coefficient (0.4), making its onset and offset of action rapid. Its disadvantages include its low boiling point (close to room temperature) and the fact that it requires a specially heated vaporizer for delivery. It is also irritating to airways, precluding its use for induction of anesthesia and making the safety of mask anesthesia questionable. It also has excitatory effects on the sympathetic nervous system, causing tachycardia and mydriasis, which can make it difficult to judge the adequacy of anesthetic depth.

When desflurane is used with the proper equipment, alveolar concentrations can be adjusted more rapidly and precisely during administration, and recovery is quicker in both the short and long term than with other agents (3).

In a prospective, randomized study of 120 patients undergoing day-surgery, desflurane and sevoflurane were associated with shorter times to awakening, extubation, and orientation than propofol by infusion (4). Average times to awakening at the end of anesthesia were 5, 5, and 8 minutes respectively.

Organs and Systems

Cardiovascular

Desflurane increases the heart rate and reduces both mean arterial pressure and systemic vascular resistance while maintaining cardiac output (5,6). In high concentrations it can cause transient activation of the sympathetic nervous system, predisposing to hypertension and dysrhythmias (7).

Despite some coronary vasodilatation in dogs, there is no evidence of coronary steal in man. Desflurane may benefit elderly patients by allowing more rapid recovery from anesthesia (8).

© 2006 Elsevier B.V. All rights reserved.

Respiratory

Desflurane is a mild respiratory irritant (6). Moderate to severe laryngospasm and moderate to severe coughing occurred often (50% of cases) during induction of anesthesia with desflurane in 206 children aged 1 month to 12 years; the authors concluded that the high incidence of these airway complications during induction limit the use of desflurane in children, but that anesthesia could be safely maintained with desflurane after induction with another anesthetic (9).

Nervous system

Increasing doses of desflurane caused no demonstrable fall in cerebral blood flow. Consequently, it can be advocated for patients undergoing neurosurgical procedures (10).

Neuromuscular function

Depression of neuromuscular function occurred 10 minutes after the introduction of desflurane 1.3% in a 32-year-old man who had previously received midazolam, fentanyl, and thiopental for induction. On withdrawal his neuromuscular function returned to baseline (11).

Liver

Poorly metabolized gases are generally safer than those that undergo extensive metabolism. Desflurane is poorly metabolized, and appeared to have no toxic effects on the liver and kidneys in 13 young men (12).

However, a case of severe hepatotoxicity after desflurane anesthesia has been reported (13).

- An obese 37-year-old woman with a past history of allergy to penicillin, nickel, and cobalt, and unexplained mild hepatitis 6 weeks after halothane anesthesia 9 years before, was given an anesthetic including etomidate, alcuronium, metamizole, piritramizide, fentanyl, nitrous oxide, and desflurane. Ten days later she developed the symptoms and signs of hepatitis, an eosinophilia, and raised hepatic enzymes, including alanine transaminase 1776 IU/l, aspartate transaminase 1258 IU/l, gamma-glutamyl transpeptidase 48 IU/l, and bilirubin 503 μmol/l. After exclusion of common causes of hepatitis, a liver biopsy confirmed acute hepatitis. There were increased titers of antitrifluoroacetylated IgG antibodies, which peaked at 0.159 on day 25 postoperatively. She eventually recovered.

This patient had multiple risk factors for anesthesia-induced hepatitis, including obesity, middle age, female sex, a history of drug allergies, and multiple exposures to fluorinated anesthetic agents. Desflurane has a very low rate of hepatic oxidative metabolism (0.02 versus 20% for halothane), and is considered to be one of the safest volatile agents as far as hepatotoxicity is concerned. Nevertheless, this case shows that it can cause severe hepatotoxicity.

Urinary tract

The effects of sevoflurane, isoflurane, and desflurane on macroscopic renal structure have been studied in 24 patients undergoing nephrectomy (14). All the anesthetics were administered using a fresh gas flow of 1 l/minute and a sodium hydroxide absorber and had an average duration of 3 hours. No injury to nephrons was observed by pathologists blinded to which anesthetic agent had been used. Postoperative creatinine concentrations and urine volumes did not differ significantly between the groups.

Body temperature

- Malignant hyperthermia has been described in a 10-year-old boy who received thiopental and suxamethonium for induction of anesthesia, followed by desflurane for maintenance of anesthesia (15).

The role of suxamethonium must also be considered in this case.

Susceptibility Factors

Age

In old people, the MAC of desflurane, with or without nitrous oxide, was less than that in patients aged 18–65 years. Doses of desflurane must therefore be reduced in older people, as with all other inhalation agents (16).

Drug–Drug Interactions

Adrenaline

Adrenaline used during anesthesia can cause ventricular dysrhythmias. The threshold dose of adrenaline for dysrhythmias is reduced by halothane, but not by desflurane; the dose of adrenaline required to produce dysrhythmias in 50% of patients was three times that needed when anesthesia was with halothane (17).

Fentanyl

The MAC of desflurane was significantly reduced 25 minutes after a single dose of fentanyl (18).

Propofol

Desflurane-based anesthesia, with and without prophylactic ondansetron, to reduce the incidence of postoperative nausea and vomiting, has been compared with a propofol infusion in 90 women of ASA grades 1 and 2 undergoing outpatient gynecological laparoscopic surgery (19). The incidence of postoperative nausea and vomiting was 80% with desflurane alone, 40% with desflurane plus ondansetron, and 20% with propofol. Postoperative antiemetic requirements were larger and times-to-home readiness longer with desflurane alone, but sedation and analgesic requirements were similar. The high incidence of postoperative nausea and vomiting suggests that routine antiemetic prophylaxis should be considered in outpatients receiving desflurane-based anesthesia.

Rocuronium

Both desflurane and sevoflurane significantly increase the neuromuscular blocking effects of rocuronium compared with isoflurane or propofol (20,21).

Desloratadine

See also Antihistamines

General Information

Desloratadine is the primary metabolite of loratadine, with superior H_1 receptor binding, potent antihistaminic activity compared with the parent compound, and proven efficacy in allergic disease (1). It is effective and well tolerated in seasonal allergic rhinitis, including relief of nasal congestion (2–4).

In a randomized, open, four-way, crossover study in 20 healthy men desloratadine was given as single doses (5, 7.5, 10, and 20 mg) in four different treatment periods with 14 days between each dose. The C_{max} for all doses occurred at 4 hours after administration, with a half-life of 21–24 hours. There were no dose-related differences in drug absorption rate, and even the 20 mg dose was well tolerated (5). The systemic availability of desloratadine was unaffected by food in healthy adult volunteers (6).

Organs and Systems

Cardiovascular

In a large, multicenter, double-blind, placebo-controlled, parallel-group study of the efficacy and tolerability of desloratadine in 346 patients with seasonal allergic rhinitis, the symptoms improved significantly and there was no significant effect on the QT_c interval (7).

In a multicenter, randomized, double-blind, placebo-controlled study in 190 patients, desloratadine was effective in the treatment of moderate to severe chronic idiopathic urticaria, with no adverse electrocardiographic effects (8).

In healthy volunteers, 12 men and 12 women, there was no prolongation of the QT_c interval after co-administration of desloratadine with erythromycin (9).

Nervous system

Desloratadine appears to be minimally sedative, given that several studies, published in abstract, have shown no impairment in terms of wakefulness or psychomotor performance (10–12). Moreover, in a study in which desloratadine was effective and well tolerated in patients with seasonal allergic rhinitis there were no clinically significant sedative effects (7).

© 2006 Elsevier B.V. All rights reserved.

Psychological, psychiatric

The results of several studies suggest that desloratadine has minimal or no effects on cognitive functions and psychomotor performance (13–15).

Susceptibility Factors

Genetic factors

The effect of race on desloratadine pharmacokinetics at steady state has been examined (16). The authors concluded that no dosage adjustments for desloratadine were required.

Age

The effect of age on desloratadine pharmacokinetics at steady state has been examined (17). The authors concluded that no dosage adjustments for desloratadine were required.

Sex

The effect of sex on desloratadine pharmacokinetics at steady state has been examined (16). The authors concluded that no dosage adjustments for desloratadine were required.

Drug–Drug Interactions

Azithromycin

The effect of co-administration of azithromycin on plasma concentrations of desloratadine has been examined in a randomized third-party-blind, placebo-controlled, parallel-group study in 90 healthy volunteers (18). An initial loading dose of azithromycin (500 mg) was given on day 3, followed by 250 mg od for 4 days. Concomitant azithromycin had little effect (<15%) on either the C_{max} or AUC of desloratadine, and there were no statistically significant increases in the PR, QT, QT_c interval, QRS complex duration, or ventricular rate after administration of desloratadine with or without azithromycin.

Erythromycin

There was no clinically relevant interaction between desloratadine and erythromycin (9).

Fluoxetine

Co-administration of desloratadine with fluoxetine did not result in clinically relevant changes in the pharmacokinetics of either drug in 54 healthy volunteers (19).

Grapefruit juice

In an unblinded, randomized, single-dose, crossover study in 24 healthy adults, grapefruit juice had no effect on the systemic availability of oral desloratadine (20). There were no clinically significant electrocardiographic changes after co-administration of grapefruit juice with desloratadine compared with desloratadine alone.

Ketoconazole

The electrocardiographic safety of desloratadine in combination with the CYP3A4 inhibitor ketoconazole has been assessed in a randomized, two-way, crossover, third-party-blind, multiple-dose, placebo-controlled study over 10 days in 24 healthy volunteers (21). Compared with desloratadine alone there were no significant or clinically important changes in QT_c, QT, PR, or QRS intervals when desloratadine (7.5 mg/day, that is 50% higher than the recommended dose) was co-administered with ketoconazole (200 mg bd). There was a 1.3-fold increase in desloratadine C_{max} when it was co-administered with ketoconazole, but this was judged not to be clinically important. The authors concluded that co-administration of desloratadine with ketoconazole has no clinically relevant electrocardiographic or pharmacodynamic implications. There was no clinically relevant interaction between desloratadine and ketoconazole (21).

Desmopressin

See also Vasopressin and analogues

General Information

Desmopressin (*N*-deamino-8-D-arginine vasopressin, dDAVP) is a longer acting analogue of vasopressin. It has very little vasoactive effect but is antidiuretic by an action on vasopressin V_2 receptors in the renal tubule and is used to treat central diabetes insipidus and nocturnal enuresis.

At higher doses desmopressin also has significant hematological effects and can significantly boost concentrations of factor VIII and von Willebrand factor (VWF) in the blood. Desmopressin is therefore a valuable agent for the treatment of mild and moderate hemophilia A (congenital or acquired) and type 1 von Willebrand disease, in which the VWF protein structure is normal but the plasma concentration is reduced (1). By contrast with conventional coagulation factor concentrates, desmopressin is cheap and is free from the risk of transmission of viral infections, which have proved such a problem in the past. It is also very useful in the treatment of carriers of hemophilia A, many of whom have significant reductions in the baseline concentration of factor VIII. By contrast, desmopressin has no effect on the concentration of factor IX, and is thus of no value in hemophilia B (Christmas disease). It is also of little value in type 2 (abnormal VWF structure) von Willebrand's disease, which accounts for about 15–20% of all cases. The administration of desmopressin to patients with type 2B von Willebrand's disease can be hazardous, as it is likely to cause thrombocytopenia (2). The use of desmopressin in bleeding disorders has been reviewed (3). Tachyphylaxis develops if desmopressin is used for prolonged periods to control bleeding disorders, because desmopressin causes release of stored factor VIII and von Willebrand factor, after which it takes time for them to accumulate again.

Intravenous injection is the most common route although subcutaneous injection may also be used. A concentrated nasal spray formulation has been proved to be efficient for home treatment of patients with bleeding episodes or even minor surgical procedures and has also been used prophylacticly (4). The nasal spray used to treat diabetes insipidus (Desmospray) is too dilute for use in disorders of hemostasis. Similarly, desmopressin in tablet form (Desmotabs) is intended for treatment of nocturnal enuresis in children and is of no use in the treatment of hemostatic disorders.

Desmopressin also shortens the prolonged skin bleeding time in patients with renal insufficiency (5,6), hepatic cirrhosis (7,8), and congenital or acquired defects of platelet function (9–11), including aspirin-induced platelet dysfunction (12).

Desmopressin reduces blood loss in patients without bleeding disorders during surgical procedures, including cardiac surgery (13,14). However, similar benefits have also been observed with other agents, including aprotinin, tranexamic acid, and aminocaproic acid. Meta-analyses have confirmed the efficacy of these agents and have shown that aprotinin is the most effective of these agents in reducing blood loss, while desmopressin was the least effective (15,16).

Children with nocturnal enuresis treated with desmopressin have fewer wet nights per week, but this effect does not persist after therapy is stopped. A meta-analysis showed an overall rate of 7.1 adverse events per 100 children (17). These were almost all local nasal reactions, including nasal irritation and epistaxis.

In an open trial of high-dose desmopressin 1.5 mg intranasally to control bleeding in 278 patients with congenital bleeding disorders, headache occurred in 3.6% and flushing in 3.2% of patients (18). Dizziness and nausea were reported in 1–1.5% and edema in 0.3% of patients.

General adverse effects

The adverse effects of desmopressin include headache, tachycardia, facial flushing, abdominal pain, tremor, and

© 2006 Elsevier B.V. All rights reserved.

sweating during or shortly after intravenous administration (1). These symptoms are quite common but are usually simply the consequence of rapid intravenous infusion, and symptoms usually quickly subside after slowing, or even temporarily stopping, the infusion. The incidence of these relatively minor adverse effects increases with the dose of desmopressin.

Organs and Systems

Cardiovascular

Facial flushing occurred in two of 25 children with either hemophilia or von Willebrand disease given high-dose intranasal desmopressin (150 micrograms) in a single-dose open study (19).

Marked hypotension with circulatory collapse has occasionally been reported with desmopressin (20,21), although both of these reports related to patients with pre-existing cardiac conditions.

Thrombotic disorders

Desmopressin stimulates the release from endothelial cells of all the multimeric forms of von Willebrand factor found in normal plasma, including large forms that are not normally present (22). These abnormal multimers can aggregate platelets, particularly at the high levels of fluid shear stress that occur at sites of arterial stenosis.

Myocardial thrombosis

There have been several reports of arterial thrombosis associated with the use of desmopressin, including myocardial infarction (23–27). One of these reports concerned a case of fatal myocardial infarction in a blood donor in excellent health, with no risk factors and no signs of vascular disease (25).

- A 59-year-old woman with hemolytic–uremic syndrome and a recent history of atypical chest pain was given prophylactic desmopressin 0.4 micrograms/kg immediately before a renal biopsy (28). Within 30 minutes she developed chest pain and bradycardia due to myocardial infarction.

Three other cases of myocardial infarction in the absence of desmopressin have been reported in patients with hemolytic–uremic syndrome, who already have an increased risk of thrombosis.

A meta-analysis of placebo-controlled trials of desmopressin in 702 cardiac surgery patients showed a significantly increased risk of myocardial infarction in treated patients (RR = 2.39, CI = 1.02, 5.60) (29). Overall mortality was not different from placebo. Desmopressin was less efficacious in reducing perioperative blood loss than either aprotinin or lysine analogues.

Cerebral thrombosis

Cerebral infarction has also been reported in association with the use of desmopressin in children (30,31). One of these cases involved a 7-month-old child with congenital nephrotic syndrome who developed a cerebral infarction after surgery (30). One child developed cerebral ischemia after *Varicella* infection and desmopressin for enuresis (31).

Thromboembolism

There are isolated reports of thromboembolic complications in recipients of desmopressin; most occurred in patients with pre-existing vascular disease. However, in nine trials of the hemostatic efficacy of desmopressin in reducing blood and transfusion requirements in 763 patients, there were no significant differences between the frequencies of thromboembolism in subjects treated with desmopressin and controls (32). An analysis of 31 clinical trials of desmopressin in patients undergoing cardiac, vascular, orthopedic, or other major surgery showed that desmopressin did not increase the incidence of thrombosis (33).

Most of the reported thromboembolic complications occurred in elderly patients and desmopressin should not be used in patients with documented arterial disease or even in elderly patients, in whom some degree of latent arterial disease may be assumed to be present (33). Concomitant use of antifibrinolytic agents, such as tranexamic acid, should also be avoided.

Ear, nose, throat

Nasal irritation and rhinitis are common adverse effects of nasal desmopressin: treatment does not normally have to be altered as a result (34,35).

Fluid balance

A potential risk of desmopressin is of water intoxication with resultant hyponatremia (36), and rapid falls in serum sodium concentration can result in seizures. The risk is increased in infants and patients receiving hypotonic intravenous fluids, and such patients need to be carefully monitored.

- A 37-year-old woman with primary enuresis continued her customary daily fluid intake (2 liters) when she started intranasal desmopressin 30 micrograms at night. Within 2 days she became severely hyponatremic, with loss of consciousness, generalized seizures, and cerebral edema.
- An 80-year-old woman with a high baseline fluid intake developed severe hyponatremia, with loss of consciousness and seizures, after a single dose of desmopressin 0.2 mg (37).
- An 89-year-old woman, who had previously been stable on desmopressin, developed severe hyponatremia and became confused and unresponsive after an increase in fluid intake (37).
- A 47-year-old woman with von Willebrand disease, who was given desmopressin and intravenous fluids perioperatively, developed hyponatremia and seizures, which resolved after water restriction (38).

In a double-blind study of desmopressin, 10 of 224 adult men had serum sodium concentrations below 130 mmol/l during a 3-week, open, dose-titration period. Men aged

© 2006 Elsevier B.V. All rights reserved.

65 years and over were more likely to develop hyponatremia (39).

In another open study of elderly men and women, one of 30 subjects developed generalized weakness in association with a serum sodium concentration of 125 mmol/l and a serum potassium concentration of 3.1 mmol/l (40).

In a double-blind, crossover study, 20 men aged 52–80 years were given desmopressin for nocturia. Three of them had symptoms due to fluid retention, particularly bloating, headache, and reversible weight gain, and two of these had a significant fall in plasma sodium (41). In a meta-analysis of 14 studies of serum sodium in 529 patients treated with desmopressin there was mild asymptomatic hyponatremia in up to 10% of patients (42).

Fluid balance and plasma electrolytes should be monitored to prevent this complication, particularly if repeated doses are required. Children seem to be particularly vulnerable to this complication (43). In a long-term, open study of 245 Swedish children given intranasal desmopressin 20–40 micrograms at night for enuresis, five had an asymptomatic fall in plasma sodium (34). Mild hyponatremia, which did not cause symptoms, was found in five of 399 children in an open, multicenter trial (44).

Convulsions have been reported after desmopressin administration, some associated with excessive fluid intake.

- In a 12-year-old boy taking desmopressin for nocturnal enuresis, hyponatremia and cerebral edema developed after high fluid intake before a urodynamic procedure (45).
- A 13 kg 3-year-old boy given 40 micrograms of desmopressin intravenously and 1.6 liters of hypotonic fluid over 12 hours had convulsions and a respiratory arrest: his plasma sodium fell to 114 mmol/l (46).

There have been several reports of seizures in association with hyponatremia after intravenous administration of desmopressin to cover surgery in young children with congenital bleeding disorders such as mild hemophilia A or von Willebrand's disease (46–48). Hyponatremia and convulsions have occurred in children without congenital bleeding disorders who received desmopressin for urine concentration tests or to treat nocturnal enuresis (42,49,50).

Pulmonary edema associated with fluid retention occurred in a 27-year-old man after the administration of desmopressin to reduce blood loss during surgery (51).

Excess water intake during desmopressin therapy was implicated in seven cases of cerebral edema in children, which occurred over a 5-year period in the Czech Republic (52). A non-metered dropper was used for the desmopressin, so overdosage may have contributed.

Hematologic

Thrombocytopenia is rarely reported in patients who receive desmopressin, and is probably due to increased platelet aggregation (SEDA-13, 1310) (53).

- In a 50-year-old woman with uremia the platelet count fell from 149×10^9/l to 45×10^9/l after an abdominal hysterectomy with prophylactic desmopressin, and she developed a fatal subdural hemorrhage (53).
- A 38-year-old man with von Willebrand disease type 2B developed severe thrombocytopenia after a single dose of desmopressin (54).

Desmopressin also stimulates fibrinolysis (55), and this may have contributed to the outcome in the first patient.

In four patients with von Willebrand disease, desmopressin caused a significant but transient reduction in platelet count without an increase in plasma glycocalicin concentrations nor enhanced expression of P selectin, suggesting that acute thrombocytopenia after the administration of desmopressin in type 2B von Willebrand disease is not related to platelet activation and consumption (56).

In 224 adult men, mean age 65 (range 37–88) years, thrombocytopenia developed in one man during a 1-week washout period after dose titration to up to 0.4 mg of oral desmopressin daily over the preceding 3 weeks; thrombocytopenia did not recur on rechallenge (39).

Second-Generation Effects

Pregnancy

There is growing evidence that desmopressin can be used safely in pregnant women and no adverse effects have been reported in either mothers with diabetes insipidus or their babies (57), or in women with clotting factor deficiencies (58). However, the manufacturers advise that it should be used with caution in women with bleeding disorders, who require high doses.

One report described adverse reactions in two pregnant women with von Willebrand disease (59). One went into premature labor after a single dose (attributed to the oxytocic effect of desmopressin) and the other had severe hyponatremia associated with seizures after repeated administration of desmopressin to cover a cesarean section.

Lactation

Insignificant quantities of desmopressin pass into breast milk (60), and so breastfeeding is not contraindicated in association with desmopressin administration to a nursing mother.

Drug–Drug Interactions

Carbamazepine

Carbamazepine increases the release of endogenous antidiuretic hormone and can therefore potentiate the antidiuretic effect of desmopressin. Of 103 children with cranial diabetes insipidus included in a retrospective analysis, 10% became hyponatremic (61). The risk of hyponatremia was three-fold higher when desmopressin and carbamazepine were given in combination.

Chlorpromazine

Chlorpromazine increases the release of endogenous antidiuretic hormone and can therefore potentiate the antidiuretic effect of desmopressin (62).

© 2006 Elsevier B.V. All rights reserved.

Lamotrigine

In 103 children with cranial diabetes insipidus, 3 children who started or had an increase in dose of lamotrigine needed a larger dose of desmopressin, suggesting an effect on the renal tubule or on drug clearance (61). Lamotrigine also increased desmopressin dosage requirements in two other children with cranial diabetes insipidus (63).

Tricyclic antidepressants

Tricyclic antidepressants increase the release of endogenous antidiuretic hormone and can therefore potentiate the antidiuretic effect of desmopressin. A hyponatremic convulsion occurred in a child who was given desmopressin and imipramine (64).

Dexamfetamine

See also Amphetamines

General Information

Dexamfetamine or (+)-amfetamine is significantly more potent than (−)-amfetamine. The use of dexamfetamine as an appetite suppressant has rapidly declined, because of appreciation of its potential for abuse and addiction. These arise mainly from euphoria, which may be followed by depression as the effect of the drug wears off. Stimulant effects were reported in 23% of 347 patients using dexamfetamine as an appetite suppressant (SED-9, 10).

Dexamfetamine is extremely variable in its effects, and can even produce drowsiness in a small proportion of subjects. Postmenopausal women are more prone to drowsiness, anger, and sadness than euphoria (1). Adverse effects due to sympathetic overactivity are fairly common but not usually serious. However, in view of dexamfetamine's addiction potential, other anorectic drugs should be considered first.

When it was first introduced, one of the most frequent uses of amfetamine was as an anorexigenic agent in the treatment of obesity. A number of anorectic

© 2006 Elsevier B.V. All rights reserved.

agents, many of them related to amfetamine, have since been manufactured. Most are stimulants of the central nervous system. In descending order of approximate stimulatory potency, they are dexamfetamine, phentermine, chlorphentermine, mazindol, diethylpropion, and fenfluramine. The last of these has a stimulatory effect only in overdosage. One of the problems that has concerned clinicians over the use of anorectic drugs for the treatment of weight reduction is that despite 6 weeks to 3 months of weight reduction efficacy, the effect begins to wear off and on withdrawal weight gain rebounds.

The anorectic agents produce adverse effects mainly of the central nervous system sympathomimetic type. Therapy should therefore only be allowed under strict medical supervision, to ensure the earliest possible detection of any signs of drug abuse. Long-term drug treatment of obesity should be avoided altogether.

Organs and Systems

Metabolism

Hyperinsulinemia secondary to chronic administration of dexamfetamine, with a fall in fasting blood sugar after a few weeks of use, has been described (SED-9, 10).

Drug Administration

Drug formulations

Introduction of modified-release formulations has provided some improvement in the use of anorectic drugs. Steady release of the drug permits a constant concentration in the blood throughout the entire day. Thus, a sudden excess of physiological hunger is prevented, and adverse effects involving the central nervous system are diminished.

Dexchlorpheniramine

See also Antihistamines

General Information

Dexchlorpheniramine maleate (SED-13, 417) is the dextrorotatory isomer of chlorphenamine.

Organs and Systems

Sensory systems

In healthy volunteers dexchlorpheniramine caused impaired selective auditory attention in the absence of subjective awareness of this impairment (1).

Hematologic

Dexchlorpheniramine caused hemolytic anemia in a 47-year-old woman who took 4 mg/day for 3 days. The direct antiglobulin test was positive, and circulating antibodies were detected in the serum, which reacted in vitro with other antihistamines as well (2).

Dextrans

General Information

Dextrans are mixtures of polymerized glucose molecules, mostly alpha-1,6-glucans, of variable molecular weight from 1 to 110 kDa. Infused dextran is mainly eliminated unmodified by the kidney at a rate of 50% in the first 24 hours and 20% in the following 48 hours. The remaining 30%, which is made up of the molecules with the highest molecular weights, is partly eliminated by the gastrointestinal tract, where it is thought to be hydrolysed by coliform bacteria, and partly metabolized by splenic and hepatic dextranase (dextrano-alpha-1,6-glucosidase).

Uses

Dextran 70, so-called because its molecules have an average weight of 70 kDa, is used as a plasma substitute, as is dextran 40. Dextran 40 has been used to improve blood flow in ischemic limbs. Dextran 40 and dextran 70 have been used to prevent deep venous thrombosis. Dextran 1 is used as a desensitizer to prevent allergic reactions to dextrans of larger molecular weight. After reproductive surgery 32% dextran 70 is sometimes administered intraperitoneally in an attempt to reduce the formation of adhesions.

Dextran deposition in tissues

In biopsy and autopsy studies 32 patients treated with regular hemodialysis for an average of 61 months, who had also received dextran 40 as a plasma expander because of hypotension during hemodialysis, were compared with a control group of 11 hemodialysed patients who were given other plasma expanders. In 11 of the former who had received the largest dose of dextran 40 (0.38 g/kg/week), particles were found in the cytoplasm of macrophages in various organs, which were PAS-positive and diastase-resistant on light microscopy and birefringent on polarization. Electron microscopy showed a fibrillar structure, but ionic analysis by electronic sampler on scanning electron microscopy excluded silicone. No intracellular inclusions were observed in the control group, or in the patients given dextran 40 in doses lower than 0.08 g/kg/week. There was a linear relation between the number of particles and dose of dextran 40 that had been given, leading the authors to suggest that the material demonstrated in the macrophages was dextran that had been structurally modified and conglomerated by macrophage activity to a water-insoluble form (1).

Organs and Systems

Cardiovascular

High output left ventricular failure has been described after hysteroscopic lysis of adhesions using dextran as a distension medium. Prolonged surgical dissection of the uterine wall (the precise duration of the operation was not stated in the report) and the large volume of dextran and fluid (2 liters of 5% dextrose and an additional 800 ml of dextran) probably caused the dextran to enter into the systemic circulation, inducing a significant shift of fluid into the intravascular compartment (2).

Respiratory

Pulmonary edema and coagulopathy following intrauterine instillation of 700 ml of 32% dextran 70 has been reported (3). The volume exceeded that recommended by the manufacturer (500 ml), and the installation time (2 hours) was in excess of that recommended (45 minutes). The authors pointed out that hyperosmolarity of the agent is such that if it enters the intravascular compartment, volume overload can result, since 100 ml of intravascular dextran 70 will osmotically expand the intravascular volume by 860 ml, by drawing interstitial fluid into the central compartment. This can further aggravate the risks of pulmonary edema and dilutional coagulopathy.

Dextrans can also cause non-cardiogenic pulmonary edema and/or respiratory distress syndrome.

- Adult respiratory distress syndrome occurred after the intravenous infusion of dextran 40 in a 30-year-old woman, a smoker with a history of insulin-dependent diabetes mellitus, who had sustained an acute inferior myocardial infarction; the dextran was given in

© 2006 Elsevier B.V. All rights reserved.

preparation for possible stent placement after angioplasty of the right coronary artery (4).

- A 43-year-old woman underwent delayed breast reconstruction 9 months after modified radical mastectomy and received 4 liters of crystalloid intraoperatively (5). Postoperatively she was given an infusion of dextran 40 preceded by a small dose of dextran 1. On the next 2 days she was febrile, with no respiratory symptoms, although her oxygen saturation was 83%. On the third day, she was febrile and dyspneic, with a respiratory rate of 29 breaths per minute. Her oxygen saturation fell to 70%. A chest X-ray showed diffuse alveolar infiltration. Dextran was withdrawn. Her lungs worsened, and on day 6 she required intubation for worsening hypoxia, dyspnea, and tachypnea. A chest X-ray showed bilateral alveolar consolidation and other signs consistent with respiratory distress syndrome. Her oxygenation slowly improved and extubation was possible on day 11.
- Acute pulmonary edema developed in a healthy patient after elective microsurgery for treatment of a malignant tumor of the forearm (6). The patient was in good physical condition before the operation, and there was no sign of volume overload perioperatively. Cardiac enzymes, electrocardiogram, and echocardiogram were normal. No other medications were likely to have caused the pulmonary edema. The gradual response to diuretics suggested a non-cardiogenic cause.

Although thromboprophylaxis of microvascular anastomoses seems advisable theoretically, there is little clinical evidence to support the use of dextran for this purpose. The pulmonary edema in these cases was thought to be non-cardiogenic, similar to that caused by heroin, methadone, propoxyphene, and salicylates, due to a direct adverse effect on the pulmonary vasculature, rather than anaphylaxis, cardiac pump failure, or volume overload.

Severe pulmonary edema developed in a patient who underwent breast reconstruction in whom dextran was used to improve the deterioration of flap perfusion during the postoperative period (7).

- A 48-year-old white woman underwent right modified radical mastectomy for infiltrative ductal carcinoma. She was given dextran 40, 10 ml/kg, on the second postoperative day because of partial ischemic changes in the flap. She then had nausea, vomiting, and fever, and 10 hours later developed dyspnea and chest pain, which worsened on the following day. Chest radiography showed bilateral pleural effusions and bilateral reticulonodular opacities that were interpreted as pneumonic infiltration. She did not have hemoptysis or pleuritic chest pain, and there were no signs of heart failure. She had a leukocytosis (16.4×10^9/l). Cultures of sputum and fluid aspirate were negative. On postoperative day 4, her dyspnea worsened, her PO_2 fell, and her pH rose to 7.53. Lymphangitic carcinomatosis was considered, but this was not supported by cytology of the effusion fluid or tumor markers. Her history of allergic reactions suggested the possibility of dextran-induced severe pulmonary edema leading to respiratory distress syndrome. Dextran was withdrawn and she was given an intravenous bolus dose of prednisolone 250 mg. Her symptoms rapidly improved and she recovered gradually over the following week.

Although severe pulmonary edema with respiratory failure is not a typical allergic reaction to dextrans, this case illustrates that it cannot be discounted.

Acid–base balance

Arterial blood gases and acid–base balance were evaluated in 50 patients with dextran-induced anaphylactic reactions. Metabolic acidosis was consistently present in severe cases, leading to cardiac arrest. Acidosis was also found in patients with less severe reactions and only slight impairment of the circulation. Bronchospastic respiratory signs were common, but acidosis also developed in the absence of these symptoms and in patients with mild or no circulatory problems. The severity of the acidosis was often underestimated during treatment. Arterial PO_2 and PCO_2 were not significantly affected during these reactions. It was suggested from this study that the circulation is unlikely to be normalized until the metabolic acidosis is corrected, despite other therapeutic efforts that may be made (8).

Liver

In a retrospective study of the adverse effects of various drugs in 197 patients who underwent infertility surgery under general anesthesia and simultaneous intraperitoneal administration of 32% dextran 70, there were increases in postoperative transaminases in 86. The use of 32% dextran 70 in combination with glucocorticoids or halothane (or other halogenized drugs) resulted in an increased risk of temporarily disturbed liver function. Of 31 patients followed after discharge from hospital, the transaminases returned to normal within 6 months in 29. The authors suggested that hepatocytes may be damaged by enhanced glycogen deposition and/or lipid accumulation in patients who receive dextran. Glucocorticoids potentially increase the risk of liver function disturbance (9).

Urinary tract

Of 207 patients with ischemic stroke, stages III or IV, treated with an intravenous infusion of dextran 40 over 4 days, 9 (4.3%) developed acute renal insufficiency attributable to the dextran. Oliguria occurred after a mean time of 4 (range 3–6) days. The incidence of dextran-induced renal insufficiency was higher in patients with pre-existing impaired kidney function. The high risk of death in the patients who developed renal insufficiency was due to non-renal complications, notably pneumonia and pulmonary embolism (10).

Of 211 patients with acute ischemic stroke, stages III or IV, treated with daily intravenous dextran 40, 500–1000 ml for 4 days, 10 (4.7%) developed acute renal insufficiency associated with dextran infusion (11). Oliguria developed after a mean time of 4 (range 3–6) days. The incidence of dextran-induced acute renal insufficiency was significantly higher in patients with pre-existing reduction of glomerular filtration rate below 30 ml/minute/1.73 m^2. Five of the patients with acute renal insufficiency died within 4–12 days after hemodilution therapy with dextran 40; this high mortality was attributable to non-renal complications.

© 2006 Elsevier B.V. All rights reserved.

In a report of two cases of anuric acute renal insufficiency induced by dextran 40, diuresis and renal function were quickly restored to normal after plasmapheresis (12). Renal biopsy showed normal kidneys, except for swelling and vacuolation of renal tubules suggestive of osmotic nephrosis.

Cases of acute renal insufficiency, apparently representing a hypersensitivity reaction, have been reported from Australia (SED-11, 726) (13), and elsewhere (14,15). On the basis of these observations it has been suggested that the pathogenesis of renal dysfunction during treatment with dextran 40 involves mainly intraluminal hyperviscosity, reduced tubular flow, and pinocytic uptake of colloid into tubular cells (16). Direct injury to the renal tubular epithelium cannot be ruled out (17).

- During surgery for an avulsed pinna, an 18-year-old Chinese man was given 500 ml of 10% dextran 40 infused over 2 hours at 12-hourly intervals (18). On day 3 he developed nausea and abdominal pain. The dextran infusion was stopped. His serum creatinine was 1092 μmol/l. Total anuria followed within 24 hours and he developed acute pulmonary edema. Renal biopsy was compatible with osmotic nephrosis caused by dextran.

Dextran is widely used in plastic surgery, but acute renal insufficiency is rare; according to one source only 60 cases have been reported (19). These patients were usually either critically ill or had pre-existing renal impairment. The authors presumed that acute renal insufficiency had occurred as a result of increased plasma oncotic pressure, reducing the filtration pressure in the glomerulus; alternatively, some dextran 40 polymers may have been filtered into the tubules, causing obstruction. The amount of dextran required before acute renal insufficiency develops varies from 50 to 1000 g. One patient received 300 g over 3 days, although renal function deterioration was not recognized until uremia developed. The authors suggested that care be taken when using dextran 40, especially in patients with pre-existing renal impairment or vascular disease. Regular monitoring of urine output, electrolytes, and renal function in all dextran recipients is recommended. Administering replacement fluids before checking renal function could lead to life-threatening fluid overload. Withdrawal of dextran should be considered if there is persistent oliguria or a rise in creatinine or urea concentrations. Treatment of dextran-induced acute renal insufficiency should comprise temporary hemodialysis alternating with plasmapheresis, to remove dextran molecules from the blood.

- A 45-year-old man with insulin-dependent diabetes associated with nephropathy, neuropathy, and retinopathy was given dextran 40 (25 ml/hour) after orthopedic surgery (20). His urine output fell from 2 to 3 liters on postoperative day, 1–40 ml/day on day 2, and his creatinine clearance fell from 54 to 32 ml/minute. There were many casts in the urine. Dextran was withdrawn, but his creatinine clearance fell to 12 ml/minute on day 5. On day 6 a large hematoma in the rectus sheath was drained, followed by plasmapheresis (to remove dextran) and hemodialysis. Over the next 24 hours, his urine output increased to 2.2 l/day and his creatinine clearance increased to 20 ml/minute. Plasmapheresis was repeated. Nine days later, his renal function had improved.

This is another case of dextran-induced renal insufficiency in a patient with pre-existing renal insufficiency, in this case caused by insulin-dependent diabetes mellitus of more than 30 years duration. The authors recommended that dextran should not be used in patients with chronic renal insufficiency and a creatinine clearance below 40 ml/minute. If dextran-induced renal insufficiency develops, dextran should be withdrawn and if renal function does not recover, plasmapheresis should be used to remove the dextran load.

Acute renal insufficiency due to dextran has rarely been reported after microsurgery (21).

- An 81-year-old woman underwent commando resection and supraomohyoidal lymphadenectomy for recurrent squamous cell carcinoma of the right inferior alveolar process. Preoperatively, she was given intravenous gentamicin 120 mg and clindamycin to be continued twice-daily postoperatively. During surgery and the first 5 postoperative days, she was given dextran 40, 1 l/day, as an antithrombotic and rheological agent. On the second postoperative day she became increasingly dyspneic. Despite furosemide her urine production fell and she became anuric on day 4. Gentamicin was stopped on day 3. On day 5, she was reintubated and artificially ventilated; thrice-weekly plasmapheresis was started. Three days later spontaneous diuresis recurred and she was extubated on postoperative day 10. On day 25, she refused further plasmapheresis and diuresis returned to normal.
- A 69-year-old man underwent radical resection, supraomohyoidal lymphadenectomy, and radial forearm flap reconstruction for squamous cell carcinoma of the oropharynx. Preoperatively, he was given intravenous gentamicin 320 mg/day and clindamycin 600 mg bd, to be continued for 5 days. He was given dextran 50, 500 ml/day. Despite extra intravenous hydration combined with dopamine and furosemide, his urine output fell to 40 ml/hour on the first postoperative day and he became anuric on day 2. Gentamicin and dextran were withdrawn, he was artificially ventilated, and thrice-weekly plasmapheresis was started. Renal biopsy showed hydropic swelling and vacuolation of the tubular epithelium and narrowing of the tubular lumen. After 6 days, he was extubated and his renal function recovered only marginally. One month after surgery, he died of respiratory failure.

The authors suggested that acute renal insufficiency had been caused by dextran rather than gentamicin, because both patients developed anuria, which is commonly present in dextran-induced acute renal insufficiency, rather than the initial non-oliguric course characteristic of aminoglycosides. Further evidence for this conclusion was the renal biopsy in the second patient, while negative immunofluorescence and the rapid return of kidney function in the first patient suggested a non-structural effect of dextran on the kidney. The authors have stopped using dextran as an antithrombotic agent in microsurgery.

© 2006 Elsevier B.V. All rights reserved.

Immunologic

Anaphylactic reactions to dextrans have been reported, for example within 10 minutes after exposure to dextran in hysteroscopy (22). It can be fatal (23).

- A 54-year-old man developed generalized pruritus, dyspnea, and sudden hemodynamic shock, with cardiac and respiratory arrest 8 hours after the resection of a hepatic hydatid cyst, while being given dextran 40. He had no prior history of atopy or adverse drug reactions. Despite intensive resuscitation he remained unconscious and hemodynamically unstable. During the succeeding days he became septic with progressive renal function impairment and died on day 5. A range of serum tests for antibodies detected dextran-reactive antibodies. In addition, there was evidence of complement protein consumption within 6–24 hours of the clinical reaction.

The authors suggested that dextran-reactive antibodies had formed immune complexes with dextran, leading to complement activation and release of mediators of anaphylaxis. There was also evidence of mast cell degranulation. They therefore recommended that titration of dextran-reactive antibodies before administration of dextrans could provide a method of identifying those who are at risk of dextran-induced anaphylactic reactions.

- A 24-year-old healthy volunteer was given 10 ml of 6% dextran 60 during a preliminary examination (24). After about 5 minutes the first clinical symptoms of anaphylactic shock were evident, with a reduction in systolic blood pressure to 90 mmHg and an increased heart rate to over 90/minute. These returned to normal after therapy in the head-down position with clemastine 2 ml (2 mg), hydrocortisone 200 mg, and etherified starch 500 ml over about 8 minutes. During this period, responsiveness was unsatisfactory although he complained of warming of the skin, paresthesia, and nausea.

The authors suggested that this reaction had been due to a dextran-induced anaphylactic reaction, but were uncertain as to the cause of these observations, as they were not accompanied by immediate symptoms of shock. It is unclear if this case was caused by an antibody reaction.

Frequency and susceptibility factors

A large-scale prospective study was carried out in 49 public and private hospitals throughout France between June 1991 and October 1992, aimed at discovering the frequency and severity of anaphylactoid reactions to colloid plasma substitutes, looking for possible risk factors, and determining the mechanisms involved (25). In all, 19 593 patients were evaluated; 48% were given gelatins, 27% starches, 16% albumin, and 9% dextrans. There were 43 anaphylactoid reactions, an overall frequency of 0.22%, or one reaction per 456 patients. The frequency differed according to the plasma substitute used: 0.35% for gelatins, 0.27% for dextrans, 0.10% for albumin, and 0.06% for starches. The reactions were serious (grades III and IV) in 20% of cases.

Multivariate analysis showed four independent susceptibility factors: the administration of gelatins (OR = 4.81), the administration of dextrans (OR = 3.83), a history of drug allergy (OR = 3.16), and being male (OR = 1.98). The relative risks of anaphylactoid reactions due to one type of plasma substitute with respect to another were estimated to be six times less with starches than with gelatins and 4.7 times less than with dextrans. The relative risk of albumin was 3.4 times less than that of gelatins, and almost identical to that of the starches. An immunological assessment was carried out in 15 patients who had been given a gelatin (Plasmion); in seven cases an IgE-dependent reaction was proved. It was concluded that gelatins and dextrans should be avoided in patients with a known history of drug allergy; when a reaction does occur, an immunological assessment should be carried out, as the reaction may be due to specific antibodies, in which case that particular plasma substitute would be contraindicated for the rest of the patient's life.

Prevention

Severe anaphylactic reactions only occur in patients with preformed dextran-reactive antibodies. Infusion of dextran causes the formation of large immune complexes that trigger activation of a cascade of enzyme systems, leukocytes, and platelets. It is possible to prevent or minimize these effects by blocking the reactive sites on the antibodies with small dextran fragments; this is hapten inhibition. The method used is to inject very low-molecular weight dextran (dextran 1, molecular weight 1 kDa) intravenously before an infusion of dextran is started; this blocks access to the antigen-combining sites by preformed circulating dextran-reactive antibodies.

In Sweden, there was a reduction in the reports of severe reactions to dextran from 22 per 100 000 units of dextran administered between 1975 and 1979 to 1.2 per 100 000 units between 1983 and 1985 (26). The number of reported fatal reactions fell over the same period from 23 to 1. More than 600 000 units of dextran were used during each period. This represented a nearly 20-fold reduction in the reported incidence of severe dextran-induced adverse reactions in the country in the 3 years following the introduction of dextran 1 for the purpose of desensitization. During the same periods the incidence of grade I reactions (which are not considered to be antibody-mediated) did not change, suggesting that the reduced incidence of severe reactions after introduction of dextran-1 was not explained by a general reduction in the reporting of adverse reactions. It was emphasized that pre-injection of dextran 1 does not eliminate completely the risk of severe reactions to dextran.

The incidence of anaphylactoid reactions to dextran was studied in 5745 patients over 63 months from January 1981 to March 1986 (27). A total of 12 646 half-liter units of dextran 70 had been administered to these patients. The average number of dextran units transfused was 2.2 per patient. There were 15 reactions, a rate of one reaction per 383 patients treated (0.26%). Seven of these reactions were potentially life-threatening (grade III or IV), giving a combined incidence of severe reactions of one in 821 patients treated (0.12%). The remaining eight reactions were less severe (grade I or II), and the combined incidence of the milder reactions was 1:718 patients treated (0.14%).

Pre- and post-reaction titers of dextran-reactive antibodies have been analysed in most Scandinavian studies (28). The incidence of severe dextran-induced anaphylactic

© 2006 Elsevier B.V. All rights reserved.

reactions to clinical dextran after the prophylactic use of hapten inhibition was approximately 1/200 000 patients receiving dextran 1. In Sweden, where reporting of severe adverse drug reactions is mandatory, the incidence was about one in 70 000, indicating a 35-fold reduction. Only two fatal reactions were reported, an incidence of one per 2.5 million doses, indicating a 90-fold reduction. Both occurred in patients with extremely high titers of dextran-reactive antibodies. Adverse reactions to dextran 1, mostly mild, were reported in about one per 100 000 doses. These adverse effects were not antibody-mediated. The author concluded that dextran with hapten inhibition has arguably become the safest plasma substitute in current clinical practice. These conclusions were reached on the basis of a postmarketing surveillance study, and were confirmed in another publication from the same center (29).

It is possible for a severe dextran-induced anaphylactic/anaphylactoid reaction to develop despite prophylaxis with monovalent hapten dextran (30). This has been reported in a 60-year-old patient with multiple trauma, who received a dextran infusion for prophylaxis of thrombosis due to severe thrombocytosis in the late postoperative period. The causal relation to dextran was considered likely, although no serum sample was taken before the reaction, due to the close time relation to the infusion of dextran 60. In addition, there were high titers of dextran-reactive antibodies in the blood drawn immediately after the reaction occurred.

Second-Generation Effects

Pregnancy

Three cases of severe allergic reactions to dextran 70 (including one pregnant woman at the time of delivery) have been reported (31). All three had received previous hapten prophylaxis. Although the pregnant woman recovered, the baby had evidence of serious brain damage at birth. Another patient with a very high titer of dextran-reactive antibodies died from myocardial infarction, which happened at the same time. The third patient recovered without sequelae. The authors concluded that dextran 70 should be avoided in pregnancy until the baby is born, and that even in the presence of immune prophylaxis, these complications of dextran 70 can develop. Vigilant observation and resuscitation facilities are necessary in all cases.

An anaphylactoid reaction in a pregnant woman occurred immediately after the administration of dextran 40 solution (32). The baby was delivered rapidly by cesarean section after the event, and was apparently dead at birth but successfully resuscitated. The case has prompted Barbier and colleagues to report on the safety in general of dextran administered during pregnancy (32). They found information on 32 moderate anaphylactoid reactions associated with severe fetal distress and they advised avoiding preventive fluid preload with dextran in pregnancy.

Drug Administration

Drug administration route

After reproductive surgery 32% dextran 70 is sometimes administered intraperitoneally as adjuvant treatment for reducing adhesion formation. Dextran is thought to keep the raw peritoneal surfaces apart and prevent adhesion formation. However, the scientific evidence in support of the use of intraperitoneal dextran as an anti-adhesion adjuvant is scant. The complications of this procedure have been described in five patients (33). In one, a right pleural effusion was detected on the third postoperative day and resolved within 4 days. In the other four cases bilateral vulvar edema developed on the first or second postoperative day, and resolved in each case at 5–9 days after surgery. One patient had combined vulvar and leg edema, not previously reported. It is thought that this edema is due to extravasation of dextran along fascial planes, increasing the colloid-oncotic pressure in these spaces and promoting movement of a large amount of fluid from the vascular into the extravascular space. The right pleural effusion was thought to be due to movement of dextran through the diaphragmatic lymphatics or through small openings in the diaphragm, the majority of which are in the right hemidiaphragm.

In 139 consecutive patients who underwent major gynecological surgery and in whom 32% dextran 70 had been used as an anti-adhesion adjuvant (the mean amount of dextran used was 183 ml), there was an acceptably low rate of complications (34). Adverse effects involved 11 patients and included postoperative ileus (2.9%), pleural effusion (2.2%), allergic reactions (1.4%), wound infection (1.4%), and labial swelling (0.7%). There was no evidence of an increased infection rate.

The complications of repeated postoperative intraperitoneal instillation of 6% dextran 60 (given for 5 days to 32 patients) have been monitored and compared with the outcome in 15 control patients. In the dextran-treated subjects abdominal pain and dyspnea occurred significantly and more frequently than in the controls. During intraperitoneal irrigation with dextran there was a significant increase in body weight and an increased central venous pressure. Bradycardia developed between the third and sixth postoperative days. Blood pressure remained unchanged. Of the patients given dextran, 75% developed pleural effusions containing dextran by the fifth postoperative day. It was concluded that the uncertain advantages of dextran in the prevention of adhesions do not offset undesired adverse effects (35).

The syndrome of acute hypotension, adult respiratory distress syndrome, non-cardiogenic pulmonary edema, anemia, coagulopathy, and anaphylactic reactions after the administration of dextran 70 is referred to as the "dextran syndrome" (36–39). Factors other than acute volume overload due to intravascular absorption of dextran are thought to account for the syndrome. A combination of diverse pathophysiological factors may be responsible, namely direct pulmonary toxicity, activation of the coagulation cascade, release of vasoactive mediators, hypotension, pulmonary edema, intravascular intravasation of fluids, dilution of blood, and impaired renal and hepatic clearance. Cases of pulmonary edema are described under the section Respiratory.

Pulmonary hemorrhage after dextran use has also been described in hysteroscopy (40).

Drug–Drug Interactions

Radiocontrast media

- Acute anuric renal insufficiency has been described after administration of dextran 40 and radiocontrast to a 59-year-old woman (41).

Radiocontrast-induced renal ischemia may have contributed to the pathogenesis of the dextran-induced renal insufficiency, as has been shown in animal studies. The mechanism of dextran-induced acute renal insufficiency may be multifactorial, with elements of hyperoncotic acute renal insufficiency, tubular obstruction, and direct tubular toxicity. Radiocontrast-induced acute renal insufficiency is unusual in patients with normal baseline creatinine concentrations. The ischemic effect of radiocontrast seemed to be important in this case. Renal function should be carefully monitored if the simultaneous administration of dextran and radiocontrast is necessary. If renal function deteriorates and oliguria or anuria occurs, plasmapheresis may be an appropriate and effective approach for clearing dextran.

Three cases of acute renal insufficiency occurred after low molecular weight dextran infusion; two of the patients had only received standard therapeutic doses (total 450 and 650 g) (42). In both of these cases a contrast medium was co-administered, and the authors suggested that this could have predisposed to acute renal insufficiency.

Dextromethorphan

General Information

Dextromethorphan is the dextrorotatory isomer of the synthetic opioid levorphanol and is thought to act as a central nervous system antitussive (1). It binds to CNS sigma opioid binding sites and increases 5-HT concentrations by inhibiting uptake and by enhancing the release of 5-HT. It is also an antagonist at NMDA receptors.

Dextromethorphan is metabolized by CYP2D6 to dextrorphan, which binds to phencyclidine receptors and is thought to account for the toxic effects of hallucinations, tachycardia, hypertension, ataxia, and nystagmus (2,3).

Drug studies

Pain relief

The role of dextromethorphan in acute and chronic pain control has been reviewed (4). There is a clear beneficial role of oral dextromethorphan (in doses of 30–90 mg) in acute pain management; it has no or few adverse effects and even reduces the need for analgesic adjuncts.

Three double-blind, crossover, randomized, placebo-controlled studies of the role of dextromethorphan in neurological pain conditions in 40 adults with diabetic neuropathy, postherpetic neuralgia, and non-specific neuropathic pain syndromes have been reviewed (5). Dextromethorphan dosages varied from 13.5 mg tds on alternate days to 120 mg qds. High-dose dextromethorphan significantly reduced pain in diabetic neuropathy with no effect in postherpetic neuralgia. Sedation (58%) and dizziness (25%) were the most commonly reported adverse effects.

In a randomized, placebo-controlled study in 60 patients given dextromethorphan 10, 20, or 40 mg intramuscularly before abdominal surgery, there was a dose-dependent effective postoperative analgesic effect, with lower total consumption of rescue morphine during the 3-day observation period (6). There were no opioid-related adverse effects in those who were given dextromethorphan 40 mg.

The effect of dextromethorphan premedication on postoperative analgesic requirements, pain scores, and adverse effects has been examined in two double-blind, randomized studies (7,8). In the first study, 60 adults scheduled for elective upper abdominal surgery were randomly allocated to three equal groups (7). One group received intramuscular dextromethorphan 120 mg 30 minutes before skin incision (preincisional group); the second group received placebo (intramuscular saline) 30 minutes before skin incision and intramuscular dextromethorphan 120 mg 30 minutes before the end of surgery (postincisional group); and the third group received placebo 30 minutes before skin incision and 30 minutes before the end of surgery (control group). Preincisional intramuscular dextromethorphan 120 mg provided pre-emptive analgesia, reduced the need for postoperative analgesic supplements, and had a minimal and non-significant adverse effects profile. In the second study, oral dextromethorphan 90 mg was compared with placebo given 90 minutes preoperatively to patients undergoing laparoscopic cholecystectomy or inguinal hernioplasty under general anesthesia (8). Pain intensity and sedation were significantly reduced in the experimental group, with sparing of postoperative analgesics for up to 24 hours. Dextromethorphan 90 mg also abolished postoperative thermal-induced hyperalgesia and hyperpathia. No adverse effects were recorded in either group.

A randomized, double-blind, placebo-controlled study of oral dextromethorphan and PCA morphine has been performed in 66 patients undergoing knee surgery (9). The study was in two parts. The first was a dose escalation study in 25 postoperative patients to determine the maximum tolerated oral dose of dextromethorphan. The second involved giving less than the maximum tolerated dose divided into three increments at 8-hour intervals. The maximum tolerated dose of dextromethorphan was 750 mg. One patient, who was given 800 mg of dextromethorphan, had adverse effects, including severe slurred speech and light-headedness followed by deep sedation. In the second part of the study 66 patients were intended to receive dextromethorphan 800 mg in three doses of 400, 200, and 200 mg. The treatment group was subsequently reduced to 22 patients, compared with 34 in the

© 2006 Elsevier B.V. All rights reserved.

placebo group, because of unexpected nausea and vomiting in five patients given dextromethorphan 400 mg. Dextromethorphan 200 mg 8-hourly caused a significant increase in nausea 2–24 hours after the first dose. One patient given dextromethorphan had mild hallucinations on one occasion only. There was an associated modest reduction in postoperative morphine consumption (29%), with no other benefits. The study failed to provide evidence that the maximum tolerated dose of dextromethorphan 200 mg 8-hourly is useful in the treatment of postoperative pain after knee surgery.

Neuropathic pain

In a double-blind, placebo-controlled, crossover pilot study in three patients with cancer-associated postamputation phantom limb pain, oral dextromethorphan 60–90 mg bd or placebo were given for 1 week each, followed by dextromethorphan or placebo again (10). Dextromethorphan satisfactorily improved phantom limb pain at a dosage of 60 mg bd in two patients and 90 mg bd in the third. Even though a relatively high total dose of dextromethorphan was used, there were no adverse effects.

There have been two randomized, placebo-controlled, double-blind trials in 19 patients with painful diabetic neuropathy and 17 with postherpetic neuralgia (11). In the first trial dextromethorphan was compared with memantine and/or lorazepam. Among the patients with diabetic neuropathy, dextromethorphan (median dose 400 mg/day) reduced pain intensity by a mean of 33% from baseline; memantine reduced pain by a mean of 17% and lorazepam by 16%, showing no significant difference to placebo. Among the patients with postherpetic neuralgia, dextromethorphan (median dose 400 mg/day) reduced pain intensity by a mean of 6.5%, which was not different from the effects of memantine and lorazepam. In the second trial the 10 patients with diabetic neuropathy who had responded to dextromethorphan shared a significant dose–response effect on pain intensity; the highest dose was significantly better than that of lorazepam. The median dose was 520 (range 240–920) mg/day. The adverse effects profiles were uneventful. These results confirm the long-term safety of high-dose dextromethorphan for selected patients with painful diabetic neuropathy (5).

Non-ketotic hyperglycinemia

A review of *N*-methyl-D-aspartic acid (NMDA) antagonist interventions in the treatment of non-ketotic hyperglycinemia included six cases in which dextromethorphan was used (3). Non-ketotic hyperglycinemia is an autosomal recessive disorder in which there is failure of the glycine cleavage enzyme system, leading to impaired oxidative decarboxylation of glycine and a toxic accumulation of this amino acid. Antagonism at NMDA receptors is hypothesized to offer partial relief to the effects of this inborn error of metabolism. Of the six cases, adverse effects were described in three. Patient 1 had profound sedation in response to a dose of 7.5 mg/kg of dextromethorphan administered as a single dose when the infant was 5 days old. The same daily dosage split into three doses relieved symptoms without sedation, but doses in excess of 7.5 mg/kg resulted in somnolence, agitation, and involuntary movements. Patient 4 developed apnea, hypotonia, nystagmus, and seizures at 38 days of age and was given dextromethorphan 1 mg/kg/day at the age of 10 months, resulting in anorexia. In patient 5 an increase in dextromethorphan dosage to 10 mg/kg/day was associated with lethargy, apnea, and a return of seizure activity. Further trials are required for clarification of the use of dextromethorphan in the treatment of non-ketotic hyperglycinemia.

Parkinson's disease

In a trial of dextromethorphan in Parkinson's disease only one-third of the initial sample entered the double-blind, placebo-controlled phase (12). One-third of the sample had a reduction in the benefits of levodopa when dextromethorphan 30 mg/day was given. A further one-third withdrew because of failure to gain clinical benefit from the highest tolerated dose of dextromethorphan. Adverse effects included drowsiness, increased dystonia, increased impotence, light-headedness, sweating, and nausea.

Huntington's disease

Of 11 patients with Huntington's disease adverse effects were reported in seven. These included eczematoid rash, clumsiness, dysarthria, drowsiness, and worsening rigidity (13).

Organs and Systems

Nervous system

Although generally safe, dextromethorphan can in some individuals cause nervous system adverse effects, including hyperexcitability, increased muscle tone, and ataxia. Respiratory depression can occur with excessive doses.

Dextromethorphan has been implicated in a case of movement disorder (14).

- An 8-year-old boy complained of abnormal facial movements and hallucinations. One day before these symptoms, he had been given his sister's Cordec DM droplets (carbinoxamine maleate 2 mg, pseudoephedrine hydrochloride 25 mg, and dextromethorphan 4 mg) for a cold. He had facial dyskinesia, dilated pupils, pyrexia, tachycardia, and reduced bowel sounds and responded to a benzodiazepine.

Psychological, psychiatric

Dextromethorphan-induced psychotic and/or manic-like symptoms have been reported.

- A 2-year-old child developed hyperirritability, incoherent babbling, and ataxia after being over-medicated with a pseudoephedrine/dextromethorphan over-the-counter combination cough formulation for upper respiratory symptoms (15). The symptoms abated after withdrawal of the product.

In another three cases (girls aged 10, 13, and 15 years) severe acute psychosis was associated with the use of an over-the-counter formulation containing ephedrine or pseudoephedrine and dextromethorphan combined with

© 2006 Elsevier B.V. All rights reserved.

other compounds (16). The psychopathology included agitation, depressed mood, flat affect, pressure of speech, visual and auditory hallucinations, and paranoia. All three improved dramatically, with residual symptoms of irritability, 2–4 days after withdrawal of the mixture and treatment with risperidone 0.5–2.0 mg/day.

- An 18-year-old student had dissociative phenomenon, nihilistic and paranoid delusions, vivid visual hallucinations, thought insertion, and broadcasting after having consumed 1–2 bottles of cough syrup (dextromethorphan 711 mg per bottle) every day for several days (17). The psychotic symptoms remitted completely without any treatment 4 days after withdrawal of dextromethorphan. He was hospitalized twice more over the next 2 months with similar symptoms; each time he had consumed large doses of dextromethorphan.

Cautious use of over-the-counter formulations is recommended in patients with a predisposition to affective illness (SEDA-21, 87).

Cognitive deterioration has been reported from prolonged use of dextromethorphan (18).

Endocrine

During a double-blind, placebo-controlled study of the effect of high doses of dextromethorphan in children with bacterial meningitis, two of four patients developed type 1 diabetes mellitus; they had received dextromethorphan and the other two placebo (19).

- A 10-year-old boy received dextromethorphan 36 mg/kg/day by nasogastric tube. He developed hyperglycemia with ketoacidosis after 5 days and required insulin. The dose of dextromethorphan was reduced over the next 4 days and withdrawn. Insulin was withdrawn 4 days later.
- A 14-year-old girl received dextromethorphan 26 mg/kg/day by nasogastric tube. She developed hyperglycemia after 2 days and needed insulin for 6 days. A later glucose tolerance test was normal.

Pancreatic beta cells in rats express NMDA receptors, stimulation of which leads to insulin secretion (20). The authors postulated that dextromethorphan inhibits insulin secretion by blocking NMDA receptors and thus impairs glucose tolerance. Both patients had reduced insulin concentrations, implying that peripheral insulin resistance was unlikely to have been the cause of diabetes.

Skin

On two occasions, a fixed drug eruption occurred on the arm of a 45-year-old woman after using dextromethorphan as an antitussive (SEDA-16, 79). Worsening of urticaria pigmentosa has been attributed to dextromethorphan (SEDA-21, 87).

Sexual function

Spontaneous ejaculation occurred in a 64-year-old man who took dextromethorphan for a common cold (21). His sexual activity normalized 7 days after stopping the dextromethorphan. He had had a similar episode 5 months before, when spontaneous ejaculation had started 3 days after he took dextromethorphan and abated 4 days after withdrawal of the drug.

Immunologic

Dextromethorphan-induced anaphylactic symptoms have been reported (22).

- A 40-year-old woman suffered repeated hives, lip swelling, and shortness of breath on taking cough suppressants containing dextromethorphan. None was sufficient to require emergency medical intervention. On challenge with dextromethorphan 1 mg, mild transient pruritus occurred. After dextromethorphan 30 mg, hives and nasal and conjunctival congestion occurred. Vital signs and peak flow remained stable. There was no bronchospasm or angioedema. No reaction occurred to hydrocodone or codeine.

The authors noted that many opioids are potent histamine releasers and most reactions to opioids are anaphylactoid rather than IgE-mediated. It was of particular interest that the patient was able to tolerate the opioids hydrocodone and codeine.

Second-Generation Effects

Teratogenicity

In 184 pregnancies exposed to dextromethorphan (128 exposures in the first trimester) there were 172 live births, 10 spontaneous abortions, one therapeutic abortion, and one stillbirth (23). There were three major malformations and seven minor malformations in the children of women who had used dextromethorphan in the first trimester. In the control group there were 174 live births, 8 spontaneous abortions, and 2 therapeutic abortions; there were 5 major and l8 minor malformations. This small study did not show that dextromethorphan used during pregnancy increases the rates of major malformations above the expected baseline rate of 1–3%.

Susceptibility Factors

Genetic factors

Individuals who are poor CYP2D6 metabolizers are at increased risk of serotonergic adverse effects, as well as the narcotic adverse effects of coma and respiratory depression (24).

Other features of the patient

Individuals who take long-acting dextromethorphan formulations are at increased risk of adverse effects.

Drug Administration

Drug formulations

Individuals who take long-acting dextromethorphan formulations are at increased risk of serotonergic adverse effects, as well as the narcotic adverse effects of coma and respiratory depression (24).

© 2006 Elsevier B.V. All rights reserved.

Drug overdose

Intentional dextromethorphan overdose has caused two deaths (SEDA-17, 210). Dextromethorphan toxicity occurred in a 3-year-old child who ingested up to 270 mg. The effects were reversed by naloxone (2).

Drug–Drug Interactions

Monoamine oxidase inhibitors

A possible interaction between dextromethorphan and the monoamine oxidase inhibitor isocarboxazid has been described, with myoclonic jerks, choreoathetoid movements, and marked urinary retention (25).

Individuals who take monoamine oxidase inhibitors are at increased risk of serotonergic adverse effects, as well as the narcotic adverse effects of coma and respiratory depression (25,26)

Four subjects had markedly reduced *O*-demethylation of dextromethorphan after they had taken moclobemide 300 mg bd for 9 days (27). *N*-demethylation was not affected. This result supports the hypothesis that moclobemide or a metabolite reduces the activity of the cytochrome enzyme CYP2D6. The clinical implications of this particular interaction remain to be clarified.

Morphine sulfate

Morphi Dex contains morphine sulfate and dextromethorphan in a 1:1 ratio. Double-blind, single-dose analgesic efficacy studies in over 800 patients with postsurgical pain have shown superior analgesic activity for the combination (60:60 mg) than separate doses of the individual components (28,29). In double-blind, multiple-dose studies in 321 patients with chronic pain the combination provided satisfactory pain control with a significantly lower mean daily dose of morphine sulfate. Other studies have shown similar responses (28) and an adverse events profile similar to that of a similar dose of morphine sulfate (30). The most common adverse events seen in a multiple-dose, non-placebo-controlled study in 1400 subjects were nausea, dizziness, vomiting, somnolence, confusion, and pruritus. There was a significant trend toward lower incidence of constipation with the combination than with morphine sulfate alone (31,32).

Quinidine (sulfate)

The effects of quinidine sulfate, 50 mg orally, an inhibitor of cytochrome CYP2D6, on the metabolism of dextromethorphan 50 mg have been studied in seven healthy volunteers in a randomized, double-blind, crossover, placebo-controlled study (24). Quinidine suppressed the conversion of dextromethorphan to dextrorphan in extensive metabolizers to the extent seen in poor metabolizers. The increased concentrations of dextromethorphan increased subjective and objective pain thresholds by 35 and 45% respectively. This result suggests that debrisoquine/sparteine-type polymorphisms account for important differences in the effect of dextromethorphan and the balance between the analgesic effect of dextromethorphan and the hallucinogenic effect of dextrorphan. Concomitant use of quinidine or other inhibitors of CYP2D6 could further affect this balance, increasing the risk of serotonergic- and narcotic-related adverse effects.

Serotonin reuptake inhibitors

Those who take serotonin reuptake inhibitors are at increased risk of adverse effects because of inhibition of CYP2D6 and pharmacodynamic potentiation; hallucinations and the serotonin syndrome have been reported (33,34).

Dextropropoxyphene

General Information

The most frequent adverse effects of dextropropoxyphene are dizziness, sedation, and nausea and vomiting. Other reported effects include constipation, abdominal pain, skin rashes, light-headedness, headache, weakness, euphoria, dysphoria, minor reversible visual disturbances, and liver dysfunction (1).

A systematic review of single-dose dextropropoxyphene for postoperative pain identified 130 published articles (2). Of these, 11 placebo-controlled studies met the inclusion criteria for the review, 6 of dextropropoxyphene (65 mg) and five of the same dose of dextropropoxyphene plus paracetamol (650 mg) (co-proxamol). Pooled data from the studies showed that the incidence of nausea, drowsiness, and headache with dextropropoxyphene alone was not significantly different from placebo. Previous reports have suggested that dextropropoxyphene is significantly associated with dizziness, sedation, and nausea and vomiting. However, co-proxamol caused significantly increased dizziness (relative risk 2.2, 95% CI = 1.1, 4.3) and drowsiness (2.1, 1.5, 2.9). The relative risk of headache was reduced to 0.5 (0.3, 0.9). Analgesic effect was greater with co-proxamol than with dextropropoxyphene alone.

Organs and Systems

Cardiovascular

Dextropropoxyphene-induced cardiogenic shock has been described (3).

- A 32-year-old man became deeply comatose, with intraventricular conduction disturbances, after taking dextropropoxyphene 4.6 g. Treatment-resistant seizures lasted for hours. He was treated with an intra-aortic balloon pump and a continuous infusion of milrinone for 7 days and recovered fully.

The mechanism of cardiotoxicity of dextropropoxyphene is unknown, but the membrane-stabilizing effect of its major metabolite, norpropoxyphene, seems to play a central part. The cardiac effects are not reversed by naloxone (4), but dopamine may be effective.

Respiratory

Hypersensitivity pneumonitis has been associated with co-proxamol (paracetamol plus dextropropoxyphene) (5).

- A 61-year-old man, who was taking prednisolone 20 mg and co-proxamol as required for cranial arteritis, presented with a 2-month history of increasing breathlessness. His chest X-ray showed vague shadowing in both lower zones, consistent with an interstitial abnormality, and a lung biopsy confirmed focal interstitial hypersensitivity pneumonitis. After a diffuse rash appeared, the co-proxamol was withdrawn and then reintroduced. The rash recurred and the breathlessness deteriorated. A subsequent challenge with paracetamol did not produce the same symptoms. The dosage of prednisolone was not altered.

Sensory systems

Nerve deafness in a 44-year-old woman, dependent on co-proxamol (dextropropoxyphene plus paracetamol), has been reported (SEDA-17, 80).

Metabolism

Severe hypoglycemia has been reported in the elderly (SEDA-17, 80).

© 2006 Elsevier B.V. All rights reserved.

Hematologic

Hemolytic anemia has been attributed to dextropropoxyphene (6).

Gastrointestinal

Four cases each of necrotizing anorectitis and proctitis have been reported after long-term (2–24 months) use of suppositories containing dextropropoxyphene and paracetamol (SEDA-10, 62). Perineal ulceration can also occur (7).

Liver

Various forms of hepatotoxicity, sometimes involving jaundice or mimicking biliary tract disease, have been reported by the UK Committee on Safety of Medicines (8). In most, but not all, cases the drug had been taken with paracetamol. In some cases, rechallenge caused hepatotoxicity within a few hours, and an immunologically based mechanism has been suggested.

Dextropropoxyphene has been implicated in hepatic injury in four patients taking co-proxamol (dextropropoxyphene plus paracetamol) (9). The cases were recorded at the Regional Centre of Pharmacovigilance in St Etienne, France between 1985 and 2000 and were similar to 29 cases published in the international literature between 1971 and 1994. The risk factors identified in the confirmed cases included age over 50 years, female sex, and a history of excessive alcohol consumption or previous pathology that might have caused liver damage. Drug withdrawal produced good outcomes.

Skin

Acute generalized pustulosis attributed to dextropropoxyphene has been reported (10).

- A 43-year-old woman, who had taken antibiotics and analgesics, including dextropropoxyphene, for parotitis, developed generalized erythema with numerous pustules on the trunk followed by a pyrexia. Patch testing was positive with dextropropoxyphene only and negative with paracetamol, spiramycin, aspirin, and tenoxicam.

Musculoskeletal

Fibrous myopathy has been reported after long-term dextropropoxyphene injections (SEDA-18, 85).

Long-Term Effects

Drug dependence

In common with other opioids, dextropropoxyphene can produce dependence (11). However, it has also been used to withdraw patients from morphine (12).

Susceptibility Factors

Age

Acute respiratory failure predominated in patients under 30 years of age whilst cardiotoxic effects predominated in the elderly.

Renal disease

Severe hypoglycemia has been reported in a patient with chronic renal insufficiency (13).

Drug Administration

Drug overdose

Dextropropoxyphene is widely prescribed in combination with aspirin or paracetamol. It is particularly dangerous when taken in overdose (14). A mortality rate of 8% was described in a series of 222 self-harm patients (15).

Drug–Drug Interactions

Alcohol

Cardiorespiratory arrest can occur only 15 minutes after drug ingestion (16). This risk is enhanced if ethanol is taken concomitantly.

Alprazolam

Inhibition of alprazolam metabolism by dextropropoxyphene has been reported (17).

Carbamazepine

Dextropropoxyphene inhibits the oxidative metabolism of carbamazepine, leading to clinically significant rises in carbamazepine concentrations (18).

Severe carbamazepine toxicity can occur if dextropropoxyphene is taken concurrently (19).

Nortriptyline

Inhibition of nortriptyline metabolism by dextropropoxyphene has been reported (20).

Warfarin

Prolongation of the prothrombin time was observed in a patient concurrently taking warfarin and a compound analgesic containing dextropropoxyphene (21).

Smoking

Heavy smoking can increase the elimination of dextropropoxyphene (22).

Dezocine

General Information

Dezocine is structurally related to pentazocine (1). It reacts primarily with OP_3 (μ) receptors, but also has some affinity for OP_1 (δ) and OP_2 (κ) receptors. It is slightly more potent than morphine, but with similar adverse effects at effective doses (2.5–10 mg). The most common adverse effects (3–9%) are nausea and vomiting, sedation, or local injection site reactions; dizziness/vertigo have also been reported (1–3%) (SEDA-16, 88). However, in some trials nausea and/or vomiting were reported in 5–22%, while headache was the most common CNS complaint (16–35%). Other adverse effects reported in 1% of patients involve the cardiovascular system, respiratory system, urogenital system, CNS, gastrointestinal system, and visual senses.

Diacerein

General Information

Diacerein (diacetylrhein), an anthraquinone derivative, is said to be effective in the treatment of osteoarthritis. Its active metabolite is rhein, about which there are very few clinical data. Diacerein does not affect arachidonic acid metabolism and might be better tolerated than other NSAIDs with regards to renal and gastric toxicity. Epigastric or abdominal pain and diarrhea are the most frequent adverse effects. Diarrhea occurred in 37% of patients with osteoarthritis taking diacerein (1). Acute hepatitis has been described (SEDA-22, 119), as have skin reactions.

Dialysis fluids

General Information

Dialysis fluids are solutions of electrolytes formulated in concentrations similar to those of extracellular fluid or plasma. They contain, or may contain:

- sodium
- chloride
- bicarbonate or lactate
- calcium
- magnesium
- potassium
- glucose
- amino acids
- icodextrin

© 2006 Elsevier B.V. All rights reserved.

Dialysis fluids are provided in a sterile concentrated form for dilution with water before use; the water used need not be sterile.

Icodextrin

Icodextrin (rINN) is a maltodextrin glucose polymer with a mean molecular weight of 20 kDa, which is broken down to maltose. It is used as an alternative to glucose as the active osmotic agent for peritoneal dialysis. Icodextrin is similar in structure to dextran, but has improved ultrafiltration properties, because it is less well absorbed than glucose.

Organs and Systems

Skin

The manufacturers have reported from pharmacovigilance data that the incidence rate of all skin reactions with icodextrin is of the order of 2.5%; in most cases the symptoms are mild, often not requiring withdrawal (1).

The adverse effects associated with icodextrin in patients with renal insufficiency over 12 months have been reviewed (2). There were three cases of exfoliative skin reactions in 102 patients. Each was acute and started within 3 days of icodextrin exposure. All resolved promptly on withdrawal. There were two acute blistering reactions on sun-exposed areas, occurring within 3–6 months after icodextrin. Both responded slowly to withdrawal, taking 6–8 weeks to resolve completely. Nine further patients reported some form of minor skin problem (itching, dryness, rash, and blistering).

- A 48-year-old woman with a long history of insulin-dependent diabetes mellitus developed a severe cutaneous reaction to icodextrin (3). This happened 10 days after changing over to 7.5% icodextrin in order to improve ultrafiltration. The rash was maculopapular and it affected most parts of her body. It was associated with severe pruritus. By the 13th day after it first appeared the rash had become exfoliative and erythrodermic. There was rapid improvement in the first few days after the icodextrin dialysate had been withdrawn and she reverted to conventional glucose peritoneal dialysate.

Allergy to icodextrin was the most likely explanation for the severe cutaneous reaction. The epitope(s) for allergic reactions to dextrans have not been defined, although they are undoubtedly immunogenic. It is possible that the same or a similar epitope may be responsible for allergic reactions to icodextrin.

- A 50-year-old woman with insulin-dependent diabetes developed end-stage renal insufficiency secondary to diabetic nephropathy, and was treated with standard CAPD containing glucose (4). About 20 months later she was given 2 liters of icodextrin 7.5% postoperatively and 11 days later complained of pruritus on the lateral aspects of the thigh with erythroderma, which quickly spread to the back, abdomen, arms, hands, and head, followed by a widespread pruritic erythematous maculopapular rash, which became exfoliated and psoriasiform. Icodextrin was withdrawn 5 days later and there was rapid healing of the dermatitis, almost completely within 7 days. Rechallenge resulted in recurrence within 2 days.

The authors pointed out that in previous cases scaly and exfoliative rashes occurred several days after starting icodextrin but regressed without the need to withdraw icodextrin, except in one case. They concluded that, given the therapeutic advances made possible by icodextrin, and the extreme rarity of such adverse events, there should be no hesitation in using it in CAPD. The possibility of cutaneous adverse events 10–12 days after starting peritoneal exchange should be borne in mind, although the normal transient nature of such reactions rarely requires withdrawal.

Serosae

Giant and atypical mesothelial cells can develop in the peritoneum in response to irritation caused by peritoneal dialysis solutions. Mesothelial hyperplasia without an increase in mesothelial cell size, cytological atypia in mesothelial cells, polynucleate cells with nucleoles, and enlarged mesothelial cells with a flat small nucleus and without evident nucleoles have all been described (5). These giant cells are not found unless there is peritonitis. During peritonitis mesothelial cells detach en masse from the basal lamina.

Continual exposure of the peritoneum over a period of years to conventional peritoneal dialysis fluids contributes to loss of membrane function in two ways: (i) by compromising peritoneal host defences mediated by resident and infiltrating leukocytes and the resident cells of the peritoneal membrane and (ii) by directly contributing to structural changes in the peritoneal membrane (6). Peritoneal dialysis fluids have significant modulatory and, in some cases, toxic effects on peripheral and peritoneal cell functions. The impact of long-term exposure of the peritoneum to peritoneal dialysis fluids and how its function as a dialysing organ is affected are less well understood. From a comprehensive review of the literature it has emerged that lactate-buffered peritoneal dialysis fluids inhibit many leukocyte and peritoneal cell functions, even when exposure times are short. This suggests the need for more biocompatible peritoneal dialysis fluids. Neutral pH bicarbonate- or bicarbonate/lactate-buffered fluids are superior in all test systems to lactate-buffered fluids, irrespective of the concentration of glucose present in the solution. The cell inhibitory and stimulatory effects of high glucose concentrations remain, and this issue will have to be addressed before the perfect biocompatible alternative is produced. It is not clear whether long-term use of bicarbonate-containing fluids will improve patient outcome by reducing infection rates and better preserving the integrity of the peritoneal membrane.

The adverse effects of peritoneal dialysis fluids on the peritoneum have been succinctly summarized by authors arguing the case for a new, less toxic, and less acidic fluid for peritoneal dialysis (7). A low pH, high osmolality and lactate concentration, and the presence of several toxic contaminants may all contribute to impaired cellular function in the peritoneal membrane. In conventional peritoneal dialysis pH is deliberately lowered to 5.0–5.6

© 2006 Elsevier B.V. All rights reserved.

in order to prevent caramelization of the glucose (that is the production of glucose degradation products) during heat sterilization and storage. Low pH, especially in combination with tissue fluid hyperosmolality and high lactate concentrations, will cause vasodilatation and recruitment of capillaries in microvascular beds. In the peritoneal membrane, acidic solutions cause an increased "effective" vascular surface area and more rapid loss of glucose gradient than a neutral solution. Thus, a neutral solution would theoretically behave more favorably with regard to transperitoneal ultrafiltration (glucose-induced osmosis) than a conventional acidic solution. This is because the glucose osmotic gradient will be better preserved over time with neutral solutions. Even neutralized peritoneal dialysis solutions seem to be cytotoxic in vitro. This cytotoxicity is related less to hyperosmolality and the presence of lactate in the fluid than the toxicity occurring at a low pH. Glucose degradation products formed during heat sterilization and storage include acetaldehyde, methylglyoxal, 2-furaldehyde, formaldehyde, 5-hydroxymethylfurfural, and formic acid. All may, in the long term, affect the peritoneum adversely and lead to a deterioration of peritoneal membrane function. The risk of losing ultrafiltration capacity after 6 years of continuous ambulatory peritoneal dialysis is as high as 31%. Glucose degradation products can also cause abdominal discomfort and pain, and can be responsible for acute losses in ultrafiltration capacity.

Infection risk

Infectious peritonitis contributes to death in 5% of patients receiving peritoneal dialysis (8). The common organisms that cause peritonitis are *Staphylococcus epidermidis*, *Staphylococcus aureus*, streptococci, Gram-negative bacilli, and fungi. Predisposing factors are exit-site infections leading to tunnel infections, catheter infections, and nasal carriage of *S. aureus*, which is associated with exit-site and tunnel infections and peritonitis. Coagulase-negative staphylococci are often resistant to methicillin, and methicillin-resistant *S. aureus* was the cause of 13% of all peritonitis episodes and 30% of catheter infections in one study (8). Vancomycin is required for treatment (but not prophylaxis) of such cases.

Diamorphine

See also Opioid analgesics

General Information

Heroin is a potent opioid that offers no substantial advantages over morphine. In the UK it is the preferred parenteral opioid for subcutaneous administration to cachectic cancer patients, because of its high solubility.

In a randomized, double-blind study, 14 patients who underwent elective surgery for correction of bilateral arthritic deformities of the feet received 15 ml of 0.9% saline containing diamorphine 2.5 mg into the cannula in one foot and 15 ml of saline into the other foot (1). Intravenous regional diamorphine did not improve postoperative pain relief or secondary hyperalgesia. There were no significant adverse effects.

High-dose diamorphine has been compared with morphine in a double-blind, crossover, randomized study in 39 intravenous opioid users who were allocated to either morphine 3% solution or diamorphine 2% solution, gradually increasing up to an individual maintenance dose adjusted to meet the patient's subjective needs (2). Those who started with diamorphine and subsequently switched to morphine terminated prematurely owing to excessive histamine reactions, all of which occurred during crossover to morphine. Symptoms included severe pruritus, flushing, swelling, urticaria, severe headaches, nausea, general malaise, hypotension, and tachycardia. Only 44% of the original cohort finished the 6-week study (14 getting diamorphine at the end and three getting morphine). Average daily doses were 491 mg for diamorphine and 597 mg for morphine. These results suggest that diamorphine produces fewer adverse effects than morphine and may be preferable for high-dose maintenance prescription. However, the study was very small and the subject selection was biased, as were the variables used to determine a successful outcome. The result was contrary to all the well-established pharmacological facts, and the authors did not mention the risks associated with high doses of short-acting opioids.

In a randomized, double-blind study, 64 patients undergoing total knee arthroplasty received either intrathecal morphine 0.3 mg or intrathecal diamorphine, 0.3 mg in 0.3 ml, with 2–2.5 ml of 0.5% heavy spinal bupivacaine (3). The patients given morphine had significantly greater analgesia at 4, 8, and 12 hours postoperatively. The incidence of opioid-related adverse effects was not significantly different between the groups.

© 2006 Elsevier B.V. All rights reserved.

In a single-blind, randomized, controlled study, 70 patients scheduled for elective cesarean section under spinal anesthesia using hyperbaric bupivacaine 0.5% received intrathecal fentanyl 20 µg, intrathecal diamorphine 300 µg, or 0.9% saline (4). Significantly less intraoperative and postoperative "analgesic control" was required in the opioid groups, especially in those given diamorphine. Diamorphine produced longer-lasting analgesia than fentanyl (12 hours versus 1 hour). Nausea, vomiting, and pruritus occurred relatively infrequently, with no differences between the groups; sedation was more frequent with fentanyl.

Organs and Systems

Respiratory

"Chasing the dragon," or inhaling heroin vapor through a straw, is a technique by which heroin users avoid the risks of injection. In Amsterdam, 85% of heroin users smoke or chase the drug. Pulmonary function can be affected by heroin inhalation. It can depress the respiratory center, release histamine (which can trigger asthma), result in septic emboli, and increase susceptibility to infectious diseases, such as tuberculosis and pneumonia. In 100 methadone maintenance users, lung function and shortness of breath were evaluated using spirometry and clinical history (5). Impaired lung function and shortness of breath correlated with chronic heroin smoking.

Heroin-induced pulmonary edema, or "heroin lung" (SEDA-19, 29) (SEDA-25, 39), is a serious complication, which may be due to release of histamine, with increased pulmonary lymph flow and capillary permeability. There have been 27 reports of non-fatal heroin overdose associated with non-cardiogenic pulmonary edema (6). In a retrospective case-control study there were 23 heroin fatalities and 12 controls with sudden cardiac deaths (7). The authors tried to verify that defects of the alveolar capillary membranes and/or an acute anaphylactic reaction can lead to pulmonary congestion, edema, and hemorrhages. There were defects of the epithelial and endothelial basal laminae of the alveoli in both groups. There was an insignificant increase in IgE-positive cells in the heroin group. The findings suggested that heroin-associated lung edema is generally not caused by an anaphylactic reaction.

Bilateral pulmonary edema associated with heroin abuse has been reported several times (8). Bronchospasm has been noted following the use of street heroin, perhaps due to contaminants (9).

Nervous system

Delayed onset oculogyric crisis and generalized dystonia occurred in a 19-year-old man after intranasal heroin use, possibly due to bilateral hypoxic infarction of the pallidum and pallidothalamic tracts (10).

There has been one report of mixed transcortical aphasia attributed to heroin (11).

Myoclonic spasm has been reported about 24 hours after withdrawal of an epidural infusion of diamorphine (SEDA-16, 81).

Demyelination has been attributed to diamorphine (12).

- A 41-year-old chronic diamorphine user developed an unsteady gait and dysarthria over 2 weeks, followed by severe cerebellar ataxia and moderate dysmetria of the arms and legs. An MRI scan suggested myelin damage, with symmetrical involvement of the cerebellar hemispheres and decussation of the superior cerebellar peduncles, the corticospinal tracts, and the centrum semiovale, suggesting spongiform leukoencephalopathy. Two years later having taken no more diamorphine he was improved, with minor regression of the MRI lesions, especially the white matter lesions.

Myelopathy has been reported after intranasal insufflation of diamorphine (13).

- A 52-year-old man with a history of diamorphine abuse presented with sudden paraplegia a few hours after intranasal insufflation. He had flaccid paralysis of both legs, acute urinary retention, and reduced rectal tone. Deep tendon reflexes were absent and plantar responses were extensor. An MRI scan of the spine and an immunoglobulin profile supported the conclusion that this was a case of acute myelopathy with an immunopathological cause, involving a protein specific to spinal cord parenchyma, triggering acute local inflammation, ischemia, and tissue damage. Seven weeks later he recovered normal neurological function.

This case of heroin myelopathy is similar to other reported cases, except that this case occurred with intranasal rather than intravenous use. The MRI findings were consistent with a transverse myelitis. The authors suggested that hypersensitivity and an immune-mediated attack on the spinal cord was the likely mechanism of injury.

Reflex sympathetic dystrophy, in which there is an excessive or abnormal sympathetic nervous system response in a limb, has been associated with rhabdomyolysis secondary to heroin abuse (14).

- A 37-year-old male heroin smoker developed tea-colored urine and pain, swelling, and tenderness in both feet. He had acute renal insufficiency and rhabdomyolysis and was treated with hemodialysis. Urine toxicology was negative. He also had persistent, burning pain in both feet, with cool, pale, thin skin on both legs, a mild reduction in sensation on the lateral aspects of the lower legs and diminished bilateral knee and ankle reflexes. Walking was restricted, with limited range of movement owing to the severe pain. His feet would swell and redden after a 5-meter walk, suggesting loss of sympathetic regulation. Nerve conduction velocity studies of the tibial, peroneal, and sural nerves were abnormal. Radiographs showed mildly reduced bone mineralization in the legs. Three-phase bone scintigraphy showed diffusely increased radiotracer accumulation over both feet in all three phases, as found in reflex sympathetic dystrophy. The diagnosis was confirmed by local anesthetic sympathetic blockade. Nasal calcitonin spray led to pain relief 2 months later. A follow-up three-phase bone scintigram showed less radiotracer uptake, consistent with a good response to calcitonin therapy.

Progressive spongiform leukoencephalopathy

A rare consequence of inhaling heated heroin ("chasing the dragon") is a progressive spongiform

© 2006 Elsevier B.V. All rights reserved.

leukoencephalopathy. The first three cases in the USA were reported in 1996 (SEDA-22, 35). The presentation includes apathy, bradyphrenia, motor restlessness, and progressive cerebellar ataxia. Another report has provided more details from physical assessments and laboratory and radiological (MRI and MRS) data, and more information about the course of this heroin-related effect (15). The three cases showed raised concentrations of intracerebral lactate (reflecting mitochondrial dysfunction), which suggests a conversion of aerobic to anaerobic metabolism seen in hypoxic-ischemic conditions, including stroke. One patient recovered quite well after antioxidant therapy, supporting a metabolic effect of the heroin-related toxin; a similar response to co-enzyme Q has been found in other mitochondrial disorders with a high CSF lactate. Thus, the authors recommended that although the role of antioxidant therapy in this condition is unclear, it may be prudent to administer oral co-enzyme Q supplemented with vitamins C and E to patients with this syndrome.

Intravenous administration of pure heroin did not cause a leukoencephalopathy in a patient in whom inhalation had caused it (16), and toxicity in these cases may have been due to the heating of the heroin. This might have implications for young heroin users who, because of the known increased risk of HIV infection, prefer to "chase" (smoke) the drug, rather than to inject it intravenously.

- A 23-year-old pregnant woman at 39 weeks of gestation developed tonic-clonic seizures and hypothermia after taking excessive heroin intravenously (17). She developed Cheyne-Stokes respiration needing intubation and a cesarean section was performed, after which she developed inappropriate secretion of antidiuretic hormone and acute renal insufficiency. She made a complete recovery.

The etiology of this leukoencephalopathy is unclear. Because cases occur in clusters, even though many others who inhale heroin do not get this effect, there is suspicion about the possible role of contaminants of small batches of drug by an unknown substance. In addition, some have suggested that heating could be important, since leukoencephalopathy has not been reported with other means of heroin use (until this year, as reported in the next case). The authors of the report postulated that there might be a relation between the amount of heroin inhaled and the severity of the illness. Once symptoms develop, progression continues, usually for 2–3 weeks, but in some individuals it progresses for up to 6 months after exposure. "Coasting," or the phenomenon of symptom progression after cessation of exposure to toxins, has been observed with other toxins, and it is proposed to result from the storage of toxin in lipid-rich neural or non-neural body tissues, with subsequent release into the bloodstream. Although the "toxin" involved in this condition is unknown, progression could be due to "coasting." Alternatively, oxidative damage could be initiated by the toxin and produce persistent metabolic changes in the affected white matter. Whatever the mechanism, the illness is extremely grave, with no known treatment and with progression to akinetic mutism and death in about 20% of reported cases.

- A 37-year-old male cocaine abuser was admitted with intoxication, mutism, and substupor (18). His toxicological screening was positive for heroin and cocaine. There was spasticity of all limbs and Babinski reflexes. The CSF contained some erythrocytes. The electroencephalogram showed generalized slowing, and a CT scan showed bifrontal confluent hypodensities in the deep white matter. The cranial MRI scan showed diffuse bihemispheric white matter lesions dominantly in the frontal lobe on T2-weighted images. There were abnormal hyperintense lesions in the pyramidal tracts and the corpus callosum. He gradually improved and made a complete recovery within 6 months, as confirmed by neurological and neuropsychological examination.

The findings of toxic leukoencephalopathy in this patient's brain-imaging studies were similar to those reported in patients who have inhaled impure heroin. However, he had used intravenous heroin and cocaine. This is therefore the first case report of leukoencephalopathy after intravenous use of these drugs. However, it should be noted that the authors did not indicate how the route of drug use was confirmed. They noted that lipophilic substances, such as hexachlorophene or triethylthin, were likely impurities in the abused substances.

- A 53-year-old man with a 7-year history of heroin abuse presented with confused speech and unsteady gait (19). A CT scan showed low attenuation in the white matter tracts and an MRI scan showed increased signal intensity in the white matter tracts extending from the centrum semiovale, corpus callosum, corona radiata, posterior limbs of the internal capsules, cerebral and cerebellar peduncles, and pyramidal tracts, suggestive of spongiform demyelination. He became bed-bound and tetraplegic and died of a chest infection.
- A 37-year-old man, with a short history of heroin and cocaine use, presented with spasticity of all limbs, a confusional state, and mutism (18). The electroencephalogram, CT scan, and MRI scan showed predominantly positive frontal pathology, with other lesions in the pyramidal tracts and corpus callosum. The diagnosis was leukoencephalopathy. The symptoms gradually abated after 4 weeks, and repeat tests after 6 months shown to be normal.

Three cases of toxic and progressive spongiform leukoencephalopathy have also been reported as a result of vapor inhalation of heroin (15). There were generalized white matter abnormalities and pathology in the cerebellum, internal capsule, corpus callosum, and brain stem.

Heroin-induced leuckoencephalopathy has been misdiagnosed as psychiatric illness (20).

- A 47-year-old woman, with a history of amphetamine abuse, depression, and paranoia, smoked heroin for 4 weeks after stopping amphetamines, and 10 days later became drowsy and confused with increased paranoia and depression. She was disoriented and restless. Her speech was garbled. She had frequent non-purposeful movements and an unsteady gait. A CT brain scan was normal. She was given chlorpromazine, doxepin, and diazepam, but her ataxia and incontinence worsened, her speech and all her

© 2006 Elsevier B.V. All rights reserved.

movements slowed, with increased tone in all limbs and cogwheel rigidity. Her power and sensation were normal. Truncal ataxia impaired walking. An MRI brain scan showed diffuse high-intensity signals in both cerebral hemispheres, and review of the CT scan showed hypodensities in the same regions. She was treated with co-enzyme Q and regained mobility and continence, but with no improvement in cognitive impairment.

Sensory systems

Profound reversible deafness with vestibular dysfunction has been attributed to heroin abuse (21).

- A 47-year-old intravenous opiate user, after a period of abstinence, injected about 0.25 g of illicit diamorphine during a period of 24 hours and developed bilateral symmetrical sensorineural hearing loss, ear fullness, and loud tinnitus 20 minutes later. His symptoms gradually subsided with no sequelae after 3 weeks.

The authors pointed out that bilateral deafness after heroin relapse after prolonged abstinence had been reported in previous two cases, suggesting resensitization of a tolerized opioid system or prolonged hypersensitization of a system in withdrawal.

Endocrine

The syndrome of inappropriate secretion of antidiuretic hormone (SIADH) has been attributed to heroin (17).

- A 23-year-old pregnant woman developed antepartum bleeding at 35 weeks and a tonic-clonic convulsion and hypothermia at 39 weeks, having used heroin 4 hours before. She had further tonic-clonic seizures, became obtunded, and required intubation. She had occasional runs of ventricular bigeminy. A cesarean section was performed. The neonate had poor respiratory effort and required ventilation. Blood chemistry suggested inappropriate secretion of antidiuretic hormone, acute renal insufficiency, and acute pancreatitis. She and the baby recovered after 2 weeks.

Urinary tract

Following an observation that many patients develop acute renal insufficiency after using heroin, the authors identified 27 patients (mostly men, average age 29 years) who developed renal insufficiency after intravenous heroin use (22). Rhabdomyolysis was the likely cause of renal insufficiency in all cases. Twelve had a history of polydrug abuse and all had a history of intravenous diamorphine use in the 24 hours before presentation. Eight patients required renal dialysis for an average of 14 days. Patients who required dialysis had a higher admission creatine kinase, a higher peak creatine kinase, and a lower urine output in the initial 24 hours. They also had a longer hospital stay. Some had positive tests for hepatitis B (10%), hepatitis C (74%) and HIV (5%); viral infections can compound rhabdomyolysis and subsequent renal impairment through glomerulonephritis. No patient died and all patients recovered normal renal function. Rhabdomyolysis is a recognized cause of renal insufficiency, but its pathogenesis after heroin use is not fully understood.

In most of 19 renal specimens from autopsies of intravenous diamorphine users there was severe lymphomonocytic glomerulonephritis as a result of activation of the classical pathway of the complement binding system (23). This could have been a result of diamorphine itself, adulterants, or active hepatitis B and/or C infection.

Heroin was presumed to be the cause of reversible nephrotic syndrome in patients dependent on heroin (24).

Renal amyloidosis can be a late effect (24).

Skin

A traumatic skin lesion with blisters and sweat gland necrosis was described in a 24-year-old man who was comatose as a result of heroin overdose; immunofluorescence showed deposits of immunoglobulin and C3 in dermal vessels (25).

Musculoskeletal

Focal myopathy has been reported after intramuscular diamorphine (26).

- A 36-year-old man developed progressive, painless stiffness of both knee joints over 3 months. It had started 4 weeks after he began to give himself heroin injections two to three times a day in alternate thigh muscles. He had a broad-based stiff gait, and he walked without bending his knees. Because of contractures of the quadriceps muscles, which were indurated, active and passive knee flexion was limited to an angle of 5–10 degrees. Electromyography of the right quadriceps muscle showed firm fibrous resistance to needling without insertional activity. Ultrasound showed a preserved but enlarged muscle structure and thickening of the connective tissue. A muscle biopsy showed variation in fiber size with scattered collection of atrophic fibers and perivascular and endomysial infiltrates comprised chiefly of lymphocytes and macrophages. The serum creatine kinase activity was normal. After 7 weeks of physiotherapy, MRI of the thighs showed severe fibrosis of the muscle, suggesting a possible inflammatory component. Following treatment with prednisone and D-penicillamine, he was entirely normal, except for slightly limited knee flexion on both sides.

This patient's main symptom was progressive stiffness, due to contractures of the quadriceps muscles induced by chronic heroin injections. The findings made it very likely that heroin caused a primarily vascular lesion leading to non-specific inflammatory changes and subsequent fibrosis. Clinically, weakness was minimal and there was painless contracture. This presumably reflects the predominantly fibrotic process within muscle tissue. Combination therapy with prednisone and D-penicillamine led to significant improvement. The regenerating process was confirmed by the second muscle biopsy, and electromyography showed reinnervation. The second biopsy did not show inflammatory cells, indicating absence of the inflammatory component. Thus, this case suggests that heroin-induced fibrotic myopathy is reversible.

Long-Term Effects

Drug abuse

Smoking heroin by heating the free base over tin foil and inhaling the vapors is known as "chasing the dragon," a method that probably originated in Southeast Asia. Some are using this to reverse the stimulant effects of ecstasy. In 102 patients (55 men and 47 women, mean age 21 years) interviewed at four clinics in Dublin, Ireland, three subgroups of opiate users were identified: (a) those who had ever used opiates to come off ecstasy, who were compared with those who had never used opiates for this purpose, (b) those whose first use of opiates had been to come off ecstasy, and (c) those who had started opiates by "chasing" and then did or did not move to injecting (27). Of the 102 patients, 92 reported having taken ecstasy, 68 of whom reported having taken opiates to come off it, and the remaining 24 of whom had not. The 68 patients who reported taking opiates to come off ecstasy had significantly heavier ecstasy use, in terms of the number of nights per week and number of tablets taken per night. Of 36 who reported that their first ever experience of using opiates was in the context of "chasing" to come off ecstasy, 28 reported this as their main reason for starting to use opiates and the other eight reported that they would probably have tried opiates independent of their ecstasy use. Of the 86 patients whose initial route of using heroin was "chasing," 61 reported changing to injecting, 23 continued to smoke heroin, and two switched to an oral formulation of methadone or morphine. When those who came to inject heroin were compared with those who did not (61 versus 23), the injectors had begun illicit drug use earlier, had started heroin at a younger age, were younger at the time of interview, and had been more likely to have a history of ecstasy use. Despite the younger age of onset of illicit drug use in those who came to inject, they had not been using illicit drugs for longer at the time of interview. This study confirmed the authors' previous findings that heroin smoking was associated with ecstasy use.

The Swiss government has developed a program called PROVE, which provides prescriptions of injectable opioids for the treatment of heroin-dependent patients. This program has generally been viewed to be successful in terms of retention in treatment, morbidity and mortality, legal behavior, and cost-effectiveness. However, during the 26-month observation period, epileptic seizures occurred in 11% of the 186 patients treated. This finding, along with previous reports of reduced regional blood supply to the brains of opioid users, led the authors to study cerebral deoxygenation after intravenous opioid administration in ten opioid-dependent subjects and to compare it with intravenous saline in ten matched controls using Near Infrared Spectroscopy (NIRS) (28). Heroin and methadone produced a rapid and dramatic reduction in both respiratory rate and cortical hemoglobin oxygenation, while saline had no effects. The authors suggested that opioid-induced acute deoxygenation of cortical hemoglobin was probably associated with respiratory depression. In one in three subjects, oxygen saturation after intravenous heroin fell rapidly, a finding that has not previously been described in humans.

The authors suggested two possible mechanisms for this phenomenon. They discounted the possibility that opioids increase the utilization of oxygenated hemoglobin in the CNS, because PET data from other studies suggest decreased utilization of glucose (indicating reduced brain activity) following opioids. They believed that it was more likely that the increase in cortical-reduced hemoglobin was related to opioid-induced respiratory depression, with carbon dioxide retention and resulting vasodilatation. Although preliminary, these data have potential implications for treatment programs involving intravenous opioid maintenance. The authors suggested that intravenous opioids may produce both systemic and cerebral hypoxia, which may at least in part account for the hyperexcitability (as measured by electroencephalography) found after intravenous opioids in other studies. Furthermore, hypoxia may mediate or contribute to the rush sensation, similar to that seen with high altitude or in cases of asphyxiophilia.

Drug withdrawal

The relation between the severity of opiate withdrawal and the dose, duration, and route of administration of heroin has been assessed in a retrospective analysis of heroin withdrawal in 22 patients (29). Abrupt withdrawal from opiates resulted in increased symptom severity, peaking on day 2 and then abating after that until day 7. Both the dose and the route of administration were related to the withdrawal score: intravenous heroin was linked to greater total and maximum withdrawal severity than smoking heroin. The authors speculated that the effect of the route of administration may have been due to lower systemic availability of smoked compared with injected heroin. Their data suggested that even the duration of the withdrawal symptoms seemed to increase with higher doses and intravenous use. However, there were several limitations to this study. It was retrospective and the period of observation lasted only 7 days although the withdrawal symptoms lasted much longer. In addition, many subjects took doxepin and benzodiazepines during the observation phase, which may have reduced or suppressed their withdrawal symptoms.

Second-Generation Effects

Fetotoxicity

A report of death associated with intravenous heroin use has provided insights about the distribution of heroin and its metabolites in the fetus (30).

- A 17-year-old girl with a history of heavy drug abuse for 2 years was found dead in a public restroom, with fresh needle puncture marks. She was 18–20 weeks pregnant with a male fetus, and had massive brain and lung edema from acute intoxication. Analysis of her hair showed that she had used heroin over the previous few months. Drug screening of body fluids showed only opiates (high concentrations of 6-monoacetylmorphine and morphine) in the maternal and fetal circulation at the time of death. Unexpectedly high amounts of morphine, 6-monoacetyl-morphine, and

© 2006 Elsevier B.V. All rights reserved.

morphine-3-glucuronide were also found in the amniotic fluid. Only morphine-3-glucuronide was detected in the fetus, whereas both morphine-3-glucuronide and morphine-6-glucuronide were detected in the mother, in the body fluids, and in all investigated organ tissues except the brain.

The authors noted that heroin is considered a "prodrug," with 6-monoacetyl-morphine, morphine, and morphine-6-glucuronide accounting for most of its narcotic activity. In blood, diamorphine is rapidly converted to the active metabolite 6-monoacetyl-morphine, which is presumably converted to morphine in the liver. The majority of the morphine is converted to morphine-3-glucuronide and small amounts are converted to morphine-6-glucuronide, which is pharmacologically active. They concluded that morphine-3-glucuronide can cross the placenta and that high concentrations of heroin and its metabolites can be found in fetal compartments during heroin abuse by the mother. Lastly, heroin and its pharmacologically active metabolites appear to be present in the fetal central nervous system for much longer than in the maternal circulation, because of low fetal drug-metabolizing capacity as well as minimal drug elimination from the amniotic fluid in advancing pregnancy.

Drug Administration

Drug dosage regimens

High-dose intrathecal diamorphine for analgesia after elective cesarean section has been studied in 40 women who were randomized to diamorphine 0.5 or 1 mg (31). All also received diclofenac 100 mg at the end of the cesarean section and morphine via a patient-controlled analgesia system. Postoperative analgesia was more prolonged and reliable in those who were given diamorphine 1 mg, who needed significantly less morphine. There was postoperative nausea in just under half of the patients in each group, and most of the patients (93%) had mild to moderate pruritus. There were no cases of excessive sedation or oxygen desaturation.

Drug administration route

Nasal diamorphine is as effective as intramuscular morphine and is much better tolerated by children, with no apparent increased risk of adverse effects (32,33). In a multicenter, randomized, controlled study, 404 children aged 3–16 years with a fracture of an arm or leg were given either nasal diamorphine 0.1 mg/kg or intramuscular morphine 0.2 mg/kg. The onset of pain relief was faster with nasal diamorphine, and there were no serious adverse effects. The frequencies of opioid-related mild adverse effects were similar in the two groups.

In a randomized, placebo-controlled, double-blind study of the relative efficacies of patient-controlled analgesia (PCA) regimens (34), 60 patients undergoing elective total hip or knee replacement were randomly allocated to receive epidural diamorphine 2.5 mg followed by a PCA bolus 1 mg with a 20-minute lockout (group 1), subcutaneous diamorphine 2.5 mg followed by a PCA bolus 1 mg with a 10-minute lockout (group 2), or epidural diamorphine 2.5 mg in 4 ml of 0.125% bupivacaine followed by a PCA bolus of 1 mg diamorphine in 4 ml 0.125% bupivacaine with a 20-minute lockout (group 3). Diamorphine demands were significantly higher in group 2 in the first postoperative 24-hour period, but pain scores were only significantly higher in group 2 in the first 3 hours postoperatively compared with group 3 and group 1. There were also fewer opioid-related adverse effects in group 2, and group 3 reported higher incidences of various adverse effects. The conclusion was that PCA diamorphine given with or without bupivacaine provides analgesia of similar efficacy once adequate pain relief has been achieved. Taking the incidences of adverse effect profiles into account, diamorphine subcutaneous PCA was a simple and effective method of providing analgesia.

In 62 women who asked for regional analgesia in labor and who were randomized to an intrathecal injection of either bupivacaine 2.5 mg with fentanyl 25 μg or bupivacaine 2.5 mg with diamorphine 250 μg, the diamorphine provided longer analgesia (35). There were significant differences in adverse effects between the groups. There were no instances of nausea or vomiting, but pruritus was more common in those who received fentanyl. The dose of diamorphine was deliberately low, and more studies are needed to confirm these findings.

Drug overdose

The main life-threatening complications of heroin intoxication include acute pulmonary edema and delayed respiratory depression with coma after successful naloxone treatment. In a prospective study of the management of 160 heroin and heroin mixture intoxication cases treated in an emergency room in Switzerland between 1991 and 1992, there were no rehospitalizations after discharge from the emergency room and there was only one death outside the hospital due to pulmonary edema, which occurred at between 2.25 and 8.25 hours after intoxication (36). A literature review found only two reported cases of delayed pulmonary edema, which occurred 4 and 6 hours after hospitalization. The authors recommended surveillance of a heroin user for at least 8 hours after successful opiate antagonist treatment.

Among heroin users, the annual rate of mortality is 1–4%; overdose and HIV infection being the leading causes. The effect of the frequency and route of heroin administration on the occurrence of non-fatal heroin overdose has been studied (37). Among 2556 subjects with heroin dependence, 10% had taken overdoses requiring emergency care in the prior 12 months. The cumulative risk of overdose increased as the frequency of heroin use fell. Among daily heroin users, the risk was greater with increased frequency of heroin injection, but not among non-daily users. The risk of overdose was greater with injection than with other routes of administration.

Drug–Drug Interactions

Alcohol

Many heroin users use heroin and alcohol together. There has been an evaluation of the pharmacokinetic interaction between heroin and alcohol and the role of

© 2006 Elsevier B.V. All rights reserved.

that interaction in the cause of 39 heroin-related deaths that were attributed to either heroin or heroin + ethanol (38). The cases were arbitrarily divided into two groups according to blood ethanol concentration (low-ethanol group, under 1000 μg/ml, and high ethanol group, over 1000 μg/ml. The high-ethanol group was associated with reduced hydrolysis of 6-acetylmorphine to morphine, and there was an inverse correlation between blood ethanol concentration and hydrolysis of 6-acetylmorphine to morphine. The concentration of total morphine was lower in the high-ethanol group. High blood ethanol concentrations were also associated with an increased ratio of unbound to total morphine and with reduced excretion of unbound and total morphine. The relative concentrations of conjugated heroin metabolites were reduced in the presence of a high blood ethanol concentration. The authors hypothesized that alcohol inhibits the glucuronidation of morphine, resulting in less conjugated morphine in the blood. Thus, in patients with high blood ethanol concentrations the additional depressant effects of unconjugated heroin metabolites may contribute to a more acute death.

Anticholinergic drugs

Combining opiates with anticholinergic drugs is a common practice in recreational abuse (SEDA-21, 34). Heroin mixed with hyoscine (scopolamine) is nicknamed "polo" and "point on point." Mixed drug toxicity, with atypical signs and symptoms of opiate abuse, has been reported (39).

- A 41-year-old woman who had taken 11 alprazolam tablets and heroin mixed with an unknown substance developed slurred speech and a staggering gait. She was also taking paroxetine. Her pupils were dilated, her skin warm and dry. Electrocardiography showed a sinus bradycardia. She was given intravenous naloxone 2.0 mg and became acutely agitated and combative. She was delirious, agitated, and disoriented, and was given an intravenous sedative and intubated. Her urine contained codeine, morphine, and atropine.

This case exemplifies the difficulty in identifying anticholinergic drugs such as atropine, and unfortunately the finding of dilated pupils did not raise the suspicion of mixed drug toxicity. The use of naloxone uncovered florid agitation due to anticholinergic drug toxicity.

Interference with Diagnostic Tests

Blood glucose

Diamorphine flattens the glucose tolerance curve and increases glycosylation of HbA_1 (40).

Antithrombin III

Diamorphine depresses the biological activity of antithrombin III (41).

Diazepam

See also Benzodiazepines

General Information

Diazepam produces less sedation in cigarette smokers, and higher (not lower, as stated in SEDA-20) doses may be required for the same sedative or anxiolytic effect. Owing in part to its continued widespread use, several unusual adverse effects of diazepam continue to be reported. These include cases of urinary retention and compartment syndrome, which are not explicable by its pharmacology. On the other hand, accumulation of diazepam and attendant complications of obtundation and respiratory depression may be understood in terms of its long half-life, particularly in elderly people and medically ill patients. Caution about the intravenous use of diazepam comes from a study that showed cardiac dysrhythmias (mainly ventricular extra beats) in a quarter of oral surgery patients; midazolam and lorazepam were much safer (1).

Organs and Systems

Cardiovascular

Cases of inadvertent intra-arterial injection of diazepam have been reported.

- A 51-year-old woman with an acute claustrophobic anxiety attack developed gangrene of the fingers after she was inadvertently given diazepam 10 mg intra-arterially (2).
- Inadvertent intra-arterial injection of diazepam (2.5 mg in 0.5 ml) has been reported in an 8-year-old girl (3). Gangrene resulted and amputation of the 4th and 5th fingers was required.

Gangrene has been previously reported with intra-arterial injection of diazepam and is also well known with other classes of drugs, such as barbiturates and phenothiazines. It appears to be caused by the drug rather than the solvent used in the intravenous formulations.

Respiratory

Respiratory difficulties are a major potential adverse effect of rectal diazepam (4).

Of 94 children who presented with seizures, 11 had respiratory depression after intravenous or rectal diazepam (5). However, this finding was challenged (6,7). The authors of the second comment stated that this complication does not occur when rectal diazepam gel is used without other benzodiazepines; they also recommended

© 2006 Elsevier B.V. All rights reserved.

that during long-term therapy families should be instructed not to give rectal diazepam more than once every 5 days or five times in 1 month.

Patients receiving intravenous benzodiazepines must be monitored for respiratory depression, which may demand artificial ventilation during intensive treatment. Diazepam may cause more respiratory depression than lorazepam at equieffective dosages (SEDA-20, 59) and is contraindicated in neonates for this reason and because it produces unacceptably prolonged sedation (8).

Nervous system

In an open study in 104 patients with acute stroke, diazepam 10 mg bd for 3 days was well tolerated (9).

In a multicenter, double-blind study, 310 patients with generalized anxiety disorder were treated for 6 weeks with abecarnil (mean daily dose 12 mg), diazepam (mean daily dose 22 mg), or placebo in divided doses for 6 weeks (10). Those who had improved at 6 weeks could volunteer to continue double-blind treatment for a total of 24 weeks. Slightly more patients who took diazepam (77%) and placebo (75%) completed the 6-week study than those who took abecarnil (66%). The major adverse events during abecarnil therapy were similar to those of diazepam, namely drowsiness, dizziness, fatigue, and difficulty in coordination. Abecarnil and diazepam both produced statistically significantly more symptom relief than placebo at 1 week, but at 6 weeks only diazepam was superior to placebo. In contrast to diazepam, abecarnil did not cause withdrawal symptoms. The absence of a placebo control makes it difficult to interpret the results of another study of the use of abecarnil and diazepam in alcohol withdrawal, which appeared to show comparable efficacy and adverse effects of the two drugs (11).

The mechanism of rare extrapyramidal effects with diazepam is unexplained (SEDA-18, 44).

Seizures

In a randomized trial, seizures occurred in 14 (16%) of 86 patients with gliomas undergoing contrast CT examinations; however, in 83 other patients with gliomas receiving diazepam prophylaxis, seizures occurred in only two patients (2.2%).

Six patients had untoward effects from excessive rectal diazepam (12). In three cases, seizures reappeared and were interrupted by rectal diazepam, followed by sedation and gradual awakening; the intervals were about 4 days. The other three patients had variable and complex symptoms, with serial seizures and alternating states of tension, apathy, and sleepiness. The plasma concentrations of diazepam and desmethyldiazepam showed rapid fluctuations.

- A 20-year-old man with complex partial seizures presented with exacerbation of his disease (13). He was taking phenytoin and sodium valproate, with plasma concentrations in the target ranges. During a video electroencephalogram recording he was given diazepam 10 mg, and the partial seizures developed into frequent generalized seizures. The same response was seen on a subsequent occasion.

The authors commented that although paradoxical reactions to benzodiazepines are rare, they should be considered in cases of refractory epilepsy.

- A 28-year old man with complex partial status, which lasted for 2 months, had a paradoxical worsening of seizure activity in response to diazepam and midazolam (13).

Neuromuscular function

Muscle rigidity after high-dose opioids can be reduced by the benzodiazepines midazolam and diazepam (SEDA-19, 82).

Psychological, psychiatric

A fugue-like state with retrograde amnesia has been associated with diazepam (14).

- A 23-year-old military officer on active duty took diazepam 5 mg tds and ibuprofen for back spasms. Three days later he was found sitting in a church, having assumed a previous role from his past life. He identified the date as 14 months before and his memory before that time was intact. However, he had no memory of events during the previous 14 months. There were no symptoms suggesting a schizophrenic disorder and his mental function was normal. His symptoms resolved within 24 hours of withdrawal of diazepam, except for amnesia of the event. He assumed his correct identity and was aware of the correct date. He had taken ibuprofen in the past with no adverse effects and this was his first exposure to a benzodiazepine. No other medications were involved and a full medical review found no cause for his symptoms other than diazepam use.

Endocrine

Gynecomastia, with raised estradiol, has been reported in men taking diazepam (15).

Skin

Cutaneous adverse effects of diazepam are rare. The incidence was 0.4 per 1000 in the Boston Collaborative Surveillance Program (16).

- A 50-year-old woman was referred to hospital for chronic depression with alcohol dependence (17). There was no history of drug allergy. She was given oral thioridazine 100 mg/day and diazepam 10 mg qds. After 2 days she noticed an erythematous eruption on her ankles. Thioridazine was withdrawn, but the eruption became more erythematous and affected both extremities and flanks within a few hours. She was given methylprednisolone 80 mg/day. The next day the eruption became bullous and she became pyrexial (39.4°C). Urea and creatinine concentrations were normal. Blood cultures were negative. A skin biopsy showed bullous vasculitis with numerous eosinophils in the dermis. Diazepam was then withdrawn, the pyrexia resolved, and the skin lesions healed, although post-inflammatory ulcers persisted on both ankles for 2 months. A lymphocyte blast transformation test was positive for diazepam.

© 2006 Elsevier B.V. All rights reserved.

Sweet's syndrome has been attributed to diazepam (18).

- A 70-year-old white man, with no significant preceding medical history, developed an acute painful rash, a fever (38.4°C), and severe arthralgia 5 days after starting to take diazepam 10 mg bd for lumbar muscular contracture due to hard physical exercise. He had taken no other medications. There were well-defined purple-red skin plaques, surmounted by vesicular and hemorrhagic blisters. He had a leukocytosis. Sweet's syndrome was confirmed by punch biopsy of a lesion. Diazepam was withdrawn, and prednisolone 30 mg/day was given for 2 weeks and then tapered. The patient improved quickly and the eruption cleared in 10 days.

Immunologic

Hypersensitivity reactions after diazepam are very rare and usually mild. However, some severe reactions have been reported.

- A 50-year-old woman with chronic depression or dysthymic disorder and alcohol dependence was given oral thioridazine 100 mg/day and diazepam 10 mg qds (19). She had no history of drug allergy. Two days later she noticed an erythematous eruption on her ankles. Thioridazine was withdrawn, but the eruption became more widespread over a few hours. She was given methylprednisolone 80 mg/day, but the following day the eruption progressively became bullous and her condition worsened. She developed a fever of 39.4°C, felt ill, and had a neutrophilia, but blood cultures were sterile and her renal function was normal. A skin biopsy showed bullous vasculitis with numerous eosinophils in the dermis. Diazepam was then withdrawn, which led to resolution of pyrexia and gradual healing of the skin lesions over the next 2 months. The lymphocyte blast transformation test was positive for diazepam.
- A 28-year-old nurse had generalized urticaria and collapsed while she was undergoing a gastroscopy for suspected *Helicobacter pylori* infection (20). Before the start of the procedure she was given lidocaine oral spray and intravenous diazepam 10 mg, and at the end intravenous flumazenil 1 mg. Skin prick tests and intradermal tests with diazepam 5 mg/ml produced a weal-and-flare reaction; flumazenil 0.1 mg/ml and lidocaine 2% had no effect.

Although in the second case, for safety reasons, a challenge test was not performed, it was suggested that the reaction had been IgE-mediated.

Second-Generation Effects

Fetotoxicity

Postnatal, longitudinal, somatic, neurological, mental, and behavioral development has been studied at birth and at 8, 15, and 24 months of life in children whose mothers had been treated during pregnancy with diazepam ($n = 126$) or promethazine ($n = 127$) and in children whose mothers had not been exposed (21). The children in the diazepam group weighed less at birth but not at 8 months or subsequently.

Diazepam has been reported to cause inappropriate ADH secretion in a neonate (22).

- A female infant was delivered vaginally at 41 weeks. Her 30-year-old mother had taken diazepam for epilepsy and hysterical attacks throughout the pregnancy. The pregnancy and delivery were uneventful. The baby was admitted to the neonatal ward in anticipation of neonatal drug withdrawal syndrome. On the first day of life, milk feeding was stopped because of poor sucking, vomiting, and increased gastric aspirate volume. On the same day oliguria was reported and the urine osmolality was increased. Secretion of antidiuretic hormone was suspected as the cause of the oliguria, and so fluid intake was restricted and a diuretic was given. Subsequently the urine output increased and the urine osmolality gradually fell. The baby's condition became stable and she was discharged on day 16.

Susceptibility Factors

Age

Five neonates who suffered an unexpected long period of respiratory failure, muscular hypotonia, and drowsiness were retrospectively investigated (8). Unusually high doses of diazepam had been given by intravenous bolus injection and serum concentrations of diazepam and its active metabolites were high. The authors emphasized the persistence of the very long-acting *N*-desmethyldiazepam, particularly in neonates and even more exaggeratedly in premature infants, owing to reduced capacity of hepatic uridine diphosphate glucuronyl transferase activity (8).

Drug Administration

Drug administration route

Although intravenous diazepam is the preferred route, the undiluted intravenous solution of diazepam can be given rectally, and is effective in the emergency management of seizures in children (23). Rectal gel is an alternative, and can be given by non-medical personnel (24). Adverse effects of rectal diazepam are rare and mild. Animal studies and clinical experience have not shown damage to the rectal mucosa.

Drug overdose

- A 54-year-old man took 2 g of laboratory-grade diazepam and was treated with activated charcoal, diuresis, and flumazenil infusion (25). He wakened, but had drowsiness, dysarthria, diplopia, and dizziness for 9 days. Blood concentrations of diazepam and its main metabolite, *N*-desmethyldiazepam, remained high for over 4 weeks.

Of 149 patients, 10 received an overdose of rectal diazepam indicated for acute repetitive seizures (51 overdoses in total) (26). There were no untoward events in 40 cases, and the adverse events were most often not drug-related. No patient had bradypnea or apnea.

Drug–Drug Interactions

Antihistamines

Drugs that depress the CNS, such as the benzodiazepines, have their effects increased by interaction with the classic antihistamines. However, the second-generation antihistamines have not yet been proven to interact with CNS depressants such as alcohol or diazepam (27–30).

Antiepileptic drugs

Some interactions of diazepam with antiepileptic drugs are listed in Table 2 in the monograph on antiepileptic drugs.

Beta-adrenoceptor antagonists

Lipophilic beta-adrenoceptor antagonists are metabolized to varying degrees by oxidation by liver microsomal cytochrome P450 (for example propranolol by CYP1A2 and CYP2D6 and metoprolol by CYP2D6). They can therefore reduce the clearance and increase the steady-state plasma concentrations of other drugs that undergo similar metabolism, potentiating their effects. Drugs that interact in this way include diazepam (31).

Bupivacaine

Animal studies have shown that diazepam can prolong the half-life of bupivacaine (32).

Caffeine

At least 40 drugs interact with caffeine, including benzodiazepines (for example diazepam, whose sedative effect is counteracted by caffeine) (33).

Cholinesterase inhibitors

Although diazepam does not have anticholinergic properties, it is possible to reverse diazepam-induced delirium by the use of cholinesterase inhibitors, such as physostigmine; however, physostigmine can on occasion induce severe arterial hypertension, especially if the dose exceeds 2 mg intravenously. In healthy volunteers sedated with diazepam, an increase in awareness was established with the use of physostigmine, but there was also a reduction in ventilatory drive (SEDA-10, 119).

Cisapride

Cisapride increases the absorption of diazepam (34).

Clozapine

Hypotension, collapse, and respiratory arrest occurred when low doses (12.5–25 mg) of clozapine were added to a pre-existing diazepam regimen (SEDA-22, 41).

- A 50-year-old man with symptoms of chronic paranoid schizophrenia resistant to typical neuroleptic drugs had a brief syncopal attack with significant electrocardiographic changes (sinus bradycardia and deep anteroseptal inverted T waves and minor ST segment changes) after the dosage of clozapine was increased to 300 mg/day while he was taking diazepam 30 mg/day (35).

The mechanism of this presumed interaction is unknown.

Disulfiram

Disulfiram inhibits hepatic drug metabolism and can prolong the effects of substances that are normally metabolized in the liver. This has been studied for various benzodiazepines. The clearances of chlordiazepoxide and diazepam were significantly reduced and their half-lives prolonged by disulfiram (36).

Heparin

In healthy non-fasting subjects, 100–1000 IU of heparin given intravenously caused a rapid increase in the unbound fractions of chlordiazepoxide, diazepam, and oxazepam (37,38), but no change in the case of lorazepam (37). The clinical implications of this finding are not known.

Ibuprofen

The effect of diazepam on the pharmacokinetics of ibuprofen has been studied in eight healthy subjects, who took ibuprofen or ibuprofen plus diazepam at 10.00 or 22.00 hours in a randomized, crossover study (39). Diazepam significantly prolonged the half-life of ibuprofen at 22.00 hours but not at 10.00 hours. The mean clearance of ibuprofen was therefore reduced by diazepam at night. This time-dependent effect of diazepam on the pharmacokinetics of ibuprofen may be due to circadian variation in the pattern of protein production in the liver and/or competitive protein binding of the two drugs during the night.

Lithium

There has been a well-documented case of profound hypothermia in a patient taking lithium and diazepam; it did not occur with either drug alone (40). Otherwise, benzodiazepines and lithium are compatible.

Naltrexone

The effects of naltrexone on diazepam intoxication were investigated in 26 non-drug-abusing subjects who received either naltrexone 50 mg or placebo and 90 minutes later oral diazepam 10 mg in a double-blind, crossover trial (41). Naltrexone was significantly associated with negative mood states, such as sedation, fatigue, and anxiety, compared with placebo, while positive states (friendliness, vigor, liking the effects of diazepam, feeling high from diazepam) were significantly more common with placebo. Naltrexone significantly delayed the time to peak diazepam concentrations (135 minutes) compared with placebo (75 minutes), but there were no significant differences in the concentrations of nordiazepam, the main metabolite of diazepam, at any stage in the study.

© 2006 Elsevier B.V. All rights reserved.

Omeprazole

In human liver microsomes, the metabolism of diazepam was mainly to 3-hydroxydiazepam (90%); omeprazole inhibited this conversion (42).

In a double blind, placebo-controlled, crossover study in eight white and seven Chinese men who were extensive metabolizers of debrisoquine and mephenytoin, omeprazole 40 mg/day reduced the oral clearance of diazepam by 38% and increased desmethyldiazepam AUC by 42%. In contrast, in the Chinese men the oral clearance of diazepam fell by only 21% and desmethyldiazepam AUC by 25%. The authors concluded that the extent of the inhibitory effect of omeprazole on diazepam metabolism depends on ethnicity (43). Differences between Caucasians and Asians may account for such effects.

Penicillamine

In one patient the use of penicillamine led to exacerbation of phlebitis that had been caused by intravenous diazepam (44).

Diazoxide

General Information

Diazoxide is a direct vasodilator that acts on vascular smooth muscle to produce systemic vasodilatation. As a result there is baroreceptor-mediated activation of the sympathetic nervous system and the renin–angiotensin system.

Vasodilators (as monotherapy) are associated acutely with flushing, headache, dizziness, reflex tachycardia, and palpitation. Chronic treatment can be complicated by fluid retention.

Organs and Systems

Cardiovascular

Rapid administration of diazoxide intravenously can cause severe hypotension. In some cases this has resulted in abnormal neurological signs associated with ischemic damage (1).

Metabolism

Diazoxide can cause hyperglycemia and diabetes mellitus and has been used to treat hyperinsulinism in infancy, although its use may be hazardous (2,3).

Dibenzepin

See also Tricyclic antidepressants

General Information

Dibenzepin is a 6,7,6 tricyclic compound of the dibenzodiazepine type. A comparison with imipramine was said to show equal efficacy; adverse effects were comparable in type and degree (1).

Reference

1. Sim M, Armitage GH, Davies WH, Gordon EB. The treatment of depressive states: a comparative trial of dibenzepin (Noveril) with imipramine (Tofranil). Clin Trial J 1971;1:29.

Dibromopropamidine

General Information

Dibromopropamidine in a cream base is used to treat herpesvirus skin lesions.

Organs and Systems

Immunologic

Contact allergy is infrequently reported with dibromopropamidine.

- A 40-year-old man with genital herpes and an acute edematous vesicobullous dermatitis on his penile shaft had a positive patch test with dibromopropamidine and not the other ingredients of the cream (1).

Reference

Dichloralphenazone

General Information

Dichloralphenazone is a complex of phenazone (antipyrine) and chloral hydrate, which dissociates in aqueous solution. It has been used as a hypnotic but is obsolete. Its adverse effects are those of its components (1,2).

Drug Interactions

Phenytoin

The phenazone component of dichloralphenazone is an enzyme inducer and hastens the metabolism of phenytoin (3).

Warfarin

The phenazone component of dichloralphenazone is an enzyme inducer and hastens the metabolism of warfarin (4).

Dichlorophen

General Information

Dichlorophen is an antihelminthic drug that was used in the treatment of tapeworm infections but has been superseded by praziquantel and niclosamide. It also has antifungal and antibacterial activity and has been used topically in the treatment of fungal infections and as a germicide in soaps and cosmetics (1).

During the first few hours after taking a single oral dose one-third of patients have nausea, diarrhea, or abdominal pain, and some experience vomiting. Urticaria, contact allergic dermatitis, and photosensitivity can occur. In the past, with larger doses, jaundice and even hepatic necrosis have been described.

Diclofenac

See also Non-steroidal anti-inflammatory drugs

General Information

The overall incidence of adverse reactions to diclofenac is about 30%, but less than 1% of patients have to have treatment withdrawn for this reason. The manufacturers' analysis of 1966 adverse effects in 987 patients over about 6 years, when over 30 million patients had been treated, provided some interesting quantitative data. Of the total number of adverse reactions, 34% were gastrointestinal and 16% hematological. Worldwide experience with diclofenac showed that the incidences of serious adverse drug reactions in phase III short-term trials (1227 patients) and long-term trials (1173 patients) in the USA were respectively as follows (1):

- peptic ulcer 0.16 and 0.34%;
- gastrointestinal bleeding 0.16 and 0.17%;
- hepatitis 0 and 0.26%;
- thrombocytopenia 0 and 0.17%.

Organs and Systems

Respiratory

Diclofenac caused eosinophilic pneumonitis in a 67-year-old man (SEDA-18, 103).

Nervous system

The frequency of central nervous system adverse effects is 1–9%. Headache, dizziness, vertigo, insomnia, drowsiness, and agitation have been reported. Hallucinatory symptoms and generalized tonic-clonic seizures have also been described (SEDA-16, 109). Toxic encephalitis can be part of a general toxic reaction (2). Diclofenac provoked aseptic meningitis in patients with systemic lupus erythematosus (SEDA-17, 109).

Sensory systems

Hyperemia, burning of the eyes, eyelid allergic contact dermatitis, and conjunctivitis can occur in patients who use diclofenac eye-drops (SEDA-20, 92) (SEDA-21, 104).

Diclofenac can cause reduced corneal sensitivity, starting from 15 minutes after instillation and measurable after 1 hour (3). This corneal hypesthesia can be useful in reducing pain and discomfort in ocular inflammation and after surgery. In chronic treatment, however, the effect of diclofenac on corneal nerves can cause either increased healing time of the corneal epithelium or a neurotrophic epitheliopathy in patients with conditions that predispose to epithelial damage, such as dry eyes. In contrast, flurbiprofen, indometacin, and ketorolac tromethamine did not cause corneal hypesthesia.

Electrolyte balance

Severe hyponatremia developed in an elderly woman treated with intramuscular diclofenac (SEDA-13, 80).

NSAIDs can cause hyperkalemic acidosis and should be used with caution in the presence of renal impairment (4).

- A 76-year-old woman developed quadriparesis associated with hyperkalemia after taking diclofenac 100 mg/day for 10 months for gouty arthritis. She had a metabolic acidosis with a normal anion gap and mild renal impairment. Her weakness resolved after withdrawal of diclofenac and correction of the hyperkalemia.

Mineral balance

At least three reports of severe hyponatremia have been described (SEDA-12, 85) (SEDA-13, 80) (SEDA-18, 103). In the last case the withdrawal of diclofenac and fluid restriction led to normal fluid and electrolyte balance within 10 days, despite concomitant treatment with nabumetone.

Hematologic

In an analysis of 447 adverse effects in 194 patients worldwide (5), 20 had blood abnormalities, including two cases of agranulocytosis and one of granulocytopenia. One of these patients, who was sensitive to pyrazolone, had taken a pyrazolone compound as well. Immune-mediated agranulocytosis and thrombocytopenia have been reported (SEDA-16, 110).

Reversible hemolytic anemia (SEDA-4, 69) (6), two cases of severe immune hemolytic anemia with acute renal insufficiency (SEDA-20, 92) (SEDA-22, 115), and fatal hemolytic anemia have occurred (7).

Diclofenac can cause panmyelopathy (8). Data from the International Agranulocytosis and Aplastic Anemia Study showed an increased risk of aplastic anemia (multivariate rate-ratio 8.8) (9). Fatal aplastic anemia has also been described (SEDA-4, 69) (10), as have purpura and thrombocytopenia, although not always with certainty. Spontaneous bleeding (subcutaneous bruises, hematoma, greater wound drainage) has been associated with diclofenac (SEDA-15, 100).

Gastrointestinal

Gastrointestinal adverse effects are particularly frequent, and affect some 14–25% of patients; the incidence of the most serious, peptic ulcer and bleeding were 0.16–0.34% and 0.16–0.17%, respectively (1). A prospective 12-week endoscopic study documented better gastrointestinal tolerability with diclofenac than naproxen (SEDA-20, 92). Upper gastrointestinal hemorrhage has been associated with transdermal application of diclofenac, with massive bleeding in two of four patients (SEDA-21, 104).

Perforation of the terminal ileum occurred in one patient who had taken a high dose (400 mg/day) of modified-release diclofenac (11).

Colonic stricture, similar to ileum "diaphragm" disease, developed in a patient during prolonged administration of modified-release diclofenac (12). Pseudomembranous colitis and colonic ulceration, with or without a diaphragm-like colonic stricture, have been reported (SEDA-16, 110) (SEDA-17, 109). Dispersible diclofenac is a formulation from which absorption is more rapid than the usual formulation, but gastrointestinal adverse events still occur (SEDA-20, 92).

Rectal administration caused adverse effects in 16% of patients (13); anorectal lesions (erosions, ulcers, stenosis of the anal margin) occurred after a relatively short period of suppository use (14).

Liver

Liver function can be impaired during diclofenac treatment, and liver damage may be more common than previously thought (SEDA-10, 83) (15). The risk is the same as with the few other NSAIDs that have been adequately studied. Biopsy-proven hepatitis with positive rechallenge and dechallenge has been described (16) and confirmed (17,18). The usual clinical presentation is acute hepatitis, but chronic active hepatitis has been described (17–20). Although recovery is usually rapid in the acute form after drug withdrawal, fatal cases have occurred (SEDA-11, 93) (SEDA-12, 85) (SEDA-13, 80) (21). Diclofenac-induced fulminant hepatic failure has been successfully treated with liver transplantation (22). Patients who developed combined reversible hepatorenal damage have also been reported (23–25) (SEDA-20, 91).

In a retrospective study, two-thirds of cases were detected by symptoms (jaundice, anorexia, nausea, vomiting, with or without fever) (26). The illness developed more than 5 weeks after starting diclofenac in more than 75% of patients, and within six months in 85%. Liver injury was classified as hepatocellular in 54% of patients and the histology was acute hepatocellular injury (nine patients) and chronic hepatitis (six patients). Factors affecting the susceptibility to diclofenac liver damage were sex (female) and type of disease (osteoarthritis). The mechanism of diclofenac-induced liver injury is unknown, but since the incidence is very low an idiosyncratic mechanism rather than intrinsic toxicity of the drug seems likely. In view of the rarity of hallmarks of hypersensitivity, the delayed development of injury and the delayed response to rechallenge, a metabolic effect rather than immunological idiosyncratic mechanism seems probable in most cases. The usefulness of monitoring serum enzymes is unknown, but it might be prudent to do so in the first 6 months of treatment.

Urinary tract

Renal papillary necrosis and interstitial nephritis with the nephrotic syndrome have been documented (27,28). Other cases of the nephrotic syndrome, with or without renal insufficiency, which were apparently due to minimal-change nephropathy (which is relatively more common in NSAID users), have been reported (29,30). The unusual feature of diclofenac-associated renal interstitial mucinosis has been described (SEDA-17, 109). Functional renal insufficiency after the use of diclofenac in a patient with burns has been described (SEDA-20, 92).

Skin

Allergic skin rashes, serous bullous dermatitis with positive rechallenge, and linear IgA deposits along the basal membrane in lesional and perilesional skin have all been reported (31). A patient who developed Stevens–Johnson

© 2006 Elsevier B.V. All rights reserved.

syndrome died (SEDA-5, 103). Contact dermatitis and a generalized maculopapular eruption caused by delayed hypersensitivity to diclofenac have been reported with topical and oral diclofenac (SEDA-18, 104). Photosensitivity after topical application has been described (SEDA-22, 115). Diclofenac triggered pemphigus vulgaris, an uncommon manifestation of NSAID toxicity (SEDA-22, 115).

- Contact dermatitis on the eyelids developed in a 70-year-old-woman after she had used eye-drops containing diclofenac. Patch tests were positive to both diclofenac and indometacin, suggesting possible cross-reactivity between the two compounds (32).
- Staphylococcal scalded skin syndrome developed in a 68-year-old man after he had taken diclofenac for knee arthritis subsequently diagnosed as septic arthritis due to *Staphylococcus aureus* (33).

NSAIDs can predispose to severe infections (SEDA-22, 112).

Nicolau syndrome (embolia cutis medicamentosa) is a very rare complication of intramuscular injections, in which there is extensive necrosis of the injected skin area, perhaps due to accidental intra-arterial and/or para-arterial injection; it usually occurs in children (34). Of the NSAIDs with which it has been reported, diclofenac is the most common (35–38).

Musculoskeletal

Massive rhabdomyolysis resulting in renal insufficiency with complete recovery after withdrawal has been described in a man who took diclofenac for 2 weeks (SEDA-21, 104).

Immunologic

Acute allergic reactions were reported in 48 patients, and included anaphylactic or anaphylactoid reactions and angioedema without shock. Two anaphylactic reactions, one fatal, to parenteral diclofenac have been reported (SEDA-18, 104). Hepatorenal damage (SEDA-15, 100), thrombocytopenia, and hemolytic anemia mediated by an immune mechanism have been reported (SEDA-16, 110).

Skin tests with diclofenac were not useful in diagnosing hypersensitivity in a series of 12 non-atopic patients who had severe symptoms of hypersensitivity (39). However, oral challenge in patients who had had only cutaneous symptoms was diagnostic.

Second-Generation Effects

Fertility

Three cases of infertility have been reported with diclofenac (SEDA-21, 104).

Fetotoxicity

As inhibitors of cyclo-oxygenase, NSAIDs given during pregnancy can cause adverse maternal and fetal effects (SEDA-22, 112).

- Premature closure of the ductus arteriosus occurred in a fetus who was exposed in utero to diclofenac at 34–35 weeks of gestation (40). Emergency cesarean section was performed and the baby girl required cardiorespiratory support and multiple medications. She gradually improved and further development was normal.

Susceptibility Factors

The Japanese Health Authority has sent a "Dear Doctor" letter warning against the use of diclofenac in patients with encephalitis or encephalopathy related to influenza, which may be associated with higher mortality (41).

Drug Administration

Drug administration route

Aseptic tissue necrosis after intramuscular injection (Nicolau syndrome) has been reported after accidental intra-arterial injection. Antirheumatic drugs are often involved in these reactions and diclofenac has also been implicated (42). Other consequences of intramuscular administration of diclofenac are asymptomatic high serum creatine kinase activity or damage to muscle, nerve, or blood vessels (SEDA-17, 109).

Necrotizing fasciitis was reported in three patients, two of whom died as a consequence of severe local reactions associated with intramuscular diclofenac (43).

If appropriately diluted and infused intravenously, diclofenac is usually well tolerated, although local venous thrombosis has been described (SEDA-17, 109).

Drug–Drug Interactions

Ciclosporin

The risk of ciclosporin-induced nephrotoxicity can be increased when NSAIDs are also used (44,45). Diclofenac in particular should be avoided, because it is more likely to cause deterioration of renal function in patients taking ciclosporin (SEDA-15, 100) (SEDA-17, 107). There is also a pharmacokinetic interaction, which may be caused by inhibition by ciclosporin of the first-pass metabolism of diclofenac (SEDA-21, 104).

In 16 healthy volunteers there were no important pharmacokinetic changes when a single dose of ciclosporin was taken during steady-state administration of aspirin, indometacin, or piroxicam, but there was an interaction with diclofenac, whose AUC was doubled in the presence of ciclosporin (46).

In patients with rheumatoid arthritis, steady-state coadministration of diclofenac with ciclosporin was associated with a significant rise in serum creatinine concentration.

Lithium

Diclofenac increases serum lithium concentrations by impairing its renal excretion (47).

Triamterene

The interaction between diclofenac and triamterene causes renal impairment (48).

© 2006 Elsevier B.V. All rights reserved.

Interference with Diagnostic Tests

Thyroid hormone tests

Diclofenac alters thyroid hormone tests, causing a fall in total serum triiodothyronine, principally by interfering with its serum protein binding (SEDA-19, 98).

Dicycloverine

See also Anticholinergic drugs

General Information

Dicycloverine, in the doses generally used (up to 450 mg/day), is of disputed value. It may have a non-specific relaxant action on the gastrointestinal muscle. The evidence of its effects is meager and it seems to be an anticholinergic drug that which has been promoted in doses that are often too low to result in either a useful therapeutic effect or in adverse effects.

Second-Generation Effects

Teratogenicity

Dicycloverine was formerly combined with doxylamine succinate and sometimes with pyridoxine in Debendox (Bendectin) tablets, which were used in certain countries for the treatment of nausea and vomiting in pregnancy. There has been a widely discussed suggestion that Debendox might cause a range of fetal malformations, but numerous studies have failed to confirm this (1).

For example, in a survey of 22 977 pregnant women in Great Britain 620 of whom had been given Debendox and 743 other women had been given agents other than Debendox containing pyridoxine during the first 13 weeks of gestation, the rates for all abnormal outcomes among women given Debendox and those not given it were 5.0 and 5.4% respectively (2).

However, the sporadic reports of such problems sometimes involved women who took the product in high doses for long periods in early pregnancy and there is some doubt as to the dosage schedule used in the larger studies. Particularly since the pattern of supposed malformations was highly variable, and they were of types which tend to occur spontaneously, the point cannot be considered settled. However, any teratogenic effect must have been very slight.

Didanosine

See also Nucleoside analogue reverse transcriptase inhibitors (NRTIs)

General Information

Didanosine (2′,3′-dideoxyinosine, ddI) is a purine analogue reverse transcriptase inhibitor. The major clinical adverse effects reported during the first years of use of didanosine were acute pancreatitis and a painful neuropathic syndrome (due to a peripheral neuropathy), which appeared to be related to both dosage and cumulative dose (SEDA-17, 340) (1). However, the incidence of acute pancreatitis and peripheral neuropathy in these studies was lower than in earlier studies with didanosine (2,3). This may be related to the fact that treatment was started earlier or to the use of lower dosages (200–400 mg/day) in these studies compared with earlier studies. In the latter studies, gastrointestinal symptoms, most notably nausea and vomiting, were the most commonly reported adverse effects in patients taking didanosine. Minor adverse effects include insomnia, headaches, anxiety, irritability, rash, increased plasma uric acid concentration, and increased hepatic transaminase activities combined with a rash (4). There were no toxic effects of didanosine on hematological laboratory indices (5).

© 2006 Elsevier B.V. All rights reserved.

Observational studies

The use of didanosine 125–200 mg bd plus interferon alfa-2b in AIDS-associated Kaposi's sarcoma has been studied in 68 patients (6). Withdrawal of didanosine was required in cases of peripheral neuropathy, rises in serum amylase activity, and hypertriglyceridemia.

Organs and Systems

Sensory systems

Eyes

Retinal depigmentation has been described in children taking didanosine (7).

Ears

Hearing loss attributed to didanosine has been reported in an HIV-infected adult (8).

- A 37-year-old HIV-infected man developed bilateral deafness while taking didanosine (400 mg/day), which had been started about 4 years before. He was also taking azithromycin, ciprofloxacin, and myambutol for about 1 month for a *Mycobacterium avium* infection. Otoscopic examination and tympanometry were normal. Audiometry showed a bilateral sensorineural hearing deficit of 40–60 dB. There were no other neurological abnormalities. An MRI scan of the brain was normal. Didanosine was withdrawn and replaced by alternative antiretroviral agents. All other medications were continued. His hearing improved progressively and returned to normal after 2 months.

In the absence of rechallenge, there was no conclusive evidence for a causative role of didanosine in the development of hearing loss in this case. However, the authors argued that the improvement on discontinuation of didanosine, which is known to cause neuritis, implicated the drug.

Extensive serial audiological studies in an HIV-infected child showed high-frequency hearing loss after 19 months of combined treatment with zidovudine and didanosine (dosages unknown), which were started at 24 months of age (9). Normal tympanograms indicated that this hearing loss was sensorineural.

While no conclusive evidence was given for a causative role of either antiretroviral drug, the authors concluded that children taking antiretroviral therapy need to be monitored for possible ototoxicity.

Hematologic

Thrombocytopenia has been observed in patients using didanosine (10,11).

Musculoskeletal

There is no evidence that didanosine contributes to the development of myopathy in patients taking didanosine and zidovudine in whom this adverse event occurs (12).

Multiorgan failure

There has been a report of a patient in whom pancreatitis, fulminant hepatic failure, and persistent lactic acidosis occurred, culminating in death from liver failure (13).

Diethyl sebacate

General Information

Diethyl sebacate is an emulsifier used in cosmetics and topical medicaments. In contrast to the emulsifying agents stearyl alcohol, stearic acid, and glyceryl stearate, diethyl sebacate is considered to be a rare sensitizer.

Organs and Systems

Immunologic

There were positive patch tests to diethyl sebacate (10 and 30% in ether and 1 and 10% in petrolatum) in a 48-year-old woman who had been using a topical antimycotic ointment (1).

Diethylcarbamazine

General Information

Diethylcarbamazine is an antihelminthic drug used in the treatment of filarial infections. With some infecting species it is effective in both the adult and microfilarial stages, whilst with others it is active only against the microfilarial stages and does not eradicate the infection.

Pharmacokinetics

Diethylcarbamazine is extensively metabolized, the half-life being 6–12 hours; the remainder enters the urine within 48 hours. Over the initial period the dosage should be increased slowly to avoid or reduce allergic responses as a result of destruction of parasites and liberation of antigen, and then maintained at 3 mg/kg tds for 34 weeks. Not all of its adverse effects are necessarily due to destruction of the parasite; weakness, lethargy, anorexia, and nausea can be due to the drug itself.

The pharmacokinetics, safety, and tolerability of co-administered diethylcarbamazine and albendazole have been investigated in a double-blind, randomized, placebo-controlled trial in 42 subjects (aged 18–52 years, weighing 46–67 kg) living in a lymphatic filariasis endemic region but without detectable microfilariae (1). Three groups of 14 patients received diethylcarbamazine 6 mg/kg alone, albendazole 400 mg alone, or diethylcarbamazine 6 mg/kg plus albendazole 400 mg. Both diethylcarbamazine and albendazole were well tolerated alone and in combination. In contrast to a study in patients with lymphatic filariasis (2), there were no adverse events in amicrofilaremic individuals. In all three treatment groups the drugs were rapidly absorbed from the gastrointestinal tract, although there was marked interindividual variation. The pharmacokinetics of diethylcarbamazine, albendazole, and albendazole sulfoxide were similar.

Observational studies

Brugia malayi and *Wuchereria bancrofti*

When treating *Brugia malayi* and *Wuchereria bancrofti* infections, reactions include headache and fever, sometimes accompanied by malaise, nausea, and vomiting. Urticarial skin rashes can occur, and subsequently lymphangitis and lymphadenopathy often appear (SEDA-17, 357). Abscess formation can occur in association with adult worms. Major systemic complications of therapy include proteinuria and severe pruritus; proteinuria has even been seen in some patients using the drug topically. Circulating immune complexes have been found to be increased in many cases. Those with CIq binding greater than 3% are at significantly increased risk of developing visual field constriction and proteinuria.

In lymphatic filariasis diethylcarbamazine can cause systemic reactions, such as fever, arthralgia, headache, and malaise, and local reactions such as swollen and painful lymph nodes. All of these reactions are thought to be caused by an allergic reaction to antigens from the dying microfilaria and not to a toxic effect of the drug itself. This causal relation is further emphasized by a study from Indonesia, in which adverse reactions to treatment with diethylcarbamazine were studied in patients with *B. malayi* filariasis—26 microfilaria-positive patients (mean 235 mf/10 ml), 12 "endemic" controls (from the endemic area, but microfilaria counts negative), and 17 patients with elephantiasis, of whom three had with high microfilaria counts (3). Adverse effects, mainly fever, headache, and body aches, started 2–24 hours after the administration of diethylcarbamazine 6 mg/kg/day for 12 days. Of the patients with positive pretreatment microfilaria counts 15% had severe adverse reactions, 19% moderate reactions, and 65% mild reactions. There was a direct relation between the severity of the adverse effects and the height of pretreatment microfilaria counts, and the more severe adverse effects occurred in the patients with the highest pretreatment microfilaria counts. In the endemic controls there were no reactions or only mild ones. In the patients with elephantiasis there were no reactions or only mild ones in all but two patients, both of whom had moderate reactions and had high pretreatment microfilaria counts.

That diethylcarbamazine may still be the more effective drug in *B. malayi* infections, despite these adverse effects, is suggested in a study from India, in which the efficacy and safety of several single-dose drug combinations, including albendazole, diethylcarbamazine, and ivermectin were compared in 51 microfilaria-positive patients with *B. malayi* and in which diethylcarbamazine was more effective in reaching a sustained reduction in microfilaria counts after 1 year than ivermectin, although the study was small (4). Adverse reactions (fever, headache, myalgia, and chills) occurred in all of the 16 patients treated with a combination of ivermectin (200 micrograms/kg as a single dose) and diethylcarbamazine (6 mg/kg as a single dose), in 15 of the 16 patients treated with albendazole (400 mg as a single dose) and diethylcarbamazine (6 mg/kg as a single dose),

© 2006 Elsevier B.V. All rights reserved.

and in 12 of the 16 patients treated with ivermectin and albendazole.

In order to assess the effects of re-treatment in *B. malayi* infections, 35 asymptomatic microfilaremic patients were re-treated at the end of the first year with an additional single dose of the combination they had previously received (5). Eleven patients received ivermectin 200 micrograms/kg plus diethylcarbamazine 6 mg/kg, nine patients received ivermectin 200 micrograms/kg plus albendazole 400 mg, and 15 patients received diethylcarbamazine 6 mg/kg plus albendazole 400 mg. The best suppression of brugian microfilaremia 1 year after re-treatment was obtained with combinations that included diethylcarbamazine. Whatever the drug regimen, both the frequency and intensity of adverse reactions after re-treatment were less than after initial treatment. The greatest difference was in patients who received ivermectin plus diethylcarbamazine, who also had the lowest mean microfilarial counts immediately before re-treatment. None of the adverse reactions after re-treatment was severe. Most of them, including fever, headache, and myalgia, were easily controlled with paracetamol. Postural hypotension and the "string sign" (dilated painful and inflamed lymphatic channels) did not occur with re-treatment.

In another study the cost-effectiveness of a revised mass annual single-dose regimen of diethylcarbamazine 6 mg/kg was estimated for large-scale control of lymphatic filariasis in a pilot program launched in Tamil Nadu (6). This regimen gave good coverage (90% of the population studied) and high compliance of 82%. Adverse effects occurred in 22% of patients and most were non-specific (giddiness in 54%, vomiting in 11%, nausea in 1%, fever in 14%, and headache in 20%).

Loa loa

In loiasis both adult and microfilariae are susceptible to diethylcarbamazine. However, encephalitis is a major risk in patients with heavy infestation (SEDA-17, 356) (7), and ivermectin should be preferred. Severe allergic reactions can need treatment with antihistamines and glucocorticoids. The risk of encephalitis has led to the recommendation that prophylactic use of diethylcarbamazine against *Loa loa* should only be contemplated when the chance of infection is considerable.

Onchocerca volvulus

In onchocerciasis, severe reactions can occur in the initial stages of therapy, particularly since diethylcarbamazine only kills the microfilariae of *Onchocerca volvulus* (resulting in the release of toxins) and does not eradicate the infection. The Mazzotti reaction, a Herxheimer-like response, can be severe and even fatal; it comprises a pruritic papular dermatitis, urticaria, fever, malaise, and postural hypotension; asthma and respiratory distress can occur and the hypotension can be associated with irreversible collapse. There can be painful lymphadenopathy.

Ocular complications are of particular importance: iritis can be induced by dying microfilariae and may call for topical or systemic glucocorticoid treatment. Associated complications include chorioretinitis, anterior uveitis, and punctate keratitis. Changes can also occur in the posterior segment (8), with visual field defects; there can be transient retinal pigment epithelial lesions at the posterior pole, globular infiltrates at the limbus, and optic disk leakage (9) with visible pallor. Similar ocular lesions can develop after topical diethylcarbamazine (SEDA-7, 316). Visual field defects are not reversible and they limit the clinical value of diethylcarbamazine in this disease.

Mass treatment with diethylcarbamazine is a key measure for control of the transmission of bancroftian filariasis. However, severe adverse reactions can occur in patients with onchocerciasis treated with high doses of diethylcarbamazine, which may limit the prospects for the use of common salt medicated with diethylcarbamazine in many parts of Africa. However, the daily dose of diethylcarbamazine-medicated salt is considerably lower than that of conventional tablets (25–50 mg od for the first 1 or 2 days followed by 100 mg bd for 5–7 days).

The adverse effects of diethylcarbamazine-medicated salt in patients with *O. volvulus* has been assessed in a double-blind, placebo-controlled trial in four groups of ten men (10). Groups I and II had *O. volvulus* microfilariae only, group III had both *O. volvulus* and *W. bancrofti* microfilariae, and group IV had *W. bancrofti* microfilariae only. Groups I, III, and IV received diethylcarbamazine-medicated salt. Group II served as a control group and received cooking salt. The medicated salt (0.33% w/w) originated from a batch previously produced for control trials. Each individual was given a total daily dose of 5.8 g of salt for 10 days, corresponding to the average daily salt intake for individuals aged over 15 years in the area. The salt supplement was spaced over three daily meals: 0.5 g, 2.5 g, and 2.8 g at breakfast, lunch, and dinner respectively. Hence, the daily dose of diethylcarbamazine was 19.1 mg. Diethylcarbamazine-medicated salt had no significant effect on *O. volvulus* microfilarial counts, but *W. bancrofti* microfilarial counts were significantly reduced in groups III and IV. The most pronounced adverse reactions occurred in groups I and III and were mild to moderate itching and rash. They were observed on days 3–4 and lasted for the remaining medication period, but did not interfere with normal daily activities. At day 30, all the reactions had abated. There were no severe adverse events, perhaps because of low pre-existing microfilarial counts and the short duration of therapy. There was no evidence that patients with *O. volvulus* and *W. bancrofti* double infection had a different adverse reaction pattern than individuals with *O. volvulus* infection only. Thus, diethylcarbamazine-medicated salt may be an important drug for the control of bancroftian filariasis in Africa. Salt with an even lower concentration of diethylcarbamazine may still have microfilaricidal properties in bancroftian filariasis without inducing microfilarial killing and adverse reactions in onchocerciasis, which may further improve treatment compliance and ease of use.

Wolbachia

In 15 Indonesian patients with *B. malayi* infection, the release of *Wolbachia* bacteria was studied in relation to adverse events after diethylcarbamazine treatment (6 mg/kg orally for 12 days) (11). Three patients had severe reactions and six patients had moderate reactions. In all samples from the three patients with severe reactions

© 2006 Elsevier B.V. All rights reserved.

and in one of the six with moderate reactions, *Wolbachia* PCR products were detected from 4 hours after treatment, and persisted for 8–20 hours. These data suggest that release of *Wolbachia* bacteria into the blood may be associated with severe inflammatory reactions after diethylcarbamazine. Adverse reactions associated with increases in proinflammatory cytokines have also been reported in bancroftian filariasis and onchocerciasis, suggesting that similar events can also occur in these filarial infections.

Comparative studies

Filariasis

The efficacy of new treatment strategies for lymphatic filariasis using a single dose of diethylcarbamazine or a combination of diethylcarbamazine plus albendazole has been studied in 30 people (aged 11–52 years, weighing 25–63 kg) infected with *Brugia timori* and compared with the results of 27 people (aged 13–52 years, weighing 27–73 kg) infected with *W. bancrofti* (2). All were allocated at random to diethylcarbamazine (100 mg on day 1 and up to a total dose of 6 mg/kg on day 3) or diethylcarbamazine plus albendazole group (placebo on day 1 and diethylcarbamazine 6 mg/kg plus albendazole 400 mg on day 3). There was no difference in adverse reactions between diethylcarbamazine alone and diethylcarbamazine plus albendazole. Headache ($n = 15$), myalgia ($n = 13$), itching ($n = 8$), and adenolymphangitis ($n = 8$) were the most common adverse effects; none were severe or life-threatening. The microfilaricidal effect of the drugs was achieved more rapidly for *B. timori*, which is associated with more adverse reactions than *W. bancrofti* filariasis. As previously shown, there was a strong correlation of microfilarial density with the frequency and severity of adverse reactions. The addition of albendazole resulted in no additional adverse reactions compared with diethylcarbamazine alone.

General adverse effects

Adverse reactions to treatment with diethylcarbamazine vary with the infecting filarial species and are most severe in onchocerciasis. Minor reactions include malaise, nausea, and headache, but diethylcarbamazine also depresses the central nervous system in some individuals, resulting in dizziness and somnolence; reversible coma has been reported in patients in poor physical condition. Nicotine-like properties can produce autonomic effects. A degree of eosinophilia during treatment is usual.

Although over 120 million individuals have lymphatic filariasis, it may be eradicable. Newer strategies for the elimination of lymphatic filariasis aim at transmission control through the use of annual doses of combinations of ivermectin, diethylcarbamazine, or albendazole, and disease control through individual patient management. Mass chemotherapy appears to be essential in the control of lymphatic filariasis. However, drug availability and the co-endemicity of onchocerciasis and loiasis play crucial roles. Although a single annual dose of diethylcarbamazine may be an effective approach toward long-term suppression of brugian and bancroftian microfilaremia, repeated multidrug chemotherapy is the preferred approach for control of lymphatic filariasis, as in other chronic infections, such as tuberculosis and leprosy. In addition, combining diethylcarbamazine with albendazole has the advantage of controlling intestinal parasites.

Organs and Systems

Immunologic

Brugia malayi is more susceptible to diethylcarbamazine than *W. bancrofti*. A study of the former, undertaken to explain the very severe effects often associated with diethylcarbamazine treatment of lymphatic filariasis, provided evidence of the involvement of the cytokine interleukin-6 (IL-6), concentrations of which were raised during treatment (12).

The involvement of inflammatory mediators in the development of adverse events has recently been studied in 29 patients with *B. malayi* microfilaremia treated with diethylcarbamazine (13). Before and at serial time points after the start of treatment, plasma concentrations of the inflammatory mediators interleukin-6, interleukin-8, interleukin-10, tumor necrosis factor-alfa, and lipopolysaccharide-binding protein were measured in relation to diethylcarbamazine concentrations and adverse events. The adverse effects of diethylcarbamazine correlated well with pretreatment microfilariae counts, consistent with previous experience with diethylcarbamazine in lymphatic filariasis and onchocerciasis. Concurrent measurements of diethylcarbamazine concentrations failed to establish a clear relation between diethylcarbamazine concentrations and adverse events. Detailed kinetic studies showed the strongest association of the severity of symptoms with interleukin-6 and lipopolysaccharide-binding protein. Concentrations of interleukin-6 started to rise as early as 2–4 hours and reached a maximum after about 8 hours. Fever also occurred at 4–8 hours, consistent with the pyrogenic activity of interleukin-6. In addition, interleukin-6 plays a central role in the induction of the acute phase proteins involved in inflammatory reactions. Indeed, concentrations of the acute phase protein, lipopolysaccharide-binding protein, started to rise at 8 hours (that is after interleukin-6), and also peaked later than interleukin-6, at 24–48 hours after diethylcarbamazine. These observations suggest that the adverse effects of diethylcarbamazine result from an exaggerated host inflammatory response stimulated by a high load of antigen released from killed or degenerating microfilariae.

Susceptibility Factors

Renal disease

The clearance of diethylcarbamazine is reduced in renal insufficiency (14), and dosages should be reduced.

Diethylenetriamine penta-acetic acid

General Information

Diethylenetriamine penta-acetic acid (DTPA) is a chelating agent that has been used in radiolabeled form as a tracer. It has been used in the following combinations:

- DTPA: to assess iron body stores (1–3);
- ^{111}indium-DTPA: to label proteins, such as albumin (4) and monoclonal antibodies (5), for the radiodetection of cancers;
- ^{99m}technetium-DTPA: for scanning organs such as the kidneys (6), lungs (7), and brain (8);
- dysprosium-DTPA: in experimental imaging of cerebral ischemia (9);
- ^{97}ruthenium-DTPA: to label cerebrospinal fluid (10);
- gadolinium-DTPA: as a contrast agent in computed tomography (11) and magnetic resonance imaging (12).

In a study of the use of $^{117m}Sn^{4+}$-DTPA for palliative pain reduction in 15 patients with bone metastases, there were no myelotoxic or other adverse effects (13).

Organs and Systems

Hematologic

In nine patients with advanced breast carcinoma, administration of a ^{90}Y-DTPA-BrE-3 complex was associated with transient and uncomplicated thrombocytopenia in four patients and leukopenia in two patients (14).

Diethylstilbestrol

General Information

For a complete account of the adverse effects of estrogens, readers should consult the following monographs as well as this one:

- Estrogens
- Hormonal contraceptives—emergency contraception
- Hormonal contraceptives—oral
- Hormone replacement therapy—estrogens
- Hormone replacement therapy—estrogens + androgens
- Hormone replacement therapy—estrogens + progestogens.

Diethylstilbestrol and other non-steroidal estrogens came into vogue at a time when the cost of producing steroidal estrogens, whether synthetic or of natural origin, was still prohibitive. They have largely fallen out of favor, in view of the association between the use of diethylstilbestrol in pregnancy and second-generation injury. There seems to be no reason for believing that the short-term acute adverse reactions to these non-steroidal compounds differ from those of estrogenic steroids.

Diethylstilbestrol continues to be recommended in some centers as one of the agents of last resort when prostate cancer proves refractory to steroid hormones or androgen deprivation therapy has done all it can (1). In a Japanese study in which 16 patients were given a daily intravenous injection of diethylstilbestrol diphosphate 250 mg for 28 days, the short-term response was favorable and the drug was well tolerated (2).

Organs and Systems

Cardiovascular

In a randomized study of men treated hormonally for prostatic cancer (3), cardiovascular adverse effects were reported more often in patients treated with diethylstilbestrol than in those treated with cyproterone acetate. The risk was highest during the first 6 months of treatment.

Mineral balance

Profound hypocalcemia occurred in a patient with osteoblastic metastatic carcinoma of the prostate after treatment with diethylstilbestrol 15 mg/day for 7 days (SED-12, 1032) (4).

Immunologic

In 13 women exposed to diethylstilbestrol in utero compared with similar control subjects with respect to the in vitro T cell response to the mitogens phytohemagglutinin, concanavalin A, and interleukin-2, incorporation of tritiated thymidine into T cells from diethylstilbestrol-exposed women was increased three-fold over a range of concentrations in response to concanavalin A, increased by 50% over a range of concentrations in response to phytohemagglutinin, and increased two-fold in response to the endogenous mitogen interleukin-2 (5). This in vitro evidence of a change in T cell-mediated immunity clearly raises questions about the clinical consequences.

Long-Term Effects

Tumorigenicity

Exposure to diethylstilbestrol during pregnancy in 4836 women has been reported to carry a relative risk of 1.27 of breast cancer later in life. However, the authors found no evidence to support the link between diethylstilbestrol exposure and ovarian, endometrial, or other cancers.

In a 25-year follow-up study there were very slightly more breast tumors in women using diethylstilbestrol in pregnancy and significantly more cancer deaths (6).

In one study there was a six-fold risk of endometrial cancer among estrogen users compared with non-users; long-term users (over 5 years) had a 15-fold risk; there were excess risks for both diethylstilbestrol and conjugated estrogens (7).

Diethylstilbestrol can cause hepatic adenomas and carcinomas in experimental animals (8), and hepatocellular carcinoma has been reported in a man who took a total of 668 g over 12 years for suspected carcinoma of the prostate (9).

Second-Generation Effects

Teratogenicity

Diethylstilbestrol was used extensively in pregnancies between 1940 and about 1975, in the belief that it could protect threatened pregnancies and counter the risk of spontaneous abortion. Toward the end of that period, increasingly clear evidence emerged that diethylstilbestrol could have an adverse effect on the second generation that

© 2006 Elsevier B.V. All rights reserved.

did not become apparent until puberty or adulthood, and perhaps could also appear in the third generation (10). It appears to be the only estrogen with this effect, but it is naturally not excluded that some structurally related non-steroidal estrogens might carry the same risk, although these have never been used in the same way in pregnancy.

History

Diethylstilbestrol provides several illustrations of how societies cope with the risks of harm from a drug. Under different brand names diethylstilbestrol has been given to a wide range of patients over many years, mostly pregnant women and aging men with prostate cancer. The history of iatrogenic disease as a result of the use of diethylstilbestrol in pregnant women shows that patients can play an important role in securing legitimacy for research and the publication of data on the harmful effects of a drug.

Diethylstilbestrol was given to pregnant women in many countries, mainly in the 1940s to 1970s, in the mistaken belief that it would prevent miscarriage and provide strong healthy babies (11,12). The application to market diethylstilbestrol in the USA was the first new drug application submitted to the FDA shortly after the 1938 Food, Drugs, and Cosmetics Act had been passed; permission was granted, although diethylstilbestrol had already been identified as a carcinogen in animals (13). Diethylstilbestrol was especially popular in some maternity clinics in North America, serving middle-class and upper-middle class women, and in the Netherlands, where the Queen's gynecologist promoted it. In other countries it was dispensed through public health maternity centers.

In the USA, evidence showing that it was ineffective for its intended purpose appeared by the 1950s. However, conclusions based on animal experiments, as well as a major double-blind, controlled clinical trial (14), remained unheeded, partly because prescribing physicians trusted their collegial loyalty more than data that implicitly threw doubt on their practice.

In 1971, a rare form of aggressive cancer in the vagina of young girls was attributed to the girls' exposure to diethylstilbestrol in utero in a report that was based on a case-control study of eight young women, two of whom had died, at the Massachusetts General Hospital (15). It was already clear from this small study that monitoring young women exposed to diethylstilbestrol would save lives. However, months and even years were to pass before the discovery led to any public action, at different times in different countries. Only after 5 months, when the risk of cancer in patients exposed to diethylstilbestrol was featured at hearings in the US Congress, did the FDA react. The FDA's Administrator then announced that diethylstilbestrol products were to be labelled with a warning that diethylstilbestrol was contraindicated in pregnancy and should not be given to pregnant women because of risk of the cancer in the offspring (16).

Drug regulatory agencies in other countries in which diethylstilbestrol had also been commonly used in pregnancy delayed taking action. In the Netherlands, the first change of labelling to include a warning to physicians that diethylstilbestrol given to pregnant women might harm the fetus was implemented in 1972. A similar change in labelling was introduced in France in 1977. In many other countries, the news that some daughters of women who had taken diethylstilbestrol while pregnant were at risk of developing a potentially lethal cancer was passed over in silence.

In Britain, the medical community was alerted to the risks by an editorial in the British Medical Journal in 1971, but it was only in 1973 that the Committee on Safety of Medicines advised against the use of diethylstilbestrol during pregnancy (17). In Britain, drugs were commonly not labelled with information about their contents, nor with warnings of risk until well into the 1990s; thus, patients were kept in ignorance. No measures have yet been taken in Britain to alert the public to the need for medical surveillance of women who have been exposed to diethylstilbestrol in utero.

It is estimated that in the USA, the Netherlands, and France, diethylstilbestrol was given to over 5.3 million pregnant women, and it is known that it has been given to pregnant women in most parts of the world. Single cases of clear-cell vaginal carcinoma from many countries are known, but systematic studies have not been conducted everywhere.

One in a thousand young women exposed to diethylstilbestrol before birth have been estimated to be at risk of developing clear-cell vaginal adenocarcinoma (18). Exposure to diethylstilbestrol in utero also has a range of other effects on exposed women, including malformations of the reproductive organs and difficulties in conception and carrying a pregnancy to term. Some of the men exposed to diethylstilbestrol in utero have urogenital malformations and an increased risk of testicular cancer (19).

Most of the women who suspected that they had taken diethylstilbestrol were to learn of the problems from the media, and they had to guess that their daughters might be at risk of developing cancer. When they tried to discover whether they had been given diethylstilbestrol during pregnancy, many of the women found that their obstetricians were not willing to give them access to their own medical records. In a report from a nationwide US survey intended to locate pregnant women who had been given diethylstilbestrol during 1940–72, the investigators complained that at some clinics they had encountered extreme difficulties in getting access to the records (20). Women who have been exposed to diethylstilbestrol sometimes say that never have so many medical files reportedly been lost through fire and inundation, as when they asked for access to records that might document the use of diethylstilbestrol during pregnancy.

Many doctors did not notice or did not heed warnings in the early 1970s about the risks of giving diethylstilbestrol to pregnant women. As late as 1974, according to one writer, some 11 000 prescriptions for diethylstilbestrol to be used during pregnancy were written in the USA (21). In 1976, it was observed that diethylstilbestrol was given to unsuspecting pregnant women in several Latin-American countries (21). In other countries, prescribing physicians' responses to reports that linked the use of diethylstilbestrol during pregnancy with cancer risks in their daughters were even slower. The latest documented prescription of diethylstilbestrol in Europe was in Spain in 1983 (22).

The first batches of educational material for physicians, with warnings and advice regarding health care for women who had been exposed to diethylstilbestrol, were distributed in the USA in 1971, in the Netherlands in

© 2006 Elsevier B.V. All rights reserved.

1974, and in France in 1989. No such material has been distributed in Britain.

Mothers in the USA who had taken diethylstilbestrol formed an organization, DES Action, to inform the public about the risks and to alert exposed mothers that their daughters needed regular medical examinations, so that potential tumor development would be detected early. Through DES Action they also gave each other mutual support during litigation against the manufacturers and acted politically to ensure that health care would be available for their daughters. DES Action groups outside the USA were formed in Australia, Belgium, Canada, France, Great Britain, Italy, Ireland, and the Netherlands. DES Action was still in the 1990s a prime mover in securing resources for research and follow-up of women who had been exposed to diethylstilbestrol, and in promoting educational programs for those women and for medical professionals.

Initiatives by medical researchers, by DES Action, and by the Public Citizen's Health Research Group secured funding in the USA for medical research on the prevalence of cancer and other effects in the young women who had been exposed in utero, and eventually also the men. The US National Institute for Environmental Health Sciences (NIEHS) has been one of the centers for toxicological studies of the effects of diethylstilbestrol. A substantial amount of research on the effects of diethylstilbestrol—animal experiments as well as epidemiological studies—has produced a valuable body of knowledge about how hormones affect the development of the fetus and prime the individual for disease later in life.

As in the case of thalidomide, the emotional engagement evoked by the harm caused by diethylstilbestrol in pregnancy led to committed action. Some physicians have devoted a major part of their careers to finding out why and how diethylstilbestrol produced adverse effects. The anger over the harm caused by diethylstilbestrol inspired patients to a commitment to prevent further harm by engaging in political action and achieving an effective response from legislators and governmental administrators. Despite the abandonment of diethylstilbestrol in pregnancy for habitual or threatened abortion, its late effects continue to be reported. Essentially, the female offspring of these pregnancies tend to develop vaginal changes (adenosis, with cervical ectropion) when reaching adolescence or adulthood and these can subsequently give rise to a clear-cell adenocarcinoma. Whereas carcinomas are a late and infrequent event, even in exposed subjects, cervical vaginal adenosis is common, the incidence probably being some 30% (23). The estimated tumor risk is only 0.14–1.4 per 1000 diethylstilbestrol-exposed subjects, but since up to 6 million fetuses were exposed to diethylstilbestrol between 1940 and 1970 the total number affected in some way may be very high indeed. There is also a high incidence of fertility disturbances among these daughters, and their own pregnancies apparently stand a high chance of not going normally to term (SED-12, 1023) (24). Analogous changes were found in male offspring (25). As in the case of thalidomide, an important element in determining cause and effect was the characteristic nature of the defect: the vaginal pathology does occur spontaneously but is highly unusual. A major problem has been the fact that the defect is as a rule only recognizable so many years after birth, by which time the history of the original treatment may be difficult or impossible to reconstruct. Even today the material is not homogeneous and strict statistical analysis of some of the epidemiological data has been claimed to point to a series of shortcomings. This does not undermine the clear conclusion that the drug is indeed responsible for the effects described (26).

Epidemiological studies on the complications of the use of diethylstilbestrol in pregnancy will certainly produce new data as time goes on: most of the data will probably continue to come from the USA and the Netherlands, where diethylstilbestrol was much more widely used to treat habitual or threatened abortion than elsewhere. In France 150 000–200 000 pregnancies were involved; in the Netherlands, with a much smaller population, 180 000–380 000 pregnant women were treated with diethylstilbestrol up to 1976.

Vaginal adenosis and adenocarcinoma

Second-generation (and possible third-generation) effects of diethylstilbestrol continue to be reported (27,28). Typical is a 1987 update analysing 519 cases of clear-cell carcinoma of the vagina and cervix identified by the Registry for Research on Hormonal Transplacental Carcinogenesis of the University of Chicago (18); in 60% of all cases the patient's mother could be shown to have used diethylstilbestrol during pregnancy. The median age at diagnosis was 19 years. The authors argued that in view of the relative rarity of the tumors, even in exposed women, one could consider that diethylstilbestrol is not a complete carcinogen and that some other factor is also involved in the pathogenesis of this type of carcinoma. The particular question of third-generation injury has actually been the subject of judicial proceedings in the USA (27,28); on the balance of evidence it seems that it can occur, although the mechanism is not clear.

Evidence has also emerged on long-term survival in young women with a clear-cell adenocarcinoma of the vagina, 20% of whom had been exposed to diethylstilbestrol and 80% had not (29). The probabilities of survival at 5 and 10 years for diethylstilbestrol-associated cases were 84 and 78% respectively, compared with 69 and 60% for those not associated with diethylstilbestrol. These differences were not due to differences in clinical prognostic factors, but suggest differences in tumor behavior for as yet undetermined reasons.

Although it is more than 30 years since the full extent of the injury to offspring by the ill-advised use of diethylstilbestrol during pregnancy became clear, details of that injury are still being filled in as the individuals concerned grow older. The picture will continue to develop as long as this generation of individuals lives, and it is even possible that findings in the third generation will throw light on the persisting injury to the family.

Psychological research among "DES daughters" has shown how traumatic it can be for a woman to learn of her prenatal exposure to diethylstilbestrol, and the extent to which this creates persistent uncertainty about her health; the failure of a physician to provide reliable information and continuing support can severely undermine her faith in health care (30).

Table 1 Outcomes in pregnancies exposed and not exposed to diethylstilbestrol

Outcome	Exposed (%)	Non-exposed (%)
Full-term delivery	64	85
Spontaneous abortion	19	10
Preterm delivery	12	4.1
Ectopic pregnancy	4.2	0.8

Long-term studies of the pregnancy experiences of women exposed to diethylstilbestrol in utero, compared with unexposed women, now include one in the US National Collaborative Diethylstilbestrol Adenosis cohort and one in the Chicago cohort and their respective non-exposed comparison groups. A review of questionnaire replies from 3373 exposed daughters and from controls has confirmed that diethylstilbestrol-exposed women were less likely than unexposed women to have had full-term live births and more likely to have had premature births, spontaneous pregnancy losses, or ectopic pregnancies (31). The data are shown in Table 1. Second-trimester spontaneous pregnancy losses were much more common in diethylstilbestrol-exposed women.

Other cancers

Long-term data are also accumulating on the actual incidence of genital cancer in women exposed to diethylstilbestrol in utero (32). In the Netherlands, a country in which diethylstilbestrol was used intensively in pregnancy, there is evidence that the risk of cervical cancer in these women is trebled, rather than doubled as was previously supposed (33).

- A diethylstilbestrol-exposed woman developed concurrent primary cancers of both the vagina and the endometrium at the age of 39 (34).

However, it is important to bear in mind that cases occur in which there is no history of the mother's having taken diethylstilbestrol during pregnancy. In one such case, HIV/AIDS infection was also a predisposing factor for vaginal carcinoma and this could explain a proportion of new cases that are being reported today (35).

A further follow-up and analysis of 3879 women, taken from two earlier US studies, who had been exposed to diethylstilbestrol during pregnancy has been presented (36). The results showed a modest association between diethylstilbestrol exposure and the risk of breast cancer (RR = 1.27; 95% CI = 1.07, 1.52). The increased risk was not further aggravated by a family history of breast cancer, by use of oral contraceptives, or by HRT. There was no evidence that diethylstilbestrol was associated with a raised risk of ovarian, endometrial, or other hormone-associated cancers.

Sensory systems

A study in the USA has produced some evidence that in people with amblyopia, those who were exposed to diethylstilbestrol before birth may be more likely to develop myopia (37).

Menstrual and vaginal disturbances

The effects of in-utero exposure to diethylstilbestrol on the menstrual cycle have been studied prospectively in 198 women and in 162 unexposed controls (38). A major limitation of this study was the exclusion of women with a severe menstrual abnormality. Exposure to diethylstilbestrol was associated with a statistical significantly lower duration of menstrual bleeding but not with dysmenorrhea. For most women exposed to diethylstilbestrol, any effects on reproductive hormonal function are in all probability minor, if present at all.

Even the classic genital manifestations of diethylstilbestrol in women who have been exposed to it in fetal life may be overlooked unless one is alert to them; vaginal discharge with ectropion should cause one to enquire as to possible prenatal diethylstilbestrol exposure (39).

Autoimmune disease

During the last 15 years, various additional aspects of the diethylstilbestrol problem have given rise to concern. One emerged in 1988 from a large multicenter epidemiological cohort study established by the US National Cancer Institute (DESAD Project), in which it was found that women exposed in utero to diethylstilbestrol had a 50% increased incidence of autoimmune disease (40).

Drug Administration

Drug formulations

The parenteral formulation diethylstilbestrol diphosphate is less commonly used than the oral formulation. In Japan, 24 elderly patients with advanced relapsed prostatic cancer were treated with high doses supplemented with ethinylestradiol (doses unclear); there was some slight therapeutic effect, but there were gastrointestinal symptoms and fluid retention (41). Also in Japan, a few patients with advanced disease were treated using intravenous diethylstilbestrol diphosphate 500 mg/day for 20 consecutive days to a total dose of 10 g; the authors' conclusion was more positive but adverse events were not specified (42).

Drug contamination

Contamination of isoniazid tablets with diethylstilbestrol was the cause of several cases of precocious puberty in a children's tuberculosis ward (43).

Diethyltoluamide

General Information

Diethyltoluamide is an insect repellent.

Organs and Systems

Nervous system

Toxic encephalopathy has been reported in children sprayed repeatedly with diethyltoluamide 10–15% (1).

Psychological, psychiatric

Acute manic psychosis has been attributed to percutaneous absorption of diethyltoluamide (SEDA-12, 138).

Reference

Difenpiramide

See also Non-steroidal anti-inflammatory drugs

General Information

Difenpiramide, a phenylacetic acid derivative, is less efficacious but has fewer adverse effects than indometacin or phenylbutazone. The most frequent reactions are in the gastrointestinal tract and skin (1). However, gastrointestinal tolerance is, as one would expect, better (2).

Difetarsone

General Information

Difetarsone is a pentavalent arsenical that often causes minor adverse effects, such as rashes, nausea, vomiting, and abdominal discomfort. Transient increases in transaminase activities can occur (SEDA-13, 834) (1).

Organs and Systems

Immunologic

Generalized angioedema occurred in a patient taking difetarsone 500 mg tds for *Entamoeba histolytica* infection (SEDA-11, 597) (2).

Diflunisal

General Information

Diflunisal is a fluorinated salicylic acid derivative, which is absorbed unchanged from the gastrointestinal tract, reaching peak concentrations after about 2 hours, and is metabolized by glucuronidation (1). Its adverse effects and other characteristics are those of aspirin, although gastrointestinal haemorrhage may be less common (2).

Diftalone

General Information

Because of hepatotoxicity and carcinogenicity (hepatoma) detected in preclinical studies, and hemotoxicity and gastrointestinal adverse effects in man, diftalone has been withdrawn by its manufacturer (1).

Reference

1. Anonymous. Dow Lepetit drops diftalone. Scrip 1977; October 15;22.

Dihydrocodeine

See also Opioid analgesics

General Information

Dihydrocodeine is an opioid analgesic related to codeine, in which the double bond in the 7th position is saturated. It is about one-tenth as potent as morphine and 2–3 times more potent than codeine. It is similar to codeine in other respects. The most common adverse effects are nausea, vomiting, and drowsiness (SEDA-16, 79) (SEDA-17, 80) (SEDA-18, 79).

In a randomized, double-blind comparison of the antitussive effect of dihydrocodeine 10 mg tds with levodropropizine 75 mg tds in 140 adults with primary lung cancer or metastatic cancer there was no significant difference between the two drugs as far as cough severity and the numbers of night wakings were concerned, both drugs leading to significant improvement (1). However, dihydrocodeine caused significantly more somnolence, which was reported by 11% and in some cases was continuous. Other adverse effects reported by those taking dihydrocodeine included erythema of the abdomen and epigastric pain, although constipation, a potential adverse effect of codeine derivatives, was not reported.

Organs and Systems

Sensory systems

Severe narcosis after therapeutic doses (2) has been reported.

Urinary tract

Acute renal insufficiency after therapeutic doses (2) has been reported.

Dihydrocodeine was implicated in cases of granulomatous interstitial nephritis (3).

Immunologic

Anaphylaxis has been reported with dihydrocodeine (4).

Susceptibility Factors

Age

There is a risk in giving dihydrocodeine to the elderly (2).

Renal disease

There is a risk in giving dihydrocodeine to those with renal insufficiency (2).

Drug Administration

Drug formulations

A modified-release formulation extends the duration of action of dihydrocodeine from 2–4 hours to 12 hours. In 12 volunteers who took modified-release dihydrocodeine 60 mg or 120 mg and 120 minutes later lactulose 40 mg diluted in 100 mg of water, the orocecal transit time was significantly prolonged by dihydrocodeine compared with placebo (5). Dihydrocodeine also significantly suppressed the pupillary light reflex. Both dosages caused similar adverse effects. Tiredness and dry mouth were reported in 80%, vertigo in 5%, and headache in 1%.

Dilevalol

See also Beta-adrenoceptor antagonists

General Information

Dilevalol is one of the four enantiomers of labetalol. It was withdrawn from the market by its manufacturers in early 1991 because of an unacceptably high incidence of liver damage (1).

Reference

1. Harvengt C. Labetalol hepatoxicity. Ann Intern Med 1990;114:341.

Diloxanide

General Information

Diloxanide often causes flatulence and, occasionally, nausea, vomiting, diarrhea, urticaria, and pruritus. It is an excellent luminal amebicide and is indicated after treatment with the 5-nitroimidazole compounds, which have relatively weak activity on the cyst stage. Experience over 14 years has been summarized by the Centers for Disease Control and Prevention (CDC, Atlanta), confirming the minimal toxicity of diloxanide. Fewer adverse effects were reported in patients aged 20 months to 10 years than in those aged over 10 years. There is no record of interactions between diloxanide and either metronidazole or tinidazole (SEDA-13, 830) (SEDA-17, 333).

Diltiazem

See also Calcium channel blockers

General Information

Diltiazem is a benzthiazepine calcium channel blocker.

Organs and Systems

Cardiovascular

Diltiazem can be associated with heart block (1,2). In a randomized trial in patients with non-Q-wave myocardial infarction, 38 of 287 patients who took diltiazem developed some degree of atrioventricular block at some time. Of these episodes, 32 were first-degree, eight were second-degree, and only two were third-degree. In the placebo-treated group there were 10 events in 289 patients; eight were first-degree, two second-degree, and none third-degree.

Atrioventricular block has been reported in three patients taking therapeutic doses of diltiazem; one died (3).

- A 47-year-old man taking furosemide for hypertension was given diltiazem 300 mg/day to achieve better blood pressure control; 1 month later he developed atrioventricular block, resolved by atropine.
- A 62-year-old hypertensive man with renal artery stenosis, an adrenal adenoma, peripheral artery disease, and an abdominal aortic aneurysm developed a hypertensive crisis with chest pain. He was treated with nitrates, heparin, aspirin, and nicardipine, which were afterwards replaced by diltiazem 200 mg/day, because of persistent chest pain. He developed atrioventricular block 2 hours after the second dose of diltiazem, and was successfully treated with a pacemaker.
- A 59-year-old woman with a previous myocardial infarction, hypertension, diabetes, and uterine cancer developed angina. She was treated with nitrates, aspirin, and heparin; diltiazem 200 mg/day was then added because of persistent chest pain. She developed atrioventricular block 72 hours later, and despite resuscitative efforts died in electromechanical dissociation.

Following the publication of a report of heart block (4), further cases (junctional bradycardia, sinoatrial block) have been reported (5).

Nervous system

Paresthesia of the hands and feet has been reported with diltiazem (SEDA-17, 237). Akathisia has been attributed to diltiazem (6). Parkinsonism associated with diltiazem has been reported (7).

- A 53-year-old man with hypertension took diltiazem 60–120 mg/day for 5 years and then developed parkinsonism. His neurological symptoms were treated without success and only after the substitution of diltiazem with an ACE inhibitor did his parkinsonian symptoms begin to regress, with eventual complete recovery.

Urinary tract

Diltiazem was associated with the development of acute renal insufficiency in a patient being treated for severe retrosternal chest pain who had neither primary kidney disease nor urinary tract obstruction (8,9).

Acute interstitial nephritis has been attributed to diltiazem (9).

- A 53-year-old man was given diltiazem for precordial pain and about 2 hours later developed an erythematous maculopapular rash mainly on the trunk and lower limbs. Four days later he developed abdominal pain radiating to both renal angles, accompanied by dysuria and tenesmus and followed 6 days later by acute renal insufficiency associated with raised liver function test results.

In this case, the self-limiting resolution in 4–5 days without relapse, the presence of the skin rash, and the liver sequelae suggested a common immunoallergic mechanism. The clinical symptoms, the time relation between drug administration and the occurrence of the syndrome, the inability to explain the syndrome otherwise, and its disappearance on withdrawal of diltiazem support an association with the drug.

A retrospective analysis of postoperative renal function in patients undergoing cardiac operations has been conducted to evaluate whether the use of prophylactic intravenous diltiazem, in order to reduce the incidence of ischemia and dysrhythmias, was associated with increased renal dysfunction (10). The incidence of acute renal insufficiency requiring dialysis was 4.4% with diltiazem versus 0.7% in the controls. Logistic regression analysis suggested that the risk of acute renal insufficiency was strongly associated with intravenous diltiazem, age, baseline serum creatinine, the presence of left main coronary disease, and the presence of cerebrovascular disease.

Skin

Skin reactions ranging from exanthems to severe adverse events have been reported in association with diltiazem

© 2006 Elsevier B.V. All rights reserved.

(SED-13, 513) (SEDA-18, 215) (SEDA-22, 216). Three cases of skin reactions (hypersensitivity syndrome reaction, pruritic exanthematous eruption, and acute generalized exanthematous pustulosis) possibly induced by diltiazem have been described and the literature on skin reactions associated with calcium antagonists has been reviewed. The number of diltiazem-induced cutaneous events was significantly greater than those induced by either nifedipine or verapamil. However, there was no difference in the proportion of serious cutaneous adverse events due to any of these three drugs (11).

Cutaneous vasculitis (12) and angioedema (13,14) have been reported with diltiazem. In 1988, the Federal German Health Authorities imposed a warning of dermal hypersensitivity reactions (including erythema multiforme) with diltiazem.

- Acute generalized exanthematous pustulosis in an 82-year-old woman was confirmed as being due to diltiazem by a positive patch test (15).
- Exfoliative dermatitis with fever occurred in a 69-year-old man with ischemic heart disease treated with mexiletine and diltiazem for three weeks; the rash resolved after withdrawal of both drugs and systemic corticosteroid therapy. Patch tests with mexiletine and diltiazem were positive. In addition to this case, 39 cases of drug eruption due to diltiazem have been reported in Japan (16).
- Lichenoid purpura of 6 months' duration occurred in a 65-year-old man with hypertension who had taken diltiazem for 1 month. Topical therapy with a very potent glucocorticoid was not effective and the eruption began to regress only after diltiazem withdrawal, after which it disappeared 3 weeks later (17).

Four cases of photodistributed hyperpigmentation associated with long-term administration of a modified-release formulation of diltiazem hydrochloride have been reported (18). All the patients were African-American women, mean age 62 (range 49–72) years. The duration of diltiazem administration before the development of hyperpigmentation was 6–11 months. The hyperpigmentation was slate-gray and reticulated. Phototesting during diltiazem therapy showed a reduced minimal erythema dose to UVA in one patient. Histological examination showed lichenoid dermatitis with prominent pigmentary incontinence. Electron microscopy showed multiple melanosome complexes. Withdrawal of diltiazem resulted in gradual resolution of the hyperpigmentation.

Acute generalized exanthematous pustular dermatitis has been reported after diltiazem (19).

Drug Administration

Drug overdose

Several cases of accidental or deliberate self-poisoning with calcium antagonists have been described (SED-12, 452) (SEDA-16, 198) (SEDA-20, 186) and different approaches to the management of these patients have been proposed.

- A 52-year-old woman with essential hypertension erroneously took a 7-day supply of modified-release diltiazem, enalapril, and trichlormethiazide, and 30 minutes later complained of nausea (20). She was treated with gastric lavage, calcium gluconate, activated charcoal, and polyethylene glycol. Her blood pressure and heart rate fell progressively to 120/62 mmHg and 40/minute respectively, 14 hours after ingestion. Afterwards, her hemodynamic status gradually normalized without further treatment.
- A 54-year-old man with severe triple vessel coronary artery disease took six modified-release diltiazem tablets 180 mg following an episode of severe angina, and 10 hours later developed bradycardia, hypotension, and severe pulmonary edema, but was free of chest pain (21). After intensive hemodynamic monitoring and noradrenaline treatment, his renal, respiratory, and cardiac problems recovered to baseline over the next 48 hours. Diltiazem overdose was confirmed by a diltiazem serum concentration of 1230 ng/ml (usual target range 40–160 ng/ml).
- A 15-year-old woman intentionally took 10 modified-release tablets of diltiazem 200 mg. She developed hypertension, oliguria, pulmonary edema, and respiratory distress syndrome, and required mechanical ventilation for 3 days, besides intravenous calcium, dopamine, and noradrenaline. After 5 days in an intensive care unit, she was transferred to a psychiatric hospital in good physical condition (22).
- A 50-year-old man took 28 modified-release tablets of diltiazem 240 mg and 28 tablets of hydrochlorothiazide and 12–14 hours later became lethargic but oriented and complaining of nausea and dizziness; he had bradypnea, hypotension, and second-degree heart block with bradycardia (23). He was given activated charcoal, oxygen, atropine, glucagon, and calcium gluconate by prolonged infusion. His heart rate, blood pressure, and electrocardiogram recovered to baseline over the next 24 hours, with no further episodes of dysrhythmias or hypotension.
- A 38-year-old white man with a history of coronary artery disease, myocardial infarction, coronary artery by-pass, alcoholism, and depression took a combined massive overdose of diltiazem and atenolol (24). He underwent cardiopulmonary resuscitation because of cardiac arrest; bradycardia, hypotension, and oliguria followed and were resistant to intravenous pacing and multiple pharmacological interventions, including intravenous fluids, calcium, dopamine, dobutamine, adrenaline, prenalterol, and glucagon. Adequate mean arterial pressure and urine output were restored only after the addition of phenylephrine and transvenous pacing. He survived despite myocardial infarction and pneumonia.

Drug–Drug Interactions

Ciclosporin

Many studies have shown an interaction of ciclosporin with diltiazem: concomitant administration allows reduction of the daily dose of ciclosporin. However, according to a study in eight renal transplant recipients, the low systemic availability and high degree of variation in

© 2006 Elsevier B.V. All rights reserved.

diltiazem metabolism within and between patients can give unpredictable results (25).

Diltiazem abolishes the acute renal hypoperfusion and vasoconstriction induced by ciclosporin in renal transplant patients. Plasma endothelin-1 may be a mediator of ciclosporin-induced renal hypoperfusion, but is not affected by diltiazem (26). This interaction has been confirmed with a new microemulsion formulation of ciclosporin in nine patients with renal transplants who took diltiazem 90–120 mg bd for 4 weeks (27). Diltiazem caused a 51% increase in the AUC of ciclosporin and a 34% increase in peak concentration, without altering the time to peak concentration. However, the ciclosporin microemulsion did not significantly affect the pharmacokinetics of diltiazem.

- Ciclosporin-induced encephalopathy was precipitated by diltiazem in a 76-year-old white woman with corticosteroid-resistant aplastic anemia and thrombocytopenia, type 2 diabetes, and coronary artery disease, who was taking diltiazem for hypertension (28). She became comatose after 13 days of therapy with ciclosporin, and clinical examination and electroencephalography showed diffuse encephalopathy of moderate severity. Ciclosporin was withdrawn and she regained consciousness after 36 hours.

Concomitant diltiazem without proper dosage adjustment of ciclosporin can cause adverse neurological events.

Methylprednisolone

Co-administration of diltiazem with methylprednisolone increased plasma concentrations of methylprednisolone and its adrenal suppressant effects in nine healthy volunteers (29). Care should be taken when these two drugs are co-administered for a long period, even if the clinical relevance of this pharmacokinetic interaction still needs to be evaluated.

Sildenafil

Sildenafil is metabolized predominantly by CYP3A4, which diltiazem inhibits. An interaction of diltiazem with sildenafil has been reported (30).

- A 72-year-old man, who regularly took aspirin, metoprolol, diltiazem, and sublingual glyceryl trinitrate for stable angina, reported chest pain during elective prognostic coronary angiography, which resolved with half of a sublingual tablet of glyceryl trinitrate. Within 2 minutes he developed severe hypotension, with an unchanged electrocardiogram and no evidence of anaphylaxis. He had taken sildenafil 50 mg 48 hours before angiography.

The interval after which even short-acting nitrates can be safely given after the use of sildenafil is likely to be substantially longer than 24 hours when elderly patients are concurrently taking a CYP3A4 inhibitor, such as diltiazem.

Sirolimus

The pharmacokinetic interaction of a single oral dose of diltiazem 120 mg with a single oral dose of sirolimus 10 mg has been studied in 18 healthy subjects, 12 men and 6 women, 20–43 years old, in an open, three-period, randomized, crossover study (31). The whole-blood sirolimus AUC increased by 60% and the C_{max} by 43% with diltiazem co-administration; the apparent oral clearance and volume of distribution of sirolimus fell by 38 and 45% respectively, consistent with the change in half-life from 79 to 67 hours. Sirolimus had no effect on the pharmacokinetics of diltiazem or on the effects of diltiazem on either diastolic or systolic blood pressures or the electrocardiogram. Single-dose diltiazem co-administration leads to higher sirolimus exposure, presumably by the inhibition of first-pass metabolism. Because of pronounced intersubject variability in this interaction, whole-blood sirolimus concentrations should be monitored closely in patients taking the two drugs.

Statins

Atorvastatin

Rhabdomyolysis and acute hepatitis have been reported in association with the co-administration of diltiazem and atorvastatin (32).

- A 60-year-old African-American man developed abdominal pain, a racing heart, and shortness of breath over 24 hours. He had also noticed increasing fatigue and reduced urine output over the previous 2–3 days. He had been taking several medications, including atorvastatin, for more than 1 year, but diltiazem had been added 3 weeks before for atrial fibrillation. On the basis of laboratory findings and physical examination, a diagnosis of acute hepatitis and rhabdomyolysis with accompanying acute renal insufficiency was made. His renal function gradually normalized and his CK activity reached a maximum of 2092 units/l on day 1 and fell to 623 units/l on discharge. His liver function tests returned to normal by 3 months.

While rhabdomyolysis from statins is rare, the risk is increased when they are used in combination with agents that share similar metabolic pathways. Atorvastatin is metabolized by CYP3A4, which is inhibited by diltiazem.

Lovastatin

The effects of co-administration of oral diltiazem, a potent inhibitor of CYP3A, on the pharmacokinetics of lovastatin have been evaluated in a randomized study in 10 healthy volunteers (33). Lovastatin is oxidized by CYP3A to active metabolites. Diltiazem significantly increased the oral AUC and maximum serum concentration of lovastatin, but did not alter its half-life. The magnitude of the increase of plasma concentration of lovastatin suggested that caution is necessary when co-administering diltiazem and lovastatin.

In another study by the same investigators, 10 healthy volunteers were randomized in a two-way, crossover study either to oral lovastatin or to intravenous diltiazem followed by oral lovastatin. Intravenous diltiazem did not significantly affect the pharmacokinetics of lovastatin (oral AUC, C_{max}, t_{max}, or half-life), suggesting that the interaction does not occur systemically and is primarily a first-pass effect (34). Drug interactions with diltiazem may therefore become evident when a patient is changed from intravenous to oral dosing.

© 2006 Elsevier B.V. All rights reserved.

Pravastatin

The effects of co-administration of diltiazem, a potent inhibitor of CYP3A, on the pharmacokinetics of pravastatin have been evaluated in a randomized study in 10 healthy volunteers (33). Pravastatin is active alone and is not metabolized by CYP3A. Diltiazem did not alter the oral AUC, maximum serum concentration, or half-life of pravastatin.

Simvastatin

The interaction of diltiazem with simvastatin has been investigated in 135 patients attending a hypertension clinic (35). Cholesterol reduction in the 19 patients taking diltiazem was 33% compared with 25% in the other 116 patients (median difference 8.6%; 95% CI = 1.1, 12). Multivariate analysis showed that concurrent diltiazem therapy, age, and the starting dose of simvastatin were independent predictors of percentage cholesterol response. The authors concluded that patients who take both diltiazem and simvastatin may need lower doses of simvastatin to achieve the recommended reduction in cholesterol.

Results from two clinical studies of the interaction of diltiazem with simvastatin showed that diltiazem increased the C_{max} of simvastatin (36) and enhanced its cholesterol-reducing effect (35).

In 10 healthy volunteers taking oral simvastatin 20 mg/day, diltiazem 120 mg bd for 2 weeks significantly increased the simvastatin C_{max} 3.6-fold, the AUC 5-fold, and the half-life 2.3-fold (36). There were no changes in the t_{max} of simvastatin or simvastatin acid.

Of 135 patients attending a hypertension clinic who were taking simvastatin for primary or secondary prevention of coronary heart disease, 19 were also taking diltiazem (35). The cholesterol reduction in the 19 patients taking diltiazem was significantly higher than in the other 116 (33 versus 25%), with less interindividual variability. Concurrent diltiazem therapy, age, and the starting dose of simvastatin were significant independent predictors of the percentage cholesterol response.

Rhabdomyolysis due to an interaction of simvastatin with diltiazem has been reported (37).

- A 75-year-old-man taking simvastatin 80 mg/day and diltiazem 240 mg/day developed extreme weakness and diffuse muscle pain. All drugs were withdrawn and he underwent hemodialysis. Within 3 weeks his muscle pain disappeared and he regained function in his legs. The activities of creatine kinase and transaminases gradually returned to normal, but he continued to need hemodialysis.

Tacrolimus

Diltiazem can increase the blood concentration of the macrolide immunosuppressant tacrolimus (38).

- A 68-year-old man developed diarrhea, dehydration, and atrial fibrillation 4 months after liver transplantation. He was taking tacrolimus (blood concentration 13 ng/ml) and was given a continuous infusion of diltiazem for 1 day followed by oral therapy. Three days later he became delirious, confused, and agitated, and the blood concentration of tacrolimus was 55 ng/ml. His mental status gradually improved after withdrawal of both drugs.

The mechanism of this interaction is likely to be the inhibition of tacrolimus metabolism in the intestine and liver by the inhibition of CYP3A4 and P glycoprotein.

Dimenhydrinate

See also Antihistamines

General Information

Dimenhydrinate (SEDA-21, 173) is an antihistamine, the diphenhydramine salt of 8-chlorotheophylline.

Organs and Systems

Sensory systems

Dimenhydrinate altered color discrimination, night vision, reaction time, and stereopsis in healthy volunteers (1).

Skin

Diphenhydramine has been associated with a fixed drug eruption, but only three such cases have been published with dimenhydrinate. In one such case patch tests were conducted; there was a positive response to the dimenhydrinate patch, but negative responses to separate patches containing either dimenhydrinate or 8-chlorotheophylline.

Dimercaprol

General Information

Dimercaprol or British Anti-Lewisite (BAL) was originally developed to counteract arsenic-containing war gases (1). It is now used for the treatment of poisoning with heavy metals, such as arsenic, gold, lead, or mercury, and is administered by intramuscular injection. Its adverse effects include nausea, vomiting, a burning sensation in the mouth, throat, eyes, and sometimes limbs, muscle pain and spasms, lacrimation, rhinorrhea, and hypersalivation. Of importance are a raised blood pressure and tachycardia. Pain in head, teeth, or abdomen can occur. The symptoms develop soon after injection and subside within about 2 hours. Injections can be painful and give rise to sterile abscesses. Fever can occur.

Susceptibility Factors

Genetic factors

Dimercaprol is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency, because of the risk of hemolysis (2,3).

Dimercaptopropane sulfonate

General Information

Dimercaptopropane sulfonate (2,3-dimercapto-1-propanesulfonate) is a water-soluble and possibly less toxic derivative of dimercaprol, used in poisoning with arsenic, bismuth, mercury, and other heavy metals.

- Dimercaptopropane sulfonate is the treatment of choice for acute arsenic poisoning and has been used safely in high doses (15.25 g in 12 days, first intravenously and later orally) in a 21-year-old man who swallowed about 1000 mg or more of arsenic trioxide (1). There were no adverse effects. A modest transient increase in serum transaminases was thought to have been due to the arsenic.

In a UK study, single oral doses of dimercaptopropane sulfonic acid or succimer in different combinations with or without acetylcysteine and potassium citrate were given to 191 patients considered to have mercury toxicity from amalgam dental fillings (2). After a single dose, about 5% of patients complained of mild gastrointestinal discomfort, fatigue, mental fuzziness, headache, and diuresis. These usually cleared within 6 hours of the dose and were considered to be due to heavy metal mobilization. There were no cases of hypersensitivity.

Reported adverse effects of dimercaptopropane sulfonate include nausea, vertigo, headache, weakness, pruritus, and allergic reactions, such as rashes (3–6). Nausea can occur after both oral and intravenous administration.

Dimetacrine

See also Tricyclic antidepressants

General Information

Dimetacrine is a 6,6,6 tricyclic acridine derivative. In a double-blind study, dimetacrine was less effective than imipramine and produced more weight loss and abnormal liver function tests more often (1).

Dimethylsulfoxide

General Information

Dimethylsulfoxide is an agent with a wide spectrum of pharmacological effects, including membrane penetration, anti-inflammatory effects, local analgesia, and weak bacteriostasis. The principal use of dimethylsulfoxide is as a vehicle for other drugs, thereby enhancing the effect of the drug, and aiding penetration of other drugs into the skin. Dimethylsulfoxide has been given orally, intravenously, or topically for a wide range of indications. It is also given by bladder instillation in the symptomatic relief of interstitial cystitis, and is used as a cryoprotectant for various human tissues.

In preparation for bone marrow transplantation, autologous hemopoietic stem cells are normally frozen in liquid nitrogen after harvesting. However, a cryoprotective agent is required, and dimethylsulfoxide is normally used. During and immediately after stem cell infusion, many adverse effects, which may be severe or life-threatening, have been reported. They include hypotension and hypertension, anaphylactic reactions, and cardiac and respiratory failure, all possibly due to dimethylsulfoxide, hemolysis induced by cryopreservation and thawing, and fluid overload.

In a retrospective study, 30 children were reviewed after bone marrow or peripheral autologous hemopoietic transplantation (1). At the time of infusion, hydrocortisone, chlorphenamine, and hyperhydration were administered to all patients, and furosemide and tropisetron to most. Vital signs and symptoms were monitored for 6 hours after the infusion. Thawing was performed rapidly at the bedside in a 42°C water-bath, and the cells were infused through a central venous catheter at 10 ml/minute. All 32 procedures were well tolerated; there were infusion-related adverse effects in 15 of 32 infusions, but none required specific therapy. There was mild bradycardia in nine patients, one reported abdominal pain, two reported headache, and three had hemoglobinuria. The authors concluded that a single-step cryopreservation technique aimed at limiting the total

© 2006 Elsevier B.V. All rights reserved.

amount of dimethylsulfoxide is effective in avoiding most toxicity while not compromising post-thawing viability.

The efficacy and safety of dimethylsulfoxide are still relatively unclear; few studies have been performed in such a way as to permit reliable conclusions. Dimethylsulfoxide penetrates quickly through the tissues, and there are no great differences between its effects after different routes of administration. Adverse reactions are common, but can be avoided in large part by using more dilute solutions (2). Although the systemic toxicity of dimethylsulfoxide is considered to be low, it can potentiate the effect of simultaneously administered drugs. Combinations of dimethylsulfoxide with other toxic agents probably constitute its greatest toxic potential (3).

Organs and Systems

Nervous system

The infusion of dimethylsulfoxide-cryopreserved autologous peripheral blood stem cells has been associated with a number of infusion-related adverse effects (4). Severe reversible encephalopathy was experienced by two patients after infusion of peripheral blood stem cells cryopreserved in 10% dimethylsulfoxide. In one patient, reduction of the plasma dimethylsulfoxide concentration by plasmapheresis resulted in marked improvement in encephalopathy (5). The presence of renal insufficiency may have predisposed to the development of neurological toxicity by delaying the excretion of dimethylsulfoxide and its metabolites. Other cases of dimethylsulfoxide-induced encephalopathy have been described (6–8).

Sensory systems

Animal studies have documented a characteristic change in the ocular lens, resulting in myopia, which becomes more severe with long-term administration or high concentrations of dimethylsulfoxide. However, studies and clinical experience have not shown similar effects in humans (9,10)

Hematologic

Intravenous dimethylsulfoxide poses the greatest problems and causes transient systemic hemolysis with hemoglobinuria, but without gross hematuria. The hemolysis is dose-dependent and appears within several minutes after infusions of dimethylsulfoxide 20–40% (11). There was no evidence of kidney damage because of handling higher amounts of hemoglobin after hemolysis.

Sulfhemoglobinemia has been reported after transdermal administration of dimethylsulfoxide (12).

Gastrointestinal

Dimethylsulfoxide caused gastrointestinal discomfort in volunteers who used a topical 80% solution (1 g/kg/day). Nausea developed in 32%, vomiting in 6%, diarrhea in 5%, constipation in 3%, and anorexia in 2% (6).

A garlic-like breath occurs in almost all patients who use topical dimethylsulfoxide (13) and probably by any other route of administration.

Skin

Dimethylsulfoxide has also been used to treat extravasation of vesicant drugs (14). However, dimethylsulfoxide can itself cause redness and blistering at the site of application in high concentrations (90–100%); this effect can be reduced by using it sparingly or in lower concentrations (70%).

Drug Administration

Drug formulations

A formulation of dimethylsulfoxide (RIMSO 100) has introduced a problem since, when it is diluted with water, a strong exothermic reaction results. This caused thermal injury on intracystic instillation unless one waits until the mixture cools (15).

Dimetindene

See also Antihistamines

General Information

Dimetindene (SEDA-21, 174) is a first-generation antihistamine. The limited published material does not suggest that the adverse reactions to dimetindene when given orally are significantly different to those of others (1). It has also been used as a nasal spray in cases of allergy (2); some local irritation can occur, as is usual with this type of administration of antihistamines.

Dinitrochlorobenzene

General Information

Dinitrochlorobenzene is a potent sensitizer that has been applied topically in the evaluation of delayed hypersensitivity. It has also been used as an immunostimulant in conditions such as leprosy, HIV infection, and some forms of cancer, and to treat alopecia and warts.

Generalized urticaria, pruritus, and dyspepsia developed in a previously healthy individual who used dinitrochlorobenzene for alopecia totalis; all the symptoms disappeared within 10 days after the drug was withdrawn, but returned after reintroduction (1).

Organs and Systems

Skin

A woman developed an itchy brownish patch on the right upper arm, in the same place where she had previously been sensitized by dinitrochlorobenzene 2% in acetone (2). A diagnosis of lymphadenosis benigna cutis was made.

References

2. Yoshida Y, Duan H, Nakayama J, Furue M. Lymphadenosis benigna cutis induced by iatrogenic contact dermatitis from dinitrochlorobenzene. Contact Dermatitis 2003;49(3):165–6.

Dinoprostone

See also Prostaglandins

General Information

Dinoprostone is PGE_2 available for exogenous administration.

Organs and Systems

Reproductive system

Uterine rupture occurred after labor had been induced with dinoprostone at 10 days after term; the baby was born dead (1).

- A 26-year-old woman, whose first child had been delivered by elective cesarean section at 38 weeks of gestation because of a breech presentation, was given two doses of dinoprostone vaginal gel 1 mg 6 hours apart; 8 hours after the second dose her cervix was soft, fully effaced, and dilated to 3 cm. Since her uterine contractions were only mild and irregular, she underwent amniotomy and an infusion of oxytocin was begun. Fetal tachycardia occurred 4 hours later, with recurrent decelerations. Prolonged deceleration of the fetal heart then occurred and there was fresh vaginal bleeding. Uterine rupture was suspected and the neonate was delivered by emergency cesarean section, but could not be resuscitated. The mother required a blood transfusion, but subsequently made a good recovery.

The authors commented that induction with prostaglandins in women with a previous lower segment cesarean scar is associated with a risk of symptomatic scar rupture no greater than 0.6%, and the vaginal delivery rate is about 75%, that is similar to rates quoted for spontaneous labor in women with a cesarean scar. At present, faced with the lack of comparative evidence, clinicians can only

© 2006 Elsevier B.V. All rights reserved.

provide women with the best estimate of risk based on uncontrolled observational data.

Dioxium

General Information

Dioxium is obsolete. Accounts of its adverse effects will be found in earlier volumes in this series (SED-10, 213) (SEDA-6, 131).

Diphencyprone

General Information

Diphencyprone is a potent sensitizing chemical used to induce a contact dermatitis of the scalp in the topical immunotherapy of alopecia areata.

Organs and Systems

Immunologic

- Pressure-induced urticaria and widespread severe dermographism developed after the first application to the scalp of a 0.003% solution of diphencyprone in a 19-year-old Japanese man (1). Diphencyprone was withdrawn, but the symptoms persisted for almost 3 months.

An IgE-mediated hypersensitivity reaction was suggested by the authors, but skin tests were not performed and neither was specific IgE measured. A similar case has been described and the adverse events of diphencyprone reviewed (2).

2. Alam M, Gross EA, Savin RC. Severe urticarial reaction to diphenylcyclopropenone therapy for alopecia areata. J Am Acad Dermatol 1999;40(1):110–12.

Diphenhydramine

See also Antihistamines

General Information

Diphenhydramine is a typically sedating first-generation antihistamine. It is still widely used, mainly in over-the-counter products, often in combination with other drugs.

Diphenhydramine inhibits CYP2D6 and can cause clinically important interactions with many CYP2D6 substrates, particularly those with a narrow therapeutic index.

Organs and Systems

Nervous system

Diphenhydramine can cause significant daytime neurological impairment comparable to intoxication with alcohol (1). In a study of injury rates in 12 106 patients taking diphenhydramine compared with 24 968 patients taking loratadine, using a health-care claims database that included employees, dependents, and retirees who filed claims from January 1991 to December 1998, there was a strong association between the use of diphenhydramine and the occurrence of injuries: 55% of all injuries were associated with its use. The loratadine and diphenhydramine groups had similar predrug intake injury rates. The authors concluded that a substantial number of excess injuries and costs had been incurred as the result of the use of diphenhydramine (2).

Neuroleptic malignant syndrome has been attributed to diphenhydramine (3).

- A 39-year-old man presented with a gait disturbance confusion, hyperthermia (38.2°C), and hyperhidrosis after massive ingestion of a formulation containing diphenhydramine. With intensive support, including bromocriptine, he recovered within 12 days. The estimated dose of diphenhydramine was 40 mg × 60 tablets, and each tablet included 26 mg of diprophylline, a xanthine derivative.

The genesis of this case was not clear. Atropine-like effects occur with diphenhydramine, although signs such as muscle rigidity, akinesia, and hyperhidrosis, cannot be ascribed to anticholinergic activity. However, the patient had also taken sulpiride, which is a potent dopamine receptor antagonist.

Diphenhydramine can cause extrapyramidal symptoms as part of an acute dystonic reaction (SEDA-19, 173).

Psychological, psychiatric

Use of diphenhydramine, mainly as a sleeping aid, has been associated with cognitive impairment in elderly people without dementia (4).

Diphenhydramine has been associated with acute delirium in elderly patients with mild dementia, even in single doses of 25 mg (SEDA-19, 173).

Children and adolescents who are given diphenhydramine as premedication, often intravenously as a bolus,

© 2006 Elsevier B.V. All rights reserved.

to prevent the adverse effects of blood transfusion, can develop drug-seeking behavior. It is recommended that in these circumstances antihistamines should be given orally or infused slowly (5).

Skin

- A 56-year-old woman developed itchy erythematous lesions on sun-exposed areas when she used diphenhydramine ointment 1% for 6 months; the condition gradually subsided with a glucocorticoid ointment (6).

Long-Term Effects

Drug abuse

Abuse of antihistamines in Scandinavia has been found in schoolchildren, and particularly involved diphenhydramine (alone or in combination with caffeine). As a consequence such formulations were changed from over-the-counter to prescription-only status (7,8). Abuse of diphenhydramine with drug-seeking behavior and anticholinergic adverse effects have been reported in five children and adolescents with chronic hematological or oncological diseases (5).

Reinforcing, subjective, and performance effects have been compared between oral diphenhydramine and the benzodiazepine lorazepam in men with a history of recreational abuse, and the results suggested that the two drugs have similar abuse potential (SEDA-21, 174).

Drug tolerance

In 15 healthy men tolerance to diphenhydramine developed rapidly in a randomized, placebo-controlled, crossover study (9). Diphenhydramine 50 mg or placebo was given twice a day for 4 days and tests of objective and subjective sleepiness together with computer-based tests of psychomotor performance were carried out. Compared with placebo on day 1, diphenhydramine caused significant impairment. However, by day 4 sleepiness and impairment of performance were indistinguishable from placebo.

Drug Administration

Drug administration route

Topical application of diphenhydramine can cause systemic toxicity.

- Acute anticholinergic toxicity with fever, hallucinations, and tachycardia occurred in a 2.5-year-old boy from applications of calamine + diphenhydramine lotion (10).
- A 5-year-old child who used a topical lotion containing 1% diphenhydramine for pruritic vesicular exanthema developed disorientation, agitation, dilated pupils, and ataxia (SEDA-13, 132).

Drug overdose

A total of 136 cases of self-poisoning with diphenhydramine (with suicidal intent) have been evaluated. The most common symptom was impaired consciousness, followed by psychotic behavior resembling catatonic stupor. Other symptoms included hallucinations, mydriasis, tachycardia, and less often diplopia, respiratory insufficiency, and seizures (SEDA-13, 132).

Although the clinical features of diphenhydramine overdose are well known, information about dose-dependent toxicity is still scarce. This has been investigated in patients with acute diphenhydramine poisoning in retrospective and prospective studies in 232 and 50 patients respectively (11). Mild symptoms (somnolence, anticholinergic signs, tachycardia, nausea/vomiting) occurred in 55–64% of patients, moderate symptoms (isolated and spontaneously resolving agitation, confusion, hallucinations, and electrocardiographic disturbances) in 22–27%, and severe symptoms (delirium/psychosis, seizures, coma) in 14–18%. Moderate symptoms occurred at doses over 0.3 g. For severe symptoms the critical dose limit was 1.0 g. Coma and seizures were significantly more frequent in those who took over 1.5 g compared with those who took 1.0–1.5 g. These data showed clear dose-dependent acute toxicity of diphenhydramine and suggested that only patients who take over 1.0 g are at risk of severe symptoms.

- A 35-year-old woman took diphenhydramine 16 g and developed hypertension and QRS prolongation; charcoal hemoperfusion and hemodialysis were used successfully (12).
- A 28-year-old died after an overdose of diphenhydramine. He developed hyperpyrexia and tachycardia and died from a cardiac arrest (13). Hemorrhagic pulmonary edema and renal shock were the most prominent findings. At the time of death, the plasma concentration of diphenhydramine was 5 μg/ml and there were particularly high concentrations in the lungs (55 mg/kg) and kidneys (50 mg/kg).

Rhabdomyolysis has been reported after overdose with diphenhydramine (SEDA-21, 175).

Drug–Drug Interactions

Metoprolol

Diphenhydramine inhibits the metabolism of metoprolol in extensive metabolizers, thereby prolonging its negative chronotropic and inotropic effects (14).

Prolintane

- Visual hallucinations occurred in an otherwise healthy 19-year-old man who took the stimulant prolintane and diphenhydramine (15). The psychiatric complications occurred 2 months after he started to take the two drugs and resolved quickly once they were withdrawn.

© 2006 Elsevier B.V. All rights reserved.

Venlafaxine

CYP2D6 is the major enzyme involved in the metabolism of venlafaxine, and diphenhydramine alters the disposition of venlafaxine, increasing plasma concentrations and predisposing to cardiovascular adverse effects (16).

Diphenoxylate

General Information

Diphenoxylate is a synthetic compound designed to have the antidiarrheal effects of the opiates, but it also retains some less desirable opiate effects. It is generally combined with atropine, as co-phenotrope, which was originally added to the formulation in the hope of preventing misuse, although it can itself cause problems, especially if the combination is intentionally or accidentally used to excess.

In one instance keratoconjunctivitis occurred in a patient taking co-phenotrope, confirmed by rechallenge but not with diphenoxylate alone (SEDA-16, 425). Adverse effects are rare during ordinary use in adults, but children can be particularly sensitive to the adverse effects of both components, and in cases of poisoning complex and prompt measures may be needed, particularly since respiratory depression can be delayed until a day after ingestion and can recur even after a good response to opioid antagonists.

Drug Administration

Drug overdose

Only six of 36 children who took overdoses of co-phenotrope had signs of atropine overdose (central nervous system excitement, hypertension, fever, flushed dry skin) (1). Opioid overdose (central nervous system and respiratory depression with miosis) predominated or occurred without any signs of atropine toxicity in 33 cases (92%). Diphenoxylate-induced hypoxia was the major problem and was associated with slow or fast respiration, hypotonia or rigidity, cardiac arrest, and in three cases cerebral edema and death. Respiratory depression recurred 13–24 hours after the ingestion in seven cases and was probably due to accumulation of difenoxine, an active metabolite of diphenoxylate. Recommended treatment is an intravenous bolus dose of naloxone, followed by a continuous intravenous infusion, prompt gastric lavage, repeated administration of activated charcoal, and close monitoring for 24 hours.

Drug–Drug Interactions

Nitrofurantoin

Co-phenotrope, and other drugs that reduce intestinal motility, can interact with other drugs by affecting their absorption. For example, the absorption of nitrofurantoin can be doubled (2).

Diphenylpyraline

See also Antihistamines

General Information

Diphenylpyraline is an antihistamine, a piperadine derivative, with antimuscarinic and sedative properties.

Organs and Systems

Skin

Cutaneous reactions have been reported with diphenylpyraline hydrochloride (1).

Reference

Diphtheria vaccine

See also Vaccines

General Information

Diphtheria vaccine contains diphtheria toxoid carried on aluminium hydroxide or calcium phosphate. Single antigen products are available only for cases in which combined antigens should not be used. The formulations used in most countries are a childhood formulation containing 25–30 Lf (flocculating units) of diphtheria toxoid (D) and an adult formulation containing 2 Lf of diphtheria toxoid (d). The formulations of choice in routine immunization are DTP (diphtheria and tetanus toxoids combined with pertussis vaccine), DT (diphtheria and tetanus toxoids) for pediatric use, and Td (tetanus and diphtheria toxoids with a limited amount of diphtheria antigen) for use in older children and adults.

Combined diphtheria + tetanus immunization

In a prospective cohort study in Italy, 380 children aged 6 years were randomly assigned to receive either the DT or the Td vaccine as a booster dose in order to determine whether a booster dose of Td (diphtheria–tetanus vaccine with a reduced amount of diphtheria toxoid, adult formulation) would produce comparable diphtheria antibody titers but lower reactogenicity than DT (childhood formulation). The frequencies of symptoms within 3 days of vaccine administration were similar in the two groups, except for local redness and swelling, which were significantly more common in the children who received DT vaccine: redness 31% versus 16%, and swelling 36% versus 26%. The mean duration of local symptoms was 3.3 days in the diphtheria–tetanus group and 2.6 days in the Td group. After booster immunization, 97% of children in the DT group and 91% of those in the Td group had antibody concentrations of at least 1 IU/ml ("long-term" protection titer) (1).

There have been comparisons of the immunogenicity and reactogenicity of different diphtheria vaccines. They have involved single or combined administration of diphtheria and/or tetanus toxoids (SEDA-13, 279) (SEDA-15, 345), booster immunization using Td vaccines including either aluminium hydroxide or calcium phosphate as adjuvant (SEDA-20, 288), or either plain or adsorbed formulations (SEDA-21, 328).

Adverse events after diphtheria–tetanus vaccine in the USA in 1982–84 have been reviewed in detail (SEDA-13, 273). The usual types of local intolerance can be seen. For example, some 5% of schoolchildren develop redness and swelling, whilst some older children develop enlargement of the regional lymph nodes. Such reactions are much less common in young children, and much more common in children given combined vaccines.

General reactions (seen in some older children and adults) are usually limited to brief fever; sustained fever and other systemic reactions are uncommon unless the person has been hyperimmunized. After the administration of DT vaccine, local reactions, generally erythema and induration, with or without tenderness, can occur. In hyperimmunized cases, Arthus-type hypersensitivity reactions can occur. These characteristically severe local reactions generally start 2–8 hours after an injection. People who have such reactions usually have very high serum antitoxin concentrations and one should be careful not to administer a booster more than once every 10 years.

The occurrence of epidemic diphtheria in Eastern Europe led to the recommendation in the UK that those aged 15–18 years should receive a combined tetanus and low-dose diphtheria toxoid vaccine instead of a tetanus booster alone. In March 1995, 220 children aged 14–16 years were inadvertently given high-dose diphtheria and tetanus toxoid vaccine, and their parents were sent a questionnaire; 153 replied. A total of 141 (92%) of adolescents reported one or more reactions, most of which were classified as mild or moderate and lasted less than 1 week. However, 47 (31%) reported at least one severe local or systemic reaction (2).

In a study of adverse events after immunization in New Zealand in 1990–95 (3), reactions at the injection site after adult tetanus–diphtheria vaccine (68 reports per 100 000 immunizations) were reported five times more often than with tetanus vaccine.

Combined diphtheria + tetanus + pertussis immunization

An overview of clinical trials with a special diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine has been published (4). The vaccine contains as pertussis components purified filamentous hemagglutinin, pertactin, and genetically engineered pertussis toxin. The vaccine induces high and long-lasting immunity and is at least as efficacious as most whole-cell pertussis vaccines and similar in efficacy to the most efficacious DTaP vaccines that contain three pertussis antigens. The vaccine is better tolerated than whole-cell vaccines and has a similar reactogenicity profile to other acellular vaccines.

© 2006 Elsevier B.V. All rights reserved.

A vaccine containing diphtheria and tetanus toxoids and DTaP with reduced antigen content for diphtheria and pertussis (TdaP) has been compared with a licensed reduced adult-type diphtheria–tetanus vaccine and with an experimental candidate monovalent DTaP vaccine with reduced antigen content (ap) (5). A total of 299 healthy adults (mean age 30 years) were randomized into three groups to receive one dose of the study vaccines. The antibody responses (antidiphtheria, antitetanus, antipertussis toxin, antipertactin, antifilamentous hemagglutinin) were similar in all groups. The most frequently reported local symptom was pain at the injection site (62–94%), but there were no reports of severe pain; redness and swelling with a diameter of 5 cm or more occurred in up to 13%. The incidence of local symptoms was similar after TdaP and Td immunization. The most frequently reported general symptoms were headache and fatigue (20–50%). The incidence of general symptoms was similar in the TdaP and Td groups. There were no reports of fever over 39°C. No serious adverse events were reported.

Data from the Third National Health and Nutrition Survey (1988–94) have been used to analyse the possible effects of DTP or tetanus immunization on allergies and allergy-related symptoms among 13 944 infants, children, and adolescents aged 2 months to 16 years in the USA (6). The authors concluded that DTP or tetanus immunization increases the risk of allergies and related respiratory symptoms in children and adolescents. However, the small number of non-immunized individuals and the study design limited their ability to make firm causal inferences about the true magnitude of effect.

Tetravalent, pentavalent, and hexavalent immunization

DTaP or DTwP vaccine can be combined with other antigens, such as *Haemophilus influenzae* type b (Hib), inactivated poliovaccine (IPV), and hepatitis B vaccine. In children DTaP or DTwP vaccines are the basis for such combinations, while in adults it is mostly Td or Tdap vaccine combined with inactivated poliovaccine (IPV). Current safety concerns regarding combination vaccines have been defined and reviewed (7). The author concluded that there is no evidence that adding vaccines to combination products increases the burden on the immune system, which can respond to many millions of antigens. Combining antigens usually does not increase adverse effects, but it can lead to an overall reduction in adverse events. Before licensure, combination vaccines undergo extensive testing to assure that the new products are safe and effective.

The frequency, severity, and types of adverse reactions after DTP-Hib immunization in very preterm babies have been studied (8). Adverse reactions were noted in 17 of 45 babies: nine had major events (apnea, bradycardia, or desaturation) and eight had minor reactions (increased oxygen requirements, temperature instability, poor handling, and feeding intolerance). Babies who had major adverse reactions were significantly younger at the time of immunization than the babies who did not have major reactions. Of 27 babies immunized at 70 days or less, nine developed major reactions compared with none of those who were immunized at over 70 days.

The Hexavalent Study Group has compared the immunogenicity and safety of a new liquid hexavalent vaccine against diphtheria, tetanus, pertussis, poliomyelitis, hepatitis B, and Hib (DTP + IPV + HB + Hib vaccine, manufactured by Aventis Pasteur MSD, Lyon, France) with two reference vaccines, the pentavalent DTP + IPV + Hib vaccine and the monovalent hepatitis B vaccine, administrated separately at the same visit (9). Infants were randomized to receive either the hexavalent vaccine ($n = 423$) or (administered at different local sites) the pentavalent and the HB vaccine ($n = 425$) at 2, 4, and 6 months of age. The hexavalent vaccine was well tolerated (for details, see the monograph on Pertussis vaccines). At least one local reaction was reported in 20% of injections with hexavalent vaccine compared with 16% after the receipt of pentavalent vaccine or 3.8% after the receipt of hepatitis B vaccine. These reactions were generally mild and transient. At least one systemic reaction was reported in 46% of injections with hexavalent vaccine, whereas the respective rate for the recipients of pentavalent and HB vaccine was 42%. No vaccine-related serious adverse event occurred during the study. The hexavalent vaccine provided immune responses adequate for protection against the six diseases.

Organs and Systems

Cardiovascular

Myopericarditis has been attributed to Td-IPV vaccine (10).

- A 31-year-old man developed arthralgia and chest pain 2 days after Td-IPV immunization and had an acute myopericarditis. He recovered within a few days with high-dose aspirin.

The authors discussed two possible causal mechanisms, natural infection or an immune complex-mediated mechanism. Infection was excluded by negative bacterial and viral serology and the favorable outcome within a few days without antimicrobial treatment.

Nervous system

Supposed neurological adverse effects of diphtheria immunization have been reported, but a causal connection was unclear (11). Of five cases of neurological complications after diphtheria or diphtheria-tetanus immunizations two were classified as vaccine-induced poliomyelitis; the other three could be traced back to a hyperergic reaction to diphtheria toxoids in the cerebral vessels (12).

Guillain–Barré syndrome (13) and polyradiculoneuritis (14,15) have rarely been reported. In a national surveillance study of Guillain–Barré syndrome in the USA, 31 of 998 cases developed the illness within 8 weeks after immunization. Of these 31 cases, 5 had been immunized with DT or DPT vaccine (16).

The bioelectric activity of the brain after DT immunization was studied in healthy children. Electroencephalography showed significant changes in 13 of 17 children, which resolved within 3 weeks (17). The question has arisen of whether this is of more than experimental significance: between 1980 and 1982 in the

© 2006 Elsevier B.V. All rights reserved.

Campana region of Italy, several cases of encephalopathy in children who had been given DT immunization 1 week before were reported to the health authorities. However, summarizing the results of a case-control study, Greco pointed out that the statistical association that he found between the incidence of encephalopathy and DT administration did not imply a causal association (18).

Sensory systems

Optic neuritis has been attributed to Td-IPV vaccine (19).

- Ten days after receiving Td-IPV vaccine a 56-year-old woman developed acute unilateral optic neuritis. Complete remission occurred within 6 weeks of prednisolone treatment. No other causes were found.

Skin

Erythema multiforme developed 8 hours after diphtheria–tetanus immunization in a 9-month-old infant (20). There have also been reports of erythema multiforme after hepatitis B vaccine, MMR vaccine, and DPT vaccine.

Bullous pemphigoid has been attributed to DTP-IPV vaccine (21).

A previous healthy 3.5-month-old infant developed bullous pemphigoid 3 days after receiving a first dose of DTP-IPV vaccine. *Staphylococcus aureus* was isolated from purulent bullae. The lesions resolved rapidly after treatment with antibiotics and methylprednisolone.

The authors mentioned 12 other cases of bullous pemphigoid, reported during the last 5 years, that had possibly been triggered by vaccines (influenza, tetanus toxoid booster, and DTP-IPV vaccine).

Immunologic

- A six-year-old child had anaphylaxis 30 minutes after a fifth dose of DT vaccine (22). Skin tests, in vitro determination of specific IgE antibodies, and immunoblotting assays showed that the IgE response was directed against tetanus and diphtheria toxoids. Cross-reactivity between the two toxoids was not demonstrated, indicating the presence of co-existing but non-cross-reacting IgE and IgG antibodies.

Susceptibility Factors

Other features of the patient

The only contraindication to administering single diphtheria toxoid or combined diphtheria and tetanus toxoids is a history of a severe hypersensitivity or neurological reaction after a previous dose.

Dipyridamole

General Information

Dipyridamole inhibits platelet aggregation by inhibiting platelet cyclic AMP phosphodiesterase, potentiating adenosine inhibition of platelet function by blocking adenosine reuptake by vascular and blood cells and breakdown of adenosine, and by potentiating prostaglandin I_2 antiaggregatory activity and enhancement of its synthesis. These independent processes inhibit platelet aggregation by increasing platelet cyclic AMP through a reduction in enzymatic breakdown of cyclic AMP and stimulation of cyclic AMP formation by activation of adenyl cyclase by adenosine and possibly prostaglandin I_2 (1).

Dipyridamole is also a potent coronary arteriolar vasodilator, perhaps by opening of vascular K_{ATP} channels (2). However, the Food and Drug Administration withdrew conditional approval for certain drug products containing dipyridamole, because of a lack of sufficient evidence of effectiveness in the long-term therapy of angina pectoris (3).

Observational studies

The incidence of major adverse reactions to dipyridamole was determined in a multicenter retrospective study, involving 73 806 patients who underwent intravenous dipyridamole stress imaging in 59 hospitals and 19 countries (4). The main conclusion was that the risk of serious dipyridamole-induced adverse effects is very low, a conclusion that is in line with other reports (5), and comparable to that reported for exercise testing in a similar patient population. Combined major adverse events among the entire patient population included 7 cardiac deaths (0.95 per 10 000), 13 nonfatal myocardial infarctions (1.76 per 10 000), 6 nonfatal sustained ventricular dysrhythmias (0.81 per 10 000) (ventricular tachycardia in 2 and ventricular fibrillation in 4), 9 transient cerebral ischemic attacks (1.22 per 10 000), 1 stroke, and 9 severe cases of bronchospasm (1.22 per 10 000). Minor non-cardiac adverse effects were less frequent among the elderly and more frequent in women and patients taking maintenance aspirin.

Placebo-controlled studies

The efficacy and safety of dipyridamole have been assessed in patients with chronic stable angina in a large-scale, international, randomized, placebo-controlled, parallel-group study, in which 400 patients with chronic stable angina pectoris and a positive treadmill exercise test were randomized to receive either modified-release dipyridamole (200 mg bd orally; $n = 198$) or placebo ($n = 202$) for 24 weeks as an add-on to conventional antianginal therapy and for 4 additional weeks as monotherapy, the latter after withdrawal of standard treatment with calcium channel blockers and/or beta-blockers and/or long-acting (prophylactic) nitrates (6). Of the 198 patients randomized to dipyridamole, 134 completed the add-on phase but only 12 completed the monotherapy phase. Of the 202 patients randomized to placebo, 162 reached the add-on phase but only 12 reached the monotherapy phase. There were serious adverse events in 15 patients who took dipyridamole and 12 who took placebo (7.6 versus 6.0%). These included chest pain, angina pectoris, and non-cardiac adverse effects, such as diarrhea, nausea, and headache.

Organs and Systems

Cardiovascular

Dipyridamole is used with ^{201}thallium imaging in the detection of coronary artery disease, but can cause dysrhythmias.

- A 41-year-old man with hypertension was investigated for chest tightness by dipyridamole–thallium single-photon emission computed tomography (7). A standard dose of dipyridamole (0.56 mg/kg) was infused intravenously over 4 minutes, during which his heart rate increased from 68 to 88/minute and his blood pressure fell slightly (from 160/80 to 140/76 mmHg). He had no subjective symptoms, such as palpitation, dizziness, or chest tightness, but had ventricular extra beats 40 seconds after completion of the dipyridamole infusion, followed 1 minute later by a sustained ventricular tachycardia. His blood pressure fell to 80/50 mmHg and he complained of dizziness. Intravenous aminophylline 125 mg was given immediately. About 30 seconds later, the ventricular tachycardia terminated and his hemodynamics stabilized. The ventricular extra beats persisted for another 30 seconds.
- Two cases of severe bradydysrhythmias (one complete heart block, one sinus bradycardia) occurred after intravenous dipyridamole (8).

Dipyridamole can also cause myocardial ischemia.

- A 43-year-old man had an acute myocardial infarction immediately after exercise and pharmacological stress echocardiography with dipyridamole + atropine 1 month after successful stent implantation (9).
- A 59-year-old man developed unstable angina 1 month after coronary artery bypass surgery (10). During dipyridamole scintigraphy, 2 minutes after the beginning of dipyridamole infusion, ST segment elevation occurred in the inferior electrocardiographic leads and there

© 2006 Elsevier B.V. All rights reserved.

were two marked anteroseptal and inferior defects on myocardial scintigraphy.

A patient with aorto-iliac occlusive vascular disease and hypertension suffered a stroke 6.5 minutes after administration of intravenous dipyridamole during a ^{201}thallium myocardial study (11). Aminophylline did not reverse its progression.

Respiratory

The practicability of dipyridamole ^{13}N-ammonia myocardial positron emission tomography for perioperative risk assessment of coronary artery disease in patients with severe chronic obstructive pulmonary disease undergoing lung volume reduction surgery has been studied in 13 men and 7 women (mean age 57 years) without symptoms of coronary artery disease (12). Nine patients had intolerable dyspnea due to bronchoconstriction and required intravenous aminophylline. Dipyridamole cannot be recommended as a pharmacological stress in this setting.

Fatal respiratory insufficiency after dipyridamole–thallium imaging has been described in patients with a history of chronic obstructive lung disease (13,14). The authors of these reports concluded that patients with a history of chronic obstructive lung disease may have an increased risk of bronchospasm after dipyridamole infusion, and caution is advised in such patients.

Nervous system

Dipyridamole in combination with aspirin was more effective in preventing secondary stroke than low-dose aspirin or dipyridamole alone in only one of several studies (15). There is some evidence that dipyridamole can sometimes cause transient ischemic attacks (16).

- A 74-year-old woman had a 3-year history of mild dysarthria, dizziness, and gait ataxia, accompanied by two transient ischemic attacks with involuntary ballistic movements of her left arm lasting several seconds each, and another transient ischemic attack with a right homonymous hemianopia lasting 30 minutes. About 45 minutes after her first-ever oral administration of dipyridamole plus aspirin she developed a transient cerebellar deficit that reproduced features of previous vertebrobasilar ischemic events, as well as severe headache, flushing, and diarrhea.

The acute onset, the pattern of the cerebellar deficit, and the absence of features of epilepsy suggested that the episode was a transient ischemic attack. Aspirin is not known to cause transient ischemic attacks, and only rarely causes headache, flushing, and diarrhea. Since headache, flushing, and diarrhea, which can be caused by dipyridamole, occurred at the same time as the transient ischemic attacks and did not recur after withdrawal, dipyridamole may have caused the transient ischemic attacks. However, it was not clear whether the attacks occurred despite treatment rather than because of it.

In the Second European Stroke Prevention Study, headaches associated with dipyridamole (in 8% of patients taking dipyridamole or dipyridamole + aspirin versus 2% of patients taking aspirin alone or placebo) often led to withdrawal of therapy.

The predictive factors for headaches were explored in a study of the bioequivalence of two formulations of dipyridamole 200 mg in a modified-release combination with aspirin 25 mg (17). The conclusion was that the rapid fall in the incidence of headaches over time implied that most patients quickly develop tolerance to dipyridamole-associated headaches. However, in the European Stroke Prevention Study 2, headache was the most common adverse event, and it occurred more often in dipyridamole-treated patients (18).

Biliary tract

Recurrent drug-containing gallstones, 18 months after a previous stone had been removed endoscopically, were attributed to dipyridamole (19).

Immunologic

Infusion of dipyridamole caused an acute allergic reaction during myocardial scintigraphy (20).

- A 56-year old man with a history of allergy to aspirin, tetracycline, and penicillin, including angioedema and dyspnea, was given a dipyridamole stress test. About 1 minute after the infusion was started he reported periorbital pruritus. The infusion was completed uneventfully with the administration of ^{99m}technetium sestamibi at 7 minutes. Twenty minutes later he had tightness in the neck, dyspnea, and generalized facial swelling. He was given oxygen and intravenous promethazine hydrochloride and hydrocortisone. He improved over the next 2 hours, with residual periorbital edema but complete recovery from the respiratory symptoms. The cardiac study was completed without further events. The result was normal.

Direct thrombin inhibitors

General Information

The class of direct thrombin inhibitors includes the hirudins, lepirudin and bivalirudin, and the tripeptide or peptidomimetic compounds argatroban, efegatran, inogatran, napsagatran, melagatran, and ximelagatran. They act by binding to the active site on thrombin and inhibiting its enzymatic activity. They thus inhibit fibrin formation, activation of anticoagulant factors V, VIII, and XIII, and protein C, and platelet aggregation. The antithrombin action occurs rapidly and is quickly reversible.

In a meta-analysis of individual patients' data from 11 randomized comparisons of direct thrombin inhibitors (hirudin, bivalirudin, argatroban, efegatran, or inogatran) with heparin, 35 970 patients were treated for up to 7 days and followed for at least 30 days (1). Compared with heparin, the direct thrombin inhibitors were associated with a lower risk of death or myocardial infarction at the end of treatment (OR = 0.85; 95% CI = 0.77, 0.94) and at 30 days (OR = 0.91; CI = 0.84, 0.99). There was no excess of intracranial hemorrhages with the direct thrombin inhibitors.

Hirudin

Hirudin is the principal anticoagulant of the medicinal leech (*Hirudo medicinalis*). Though long known in its natural form, this is now produced by recombinant DNA techniques and characterized by a high affinity for thrombin, whether it is free in the plasma or absorbed onto the fibrin clot. The high incidence of hemorrhagic strokes in patients treated with both thrombolytic drugs and hirudin led to the redesign of three major trials (GUSTO-IIA, TIMI-9A, HIT III) of the effect of these antithrombotic agents in myocardial infarction (2–4). Hirudin is now regarded as the treatment of choice for heparin-induced thrombocytopenia. It is not recommended for use in pregnancy as it can cross the placenta; however, its safe use has been reported (5).

There is no specific antidote for the direct thrombin inhibitors: they are not neutralized by protamine sulfate.

Desirudin

Desirudin, similarly produced by recombinant techniques, has been used to prevent venous thromboembolism. It has been investigated in studies in patients with total hip replacements. In a large comparison of desirudin and low molecular weight heparin (enoxaparin), desirudin produced better prophylaxis against proximal deep vein thrombosis after total hip replacement (6) with no differences between the two groups with respect to perioperative, postoperative, and total blood loss. There were no cases of thrombocytopenia associated with desirudin.

Argatroban

Argatroban has been approved in the USA and Canada for the prophylaxis and treatment of thrombosis in patients with heparin-induced thrombocytopenia, and in Japan and Korea for various thrombotic disorders. Its effects can be monitored using the activated partial thromboplastin time for low doses and the activated clotting time for high doses. Its pharmacology, clinical pharmacology, and uses have been reviewed (7–14).

Organs and Systems

Immunologic

The effects on activated partial thromboplastin time and the incidence and clinical relevance of antihirudin antibodies in patients treated with lepirudin have been studied using data from two prospective multicenter studies, in which patients with heparin-induced

© 2006 Elsevier B.V. All rights reserved.

thrombocytopenia received one of four intravenous lepirudin dosage regimens (15). Of 196 evaluable patients, 87 (44%) had IgG antihirudin antibodies. The development of antihirudin antibodies depended on the duration of treatment (antibody-positive patients 18.6 days versus antibody-negative patients 11.6 days). Antihirudin antibodies were not associated with increases in clinical endpoints (limb amputation, new thromboembolic complications, or major bleeding). In 23 of 51 evaluable patients in whom antihirudin antibodies developed during treatment with lepirudin, the antibodies enhanced the anticoagulatory effect of lepirudin. During prolonged treatment with lepirudin, anticoagulatory activity should be monitored daily.

Desirudin has a very low immunogenic potential. During repeated administration to 263 healthy volunteers, there were no signs or symptoms directly attributable to desirudin and only three volunteers exposed to a second course had allergic reactions with pruritic erythema attributable to desirudin in one case (16). In this study, specific antibodies directed against desirudin were detected in only one subject.

Drug–Drug Interactions

Digoxin

The pharmacokinetics of intravenous argatroban 1.5–2.0 μg/kg/minute were unaffected by co-administration of oral digoxin in healthy volunteers (17).

Erythromycin

Argatroban is metabolized by CYP3A4/5, and its pharmacokinetics might therefore be expected to be altered by inhibitors of CYP3A. However, in 14 healthy men erythromycin 500 mg qds had no effects on the pharmacokinetics of argatroban 1 μg/kg/minute infused over 5 hours (18).

Lidocaine

The pharmacokinetics of intravenous argatroban 1.5–2.0 μg/kg/minute were unaffected by co-administration of intravenous lidocaine in healthy volunteers (17).

Paracetamol

The pharmacokinetics of intravenous argatroban 1.5–2.0 μg/kg/minute were unaffected by co-administration of oral paracetamol in healthy volunteers (17).

Dirithromycin

See also Macrolide antibiotics

General Information

Adverse effects of dirithromycin were studied in 4263 patients (1). There was abdominal pain in 5.6%, diarrhea in 5.0%, and nausea in 4.9%. Headache was relatively common (4.5%). In 63% of cases the adverse events were considered mild, in 31% moderate, and in 6.3% severe. Adverse events resulted in withdrawal in 3.1%, mainly because of gastrointestinal symptoms such as nausea and abdominal pain.

Organs and Systems

Respiratory

Adverse events involving the respiratory system (dyspnea, increased cough, or asthma) were reported in about 2% of patients taking dirithromycin (1).

Drug–Drug Interactions

Ciclosporin

Dirithromycin has a small effect on ciclosporin concentrations but to a clinically insignificant extent (2).

Oral contraceptives

Oral dirithromycin reduced the mean ethinylestradiol 24-hour AUC and increased its oral clearance in women using an oral contraceptive (3). However, since there was no effect on inhibition of ovulation, the clinical importance of this interaction may be negligible.

Theophylline and other xanthines

Drug interactions with dirithromycin have rarely been reported, since it does not interact with cytochrome P450. Nevertheless, in 13 healthy volunteers 500 mg/day for 10 days caused a significant 18% fall in the average steady-state plasma theophylline concentration and a 26% fall in peak concentration, with a 14–15% increase in clearance (4). In contrast, the steady-state pharmacokinetics of theophylline did not change in 14 patients with chronic obstructive airways disease who took dirithromycin for 10 days (5).

Disinfectants and antiseptics

See also Individual agents

General Information

Antimicrobial drugs are widely used in topical medicaments, cosmetics, household products, and industrial biocides. Depending on their concentrations, they can function as disinfectants, antiseptics, or preservatives. The prevalence and rank order of sensitization to antimicrobial allergens in Europe have been reviewed (1,2). The most frequent antimicrobial allergens in 8521 patients who were patch-tested between 1985 and 1997 in Belgium are given in Table 1 (2).

In the multicenter study of the Information Network of Departments of Dermatology, sensitization rates of preservatives in the standard series were all over 1% in the test population of 11 485 patients. Thiomersal was rating highest (5.3%), chloromethyl-isothiazolinone/methyisothiazolinone, formaldehyde, and methyl-dibromoglutaronitrile/phenoxyethanol were next at about 2%, and parabens rating lowest at 1.6%. Glutaral, a biocide

Table 1 Most frequent antimicrobial allergens in Belgium out of 8521 patients in 1985–97

Rank	Allergen	Number
1	Methyl(chloro)isothiazolinone	143*
2	Thiomersal	136
3	Merbromine	94
4	Iodine	89
5	Cetrimide	88
6	Formaldehyde	80
7	Parabens	71
8	Chloramine	43
9	Quaternium-15	32
10	Nitrofurazone	29
11	Quinoline mix	28
12	Benzyl alcohol	25
	Benzoic acid	25
	Thiocyanomethylbenzothiazole	25
	Chlorhexidine	25
13	Glutaral (glutaraldehyde)	22

mainly used as a disinfectant, showed a remarkable increase in sensitization from less than 1% in 1990 up to more than 4% at the end of 1994. Health personnel and cleaning personnel were often affected and showed a sensitization rate of 10% (1,3).

The individual compounds that are covered in separate monographs are:

- Acrisorcin
- Aliphatic alcohols
- Benzalkonium
- Benzethonium
- Benzoxonium
- Benzyl alcohol
- Boric acid
- Cetrimonium bromide and cetrimide
- Chlorhexidine
- Chloroxylenol
- Ethacridine
- Ethylene oxide
- Formaldehyde
- Glutaral (glutaraldehyde)
- Hexachlorophene
- Hexetidine
- Parabens
- Peroxides
- Phenols
- Polyhexanide
- Polyvidone
- Salicylanilides
- Sodium hypochlorite
- Sulfites
- Tosylchloramide
- Triclocarban.

Disopyramide

See also Antidysrhythmic drugs

General Information

The use, clinical pharmacology, and adverse effects of disopyramide have been reviewed thoroughly (1,2).

Comparative studies

Disopyramide (by intravenous infusion of 2 mg/kg/minute up to a maximum total dose of 100 mg) has been compared with pilsicainide (in a single oral dose of 100–150 mg) in the treatment of paroxysmal atrial fibrillation in 72 patients (3). Conversion to sinus rhythm occurred in 29 of the 40 patients given pilsicainide and 18 of 32 patients given disopyramide, a non-significant difference. However, the mean time to conversion was faster with disopyramide (23 versus 60 minutes). No adverse effects were observed with either drug.

General adverse reactions

The adverse effects of disopyramide are mostly mediated by its effects on the cardiovascular system and by its anticholinergic effects. Disopyramide has a strong negative inotropic effect on the myocardium and can cause heart failure and hypotension. It prolongs the QT interval and can cause serious ventricular tachydysrhythmias. Anticholinergic effects can cause dry mouth, blurred vision, urinary retention, glaucoma, and erectile impotence. Hypoglycemia can also occur. Disopyramide can cause uterine contractions and should not be used during pregnancy. Angioedema has been reported rarely. Tumor-inducing effects have not been reported.

Organs and Systems

Cardiovascular

Disopyramide has three effects that can lead to cardiovascular complications (4).

1 *Anticholinergic* The anticholinergic effects of disopyramide on the vagus have been reported to cause tachycardia with bundle branch block or conversion to 1:1 conduction of a supraventricular tachycardia with block.
2 *QTc interval prolongation* There have been several reports of ventricular dysrhythmias (for example polymorphous ventricular tachycardia, ventricular fibrillation, ventricular tachycardia) in association with a prolonged QTc interval (SEDA-5, 180).
3 *Negative inotropic effect* Disopyramide can worsen cardiac failure and occasionally causes hypotension.

The risk of adverse cardiac effects of disopyramide during intravenous administration relates to the speed of its administration rather than to the total dose given (SEDA-10, 149).

Torsade de pointes due to disopyramide is well described (SEDA-4, 180). This effect is associated with prolongation of the QT interval. There has been a study of the effects of disopyramide on the QT interval in patients with pre-existing QT interval prolongation (5). In eight patients with QT interval prolongation during bradycardia and five patients without QT interval prolongation, disopyramide significantly prolonged the QT interval; however, the change was more pronounced in those with pre-existing bradycardia (78 versus 35 ms). The authors proposed that this difference might be due to an underlying abnormality of potassium channels in those with pre-existing bradycardia. Thus, those who are genetically predisposed to cardiac dysrhythmias may be at greater risk of the prodysrhythmic effects of antidysrhythmic drugs.

© 2006 Elsevier B.V. All rights reserved.

The risk of myocardial depression with consequent hypotension is greatest when disopyramide is infused rapidly intravenously (SEDA-10, 149). Loading doses of disopyramide should therefore be infused slowly (over 30–60 minutes).

Respiratory

- Pneumonitis has been attributed to disopyramide in a 72-year-old man; the symptoms began soon after the first dose (6). Bronchoalveolar lavage fluid contained a high percentage of lymphocytes (65%) and a high CD4:CD8 ratio (69:1).

The results of a lymphocyte stimulation test suggested that disopyramide had been responsible.

Nervous system

Through its anticholinergic effects disopyramide causes dry mouth and blurred vision and can occasionally cause serious adverse effects, including glaucoma and acute urinary retention (1).

Neuropathy has rarely been attributed to disopyramide (7).

- A 71-year-old woman, who had taken disopyramide 500 mg/day for 4 years, developed fatigue, paresthesia, pain, and cramps in her legs (8). She had proximal weakness in all four limbs and an unsteady gait. Electrophysiology showed a sensorimotor polyneuropathy, with reduced motor conduction velocity and muscle denervation. All antibodies were negative. The symptoms did not respond to prednisone but improved in the months after disopyramide withdrawal.

Psychological, psychiatric

Acute psychosis has been attributed to disopyramide (9,10).

Metabolism

Disopyramide can cause hypoglycemia (SEDA-6, 180) (SEDA-17, 222) (11), perhaps due to increased secretion of insulin, and can also potentiate the effects of conventional hypoglycemic drugs (12). This effect may be due to its chief metabolite mono-*N*-dealkyldisopyramide, since many of the reported cases of hypoglycemia have been in patients with renal impairment, in which the metabolite accumulates. In six subjects who were being considered for treatment with disopyramide, serum glucose concentrations were measured at 13, 15, 17, and 19 hours after supper, with no further food, with and without the added administration of two modified-released tablets of disopyramide 150 mg with supper and 12 hours later (13). Disopyramide significantly reduced the serum glucose concentration at all measurement times by an average of 0.54 mmol/l. The fall in serum glucose concentration was not related to the serum concentration of disopyramide or the serum creatinine concentration; it was greater in older patients and in underweight patients.

- Hypoglycemia has also been reported in a 70-year-old woman with type 2 diabetes mellitus taking disopyramide (14).

Hematologic

Disopyramide has caused neutropenia (15) and a coagulopathy (16).

Liver

Liver damage was reported in 22 (0.35%) of 6294 patients given disopyramide, with jaundice in 6 (0.09%) (17). Liver damage due to disopyramide can be associated with direct hepatocellular damage (18) and intrahepatic cholestasis (19,20). However, it can also occur indirectly, because of heart failure and hepatic congestion (21). Thus, the incidence of direct liver damage quoted above may be an overestimate.

Sexual function

Erectile impotence has been attributed to disopyramide (22,23).

Immunologic

Angioedema has been attributed to disopyramide (24).

Second-Generation Effects

Pregnancy

Disopyramide can cause uterine contractions (SEDA-3, 156) (25), and has been reported to have caused the onset of uterine contractions in eight of 10 patients at term (25).

- A 26-year-old woman with Wolff–Parkinson–White syndrome was given two doses of disopyramide at 36 weeks and shortly afterwards went into active labor with prepartum hemorrhage (26). The child was delivered by cesarean section and the woman made a full recovery.

In view of these reports disopyramide should be avoided in pregnancy.

Lactation

Although disopyramide and its *N*-monodesalkyl metabolite are both excreted in breast milk, the amounts are probably too small to be of importance (27).

Susceptibility Factors

Renal disease

In renal insufficiency there are complex changes in the pharmacokinetics of disopyramide, but the overall effect is accumulation of it and its active metabolite, due to reduced renal clearance (28).

Other features of the patient

Because of the anticholinergic effects of disopyramide, care should be taken both in patients with symptoms of prostatic hyperplasia (because of the risk of urinary retention) and in patients with glaucoma.

Disopyramide is highly bound to plasma proteins and this binding is saturable within the therapeutic range. Thus, at high dosages there may be an increase in the

© 2006 Elsevier B.V. All rights reserved.

unbound fraction of drug in the plasma with proportionately greater effects. However, this is probably of no clinical relevance.

Drug Administration

Drug overdose

Overdosage of disopyramide is associated with apnea, loss of consciousness, loss of spontaneous respiration, hypotension, and cardiac dysrhythmias (29,30). Suggested treatment (31) includes arterial blood pressure monitoring, correction of acidosis and hypokalemia, and the intravenous infusion of a pressor agent for severe hypotension. Cardiac depressant drugs (for example class I antidysrhythmic drugs) should not be used to treat dysrhythmias, and the use of pyridostigmine to reverse the anticholinergic effects of disopyramide (32) is not recommended (SEDA-10, 149).

Drug–Drug Interactions

Class I antidysrhythmic drugs

There is an increased risk of dysrhythmias if disopyramide is used in conjunction with other drugs that prolong the QT interval, for example class I or class III antidysrhythmic drugs (33).

Macrolide antibiotics

Some of the macrolide antibiotics have been reported to inhibit the clearance of disopyramide (SEDA-21, 200) (SEDA-22, 207), resulting in serious dysrhythmias or hypoglycemia. The mechanism of this interaction is presumed to be inhibition of dealkylation of disopyramide to its major metabolite, mono-*N*-dealkyldisopyramide. For example, in human liver microsomes the macrolide antibiotic troleandomycin significantly inhibited the mono-*N*-dealkylation of disopyramide enantiomers by inhibition of CYP3A4 (34). This interaction can result in serious dysrhythmias or other adverse effects of disopyramide.

- A 76-year-old woman developed torsade de pointes 5 days after starting to take clarithromycin 200 mg bd in addition to disopyramide 100 mg tds (35). Her serum potassium concentration was 2.8 mmol/l and the QT_c interval was prolonged to 0.71 seconds. The plasma disopyramide concentration was in the usual target range (3.2 μg/ml). The disopyramide and clarithromycin were withheld and potassium was given; 14 hours later the serum potassium concentration was 4.3 mmol/l and there was no further dysrhythmia, despite prolongation of the QT_c interval to 0.67 seconds, falling to 0.45 seconds 10 days later.
- A 35-year-old woman taking disopyramide phosphate modified-release capsules 150 mg qds was given azithromycin 500 mg initially and 250 mg/day thereafter (36). In 11 days she developed malaise, light-headedness, and urinary retention. After the insertion of a urinary catheter she developed a monomorphic ventricular tachycardia with left bundle branch block. She was successfully cardioverted and the electrocardiogram showed a markedly prolonged QT interval of 560 ms and T wave inversion in the anterolateral leads. Her serum disopyramide concentration, which had previously been 2.6 μg/ml, was 11 μg/ml.
- In a 59-year-old man taking disopyramide 50 mg/day the addition of clarithromycin 600 mg/day caused hypoglycemia, and the serum disopyramide concentration rose from 1.5 to 8.0 μg/ml (37). The ratio of plasma insulin concentration to blood glucose concentration was greatly increased, suggesting that hypersecretion of insulin was responsible, confirming the likelihood that the hypoglycemia was due to disopyramide intoxication secondary to inhibition of its metabolism by clarithromycin. There was also slight prolongation of the QT_c interval, but no cardiac dysrhythmias. After withdrawal of clarithromycin and disopyramide both the blood glucose concentration and the QT_c interval returned to normal.
- An 86-year-old woman presented with severe hypoglycemia after clarithromycin 500 mg/day had been added for 3 days to her other therapy, which included disopyramide 500 mg/day (38). The hypoglycemia resolved completely after withdrawal of disopyramide.

Potassium-sparing drugs

Hyperkalemia has been reported to increase the risk of dysrhythmias in patients taking disopyramide (39), and disopyramide should therefore be used with caution in patients who are taking drugs that can increase body potassium, such as potassium-sparing diuretics and ACE inhibitors.

Practolol

The combination of disopyramide and practolol can cause profound sinus bradycardia and asystole (40,41).

Warfarin

Disopyramide can potentiate the effects of warfarin (42), although it is not known whether this is of any importance (43).

Disulfiram

General Information

Disulfiram (tetraethylthiuram) has been widely used since the late 1940s to facilitate abstinence from alcohol (1). Concomitant use of alcohol during disulfiram therapy results in an autonomic symptom complex that can involve headache, flushing, nausea and vomiting, sweating, tachycardia, hypotension, and confusion. The mechanism of action of disulfiram is inhibition of aldehyde dehydrogenase; alcohol is metabolized to acetaldehyde, which accumulates (2).

Sulfiram

Sulfiram is similar in structure to disulfiram, but has one less sulfur atom in its central chain. It is a much weaker inhibitor of aldehyde dehydrogenase than disulfiram and is used in the topical treatment of scabies.

© 2006 Elsevier B.V. All rights reserved.

General adverse effects

Several adverse effects of disulfiram itself (as opposed to the aldehyde that it allows to accumulate) have been described. They include neurological reactions and skin reactions, but hepatotoxicity is the only previously reported life-threatening reaction, and it is rare (3).

Disulfiram modifies the metabolism of many drugs by inhibiting the cytochrome CYP2E1. Adverse reactions to disulfiram occur with a frequency of 1 in 200 to 1 in 2000 per treatment-year (4). The death rate is about one per 25 000 patients per year, and hepatic failure accounts for most of these (4). Allergic reactions can occur. Tumor-inducing effects have not been described.

Organs and Systems

Cardiovascular

Disulfiram in a dose of 250–300 mg/day does not affect pulse rate, blood pressure, or plasma noradrenaline concentrations, but 500 mg/day causes an increase in plasma noradrenaline, increased systolic blood pressure both recumbent and erect, and an increased erect pulse rate. The raised blood pressure does not reach hypertensive values, but the results suggest increased sympathetic nervous system activity in patients who take disulfiram. Caution should therefore be exercised in using disulfiram in hypertensive patients. Close monitoring of blood pressure is advised, and the dose of disulfiram should preferably be reduced to 250 mg/day (5).

Cardiac dysrhythmias occurred during a disulfiram + alcohol test in a 48-year-old man who had been an alcoholic for 5 years (6). After drinking a test amount of alcohol, he developed flushing, nausea, vomiting, sweating, dyspnea, and hyperventilation, palpitation, tremor, confusion, and syncope. The electrocardiogram showed atrial fibrillation and non-sustained bouts of ventricular tachycardia of 7–8/minute. He also had severe hypotension.

Nervous system

Disulfiram can cause a polyneuritis (7), which can occasionally be fulminant and irreversible.

- A 39-year-old woman developed a severe sensori motor polyneuritis after taking ethanol and disulfiram in high doses (8). The disorder was similar to other cases of disulfiram neuropathy, but was acute and more severe.

The neurotoxic effects of disulfiram have been compared with those of carbon disulfide, a disulfiram metabolite (9). The results suggested that carbon disulfide may be responsible for the behavioural and neurological adverse effects of disulfiram. If so, other toxic effects of carbon disulfide might follow administration of high doses of disulfiram, such as parkinsonism, psychotic behaviour, and encephalopathy.

Disulfiram-induced neurotoxicity caused parkinsonism in a man who had been an alcoholic for 10 years (10).

- A 52-year-old alcoholic stopped drinking in August 1996 and started to take disulfiram 500 mg/day. His usual medications had been aspirin 300 mg/day and levothyroxine 100 µg/day. He had had severe loss of visual acuity (2/10) in the left eye 3 months before admission. He was admitted to hospital because of drowsiness. Neurological examination showed severe hypophonia, difficulty in swallowing, and mild rigidity of the limbs. Disulfiram was withdrawn but the other medications were maintained. His drowsiness improved over 5 days, but he remained bradykinetic, with extrapyramidal hypertonia, facial hypomobility, and abnormal posture. His gait was slow and shuffling.
- A 20-year-old woman was referred for implantation of an intrathecal baclofen pump (11). She had had severe dystonia and spasticity following a suicide attempt with disulfiram at age 14 years. T1-weighted MRI scanning of her brain showed bilateral globus pallidus infarction. She had profound relief of spasticity after intrathecal test injections of baclofen and underwent implantation of an intrathecal baclofen pump. Her spasticity subsequently improved.

Sensory systems

Retrobulbar neuritis can be part of a disulfiram-induced polyneuritis, with dramatic reduction in visual acuity and impaired colour perception (SEDA-10, 349) (12). This complication is rare but serious. It occurs at dosages of 500 mg/day, and there is a latent period of 2–36 months. Tobacco abuse is thought to be a predisposing factor.

Disulfiram can cause optic neuropathy (13,14).

Psychological, psychiatric

Disulfiram can cause distressing neuropsychiatric effects including paranoia, impaired memory and concentration, ataxia, dysarthria, and frontal release signs (signs that can be indicative of permanent structural damage or temporary metabolic or infectious changes to the brain's frontal lobes), such as snout and grasp reflexes (2,15). The mechanisms are not properly understood, but adverse effects develop more frequently in subjects with low plasma dopamine beta-hydroxylase activity. In one study, a research subject with low dopamine beta-hydroxylase activity developed a schizophrenic reaction to disulfiram; it would be useful to know whether determining blood dopamine beta-hydroxylase activities predicts the risk of adverse reactions to disulfiram (16).

Of 52 patients with alcohol dependence/abuse who were given disulfiram 250 mg bd after food, six developed psychotic symptoms; all had a mood disorder but no thought disorder (17). The psychotic symptoms remitted completely after withdrawal and a short course of antipsychotic therapy, except in one patient who had to be given lithium.

- A 47-year-old man with alcohol abuse took disulfiram (18). He developed a psychosis while taking it and for 2 weeks after. He stated that he had not taken alcohol. He was successfully treated with antipsychotic drugs. Afterwards it was discovered that his family history was positive for schizophrenia; it is therefore possible

© 2006 Elsevier B.V. All rights reserved.

that he was more vulnerable to develop psychosis due to disulfiram.

Prolonged toxic delirium related to disulfiram and alcohol intake has been reported (19). The predominant presenting feature was neuropsychiatric rather than autonomic symptoms.

- A 50-year-old woman with a history of bipolar disorder type I and alcohol dependence taking disulfiram had a 4-day history of a change in mental status, including visual hallucinations and deficits in orientation and concentration. Other features included a tachycardia and non-focal neurological signs. Extensive metabolic, infectious, and neurological investigations revealed no abnormalities that alone could explain her acute confusional state. It was subsequently discovered that she had drunk alcohol on at least two separate occasions while taking disulfiram before her change in mental status, and that a similar, although shorter, episode had occurred previously.

Gastrointestinal

In a colostomy patient, the smell of the colostomy was present only so long as disulfiram exposure continued (20). The cause was obscure.

Liver

About 25 cases of disulfiram-induced liver damage (apparently as a result of an immunological mechanism) have been reported, some fatal. The cause is not known, since many alcoholic patients who use disulfiram have pre-existing liver damage. Nevertheless, it is believed that disulfiram does sometimes trigger serious liver damage (SEDA-10, 438); severe hepatitis, sometimes fatal, has been reported (21–24). Liver function should be checked before giving disulfiram, especially since there may be a long history of alcohol abuse (25).

The Swedish adverse drug reactions register, SWEDIS, received 149 case reports of 157 adverse reactions associated with disulfiram from 1971 to 1999, of which 63 cited disorders of the liver and biliary tract (26). Of these 63 reports, seven were classified as serious. In three cases of severe liver damage with a fatal outcome, disulfiram was suspected to have caused the reaction. If signs of liver damage appear, it is recommended that disulfiram be withdrawn and liver function tests performed.

Skin

A fatal rash has been attributed to disulfiram.

- A 47-year-old man developed a generalized rash and malaise (27). He had chronic alcoholism and had taken disulfiram 250 mg/day for 1 month. He denied previous liver disease, blood transfusions, or having taken hepatotoxic drugs or alcohol. He was given clarithromycin 500 mg bd and paracetamol 500 mg tds and 1 week later noticed non-pruritic cutaneous maculopapular lesions on the legs, which spread to the rest of his body, excluding the palms and soles. His temperature was 41°C, his blood pressure 90/60 mmHg, and his heart rate 130/minute. There were no signs of encephalopathy. His conjunctivae were yellow. There was furfuraceous desquamation on his face and confluent erythematous annular lesions with a purpuric component on the groins, thighs, and the undersides of his arms. There was edema of the hands and feet. During the next several days the skin lesions worsened. He developed blisters, initially covering less than 10% of the body surface, but then extending all over the body. He developed septic shock and, despite supportive measures, died.
- A 49-year-old woman developed pruritic erythema 2 weeks after the implantation of a modified-release formulation of disulfiram, Esperal, in her left buttock (28). Three months later she started drinking alcohol and developed generalized erythema with numerous papules on her face and limbs; the dermatitis at the site of the implant became more severe. The serum ethanol concentration was 270 mg/dl. Methanol was not detected.
- A 55-year-old man developed yellow palms and soles while taking disulfiram (29).

The authors speculated that the mechanism was inhibition of carotene metabolism by disulfiram.

Immunologic

Allergic reactions to disulfiram tend to be limited (30). However, the possibility of hypersensitivity should be borne in mind in patients who have had allergic reactions in the past, regardless of the allergen concerned.

Second-Generation Effects

Pregnancy

Disulfiram should not be used in women who may become pregnant because of potential teratogenicity (31).

Drug–Drug Interactions

Alcohol

The interaction of disulfiram with alcohol, the metabolism of which is interfered with at the aldehyde stage, is the basis for its therapeutic use; disulfiram renders alcohol intake unpleasant, and dangerous if much alcohol is taken.

Sulfiram is related to disulfiram, and after repeated topical treatment the ingestion of alcohol can rarely cause a similar reaction, with generalized flushing, malaise, and rhinorrhea (32).

Amitriptyline

Amitriptyline potentiates the disulfiram reaction (33).

Benzodiazepines

Disulfiram inhibits the hepatic metabolism of other drugs and can prolong their effects. The half-lives of chlordiazepoxide and diazepam increase significantly after disulfiram, while the clearances are reduced, with accumulation. No change in half-life or clearance has been noted for oxazepam (which is not metabolized in

© 2006 Elsevier B.V. All rights reserved.

the liver) (34). The benzodiazepines reduce the disulfiram reaction to alcohol.

Caffeine

Disulfiram reduces caffeine clearance (35).

Cocaine

Simultaneous abuse of cocaine and alcohol is common and alcohol reduces negative stimulant effects and potentiates "highs." Disulfiram has therefore also been used to treat cocaine dependence, with the rationale that an inability to modulate the effects of cocaine with alcohol may reduce cocaine use.

Six volunteers with cocaine dependence and alcohol abuse or dependence, mean age 32 years, took disulfiram 250 mg/day or placebo (36). After 3 days they participated in cocaine administration sessions (one session daily for 3 days). The study drugs were separated by at least 5 days, based on the time needed for enzyme regeneration (37). After disulfiram, cocaine significantly increased heart rate and blood pressure, and they remained high when plasma cocaine concentrations were falling at later times, and were greatest for cocaine 2 mg/kg. These findings contrast with those obtained when multiple doses of cocaine alone have been given to healthy volunteers, in whom there was evidence of acute tolerance to the cardiovascular effects of cocaine (38,39). Disulfiram therefore has potential as a treatment for cocaine + alcohol abuse, but could also increase the risk of toxicity as a result of its pharmacokinetic interaction with cocaine.

Warfarin

Bad breath has been reported in patients taking disulfiram concurrently with warfarin (40).

Diuretics

See also Individual agents

General Information

Diuretics are among the most widely used drugs, particularly for the treatment of hypertension and of various conditions associated with sodium retention.

Considering the widespread use of diuretics over a long period (chlorothiazide was introduced in 1957) their safety record is remarkable, and reports of adverse effects of any significance with the best-known drugs of this type are uncommon.

When problems do arise they usually reflect either interactions, which with caution could have been avoided, or relative overdosage. In the course of time the recommended antihypertensive doses of diuretics have been reduced, and some adverse effects that were noted in the early years are now of less significance; these include hypotension, dehydration, reduction of the glomerular filtration rate, and severe hypokalemia. Continued use of thiazides in excessive doses may reflect ignorance of their very flat dose–response curve (1). At currently recommended low doses, diuretics improve overall quality of life, even in asymptomatic patients with mild hypertension (2). The large HANE study (3) provided no evidence of superior efficacy or tolerability of new classes of antihypertensive drugs.

Uses

Hypertension

The popularity of thiazide diuretics in the management of hypertension reflects three major factors (4):

- recognition of the effectiveness of much lower dosages than those used previously, thereby providing good antihypertensive efficacy with fewer adverse effects (SED-13, 558);
- the excellent reductions in morbidity and mortality that have been achieved by low-dosage diuretic-based therapy in multiple randomized, controlled trials (SED-13, 558);
- the increasing awareness that some diuretic-induced shrinkage of effective blood volume is essential for adequate treatment of most patients with hypertension.

The Seventh Joint Committee Report on Detection, Evaluation, and Treatment of High Blood Pressure (5) concluded that a diuretic should be the first-step drug of choice, unless there are specific indications for other drugs. Although there may be theoretical advantages of certain newer types of drugs, the data thus far have not consistently shown that these drugs are more effective in reducing morbidity and mortality than therapy based on diuretics or beta-blockers (6). Emphasis is correctly placed on the important role of ACE inhibitors in retarding progression of renal insufficiency in diabetic and other nephropathies (7). However, in these circumstances, ACE inhibitors are added to a background of other antihypertensive therapies, commonly including a diuretic. Therefore, the renal protective action of ACE inhibitors is in the context of combination regimens. The ability of low doses of diuretics to enhance efficacy has been demonstrated for all other classes of drugs (8). Moreover, the tendency for increased retention of sodium by the hypertensive kidney when non-diuretic drugs cause the blood pressure to fall has long been recognized to contribute to loss of antihypertensive efficacy, which can be restored immediately by the addition of a diuretic.

Clinical trials

The LIVE (Left ventricular regression, Indapamide Versus Enalapril) study was a 1-year, prospective, randomized, double-blind comparison of modified-release indapamide 1.5 mg and enalapril 20 mg in reducing left ventricular mass in 411 hypertensive patients with left ventricular hypertrophy (9). For equivalent reductions in blood pressure, indapamide was significantly more effective than enalapril in reducing left ventricular mass index.

The effectiveness of specific first-line antihypertensive drugs in lowering blood pressure and preventing adverse outcomes has been systematically quantified in a meta-analysis of randomized controlled trials that lasted at least 1 year, and compared one of six possible first-line antihypertensive therapies either with another of the six drug therapies or with no treatment (10). Of 38 trials identified, 23 in 50 853 patients met the inclusion criteria. Four drug classes were evaluated: thiazides (21 trials), beta-blockers (5 trials), calcium antagonists (4 trials), and ACE inhibitors (1 trial). In five comparisons of thiazides with beta-blockers, thiazides were associated with a significantly lower rate of withdrawal because of adverse effects (RR = 0.69; 95% CI = 0.63, 0.76). In the trials that had an untreated control group, low-dose thiazide therapy was associated with a significant reduction in the risk of death (RR = 0.89; CI = 0.81, 0.99), stroke (RR = 0.66; CI = 0.56, 0.79), coronary heart disease (RR = 0.71, CI = 0.60, 0.84), and cardiovascular events (RR = 0.68; CI = 0.62, 0.75). Low-dose thiazide

© 2006 Elsevier B.V. All rights reserved.

therapy reduced the absolute risk of cardiovascular events by 5.7% (CI = 4.2, 7.2); the number needed to treat (NNT) for approximately 5 years to prevent one event was 18. High-dose thiazide, beta-blocker, and calcium antagonist therapy did not significantly reduce the risk of death or coronary heart disease. Thiazides were significantly better than the other drugs in reducing systolic pressure, but antihypertensive efficacy did not differ between the high- and low-dose thiazide trials.

In the UK Medical Research Council (MRC) trial, the outcome of antihypertensive treatment based on diuretics was compared with placebo in a very large number of hypertensive subjects (11). Treatment based on a thiazide did not increase the incidence of coronary events or sudden death; indeed, thiazide-based treatment reduced the incidence of strokes by 67% and of all cardiovascular complications by 20%. It should be noted that the dose of bendroflumethiazide used in the MRC trial (10 mg/day) is now known to be unnecessarily high and that it was used without prophylaxis against hypokalemia. Even so, a subgroup analysis of data from the MRC Trial provided no evidence that the association between major electrocardiographic abnormalities and an increased likelihood of a clinical event was strengthened by bendroflumethiazide treatment (12).

A series of trials in elderly hypertensive subjects has shown a very pronounced reduction in cardiac events as a result of treatment based on thiazide diuretics. In the European Working Party on Hypertension in the Elderly (EWPHE) trial (13), total cardiovascular deaths were reduced by 38%, all cardiac deaths by 43%, and deaths due to myocardial infarction by 60%. Benefits in the Systolic Hypertension in the Elderly Program (SHEP) included a reduction in fatal and non-fatal myocardial infarction of 25% and major cardiovascular events of 32% (14) and were seen in those with and without electrocardiographic abnormalities at entry. The risk of heart failure was also reduced in patients taking chlortalidone-based therapy (15). Relative risk was similar in patients with and without non-insulin dependent diabetes mellitus; absolute risk reduction was twice as great in the diabetic subjects (16). The Swedish Trial of Old Patients with Hypertension (STOP-Hypertension) reported a significant reduction in myocardial infarction and all-cause mortality (17). In the MRC Trial in elderly adults (18), diuretic treatment reduced coronary events by 44% and fatal cardiovascular events by 35%.

In the MRC trials (11,18), the IPPPSH trial (19), and the HAPPHY trial (20), antihypertensive treatment based on a thiazide diuretic was compared with treatment based on a beta-blocker. The results with diuretic treatment were no less favorable as regards cardiac events than those when using a "cardioprotective" beta-blocker (20). In the IPPPSH trial, the group using no beta-blockers (but with a higher incidence of diuretic use and of hypokalemia) showed no excess of cardiac events, even in patients who had an abnormal electrocardiogram when they entered the study. The MRC trial in elderly adults (18) showed a significantly lower risk of cardiovascular events with the diuretic compared with the beta-blocker, raising the possibility that diuretics confer benefit through a mechanism other than the reduction of blood pressure.

In the MAPHY study (21), total mortality was significantly lower for metoprolol than for thiazide, because of fewer deaths from coronary heart disease and stroke. However, the MAPHY study population comprised a subgroup of about half of the patients from the HAPPHY trial followed for an extended period. The difference in mortality between metoprolol and diuretics did not emerge during this extended follow-up, but was present during the first period of observation (that is during the HAPPHY trial), when there was no overall difference between beta-blockers and thiazides. Therefore, patients treated with atenolol in the HAPPHY trial must have fared worse than those treated with thiazides and much worse than those treated with metoprolol. Since there was no prior hypothesis for a difference between atenolol and metoprolol (and no plausible explanation for it), it seems reasonable to conclude that the apparent advantage of metoprolol was a chance finding produced by post-hoc subgroup analysis. The MAPHY study should be interpreted with extreme caution.

A review of the large trials has shown that the reduction in the incidence of events with usual thiazide-based treatment is 16% (95% CI = 8, 23%) against the prediction from epidemiological studies of 20–25% (22). This shortfall in benefit could easily be due to chance.

In the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), over 40 000 participants aged 55 years or older with hypertension and at least one other risk factor for coronary heart disease were randomized to chlortalidone, amlodipine, doxazosin, or lisinopril (23,24). Doxazosin was discontinued prematurely because chlortalidone was clearly superior in preventing cardiovascular events, particularly heart failure (24). Otherwise, mean follow-up was 4.9 years. There were no differences between chlortalidone, amlodipine, and lisinopril in the primary combined outcome or all-cause mortality. Compared with chlortalidone heart failure was more common with amlodipine and lisinopril, and chlortalidone was better than lisinopril at preventing stroke. The authors concluded that diuretics are superior to other antihypertensive drugs in preventing one or more major form of cardiovascular disease and are less expensive. They should therefore be used as the preferred first-step treatment of hypertension. Although the design, conduct, and analyses of ALLHAT can be criticized (25), it was a huge, prospective, randomized study and its results suggest that diuretic-based therapy is unsurpassed in the management of hypertension.

Adverse effects

The frequencies and the profile of adverse effects of five major classes of antihypertensive agents have been assessed in an unselected group of 2586 chronically drug-treated hypertensive patients (26). This was accompanied by a questionnaire-based survey among patients attending a general practitioner. The percentages of patients who reported adverse effects spontaneously, on general inquiry, and on specific questioning were 16, 24, and 62% respectively. The percentage of patients in whom discontinuation was due to adverse effects with diuretics was 2.8%. The authors did not find a significant effect of age on the pattern of adverse effects. Women reported more effects and effects that were less related to the pharmacological treatment.

Heart failure

Loop and thiazide diuretics

Loop and thiazide diuretics have been the mainstay of treatment for symptomatic heart failure (27), relieving symptoms and improving cardiovascular hemodynamics. However, despite their widespread use, they have not been shown to improve survival in patients with heart failure. As it is not feasible to conduct such a trial in patients with pulmonary edema due to heart failure, the place of diuretic therapy in the management of heart failure appears secure.

Aldosterone receptor antagonists

Although they are widely used in the management of heart failure, loop and thiazide diuretics have not been shown to prolong survival. However, spironolactone and eplerenone must be added to the list of medications that offer improved survival for patients with heart failure.

In the Randomized Aldactone Evaluation Study (RALES) in 1663 patients with New York Heart Association (NYHA) class III (70%) or IV (30%) symptoms and an ejection fraction less than 35%, the addition of spironolactone 25 mg/day to conventional treatment (an ACE inhibitor, a loop diuretic, in most cases digoxin, and in 11% a beta-blocker) for an average of 24 months lowered the risk of all-cause mortality by 30% (from 46% to 35%), death from progressive heart failure, and sudden death (28). There were similar reductions in hospital admissions for worsening heart failure and for all cardiac causes. The magnitude of the overall effect was similar and additional to the proven benefit from ACE inhibition in severe heart failure.

In the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS), in 6632 patients with an acute myocardial infarction complicated by left ventricular dysfunction and heart failure, the addition of eplerenone 25–50 mg/day to optimal medical therapy significantly reduced all-cause mortality by 15% and cardiovascular mortality by 17% over a mean follow-up period of 16 months; hospitalization rates were also reduced (29).

Mechanisms

Several mechanisms have been postulated to underlie the benefits of aldosterone receptor antagonists in heart failure (30). Aldosterone-induced cardiac fibrosis may reduce systolic function, impair diastolic function, and promote intracardiac conduction defects, with the potential for serious dysrhythmias. Aldosterone may also increase vulnerability to serious dysrhythmias by other mechanisms. The diuretic and hemodynamic effects of spironolactone in RALES and EPHESUS were subtle, and there were no significant changes in body weight, sodium retention, or systemic blood pressure.

Clinical use

The safe and effective dose of spironolactone remains uncertain (30). Pilot data from RALES showed that the frequency of hyperkalemia and uremia increased with doses of spironolactone above 50 mg/day (SEDA-20, 202). Doses up to 50 mg/day are appropriate, with adequate monitoring of serum electrolytes and renal function. The optimum strategy in the face of hyperkalemia, uremia, or symptomatic hypotension (reduction in frequency of spironolactone to alternate-day dosing, reduction in dose of ACE inhibitor, and/or increased dose of loop diuretics) is unclear, and how frequent such dose adjustments were necessary in RALES was not stated (28).

Adverse effects

The only frequent adverse effects were gynecomastia, breast pain, or both in 10% of men. The rate of discontinuation because of these events was 2%. The risk of gynecomastia should not be an argument against the use of spironolactone in men with severe heart failure, since it reduces both morbidity and death.

At the dose of spironolactone used in RALES (28), there was serious hyperkalemia, defined as a serum potassium concentration over 6.0 mmol/l, in 2% (compared with 1% of controls) and uremia was rare. However, a serum potassium concentration over 5 mmol/l and a serum creatinine concentration over 220 µmol/l were exclusion criteria. Although 29% of patients in the spironolactone group used potassium supplements, the benefit of spironolactone in these patients was similar to that in patients who did not.

In EPHESUS, as in RALES, the exclusion criteria included a serum potassium concentration over 5 mmol/l and a serum creatinine concentration over 220 µmol/l. There was serious hyperkalemia (a serum potassium concentration of 6.0 mmol/l or over) in 5.5% of those who took eplerenone and in 3.9% of those who took placebo. In each treatment group the incidence of hyperkalemia was higher among patients with the lowest baseline creatinine clearances.

The use of diuretics in patients with renal insufficiency

About 84% of the patients in the Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan Study (RENAAL) required diuretic therapy to effect blood pressure control (31). Although not specifically reported, a similarly high proportion of patients were likely to have required diuretic therapy to reach the target blood pressure in the Irbesartan Diabetic Nephropathy Trial (IDNT) (32). These studies remind us once again of the importance of targeting volume control in order to reduce blood pressure in patients with chronic renal insufficiency.

In a cohort study of 552 patients with acute renal insufficiency studied from 1989 to 1995 diuretic use was associated with a significant increase in the risk of death or non-recovery of renal function (33). This increased risk was largely borne by patients who were relatively unresponsive to diuretics. Although this study was observational, which prohibits causal inference, it is unlikely that diuretics afford any material benefit in the setting of acute renal insufficiency.

Thiazide and loop diuretics

Various factors influence the choice of a diuretic in patients with renal insufficiency. First, it is widely believed that thiazide diuretics are ineffective once renal

© 2006 Elsevier B.V. All rights reserved.

function falls below a creatinine clearance of 40–50 ml/minute. Diuretics need to enter the renal tubule to reach their luminal sites of action. In renal insufficiency, higher diuretic doses are required to overcome disease-related impediments to drug delivery to their sites of action. In the case of the loop diuretics the common practice is to titrate the dose of the diuretic until the desired response occurs (34). No such titration generally occurs with thiazide-type diuretics; consequently they are likely to fail, although for no reason other than their not being titrated to a truly effective dose. The true basis for "failure" of thiazide-type diuretics in patients with renal insufficiency resides in the fact that these diuretics are not of sufficient maximal efficacy to produce adequate volume control in these typically volume-expanded patients (35).

However, resistance to loop diuretics can occur by various mechanisms (36). These include poor adherence to therapy, poor absorption, progressive worsening of heart failure, excess volume loss, renal insufficiency, secondary hyperaldosteronism, and hypertrophy of the tubular cells of the distal nephron. Resistance due to inadequate drug absorption—either its speed or extent—is common with furosemide, which is poorly absorbed (34). Once recognized, this hurdle to response can be overcome by using loop diuretics that are predictably well absorbed, such as bumetanide and torasemide or by giving intravenous furosemide (37).

If loop diuretics fail to produce the desired diuretic response, combination diuretic therapy can be considered by adding a thiazide or a thiazide-like diuretic, such as metolazone. Such combinations are generally quite successful in both advanced congestive heart failure and late-stage chronic renal insufficiency, although excessive diuresis is a constant risk with such combinations. An excess diuresis with combination loop plus thiazide diuretic therapy is best managed by temporarily withdrawing both diuretics. Generally, diuretic doses are reduced when therapy is resumed (38).

An alternative in the diuretic-resistant patient is the use of continuous infusions of loop diuretics rather than bolus diuretic therapy. Such infusions can also be given with a small volume of hypertonic saline, with good effect (39). The reasons why continuous infusions of loop diuretics work when bolus doses have failed may relate to a more efficient time-course of diuretic delivery and/or less activation of the renin–angiotensin system (40). Furosemide and torasemide may be the safest loop diuretics to be given as infusions, in that infusion of bumetanide has been associated with severe musculoskeletal symptoms (41).

The importance of volume control in patients with renal insufficiency extends beyond its effect on blood pressure. Accordingly, the addition of hydrochlorothiazide can overcome the blunting by a high sodium intake of the therapeutic efficacy of ACE inhibition on proteinuria (42). This presumably relates to volume-related activation of the renin–angiotensin system.

Finally, loop diuretics reduce the metabolic demand of tubular cells, reducing oxygen requirements and thereby, in theory, increasing resistance to ischemic insults and perhaps other toxic circumstances. This property has been advanced as the basis for using diuretics in acute renal insufficiency. Although an attractive hypothesis to date, there is no compelling evidence to suggest any benefit from loop diuretics in established acute renal insufficiency. Alternatively, loop diuretics can convert oliguric to non-oliguric acute renal insufficiency, thereby easing the fluid restriction that would otherwise be necessary in such patients (43).

Aldosterone receptor antagonists

It is no longer appropriate to consider the endocrine or paracrine properties of aldosterone as being restricted to the classical target cells. Hemodynamic and humoral actions of aldosterone have important clinical implications for the pathogenesis of progressive renal disease, and may therefore affect future antihypertensive strategies. Initially, one might anticipate that the adverse effects of aldosterone could be attenuated merely by blocking aldosterone release with either an ACE inhibitor or angiotensin-II receptor antagonists. However, this appears not to be the case. Several investigators have now shown that ACE inhibitors acutely reduce aldosterone concentrations, but that with continued use this suppression fades. Thus, the presumption that ACE inhibitors would suppress the production of both aldosterone and angiotensin-II was incorrect. So, although ACE inhibitors and angiotensin-II receptor antagonists are individually very effective in retarding disease progression, additional benefit may be realized with a concurrent aldosterone receptor antagonist. As observed in clinical studies of congestive heart failure, as well as in animals with renal disease, antagonism of aldosterone receptors protects against end-organ damage through a combination of both hemodynamic and direct cellular actions (44).

An important consideration regarding the feasibility of aldosterone receptor antagonist therapy in chronic renal insufficiency is the risk of provoking hyperkalemia. Many patients with chronic renal insufficiency are already taking an ACE inhibitor or an angiotensin-II receptor antagonist, with the attendant risk of hyperkalemia. Despite such concerns, the results of the RALES and EPHESUS trials have been reassuring (28). In those studies, patients taking an ACE inhibitor who were randomized to spironolactone or eplerenone 25–50 mg/day had only small increases in potassium concentrations. Although the differences between those who took aldosterone receptor antagonists and those who took placebo were statistically significant, the mean increases were not clinically important, and serious hyperkalemia was uncommon. However, in clinical practice the risk of hyperkalemia may be greater (45), and close laboratory monitoring and judicious use of these drugs is necessary to minimize the risk.

Although it is an effective aldosterone receptor antagonist, spironolactone is limited by its tendency to cause undesirable sexual adverse effects. At standard doses, impotence and gynecomastia can occur in men, and premenopausal women can have menstrual disturbances. These adverse effects, caused by the binding of spironolactone to progesterone and androgen receptors, are substantial causes of drug withdrawal. In the RALES study there was a 10% incidence of gynecomastia or breast pain in men, compared with 1% with placebo, and significantly more patients discontinued treatment (2 versus 0.2%).

© 2006 Elsevier B.V. All rights reserved.

Although troublesome, these adverse effects are reversible and dose-related. The advent of selective aldosterone receptor antagonists, such as eplerenone, should reduce these adverse effects and thereby improve patient compliance. In EPHESUS there was no increase in the incidence of gynecomastia, breast pain, or impotence in men or menstrual irregularities in women who took eplerenone.

Organs and Systems

Cardiovascular

Cardiac dysrhythmias

Changes in potassium metabolism supposedly cause electrical instability in the heart, cardiac dysrhythmias, and increased mortality; replacement of potassium has been said to eliminate the risk of dysrhythmias (46–48). Mild hypokalemia might be expected to cause dysrhythmias in patients with serious organic heart disease (cardiomegaly, an abnormal electrocardiogram, frequent ventricular extra beats before treatment). However, the evidence suggests that hypokalemia after myocardial infarction is not the cause of dysrhythmias, but that both are the result of excess catecholamines. Furthermore, although hypertensive patients with left ventricular hypertrophy have an increased frequency of ventricular dysrhythmias, extra beats do not increase in frequency during diuretic treatment, even in the face of profound hypokalemia (49).

Early evidence linking thiazide-induced hypokalemia with dysrhythmias and sudden death was indirect and tenuous at best (50,51). One study suggested that diuretics are not responsible for the relation between hypokalemia and ventricular fibrillation in acute myocardial infarction (50). Chronic preoperative hypokalemia due to diuretics was not a risk factor for intraoperative dysrhythmias (52). Two large studies using 24-hour electrocardiographic monitoring failed to show a relation between diuretic-induced hypokalemia and ventricular dysrhythmias (53,54).

However, a retrospective analysis of 6797 patients with ejection fractions below 0.36 enrolled in the Studies Of Left Ventricular Dysfunction (SOLVD) was conducted to assess the relation between diuretic use at baseline and the subsequent risk of dysrhythmic death (54). Patients who were taking a diuretic at baseline ($n = 2901$) were significantly more likely to have such an event than those not taking a diuretic ($n = 2896$): 3.1 versus 1.7 per 1000 person-years. On univariate analysis and after controlling for important co-variates, the relation remained significant (relative risks 1.85 and 1.37 respectively). However, the association was seen only with non-potassium-sparing diuretics ($n = 2495$; relative risk 1.33); for potassium-sparing diuretics, alone or in combination with a non-potassium-sparing diuretic ($n = 406$), the relative risk was 0.90.

These data suggest that diuretic-induced potassium disturbances can cause fatal dysrhythmias in patients with left ventricular systolic dysfunction. SOLVD were not randomized trials of the risk of dysrhythmic death caused by diuretics. On average, patients retaking diuretics not only had lower serum potassium concentrations, but were also older, had more severe heart failure and were more likely to be taking antidysrhythmic drugs at baseline, although they had fewer indicators of ischemic heart disease. Even controlling for bias in multivariate analysis does not exclude the influence of unrecognized confounders. It is unknown whether diuretics were continued or changed during the 3 years of the trial. Thus, it remains uncertain that diuretic therapy is related to a risk of sudden dysrhythmic death in patients with heart failure.

Diuretic-induced hypokalemia is undoubtedly associated with a risk of serious ventricular dysrhythmias if diuretics are co-administered with drugs that prolong the QT interval (SED-13, 563). Diuretics increase the risk of torsade de pointes during antidysrhythmic drug therapy, independent of serum potassium concentration (54). The list of cardiac and non-cardiac drugs that prolong the QT interval continues to lengthen (54). It includes various antidysrhythmic drugs, including ibutilide, almokalant, and dofetilide; antimicrobial drugs, including clarithromycin, clindamycin, co-trimoxazole, pentamidine, imidazoles (such as ketoconazole), some fluoroquinolones, and antimalarial drugs (quinine, halofantrine); histamine H_1 receptor antagonists (terfenadine and astemizole); the antidepressant zimeldine; antipsychotic drugs (pimozide and sertindole); tricyclic/tetracyclic antidepressants; and cisapride. Particular care should be taken to avoid diuretic-induced hypokalemia when any of these agents is co-prescribed.

Coronary heart disease

There is no valid evidence that diuretics contribute to myocardial infarction, sudden death, or a failure of antihypertensive treatment or other risk factor interventions to prevent coronary deaths (50). An association between diuretics and sudden death has been suggested only in selected subset analyses, which allow no valid conclusions. Even in subjects with electrocardiographic abnormalities before treatment, there is no sound or consistent evidence to support the suggestion that diuretics predispose to sudden death.

Two retrospective case-control studies have reported an increased risk of cardiac arrest in hypertensive patients treated with thiazide-type diuretics (55,56). The risk was less among those treated with low-dose thiazides (equivalent to hydrochlorothiazide 25 mg/day) or with thiazides plus potassium-sparing drugs. The case-control design lacks one of the major advantages of randomized clinical trials, a tendency to equalize unknown, but important, differences between the comparison groups. Underadjustment is usual in case-control studies; for example, patients with more severe hypertension were more likely to have been treated with higher doses and less likely to have received potassium-sparing drugs because of renal dysfunction. Failure to randomize treatment tends to exaggerate differences between groups. Data from the prospective observational Gothenburg study suggested that metabolic changes during long-term treatment with antihypertensive drugs (predominantly beta-blockers and thiazides) are not associated with increased risk of coronary heart disease (57).

Metabolism

Despite their safety record, speculation persists that the metabolic effects of long-term diuretic treatment

© 2006 Elsevier B.V. All rights reserved.

predispose to myocardial infarction or sudden death, and that diuretic treatment may therefore be hazardous. It is worth noting that much of this speculation is found outside the columns of the legitimate medical press (SEDA-10, 185). The supposed risks of diuretics are broadcast in countless symposium proceedings, monographs, and such like, sponsored by pharmaceutical companies with a vested interest in diverting prescriptions from diuretics to other drugs. Needless to say, these publications do not present a balanced view. Studies of dubious quality are published repeatedly without ever appearing in refereed journals, and eventually come to be cited in independent reviews and articles. There can be no doubt that these publications have a large impact on prescribing practices.

It is relatively easy to foster these concerns, particularly since antihypertensive therapy would be expected to prevent myocardial infarction and sudden death, but in selected studies does not appear to do so. To explain this, it is suggested that the beneficial effects of lowering blood pressure are offset in part by adverse effects related to thiazide-induced biochemical disturbances. Hypokalemia and hypomagnesemia might, for example, be dysrhythmogenic and cause sudden death; or hyperlipidemia and impaired glucose tolerance might be atherogenic and promote myocardial infarction. Some authors have suggested that thiazides should certainly be avoided in left ventricular hypertrophy and coronary heart disease, because of an increased risk of ventricular extra beats (58,59), and that diuretics are not appropriate options in those who already have hyperglycemia, hyperuricemia, or hyperlipidemia (60). The argument has been taken ad absurdum by a suggestion that the use of diuretics as first-line treatment of hypertension is illogical (27). Others have argued effectively that we should not be impressed by such speculations and that treatment should be based on long-term experience (61), a conclusion similar to that reached in volumes of SEDA, from SEDA-9 to SEDA-19.

Impaired glucose tolerance and insulin resistance

There is little doubt that high dosages of diuretics carry an appreciable risk of impairing diabetic control in patients with established diabetes mellitus. However, their role in causing de novo glucose intolerance is not clear (63). Long-acting diuretics are more likely to alter glucose metabolism. Impaired glucose tolerance is a relatively rare complication with loop diuretics, although isolated cases of non-ketotic hyperglycemia in diabetics have been described (SED-9, 350).

The effects of thiazide-type diuretics on carbohydrate tolerance cannot be ignored (50). There is a definite relation between diuretic treatment, impaired glucose tolerance, and biochemical diabetes, and a possible relation with insulin resistance (64). It is well established that the effect of thiazides on blood glucose is dose-related, probably linearly, while the antihypertensive effect has little relation to dose (65–67). There is relatively little information on the time-course; numerous short-term studies have shown that the blood glucose concentration increases in 4–8 weeks (68). The evidence that current low dosages impair glucose tolerance in the long term is not entirely consistent, perhaps because of differences between studies in dosages, diuretics used, durations of treatment, and types of patient (68,69). In SHEP, low-dosage chlortalidone in elderly patients for 3 years resulted in a non-significant excess of diabetes (8.6 versus 7.5%) compared with placebo (70). The apparent differences between diuretics may be due to comparisons of dosages that are not equivalent (71). Important differences between individual diuretics will be established only when their complete dose–response relations for metabolic variables and blood pressure have been defined (68).

In contrast to the wealth of evidence on impaired glucose tolerance in diabetics, sound clinical trials of the effect on insulin resistance are difficult to find, considering the amount of comment and speculation on the topic (SEDA-15, 216). It is not known whether insulin resistance is completely or even partly responsible for the changes in glucose tolerance that occur during long-term thiazide treatment; impaired insulin secretion may also have a role (72). Hypokalemia or potassium depletion may contribute to impaired glucose tolerance, by inhibiting insulin secretion rather than by causing insulin resistance, but is not the only or even the main cause of impaired glucose tolerance during long-term diuretic treatment (68,69). The routine use of potassium-sparing diuretics with relatively low dosages of thiazides does not prevent impaired glucose tolerance.

Diuretics worsen metabolic control in established diabetes, but it is not known whether this adversely affects prognosis (68). Disturbances of carbohydrate homeostasis have been detected by detailed biochemical testing, but their clinical importance is uncertain (64). The major clinical trials have not shown a major risk of diabetes mellitus. The incidence of diabetes mellitus in diuretic-treated subjects is only about 1%, even when large dosages are used (73). In ALLHAT, among patients classified as non-diabetic at baseline, the incidence of diabetes after more than 4 years was 12% with chlortalidone compared with 9.8% (amlodipine) and 8.1% (lisinopril). Despite these trends, there was no excess of cardiovascular events or mortality from chlortalidone in the entire population or among patients with diabetes. Although these data are reassuring, observational data suggest that diuretic-induced new-onset diabetes carries an increased risk of cardiovascular morbidity and mortality, but that this may take 10–15 years to become fully apparent (74).

Since changes in glucose balance after diuretics tend to be reversible on withdrawal, measures of carbohydrate homeostasis should be assessed after several months of thiazide treatment to detect those few patients who experience significant glucose intolerance (75). With this approach, the small risk of diabetes mellitus secondary to diuretic therapy can be minimized.

Hyperuricemia

Most diuretics cause hyperuricemia. Increased reabsorption of uric acid (along with other solutes) in the proximal tubule as a consequence of volume depletion is one reason; however, diuretics also compete with uric acid for excretory transport mechanisms. There is a small increased risk of acute gout in susceptible subjects (73). In the large outcome trials, about 3–5% of subjects treated with diuretics for hypertension developed clinical gout

© 2006 Elsevier B.V. All rights reserved.

(76). In those with acute gout during diuretic treatment, attacks were more strongly related to loop diuretics than to thiazides (77). Gout was significantly associated with obesity and a high alcohol intake in the subgroup taking only a thiazide diuretic. About 40% of cases of acute gout may have been prevented by avoiding thiazides in those 20% of men who weighed over 90 kg and/or who consumed more than 56 units of alcohol per week.

Well-conducted studies have shown that diuretic-induced changes in serum uric acid are dose-related (66,78). In low-dosage regimens, as currently recommended, alterations are minor, and other than the risk of gout the long-term consequences of an increased serum uric acid are unknown.

The issues of whether hyperuricemia is an independent risk factor for cardiovascular disease and the clinical relevance of the rise in serum uric acid caused by diuretic treatment are controversial (SED-14, 660) (50). In the Systolic Hypertension in the Elderly Program (SHEP), diuretic-based treatment in 4327 men and women, aged 60 years or more, with isolated systolic hypertension was associated with significant reduction in cardiovascular events (SED-14, 657). Serum uric acid independently predicted cardiovascular events in these patients (79). The benefit of active treatment was not affected by baseline serum uric acid. After randomization, however, an increase in serum uric acid of less than 0.06 mmol/l (median change) in the active treatment group was associated with a hazard ratio (HR) of 0.58 (CI = 0.37, 0.92) for coronary heart disease compared with those whose serum uric acid rose by 0.6 mmol/l or more. This was despite a slight but significantly greater reduction in both systolic and diastolic blood pressures in the latter. Those with serum uric acid increases of 0.6 mmol/l or more in the active group had a similar risk of coronary events as those in the placebo group.

This analysis of the SHEP database confirms the findings of a systematic worksite hypertension program (80). In 7978 treated patients with mild to moderate hypertension, cardiovascular disease was significantly associated with serum uric acid (HR = 1.22; CI = 1.11, 1.35), controlling for known cardiovascular risk factors. The cardioprotective effect of diuretics increased from 31% to 38% after adjustment for serum uric acid.

These observations suggest that persistent elevation of serum uric acid during diuretic-based antihypertensive therapy may detract from the benefit of blood pressure reduction. However, the relation between serum uric acid and cardiovascular disease was independent of the effects of diuretics. Furthermore, low-dose thiazide regimens have a smaller impact on serum uric acid (SED-14, 660).

Lipid metabolism

Reviews of the influence of diuretics on serum lipids (81–84) are in broad agreement as regards short-term effects. Thiazide and loop diuretics increase low-density lipoprotein (LDL) cholesterol, very-low-density lipoprotein (VLDL) cholesterol, total cholesterol, and triglycerides. The effect on high-density lipoprotein (HDL) cholesterol has been variable. The ratio of LDL/HDL or total cholesterol/HDL is generally increased, but not in all studies. Spironolactone 50 mg bd caused modest falls in HDL cholesterol and triglycerides (85). The effects of other potassium-sparing drugs on lipid metabolism have not been well documented. The possible mechanisms of these various short-term effects have been discussed (84).

Diuretic-induced effects on lipid metabolism are dose-related (66,67): at low dosages of thiazides, changes are very slight while antihypertensive efficacy is well maintained. Diuretic-induced lipid changes have not been prominent in studies lasting one year or longer (11,20,81,84,86). An association between thiazide use or antihypertensive treatment and changes in serum lipids has been shown in some population surveys (87,88) but not in others (89).

Most studies of the effects of diuretics on serum lipids have lacked a placebo control to allow identification of time-dependent or environmental changes, or have been confounded intentionally or unknowingly by life-style interventions, including weight loss, diet, and exercise (69). The argument that the effects of diuretics on lipids may limit the beneficial effect of blood pressure reduction is difficult to sustain (50). The effect of thiazides is largely transient, and in the long term total cholesterol and LDL cholesterol are raised only slightly and HDL cholesterol is unchanged. It is not known whether diuretic-induced changes in cholesterol carry the same prognostic significance as naturally occurring hyperlipidemia (50,90). Attempts to calculate a potential impact of diuretic-induced increases in total cholesterol and LDL cholesterol on coronary prognosis are premature. Observations have so far been limited largely to serum concentrations. However, binding of lipids to vascular cells, rather than in the bloodstream, is decisive for atherogenesis, and the effect at the cellular level remains to be investigated.

It has been suggested that even small changes in lipids might be clinically significant (91). However, the study was underpowered to show statistical significance of minor effects. Since under 50% of the patients in each group were followed for 1 year, selection bias may also have been introduced. It should be remembered that lipid changes are subsidiary to mortality. In this respect, diuretics are the best established of the antihypertensive drug classes.

There is little or no evidence that thiazides should be avoided in patients with hyperlipidemia (75), although some physicians continue to make this recommendation. Serum lipids should be checked within 3–6 months of starting thiazides to detect the very few patients who have an increase in total cholesterol or LDL cholesterol. This should not add to the cost of care, since serum chemistry need only be obtained once or twice a year and is no reason to avoid the use of these drugs as initial monotherapy.

Electrolyte balance

Potassium-wasting diuretics can cause sodium and potassium depletion with hyponatremia and hypokalemia. Potassium-retaining diuretics can cause hyperkalemia.

Hyponatremia

Treatment with thiazide diuretics is one of the most common causes of hyponatremia (92). Patients can present with variable hypovolemia or apparent euvolemia,

© 2006 Elsevier B.V. All rights reserved.

depending on the magnitude of sodium loss and water retention.

Two major surveys have reviewed the features of diuretic-induced hyponatremia (93,94). Thiazide-like diuretics alone or in combination with potassium-sparing diuretics are responsible for more than 90% of cases. Hyponatremia occurs mainly in elderly women, although the relation with age probably merely reflects the widespread use of diuretics in older subjects. In most cases, the interval between starting thiazide and clinical presentation is less than 2 weeks; serum sodium may fall by 5 mmol/l or more in 24 hours or less in patients who develop severe hyponatremia. In contrast, when loop diuretics cause hyponatremia, the lag period is usually several months. Hypertension is the indication for diuretics in over 80% of cases. The patient is clinically euvolumic, but in the majority excess antidiuretic hormone (ADH) activity, hypokalemia, excess water intake, and increased free water clearance singly or together appear to contribute to the development of hyponatremia. The urine is inappropriately concentrated and contains moderately large amounts of sodium. The findings may be clinically indistinguishable from those of the syndrome of inappropriate ADH secretion. Severe neurological complications are seen in about 60%; seizures (30%), stupor or coma (30%), and death (5–10%). The extent of irreversible loss of intellectual function is unknown. Serum sodium concentration is usually in the range 105–120 mmol/l. If diuretics are withdrawn, the serum sodium concentration returns to normal, but hyponatremia is reproducible on rechallenge.

Comprehensive accounts of the pathophysiology, etiology, and management of hyponatremia have stressed the care required in correction of symptomatic hyponatremia (95). Neurological signs are an indication for active sodium replacement using hypertonic saline. Correction should be planned over 24–48 hours to increase serum sodium by 1 mmol/l each hour with a target increase of 20–25 mmol/l, a serum sodium concentration of 130 mmol/l or abolition of symptoms. If onset is within 24 hours of starting diuretics, correction should be rapid but within a total increase of 20 mmol/l in the first 24 hours. If the onset is over several days or longer, correction should be slower, aiming for 12–15 mmol/l in 24 hours. There is concern that rapid correction of hyponatremia and a relatively high total correction (more than 20 mmol/l in the first 24 hours) can be associated with higher morbidity or a demyelinating syndrome (94), but the rate of correction does not appear to be important to the outcome if the absolute increase is limited to 25 mmol/l over 48 hours (95). An extensive review of the literature suggested that rate of correction is not a factor in the genesis of hyponatremic brain syndrome (95).

The use of fixed combination of a thiazide and a potassium-sparing drug, often Moduretic (hydrochlorothiazide 50 mg with amiloride 5 mg), has been consistently implicated in diuretic-induced hyponatremia. Treatment with chlorpropamide (200–800 mg/day) along with Moduretic has precipitated hyponatremia in several cases (96). Simultaneous use of Moduretic with trimethoprim has also been reported to increase the risk (97). The mechanism appears to be impairment of the clearance of free water, resulting in dilutional hyponatremia. Whether data such as these point to a special risk of Moduretic as a product or merely reflect its extraordinarily widespread use in old people is not clear. In a survey of electrolyte disturbances in 1000 geriatric admissions, the incidence of hyponatremia with the combination of hydrochlorothiazide and amiloride was twice that with other diuretics, although the difference failed to reach statistical significance (98).

Management

There is no consensus about the optimal treatment of symptomatic hyponatremia. The authors of a comprehensive review recommended a targeted rate of correction that does not exceed 8 mmol/l on any day of treatment (92). Remaining within this target, the initial rate of correction can still be 1–2 mmol/l/hour for several hours in patients with severe symptoms (SED-13, 562). They suggested the following formulae for calculating the effect of giving 1 liter of infusate on serum sodium.

- Solutions containing sodium only:
  Change in serum sodium concentration (mmol/l)
  $= (\text{infusate } Na^+ - \text{serum } Na^+)/(\text{total body water} + 1)$
- Solutions containing sodium and potassium:
  Change in serum sodium concentration (mmol/l)
  $= (\text{infusate } Na^+ + \text{infusate } K^+ - \text{serum } Na^+)/(\text{total body water} + 1)$

Estimated total body water (in liters) is calculated as a function of body weight: 0.6 l/kg in children; 0.6 and 0.5 l/kg in non-elderly men and women respectively; 0.5 and 0.45 l/kg in elderly men and women respectively.

Loop diuretics can cause hypernatremia by increasing free water clearance (net water loss in the form of hypotonic fluid) (99). Over-rapid correction should be avoided.

Hypokalemia

The loss of potassium caused by diuretics is their most intensively debated adverse effect, and the extent and significance of the problem has long been disputed. The effect of diuretics on potassium balance and their clinical consequences have been reviewed extensively (50–52,65,100–102). The risks of diuretic-induced hypokalemia have been greatly exaggerated (50,65,102). A fall in plasma potassium is common, but sound studies have consistently showed that diuretics do not deplete body potassium or cause potassium deficiency during long-term therapy in hypertensive patients (50).

Susceptibility factors

In most patients, routine monitoring of serum potassium and routine administration of potassium-sparing diuretics is unnecessary (65,102), although patients at special risk require particular attention. Routine administration of potassium-sparing diuretics may have some justification in such patients. The following postulates seem to summarize the present position:

- When there is severe hypokalemia, it should not be attributed immediately to diuretic treatment. It may well be due to primary hyperaldosteronism, occult chronic liver disease, or abuse of licorice or laxatives.

© 2006 Elsevier B.V. All rights reserved.

- Relatively mild degrees of hypokalemia can be dangerous in patients taking cardiac glycosides, because their effects on the myocardium are potentiated in the absence of potassium (51).
- Diuretic-induced hypokalemia should also be avoided in patients taking drugs that prolong the QT interval, for example some antidysrhythmic drugs (quinidine, procainamide, disopyramide, encainide, sotalol, amiodarone), some psychotropic drugs (thioridazine, imipramine, phenothiazines), the lipid lowering drug probucol, the antibiotic erythromycin, and the 5-HT_2 receptor antagonist ketanserin.
- The risk of a clinically important degree of hypokalemia is increased in patients with liver cirrhosis and those with severe cardiac failure complicated by secondary hyperaldosteronism.
- In heart failure, depletion of potassium can provoke fatigue and lethargy and can cause ventricular dysrhythmias in the failing heart (102). Potassium depletion can occur in cardiac failure when neurohumoral systems are stimulated by diuretics and can be especially profound when skeletal muscle wasting is advanced (101). However, since heart failure itself, independent of diuretic treatment, is associated with loss of total body potassium, it is difficult to assess the independent contribution of diuretic treatment to this potassium deficit.

Critical reviews have concluded that in most patients (that is in the absence of the occasional risk factors listed above) diuretics can be prescribed alone, and that there is no need to take precautions against hypokalemia (63,103). Precautions, including the monitoring of serum potassium, have to be taken when there are risk factors or when symptoms (for example muscle pain) occur, or in patients who require aggressive treatment with both a thiazide and a loop diuretic; such a combination is indeed likely to provoke considerable falls in serum potassium, even to concentrations below 2.5 mmol/l (104). An observational study in 43 738 American men aged 40–75 years and without cardiovascular disease or diabetes showed that stroke was less likely in those with high potassium intake and that use of potassium supplements was related inversely to stroke in men taking diuretics (105). Diuretic-based treatment was associated with a significant mean reduction in serum potassium in SHEP (70). Although there were notable reductions in stroke in SHEP (14), potassium supplements were used if the serum potassium fell below 3.5 mmol/l. Therefore, avoidance of hypokalemia may be important in ensuring the cardiovascular benefits of thiazides in the management of hypertension.

Well-conducted studies (66,78) have underlined the fact that the dose–response curves for lowering blood pressure and lowering plasma potassium during diuretic treatment are dissociated. There is little if any loss of antihypertensive effect with low doses of diuretics, whereas hypokalemia is much less prominent. Although low dosages of diuretics are to be preferred in uncomplicated hypertension, very low dosages of thiazides may not be as effective as higher dosages (106).

Management

In patients in whom hypokalemia needs to be prevented or corrected, potassium-sparing diuretics should be preferred to potassium supplements, which are relatively ineffective, even in high dosages (SEDA-14, 180) (SEDA-15, 214).

The National Council on Potassium in Clinical Practice has provided guidelines on potassium replacement (107). In hypertensive patients with drug-induced hypokalemia, an effort should be made to achieve and maintain the serum potassium concentration at 4.0 mmol/l or over. Potassium replacement should be considered routinely in patients with congestive heart failure, even if the initial potassium determination is normal. Regular monitoring of serum potassium is essential in these patients, because of the risk of hyperkalemia in patients given potassium (or potassium-sparing diuretics) and ACE inhibitors or angiotensin receptor antagonists. Maintenance of optimal potassium concentrations (4.0 mmol/l or over) is critical in patients with cardiac dysrhythmias, and again routine potassium monitoring is obligatory.

Angiotensin-converting enzyme inhibitors are widely believed to attenuate diuretic-induced falls in plasma potassium. However, captopril 25 mg bd had no effect on plasma potassium in hypertensive patients treated with bendroflumethiazide 5 mg/day (108).

Hyperkalemia

All potassium-sparing diuretics can cause hyperkalemia. Several groups of patients are at particularly high risk of developing hyperkalemia if they take potassium-sparing diuretics (109). These include patients with moderate to severe chronic renal insufficiency, hypoaldosteronism, and diseases associated with impaired response to the potassium secretory effects of aldosterone. Hypoaldosteronism is often seen in elderly patients, those with chronic renal impairment or diabetic nephropathy, those with AIDS, or those with primary adrenal disease. In addition, patients with sickle cell disease, obstructive uropathy, systemic lupus erythematosus with nephropathy, and renal transplants may have tubular resistance to the effects of mineralocorticoids. Spironolactone 300 mg can significantly increase the serum potassium concentration in hemodialysis patients, suggesting that aldosterone may affect the cellular handling and gastrointestinal excretion of potassium. Commonly forgotten is the patient for whom these diuretics are prescribed as a precautionary measure and who for many years has been flavoring a low-salt diet with "salt substitutes," which are often based on potassium chloride (110).

Life-threatening hyperkalemia has been observed in patients receiving potassium-sparing diuretics (111). The most distressing finding in this study was that these agents were far more often prescribed in patients with abnormal kidney function than were other diuretics. Combining potassium-sparing diuretics with potassium supplements borders on malpractice; regular monitoring of serum potassium is mandatory in all patients treated with potassium-sparing diuretics, particularly if they are elderly or have abnormal renal or hepatic function.

Mineral balance

Thiazide and thiazide-like diuretics reduce the renal clearance of calcium by inhibiting the tubular secretion

© 2006 Elsevier B.V. All rights reserved.

of calcium ions. In contrast, furosemide (which does not promote reabsorption of calcium in the distal tubule) causes transient hypercalciuria, an effect that has been exploited on occasion in the treatment of hypercalcemia (SED-9, 346) (112).

Metal metabolism

Diuretic-induced magnesium loss has been heavily stressed both by some independent investigators and by those seeking for commercial reasons to discredit the diuretics; there are far more reviews on the subject than sound original studies. It has been declared (113) that diuretic-induced magnesium deficiency "positively contributes" to myocardial infarction, delayed infarct healing, coronary and cerebral arterial spasm, hyperlipidemia, and cardiac dysrhythmias, with the addition of a horrific catalog of clinical manifestations, including ataxia, delirium, convulsions, coma, and ventricular fibrillation. Ramsay has remarked that this review, and others like it, belongs to the category of science fiction rather than that of serious medical writing (SEDA-10, 187).

Most reviews of the effects of diuretics on magnesium metabolism are uncritical and extrapolate wildly from the little sound evidence that is available (50). Several uncontrolled studies and very few controlled studies have suggested that long-term thiazide treatment causes a small fall in serum magnesium within the reference range. The complex relation between intracellular free and total magnesium content remains to be clarified, and there is absolutely no evidence that diuretic treatment reduces intracellular magnesium, and the few competent investigations have suggested that it does not. Diuretic-induced disturbances of magnesium balance do not cause depletion of intracellular potassium. The clinical significance of the small diuretic-induced alterations in magnesium balance, if any, is obscure. There is no satisfactory evidence that diuretic-induced magnesium disturbances cause or predispose to cardiac dysrhythmias, either in general or specifically after myocardial infarction (114).

A balanced account (115) concluded that the controlled trials, of which there are few, do not substantiate a role of diuretics in causing magnesium deficiency. Consequently, the vast majority of patients taking conventional doses of thiazides do not need magnesium supplements. On balance, potassium-sparing diuretics tend to increase serum and intracellular magnesium content, but this should not be taken as evidence of prior magnesium deficiency. It remains theoretically possible that large doses of loop diuretics given more than once-daily for long periods could induce negative magnesium balance and magnesium deficiency. However, it is difficult to conduct appropriately controlled trials in heart failure, in which such treatment is needed, and until more reliable information becomes available no absolute recommendation can be made. Magnesium depletion should be regarded as no more than a possible, as yet unproven, risk factor for cardiovascular morbidity and mortality (116).

In ordinary practice, serum magnesium need not be monitored in patients taking diuretics, and potassium-sparing drugs should not be used to prevent non-existent magnesium problems (SEDA-10, 190).

Gastrointestinal

Potassium, given separately or in combination with a diuretic, introduces the risk of esophageal injury; attempts to provide potassium in modified-release formulations have simply transposed the site of injury from the esophagus to the small bowel (SEDA-10, 187).

Urinary tract

Since diuretics act primarily on the kidney, it is hardly surprising that renal damage can occur including interstitial nephritis (117,118). However, toxic damage is very rare in relation to the number of patients treated. Renal damage due to interstitial nephritis is more likely to occur in patients with pre-existing glomerular disease. It tends to present 4–10 weeks after starting treatment, with non-oliguric acute renal insufficiency and in some cases pyrexia and eosinophilia. This complication probably always recovers spontaneously and completely, although some consider it prudent to give high doses of glucocorticoids.

Sexual function

The adverse effects of thiazide and thiazide-like diuretics on male sexual function include reduced libido, erectile dysfunction, and difficulty in ejaculating. The exact incidence of sexual dysfunction in patients taking diuretics is poorly documented, perhaps because of the personal nature of the problem and the reluctance of patients and/or physicians to discuss it. However, these abnormalities have been reported with incidence rates of 3–32%. The true incidence of sexual dysfunction probably lies closer to the lower end of this range (119). In a meta-analysis of 13 randomized, placebo-controlled trials conducted over a mean of 4 years the NNH (number needed to harm) for erectile impotence with thiazide diuretics in hypertension was 20 and the relative risk was 5.0 (120).

The mechanisms by which thiazides affect erectile dysfunction or libido are unclear, but it has been suggested that they have a direct effect on vascular smooth muscle cells or reduce the response to catecholamines. Sexual dysfunction does not appear to be mediated by either a low serum potassium concentration or a low blood pressure. Since sexual dysfunction can adversely affect the quality of life of hypertensive patients, physicians or health-care providers should take an accurate baseline sexual history and monitor sexual status for changes during therapy. If there are significant changes in sexual function, diuretic therapy can be withdrawn and an alternative drug class substituted. However, not uncommonly sexual dysfunction will persist despite withdrawal of the diuretic, suggesting that elements of the hypertensive state itself contribute to the process.

Analysis of the risk of erectile impotence has been hampered by the fact that impotence is common in men beyond middle age and is likely to be even more common in hypertension, treated or otherwise. The UK MRC trial (11) was the first to provide quantified evidence of a link with diuretics; in men taking bendroflumethiazide 10 mg/day, the withdrawal rate for impotence was 19.6 cases per 1000 treatment years, compared with 0.9 cases with placebo. However, these figures may exaggerate the effect, since the trial was single-blind. A questionnaire

© 2006 Elsevier B.V. All rights reserved.

pointed to a less striking difference; after 3 months impotence was noted in 16% of diuretic-treated patients and 9% of those taking placebo, and the roughly 2:1 ratio was again noted after 2 years. Later studies (16,86,121–123), pointed to a similar effect, even when low-dosage regimens were used (16,86). Some studies (123) but not others (86) have suggested that weight reduction ameliorates diuretic-induced sexual dysfunction. Erectile dysfunction occurs early and is often tolerable; onset after 2 years is unlikely (86).

Erectile impotence is particularly common in men with diabetes (16), who are likely to have difficulties because of autonomic dysfunction. It is unclear whether younger men and women are similarly affected and whether normotensive men have fewer such problems (124). Most investigations of the effects of diuretics on sexual function have been characterized by poor study design (125); the majority had no placebo control and relied on comparisons with baseline. The best studies have suggested an increase in erectile dysfunction in thiazides users compared with placebo. Bearing in mind all the confounding factors, it can be concluded that diuretics will sometimes cause impotence, but that in the population as a whole the effect is slight compared with other causes (SEDA-11, 197) (SEDA-11, 198).

Sexual problems due to diuretics are very rare in women (16,86).

Long-Term Effects

Drug abuse

When diuretics are abused it is mostly in the course of a misguided attempt to lose weight; in the past, various "slimming remedies" offered for sale outside normal trading channels have been found to contain diuretics, sometimes with components such as thyroid extract. The unnecessary use of diuretics by a healthy individual, perhaps in excessive doses, can lead to dehydration, hypokalemia, and hypotension; when furosemide is abused, even tetany can occur because of hypocalcemia (126). The weight loss achieved by using diuretics in this way is purely due to dehydration and will soon be annulled by extra fluid intake.

One complication of long-term diuretic therapy in otherwise healthy individuals is edema, and it has been suggested that surreptitious use of diuretics can explain some otherwise paradoxical cases of idiopathic edema; presumably the diuretic induces a persistent increase in plasma renin activity and secondary hyperaldosteronism, and attempts to stop the diuretic intake can at first actually aggravate the condition (127). However, three studies have furnished strong evidence that diuretic abuse is not an important cause of idiopathic edema (128–130).

In some patients the covert use of diuretics leads to a complete replica of Bartter's syndrome, characterized by hypokalemia and hyper-reninemia without hypertension (131,132). In a patient who denies having taken diuretics, the true diagnosis may only be made by finding the drug or its metabolites in the urine, although challenge with diuretic may provoke the syndrome, while withdrawal leads to weight gain and the resolution of metabolic alkalosis.

The dangers of diuretic abuse among athletes have been discussed (SEDA-21, 228). Diuretics are used illegitimately by many athletes and amount for 6% of all drugs abused. They are taken by body builders to dehydrate the tissues, giving better definition to muscle shape, as well as to offset the fluid retaining effect of concomitant anabolic steroids and growth hormone, used to increase muscle mass. Diuretics are used in other sports to reduce weight, allowing competition in lower body weight classes, and to dilute the urine, reducing its specific gravity and making difficult the detection of other banned drugs. This practice is not only unethical but also hazardous.

Tumorigenicity

There is an association between diuretic use and renal cell carcinoma (133). Some of the studies that support this association can be dismissed, since the epidemiological data on which they were based were not suitably adjusted for confounding variables, including obesity, hypertension, age, and cigarette smoking. However, other case-control studies have shown a small risk of renal cell carcinoma in patients taking long-term diuretics after adjustment of the data for potentially confounding variables.

The carcinogenic mechanism of diuretics is not known, but could be related to a carcinogenic action of *N*-nitroso metabolic derivatives of thiazide and loop diuretics or structural changes in the transporting tubular epithelia, which provoke different stages of apoptosis. Rats and mice treated with diuretics have been reported to develop nephropathies and renal adenomas. Renal cell carcinoma arises in renal tubular cells, which are the principal site of action of diuretics. Contact over years or decades may have a low-grade carcinogenic effect. However, most prospective randomized trials provide too short a period of observation to assess the potential for carcinogenicity unequivocally. Furthermore, the findings may have been confounded by other risk factors for renal cell carcinoma. Adjustment for confounders greatly attenuated the risk (to non-significance) in one study, and in another the association with diuretic use disappeared completely. Therefore, the findings from these observational studies may have resulted from uncontrolled confounding by known or unrecognized risk factors.

The relation between diuretic therapy and the risk of malignancies has been examined in a review of pertinent publications between 1966 and 1998 (134). In nine case control studies (4185 cases), the odds ratio for renal cell carcinoma in patients treated with diuretics was 1.55 (95% CI = 1.42, 1.71) compared with non-users of diuretics. In three cohort studies of 1 226 229 patients (802 cases), patients taking diuretics had a more than two-fold risk of renal cell carcinoma compared with patients not taking diuretics. Women had an odds ratio of 2.01 (CI = 1.56, 1.67) compared with 1.96 (CI = 1.34, 2.13) in men. Thus, the cumulative evidence suggests that long-term use of diuretics may be associated with renal cell carcinoma.

The findings linking diuretic therapy with renal cell carcinoma need careful scrutiny. The strength of evidence provided by observational studies is limited, and such studies have yielded contradictory and controversial results in the past. An accompanying editorial (135)

© 2006 Elsevier B.V. All rights reserved.

pointed out that some of the studies reviewed appear to have been designed to evaluate predictors of renal cell carcinoma without an a priori hypothesis that diuretics might be implicated. Statistical significance (set at $P < 0.05$) may have emerged merely by chance if 20 risk factors were examined.

Another commentary (136) emphasized the potential bias of observational studies and also publication bias in meta-analysis. The contemporary relevance of the findings is further reduced, since many of the studies included patients taking very high doses of thiazides. It is difficult to disentangle a drug-related effect from the association between hypertension and renal cell carcinoma.

Since renal cell carcinoma is rare, the practical importance of these observations is small: one extra case of renal cell carcinoma in 1500 patients treated for 20 years. If the hypothesis is correct, antihypertensive therapy with diuretics will prevent 20–40 strokes, 3–28 heart attacks, 3–10 cardiovascular deaths, and 4–14 deaths overall for every extra case of renal cell carcinoma. Even middle-aged women would be spared six strokes for each potential case of renal cell carcinoma. If a low grade carcinogen is involved, most patients will not live long enough for its effect to be expressed. The available information does not support a change in current prescription practices for diuretics in the treatment of hypertension and cardiac failure. Physicians should be more concerned about controlling blood pressure rather than concerning themselves with what at best might be a small risk of renal cell carcinoma.

Other cancer types have been evaluated for their association with diuretic therapy. The development of colon cancer has been studied in 14 166 patients aged 45–74 years with a previous myocardial infarction and/or stable angina, screened for participation in the Bezafibrate Infarction Prevention Study (137). Of these, 2153 used diuretics and 12 013 did not. Multivariate analysis identified diuretics as an independent predictor of an increased incidence of colon cancer (hazard ratio 2.0) and colon cancer mortality (hazard ratio 3.7). However, the association between diuretic therapy and a higher incidence of colon cancer was observed only among non-users of aspirin. There was a relatively lower incidence of colon cancer in furosemide users and a higher incidence in the small combined subgroup of those who took amiloride and/or hydrochlorothiazide. Further studies to test the association between diuretics and colon cancer, as well as the potential protective effects of aspirin, are needed. Until these data become available, physicians should be aware of the potential effects of diuretics, especially when choosing long-term treatment for young patients with mild hypertension.

Second-Generation Effects

Pregnancy

Diuretics have been used for the treatment of both hypertension and edema in pregnancy. While regimens including thiazides have improved the outcome in hypertension developing during the first 20 weeks of pregnancy, the situation in later pregnancy seems to be different. Some controlled studies have shown that the thiazides do not influence the development of pre-eclampsia (138) and can even aggravate it.

Edema is a relatively frequent finding in normal pregnancy. It appears to be benign and can even be associated with improved obstetric performance (139). Edema, even in the presence of hypertension or proteinuria, is not a useful predictor of obstetric complications (140). These observations are important, in view of the finding that treatment with thiazide diuretics is associated with a reduced birth weight in normotensive pregnant subjects (141).

In a review of eight large-scale trials, four well-controlled studies did not show any benefit, whereas four others, which showed some benefit, were judged to be totally unsatisfactory, either because control was not strict enough or because inclusion and exclusion criteria were either not sufficiently well-defined or were scientifically unacceptable (142). The general consensus in earlier publications was that diuretics are useless, because they reduce the already lowered cardiac output in pre-eclamptic toxemia and so further reduce placental and uterine perfusion (143,144); diuretics do not alter the incidence of pre-eclamptic toxemia and eclampsia and they do not improve perinatal mortality or birth weight. Both the maternal adverse effects (hypokalemia, metabolic acidosis, hyperglycemia, hyperuricemia, hemorrhagic pancreatitis, and even death due to abuse) and the fetal and perinatal adverse effects (hyponatremia, fetal dysrhythmias induced by hypokalemia, thrombocytopenia, and jaundice) preclude the use of diuretics in pre-eclamptic toxemia.

Nine randomized, controlled studies of the use of diuretics in pre-eclampsia have been analysed (145). There were almost 7000 subjects in whom thiazides had been compared with placebo or no treatment. In the pooled analysis, diuretic treatment was associated with a non-significant reduction in perinatal mortality (about 10%) and stillbirths (about 33%). There was no excess of serious adverse reactions, either in the mothers or the neonates. These findings thus give no support to the belief that diuretics are harmful in pregnancy. It should not be concluded that diuretics ought to be used in pre-eclampsia in preference to other well-established agents, but they certainly can be used with confidence when they are really needed, for example in patients with severe hypertension that predates pregnancy and in heart failure.

Nevertheless, substantial numbers of pregnant women use these agents during pregnancy. In a Swedish study (146), 11% of 341 women took diuretics in the third trimester, while in a Tennessee Medical study (147) diuretics were prescribed as frequently as hypnotics and minor tranquilizers (7% for each category of drug). On the other hand, a study based on a University obstetrics programme in Florida (148) found that diuretics had been prescribed for only 2.4% of the patients.

Obviously treatment with any drug during pregnancy will affect both mother and fetus, and two aspects of such therapy are important: the adverse effects of the drug and the potential for teratogenicity.

Chlorothiazide readily crosses the placenta (149), but there have been few studies of the effects of diuretic treatment on the fetus. There are case reports of abnormalities of glucose handling (150) and severe electrolyte disturbances (151) in pregnant women taking diuretics,

© 2006 Elsevier B.V. All rights reserved.

but these reports generally do not mention the metabolic values in the neonate. There has been one report of chronic fetal bradycardia associated with a low serum potassium in the diuretic-treated mother (152). Infusion of potassium restored maternal electrolytes and fetal heart rate. Normal delivery followed later, and electrolyte values in the child were normal. With regard to glucose handling, Senior and others (153) have raised the possibility that thiazide treatment of the mother can lead to neonatal hypoglycemia. In the absence of other predisposing factors, thiazides had been given to the mothers of 57% of their affected children, and, in the general population, the risk of neonatal hyperglycaemia was increased five-fold by thiazide treatment of the mother.

Hematological effects in the neonate have also been ascribed to maternal diuretic treatment. Seven cases of neonatal thrombocytopenia attributed to chlorothiazide have been described (154) and one case in which hydrochlorothiazide may have played a role (155). None of the mothers had thrombocytopenia. There was one death among the affected infants. Neonatal hemolysis occurred in two infants and was attributed to maternal thiazide therapy (156).

There is no evidence of a teratogenic effect of diuretics in humans, although one case of teratoma has been reported in the offspring of a woman treated for the first 19 weeks of pregnancy with acetazolamide (157), which is teratogenic in experimental animals. The lack of evidence of teratogenicity is not surprising. Assuming a basic malformation rate of 0.1% and that a drug that is used by 2% of pregnant women increases the malformation rate six times, it would require more than 100 000 women to be sure of detecting such an effect (146).

Susceptibility Factors

Age

There has been much discussion about the safety or risks of diuretics in elderly people. Although diuretic use has been implicated as a cause of urinary incontinence, no evidence has been presented to confirm this. An epidemiological survey of 1956 respondents aged at least 60 years showed no significant difference between diuretic-users and non-users in the prevalence of incontinence (158).

Orthostatic hypotension, although often loosely referred to in older literature (SED-10, 370) (159), is in fact only likely to become a problem in very old subjects, aged 90 years or more, even if a potent loop diuretic is used; this was the clear conclusion of a good prospective study published in 1978 (159). In 843 independent living men and women aged 60–87 years, postural fall in systolic blood pressure was not related to treatment with diuretics, after correction for initial blood pressure (160). At currently recommended doses, older subjects do not generally experience particular problems from hypokalemia and do not appear to be at special risk of cardiac dysrhythmias in the face of diuretic-induced hypokalemia (SEDA-15, 218).

Reviews of the age-related effects of diuretics in hypertensive subjects (161,162) have concluded that symptomatic adverse reactions are not more frequent in older patients and some trials have suggested a lower frequency than in younger subjects. Although the elderly may be susceptible to some metabolic effects of diuretics, the evidence for cardiotoxic potential is not conclusive.

The best overall evidence of the safety of diuretics in old people comes from the large-scale outcome trials in hypertensive patients (11,13,15,17,18). These studies in over 10 000 subjects aged over 60 years showed clearly that thiazide-based treatment reduces the risk of stroke, coronary heart disease events, and cardiovascular events in older hypertensive patients. A meta-analysis (163) of randomized trials lasting at least 1 year and involving 16 164 individuals aged at least 60 years showed that diuretics were superior to beta-blockers with regard to all endpoints (stroke, coronary heart disease events, cardiovascular mortality, and all-cause mortality). The beneficial effects noted in these trials should dispel any doubts about the safety and efficacy of diuretics in old people.

Drug Administration

Drug formulations

Fixed combinations of thiazides and loop diuretics with potassium and of thiazides with beta-blockers serve little useful purpose and can in fact do harm. Combinations of thiazides and loop diuretics with potassium-sparing diuretics serve the needs of the small minority of patients who develop clinically significant hypokalemia when given diuretics alone, or in whom hypokalemia is particularly risky. In fact, these combinations are much too widely used, and since individual needs vary so much there is a spectrum of risk, ranging from hypokalemia to hyperkalemia (SEDA-10, 370) (SEDA-10, 371).

Drug–Drug Interactions

Antidysrhythmic drugs

Hypokalemia due to diuretics potentiates the dysrhythmogenic actions of antidysrhythmic drugs that prolong the QT interval, such as Class I and Class III antidysrhythmic drugs, increasing the risk of torsade de pointes (164). This can also happen with other drugs that prolong the QT interval, such as phenothiazines (165).

Beta-blockers

Interaction of thiazides with beta-blockers can cause a greater risk of hyperglycemia than if either component is given separately (166,167).

Cardiac glycosides

Hypokalemia due to diuretics potentiates the actions of cardiac glycosides and can result in digitalis toxicity. In 67 patients taking a maintenance dose of digoxin, 42 with digoxin toxicity and 25 without, the mean serum digoxin concentration was significantly higher in the former and the mean serum potassium concentration was significantly lower (168). Among the patients with toxicity, 24% had hypokalemia due to diuretics. The mean serum digoxin concentration in those with hypokalemia and toxicity was significantly lower than in those with normokalemia and toxicity.

Dobutamine

General Information

Dobutamine is a relatively selective $beta_1$-adrenoceptor agonist with only slight $beta_2$- and alpha-adrenoceptor activity. It has been developed as a positive inotropic agent that is less vasoconstrictive than high doses of dopamine.

Organs and Systems

Cardiovascular

Dobutamine stress testing, particularly combined with echocardiography, is a very widely used tool in cardiological investigation, and its safety continues to be examined in great detail. In a review of 37 publications, each reporting on 100 or more patients, with a total of over 26 000 tests, 79 life-threatening complications were described, including acute myocardial infarction, a variety of cardiac dysrhythmias, and severe hypotension (1). The authors also referred to 29 isolated case reports of severe complications, including two deaths. They concluded that there must be a clear indication for the procedure, informed consent must be obtained, a physician should be present during the test, and patients should be carefully followed as outpatients in case of delayed problems.

An Israeli group has reviewed the hemodynamic and adverse effects of dobutamine in 400 patients, of whom 187 were aged 65–79 years and 49 were 80 years or older (2). They found a very low incidence (1.5%) of serious adverse effects, even at high doses of up to 50 micrograms/kg/minute, and noted that most problems occur transiently at a lower dose and then resolve. Hypotension and dysrhythmias were the most common adverse effects, and their incidence was not related to age.

Acute subaortic left ventricular outflow tract obstruction has been described during dobutamine infusion in a patient who had no evidence of this at rest but developed severe obstruction when his pulse rate exceeded 105/minute (3). The subaortic gradient eventually reached the very high figure of 182 mmHg, even though the patient remained asymptomatic and there was no clear reason why this occurred in this particular patient.

In 47 consecutive patients (mean age 64 years, 46 men) with three or more cardiovascular risk factors, intravenous dobutamine was given at a rate of 40 micrograms/kg/minute until the target heart rate was achieved, which took a mean of 11.6 minutes (4). Subjective sensations occurred in 49% of the patients (palpitation 21%, chest pain 6%, nausea 6%, headache 6%, dizziness 13%), while half the patients had abnormal cardiac rhythms (ventricular extra beats 38%, supraventricular tachycardia 10%, and non-sustained ventricular tachycardia 2%). The authors concluded that the safety and tolerability of this procedure is comparable to that of standard dobutamine stress testing, although its specificity and selectivity are still uncertain.

The value and safety of dobutamine stress echocardiography have been studied in 135 patients aged 70 years or older (mean age 74 years; 58% men) soon after

© 2006 Elsevier B.V. All rights reserved.

myocardial infarction (5). A diagnostic end-point was reached in 83% of patients, a figure comparable to younger populations. No major complications were reported. The procedure was terminated prematurely because of symptomatic hypotension ($n=8$), non-sustained ventricular tachycardia ($n=2$), systolic hypertension ($n=2$), atrial fibrillation ($n=1$), or bladder discomfort ($n=1$). All of these problems resolved rapidly after the procedure was stopped. At the time of discontinuation, seven of these 16 patients had objective evidence of myocardial ischemia.

Cardiac dysrhythmias

Dobutamine increases cardiac output after acute myocardial infarction without exacerbating myocardial infarction or ventricular dysrhythmias. However, a mild increase in heart rate often occurs, and occasionally a more marked tachycardia.

Cardiac dysrhythmias of various types (including occasional ventricular dysrhythmias) when dobutamine is used as a stress-inducing agent during echocardiography have been described (SEDA-18, 158).

- A 56-year-old woman with dilated cardiomyopathy developed QT interval prolongation and torsade de pointes during infusion of dobutamine in a low dose (2.5 micrograms/kg/minute). She had no previous documented dysrhythmias (6). She was hypokalemic and when her plasma potassium concentration was restored to normal the dysrhythmia disappeared and the QT interval normalized. The authors observed that this was the first case of its kind and emphasized the importance of normokalemia in dobutamine-treated patients.
- A 55-year-old man with stable angina was admitted for dobutamine stress testing (7). He had been taking metoprolol, but this was withdrawn 2 days before the test. During the lowest dose of the dobutamine infusion (5 micrograms/kg/minute) his heart rate rose to 143/minute and he developed chest pain and ST segment depression in the lateral chest leads of the electrocardiogram. The drug was stopped and metoprolol and glyceryl trinitrate were given immediately, but a few minutes later he developed torsade de pointes followed by ventricular fibrillation. Resuscitation was unsuccessful. There was no evidence of acute myocardial infarction at autopsy.
- A 74-year-old man with idiopathic dilated cardiomyopathy was given dobutamine (5 micrograms/kg/minute) to determine whether it would produce a positive inotropic effect (8). After 14 minutes he developed asymptomatic pulsus alternans, which resolved within 20 minutes of withdrawal.

A much more serious complication of dobutamine therapy is ventricular dysrhythmias. Of 305 patients with acutely decompensated congestive heart failure, 58 were given dobutamine (although it is difficult to ascertain the dose), 44 were given other standard inotropic drugs such as milrinone, and 203 were treated with brain natriuretic peptide (nesiritide, 0.015 or 0.03 micrograms/kg/minute) (9). Of those given dobutamine 7% had sustained ventricular tachycardia, 17% had non-sustained ventricular tachycardia, and 5% had a cardiac arrest. In contrast, the figures for nesiritide were 1, 11, and 0% respectively. There was no analysis of other outcomes but these results certainly do not encourage the use of dobutamine in these very vulnerable patients.

A study from Rotterdam, has examined the consequences of adding atropine to dobutamine in 200 patients with impaired left ventricular function (ejection fraction less than 35%) (10). There were cardiac dysrhythmias in 6% of patients and significant hypotension in 11%, figures comparable to those in other published studies. In the 36 patients who required atropine to achieve target heart rates the incidence of adverse effects was not increased. The same group has studied over 1000 consecutive patients undergoing dobutamine stress scintigraphic imaging of the myocardium (11). In these patients the incidence of dysrhythmias was about 8%, of whom about half had transient ventricular tachycardia, but only about 3% had significant hypotension (defined as a fall in systolic blood pressure of 40 mmHg). Atropine was required in nearly 40% of the patients in order to achieve target heart rates, but it is difficult to determine whether this had any influence on the occurrence of adverse effects.

A report from the Mayo Clinic has described 27 elderly patients (mean age 71 years) with aortic stenosis in whom dobutamine stress hemodynamic testing was used to assess the severity of the stenosis (12). There were no severe adverse effects, but relatively minor problems occurred in 16 patients, including chest pain and ventricular extra beats ($n=9$ each) and atrial dysrhythmias ($n=4$). The authors concluded that the procedure appears to be safe in these high-risk patients, although its diagnostic value may be limited.

There are variants of the standard procedure that do not appear to be associated with increased risk. An accelerated high-dose protocol, in which a constant infusion of 50 micrograms/kg/minute was given for up to 10 minutes in 100 patients, has been compared with the standard stepwise procedure in a similar number (13). The cumulative dose was somewhat lower in the accelerated protocol, while the duration of the test was halved. Dysrhythmic adverse effects occurred in 28 patients on the accelerated protocol and in 39 of those tested by the standard method: this difference was said to be non-significant. In another study, transesophageal was compared with transthoracic dobutamine stress echocardiography in 63 and 100 patients respectively (14). Baseline pulse and blood pressure were higher in the transesophageal group. The authors noted that there were no cases of ventricular tachycardia or fibrillation in either group, or of myocardial infarction. They also stated that the incidence of less serious dysrhythmias was similar in the two groups; however, no figures were quoted.

In the PRECEDENT study, dobutamine was compared with nesiritide (B natriuretic peptide) in patients with acutely decompensated congestive heart failure (15). The primary objective of the study was to assess the risk of ventricular dysrhythmias with the two therapies. Altogether 255 patients (mean age 61 years, 67% men) were randomized to receive dobutamine 5 micrograms/kg/hour or one of two doses of nesiritide 0.015 or 0.03 micrograms/kg/hour. Dobutamine significantly

© 2006 Elsevier B.V. All rights reserved.

increased the number of episodes of ventricular tachycardia by 48/day, ventricular extra beats by 69/hour, and overall heart rate by 5/minute. These parameters were unchanged or improved by nesiritide. Since the two drugs had similar effects on the hemodynamic features of heart failure and its symptoms, the authors concluded that nesiritide should be considered as an alternative to dobutamine in this type of patient.

Myocardial ischemia

Angina and coronary artery spasm (16) have also occurred under these and other conditions. Some 10% of patients require treatment for angina occurring during stress testing, but up to a quarter have ischemic changes on the electrocardiogram (SEDA-17, 163), while others have headache, palpitation, anxiety, nausea, tingling, and flushing.

Myocardial ischemia has also been reported in susceptible patients. A Japanese group carried out dobutamine stress echocardiography in 51 patients with a presumptive diagnosis of variant angina (17). All had coronary vasospasm in response to intracoronary acetylcholine and seven also had chest pain and reversible ST segment elevation. One must incidentally wonder whether this procedure was entirely advisable.

In 47 patients in Mannheim (mean age 61 years, 34 men) dobutamine echocardiography was carried out, with blood sampling immediately before and after the procedure and then at 1, 2, 4, 6, and 12 hours (18). Assays were carried out for creatine kinase-MB, troponins I and T, myoglobin, and fibrin monomer antigen. There were no significant increases in these markers of myocardial damage and coagulation, regardless of the outcome of the stress test. These findings have confirmed those of an earlier study, although the data do not absolutely exclude abnormal findings in a minority of individuals (19).

Hypotension

In one study 38% of patients undergoing dobutamine stress echocardiography developed hypotension. Increases in blood pressure are more in line with what one would expect. Although dobutamine does not as a rule cause a marked increase in systolic blood pressure in normotensive patients, hypertensive patients can develop marked systolic hypertension during an infusion of the drug. When stress echocardiography with dobutamine is performed in subjects who prove to be entirely healthy, an audible Still's-like vibratory systolic ejection murmur is nevertheless produced.

Severe peripheral ischemia (even leading to dermal necrosis) can occur, as with dopamine (20).

Urinary tract

Urinary urgency can occur during infusion of a relatively high dose (15 micrograms/kg/minute) of dobutamine (21).

Docetaxel

See also Cytostatic and immunosuppressant drugs

General Information

Docetaxel is a taxane that is used in combination with doxorubicin in the treatment of metastatic breast cancer and as a single agent in metastatic lung cancer.

Organs and Systems

Respiratory

Interstitial pneumonitis has been attributed to docetaxel in four cases (1). None of the patients had lung disease and they all had normal liver function. Within 8–14 days of receiving a second cycle of docetaxel (75 mg/m^2 in three cases and 60 mg/m^2 in the other), all developed acute dyspnea and fever, which progressed until they needed ventilation; two died. In contrast, in a study of 33 patients treated with paclitaxel and carboplatin, only one had reduced diffusion capacity for carbon monoxide, with no accompanying clinical or radiological changes (2).

Fluid balance

Fluid retention has previously been reported with docetaxel. Some believe that this effect depends on the dose and the duration of infusion (3,4) and that high concentrations of M4, the cyclized oxazolidinedione metabolite of docetaxel, cause more pronounced fluid retention.

Hematologic

In 46 chemotherapy-naive patients, docetaxel had an important but reversible non-specific lymphopenic effect, thought to be associated with an increased risk of non-neutropenic infections (5).

Gastrointestinal

Three of 14 patients in a phase 1 study of docetaxel plus vinorelbine for metastatic breast cancer developed colitis (6). A further three patients were identified in other studies of docetaxel.

Skin

Of 99 patients who received low-dose docetaxel (60 mg/m^2 every 3 or 4 weeks), 25 had skin toxicity, mainly erythema and nail changes (7). Of a subset of 25 patients who received irradiation before docetaxel, four had recall dermatitis during their first infusion of docetaxel. All had previously received doxorubicin, which may in part have explained some of the toxicity.

Maculopapular eruptions and desquamation of hands and/or feet occurred in 35% of patients with non-small cell lung cancers given docetaxel (8).

Four cases of fixed plaques of erythrodysesthesia have been attributed to intravenous docetaxel (9). There had been no extravasation or previous skin injury. While this was a new presentation, the authors did not explain why the lesions were not just late presentations of small-volume extravasation injuries.

Nails

Onycholysis has been reported in patients receiving docetaxel (10).

Immunologic

A 25% incidence of grade 2 or more severe immunological reactions to docetaxel has been reported after the use of oral prednisone (100 mg orally before treatment and 50 mg once on the morning of treatment and the following 2 days) in 20 patients with non-small-cell lung cancers (8). No other premedications were given routinely. If infusion-related symptoms occurred, the infusion was interrupted and diphenhydramine was given. On subsequent cycles those patients then were routinely premedicated with diphenhydramine 25 or 50 mg intravenously and cimetidine 300 mg intravenously.

Dofetilide

See also Antidysrhythmic drugs

General Information

Dofetilide is a pure Class III antidysrhythmic drug, without actions of any other class. It was developed following the observation that bis(arylalkyl)amines with methanesulfonamido moieties on both aryl groups prolong the cardiac action potential without significantly altering the maximum rate of depolarization (1). The pharmacology, clinical pharmacology, uses, adverse effects, and interactions of dofetilide have been reviewed (2–8). Cardiovascular adverse effects of dofetilide are the most troublesome. Other common effects have included mild headache, dizziness, dyspepsia, nausea, and vomiting (9).

Pharmacology

Dofetilide is a highly selective blocker of the rapidly activating component of the inward rectifier potassium channel, IK_r (10–16). It therefore delays ventricular repolarization, which becomes less heterogeneous (17), and prolongs the action potential duration and effective refractory period (14,18,19); it has the same effects in ventricular muscle in dilated cardiomyopathy and chronic ischemic cardiomyopathy (10). It has greater affinity for atrial than ventricular tissues in animals (20), but probably not in man (14,18). It preferentially blocks open channels and has Group 3 actions (SEDA-25, 209), with slow-onset kinetics (21) and an increased likelihood of being prodysrhythmic at slower heart rates (22).

Dofetilide causes a dose-related and plasma concentration-related prolongation of the QT_c interval (14,18,19,23–27), and either reduces QT_c dispersion (26) or has no effect on it (28,29). The effects on the QT_c interval are rate-dependent, being greater at slower heart rates (30). Dofetilide does not usually broaden the QRS complex, but this was reported (and published twice) in a single patient with atrial fibrillation, in whom it was attributed to aberrant conduction (31,32).

During repeated oral administration of dofetilide 1.0–2.5 mg/day for 5 days the effect on the QT interval was slightly greater on day 1 than on day 5 at a range of plasma concentrations of about 1–4 ng/ml; this observation suggests the occurrence of tolerance, but in that case one would have expected a clockwise hysteresis loop in the effect concentration curve, and no hysteresis was seen either after a single dose or at steady state (25).

Dofetilide has a small positive inotropic effect in animal hearts (15,33). In a double-blind, placebo-controlled study of oral dofetilide 125, 250, or 500 mg bd for the maintenance of sinus rhythm after cardioversion of sustained atrial fibrillation or flutter in 201 patients, there were small changes in echocardiographic measures of atrial contractility, but no changes in stroke volume or cardiac output (34).

Clinical pharmacology

The pharmacokinetics of dofetilide are linear after single oral doses of 2–10 micrograms/kg (24,35) and repeated doses of 1.0–2.5 mg/day (25). Dofetilide is well absorbed (about 90%) after oral administration (24,35,36). Its absorption is relatively slow and peak concentrations are not reached for 1–2.5 hours; absorption is slower after food. It is a low clearance drug, with a clearance rate of about 6 ml/minute/kg, and has a volume of distribution of about 3 l/kg (23,36). It is mostly excreted unchanged by the kidneys, with a half-life of about 8 hours. Its clearance is therefore roughly proportional to creatinine clearance, particularly at high rates of clearance. A small proportion is metabolized in the liver by CYP3A4 to inactive metabolites (37).

In a pharmacokinetic–pharmacodynamic study in 10 healthy volunteers intravenous dofetilide 0.5 mg caused a mean maximum prolongation of the QT_c interval of 121 ms and the mean plasma concentration associated with half-maximal effect was 2.2 ng/ml (36).

Uses

Dofetilide has been used to convert atrial fibrillation and atrial flutter to sinus rhythm, in maintaining sinus rhythm thereafter, in suppressing paroxysmal supraventricular tachycardia, inducible atrioventricular nodal re-entry tachycardia, and inducible sustained ventricular tachycardia, in suppressing the dysrhythmias of the Wolff–Parkinson–White syndrome, and in facilitating conversion of ventricular fibrillation.

Open clinical studies

In 19 patients with atrial fibrillation and five with atrial flutter, dofetilide 2.5–8.0 micrograms/kg caused conversion to sinus rhythm in 14 (10 with atrial fibrillation and four with atrial flutter) (38).

In patients with sustained monomorphic ventricular tachycardia inducible by programmed electrical stimulation, who had previously been unsuccessfully treated with

© 2006 Elsevier B.V. All rights reserved.

0–7 other drugs, intravenous dofetilide 3–15 micrograms/kg suppressed or slowed inducible ventricular tachycardia in 17 of 41 patients, compared with none of nine patients who received only 1.5 micrograms/kg (19).

Intravenous dofetilide 2.5–5.0 micrograms/kg produced sinus rhythm in seven patients with paroxysmal atrial fibrillation of recent onset (under 7 days) and terminated paroxysmal supraventricular tachycardia in four of six patients (39).

In patients with electrically inducible atrioventricular re-entrant tachycardia intravenous dofetilide 1.5–15 micrograms/kg had no effect on tachycardia inducibility at two lower doses but prevented the re-induction of tachycardia at three higher doses in 11 of 31 patients (40).

Placebo-controlled studies

Conversion of atrial fibrillation and flutter

In a crossover, placebo-controlled study in 16 patients with recent onset atrial fibrillation, cardioversion was achieved in two of six patients who received dofetilide 8 micrograms/kg and in two of nine who received 12 micrograms/kg (41). None cardioverted with placebo. However, the average duration of atrial fibrillation was 35 days in those who cardioverted with dofetilide and 83 days in those who did not. The authors concluded that dofetilide had only limited effect in cardioverting atrial fibrillation of moderate duration.

In a double-blind, placebo-controlled study 98 patients, who developed atrial fibrillation/flutter within 1–6 days after coronary artery bypass graft surgery, were given dofetilide 4 or 8 micrograms/kg intravenously over 15 minutes (42). Eight of 33 patients converted to sinus rhythm after placebo, 12 of 33 after dofetilide 4 micrograms/kg, and 14 of 32 after dofetilide 8 micrograms/kg.

In a double-blind, placebo-controlled study in patients with sustained atrial fibrillation ($n = 75$) or atrial flutter ($n = 16$), dofetilide 8 micrograms/kg terminated the dysrhythmia in nine of 29 patients, compared with only four of 32 who received 4 micrograms/kg and none of 30 who received placebo (43). Patients with atrial flutter had a greater response to dofetilide (six of 11) than those with atrial fibrillation (five of 49).

In a placebo-controlled study in patients with atrial fibrillation or atrial flutter with a median dysrhythmia duration of 62 (range 1–180) days, there was conversion to sinus rhythm in 20 of 66 patients given dofetilide, compared with one of 30 patients given placebo (44). The conversion rate was higher in atrial flutter (seven of 11 patients) than in atrial fibrillation (13 of 55).

In a double-blind, placebo-controlled study in 325 patients with atrial fibrillation or flutter cardioversion, rates for dofetilide 125, 250, and 500 micrograms bd were 6.1, 9.8, and 30% respectively, compared with 1.2% with placebo (45). The probabilities of remaining in sinus rhythm at 1 year with dofetilide 125, 250, and 500 micrograms bd were 0.40, 0.37, and 0.58 respectively, and 0.25 for placebo.

In a double-blind, placebo-controlled study in 69 patients with atrial fibrillation or flutter, intravenous dofetilide 2–8 micrograms/kg caused conversion to sinus rhythm in 16 of 51 patients, compared with one of 18 who were given placebo; conversion of atrial flutter occurred in five of seven who were given dofetilide compared with none of three who were given placebo (46).

In a randomized, placebo-controlled, crossover study in 15 men, mean age 34 (range 18–63) years, with Wolff–Parkinson–White syndrome and atrial fibrillation or atrioventricular re-entrant tachycardia induced electrophysiologically, six of ten patients who were given dofetilide converted to sinus rhythm, compared with one of five who were given placebo (47). There were no dysrhythmias.

Ventricular tachydysrhythmias

In a placebo-controlled study, sustained ventricular tachycardia or fibrillation, reproducibly inducible electrophysiologically, was no longer inducible in eight of 18 patients who were given intravenous dofetilide 0.1–8.0 ng/ml, compared with one of six patients who received placebo (48).

In a randomized, double-blind, placebo-controlled study in 32 patients with ventricular extra beats (more than 30/hour on two consecutive 24-hour Holter recordings while drug free and more than 50/hour during 2-hour telemetric electrocardiography), dofetilide 7.5 micrograms/kg produced an 83% and placebo a 2.9% median reduction in ventricular extra beats (49).

Sudden death

The Danish Investigations of Arrhythmia and Mortality ON Dofetilide (DIAMOND) study comprised two studies in patients at high risk of sudden death: one in patients with congestive heart failure and one in patients with acute myocardial infarction within the previous 7 days (50).

In the congestive heart failure study, 1518 patients with symptomatic congestive heart failure and severe left ventricular dysfunction were recruited at 34 Danish hospitals; 762 were randomized double-blind to dofetilide and 756 to placebo (51). After 1 month, 22 of 190 patients with atrial fibrillation at baseline had sinus rhythm restored by dofetilide, compared with only three of 201 who took placebo. Dofetilide was also significantly more effective than placebo in maintaining sinus rhythm (hazard ratio for the recurrence of atrial fibrillation = 0.35; CI = 0.22, 0.57). Dofetilide significantly reduced the risk of hospitalization for worsening congestive heart failure (risk ratio = 0.75; CI = 0.63, 0.89). During a median follow-up of 18 months, 311 patients taking dofetilide and 317 patients taking placebo died (hazard ratio = 0.95; CI = 0.81, 1.11).

In the corresponding myocardial infarction study, 1510 patients with severe left ventricular dysfunction after myocardial infarction were recruited in 37 Danish coronary-care units; 749 were randomized double-blind to dofetilide and 761 to placebo (52). There were no significant differences between dofetilide and placebo in all-cause mortality or total dysrhythmic deaths. Dofetilide was significantly better than placebo at restoring sinus rhythm in patients with atrial fibrillation or flutter.

Comparative studies with other antidysrhythmic drugs

Amiodarone

In a comparison of intravenous dofetilide (8 micrograms/kg; $n = 48$), amiodarone (5 mg/kg; $n = 50$),

© 2006 Elsevier B.V. All rights reserved.

or placebo ($n = 52$) in converting atrial fibrillation or flutter to sinus rhythm in 150 patients, sinus rhythm was restored in 35, 4, and 4% respectively (53).

Flecainide

In a non-randomized comparison of flecainide (2 mg/kg; $n = 11$) and dofetilide (8 micrograms/kg; $n = 10$) in patients with atrial flutter, only one patient given flecainide converted to sinus rhythm compared with seven of the 10 patients given dofetilide (54).

Propafenone

In a randomized, placebo-controlled, parallel-group comparison of oral dofetilide 500 micrograms bd, propafenone 150 mg tds, or placebo in preventing the recurrence of paroxysmal supraventricular tachycardia in 122 symptomatic patients, the respective probabilities of remaining free of episodes of paroxysmal supraventricular tachycardia were 50, 54, and 6%; both dofetilide and propafenone also reduced the frequency of episodes (median numbers 1, 0.5, and 5 respectively) (55).

Sotalol

In a double-blind, randomized, crossover comparison of oral dofetilide 500 micrograms bd with sotalol 160 mg bd in 128 patients with ischemic heart disease and inducible sustained ventricular tachycardia, 46 patients responded to dofetilide and 43 to sotalol; however, only 23 patients responded to both dofetilide and sotalol (9).

The hemodynamic effects of dofetilide 500 micrograms bd and sotalol 160 mg bd for 3–5 days have been studied in 12 patients with ischemic heart disease and sustained ventricular tachycardia (56). There were significant reductions in heart rate, mean systemic pressure, and cardiac index (–13%) with sotalol, but cardiac index increased significantly with dofetilide (11%) with no effect on heart rate or systemic blood pressure. The authors suggested that oral dofetilide could be useful in patients with ventricular tachydysrhythmias associated with impaired left ventricular function. One patient taking dofetilide reported mild dizziness and there were no cardiac dysrhythmias.

Organs and Systems

Cardiovascular

Because dofetilide prolongs the QT interval, there is a risk of ventricular tachydysrhythmias, which have often been reported, after both intravenous and oral administration.

In 154 patients with implantable cardioverter-defibrillators randomly assigned to dofetilide or placebo, there were pause-dependent runs of polymorphic ventricular tachycardia in 15 of the 87 patients who received dofetilide and in only five of the 87 who received placebo (57). There were five early events (at less than 3 days of therapy), all torsade de pointes in patients taking dofetilide. There were 15 late events, 10 with dofetilide and five with placebo. The median time to a late event was 22 (range 6–107) days for dofetilide and 99 (34–207) days for placebo.

In the DIAMOND study in congestive heart failure, there were 25 cases of torsade de pointes in the dofetilide group (3.3%) compared with none in the placebo group (51). In the DIAMOND myocardial infarction study there were seven cases of torsade de pointes (0.93%), all in those who were given dofetilide (52).

In a double-blind, placebo-controlled study in 325 patients with atrial fibrillation or atrial flutter randomized to dofetilide 125, 250, or 500 micrograms bd or placebo, there were two cases of torsade de pointes, one on day 2 and the other on day 3 (0.8% of all patients given the active drug); there was one sudden cardiac death, classified as prodysrhythmic, on day 8 (0.4% of all patients given the active drug). The authors recommended that dosage adjustment based on QT_c interval and renal function would minimize the small but not negligible prodysrhythmic risk of dofetilide.

In 128 patients who received dofetilide and sotalol in a crossover study, there were treatment-related adverse events in 2.3% of the patients who received dofetilide and 8.6% of those who received sotalol (9). Three patients who took dofetilide had torsade de pointes.

In a comparison of intravenous dofetilide (8 micrograms/kg; $n = 48$), amiodarone (5 mg/kg; $n = 50$), or placebo ($n = 52$) in converting atrial fibrillation or flutter to sinus rhythm in 150 patients, two patients given dofetilide had non-sustained ventricular tachycardias; four had torsade de pointes, in one case requiring electrical cardioversion (53).

- In one of 10 healthy men given intravenous dofetilide 0.5 micrograms/kg there was prolongation of the QT_c interval from 451 to 808 ms 5 minutes after the end of the infusion; this was associated with five beats of polymorphic ventricular tachycardia, several multifocal ventricular extra beats, and ventricular couplets and triplets, all within 10 minutes after the end of the infusion (24).
- In a 37-year-old woman with atrial flutter with 1:1 conduction and partial right bundle branch block, intravenous dofetilide 5 micrograms/kg given over 5 minutes not only suppressed the atrioventricular nodal block to 2:1 or 3:1 but also caused complete right bundle branch block and QT interval prolongation (58).
- Self-limiting torsade de pointes developed in a 67-year-old man who was given 12.8 micrograms/kg (plasma concentration 7.1 ng/ml) in an open study; the QT_c interval was prolonged to over 600 ms (19).

This patient had stopped taking amiodarone 1 month before the administration of dofetilide, and that may have contributed to the prolongation of the QT_c interval.

- A woman with atrial fibrillation developed torsade de pointes after receiving intravenous dofetilide 6 micrograms/kg (plasma concentration 26 ng/ml) (41).
- A patient with atrial fibrillation received intravenous dofetilide 8 micrograms/kg and developed torsade de pointes before reverting to sinus rhythm (41).
- One of 18 patients with sustained ventricular tachycardia or fibrillation, reproducibly inducible electrophysiologically, developed torsade de pointes after receiving intravenous dofetilide 8 micrograms/kg (plasma concentration 5.3 ng/ml) (48).
- Short episodes of aberrant ventricular conduction and ventricular tachycardia occurred in three of 32

© 2006 Elsevier B.V. All rights reserved.

patients with atrial fibrillation who were given dofetilide 8 micrograms/kg (42).

- Torsade de pointes occurred in two of 62 patients with atrial tachydysrhythmias who received dofetilide 4 or 8 micrograms/kg; two other patients had ventricular extra beats associated with prolongation of the QT_c interval (43).
- In a placebo-controlled study of the effect of dofetilide 8 micrograms/kg in converting atrial fibrillation or flutter, transient torsade de pointes occurred in two men, aged 57 and 67, with prolongation of the QT_c interval from 370 and 420 ms to 450 and 510 ms respectively (44).
- A 58-year-old woman developed torsade de pointes with prolongation of the QT_c interval to 490 ms after receiving intravenous dofetilide 4.3 micrograms/kg; she responded to intravenous magnesium sulfate plus isoprenaline (46).

Other cardiac dysrhythmias that have been reported have included episodes of junctional rhythm with bundle branch block, spontaneous atrioventricular re-entrant tachycardia, and sustained supraventricular tachycardia (40).

Hypotension occasionally occurs after intravenous dofetilide (40).

Death

The risk of death in patients with supraventricular dysrhythmias taking dofetilide has been studied in a systematic review of randomized controlled trials (59). After adjusting for the effects of dysrhythmia diagnosis, age, sex, and structural heart disease, the hazard ratio was 1.1 (CI = 0.3, 4.3).

Drug–Drug Interactions

Digoxin

In 14 healthy men dofetilide 250 micrograms bd for 5 days had no effect on the pharmacokinetics of digoxin at a steady-state trough concentration of 1.0 ng/ml (60). However, in a placebo-controlled study in patients with atrial fibrillation or atrial flutter, conversion to sinus rhythm in patients given dofetilide was more likely if they were also given digoxin (44), suggesting that there may be a pharmacodynamic interaction.

Histamine (H_2) receptor antagonists

In a randomized, placebo-controlled study of the effects of cimetidine and ranitidine on the pharmacokinetics and pharmacodynamics of a single dose of dofetilide 500 micrograms in 20 healthy men, ranitidine 150 mg bd did not affect the pharmacokinetics or pharmacodynamics of dofetilide, but there was a dose-dependent increase in exposure to dofetilide with cimetidine (61). With cimetidine 100 and 400 mg bd the AUC of dofetilide increased by 11 and 48%, the maximum plasma dofetilide concentration increased by 11 and 29%, renal clearance fell by 13 and 33%, and non-renal clearance by 5 and 21%; dofetilide-induced prolongation of the QT_c interval was increased by 22 and 33%. The authors suggested that cimetidine inhibited renal tubular dofetilide secretion, an effect that is specific to cimetidine in its class. Cimetidine should be avoided in patients taking dofetilide.

Verapamil

Pharmacokinetic and pharmacodynamic interactions between dofetilide 0.5 mg bd and verapamil 80 mg tds have been studied in 12 healthy men (62). At steady state verapamil increased the peak plasma concentration of dofetilide from 2.40 to 3.43 ng/ml, without other pharmacokinetic effects. This was accompanied by a small increase in the prolongation of the QT_c interval produced by dofetilide alone, from 20 to 26 ms. Although this small effect is unlikely to be of clinical significance, it would be wise to avoid verapamil in patients taking dofetilide.

Domperidone

General Information

Domperidone is a neuroleptic antiemetic, a dopamine receptor antagonist. It produces the expected range of dystonic and extrapyramidal adverse effects (1), which seem, as with metoclopramide, to be more likely to occur in children (2). It is difficult to accept that claims for lower frequencies than with metoclopramide are justified, particularly when one reads a report of neuroleptic malignant syndrome (3). Like its congeners, domperidone has repeatedly been shown to cause symptoms attributable to hyperprolactinemia (galactorrhea, amenorrhea, and breast tenderness), despite claims that there is a lower incidence of effects on prolactin concentrations. However, a study in patients with Parkinson's disease using domperidone did not suggest that the adverse effects are especially problematical in these patients (4).

Observational studies

The mechanism of action and clinical use of domperidone and its specific use in diabetic gastroparesis have been reviewed (5,6). Domperidone is generally well tolerated and has a low incidence of adverse effects. Adverse effects after oral administration include headache, dry mouth, diarrhea, itching, muscle cramps, and anxiety. Galactorrhea, breast tenderness, and pseudopregnancy can occur in women because of a dopamine-induced increase in serum prolactin concentration.

Comparative studies

The efficacy and adverse effects of domperidone and metoclopramide have been compared in a double-blind, multicenter, randomized trial in 93 insulin-dependent diabetics with symptomatic gastroparesis (7). Domperidone 20 mg qds and metoclopramide 10 mg qds, for 4 weeks, were equally effective in alleviating symptoms of gastroparesis. Somnolence, akathisia, anxiety, and depression were more

© 2006 Elsevier B.V. All rights reserved.

severe with metoclopramide. Of the spontaneously reported adverse effects, nausea, vomiting, headache, insomnia, and diarrhea occurred in 6–10% of patients treated with domperidone and in up to 4% of patients treated with metoclopramide. The incidence of prolactin-related adverse effects was similar in the two groups (6%).

Organs and Systems

Cardiovascular

Intravenous infusion of domperidone, withdrawn some years ago, has caused convulsions and cardiac arrest (8–10).

Nervous system

- A 9-year-old child developed dysphagia and involuntary movements of the facial muscles after being treated with domperidone 0.25 mg/kg/day (11). There was complete recovery after withdrawal.

Drug–Drug Interactions

Anticholinergic drugs

Concomitant administration of anticholinergic drugs can antagonize the beneficial effects of domperidone (12).

Azole antifungals

Because domperidone is metabolized mainly by CYP3A4, interactions of azole antifungals with domperidone can occur. In human liver microsomes domperidone underwent hydroxylation to 5-hydroxydomperidone and N-dealkylation to 2,3-dihydro-2-oxo-1H-benzimidazole-1-propionic acid and 5-chloro-4-piperidinyl-1,3-dihydro-benzimidazol-2-one (13). The rate of domperidone metabolism correlated with the activity of CYP3A. Ketoconazole 1 μmol/l inhibited the metabolism of domperidone 5 μmol/l by 87%.

Cimetidine and antacids

Since cimetidine and antacids can interfere with the systemic availability of domperidone (SEDA-22, 389), they should not be co-administered.

Troleandomycin

In human liver microsomes domperidone underwent hydroxylation to 5-hydroxydomperidone and N-dealkylation to 2,3-dihydro-2-oxo-1H-benzimidazole-1-propionic acid and 5-chloro-4-piperidinyl-1,3-dihydro-benzimidazol-2-one. The rate of domperidone metabolism correlated with the activity of CYP3A. Troleandomycin 50 μmol/l inhibited the metabolism of domperidone 5 μmol/l by 64%.

Donepezil

General Information

The approval of donepezil in several countries in America and Europe has been hailed as a major milestone, because it has met regulatory guidelines for the approval of antidementia drugs (1). Donepezil belongs to a piperidine class of reversible acetylcholinesterase inhibitors, chemically unrelated to either tacrine or physostigmine. It is highly specific for acetylcholinesterase and does not inhibit butyrylcholinesterase. The incidence of adverse effects with donepezil is comparable to that of placebo in controlled trials, and unlike tacrine, liver enzyme monitoring is not required. The long-term effectiveness of donepezil in large populations is yet to be established. Moreover, while it improves cognitive symptoms, it does not alter the course of the disease. Based on a limited number of studies, support for the use of donepezil in Alzheimer's disease has emerged (2–5).

Clinical trials of donepezil were funded by the manufacturer and appear to have been methodologically sound, although the absence of caregiver quality-of-life measures

© 2006 Elsevier B.V. All rights reserved.

and outcomes related to activities of daily living is difficult to reconcile. An earlier 12-week study showed no improvement in caregiver quality of life with donepezil (4). As with most phase 3 studies, extrapolation of these results to routine practice is hampered by the fact that study populations are likely to be healthier than patients seen in routine clinical practice. Whether the results would be any different in a more heterogeneous population remains to be seen (6).

In a more recent 12-week double-blind, placebo-controlled, parallel-group study, aimed at establishing the efficacy and safety of donepezil in patients with mild to moderately severe Alzheimer's disease, donepezil (5 and 10 mg od) was well tolerated and efficacious (7). Adverse events significantly more common with donepezil were nausea, insomnia, and diarrhea, which appeared to be dose related and did not require treatment. Seven patients treated with placebo and six in each of the donepezil groups had serious adverse events during the trial. Three had events that were considered possibly related to donepezil. These included gastric ulceration with hemorrhage, syncope and a transient ischemic attack, nausea, aphakia, tremor, and sweating. Both groups of patients treated with donepezil had falls in mean heart rate that were larger than with placebo. Two patients treated with donepezil had electrocardiographic changes: one developed an intraventricular conduction defect and ventricular extra beats, while the other had sinus arrhythmia, left axis deviation, and increased QRS voltage, possibly secondary to left ventricular enlargement. Neither reported cardiovascular adverse events. Two patients taking placebo also had electrocardiographic abnormalities: one with bundle branch block, the other with sinus bradycardia and ventricular extra beats.

The launch of donepezil has attracted intense interest among both the scientific community and the public. The debate regarding "lessons for health care policy" (8) has been summarized:

(1) Licensing trials in highly selected patients may provide insignificant information on which to base clinical decisions, especially when the effect sizes are small and comorbidity is common.
(2) All trial evidence should be published before new drugs are marketed, and medical journals should not carry advertisements referring to unpublished data.
(3) Communication of benefits and risks should emphasize clinical effect sizes rather than statistical significance.
(4) Claims about effects on populations or services should be based on evidence.
(5) Secrecy surrounding licensing should be ended, and data from trials should be available for independent analysis.
(6) Overvaluation of new technology could threaten funding for vital but more mundane care.

There was intense debate in response to the above publication, as reflected by several letters to the Editor of the *British Medical Journal* (9–14).

Further evidence that donepezil is effective and well tolerated in treating symptoms of mild to moderately severe Alzheimer's disease has emerged from a multinational trial (15). Common adverse effects were nausea, vomiting, diarrhea, anorexia, dizziness, and confusion, consistent with previous findings.

A meta-analysis of various drugs approved for treating Alzheimer's disease in the USA and Canada has suggested that donepezil can delay cognitive impairment and deterioration in global health for at least 6 months in patients with mild-to-moderate Alzheimer's disease (16). Patients taking active treatment will have more favorable Alzheimer's Disease Assessment Scale cognitive subscale (ADAS-cog) scores for at least 6 months, after which their scores will begin to converge with those who are taking placebo. The cost-effectiveness data were inconclusive.

Although once-daily donepezil is effective and well tolerated for the symptoms of mild-to-moderate Alzheimer's disease (17), two practical questions arise:

(1) Which patients are too severely affected to be treated with donepezil?
(2) At what point should donepezil be discontinued if the patient continues to deteriorate?

The current status of donepezil in the management of Alzheimer's disease has been comprehensively reviewed (18). Several recent studies have confirmed the efficacy and tolerability of donepezil using different doses, study designs, and durations of treatment (19–23). Some relevant conclusions were the following:

(1) Younger patients should be targeted for assessment and treatment (24).
(2) Of the patients 6% discontinued medication owing to adverse events (23).
(3) Sleep disturbances were more common in trials with bedtime dosing of donepezil (22).
(4) Long-term safety and realistic improvement were observed over a period of up to 4.9 years (25).
(5) The presence of the apolipoprotein E4 allele did not predict donepezil failure (20).

Seven elderly patients with psychotic or non-psychotic behavioral symptoms in Lewy body dementia had some benefit from donepezil (26). Donepezil was withdrawn prematurely in three patients owing to poor response and/or adverse events. The adverse events were sedation, somnolence, worsening of chronic obstructive pulmonary disease, syncope, sweating, and bradycardia. These results have to be confirmed in controlled trials.

In two patients with Alzheimer's disease, donepezil provided some benefit in relieving cognitive symptoms, but there were increased behavioral problems, such as anxiety, agitation, irritability, and lack of impulse control; these were then successfully controlled by adding gabapentin (27).

The adverse effects of donepezil in general practice have been evaluated in a post-marketing pharmacovigilance study in 1762 patients in the UK (28). This observational cohort study used the technique of prescription-event monitoring for a minimum period of 6 months. The commonest adverse events were nausea, diarrhea, malaise, dizziness, and insomnia. Aggression, agitation, and abnormal dreams were uncommonly associated with the drug. There were no causally associated cardiac rhythm disturbances or liver disorders. The authors suggested that the abnormal dreams and psychiatric disturbances were possible adverse drug reactions that require further confirmation.

The beneficial effect of donepezil on global ratings of dementia symptoms, cognition, and activities of daily living has been confirmed (29,30). Donepezil was to be well tolerated for periods up to 1 year, and adverse events were usually mild and transient, lasted only an initial few days, and typically resolved without the need for dosage modification. It has been suggested that patients with Alzheimer's disease do best while taking donepezil 10 mg/day and when the dosage is maintained at that level without interruption. Donepezil treatment effects that are lost after prolonged withdrawal do not fully recover when the drug is restarted (31).

Organs and Systems

Cardiovascular

Symptomatic sinus bradycardia is a possible adverse effect of treatment with donepezil in Alzheimer's disease (32).

- An 84-year-old patient with hypertensive cardiomyopathy developed bradycardia, fainting, and left-sided heart failure 3 weeks after starting treatment with donepezil. When donepezil was withdrawn, the sinus bradycardia disappeared; 24-hour electrocardiography showed no signs of sinus node disease, and no episodes of this type recurred during the next 6 months.

It is important to emphasize that disorders of cardiac rhythm associated with the use of donepezil are extremely unusual.

Nervous system

Convulsions have been reported during treatment with donepezil (33).

- A patient with mild Alzheimer's disease taking donepezil, 5 mg/day for 2 weeks and then 10 mg/day for 23 days, was admitted with convulsions. His only other medication was aspirin 100 mg/day. Blood analysis was normal, and a computerized tomographic (CT) scan showed a mild degree of cortical atrophy with no structural lesions. Donepezil was withdrawn, and no other drug treatment was given. Six weeks later, donepezil 5 mg/day was restarted. On day 52, he developed loss of consciousness and convulsions, necessitating withdrawal of donepezil.

Convulsions in Alzheimer's disease are very rare until late in the illness, and the authors attributed this patient's convulsions to donepezil.

Restless legs, mumbling, and stuttering have been reported in a patient taking donepezil (34). According to the Naranjo probability scale, the causality was probable, since rechallenge was positive.

Extrapyramidal effects have been reported in three patients taking donepezil; in two cases, the effects disappeared when donepezil was withdrawn (35).

Psychological, psychiatric

Behavioral worsening in seven patients with Alzheimer's disease after the start of donepezil therapy has been described (36). Their mean age was 76 years, and their mean score on the Mini-Mental State Examination was 18. Five patients had had dementia-related delusions and irritability before taking donepezil, one had had a history of major depression, and another had had a history of somatization disorder. At the start of treatment with donepezil, four were taking sertraline, one paroxetine, one venlafaxine, and four risperidone. All took donepezil 5 mg/day, and after 4–6 weeks the dosage in five patients was increased to 10 mg/day. In the other two cases, donepezil was discontinued after 5 weeks: in one case because of gastrointestinal symptoms and in the other because of increasing agitation. After an average of 7.3 (range 1–13) weeks after starting donepezil, all seven patients had a recurrence of previous behavioral problems. Five became agitated, one became depressed, and the other became more anxious and somatically preoccupied. The pattern of behavioral change involves regression to an earlier behavioral problem.

Violent behavior has been described with donepezil (37).

- A 76-year-old man who was taking oxybutynin 3 mg tds for bladder instability took donepezil 5 mg/day for presumed Alzheimer's disease and 5 days later became very paranoid, believing that his wife had been stealing his money. He beat her and held her hostage in their house with a knife until their daughter intervened. He was given haloperidol 0.5 mg bd, and donepezil and oxybutynin were withdrawn. His paranoid ideation resolved within a few days and did not recur despite withdrawal of haloperidol.

Although a causal relation between this violent incident and donepezil cannot be proved, the temporal relation was suggestive.

Liver

Donepezil has not been associated with hepatotoxic effects, which is a distinct advantage over tacrine. Donepezil treatment benefit persisted over 98 weeks, with no evidence of hepatotoxicity (38).

Urinary tract

Urinary incontinence may often be disregarded as a manifestation of dementia, but it has also been attributed to donepezil.

Of 94 patients with mild-to-moderate disease treated with recommended dosages of donepezil (3 mg/day during the first week and then 5 mg/day), 7 developed urinary incontinence (39). In five of them, the incontinence was transient, and there was no need to change the prescription. Incontinence occurred in both sexes, in relatively young and old patients, and in those with very mild-to-moderate dementia. In six patients the incontinence occurred at the higher dosage of 5 mg/day, in one patient it disappeared when donepezil was withdrawn, and in another an increase in dosage caused the reappearance of incontinence, suggesting a likely causal, dose-dependent relation between donepezil and urinary incontinence.

Urinary incontinence in patients with Down syndrome treated with donepezil has been described before (40). Urinary incontinence can be a major concern and a source of distress, not only for patients but also for caregivers. Clinicians should be alert to the possibility of urinary incontinence when prescribing donepezil for individuals

© 2006 Elsevier B.V. All rights reserved.

with Alzheimer's disease. The authors emphasized that the incontinence may often be transient and not serious, but it could limit a patient's activities and quality of life and could also affect therapeutic adherence.

Skin

A purpuric rash associated with donepezil has been reported (41).

- An 82-year-old woman with hypertension, taking long-term atenolol and doxazosin, developed moderate cognitive impairment attributed to Alzheimer's disease. She was given donepezil 5 mg/day and, after 4 days, developed diarrhea, vomiting, and a purpuric rash on her trunk, arms, and legs. Platelet counts were 119–157 $\times$ 10^9/l. Donepezil was withdrawn, with resolution of the gastrointestinal symptoms.

Donepezil was the probable cause of this rash, because of the temporal association with treatment and its recurrence on rechallenge.

Susceptibility Factors

Other features of the patient

Three patients with Alzheimer's disease associated with Down syndrome were treated with donepezil (40). One became agitated and aggressive; the other two developed urinary incontinence. In all three cases donepezil was withdrawn. These results are important, because many individuals with Down syndrome develop clinical and neuropathological evidence of Alzheimer's disease after the age of 40 years. Also, patients with Down syndrome were excluded from donepezil clinical trials. Therefore, lesser data on the efficacy or safety of donepezil are available for this population.

Drug Administration

Drug overdose

Two cases of donepezil overdose have been reported (42,43).

- A 79-year-old nursing home patient was given donepezil 50 mg in error. She developed nausea, vomiting, and persistent bradycardia—typical cholinergic adverse effects. She was treated with atropine, 0.2 mg as needed, for bradycardia (total dose 3 mg over 18 hours) and was discharged on the second day.
- A 74-year-old woman with a history of stroke, myocardial infarction, hypothyroidism, and probable multi-infarct dementia took nine donepezil tablets (a total dose of 45 mg). She developed nausea and vomiting 2 hours later. She fell asleep for 4–5 hours but remained rousable. About 9 hours after ingestion, she became flushed and had a bout of diarrhea. Donepezil was withdrawn for 3 days, and there were no adverse effects when it was reintroduced.

Drug–Drug Interactions

Neostigmine

An additive inhibitory effect of donepezil and neostigmine on acetylcholinesterase has been proposed to explain prolonged neuromuscular blockade during anesthesia in an 85-year-old woman taking donepezil (44).

Paroxetine

A possible interaction between donepezil and paroxetine has been described (45).

- Two elderly patients with Alzheimer's disease and a mood disorder were treated with donepezil 5 mg/day and paroxetine 20 mg/day. One of them became agitated, confused, and aggressive, and donepezil was withdrawn after 8 days. On reintroduction of donepezil she again became rapidly confused, irritable, and verbally aggressive. In the other case, while the patient was taking paroxetine, donepezil 5 mg/day resulted in severe diarrhea, flatulence, and insomnia. The dosage of donepezil was reduced to 5 mg on alternate days, but the diarrhea and flatulence persisted. The symptoms resolved when donepezil was stopped.

Donepezil is metabolized in the liver by CYP2D6 and CYP3A4. Selective serotonin re-uptake inhibitors (SSRIs), such as paroxetine, are potent inhibitors of CYP2D6. Mood disorders are common in patients with Alzheimer's disease, and SSRIs are used in these patients and can increase the plasma concentration of donepezil, increasing the risk of severe adverse reactions.

Risperidone

Extrapyramidal effects occurred in a patient who took donepezil and risperidone concurrently (46). Although risperidone is less likely than conventional antipsychotic drugs to cause extrapyramidal effects, and is therefore particularly useful for older patients who are very susceptible to developing extrapyramidal disturbances, an increase in brain acetylcholine resulting from donepezil, along with dopamine receptor blockade by risperidone, would have led to an imbalance between cholinergic and dopaminergic systems. Although a clinically significant interaction between donepezil and risperidone seems to be rare, clinicians should be alert to such a possibility.

Tiapride

Parkinsonism has been reported in a patient concurrently taking donepezil and tiapride, probably through a pharmacodynamic interaction (47).

Dopamine

General Information

Dopamine is a naturally occurring catecholamine and central neurotransmitter capable of raising cardiac output, reducing peripheral resistance, and specifically increasing renal blood flow. Infusions (generally up to 10 micrograms/kg/hour) have proven valuable in shock and congestive heart failure.

Common adverse reactions during infusion include extra beats, tachycardia, and palpitation. Angina pectoris, bradycardia, altered cardiac conduction, nausea and vomiting, headache, and dyspnea can occur. Piloerection and uremia have been reported and blood pressure can either rise or fall.

Organs and Systems

Cardiovascular

The major risk during dopamine treatment is that of severe peripheral ischemia, particularly in patients in whom the peripheral circulation is already impaired, since dopamine is converted to noradrenaline; gangrene has repeatedly resulted. In some of the reported cases the error lay in extravasation of dopamine from a peripheral venous infusion site; in others the dosage had been high and prolonged, or ergometrine had also been given. In cases of pre-existing vascular damage from arteriosclerosis, diabetes, Raynaud's disease, or frostbite, particular care must be taken. If discoloration appears, the infusion should be stopped and phentolamine 5–10 mg given intravenously. Nitroprusside may fail to prevent the onset of gangrene.

Nervous system

In one case, dopamine was considered to have produced myoclonic encephalopathy (1).

Hematologic

When used to treat low-output congestive heart failure, dopamine can inhibit platelet aggregation, in contrast to the platelet-aggregating properties of many catecholamines (2).

Susceptibility Factors

Other features of the patient

For obvious reasons, the use of dopamine may be dangerous in cases of coronary or peripheral vascular disorders. Dopamine used for hypotension during percutaneous transluminal angioplasty (PTCA) can be associated with diffuse coronary spasm, and it should therefore be used with caution, particularly if high doses are required. When dopamine aggravates pulmonary hypertension and right ventricular failure, isoprenaline should be considered as an alternative inotropic drug.

Drug–Drug Interactions

Alkali

Dopamine is unstable in the presence of alkalis (3). It should not be infused in bicarbonate solutions.

Cyclopropane and halogenated hydrocarbon anesthetics

In the nucleus accumbens of rats the dopamine concentration was increased by both cyclopropane and halothane anesthesia; cyclopropane, but not halothane, also increased the dopamine concentration in the caudate nucleus halothane, but not cyclopropane, significantly reduced the dopamine concentration in the ventral nucleus of the thalamus (4). It has been suggested that potentiation of the actions of dopamine could occur with cyclopropane or halogenated hydrocarbon anesthetics, but there is no direct evidence that this interaction occurs in humans.

Monoamine oxidase inhibitors

The hypertensive effect of dopamine is potentiated by monoamine oxidase inhibitors.

- A 75-year-old man who was taking selegiline 5 mg bd for Parkinson's disease was given an intravenous infusion of dopamine for reduced urine output and hypotension (5). Within minutes of starting the infusion, his systolic blood pressure rose from 105 to 228 mmHg. Similar reactions occurred during two subsequent rechallenges.

The authors proposed that selegiline may have caused this effect by inhibiting dopamine metabolism, and that selegiline may not be as specific an inhibitor of monoamine oxidase type B as previously thought.

Dopexamine

General Information

Dopexamine, which is related structurally to dopamine, is a potent beta$_2$-adrenoceptor agonist (1). Its reported adverse effects include cases of atrial fibrillation and single instances of supraventricular tachycardia and hypotension.

Dornase alfa

General Information

Dornase alfa is human recombinant deoxyribonuclease. Daily therapy with dornase alfa in patients with cystic fibrosis can reduce the frequency of respiratory infections and improve lung function in patients with bronchiectasis.

Therapeutic studies

The role of dornase alfa in modifying bronchial secretions in patients with cystic fibrosis has been evaluated in 54 subjects aged 5 years or over (1). They were treated for 12 months with mesna by nebulizer bd and oral ambroxol (30 mg bd). Dornase alfa was then given once daily by aerosol 2.5 mg for 12 months. Mesna and ambroxol caused reductions in FEV_1 and FVC (FEV_1 fell by 11%, FVC by 13%). After 12 months of dornase alfa, FEV_1 had increased by 7.7% and FVC by 5.3%. The patients found treatment with dornase alfa more acceptable than mucolytic therapy. Hemoptysis was the only reported adverse effect, but it occurred frequently in only one patient.

The effect of daily nebulized dornase for 24 weeks has been studied in a randomized, double-blind, placebo-controlled trial in 349 patients with idiopathic bronchiectasis (2). Three patients withdrew from the trial; two in the placebo group (hemoptysis and sinusitis) and one in the treatment group (increased sputum production, probably an adverse event). The primary outcome measures were the number of infective exacerbations and a fall in FEV_1. There were more exacerbations in the treatment group, with a relative risk of 1.35 (not statistically significant). The rate of fall in FEV_1 and FVC was significantly higher in the treatment group than in the placebo group, and the treatment group required more days of antibiotics and corticosteroids. Four patients died during the study, three in the treatment group. No deaths were considered to have been due to the treatment. Adverse events occurred equally in both groups, the commonest being non-specific respiratory disorders (10% in the placebo group and 15% in the treatment group). No other adverse events were detailed. These results suggest that dornase is not effective in patients with idiopathic bronchiectasis and may even be detrimental. Dornase should not be used in these patients.

Dosulepin

See also Tricyclic antidepressants

General Information

Dosulepin (dothiepin) is a tricyclic antidepressant that has been available in Europe for over 30 years and is particularly popular in the UK. Its animal and clinical pharmacology has been described in an extensive review (1). It appears to be equivalent to amitriptyline, although few studies have reported dosages above 225 mg/day. Dosulepin is as effective and sedative as amitriptyline, with somewhat fewer anticholinergic adverse effects in several studies. However, it does not appear to have been compared with other less sedative or anticholinergic tricyclic compounds or second-generation drugs. Although it is claimed to have fewer cardiovascular effects, this has not been well substantiated in controlled comparative studies, and the cardiovascular and other effects of overdosage appear to be identical for all tricyclic compounds. Fetal tachydysrhythmias were believed to be caused by maternal ingestion of dosulepin (2).

Doxacurium chloride

See also Neuromuscular blocking drugs

General Information

Doxacurium chloride is a long-acting non-depolarizing neuromuscular blocking agent. It is a bisquaternary benzylisoquinolinium derivative (a diester). It is subject to minimal hydrolysis by plasma cholinesterase (at about 6% of the rate of hydrolysis of suxamethonium when incubated with purified pooled human plasma cholinesterase) (1). Antagonism by edrophonium (1 mg/kg) was considered inadequate in one study, whereas no difficulties were experienced with neostigmine (0.05 mg/kg) (2).

Organs and Systems

Cardiovascular

No rise in plasma histamine concentration was found with bolus doses up to 0.08 mg/kg (1), but in one case there was transient hypotension 1 minute after a bolus dose of 0.05 mg/kg via a pulmonary artery cannula, with cutaneous flushing at 2 minutes, suggesting that histamine release can occur on occasion (3). There was no tachycardia or bronchospasm, but the mean arterial pressure fell from 88 to 40 mmHg and recovered with therapy within 3 minutes, by which time the skin flushing was fading.

In a study of 54 patients, plasma histamine concentrations increased by 200% following doxacurium in two patients, but there were no changes in heart rate or blood pressure (4). Indeed, cardiovascular stability has been reported in several studies (1,4) and only minor clinically insignificant changes have been seen with doses up to 0.08 mg/kg, even in cardiac patients (AHA classes III–IV) (5,6).

Bradycardia is occasionally seen (2), but this may be due to co-administration of vagotonic drugs with atracurium, vecuronium, and pipecuronium.

Susceptibility Factors

Renal disease

Renal excretion is the main route of elimination of doxacurium, and its duration of action would be expected to be prolonged in patients with renal dysfunction. There have been two reports of the use of doxacurium in patients with chronic renal insufficiency. In the first it was reported that the action of doxacurium (0.025 mg/kg bolus dose) was "markedly but not statistically prolonged"; the mean time to 25% recovery of the twitch height was 121 minutes in the group of patients with renal insufficiency as opposed to 67 minutes in the control group, with great interindividual variation in both groups (7). The second was a study of the pharmacokinetics and pharmacodynamics of doxacurium in patients undergoing cadaveric kidney or liver transplantation (8). The duration of action of doxacurium was more variable and greatly prolonged in patients with end-stage renal insufficiency, although once again the results were clinically but not statistically significant, because of the small numbers of patients and large variability. Plasma clearance was significantly slower and mean residence time significantly greater in the renal transplant group than in control patients. In the patients with liver disease there were no significant pharmacokinetic changes, but the duration of action of the low dose used (15 mg/kg) did tend to be somewhat prolonged.

Doxapram

General Information

Generalized stimulation of the central nervous system has been observed with doxapram, particularly in large doses. Adverse reactions have included hyperactivity, tachycardia, increased deep tendon reflexes and muscle twitching, and laryngospasm. Raised blood pressure can also occur.

© 2006 Elsevier B.V. All rights reserved.

Doxapram is contraindicated in epilepsy and other convulsive disorders and in hypertension. Doxapram has been used to treat post-anesthetic shivering; in one study it was effective (1).

Adverse effects of doxapram are not long-lasting, because of its short half-life of 2–4 hours.

In seven patients treated with doxapram after anesthesia, the adverse effects were not serious and comprised excessive coughing, weeping, muscle tremor, nausea, and hysterical reactions to dreams. However, sweating, excessive salivation, and vomiting were noted in the control patients, and the authors concluded that recovery was smoother with doxapram.

There was a very high incidence of adverse reactions, such as hot flushes, sweating, hyperventilation, tremor, nausea, and vertigo, in postoperative analgesia combined with doxapram 1 mg/kg (2).

In a controlled study of the use of doxapram infusion for late postoperative hypoxemia (3) three of nine patients who received doxapram had an adverse event, compared with none of the placebo patients. In 18 patients there was a significant trend toward higher mean oxygen saturation in the doxapram group and a significantly higher minimum oxygen saturation and reduced number of hypoxemic events on the first postoperative night. The authors concluded that although the results were promising, continuous nocturnal postoperative doxapram infusion should be postponed until there is more information about its pharmacokinetics in this condition.

The effects of doxapram given enterally or intravenously have been studied in a prospective randomized trial in 15 infants with apnea of prematurity who had not responded to caffeine (4). Of the nine infants randomized to receive enteral treatment, five had to be changed to intravenous treatment, largely owing to doxapram-induced upper gastrointestinal symptoms (vomiting and large gastric residuals). Doxapram significantly reduced the frequency of attacks of apnea and associated bradycardia and hypoxia in 82% of the infants. The major adverse event was feeding intolerance in one-third of infants given enteral treatment. This resolved when doxapram was given intravenously. Importantly, some infants responded to and could tolerate enteral treatment, thus avoiding the need for an intravenous line.

Organs and Systems

Cardiovascular

Dysrhythmias consisting of self-limiting or single ventricular extra beats were observed after doxapram was given by injection; it was suggested that electrocardiographic dysrhythmias occurring in anesthesia could be associated with analeptic drug administration (5).

Doxapram is used to treat idiopathic apnea in premature infants. Second-degree atrioventricular heart block developed after its administration to three neonates (6).

- Thirty-six hours after an infusion of doxapram was started, the first infant developed second-degree AV block, with QT interval prolongation and an increase in the QRS interval. There was no hypotension. Sinus rhythm returned 92 hours after stopping the infusion.
- Doxapram was given orally, every 6 hours, to the second infant. After 43 hours second-degree AV block with a prolonged QT interval was noted. Echocardiography showed a normal heart. Doxapram was discontinued and 8 hours later sinus rhythm returned.
- The third infant was given aminophylline orally and doxapram by intravenous infusion; 5 days later cisapride was added to treat suspected gastro-esophageal reflux. The next day the infant had developed second-degree AV block, with a prolonged QT interval. Doxapram was withdrawn and sinus rhythm returned 36 hours later.

Heart block did not occur in the third case until cisapride, which can prolong the QT interval, was added.

There has been another report of three cases of second-degree atrioventricular block and QT interval prolongation associated with doxapram; sinus rhythm returned after withdrawal (7).

The mean pulmonary arterial pressure was significantly, but not severely, increased in 10 patients receiving intravenous infusions of doxapram (8).

There have been two studies of doxapram in very low birth weight infants before extubation. In one it was concluded that doxapram did not increase the likelihood of successful extubation. In the other there was an increase in systolic blood pressure along with much higher plasma doxapram concentrations than expected (9,10).

Nervous system

Of 20 patients, mean age 72, treated with low doses of doxapram by infusion, four developed violent restlessness, confusion, and hallucinations (SED-9, 5). Of these, three were known to drink excessive alcohol and two had abnormal liver function. The reactions were relatively brief and occurred at the beginning and end of doxapram administration.

In a controlled study of the use of doxapram infusion for late postoperative hypoxemia (3) the drug was withdrawn because of brainstem infarction in a 90-year-old woman.

In 285 surgical patients, respiratory stimulation was safely performed with doxapram, especially with small, frequently repeated doses. Adverse effects included neuromuscular signs of excessive central nervous system stimulation in a very few patients at 1 mg/kg. Seven patients had excitement and there was tremor in three and rigidity in two. Coughing, laryngospasm, and salivation are probably physiological manifestations of the return of protective reflexes secondary to arousal (11).

Liver

Reversible hepatotoxicity has been attributed to doxapram (12).

Doxazosin

See also Alpha-adrenoceptor antagonists

General Information

The alpha$_1$-adrenoceptor antagonist doxazosin has similar adverse effects to those of prazosin. In a review of its clinical pharmacology and therapeutic uses, reports of tolerability included an update from previously unpublished pooled data on file (1). In 339 patients treated with doxazosin for hypertension compared with 336 treated with placebo, adverse effects were essentially the same as those reported in 665 patients being treated for benign prostatic hyperplasia compared with 300 treated with placebo. Dizziness (19 versus 9% and 16 versus 9%) and fatigue (12 versus 6% and 8 versus 2%) were reported significantly more often than with placebo (figures for patients with hypertension and benign prostate hyperplasia respectively, versus placebo). However, in hypertensive patients somnolence was reported more often than with placebo (5 versus 1%). In patients with benign prostatic hyperplasia the following adverse effects were reported significantly more often than with placebo: hypotension (17 versus 0%), edema (2.7 versus 0.7%), and dyspnea (2.6 versus 0.3%).

The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) (2) was a multicenter comparison of drugs from each of three classes of antihypertensive agents (amlodipine, lisinopril, and doxazosin) with chlortalidone as an active control, in 24 335 adults with hypertension and at least one other coronary heart disease risk factor. In an interim analysis (median follow-up 3.3 years) there was no significant difference in the rates of fatal coronary heart disease or non-fatal myocardial infarction, or in total mortality between doxazosin and chlortalidone, but doxazosin was associated with higher rates of stroke (RR = 1.19; CI = 1.01, 1.40) and combined cardiovascular disease (RR = 1.24; CI = 1.17, 1.33). Considered separately, the risk of congestive heart failure was doubled (RR = 2.04; CI = 1.79, 2.32). Mean systolic blood pressure with doxazosin was about 2–3 mmHg higher than with chlortalidone and mean diastolic pressure was similar in the two groups. The authors concluded that the difference in blood pressure control did not account for the differences in cardiovascular end-points.

Doxazosin, and perhaps the whole class of alpha-blockers, should no longer be considered as first-line antihypertensive therapy. Doxazosin can still be used for symptom relief in patients with nocturia secondary to prostatic hyperplasia, although it should probably be avoided in patients with manifest or latent congestive heart failure (3). This issue has been intensely debated (4).

Phenoxybenzamine and doxazosin have been compared in 35 patients with pheochromocytoma (5). Hemodynamic, pharmacological, and biochemical indicators of alpha- and beta-adrenoceptor blockade were measured before, during, and after anesthesia and surgery in eight patients pretreated with phenoxybenzamine and in 27 patients pretreated with doxazosin. Doxazosin (2–16 mg/day) was as effective as phenoxybenzamine in controlling arterial blood pressure and heart rate before and during surgery and it caused fewer adverse effects.

Organs and Systems

Cardiovascular

Hypotension is a risk with doxazosin and has been reported to cause stroke (6).

- A 64-year-old man developed a right hemiparesis after taking one dose of doxazosin 4 mg for prostatic symptoms. A CT scan of the brain and carotid ultrasound studies were normal. He recovered most of his neurological function within a few days. Ambulatory blood pressure monitoring after treatment with doxazosin 2 mg showed striking blood pressure reduction during sleep.

Psychological, psychiatric

Doxazosin, 16 mg/day, has been reported to have caused an acute psychosis.

- A 71-year-old woman with type II diabetes and hypertension began to hear voices and to have auditory hallucinations. Doxazosin was progressively withdrawn over the next 14 days and by the time the dosage had been reduced to 8 mg a day the psychosis was much less severe; it disappeared completely after withdrawal (7).

© 2006 Elsevier B.V. All rights reserved.

Drug Administration

Drug formulations

Doxazosin can cause a sharp fall in blood pressure at the start of therapy, and a modified-release formulation has been developed in an attempt to obviate this. In an open, non-comparative, sequential study in primary care, the ordinary formulation (1–16 mg/day for 3–6 months) was replaced by the modified-release formulation (4–8 mg/day for 3 months) in 3537 patients (8). The most common reasons for withdrawal from the study were loss to follow-up (37%) and adverse events (28%). Blood pressure fell from 160/95 to 139/82 mmHg with the ordinary formulation and to 135/79 mmHg when the modified-release formulation was used instead. The most common adverse events were weakness, headache, dizziness, and hypotension, all of which were more common with the ordinary formulation. However, these differences could have been due to a healthy survivor effect, in which those who had an adverse event early on (that is while taking the ordinary formulation) dropped out before taking the modified-release formulation, which would therefore appear to be safer. Thus, the lack of crossover in this study makes the results hard to interpret, although it appears that the two formulations were at worst no different from each other.

Drug overdose

A case of doxazosin overdose has been reported.

- Hypotension, bradycardia, and ST segment elevation on the electrocardiogram occurred in a patient who took doxazosin 40 mg (9). His blood pressure was 90/60 mmHg and his heart rate fell to 50/minute. Eight hours after aggressive saline infusion and gastric lavage the patient was awake, but his hypotension and bradycardia were corrected only after 96 hours and the administration of intravenous atropine 0.5 mg.

Doxepin

See also Tricyclic antidepressants

General Information

Doxepin is a tricyclic antidepressant that has also been used topically in the treatment of atopic dermatitis and other forms of eczematous dermatitis. It causes the adverse effects that one would expect, and systemic effects can result from absorption after topical administration.

Organs and Systems

Nervous system

Short-term treatment with 5% doxepin cream caused mild transient drowsiness in 16–28% of patients, severe enough to necessitate withdrawal in about 2% (1). In addition, 5% of treated patients noted a dry mouth. Excessive use in children can result in intoxication, with seizures, respiratory depression, electrocardiographic abnormalities, and coma (2).

Doxifluridine

See also Cytostatic and immunosuppressant drugs

General Information

Doxifluridine is a derivative of 5-fluorouracil. It has been used to treat a variety of solid tumors, including cancers of the breast, pancreas, stomach (1), and large bowel.

Organs and Systems

Nervous system

In a neurological evaluation of 17 patients treated with doxifluridine 3 or 5 g/m^2/day for 5 days every 4 weeks for 3 months, 10 developed symptoms of central nervous system toxicity. The neurological symptoms, cerebellar and encephalopathic, developed simultaneously and were commonly first noted during the second week of the first cycle. The neurotoxicity was dose-related and worsened during subsequent treatment. The symptoms of cerebellar disease ranged from a subjective feeling of unsteady gait to disability, while the encephalopathy resulted in difficulties with concentration and memory. Patients with marked weight loss and with generalized electrocardiographic dysrhythmias are at greatest risk of developing neurotoxicity with doxifluridine (2).

Gastrointestinal

Anorexia has been reported with doxifluridine in the absence of nausea or vomiting (3).

Doxycycline

See also Tetracyclines

General Information

Doxycycline and minocycline are more lipophilic tetracyclines. They are well absorbed after oral administration. Their half-lives are 16–18 hours. Their higher affinity for fatty tissues improves their effectiveness and changes their adverse effects profile. Local gastrointestinal irritation and disturbance of the intestinal bacterial flora occur less often than with the more hydrophilic drugs, which have to be given in higher oral doses for sufficient absorption.

Nevertheless, their toxic effects are similar to those of other tetracyclines and arise from accumulation in fatty tissues. Accumulation in a third compartment and the resulting long half-life may contribute to an increased incidence of various toxic adverse effects during long-term treatment, even if lower daily doses are used. This seems also to be the case for pigmentation disorders and possibly for neurological disturbances (1).

Minocycline and doxycycline are predominantly eliminated by the liver and biliary tract (70–90%). Therefore, no change in dose is needed in patients with impaired renal function. However, it should be considered that hepatic elimination of doxycycline or minocycline might be accelerated by co-administration of agents that induce hepatic enzymes.

Organs and Systems

Nervous system

Peripheral neuropathy from doxycycline has been reported (2).

- A 61-year-old doctor with recurrent bronchopneumonia took two courses of doxycycline. During the first course he had persistent numbness in his feet. During the second course, a few months later, he noticed after only 2 or 3 days that the numbness accelerated markedly and was associated with a low threshold for muscle cramps in the feet. He stopped taking doxycycline and during the following weeks noticed slight improvement. However, some symptoms persisted and he had neurological investigations. A wide range of clinical and laboratory tests showed no cause for his neuropathy.

A search for an association between doxycycline and polyneuropathy failed to identify any documented cases. An inquiry to the Swedish Adverse Drug Reactions Advisory Committee elicited information about three cases of "paresthesia," two cases of "sensitivity disturbance," and one case of "neuropathy." The last was a man who had had pain and paresthesia in the feet, arms, and face after taking doxycycline 100 mg/day for 2 weeks for prostatitis. The symptoms began to wane 1 week after treatment was stopped, and disappeared completely 1 week later.

Metabolism

Doxycycline can cause hypoglycemia.

- A 70-year-old man with type 2 diabetes mellitus presented with sudden confusion, which rapidly progressed to loss of consciousness (3). The only drug he had taken during the previous 2 months was doxycycline (100 mg/day), which he had taken for 5 days for an upper respiratory tract infection. Urine tests for sulfonylureas were negative. Routine hematological and biochemical tests and an electrocardiogram were normal. He improved with intravenous glucose and withdrawal of doxycycline and had no further episodes of hypoglycemia over the next 3 months.

Plasma insulin was not measured in this case, so the mechanism of hypoglycemia was unclear.

Hypoglycemia has also been attributed to doxycycline in a non-diabetic patient (4).

© 2006 Elsevier B.V. All rights reserved.

Gastrointestinal

Esophageal ulcers have been described in association with oral doxycycline or tetracycline. Acute onset of substernal burning pain and dysphagia was noted within hours of taking the drug (5–9). Remaining parts of the ingested capsule were identified by esophagoscopy.

Thirty centers for pharmacovigilance in France have reported 81 cases of esophageal damage after treatment with tetracyclines collected between 1985 and 1992 (10). There were 64 ulcers, eight cases of dysphagia, and nine of esophagitis. Most (96%) of the cases were caused by doxycycline and 73% of the patients were female, mean age 29 years. Prescriptions were for dermatological (54%), urogenital (23%), and ENT diseases. In one patient, a 71-year-old man, an esophagobronchial fistulation required esophagectomy. In 92% the drugs were not taken correctly, that is at bedtime or without a sufficient quantity of fluid. Treatment with sucralfate 1 g tds did not change the outcome of tetracycline-induced esophageal ulcers (11).

Two cases of esophagitis in children have been reported (12).

- A 12-year-old boy developed lower chest pain, having taken doxycycline for 7 days for presumed epididymitis. He had a normal chest X-ray and electrocardiogram and no signs of infection. Doxycycline was withdrawn, but the chest pain persisted. After 4 days endoscopy showed two very large ulcerated craters measuring about 5×12 mm in the distal esophagus.
- A 15-year-old girl developed chest pain and difficulty in swallowing after having taken five doses of doxycycline. Physical examination was normal and she had a normal chest X-ray and electrocardiogram. Doxycycline was withdrawn and she was given sucralfate 10 ml tds, omeprazole having been ineffective. Gastroscopy was not performed. Her pain began to improve 2 days later.

The authors stated that it is important to inquire about the use of tetracyclines in children with chest pain, and to consider them as a possible cause of the pain.

Esophageal ulceration occurred in two adults taking doxycycline as malaria chemoprophylaxis (13).

- A 20-year-old woman, who had been taking doxycycline malaria prophylaxis, took a doxycycline capsule (dose not given) before going to bed and awoke hours later with the feeling that the capsule was stuck in her esophagus. Over the next 4 days she developed worsening dysphagia. Esophagoscopy showed an esophageal ulcer over 20% of the esophageal surface. She was treated with ranitidine and sucralfate and improved over the next 2 days.
- A 27-year-old man with an 8-day history of dysphagia and retrosternal pain was taking doxycycline prophylaxis and occasional terfenadine (doses not stated). He recalled no problems with taking any of his doxycycline prophylaxis. He had an esophagoscopy, which showed a 1 cm esophageal ulcer. He improved with ranitidine.

Liver

Doxycycline-induced liver injury has been reported (14). The patient took oral doxycycline 200 mg/day for 8 days and had markedly altered liver function. The liver enzyme activities normalized only 109 days after withdrawal.

Skin

Fixed drug eruptions have been attributed to doxycycline (15).

Immunologic

Renal small-vessel vasculitis related to doxycycline has been reported (16).

Second-Generation Effects

Teratogenicity

Doxycycline has not been shown to be teratogenic (17).

Susceptibility Factors

Renal disease

Doxycycline is almost completely eliminated via the liver and the biliary tract and is therefore safe in patients with pre-existing renal insufficiency. However, for intravenous administration, doxycycline is solubilized with polyvinylpyrrolidone, the clearance of which is less than that of doxycycline. In patients with a serum creatinine concentration of more than 250 μmol/l (3 mg/dl), it is therefore advisable to limit the duration of treatment to a few days.

Drug Administration

Drug administration route

When intravenous tetracycline became no longer available, many centers began to use doxycycline as a sclerosant. In one review (18), chest pain was the most frequent adverse event with doxycycline, occurring in about 40% of the 60 patients in whom it had been used, and fever occurred in about 7%. In a more recent controlled trial in 106 patients treated with either doxycycline or bleomycin, there was chest pain in 20% of the patients treated with doxycycline, and nausea in one patient (19).

Drug–Drug Interactions

Methotrexate

Doxycycline can be added to the long list of drugs (SEDA-18, 262) (SEDA-23, 253) that can interact with methotrexate (20).

- A 17-year-old girl with a femoral osteosarcoma received her 11th cycle of methotrexate and simultaneously oral doxycycline 100 mg bd for a palpebral abscess. As in previous cycles, pharmacokinetic monitoring of methotrexate was performed. On this occasion the half-life of methotrexate was more than doubled. She developed hematological and gastroenterological toxicity.

The authors recommended that in patients receiving methotrexate an alternative to doxycycline should be used.

© 2006 Elsevier B.V. All rights reserved.

Warfarin

There has been a report of bleeding and prolonged international normalized ratio in a 69-year-old man given warfarin and doxycycline (21).

Doxylamine

See also Antihistamines

General Information

Doxylamine is an antihistamine, a monoethanolamine derivative, with antimuscarinic and pronounced sedative effects.

Second-Generation Effects

Teratogenicity

The mixture of doxylamine succinate and pyridoxine (at one time combined with dicycloverine), known under the brand names of Bendectin and Debendox, was withdrawn after a campaign had incriminated it as a teratogen. Used mainly in some English-speaking countries, it was used primarily to treat nausea and vomiting during pregnancy in circumstances in which, in other countries, dietary measures and/or low doses of antihistamines alone are more customary. No consistent picture of the congenital defects that it was alleged to produce (for example pyloric stenosis) ever emerged, and reviews have never concluded otherwise than that it was at most a low-grade teratogen (SEDA-9, 311) or entirely innocent. A review of the literature (1) and a meta-analysis failed to detect any evidence that Bendectin has a teratogenic effect (2).

Droperidol

See also Neuroleptic drugs

General Information

Droperidol is a butyrophenone with actions similar to those of haloperidol.

Of 20 volunteers who took droperidol 5 mg orally in orange juice, none had a neutral or pleasant experience (1). All reported restlessness, 17 felt sedated, and 11 reported dysphoria, the onset being relatively immediate; one subject broke down in tears within an hour of taking droperidol. Suicidal feelings emerged acutely in two subjects and were entertained in two more subjects. Among other adverse events were skin hypersensitivity ($n = 5$), aching in the muscles ($n = 6$), wheezing consistent with respiratory dyskinesia ($n = 1$), change in voice quality ($n = 1$), and marked rhinorrhea ($n = 1$). Mental effort

© 2006 Elsevier B.V. All rights reserved.

was difficult, and all subjects reported some problems with concentration.

Droperidol 5–7.5 mg given during induction of anesthesia was associated with impaired well-being scores 6 hours postoperatively in a randomized double-blind comparison of similar doses of droperidol ($n = 78$) and midazolam ($n = 72$) for preventing postoperative nausea and vomiting (2).

Organs and Systems

Cardiovascular

Droperidol has been associated with QT interval prolongation (SED-14, 141) (3–5) and torsade de pointes has been reported (6).

- A 59-year-old woman with no history of cardiac problems, except for hypertension, who was taking amlodipine 5 mg qds, cyclobenzaprine 10 mg qds, and co-triamterzide 37.5 + 25 mg qds, and who had a QT_c interval of 497 ms, was given intravenous droperidol 0.625 mg and metoclopramide 10 mg 45 minutes before surgery. About 1.75 hours after surgery she developed a polymorphic ventricular tachycardia with findings consistent with torsade de pointes, which resolved with defibrillation.

Nervous system

Intramuscular droperidol 2.5 mg was used to treat 23 consecutive patients with acute migraine who had not responded to other drugs (7). If no relief was achieved by 30–60 minutes after treatment, and no significant adverse effects were reported, a second dose of droperidol 2.5 mg was given. Varying degrees of akathisia after treatment were reported by six patients. Similarly, in a retrospective series of 37 patients who received droperidol 2.5 mg for migraine, 3 developed mild akathisia and 5 had drowsiness (8).

Balance disturbances have been described with droperidol in 120 women undergoing gynecological dilatation and curettage, who were randomly assigned to receive either 0.9% saline (placebo) or droperidol 0.625 mg intravenously before surgery (9). The change in body sway from the baseline before anesthesia was significantly greater after droperidol (61%) than after placebo (33%).

Drug–Drug Interactions

Fentanyl

An exception to the relatively safe use of high-potency agents has been noted in the combination of droperidol with the narcotic fentanyl, which can cause marked hypotension (10).

Neuromuscular blocking agents

Animal studies suggest that large doses of pethidine and droperidol can augment the myoneural effects of neuromuscular blocking agents (11).

Droseraceae

See also Herbal medicines

General Information

The family of Droseraceae contains two genera:

1. *Dionaea* (Venus flytrap)
2. *Drosera* (sundew).

Dionaea muscipula

The expressed sap of *Dionaea muscipula*, a fly-catching plant (Venus flytrap), was once available in Germany as an herbal oncolytic in the form of ampoules and oral drops (1). However, when it became apparent that intramuscular administration could produce shivers, fever, and anaphylactic shock, the health authorities banned the ampoules. They also ruled that the product information on the oral drops should warn against use in pregnancy and should list reddening of the face, headache, dyspnea, nausea, and vomiting as adverse effects.

Droxicam

See also Non-steroidal anti-inflammatory drugs

General Information

Droxicam, a piroxicam prodrug, has similar adverse effects (SEDA-16, 113) (1). Because of many Spanish reports of non-fatal liver damage, according to the CPMP the Summary of Product Characteristics should state that serious hepatic damage can occur (SEDA-17, 113). Owing to its hepatotoxicity, droxicam has been withdrawn in many countries (SEDA-19, 99).

Dryopteraceae

See also Herbal medicines

General Information

The genera in the family of Dryopteraceae (Table 1) include various types of fern.

Table 1 The genera of Dryopteraceae

Arachniodes (holly fern)
Athyrium (ladyfern)
Bolbitis (creeping fern)
Ctenitis (lacefern)
Cyclopeltis (cyclopeltis)
Cyrtomium (netvein hollyfern)
Cystopteris (bladderfern)
Deparia (false spleenwort)
Diplazium (twinsorus fern)
Dryopteris (wood fern)
Elaphoglossum (tongue fern)
Fadyenia (dotted fern)
Gymnocarpium (oak fern)
Hemidictyum (hemidictyum)
Hypoderris (hypoderris)
Lastreopsis (shield fern)
Lomagramma (lomagramma)
Lomariopsis (fringed fern)
Matteuccia (ostrich fern)
Megalastrum (megalastrum)
Nephrolepis (sword fern)
Nothoperanema (island lace fern)
Oleandra (oleander fern)
Olfersia (island fern)
Onoclea (sensitive fern)
Phanerophlebia (phanerophlebia)
Polystichum (holly fern)
Rumohra (rumohra)
Tectaria (halberd fern)
Triplophyllum (triplophyllum)
Woodsia (cliff fern)

Dryopteris filix-mas

The rhizome of *Dryopteris filix-mas* (male fern) was formerly used as an antihelminthic drug (1), but it is highly toxic and has been superseded by other less-dangerous agents. In spite of poor absorption, serious poisoning can occur, for example when absorption is increased by the presence of fatty foods. Poisoning is characterized by vomiting, diarrhea, vertigo, headache, tremor, cold sweats, dyspnea, cyanosis, convulsions, mental disturbances, disturbed vision, and even blindness, which in a few instances is permanent.

Ebastine

See also Antihistamines

General Information

Ebastine is a second-generation antihistamine with proven efficacy in the treatment of allergic disease (1). It is rapidly absorbed after oral administration, and undergoes extensive first-pass metabolism by CYP3A4 to its active carboxylic acid metabolite, carebastine.

Organs and Systems

Cardiovascular

Cardiac effects were reported from early experimental work using very high doses of ebastine, but they are not believed to be clinically relevant in normal use. In one study serial electrocardiograms showed no changes with doses up to the maximum used (30 mg). Ebastine in doses up to five times the recommended therapeutic dose did not cause clinically relevant changes in QT_c interval in healthy subjects (2). Co-administration of ebastine with ketoconazole or erythromycin did not lead to significant changes in the QT_c interval (3,4).

Psychological, psychiatric

The effects of ebastine 10 mg on cognitive impairment have been assessed in 20 healthy volunteers who performed six types of attention-demanding cognitive tasks, together with objective measurements of reaction times and accuracy (5). Ebastine was compared with placebo and a positive control, chlorphenamine 2 mg and 6 mg. Compared with placebo, ebastine had no effect on any objective cognitive test nor any effect on subjective sleepiness. In contrast, chlorphenamine significantly increased reaction times, reduced accuracy in cognitive tasks, and increased subjective sleepiness. The effect of chlorphenamine increased with plasma concentration.

Susceptibility Factors

Age

The effect of age on the pharmacokinetics of ebastine and carebastine has been studied (6). Ebastine can be safely given to elderly subjects and there are no clinically important age-related differences in the pharmacokinetics of ebastine/carebastine.

Sex

The effect of sex on the pharmacokinetics of ebastine and carebastine has been studied (6). There were no clinically important sex-related differences in the pharmacokinetics of ebastine/carebastine.

Food–Drug Interactions

Like other antihistamines that rely on activation by metabolism, the systemic availability of ebastine can be affected by food. In a double-blind, placebo-controlled, parallel-group study, 215 patients with seasonal allergic rhinitis took ebastine with solid food (immediately after breakfast), while 218 took it 1–2 hours after breakfast (7). Food taken at the time of dosing did not alter the therapeutic or adverse effects of ebastine for 2 weeks in seasonal allergic rhinitis. Although carebastine steady-state concentrations were 15% higher when ebastine was taken with food this was not considered clinically important.

Echinocandins

General Information

The echinocandins are a class of semisynthetic antifungal lipopeptides that are structurally characterized by a cyclic hexapeptide core linked to a variably configured lipid side chain. The echinocandins act by non-competitive inhibition of the synthesis of 1,3-α-D-glucan, a major polysaccharide component of the cell wall of many pathogenic fungi, which plays a key role in cell division and cell growth and is absent from mammalian cells. In concert with chitin, the rope-like glucan fibrils are important in maintaining the osmotic integrity of

© 2006 Elsevier B.V. All rights reserved.

the fungal cell and play a key role in cell division and cell growth.

The currently available echinocandins are anidulafungin (rINN; Versicor Inc, Freemont, CA), caspofungin (rINN) (Merck & Co, Inc, Rahway, NJ), and micafungin (rINN; Fujisawa Inc, Deerfield, IL). They have relatively similar pharmacological properties. All three have potent and broad-spectrum antifungal activity against *Candida* species and *Aspergillus* species without cross-resistance to existing agents. They have prolonged post-antifungal effects and fungicidal activity against *Candida* and they cause severe damage to *Aspergillus* at the sites of hyphal growth. Their efficacy against these organisms in vivo has been demonstrated in animals (1,2). Their activity against other fungal pathogens in vitro is variable (3).

Pharmacokinetics

The echinocandins are currently available only for intravenous administration. They have dose-proportional plasma pharmacokinetics, with half-lives of 10–15 hours, which allows once-daily dosing. All echinocandins are highly protein-bound (over 95%) and distribute into all major tissues, including the brain; concentrations in non-inflammatory CSF are low. The echinocandins are eliminated by degradation and/or hepatic metabolism, and are slowly excreted as inactive metabolites in the urine and feces; only small fractions are excreted unchanged in the urine. As a class they are generally well tolerated and lack significant potential for drug interactions mediated by CYP450 isozymes (1–4). In vitro biotransformation studies of caspofungin have shown that it is not a substrate of P-glycoprotein and is a poor substrate and a weak inhibitor of cytochrome P450 enzymes (5). However, other in vitro studies have shown that it may inhibit CYP3A4 (6).

Observational studies

The clinical efficacy of anidulafungin, caspofungin, and micafungin against *Candida* species has been documented in phase II or phase III studies in immunocompromised patients with esophageal candidiasis. All achieved therapeutic efficacy at least comparable with standard agents. Phase III efficacy studies of caspofungin for esophageal candidiasis, invasive candidiasis, and empirical antifungal therapy in persistently febrile neutropenic patients have been completed. Caspofungin had no serious adverse effects and had therapeutic efficacy that was at least as good as standard agents (7–9). It is approved in the USA and the EU for second-line therapy of definite or probable invasive aspergillosis and for primary therapy in non-neutropenic patients with invasive *Candida* infections (3,5).

Caspofungin has been studied in a multicenter, open, non-comparative phase II trial in 83 patients with definite or probable invasive aspergillosis refractory to or intolerant of standard therapies (10,11). Common underlying conditions included hematological malignancies (48%), allogeneic blood and marrow transplantation (25%), and solid organ transplantation (11%). Caspofungin was administered in a dose of 70 mg on day 1, followed by 50 mg/day for a mean duration of 34 (range 1–162) days. There was a favorable response to caspofungin in 37 patients, including 32 of 64 with pulmonary aspergillosis and 3 of 13 with disseminated aspergillosis. Caspofungin was generally well tolerated. One serious adverse event was reported as possibly drug-related. Infusion-related reactions, nephrotoxicity, and hepatotoxicity were uncommon. Two patients discontinued caspofungin because of adverse effects.

The safety and tolerability of caspofungin have been studied in 623 patients, including 295 who received at least 50 mg/day for at least 1 week in clinical studies. In 263 patients who received caspofungin in randomized, double-blind, active-control trials, there were no serious clinical or laboratory drug-related adverse events; caspofungin was withdrawn in 2% of these patients because of drug-related adverse effects (12).

Comparative studies

Amphotericin

Caspofungin (Cancidas; 50 and 70 mg/day for 14 days; $n = 74$) has been compared with conventional amphotericin (0.5 mg/kg/day for 14 days; $n = 54$) in the treatment of esophageal candidiasis in a randomized, double-blind, multicenter trial in South America (13). Most of the patients (over 75%) were HIV-infected and about half of them had CD4+ lymphocyte counts of under 50×10^6/l. Caspofungin was well tolerated: eight patients in the amphotericin group and one patient in the combined caspofungin group developed a raised serum creatinine of over 176 μmol/l (2 mg/dl) during treatment. Of the patients who received caspofungin, 4.1% withdrew prematurely owing to drug-associated adverse effects, compared with 22% in the amphotericin arm. There was a clinical response (symptoms plus endoscopy) in 85% of the patients in the combined caspofungin group versus 67% in the amphotericin group.

Caspofungin has been compared with amphotericin in a multicenter, double-blind, randomized trial in 128 adults with endoscopically documented symptomatic *Candida* esophagitis (7). There was endoscopically verified clinical success in 74 and 89% of the patients who received caspofungin 50 and 70 mg/day respectively, and in 63% of patients given amphotericin deoxycholate 0.5 mg/kg/day. Therapy was withdrawn because of drug-related adverse events in 24% of the patients who were given amphotericin and in 4 and 7% of those who were given caspofungin 50 and 70 mg/day respectively. The most frequent adverse events with caspofungin were fever, phlebitis, headache, and rash. Fewer patients who received caspofungin had drug-related fever, chills, or nausea than those who received amphotericin. More patients who received amphotericin (91%) than caspofungin (61 and 32%) developed drug-related laboratory abnormalities, the most common in the caspofungin groups being hypoalbuminemia and increased serum activities of alkaline phosphatase and transaminases. There were drug-related increases in blood urea nitrogen concentrations in 15% of the patients who received amphotericin but in none of those who received caspofungin. Likewise, serum creatinine concentrations increased in 16 patients who

© 2006 Elsevier B.V. All rights reserved.

received amphotericin but in only one who received caspofungin. In summary, caspofungin was as effective as amphotericin but better tolerated in the treatment of esophageal candidiasis.

In a double-blind, randomized trial, caspofungin was compared with amphotericin deoxycholate for the primary treatment of invasive candidiasis (9). Patients who had clinical evidence of infection and a positive culture for *Candida* species from blood or another site were enrolled. They were stratified according to the severity of disease, as indicated by the presence or absence of neutropenia and the Acute Physiology and Chronic Health Evaluation (APACHE II) score, and were randomly assigned to receive either caspofungin (50 mg/day with a loading dose of 70 mg on day 1) or amphotericin (0.6–0.7 mg/kg/day or 0.7–1.0 mg/kg/day for patients with neutropenia). Of the 239 patients enrolled, 224 were included in the modified intention-to-treat analysis. Baseline characteristics, including the percentage of patients with neutropenia and the mean APACHE II score, were similar in the two treatment groups. The efficacy of caspofungin was similar to that of amphotericin, with successful outcomes in 73% of the patients treated with caspofungin and in 62% of those treated with amphotericin. There were significantly fewer drug-related adverse events associated with caspofungin: fever, chills, and infusion-related events were less frequent with caspofungin. Caspofungin caused less nephrotoxicity (as defined by an increase in serum creatinine of at least twice the baseline value or an increase of at least 88.4 μmol/l: 8.4 versus 25%). Only 2.6% of those who were given caspofungin were withdrawn because of adverse events, compared with 23% of those who were given amphotericin. Thus, caspofungin was at least as effective as amphotericin for the treatment of mostly non-neutropenic patients with invasive candidiasis but significantly better tolerated.

The safety, tolerability, and efficacy of caspofungin in patients with oropharyngeal and/or esophageal candidiasis have been investigated in a phase II dose-ranging study (14). The patients were randomized, double-blind to either caspofungin acetate (35, 50, or 70 mg) or amphotericin (0.5 mg/kg intravenously) once daily for 7–14 days. Of 140 patients, 63% had esophageal involvement and 98% were infected with HIV. Response rates with caspofungin groups were 74–91%, and 63% with amphotericin. Fewer patients receiving any dose of caspofungin had drug-related adverse effects (fever, chills, nausea, vomiting). Two patients who took caspofungin 35 mg and one who was given amphotericin withdrew because of adverse effects. Drug-related laboratory abnormalities were also more common in patients who received amphotericin. The most common drug-related laboratory abnormalities in patients who received caspofungin were raised alanine transaminase, aspartate transaminase, and alkaline phosphatase, which were typically less than five times the upper limit of normal and resolved despite continued treatment. None of the patients receiving caspofungin and nine of those who received amphotericin developed drug-related increases in serum creatinine concentrations. No patient withdrew because of drug-related laboratory adverse effects.

Antifungal azoles

Caspofungin and fluconazole have been compared in adults with *Candida* esophagitis in a double-blind, randomized trial (8). Eligible patients had symptoms compatible with esophagitis, endoscopic mucosal plaques, and microscopic *Candida*. They were randomized to receive caspofungin (50 mg) or fluconazole (200 mg) intravenously once a day for 7–21 days. Most of them (154/177) had HIV infection, with a median CD4 count of 30×10^6/l. Favorable response rates were achieved in 66 of the 81 patients in the caspofungin arm and in 80 of the 94 patients in the fluconazole arm; symptoms had resolved in over 50% of the patients in both groups by the fifth day of treatment. Drug-related adverse effects were reported in 41% of patients given caspofungin and 32% of those given fluconazole; the most common events in both groups were phlebitis, headache, fever, nausea, diarrhea, abdominal pain, and rashes. Drug-related laboratory abnormalities developed in 29% of patients given caspofungin and in 34% of those given fluconazole. The most frequent laboratory abnormalities included reduced white blood cell count, hemoglobin concentration, and serum albumin concentration, and increased alkaline phosphatase and transaminases. No patient given caspofungin developed a serious drug-related adverse effect; therapy was withdrawn in only one patient (who was receiving fluconazole), because of an unspecified adverse effect.

Drug–Drug Interactions

Amphotericin

There were no pharmacokinetic interactions of caspofungin with amphotericin deoxycholate in healthy volunteers (5).

Antifungal azoles

In rats, caspofungin did not alter the plasma pharmacokinetics of ketoconazole, a potent inhibitor of CYP3A4 (5). Co-administration of caspofungin 50 mg/day and itraconazole 200 mg/day to healthy subjects for 14 days did not alter the pharmacokinetics of either drug (15).

Ciclosporin

Ciclosporin increased the AUC of caspofungin by about 35%, but caspofungin did not increase the plasma concentrations of ciclosporin. Because of transient rises in hepatic transaminases not exceeding 2–3 times the upper limit of the reference range in single-dose interaction studies, concomitant use of caspofungin with ciclosporin should be undertaken with care (5), although limited experience in patients studied by the manufacturers suggests that it may be safe.

Enzyme inducers

Regression analysis of pharmacokinetic data from patients has suggested that co-administration of caspofungin with inducers of drug metabolism and mixed inducer/inhibitors, namely carbamazepine,

© 2006 Elsevier B.V. All rights reserved.

dexamethasone, efavirenz, nelfinavir, nevirapine, phenytoin, and rifampicin, can cause clinically important reductions in caspofungin concentrations. However, no data are currently available from formal interaction studies, and it is not known which clearance mechanisms of caspofungin are inducible. The manufacturer currently recommends considering an increase in the daily dose of caspofungin to 70 mg in patients who are taking these drugs concurrently and who are not responding (5).

Indinavir

In rats, caspofungin did not alter the plasma pharmacokinetics of indinavir, a substrate and competitive inhibitor of CYP3A2 (5).

Tacrolimus

While tacrolimus had no effect on the plasma pharmacokinetics of caspofungin, chronic caspofungin reduced the AUC of tacrolimus by about 20% (5).

Edetic acid and its salts

General Information

Edetic acid is a metal chelator. The effect of an intravenous dose of 1 g of calcium disodium edetate on the urinary excretion on the elements aluminium, boron, barium, calcium, copper, iron, lead, magnesium, manganese, phosphorus, potassium, silicon, sodium, strontium, sulphur, and zinc was measured in healthy volunteers. The ratio of the increase of urinary elimination was about two for iron, five for aluminium, lead, and manganese, and 15 for zinc (1).

Salts of edetic acid are still used in intravenous "chelation therapy" as an alternative treatment for atherosclerotic disease in several countries (SEDA-10, 225) (2–7). Many of the data on their adverse effects are derived from older studies. There is some evidence of efficacy, although the dangers are obvious (SED-14, 722) (8,9).

Urea edetate (with methylhexyl ether) has been used for the dissolution of calcified gallbladder stones, without adverse effects (10).

Adverse effects of disodium edetate include hypocalcemia, tetany, convulsions, cardiac dysrhythmias, respiratory arrest, and renal insufficiency. Other possible symptoms include nausea, vomiting, diarrhea, fever, headache, and urinary urgency. Pain and phlebitis at the site of injection can occur (11). The sodium load in "chelation therapy" can precipitate heart failure. Renal tubular necrosis can occur (2).

© 2006 Elsevier B.V. All rights reserved.

Sodium calcium edetate can cause the same adverse effects as the disodium salt, with the exception of hypocalcemia.

In children receiving disodium ethylenediaminetetraacetate by intravenous infusion, an influenza-like syndrome developed, characterized by lacrimation, rhinorrhea, sneezing, and cough (12). Other symptoms included malaise, fatigue, nausea, and vomiting; one patient had a fever of 39.2°C.

Five patients became ill shortly after chelation therapy at an out-patients clinic, where they had received an infusion of Na_2EDTA 3 g, MgCl 2 g, vitamin B_1 100 mg, vitamin B complex 1 ml, and vitamin C 15 g in sterile water at a rate of 180 ml/hour (13). One patient also received 10 ml of 50% dimethylsulfoxide. All initially had gastrointestinal and musculoskeletal symptoms (trembling, muscle spasms) and complained of dry mouth or excessive thirst. All had fever and hypotension, four had tachycardia and sweating. Laboratory data were collected in four patients, all of whom had varying degrees of thrombocytopenia, leukopenia, and lymphocytopenia, reflecting transient bone marrow suppression. Subsequent measurements showed leukocytosis with early cell forms. Urinalysis showed transient proteinuria (in four), microscopic hematuria (in three), hyaline casts (in two), and ketonuria (in four). Three had mild transient rises in serum urea and creatinine concentrations. Three had hypocalcemia, requiring supplementation in one (probably accounting for the muscular symptoms). In these patients, acute edetate toxicity appeared to be related to errors in dosage or the rate at which the formulation was administered.

Organs and Systems

Respiratory

Additives to drug for inhalation, such as disodium edetate or benzalkonium chloride, can cause bronchoconstriction (14). This can lead to reduced therapeutic effectiveness of bronchodilators, for example salbutamol or ipratropium. Some products do and others do not contain these additives and an unexpected reduction in response to a bronchodilator may be the result of a casual change of product.

- In one case, paradoxical bronchoconstriction and laryngospasm necessitated emergency admission after the use of salbutamol in a metered-dose inhaler, which also contained edetate disodium as a preservative (15). Although there was prompt relapse on re-exposure, there were no positive findings demonstrating the role of edetate disodium.

Sensory systems

In two patients with atypical band keratopathy, the combined use of the preservatives sodium edetate, boric acid, and benzalkonium chloride in eye-drops for glaucoma treatment was identified as the cause (16).

Metal metabolism

Salts of edetic acid have been reported to cause symptomatic zinc deficiency, with abnormalities of the skin, including crusted lesions of the mouth and eyelids, leukokeratosis of the tongue, stomatitis, and a papular, pustular, erosive rash of the face and perianally, alopecia, and white bands on the nails (17,18).

Hematologic

For pseudothrombocytopenia, pseudoneutropenia, and pseudoleukocytosis caused by the use of edetic acid as an in vitro anticoagulant, see the section on "Interference with diagnostic tests" in this monograph.

Urinary tract

Intravenous administration of disodium edetate can cause renal insufficiency and acute tubular necrosis (2). In children with subclinical lead poisoning, the administration of sodium calcium edetate and dimercaprol together was associated with mild and transient biochemical evidence of renal damage in 13% of patients, whereas another 3% had acute renal insufficiency (19).

Edetate-induced renal damage is associated with vacuolization of the proximal tubules, loss of the brush border, and eventually degeneration of the proximal tubular cells. A possible mechanism underlying this renal toxicity is an interaction between edetate and endogenous metals in the proximal tubule (13).

Skin

Disodium edetate can cause contact dermatitis, for instance when used in local anesthetics (20).

Immunologic

Derivatives of edetic acid are allergenic and can cause allergic reactions, with rashes, fever, edema, and arthralgia. There can be cross-allergy to ethylenediamine, which is a constituent of various drug formulations (for example aminophylline, some ointments) (SED-8, 538). In addition, disodium edetate is found in small amounts in certain drugs, as a result of the removal of trace quantities of heavy metals. However, ethylenediaminetetraacetate was administered for lead poisoning without ill effects to a child with a proven allergy to ethylenediamine hydrochloride (21).

Second-Generation Effects

Teratogenicity

Salts of edetic acid are teratogenic in animals, probably by causing zinc deficiency (22,23). However, there is no evidence of teratogenicity in humans.

Drug–Drug Interactions

Phenylmercuric preservatives

The activity of phenylmercuric preservatives can be reduced by interaction with disodium edetate (24).

© 2006 Elsevier B.V. All rights reserved.

Warfarin

Reduced anticoagulation has been reported in a patient taking warfarin when he was given chelation therapy (25).

- A 64-year-old man with coronary artery disease taking atenolol, lisinopril, atorvastatin, glyceryl trinitrate, triamterene, hydrochlorothiazide, omeprazole, nizatidine, enteric-coated aspirin, and a liquid multivitamin formulation containing spinach and broccoli extracts was given warfarin for bilateral pulmonary embolism. About 3 weeks later he received chelation therapy with a cocktail including sodium edetate 3 g and heparin 2500 units. The next day his INR had fallen from 2.6 to 1.6. He denied having missed a dose of warfarin, having taken other drugs, or having made dietary changes. The dose of warfarin was increased and the INR reached the target range.

The authors did not propose a mechanism for this interaction, although the rapidity of the effect suggests protein binding displacement of warfarin; nor did they comment on the possible role of the extract of broccoli, which contains vitamin K.

Interference with Diagnostic Tests

Cell counters

A major unwanted effect of edetic acid, related to its use as an in vitro anticoagulant in blood samples, is the phenomenon of pseudothrombocytopenia by interference with electronic cell counters, which occurs in 0.1–2.0% of blood samples (26–36). It is assumed that about 15–30 minutes after collecting blood, edetic acid, presumably by extraction of calcium, causes changes in the platelet membrane, exposing a hidden glycoprotein antigen (28). An already circulating immunoglobulin — mostly IgG, but sometimes IgM or IgA — behaves as a drug-dependent antibody and reacts with glycoproteins in the cell membrane, resulting in the agglutination of platelets and falsely low platelet counts (26,30,35). It is more frequent in hospital patients with significant concurrent illnesses, suggesting that the antibody involved is acquired. A variety of disorders, including viral infections, neoplastic diseases, autoimmune disorders, liver disease, trauma, atherosclerosis, and thrombotic disorders, are thought to be risk factors (26). Sometimes the use of a medicine, for example mexiletine (37), is involved in the development of edetic acid-induced pseudothrombocytopenia. Pseudothrombocytopenia is more likely to occur when there is a delay between taking and testing the blood samples. The agglutinin crosses the placenta and can cause transient pseudothrombocytopenia in neonatal blood samples (26).

The clinical importance of edetic acid as a cause of pseudothrombocytopenia can be illustrated by the following findings. In a retrospective study, 15% of patients thought to have true thrombocytopenia were found to be cases of edetic acid-induced pseudothrombocytopenia (28). In another study, there were eight cases of pseudothrombocytopenia, compared with only three patients with Werlhof's disease (idiopathic thrombocytopenic purpura) during the same period (26). Among pregnant women with isolated thrombocytopenia, 7% had edetic acid-mediated pseudothrombocytopenia (38). Although it is rarer, pseudothrombocytopenia can also occur in connection with other anticoagulants, such as citrate or heparin. Sometimes different anticoagulants cause pseudothrombocytopenia in one and the same patient (26). Moreover, similar antibodies can occur that are not edetate dependent (39). Obviously, pseudothrombocytopenia deserves a place in the differential diagnosis of thrombocytopenia.

Failure to recognize pseudothrombocytopenia can lead to diagnostic errors, unnecessary invasive procedures (for example bone marrow puncture), delayed surgery, and wrong treatments (for example unnecessary withdrawal of wrongly suspected drugs, unnecessary transfusions, the use of potentially harmful drugs, splenectomy). Confusion can arise when pseudothrombocytopenia develops during hospitalization, especially in patients with pre-existing or expected (true) thrombocytopenia.

Artefactual pseudothrombocytopenia is typically an error of automated cell counters. When platelet clumps are mistaken for leukocytes this can result in pseudoleukocytosis (30,36). Edetic acid can also cause agglutination of granulocytes, and confusing findings such as combined pseudothrombocytopenia, pseudoneutropenia, and pseudolymphocytosis can occur (28).

Whenever pseudothrombocytopenia is suspected, for example in the case of unexpected thrombocytopenia without signs of bleeding, the diagnosis can be confirmed by finding normal platelet counts immediately after drawing the blood specimen or by examination of a blood smear. When serial counts are made, the number of platelets falls linearly with time. Pseudothrombocytopenia is usually associated with a normal mean platelet volume, whereas true thrombocytopenia is associated with a reduced mean platelet volume (28).

A case report from Germany has underlined the clinical importance of early recognition of edetate-induced pseudothrombocytopenia (SEDA-21, 250) (40). In this case, artefactual thrombocytopenia led to a bone marrow puncture and treatment with high doses of glucocorticoids, with severe Cushing's syndrome as a result. In such patients, concomitant bleeding disorders (without true thrombocytopenia), for example menorrhagia due to an intrauterine contraceptive device, can add to the confusion.

Edrecolomab

See also Monoclonal antibodies

General Information

Edrecolomab (17-1A antibody), a mouse monoclonal antibody, has been used in the adjuvant treatment of colorectal cancer.

Organs and Systems

Immunologic

Severe exacerbation of Wegener's granulomatosis with multiorgan involvement has been reported after the first infusion of edrecolomab (500 mg over 2 hours) in a 64-year-old man (1).

© 2006 Elsevier B.V. All rights reserved.

Hypersensitivity and anaphylactic reactions have been noted, and urticaria prolonged over a 4-month period was reported in one patient (2).

Efavirenz

See also Non-nucleoside reverse transcriptase inhibitors (NNRTIs)

General Information

Efavirenz is a non-nucleoside reverse transcriptase inhibitor with excellent inhibitory activity against HIV-1. Its most frequent adverse effects involve the central nervous system and the skin (1). At the start of therapy, dizziness, insomnia, or fatigue is observed in most patients, and headache and even psychotic reactions have also been observed. A maculopapular rash is seen in about 10%. These adverse effects usually vanish within the first 2–4 weeks of therapy (2). About 1–2% of individuals stop taking efavirenz because of neurological or dermatological adverse events. Administration of efavirenz at bedtime reduces the incidence of severe adverse effects, and the rash can be managed by short-term antihistamines or topical corticosteroids (1). Nausea and vomiting are less often observed than in patients treated with zidovudine, lamivudine, or indinavir.

There is other evidence that efavirenz is in some respects better tolerated than certain of the alternatives used in HIV infection. However, comparisons are difficult, since efavirenz will generally be used with drugs of other types in order to avoid the rapid development of resistance. Combined efavirenz with nucleoside analogues reduces toxicity (3). Efavirenz-induced adverse effects often begin on the first day of therapy and resolve within 14–28 (median 13) days (4).

Because efavirenz is metabolized by cytochrome P450, several clinically significant interactions have been described. Efavirenz induces CYP3A4 (5); there was 55% mean induction at a dose of 400 mg/day and 33% at 200 mg/day. However, no significant interaction was noted with co-administration of nelfinavir, zidovudine, lamivudine, fluconazole, or azithromycin (2).

Observational studies

In 77 HIV-positive subjects randomized to switch from protease inhibitors to nevirapine or efavirenz or to continue taking protease inhibitors, quality of life significantly improved among those who switched (6). In those who took efavirenz there was an increase in gamma-glutamyltransferase activity and three patients interrupted treatment because of central nervous system symptoms. Eight patients withdrew because of adverse events: rashes ($n = 3$), dizziness ($n = 2$), irritability and depression ($n = 1$), depression ($n = 1$), or hepatotoxicity ($n = 1$).

Comparative studies

In an open comparison of efavirenz and indinavir (plus two nucleoside analogues) in predominantly treatment-naive patients efavirenz-based triple therapy provided at least similar antiviral effects over 48 weeks (7). Furthermore, fewer patients discontinued efavirenz-based triple therapy than indinavir-based therapy because of adverse events. Adverse effects associated with efavirenz included a maculopapular rash and central nervous system disturbances (dizziness, vivid dreams, poor concentration, sleep disturbances), which generally occurred (but later resolved) within the first weeks of therapy.

Organs and Systems

Nervous system

In a randomized comparison of an efavirenz-containing regimen and a protease inhibitor-containing regimen, nervous system adverse effects were specifically sought (8). Patients were randomized to two NRTIs plus efavirenz ($n = 51$) or two NRTIs plus one or more protease inhibitors ($n = 49$). The patients who took efavirenz reported the following at week 4: dizziness (66%), abnormal dreaming (48%), light-headedness (37%), and difficulty in sleeping (35%). At week 24, dizziness (13%), abnormal dreaming (18%), light-headedness (13%), difficulty in sleeping (7%), and nervousness (13%) were significantly less common. Irritability, abnormal dreaming, and nervousness persisted at week 48 in 13%, 10%, and 8% respectively.

Psychological, psychiatric

Efavirenz has been associated with psychiatric problems, such as anxiety, depression, and confusion (9,10). In a retrospective study of 1897 patients, dementia and depression were significantly associated with efavirenz compared with other drugs; the respective odds ratios were 4.0 (95% CI = 1.2, 14) and 1.7 (1.0, 3.0) (11). However, those who were given efavirenz were perhaps more ill than those who were not, judging by CD4 counts and opportunistic infections.

Most clinicians tend to avoid efavirenz in patients with a psychiatric history. However, it is important to remember that efavirenz can precipitate sudden and severe psychiatric symptoms in patients with no such history. Three patients developed sudden irritability; excitability with anxiety; and insomnia, confusion, and amnesia (12).

The psychiatric adverse effects of efavirenz correlate with its plasma concentrations. In 130 HIV-infected patients, toxicity was three times more common in patients who had an efavirenz concentration over 4000 ng/ml (13).

Metabolism

In a randomized, double blind study of 327 patients, cholesterol and triglycerides were raised in patients taking

© 2006 Elsevier B.V. All rights reserved.

efavirenz, although this did not reach statistical significance (4).

Liver

In a prospective study of the incidence of severe hepatotoxicity among 312 patients taking efavirenz, hepatitis C and hepatitis B viruses were detected in 7.7% of the patients (14). There was severe hepatotoxicity in 8.0%, but only 50% of the episodes were detected during the first 12 weeks of therapy. The risk was significantly greater among those with chronic viral hepatitis (69% of cases) and those taking concurrent protease inhibitors (82% of cases). However, 84% of patients with chronic hepatitis C or hepatitis B did not have severe hepatotoxicity.

Skin

Efavirenz has been associated with UV photosensitivity, which recurred after skin challenge with efavirenz powder (15).

Reproductive system

Gynecomastia and breast hypertrophy have been reported in at least three patients. All had had indinavir replaced by efavirenz. No other medications were changed, and gynecomastia was not present before substitution (16). The breast enlargement was generally asymmetrical and painful. Needle biopsy was consistent with gynecomastia. Six other reports have confirmed painful breast hypertrophy in patients taking efavirenz (17).

However, gynecomastia has also been reported in 15 patients taking a variety of antiretroviral drugs (18). The authors suggested that it was due to increased cytokine concentrations following immune restoration and this adverse effect may therefore not be unique to efavirenz among drugs used to treat HIV infection.

Immunologic

The incidence of allergic reactions to efavirenz is 10–34%. They usually cause an erythematous maculopapular rash, with or without fever, 1–3 weeks after the start of therapy. Desensitization has been reported (19).

- A 37-year-old HIV-positive white man was given efavirenz, amprenavir, stavudine, lamivudine, and didanosine after failure of a previous regimen. After 8 days he developed a generalized pruritic rash and all the drugs were withdrawn. Two weeks later he was given efavirenz, stavudine, didanosine, lamivudine, and lopinavir, but developed red itchy skin within a day. All the drugs were withdrawn. He was then successfully restarted on stavudine, didanosine, lamivudine, lopinavir, and amprenavir. Desensitization to efavirenz was undertaken, but on day 12 he again developed a rash on the trunk and limbs, which was treated with a topical steroid and diphenhydramine 45 minutes before each dose of efavirenz. The desensitization protocol was continued for another 4 days, and 16 months later he was taking full-dose efavirenz in combination with the other antiretroviral drugs.

Efavirenz can cause an allergic syndrome called the DRESS syndrome (Drug Rash with Eosinophilia and Systemic Symptoms). It is a life-threatening reaction that typically includes a rash, fever, lymphadenopathy, hepatitis, interstitial nephritis, pneumonia, myocarditis, and hematological abnormalities, particularly eosinophilia and a mononucleosis-like atypical lymphocytosis. The DRESS syndrome has been described in an HIV-infected woman taking efavirenz (20).

- A 44-year-old HIV-1 infected woman from the Ivory Coast, who was taking stavudine, lamivudine, efavirenz, and pyrimethamine plus sulfadiazine for *Toxoplasma* encephalitis, developed a maculopapular rash on both arms. The sulfadiazine was withdrawn and clindamycin was added. Ten days later her condition had worsened. Her temperature was 40°C, pulse rate 137/minute, and respiratory rate 26/minute. She had a generalized maculopapular rash without mucosal involvement, moderate abdominal tenderness, hepatomegaly, jaundice, and bilateral crackles. Her white cell count was 16×10^9/l with 9% eosinophils and 51% lymphocytes. A chest X-ray showed moderate bilateral interstitial pneumonitis. All drugs were withdrawn and she was given intravenous methylprednisolone. The skin rash and all systemic manifestations resolved within 1 week and HIV treatment was restarted uneventfully with lamivudine, stavudine, and nelfinavir.

Although this syndrome has been described with sulfonamides (which the patient had taken), the fact that her condition worsened after withdrawal of sulfadiazine, and the characteristic timing of the syndrome (2–6 weeks after starting a drug), suggested efavirenz as the cause.

- In a 39-year-old man efavirenz caused a confluent maculopapular rash, and pulmonary interstitial infiltrates without lymphadenopathy (21). The symptoms resolved when efavirenz was withdrawn while other antiretroviral drugs were continued. The patient was rechallenged, and the rash and fever reappeared; however, recurrence of the pulmonary infiltrates was not addressed.

A leukocytoclastic vasculitis has been attributed to efavirenz (22).

- A 44-year-old man, having taken various antiretroviral drugs, started to take efavirenz; 5 days later he developed palpable purpura on both legs, with pruritus. His white cell count was 14.4×10^9/l and a skin biopsy showed a leukocytoclastic vasculitis. Efavirenz was withdrawn and he was given prednisolone for 3 days; the lesions disappeared, leaving only minimal hyperpigmentation.

Second-Generation Effects

Teratogenicity

- A boy, born at full term to a woman who had taken efavirenz, stavudine, and zidovudine before pregnancy and for the first 24 weeks, had a myelomeningocele (23). The baby was HIV-positive.

The authors suggested that the efavirenz had been responsible, based on previous studies in monkeys.

Drug–Drug Interactions

Ciclosporin

Efavirenz causes increased requirements of ciclosporin by inducing CYP3A4.

- A 39-year-old man took ciclosporin 200 mg bd after a kidney transplant (24). The blood ciclosporin concentration was 307 ng/ml. The co-administration of prednisone caused the blood ciclosporin concentration to rise to 372 ng/ml, but it fell to 203 ng/ml when the dose was reduced to 175 mg bd. Efavirenz 600 mg/day, zidovudine 300 mg bd, and lamivudine 150 mg bd were added, and 7 days later the blood ciclosporin concentration fell to 80 ng/ml and later to 50 ng/ml.

HIV protease inhibitors

The effect of multiple-dose efavirenz 600 mg/day on the steady-state pharmacokinetics of the combination of indinavir (800 mg) + low-dose ritonavir (100 mg) bd, in which ritonavir is used to increase indinavir plasma concentrations, has been investigated in 14 healthy men (25). Efavirenz significantly reduced indinavir AUC (25%), C_{max} (17%), and C_{min} (50%). Ritonavir AUC, C_{max}, and C_{min} were reduced by 36%, 34%, and 39% respectively. The authors proposed that efavirenz had induced the activity of CYP3A and concluded that the dose of indinavir or ritonavir may need to be increased to maintain similar indinavir drug concentrations after the addition of efavirenz.

Indinavir

Increased dosage of indinavir is recommended if efavirenz is co-administered (25).

Methadone

Following a report of withdrawal symptoms in three patients taking methadone maintenance therapy, serum methadone concentrations were measured before and after starting efavirenz in one patient (26). Serum methadone concentrations were as follows: (*R*)-methadone (the active enantiomer) 168 ng/ml and 90 ng/ml before and after efavirenz. The corresponding (*S*)-methadone concentrations were 100 and 28 ng/ml. The dosage of methadone was increased from 100 to 180 mg/day before the patient's withdrawal symptoms resolved.

- Three patients taking methadone were given efavirenz-containing regimens and started to complain of opioid withdrawal symptoms 3–7 days later (27). In one case the plasma methadone concentration fell from about 170 ng/ml to about 50 ng/ml over 6 days.

Since methadone is partly metabolized by CYP3A4, the interaction of efavirenz with methadone has been investigated prospectively in 11 patients taking stable methadone maintenance therapy (28). Efavirenz reduced the steady-state methadone AUC by 50%. However, patients generally only needed a 22% increase in their methadone dose to eliminate the symptoms of methadone withdrawal, and the full basis of the interaction is not understood.

Rifamycins

Rifampicin induces the metabolism of efavirenz. In 24 patients (21 men, 3 women; mean age 37 years) with HIV infection and tuberculosis the C_{max}, C_{min}, and AUC of efavirenz interval fell by 24%, 25%, and 22% respectively in the presence of rifampicin (29).

Eflornithine

General Information

Eflornithine is a specific irreversible inhibitor of ornithine decarboxylase, the enzyme involved in the first step of mammalian polyamine biosynthesis (1). Decarboxylation of ornithine is an obligatory and rate-limiting step in the biosynthesis of polyamines, such as putrescine, spermidine, and spermine. These low molecular weight polyamines play an essential role in the growth, differentiation, and replication of the cell by participating in nucleic acid and protein synthesis, and are needed in the process of decoding genetic messages. In vitro studies of different types of cell lines (including human malignant cells) exposed to eflornithine demonstrated inhibition of growth. Eflornithine added to human erythrocytes infected with *Plasmodium falciparum* reduced parasite growth and intracellular polyamine content. Polyamines play an important role in the cellular metabolism of trypanosomatids (SED-12, 708) (2,3). Eflornithine can arrest viral replication.

Eflornithine hydrochloride can be given intravenously and orally. Absorption after oral administration is adequate. After intravenous administration, 80% is excreted unchanged in the urine within 14 hours. It penetrates the nervous system, and cerebrospinal fluid concentrations are 10–45% of serum concentrations.

Eflornithine has been used in the chemotherapy and chemoprevention of some tumors, including glioblastoma and colorectal carcinoma in the presence of polyposis coli (4). It has been used in the treatment of malaria tropica, in AIDS, and in *Pneumocystis jiroveci* infections, with varied success. It has also been approved for use in *Trypanosoma gambiense* (SED-12, 708) (5,6).

The most important adverse effect of eflornithine is a natural consequence of its mode of action, myelosuppression, which is frequent and sometimes treatment-limiting. Gastrointestinal toxicity is also common, and is more marked with oral administration. Seizures, hearing loss, alterations in liver function tests, and rash have been described in the treatment of *P. jiroveci* infections in patients with AIDS (SED-13, 835). In 31 patients with AIDS and *P. jiroveci* pneumonia, intolerant of and/or unresponsive to co-trimoxazole or pentamidine, about 50% reacted favorably to eflornithine. The adverse effects were no different from those seen in patients without AIDS, but the frequency of adverse effects was higher. The most common effects in this group were myelosuppression, thrombocytopenia being the most serious, with hepatitis (3%) and hearing loss (9%) among the others (SEDA-17, 332).

Eflornithine in trypanosomiasis

Melarsoprol (an arsenical compound) is still the most effective compound against stage II (nervous system) disease in both East and West African trypanosomiasis. However, it is toxic and causes death in about 2–8% of subjects treated. Eflornithine is an alternative to melarsoprol for West African trypanosomiasis (both early and late). However, it is very expensive, and its usefulness in endemic areas may therefore be limited. The standard regimen is 100 mg/kg intravenously 6-hourly for 14 days.

There have been some anecdotal reports that a shorter 7-day course may be equally effective, with obvious cost-saving advantages.

There has been a multicenter, randomized, open comparison of treatment with eflornithine for 7 or 14 days ($n = 321$) (7). The subjects were divided into new cases and relapses. The 14-day course of eflornithine was superior to the 7-day course for the new cases, but there was no difference in the relapsing cases. However, the numbers of patients who relapsed were small ($n = 47$) and this may not have allowed the detection of a small difference between the groups. The most common adverse events associated with eflornithine were convulsions, altered consciousness, diarrhea, vomiting, nausea, abdominal pain, and secondary infections. Diarrhea and secondary infection were more common in subjects who took the 14-day course.

In 42 patients with late-stage *Trypanosoma brucei gambiense* trypanosomiasis, who relapsed after initial treatment with melarsoprol, a sequential combination of intravenous eflornithine (100 mg/kg every 6 hours for 4 days) followed by three daily injections of melarsoprol (3.6 mg/kg, up to 180 mg) was used (8). They were followed for 24 months. In one case, the administration of eflornithine had to be interrupted for 48 hours because of convulsions, but treatment was then resumed without recurrence. Other adverse effects during treatment were abdominal pain or vomiting ($n = 4$ each), diarrhea ($n = 1$), and loss of hearing ($n = 1$). Two patients died during treatment:

- A 37-year-old man died of an acute cholera-like syndrome, with severe diarrhea, vomiting, and dehydration, after the last dose of eflornithine but before receiving his first dose of melarsoprol.
- A 34-year-old man died of an unknown cause after having received all 16 doses of eflornithine as well as the first injection of melarsoprol.

Organs and Systems

Nervous system

The frequency of seizures in patients with trypanosomiasis taking eflornithine is about 7% (SEDA-16, 316) (9).

Sensory systems

Hearing loss is the dose-limiting toxic effect for eflornithine in patients taking over 2 g/m^2/day (10) (SEDA-11, 394). In one study, it was found in 48% of patients. In some cases the hearing loss was characterized audiographically as bilateral, sensorineural, primarily high frequency, with a median loss of 25–30 dB. All patients recovered within 1–3 months of withdrawal of therapy. There was no clear association between the total dose of eflornithine and the degree of hearing loss (11). Tinnitus has been reported in some patients taking eflornithine (12).

Hearing loss due to eflornithine is usually reversible, but irreversible hearing loss has also been described.

- A patient in a Barrett's esophagus chemoprevention trial developed a hearing deficit of 15 dB at frequencies of 250, 2000, and 3000 Hz in the right ear and a deficit of 20 dB or more at 4000–6000 Hz in the left ear after taking eflornithine 0.5 g/m^2/day for about 13 weeks (cumulative dose 45 g/m^2); clinical hearing was not affected, but the threshold shifts persisted 7 months after eflornithine was withdrawn (13).

In a placebo-controlled study in 123 patients with colorectal polyps and normal hearing at frequencies of 250–2000 Hz, eflornithine 0.075–0.4 g/m^2/day for 12 months had no effect on auditory pure-tone thresholds or distortion product otoacoustic emission (14). There was no hearing loss, in contrast to studies with higher dosages.

In 58 patients with metastatic malignant melanoma, 179 sequential audiograms were obtained from patients treated with eflornithine 2–12 g/m^2/day alone ($n = 16$) or in combination with interferon alfa-2b ($n = 42$) for 2–50 weeks (15). Total doses of 60–1390 g/m^2 correlated with clinical effects and pure-tone audiometric changes at multiple frequencies (500, 1000, 2000, 4000, and 8000 Hz). Patients with normal baseline audiography had more hearing loss than those with abnormal baseline audiography at the higher frequencies. Of the patients with normal prestudy hearing thresholds 10% or less developed a demonstrable hearing deficit at cumulative doses below 150 g/m^2. Conversely, up to 75% of the patients who received more than 250 g/m^2 developed hearing loss. Other factors that adversely affected hearing included age, male sex, and the concomitant use of interferon alfa-2b.

Hematologic

Myelosuppression, as evidenced by anemia, leukopenia, and thrombocytopenia, is common in patients taking eflornithine. The manufacturers quote respective incidence rates of 55, 37, and 14%. However, other reports have suggested that thrombocytopenia is the most frequent problem; it is dose-dependent and occurred in 90% of patients with cancer on a dose of 6–8 g/m^2 with eflornithine concentrations over 400 mmol/l (SED-12, 709) (16).

- A 32-year-old Haitian man with AIDS developed complications of *Isospora belli* enteritis (17). He was given intravenous eflornithine and developed severe thrombocytopenia, nausea, and vomiting, which recurred on rechallenge with low-dose oral eflornithine.

There is an impression that patients with AIDS have a higher incidence of adverse effects. The myelosuppression is reversible on withdrawal (SED-12, 708) (SEDA-16, 316).

Gastrointestinal

Nausea, vomiting, abdominal pain, and diarrhea, mild or severe, are seen with parenteral and oral administration, but more markedly after oral administration (SED-12, 708) (18).

Hair

Alopecia has been reported in 5–10% of patients with trypanosomiasis taking eflornithine (9).

Second-Generation Effects

Teratogenicity

Animal studies have shown arrest of the growth of malignant cells and decrease in tumor size, but as one might expect, there was also an arrest of embryonic growth if eflornithine was given in the first days of pregnancy (SED-12, 708). On theoretical grounds, one would expect an effect on the development of the fast-growing embryo; whether or not this could lead to defects and/or deformities is not known.

Emedastine

See also Antihistamines

General Information

Emedastine is a potent second-generation antihistamine with proven efficacy in allergic conjunctivitis (1).

Organs and Systems

Nervous system

The potential sedative effects of single and repeated doses of emedastine 2 mg and 4 mg bd on actual driving performance have been assessed in healthy volunteers (9 men and 10 women, aged 21–45 years) (2). The study was a four-period, double-blind, crossover design, and driving performance was measured in a standardized test at 3–4 hours after administration of the morning dose on days 1, 4, and 5. Emedastine significantly impaired driving in every test at both doses and the authors concluded that the drug could constitute a traffic hazard and that its users should be warned accordingly.

Drug–Drug Interactions

Ketoconazole

In a study of the interaction of emedastine difumarate 4 mg bd with ketoconazole 200 mg bd in 12 subjects there was a moderate but statistically significant interaction; however, there was no increase in the QT_c interval during concomitant therapy (3). The authors concluded that these findings are consistent with the multiple metabolic pathways that supplement the metabolism of emedastine by different enzymatic isoforms of CYP450, and that concomitant treatment with emedastine and ketoconazole in people with normal QT intervals can be undertaken without special precautions. However, it is difficult to determine the precise cardiac risk, if any, posed by the administration of emedastine eye-drops (4).

Emepronium bromide

See also Anticholinergic drugs

General Information

Emepronium bromide is an anticholinergic drug. Doses of 200 mg tds (sometimes with a double dose in the evenings) are useful in relieving urinary frequency. It causes the expected milder anticholinergic adverse effects.

Organs and Systems

Gastrointestinal

Emepronium has repeatedly been shown to cause ulceration of the mouth and esophagus and widespread esophagitis (1–3). The buccal irritation is particularly marked if the tablets are retained in the mouth instead of being swallowed, and the problem as a whole is greater if the drug is not taken with sufficient fluid.

- Two women taking emepronium bromide developed extended ulcers of the esophageal mucosa. They had taken the tablets late in the evening with only a little fluid (4).

Drug Administration

Drug overdose

Central effects of emepronium are only serious in gross overdosage. In one case of attempted suicide with 100 tablets, there was severe confusion and derangement of breathing (due to neuromuscular paralysis) demanding mechanical ventilation (SED-12, 330).

Emorfazone

General Information

Emorfazone is a pyridazinone NSAID that was developed in Japan. Sleepiness, dry mouth, rash, and various gastrointestinal disturbances are its most important adverse effects (1).

Reference

1. Anonymous. Emorfazone. Drugs Today 1985;21:63.

Enadoline

General Information

Enadoline is an opioid agonist at OP_2 (κ) receptors and has no effects attributable to OP_3 (μ) receptor actions, such as respiratory depression. However, enadoline does not offer any benefits over other currently available opioids (1).

Reference

Enalapril

See also Angiotensin converting enzyme inhibitors

General Information

Enalapril is an ACE inhibitor used in the treatment of hypertension and heart failure and prophylactically in patients with asymptomatic left ventricular dysfunction.

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Cardiovascular

Of all studies of the effects of ACE inhibitors on mortality in acute myocardial infarction, only the CONSENSUS II trial did not show a positive effect. In this trial enalaprilat was infused within 24 hours after the onset of symptoms, followed by oral enalapril. The reasons for the negative result of CONSENSUS II remain unresolved, but hypotension linked to a poorer prognosis has been suggested as an explanation. In a small substudy of this large trial, 60 patients were investigated for residual ischemia before discharge, with exercise testing and Holter monitoring (1). Episodes of hypotension and predischarge ischemia were more common with enalapril than with placebo. The authors suggested that enalapril induced a proischemic effect in hypotension-prone patients, mediated through exacerbation of the hemodynamic response, since the initial blood pressure fall after myocardial infarction is related to residual ischemia and recurrent acute ischemic syndromes. This conclusion seems very speculative. The data were derived from a small substudy with multiple subanalyses and cannot support a cause-and-effect relation between the acute hemodynamic effect and the predischarge ischemic conditions. ACE inhibitors should still be used in acute myocardial infarction with cautious dose titration.

Neuromuscular function

Muscular weakness has been reported in a patient with mild renal impairment taking enalapril (2).

- A 78-year-old man, taking enalapril (10 mg/day), furosemide, and digoxin for cardiac failure due to ischemic heart disease, suddenly developed generalized muscle weakness. He had grade 3/5 weakness of all four limbs, his cranial nerves were intact, and there was no sensory impairment. His tendon reflexes were reduced and he had flexor plantar reflexes. The initial diagnosis was Guillain–Barré syndrome. Further investigation showed peaked T waves on his electrocardiogram, with a serum potassium of 9.4 mmol/l and a creatinine of 266 μmol/l. He was treated with glucose plus insulin, calcium gluconate, and sodium bicarbonate. Enalapril was withdrawn. His potassium concentration normalized.

Hyperkalemic muscle paralysis has been reported in renal insufficiency and trauma and in patients taking spironolactone and amiloride plus hydrochlorothiazide (co-amilozide). ACE inhibitors inhibit the release of aldosterone, reducing renal potassium loss, which can be enhanced by potassium-sparing diuretics or pre-existing renal insufficiency.

Endocrine

A single case of the syndrome of inappropriate secretion of antidiuretic hormone has been reported with enalapril (3).

Hematologic

Thrombocytopenia has been reported with enalapril in two elderly sisters (4). Both had the same HLA phenotype (B8DR3), which the authors postulated may reflect a genetic predisposition to this reaction. However, no further cases have been reported.

Enalapril-induced anemia has been reported in hemodialysis patients and in kidney transplant recipients. The anemia is usually normocytic, normochromic, and nonregenerative. Deficient bone-marrow erythropoiesis has occasionally been described. The anemia is reversible after withdrawal. Although the hypothesized mechanism of a reduction in erythropoietin blood concentrations by enalapril is controversial, in a prospective controlled study enalapril increased recombinant human erythropoietin requirements to maintain hemoglobin concentrations (5).

Enalapril-induced anemia has been reported in a child (6).

- A 7-year-old girl with segmental glomerulosclerosis and nephrotic syndrome failed to respond to prednisolone and cyclophosphamide, which were withdrawn. While her renal function was deteriorating she was given enalapril 2.5 mg bd. After 3 months, the enalapril was withdrawn because her hemoglobin fell from 12.7 to 6.2 g/dl. Ferritin, folate, and vitamin B_{12} were normal. Recovery was incomplete. Only 10 weeks after enalapril withdrawal her hemoglobin rose to 8.5 g/dl and remained unchanged thereafter.

The incomplete resolution of anemia in this case suggests that factors other than the speculated enalapril-related inhibition of erythropoietin may have contributed to the initial anemia (worsening renal function, frequent blood sampling, withdrawal of prednisolone).

An equivocal case of neutropenia has been ascribed to enalapril (7).

- A 52-year-old male renal transplant recipient on stable therapy (4.5 months) with ciclosporin, mycophenolate mofetil, and co-trimoxazole developed erythrocytosis and hypertension. His leukocyte count fell 19 days after he started to take enalapril. Enalapril was withdrawn, the dose of co-trimoxazole was halved, and the dose of mycophenolate was first reduced and then withdrawn on day 25. On day 28 the leukocyte and neutrophil counts were so low that granulocyte-stimulating factor had to be used. The leukocyte count normalized during continued treatment with ciclosporin and co-trimoxazole. CMV tests were negative.

The authors suggested a synergistic effect between enalapril and mycophenolate. As leukopenia is the commonest clinically significant adverse effect of mycophenolate, the evidence in this case is inadequate to support this hypothesis, particularly in the absence of information on mycophenolate blood concentrations.

Liver

Hepatitis has been attributed to enalapril.

- A 45-year-old man who had taken enalapril (dose not reported) for more than 2 years presented with hepatitis with negative viral serology (8). Biopsy showed necrosis and cholestasis. He recovered fully after drug withdrawal (timing not reported).
- A 46-year-old man had taken enalapril for hypertension for 3 years before he presented with jaundice and progressive liver failure (9). He was taking no other drugs and had a moderate daily consumption

© 2006 Elsevier B.V. All rights reserved.

of alcohol. All known causes of acute liver failure were excluded by careful and extensive investigation. Analysis of liver biopsies showed a pathological pattern comparable to that observed in severe halothane hepatitis. Serological studies, including T cell stimulation with enalapril and a broad spectrum of tests for autoimmunity, were negative. The hepatitis persisted despite enalapril withdrawal and finally led to orthotopic liver transplantation and subsequently to death.

The mechanism of enalapril-induced liver injury in this case was obscure. The causal relation was unconvincing.

Skin

Adult Henoch-Schönlein purpura has been attributed to enalapril (10).

- A 41-year-old man with a history of hypertension and a recent stroke was admitted 10 days after starting to take enalapril (dose not reported). He complained of severe abdominal pain, myalgia, arthralgia, paresthesia, and Raynaud's phenomenon, and had a high erythrocyte sedimentation rate, but no leukocytosis or thrombocytopenia. He developed purpura-like cutaneous lesions with acute renal insufficiency, severe hematuria, and proteinuria. Liver tests became altered. There was a polyclonal rise in IgA concentrations. Skin biopsy suggested leukocytoclastic vasculitis, with deposition of IgA and complement. Other diagnostic procedures were negative. Enalapril was withdrawn and he was given glucocorticoids, after which he fully recovered (timing not reported).

The acantholytic potential of enalapril has been shown in vitro in skin cultures and in vivo acantholysis without pemphigus has been reported.

- A 66-year-old man, who had taken enalapril 10 mg/day for 1 year, had a basal cell carcinoma removed surgically (11). Histology showed suprabasal acantholytic clefts in the perilesional epidermis. Direct immunofluorescence did not show intracellular deposits of IgG, IgA, IgM, or C3. Indirect immunofluorescence showed serum anticellular antibodies (titer 1:80). He stopped taking enalapril, and 3 months later his anticellular antibody titer was 1:320. A further biopsy of apparently healthy skin on the back showed new foci of acantholysis. Another biopsy in the same location 2 months later showed no acantholytic changes. Direct immunofluorescence was negative and the anticellular antibody titer was 1:80. HLA typing showed pemphigus-predisposing antigens (DR14, DQ1), which has previously been reported as a predisposing factor for acantholytic changes in the epidermis exposed to enalapril.

As pemphigus vulgaris has been attributed to ACE inhibitors, it is not surprising that giving an ACE inhibitor to a patient with pemphigus could worsen the disease. Aggravation of pre-existing childhood pemphigus by enalapril has been reported (12).

- A 12-year-old boy with pemphigus vulgaris was treated with intravenous dexamethasone and prednisolone. He developed severe hypertension, which was unresponsive to atenolol, and he was given enalapril 2.5 mg bd. Although the blood pressure responded, the pemphigus deteriorated markedly over the next 2 weeks. Additional dexamethasone did not produce improvement. Enalapril was replaced by amlodipine, and the disease resolved over 3 weeks.

The evidence to date suggests that ACE inhibitors should be avoided in patients with pre-existing pemphigus.

Immunologic

Eosinophilic gastroenteritis after enalapril has been described (13). The authors briefly reviewed this rare condition, which is diagnosed on the basis of the presence of gastrointestinal symptoms, eosinophilic infiltration of the gastrointestinal tract, and the absence of parasitic or extra-intestinal disease. It has also been reported after clofazimine and naproxen.

- A 63-year-old hypertensive woman, who had a carcinoma of the distal esophagus resected 19 months earlier, developed chronic diarrhea. *Clostridium difficile* toxin was identified in her stools and the diarrhea resolved after treatment with metronidazole. Enalapril was added to her antihypertensive treatment, and 3 months later the diarrhea recurred. Stool examination was negative and there was no *Clostridium difficile* toxin. Her condition worsened and she lost 5 kg in weight. She had marked eosinophilia (2.4×10^9/l), and a small bowel biopsy showed mild chronic inflammation and edema, partial villous atrophy, and large clusters of eosinophils in the lamina propria with some focal infiltration of the epithelium. She stopped taking enalapril and her diarrhea promptly abated and the eosinophil count fell to 0.5×10^9/l at 3 weeks and 0.1×10^9/l at 2 months.

Body temperature

Fever has been attributed to enalapril (14).

- A 50-year-old man with heart failure and a valve prosthesis, taking digoxin, furosemide, and spironolactone, was given enalapril 5 mg/day. Two days later, after increasing the dose to 10 mg, he developed a fever with cough and clear sputum, with a normal chest X-ray. Enalapril was withdrawn and 24 hours later the fever resolved. It recurred immediately after rechallenge.

Drug Administration

Drug overdose

A single case of overdose of enalapril has been reported (15).

Encainide

See also Antidysrhythmic drugs

General Information

Encainide is a class I antidysrhythmic drug. Reviews of its clinical pharmacology, clinical use, efficacy, and adverse effects have appeared (1–6).

Organs and Systems

Cardiovascular

In the wake of the preliminary and final reports of the Cardiac Arrhythmia Suppression Trial (CAST) (7,8), which showed that there was an increased risk of death among patients who took encainide and flecainide after myocardial infarction, there have been many publications in which the implications of these findings have been thoroughly discussed (9–13). The relative risk of death or cardiac arrest due to dysrhythmias in the treated patients was 2.6 and the relative risk due to all causes was 2.38. The risk of non-fatal cardiac adverse effects was no different in treated patients from that in those taking placebo and there was no difference between the groups in the use of other drugs.

Although there is a consensus that encainide and flecainide were associated with an increase in the rate of mortality in CAST, there are still some open questions. First, all the patients recruited to CAST had asymptomatic ventricular dysrhythmias after myocardial infarction, and it is not clear whether the results can be extrapolated to other patients. Secondly, the reasons for the increased mortality in the treated patients are not clear: ventricular dysrhythmias and worsening of left ventricular function are both possible. Thirdly, it is not clear whether the results of CAST in patients with asymptomatic ventricular dysrhythmias after myocardial infarction can also be applied to other Class I antidysrhythmic drugs.

Separate studies have confirmed the prodysrhythmic actions of encainide (14–17). The incidence of prodysrhythmias is much higher in patients being treated for ventricular dysrhythmias than in those being treated for supraventricular dysrhythmias (18).

Encainide has been reported to cause sinus node arrest in association with prolonged sinus node recovery time (19). It also raises the pacing threshold in patients with chronic implanted pacemakers (20), although this has not been reported to increase the failure rate of pacemakers.

Encainide has a negative inotropic effect on the heart and can cause hypotension (21) or worsen heart failure (22).

Nervous system

The most common non-cardiac effects of encainide are on the central nervous system, and include abnormal or blurred vision (11%), dizziness (7.3%), headaches (6.0%), nausea (4.3%), vertigo (2.3%), insomnia, and fatigue. The figures in parentheses are taken from a review of 349 patients with supraventricular dysrhythmias treated with encainide (14). These effects are common during long-term therapy, but may also occur transiently during intravenous administration and appear to be dose-related (23,24).

A case of encephalopathy has been attributed to encainide (25).

Sensory systems

There have been reports of a metallic taste in the mouth after intravenous administration of encainide (24).

Endocrine

Encainide can cause hyperglycemia (26), perhaps due to insulin resistance.

Gastrointestinal

Nausea can occur during long-term therapy with encainide, probably due to a central nervous effect (27).

© 2006 Elsevier B.V. All rights reserved.

Skin

Skin rashes have been reported occasionally during long-term therapy with encainide (27).

Musculoskeletal

There have been reports of leg cramps after intravenous administration of encainide (24).

Susceptibility Factors

Genetic factors

Encainide is metabolized, at least partly, by oxidation to *O*-desmethylencainide, 3-methoxy-*O*-desmethylencainide, *N*-desmethylencainide, and *N*,*O*-didesmethylencainide. Of 112 healthy Caucasians 9 (8%) were defective in their ability to 4-hydroxylate debrisoquine (28). The cumulative frequency distribution of the 8-hour urinary recovery ratio of encainide/*O*-desmethylencainide indicated two distinct populations, an extensive metabolizer (EM) phenotype and a poor metabolizer (PM) phenotype. There was no 3-methoxy-*O*-desmethylencainide in the urine of the poor metabolizers. As *O*-desmethylencainide is a more potent antidysrhythmic drug than encainide and 3-methoxy-*O*-desmethylencainide is at least equipotent, these metabolites contribute significantly to the overall antidysrhythmic effect in extensive metabolizers. The low plasma concentrations of *O*-desmethylencainide and 3-methoxy-*O*-desmethylencainide in poor metabolizers would be expected to result in ineffective therapy when usual doses of encainide are given. However, in such individuals, chronic oral therapy results in accumulation of unmetabolized encainide to far higher concentrations than in extensive metabolizers, and as encainide itself has antidysrhythmic activity at these concentrations, this generally results in the desired response. It is possible that poor hydroxylators are at greater risk of adverse effects than extensive hydroxylators.

In 110 healthy subjects the changes in atrioventricular (PR) and intraventricular (QRS) conduction times produced by encainide were different in extensive and poor metabolizers and correlated with CYP2D6 activity, although the electrocardiographic response was never 100% specific and sensitive for the identification of either phenotype (29). Moreover, genotypic identification of heterozygous and homozygous extensive metabolizer subjects did not predict CYP2D6 activity, as determined by encainide metabolic ratios or encainide responses, as determined by intraventricular and atrioventricular changes.

Age

Children under the age of 6 months may be more liable to the prodysrhythmic effects of encainide than older children (30).

Endothelin receptor antagonists

See also Individual agents

General Information

It is disappointing that mechanistically novel antihypertensive drugs have not emerged during the last decade or two. The only real novelty was the addition of angiotensin II receptor antagonists as a refinement of the approach introduced with ACE inhibitors. The expectations for direct renin antagonists have not been realized. Some of the cornerstone classes of antihypertensive drugs, such as the diuretics, beta-adrenoceptor antagonists, calcium channel blockers, and direct vasodilators, have been around for several decades. Advances have predominantly been made in the pharmacokinetic properties and pharmacodynamic specificities of compounds in existing antihypertensive drug classes.

With the emergence of knowledge about endothelial factors such as nitric oxide and endothelin, there was much expectation that endothelin antagonists would become useful in the management of hypertension. Endothelin was discovered in 1988 (1) and is the most potent vasoconstrictor known. In terms of pathophysiology, endothelin receptor antagonists could play a role in a variety of diseases associated with vasoconstriction, such as hypertension, renal disease, occlusive vascular disease, pulmonary hypertension, and congestive heart failure (2). Apart from vasoconstriction, endothelin is also involved in the structural changes associated with these diseases, and it is now recognized that there is a wider target in hypertension treatment than lowering blood pressure. Vascular and myocardial remodelling may be key issues in determining long-term outcome (3) and effects on myocardial fibrosis and vascular compliance may be as important as lowering blood pressure. ACE inhibitor treatment can produce regression of hypertensive myocardial fibrosis in animal models (4) and in hypertensive patients (5).

Trials of the effects of endothelin receptor antagonists in patients with heart failure, coronary artery disease, arterial hypertension, and pulmonary hypertension have been reviewed (6), as have their uses in treating cancers (7) and cerebral vasospasm (8), and their potential uses in atherosclerosis, re-stenosis, myocarditis, shock, and portal hypertension (9)

As far as hypertension is concerned, there is a substantial body of preclinical evidence of the potential efficacy of endothelin antagonists in hypertension, and this has been extensively reviewed (10). Circulating endothelin concentrations are not increased in hypertension, but it is postulated that there is an imbalance between the vasodilatory effects of nitric oxide and the vasoconstrictor effects of endothelin at a local vascular level, resulting in increased endothelin vasoconstrictor tone and endothelin-mediated end-organ damage (11,12).

Enflurane

See also General anesthetics

General Information

Enflurane is a non-explosive halogenated volatile anesthetic that was first marketed in 1966. It was developed in the search for agents safer than halothane and methoxyflurane (1). However, the list of its halothane-like adverse effects has continued to grow.

Organs and Systems

Cardiovascular

Despite conflicting results, enflurane is generally considered to have little effect on the cardiovascular system. Cardiac output was mildly influenced in healthy men and the negative inotropic effects of enflurane (2) were more pronounced in patients with congestive heart failure (3). Myocardial damage was suggested to be an unlikely complication of enflurane anesthesia, even in patients with ischemic heart disease (4).

Cardiac dysrhythmias are generally considered to be less frequent, or at least less severe, with enflurane than with halothane (5,6). However, caution in the use of adrenaline is advisable, especially in patients with cardiac disease or hyperthyroidism. Isorhythmic atrioventricular dissociation was seen in 16 of 105 patients after the use of 1.0–1.5% enflurane (7).

Respiratory

Enflurane is usually not irritant to the respiratory tract, although bronchospasm has been reported (8). However, it is generally considered to be a bronchodilator. It causes respiratory depression at concentrations over 2%.

Nervous system

Cerebral irritability is a potential consequence of enflurane anesthesia, as evidenced by electroencephalographic recordings and by reported cases of convulsions (SED-11, 208) (9). Enflurane should be used with care (although it is probably not absolutely contraindicated) in patients with epileptiform tendencies, especially if they are deeply anesthetized and hyperventilated. There are reports of delayed convulsions after light general anesthesia not involving hyperventilation. A patient had a convulsion in a car after being discharged from a day-care anesthetic involving enflurane (9).

Motor neuron disease has been attributed to enflurane (10). The authors proposed that enflurane-induced release of glutamate may have caused changes in the spinal cord motor neurons. It is not clear what role alcohol abuse had in this case.

Neuromuscular function

Enflurane increased the sensitivity of the neuromuscular junction to d-tubocurarine in man (11).

Psychological, psychiatric

There was a reduced capacity for learning and decision-making in healthy volunteers after exposure to subanesthetic concentrations of enflurane (12,13).

Endocrine

The endocrine effects of enflurane anesthesia are minimal and clinically insignificant (14).

Metabolism

The effect of enflurane on heme metabolism has been tested in mice (15); the authors suggested that enflurane be added to the list of drugs that can precipitate acute attacks of porphyria.

Liver

One of the main advantages of enflurane over halothane is a reduced rate of liver damage, although such damage can occur (about one in 800 000 exposures) (16,17). With increasing use since 1980 there has been an increasing number of reports of enflurane-induced hepatitis (SED-11, 209), some in patients previously affected by halothane (18), and with some evidence that the risk may be higher in obese middle-aged women (19); some deaths have occurred. All the same, its hepatotoxic potential, although not entirely defined, is probably low, as evidenced by prospective studies of liver function during repeated enflurane anesthesia (20). Indeed, in May 1982 the FDA decided against incorporating a warning of hepatotoxicity on the drug's American labelling, and this policy has been maintained since.

Two patients with hepatic failure after enflurane anesthesia were reported from a hepatic transplant unit in France; both died while waiting for a liver transplant (21). In common with halothane, hepatic failure after enflurane is thought to be caused by the metabolite trifluoroacetic acid.

Urinary tract

Nephrotoxicity leading to renal insufficiency, particularly after prolonged anesthesia, is a potential consequence of general anesthesia with enflurane (22). Several cases of renal insufficiency have been described (SED-11, 209) (23,24), and the mechanism studied. On experimental

© 2006 Elsevier B.V. All rights reserved.

grounds, it has been suspected that the inorganic fluoride ions to which enflurane is transformed may play a role. Despite evidence that enflurane can cause a significant reduction in maximum urinary osmolarity (tested using vasopressin administration) and in creatinine clearance in healthy volunteers (25), further investigations are warranted. Superimposition of nephrotoxic factors, for example drugs or underlying disease, should be avoided (1).

Musculoskeletal

Myoglobinuria, developing immediately after enflurane anesthesia, has been reported (26).

Second-Generation Effects

Teratogenicity

Experimental evidence is against a teratogenic role of enflurane (1).

Susceptibility Factors

Renal disease

It has been thought that patients with chronically impaired renal function might be at increased risk of nephrotoxicity due to enflurane, because of an increased fluoride load due to reduced excretion. However, this was not confirmed in 41 patients undergoing elective surgery with a stable increased preoperative serum creatinine concentration who were randomly allocated to receive sevoflurane ($n = 21$) or enflurane ($n = 20$) at a fresh gas inflow rate of 4 l/minute for maintenance of anesthesia (27). Peak serum inorganic fluoride concentrations were significantly higher after sevoflurane than after enflurane anesthesia. Laboratory measures of renal function remained stable throughout the postoperative period in both groups. No patient had permanent deterioration of pre-existing renal insufficiency and none required dialysis.

Drug–Drug Interactions

Amitriptyline

Amitriptyline may potentiate enflurane-induced cerebral irritability (19).

Enoximone

See also Phosphodiesterase type III, selective inhibitors of

General Information

Enoximone is an inhibitor of phosphodiesterase type III, and has a positive inotropic effect. Its most common adverse effects are gastrointestinal and cardiac. The gastrointestinal effects include anorexia, nausea, vomiting, and diarrhea (1,2).

Other rarely reported adverse effects include thrombocytopenia, leukocytosis, increased appetite, increased serum activity of alanine transaminase, hyperglycemia, headache, lethargy, anxiety, dyspnea, and skin rashes (2–6).

Organs and Systems

Cardiovascular

The cardiac effects of enoximone include hypotension, transient atrial fibrillation, and bradycardia (3). Ventricular tachydysrhythmias have been reported in about 4% of patients (2) and myocardial ischemia can also occur (4,7).

Musculoskeletal

Enoximone has been reported to cause increased contraction in skeletal muscle in vitro in patients with a predisposition to malignant hyperthermia (8,9).

- Vastus lateralis muscle from a 48-year-old man with rhabdomyolysis had an increased in vitro response to increasing concentrations of enoximone above 0.6 mmol/l (10). He also had a heterozygous mutation in his ryanodine receptor gene, with substitution of arginine for glycine in position 2433, a mutation that is associated with malignant hyperthermia.

Phosphodiesterase inhibitors, such as enoximone, increase the release of calcium from the sarcoplasmic reticulum by activating ryanodine receptors, and the authors suggested that this may have been the mechanism whereby enoximone precipitated rhabdomyolysis in this case.

Death

Long-term treatment with inhibitors of phosphodiesterase type III is associated with increased mortality in congestive heart failure (SEDA-17, 217).

In 102 patients taking digoxin and diuretics the addition of enoximone did not confer any therapeutic advantage and there was a significantly higher dropout rate and a significantly higher mortality rate in those taking enoximone (11).

The use of a lower dose of enoximone in 105 patients with heart failure (New York Heart Association classes 2 or 3) has been studied over 12 weeks (12). Enoximone 25–50 mg tds improved exercise capacity and reduced dyspnea. There was no evidence of a dysrhythmic effect. The rates of adverse events were similar with enoximone and placebo, and there were fewer cases of dizziness, vertigo, or hypotension in those who took enoximone. There were two deaths in the 70 patients who took enoximone compared with four of the 35 who took placebo. However, this small short-term study does not rule out the possibility that even this small dose of enoximone can cause increased mortality during long-term administration or in patients with more severe cardiac failure.

Enprofylline

General Information

Enprofylline (3-propylxanthine) is a xanthine derivative that has some actions in common with theophylline but has a negligible antagonistic effect at most adenosine receptor subtypes (1,2). Enprofylline is a more potent smooth muscle relaxant and antiasthmatic drug than theophylline but does not produce, for example diuresis, stimulant behavioral effects (restlessness and seizures) in the nervous system, gastric secretory effects, or free fatty acid release. Selectivity for the A_{2B} adenosine receptor subtype may underlie this lack of typical adverse effects associated with other theophylline-related drugs (3). Enprofylline has a short half-life (about 2 hours). The target plasma concentration is about 3 μg/ml. Its efficacy and tolerability have been briefly reported (4).

The most severe adverse effects of theophylline, namely seizures, are claimed to be absent even at high doses of enprofylline, although there are other disadvantages, such as cardiovascular effects, nausea, vomiting, and headache. Much more information is needed before claims of greater safety can be taken seriously.

The possibility of obtaining a steady-state plasma enprofylline concentration of 5 μg/ml by two constant rate infusions was examined in six asthmatic patients (5). The resulting adverse effects and bronchodilatation were compared with those obtained with theophylline at a steady-state concentration of 15 μg/ml. Headache, nausea, and vomiting became pronounced in two patients in whom the plasma enprofylline concentration was about 6 μg/ml. The authors concluded that by varying the infusion rate the plasma concentration of enprofylline can be controlled like that of theophylline, but they stressed the need for further studies of efficacy versus adverse effects.

Enprostil

See also Prostaglandins

General Information

Enprostil is a synthetic analogue of PGE_2.

Organs and Systems

Gastrointestinal

Even in doses insufficient to control ulcer symptoms, enprostil has a higher incidence of adverse effects than the H_2-receptor antagonists. In a randomized, double-blind, endoscopically controlled study, 98 patients with gastric ulcers were treated with either enprostil 70 micrograms bd or ranitidine 150 mg bd (1). The healing rates at 4, 8, and 12 weeks were similar. After ulcer healing, half the patients were followed for 1 year without treatment and the others were given enprostil 70 micrograms/day. Diarrhea was a common adverse effect of enprostil, and seven patients withdrew because of diarrhea or abdominal pain.

Entacapone

General Information

Entacapone is an inhibitor of catechol-*O*-methyltransferase, which catalyses a relatively minor pathway of dopamine metabolism. It therefore enhances the action of dopamine.

The safety of entacapone has been specifically addressed in a Finnish study in 326 patients (mean age 62 years, 217 men) taking levodopa plus a decarboxylase inhibitor (1). Two-thirds were randomized to take entacapone 200 mg/day and the remainder to take placebo. The withdrawal rate due to adverse events was 14% with entacapone compared to 11% with placebo. Dyskinesias were greatly increased in the former (29 versus 11%) and entacapone was also associated with increased incidences

© 2006 Elsevier B.V. All rights reserved.

of diarrhea (9.2 versus 1.9%), dry mouth (6.0% versus 0), and discolored urine (6.9% versus 0). However, there was no evidence of liver toxicity with entacapone.

Placebo-controlled studies

In a placebo-controlled study in Germany and Austria, 301 patients with Parkinson's disease were randomized to receive placebo or entacapone 200 mg with each dose of levodopa, together with their other usual therapy (2). The mean age was 61 years and 40% of the entacapone group and 48% of the placebo group were men; the groups were also unequal in size (197 versus 104), for reasons that were not clearly defined. Entacapone reduced the Unified Parkinson's Disease Rating Scale score, increased "on" periods, and reduced "off" periods. In the patients who took entacapone there was more frequent dyskinesia (34 versus 26%), nausea (10 versus 4.8%), and diarrhea (8.1 versus 3.8%). All of these findings are consistent with enhanced dopaminergic activity. There was no evidence of hepatotoxicity in any of the patients.

Comparative studies

In 40 patients (mean age 64 years, 22 men) who took tolcapone for 3–7 months and were given entacapone in dosages titrated to 800–2000 mg/day after a transition period of 3–6 months with co-beneldopa, the improvements in "on" and "off" times were less impressive than they had been with tolcapone and there were more adverse effects (3). One patient had diarrhea and orthostatic hypertension with both drugs, but another six patients had increased dyskinesias and hallucinations and one developed myoclonus. There was no evidence of liver toxicity with either drug. The authors pointed out that entacapone, unlike tolcapone, not only increases the half-life of levodopa but also its peak concentration, causing significantly enhanced levodopa-related adverse effects. There is therefore a paradox: entacapone appears to be safer but overall causes more adverse effects.

Organs and Systems

Nervous system

Fatigue and light-headedness or dizziness have occurred relatively frequently during oral entacapone administration in small studies (up to 60% of patients) (4). Other less frequent central nervous system effects include confusion, anxiety, syncope (related to postural hypotension), and insomnia (5,6). Mood elevation has been observed occasionally (5). The inclusion of entacapone in levodopa therapy for Parkinson's disease increases the risk of dyskinesias, possibly through enhanced brain penetration of levodopa (4,5,7). This can be adjusted by reducing the dose of levodopa.

Gastrointestinal

Gastrointestinal adverse effects have been reported in up to 50% of patients taking oral entacapone, and include epigastric pain, abdominal pain, nausea, anorexia, and loose stools or diarrhea (4–6,8). These effects have generally been mild and not dose-limiting.

Liver

Whether entacapone is hepatotoxic is debatable.

- A 76-year-old Australian woman complained of nausea, anorexia, and malaise 2 weeks after starting to take entacapone 200 mg five times a day (9). A week later her bilirubin, alanine transaminase, alkaline phosphatase, and gamma-glutamyl transpeptidase were all raised (2–8 times higher than the upper limits of the reference ranges). Clotting was normal. Over the next 3 days her liver function tests deteriorated and the entacapone was withdrawn. All the laboratory data improved within 2 days, but not all were fully normal 4 weeks later. She refused a rechallenge.

The authors noted that two other patients in the Australian adverse reactions database also appeared to have had hepatotoxicity related to entacapone. In response, representatives of the manufacturers (Novartis) strongly contested the conclusion that any of the three reported cases demonstrated entacapone-induced hepatotoxicity, and concluded that two of the three patients had cholestasis, which is unlikely to be related to entacapone, while the third had no real evidence of hepatic dysfunction (10). These arguments were in turn rebutted by the original authors, and the possible hepatotoxicity of entacapone remains a matter of debate, although there can be no doubt that it is safer than tolcapone.

Enteral nutrition

General Information

Enteral nutrition refers to any method of feeding that involves instillation of food into the gastrointestinal tract, such as normal feeding, feeding by nasogastric or nasoenteric tube, or feeding into a gastrostomy or enterostomy (for example a so-called PEG, a percutaneous endoscopic gastrostomy). Enteral nutrition should be tailored to the needs of the individual, but on average should provide about 30–40 kcal/kg/day.

Organs and Systems

Gastrointestinal

There is a risk of gastroesophageal reflux during nasogastric feeding, especially in mechanically ventilated and sedated patients (1).

- A 77-year-old man had a ruptured abdominal aortic aneurysm repaired and developed acute renal, respiratory, and heart failure. Six days postoperatively, enteral feeding was started with a standard formulation. This was well tolerated and the volume was increased to 2 l/day continuously. After 9 days, the nasogastric tube was accidentally dislodged. Reinsertion was attempted but failed owing to apparent obstruction at 25 cm. Until this, the patient had been nursed supine. Esophagoscopy showed impacted enteral feed obstructing the esophagus almost completely.

Gastroesophageal reflux during enteral nutrition is caused by a number of factors, including the presence of the nasogastric tube, the supine position, leakage from the tube at the teeth, and the administration of sucralfate. While the cause in this case was not entirely clear, it does show that mechanical obstruction of the esophagus due to reflux can occur without any obvious symptoms.

Ephedra, ephedrine, and pseudoephedrine

General Information

Ephedra consists of a mixture of different members of the Ephedraceae family (*E. sinica*, *E. equisetina*, and *E. gerardiana*). Its actions are due to the presence of ephedrine and pseudoephedrine.

Ephedrine is a sympathomimetic drug prepared from members of the *Ephedra* family, such as *Ephedra vulgaris*, also called the sea grape. It is available as ordinary pharmaceutical formulations of ephedrine, but also in herbal formulations of *Ephedra*, including a Chinese herbal medicine called Ma huang, which has been used since ancient times as a stimulant and in the treatment of asthma, and in formulations combined with caffeine. It is used to treat asthma, nasal congestion, fever, obesity, and anhidrosis. It is also abused as a recreational drug. Of 140 reports of adverse events related to *Ephedra* supplements submitted to the FDA between June 1997 and March 1999, 31% were definitely or probably causally related to *Ephedra* (1). In 47% of the cases, there were cardiovascular symptoms and in 18% central nervous system effects; 10 patients died.

Pseudoephedrine is a stereoisomer of ephedrine, in which two of three chiral centers are different.

"Herbal ecstasy" is a term used for many different herbal formulations, none of which contains ecstasy. Some of the names for these herbs (which can be sold in stores) include "The Bomb," "Reds," and "Sublime." In New Zealand analysis of "The Bomb" showed substantial amounts of ephedrine and the Ministry of Health removed it from the market. Some symptoms associated with herbal ecstasy include headache, dizziness, palpitation, tachycardia, and raised blood pressure. Thus, in countries where the term "herbal ecstasy" is commonly used, it is important that those who see patients who have taken Herbal Ecstasy should not confuse it with ecstasy, as toxicity and medical management may be quite different (2).

Ephedrine is longer-acting than adrenaline and can exert any type of adrenergic effect, including metabolic changes and dysuria. It has a somewhat smaller effect on the cardiovascular system than adrenaline but a relatively larger effect on the central nervous system; even low doses can, in sensitive patients, cause tremor, insomnia, and anxiety, and such problems are much more marked if ephedrine is given together with caffeine, as it sometimes is for appetite control (SEDA-17, 161). In children, ephedrine sometimes paradoxically induces sedation. Psychosis has resulted from excessive self-medication (3).

Both ephedrine and pseudoephedrine remain worryingly popular (4) and are widely available without prescription. Based on increasing evidence of the risks of *Ephedra* self-medication, various national regulatory authorities are currently considering recalling *Ephedra* products from over-the-counter sales. Oral doses of ephedrine 25–30 mg are often prescribed, for example for orthostatic hypotension. Lower oral doses, present in some "cold remedies" in tablet form, are unlikely to be efficacious, although they are risky where the drug is

© 2006 Elsevier B.V. All rights reserved.

contraindicated, for example in patients with cardiac disease. Ephedrine used in nasal sprays and drops can have systemic effects in the doses normally used. Such products are widely available over the counter in many countries. In Texas some 500 cases of adverse reactions were reported between 1993 and 1995 (SEDA-21, 153). Three of these cases have been highlighted because of their serious nature: one patient died from myocardial infarction, one had a series of generalized absence seizures, and a third had a fatal subarachnoid hemorrhage as the result of taking an unsuitable dose (SEDA-21, 153).

Organs and Systems

Cardiovascular

Cardiologists and pharmacologists from Boston have reviewed cases of possible cardiovascular toxicity associated with the use of Ma huang. Among over 900 cases of possible toxicity reported to the Food and Drug Administration, they identified 37 patients (23 women) in whom stroke ($n = 16$), myocardial infarction ($n = 10$), and sudden death ($n = 11$) appeared to be temporally related to consumption of Ma huang. The authors noted that in all but one of these cases the doses used were within the range recommended by the manufacturers. In the seven patients on whom autopsies were performed, coronary artery disease was found in three and cardiomyopathy in another three, with features suggesting sympathomimetic toxicity. The authors emphasized the toxicity of Ma huang in relatively young individuals—the mean age of the 37 patients was about 43 years—even though the relevant pathogenic mechanisms remain to be fully defined.

Hypertension

The cardiovascular effects, subjective effects, and abuse potential of single intranasal doses of ephedrine 5 and 10 mg have been compared with oral doses of (−)ephedrine 50 mg in 16 healthy Caucasian men with no drug/alcohol/nicotine abuse or dependence (5). Intranasal ephedrine caused an increase in blood pressure but associated orthostatic hypotension.

Pseudoephedrine is a component of some non-prescription basal decongestants given by mouth; even quite ordinary doses of such products (for example 120 mg) can cause a hypertensive reaction in sensitive subjects, such as those with a pheochromocytoma and those with at least a family history of hypertension (SEDA-17, 162).

- A 21-year-old man presented with hypertension (blood pressure 220/110 mmHg) and ventricular dysrhythmias after taking four capsules of herbal ecstasy (6). He was treated with lidocaine and sodium nitroprusside and his symptoms resolved within 9 hours.

Severe hypertension has been attributed to pseudoephedrine abuse (7).

- A 36-year-old man with hypertension taking no less than seven antihypertensive drugs had outpatient systolic pressures of over 190 mmHg. Investigations for primary causes of hypertension were negative and there was increasing suspicion of treatment noncompliance or factitious hypertension. Urine screening showed the presence of pseudoephedrine, which the patient could not explain. When he was given his normal antihypertensive drugs under close supervision his systolic blood pressure fell to 70 mmHg and his serum creatinine doubled. His blood pressure became normal when his medication was briefly suspended but he continued to deny any deliberate attempt to alter his blood pressure and discharged himself soon afterwards.

The authors concluded that this represented factitious hypertension due to pseudoephedrine, the first such case reported and a very unusual example of Munchausen's syndrome.

Cardiac dysrhythmias

Cardiac dysrhythmias have been attributed to ephedrine both in therapeutic doses (8) and when used as a drug of abuse (6).

- A 25-year-old woman became hypotensive after the administration of epidural anesthesia for an elective cesarean section. She was given intravenous ephedrine 9 mg, after which she complained of nausea. For an unexplained reason this was taken as an indication to give a further 9 mg of ephedrine. She immediately developed sinus tachycardia with atrial and multifocal ventricular extra beats, followed by short runs of ventricular tachycardia. She remained asymptomatic and recovered after about 5 minutes.

One must have some concerns about the high dose used here for a relatively modest level of hypotension with a systolic blood pressure of 100 mmHg.

- A 21-year-old Canadian man presented with severe headache, nausea and vomiting, hypertension (220/120 mmHg), and a sinus tachycardia of about 120/minute with frequent multifocal ventricular extra beats. He was treated with intravenous sodium nitroprusside and lidocaine and recovered fully within 24 hours.

The authors concluded that ephedrine was very largely responsible for the cardiovascular toxicity.

Myocardial ischemia

Myocardial infarction has been attributed to *Ephedra* (9).

- A previously healthy 19-year-old man took tablets containing a total of 24 mg of Ephedra alkaloids and 100 mg of caffeine, and 15 minutes later developed severe chest pain radiating down the left arm. An electrocardiogram showed an inferolateral myocardial infarct, confirmed by creatine kinase and troponin I measurements. He made a full recovery, and coronary angiography showed only minimal atherosclerotic disease of the left anterior descending artery.

The authors emphasized the dangers of *Ephedra*-containing over-the-counter formulations, even in fit young people.

Ephedrine is sometimes used to treat vasovagal episodes and has been reported to cause coronary artery spasm and myocardial infarction in these circumstances (10).

- Two apparently healthy women, aged 26 and 34 years, who were given spinal anesthesia for pelvic or hip surgery, both developed hypotension and bradycardia and were given intravenous ephedrine in divided doses, in

© 2006 Elsevier B.V. All rights reserved.

one case a total of 20 mg and in the other 30 mg. In both cases this resulted in ventricular tachycardia and raised troponin I concentrations and creatine kinase activity, but Q waves did not follow. Coronary angiography showed normal arteries in both cases and the women recovered, apparently fully.

The authors rightly pointed out that atropine is a safer and more appropriate intervention in circumstances such as these.

Arteritis

Arteritis has been attributed to ephedrine (11).

- A 44-year-old French woman was given intravenous ephedrine during anesthesia and developed hypertension (systolic pressure 180 mmHg) with nausea, vomiting, and progressive drowsiness. She had a history of migraine, antiphospholipid antibodies, mitral valve prolapse, and atrial fibrillation treated with propranolol. Immediately after anesthesia she developed headache, vomiting, and drowsiness. CT scanning showed frontal and parietal hemorrhagic infarcts, and cerebral angiography showed multiple segments of constriction and dilatation consistent with arteritis. She was left with residual visual and memory deficits.

This is the first case of this kind associated with ephedrine, and it seems plausible that the patient's previous history indicated a genetic predisposition to vascular disease.

Others

A form of toxic shock syndrome on more than one occasion occurred in one patient who used pseudoephedrine (SEDA-18, 158).

Nervous system

In a consecutive stroke registry since 1988, 22 patients (10 men and 12 women) had strokes associated with over-the-counter sympathomimetic drugs (12). There was intracerebral hemorrhage in 17, subarachnoid hemorrhage in four, and ischemic stroke in one. Stroke was associated with the use of pseudoephedrine (60–300 mg) in four cases.

The largest manufacturer of *Ephedra*-containing supplements is Metabolife. The firm has repeatedly insisted that it was not aware of adverse events associated with its products, and claimed that they were "absolutely safe" (13). An investigation by the US Justice Department into the truth of these statements showed that between 1997 and 2002 the company had received over 13 000 reports of suspected adverse drug reactions; they included nearly 2000 reports of significant adverse reactions.

- A 33-year-old man had a stroke while taking a herbal remedy (Thermadrene) containing *Ephedra* alkaloids and guaraná for "boosting his energy" (14). He was immediately treated with alteplase and was referred for rehabilitation 9 days later. At follow-up 5 months later he still had a minor neurological deficit.

Psychological, psychiatric

Ma huang can cause psychiatric complications, which can last several weeks. These have been reviewed in the context of two cases of psychotic reactions (15).

- A 27-year-old US Marine presented with depressed affect, irritability, and poor concentration and eventually admitted 2 years self-medication with Ma huang to improve workout performance.
- A 27-year-old US Marine developed a frank psychosis with ideas of reference and some paranoid ideation. He had been taking two preparations containing Ma huang, although the duration of use was unclear.

After discontinuing the drug both made a full recovery. The authors emphasized the importance of recognizing possible abuse of such "natural" medications, widely perceived to be harmless despite warnings and attempted restrictions by regulatory authorities. Treatment is supportive while awaiting spontaneous recovery after drug withdrawal.

Pseudoephedrine is often used by scuba divers to avoid ear barotrauma. The psychometric and cardiac effects of pseudoephedrine have been evaluated at 1 atmosphere (100 kPa, sea level) and 3 atmospheres (30 kPa, 20 m) in a double-blind, placebo-controlled, crossover study in 30 active divers in a hyperbaric chamber (16). Pseudoephedrine did not cause significant alterations in psychometric performance at 3 atmospheres.

A young child suffered from visual hallucinations caused by high doses of pseudoephedrine (17).

Endocrine

One patient with Graves' disease who used pseudoephedrine developed a thyroid storm, suggesting that hyperthyroidism is a susceptibility factor (18).

Gastrointestinal

The vasoconstrictor action of pseudoephedrine can predispose susceptible patients to ischemic colitis, particularly in the watershed area of the splenic flexure. Perimenopausal women may be more susceptible (19). A group from Yale have described four patients, women aged 35–50 years, who developed ischemic colitis while taking pseudoephedrine (19). Three of them had taken the drug for about 1 week, the fourth for 6 months. In all cases there was ischemic colitis affecting predominantly the splenic flexure, and there was full recovery after drug withdrawal.

- A 33-year-old man took pseudoephedrine 240 mg/day for 5 days (20). His mesenteric vasculature was normal on subsequent magnetic resonance angiography and no other abnormalities were found, leading to the presumption that the drug had caused mesenteric vasoconstriction. He made a full recovery.
- A 51-year-old woman presented for the second time in 4 months with abdominal pain (21). On this as on the previous occasion, emergency laparotomy was needed and she was found to have patchy infarction of the terminal ileum and the ascending colon. It emerged that she had been taking pseudoephedrine for 2 years, because she found that it relieved her headaches. In fact she had often noticed abdominal pain and distension, with occasional bloody diarrhea, after taking

© 2006 Elsevier B.V. All rights reserved.

pseudoephedrine. Before each of her two admissions she had been taking a remarkably high dose of 900 mg/day, and on many other occasions had taken as much as 600 mg/day. She made a good recovery and was said to have stopped taking pseudoephedrine.

The authors quoted seven other published cases of pseudoephedrine-related ischemic colitis, all occurring at much lower dosages, at most 240 mg/day.

Urinary tract

Seven patients (four men, three women, aged 21–52 years) taking large doses of over-the-counter formulations containing ephedrine and guaifenesin developed urinary stones (22). These largely contained guaifenesin metabolites, but presumably dependence on ephedrine was the reason for abuse of these formulations.

Skin

Non-pigmenting fixed drug eruptions proven by oral rechallenge have been reported with pseudoephedrine; in each of these cases the erythematous lesions spontaneously remitted without residual pigmentation (23–25).

- A 10-year-old boy given pseudoephedrine 60 mg/day developed a solitary eruption in the groin; rechallenge was positive (24).

Generalized skin reactions are even less frequent. A group of allergy specialists in Madrid have described two cases of generalized dermatitis with dissimilar histological findings in men aged 64 and 73 years (26). In one case there was severe eczema, in the other vacuolar interface dermatitis, which is rarer. Both patients had taken a proprietary formulation containing codeine and chlorphenamine as well as pseudoephedrine. Oral challenges with the former two drugs was negative in both cases, but was positive for pseudoephedrine in one patient; the other was not rechallenged, because of the severity of the original reaction.

- A hypersensitivity reaction was confirmed by patch testing in a 73-year-old woman who had taken a single (unspecified) dose of a compound formulation containing pseudoephedrine (27). This caused the memorably named baboon syndrome, a widespread symmetrical erythematous rash with papules and pustules.

Immunologic

Pseudoephedrine can cause hypersensitivity, as in three cases reported by allergy specialists from Spain (28).

- A 33-year-old man developed anaphylaxis on a second exposure to pseudoephedrine, having developed urticaria after a first exposure.
- A 24-year-old woman developed severe urticaria and fever, but no other systemic reaction, after a single dose of pseudoephedrine.
- A 67-year-old woman developed urticaria and angioedema of the eyelids after a single dose of pseudoephedrine.

In all three cases skin testing was performed; it was positive in the first two instances but not the third. The authors noted that such cases are reportedly uncommon and that cross-sensitivity is to be expected between pseudoephedrine and ephedrine.

Body temperature

Pseudoephedrine may have played a role in an episode of hyperthermia (29).

- A 21-year-old American military recruit, moderately obese, collapsed during a 3-mile run and was asystolic and hyperthermic (rectal temperature 42.2°C); he could not be resuscitated. Only 75 minutes earlier he had received vaccinations against typhoid and Japanese encephalitis and he was taking over-the-counter pseudoephedrine to promote weight loss.

The authors noted that this was only one of the factors predisposing to hyperthermia; one might also wonder whether it was wise to undertake such a run so soon after the vaccinations.

Death

Ephedra was implicated in the deaths of eight patients, and although it was pointed out that several had pre-existing conditions such as chest pain and hypertension (30), the authors justifiably responded that these were contraindications to the use of *Ephedra* in the first place, and they cast doubt on the adequacy of the warnings provided (31).

Susceptibility Factors

In patients with ischemic heart disease, ephedrine can cause myocardial infarction and potentially fatal dysrhythmias (31). Caution is needed in patients with any form of cardiac disease. At one time an attempt was made to use high doses of ephedrine for the early treatment of ventricular fibrillation, but its pharmacological effects militated against its use, since the immediate survival rate actually fell.

Thyrotoxic patients are unduly sensitive to the effects of ephedrine (SEDA-14, 179).

Drug Administration

Drug overdose

- In a suicide attempt, a 32-year-old woman took 60 tablets of a weight-loss supplement containing Ephedra (32). She was delivered to hospital comatose. Her symptoms resolved over the next 5 days without treatment. At follow-up 5 months later she was euthymic, had no suicidal ideation, and was not taking any psychotropic medications.

Drug–Drug Interactions

Amfebutamone

Acute coronary syndrome has been attributed to a combination of pseudoephedrine with amfebutamone (bupropion) (33).

- A 21-year-old man developed acute myocardial ischemia. Smoking was the only risk factor for coronary artery disease and he denied using cocaine. Angiography

© 2006 Elsevier B.V. All rights reserved.

showed normal coronary arteries. He had recently started to take amfebutamone for smoking cessation and pseudoephedrine as a non-prescription influenza remedy.

The authors postulated that the combination of two sympathomimetics had caused acute coronary artery vasospasm. This is the first report linking amfebutamone to acute coronary syndrome, and one of a few cases associated with pseudoephedrine. It is also possible that erythromycin, which this patient was also taking, could have impaired the hepatic metabolism of amfebutamone.

Antihypertensive drugs

In patients taking antihypertensive drugs, self-medication with ephedrine-containing remedies can cause an increase in blood pressure (31).

Barbiturates

In intravenous solutions, ephedrine is physically incompatible with several barbiturates (34).

Cocaine

Chronic cocaine use sensitizes coronary arterial alpha-adrenoceptors up to agonists (SEDA-22, 154).

Dextromethorphan

Combinations of pseudoephedrine with dextromethorphan are often used in over-the-counter formulations. Although they are generally considered safe, two reports have emphasized the potential adverse effect of these cold and cough formulations (35,36).

- A 2-year-old child developed hyperirritability, psychosis, and ataxia after being overmedicated with a cough formulation containing pseudoephedrine and dextromethorphan. The child made an uneventful recovery after an observation period of 4 hours in the emergency department.
- Three adolescent girls developed acute psychoses associated with the use of similar over-the-counter formulations. They required several days of hospitalization, extensive invasive medical evaluation, and consultations with neurologists, infectious disease specialists, toxicologists, and psychiatrists. They were treated with risperidone.

It is not clear which was the primary causative drug in these cases or whether there was some degree of synergy or at least additive toxicity.

Entacapone

An interaction of ephedrine with entacapone, a specific, reversible, peripherally acting inhibitor of catechol-*O*-methyl transferase, has been reported (37).

- A 76-year-old woman with Parkinson's disease and closed-angle glaucoma was scheduled for eye surgery. She had severe choreoathetoid movements, and 3 weeks before surgery began to take entacapone 200 mg/day, in addition to her five daily doses of co-careldopa. General anesthesia was induced with intravenous propofol 80 mg and fentanyl 25 mg, and maintained with nitrous oxide–oxygen (2:1) and sevoflurane 1–1.5%. After 30 minutes her blood pressure fell from 145/85 to 85/35 mmHg. She was given an intravenous bolus of ephedrine 3 mg and her blood pressure immediately rose to 225/125 mmHg; it remained high despite an increase in the dose of sevoflurane, but was controlled by repeated doses of hydralazine 2 mg.

The effect of ephedrine, which is both a direct and indirect sympathomimetic, may have been enhanced by its not being metabolized by catechol-*O*-methyl transferase, because of the action of entacapone.

Halothane

Halothane and some other anesthetics sensitize patients to the risk of ephedrine-induced ventricular dysrhythmias and acute pulmonary edema, especially if hypoxia is present (31).

Hydrocortisone

In intravenous solutions, ephedrine is physically incompatible with hydrocortisone (34).

Monoamine oxidase inhibitors

Monoamine oxidase inhibitors can dangerously potentiate the hypertensive effects of ephedrine (38).

Propofol

An interaction of propofol with ephedrine has been described (11).

- A 44-year-old woman was given ephedrine intravenously, to manage hypotension during spinal anesthesia. She developed intracranial hypertension and focal cerebral deficits related to multiple hemorrhagic cerebral infarcts. Angiography showed reversible beading, consistent with cerebral arteritis.

Owing to the risk of tachycardia, resulting in myocardial ischemia, the combination of propofol with ephedrine in elderly patients undergoing genitourinary surgery is not recommended (39). These reports should alert physicians to the potential hazards associated with the use of ephedrine during anesthesia.

SSRIs

- A 37-year-old New Zealand woman took a total of 480 mg of pseudoephedrine in various cold remedies over 4 days (40). She had also been taking fluoxetine 20 mg/day for seasonal affective disorder. She developed rapidly swinging mood changes, alternating between laughing and crying, and was sweating and shaking violently. Although her pulse rate was only 70/minute her blood pressure was 220/130 mmHg. She recovered within 4 hours and had no recurrence of her behavioral disturbance.

Although pseudoephedrine toxicity was a possible diagnosis, the authors concluded that serotonin syndrome was more likely, from an interaction of pseudoephedrine with fluoxetine. Patients should be warned about the hazards of taking selective serotonin re-uptake blockers and then self-medicating with ephedrine or pseudoephedrine.

© 2006 Elsevier B.V. All rights reserved.

Tricyclic antidepressants

Tricyclic antidepressants inhibit the uptake of catecholamines, such as ephedrine, into sympathetic neurons and can enhance their cardiovascular effects (41).

- A 61-year-old woman taking amitriptyline 25 mg/day underwent oophorectomy for ovarian cancer under combined general and epidural lumbar anesthesia. After the administration of the local anesthetic she developed hypotension refractory to high doses of ephedrine and dopaminergic drugs. Control was achieved with noradrenaline 200 μg.

The authors suggested that even the small amounts of ephedrine present as additives in some local anesthetics can have a marked effect on the cardiovascular system.

Vaccines

Hyperthermia occurred shortly after immunization with typhoid and Japanese encephalitis vaccines in a service member using an over-the-counter formulation of pseudoephedrine (29).

- While exercising in mild weather the patient collapsed 75 minutes after vaccination. He presented with asystole, with a core temperature of 42.2°C, and there was no evidence of urticaria or angioedema.

Eplerenone

See also Diuretics

General Information

Eplerenone is a potassium-sparing diuretic. It is similar to spironolactone as an aldosterone antagonist, but has less affinity for androgen and progesterone receptors and may therefore have fewer adverse effects (1).

Eplerenone is metabolized by CYP3A4 (2) and should not be given with inhibitors of CYP3A4 because of the risk of hyperkalemia (3).

Eplerenone has been compared with spironolactone in patients with heart failure (NYHA classes II–IV). In a dose-finding study, 321 patients maintained on ACE inhibitors and diuretics, with or without digoxin, were randomized to receive eplerenone 25–100 mg/day, spironolactone 25 mg/day, or placebo (4). After 12 weeks there was no improvement in heart failure in patients taking either eplerenone or spironolactone. Increases in plasma testosterone were significantly greater in men taking spironolactone than in those taking eplerenone. However, hyperkalemia was more frequent in patients taking eplerenone 100 mg/day (12%) than in those taking spironolactone 25 mg/day (8.7%). The potency of eplerenone relative to spironolactone remains to be established in patients with heart failure.

Organs and Systems

Electrolyte balance

In the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS), the addition of eplerenone 25–50 mg/day to optimal medical therapy in patients with an acute myocardial infarction complicated by left ventricular dysfunction and heart failure significantly reduced all-cause and cardiovascular mortality (5). Patients with a serum potassium concentration over 5.0 mmol/l at baseline were excluded. The incidence of hypokalemia was significantly lower with eplerenone. However, there was serious hyperkalemia (serum potassium 6.0 mmol/l or more) in 5.5% of those who took eplerenone compared with 3.9% of those who took placebo.

Reproductive system

Eplerenone has been reported to produce less gynecomastia than spironolactone (6,7). In patients with gynecomastia from spironolactone, eplerenone can be substituted and gynecomastia status reassessed.

Drug–Drug Interactions

ACE inhibitors

Co-administration of potassium-sparing diuretics with ACE inhibitors can cause severe hyperkalemia (SED-14, 674).

NSAIDs

The interaction between potassium-sparing diuretics and NSAIDs is well documented (SED-14, 674). The major complications are deterioration of renal function and hyperkalemia. The risk associated with the non-selective COX-2 inhibitors is unknown. However, three patients had hyperkalemia (8.5, 5.4, and 5.1 mmol/l) after developing acute renal insufficiency while taking these drugs (8).

Epoprostenol

See also Prostaglandins

General Information

Epoprostenol is PGI_2 available for exogenous administration. It has become the preferred long-term treatment for patients with primary pulmonary hypertension who continue to have symptoms in spite of conventional therapy. However, tolerance, which always occurs, has made dosing uncertain. The effectiveness of epoprostenol given according to an aggressive dosing strategy for longer than 1 year has been investigated in these patients (1). The dose of epoprostenol was increased by 2.4 nanograms/kg/minute each month to the maximum tolerated dose. Adverse effects were common and included diarrhea, jaw pain, headaches, and flushing in all patients.

Organs and Systems

Respiratory

Pulmonary veno-occlusive disease is a rare form of pulmonary hypertension associated with fibrotic occlusion of the smaller pulmonary veins. Although vasodilator therapy is effective in many patients with primary pulmonary hypertension, the role of vasodilators in veno-occlusive disease is unclear, because of concerns about precipitating pulmonary edema. There have been reports of successful therapy with oral vasodilators or intravenous prostacyclin. In contrast, there has been a description of a patient who developed acute pulmonary edema and respiratory failure 15 minutes after the start of a low-dose prostacyclin infusion 2 nanograms/kg/minute, leading to death an hour later (2). This case has several important implications for the management of patients with pulmonary hypertension. Although previous reports suggested that prostacyclin may be safe in patients with pulmonary veno-occlusive disease, the experience reported here suggests that even in very low doses prostacyclin can produce acute decompensation. Thus, consideration must be given to the diagnosis of pulmonary veno-occlusive disease in all patients with suspected primary pulmonary hypertension.

Further cases of pulmonary edema have been reported during continuous intravenous epoprostenol in patients with severe pulmonary hypertension and pulmonary capillary hemangiomatosis, a rare condition characterized by proliferation of thin-walled microvessels in the alveolar walls (3). This report suggests that epoprostenol should not be used in such patients.

- A 66-year-old woman with scleroderma and severe pulmonary hypertension was given continuous intravenous epoprostenol 2 and then 4 nanograms/kg/minute (total duration 48 hours) (4). Two weeks later her dyspnea had improved, but her leg was swollen and her oxygen saturation had fallen. Her dosage of epoprostenol was increased to 5 nanograms/kg/minute. One month later she developed increasing dyspnea, a non-productive cough, severe edema of her legs, and severe hypoxemia. She had gained 5 kg in weight and there were new bibasal lung crackles. A chest X-ray showed bilateral air-space opacities and bilateral effusions. Her PaO_2 was 5.7 kPa, $PaCO_2$ 3.9 kPa, and the arterial pH 7.51. Pulmonary veno-occlusive disease was diagnosed and the infusion of epoprostenol was gradually tapered over the next 48 hours. She died 6 days later with right-sided heart failure. At autopsy, histological examination showed thickening of the alveolar septa by proliferation of dilated capillaries on both sides of the alveolar walls, consistent with pulmonary capillary hemangiomatosis.
- A 61-year-old woman developed pulmonary edema during treatment with epoprostenol for severe pulmonary hypertension associated with limited scleroderma (5). She received an infusion of epoprostenol 1 nanogram/kg/minute, and the dosage was increased by 1–2 nanograms/kg/minute every 15 minutes. At a dosage of 6 nanograms/kg/minute, her pulmonary vascular resistance had fallen by 60% and her cardiac output had increased by 55%. However, at this dosage, she became acutely dyspneic. Epoprostenol was withdrawn, she was treated with furosemide and high-flow oxygen, and her symptoms resolved. Because no other therapy was available, she agreed to restart epoprostenol therapy the next day, 1 nanogram/kg/minute, increasing by 1 nanogram/kg/minute every 24 hours to 3 nanograms/kg/minute at discharge. Over the next 6 months, the dosage of epoprostenol was gradually increased to 20 nanograms/kg/minute. She had a significant improvement in her exercise tolerance and there was no evidence of pulmonary edema. However, after about 7 months of marked clinical improvement, she developed right ventricular decompensation. Increased doses of epoprostenol were ineffective and she died. Autopsy showed severe obliterative and plexogenic pulmonary arteriopathy.

This is the first case in which epoprostenol has been successfully restarted. The authors commented that pulmonary edema during acute infusion of epoprostenol is considered a contraindication to its further use. They theorized that the pulmonary edema could have occurred secondary to the dramatic increase in pulmonary perfusion at 6 nanograms/kg/minute of epoprostenol and subsequent rapid shifts in vascular hydrostatic pressure. The slow increase in dosage during reinstitution may have averted the dramatic increase in pulmonary perfusion.

Hematologic

Patients with end-stage liver failure, portal hypertension, and associated pulmonary artery hypertension (portopulmonary hypertension) have a high mortality when undergoing liver transplantation. Successful transplantation in these patients may depend on efforts to reduce pulmonary artery pressure. To this end, some centers are using a continuous intravenous infusion of epoprostenol, which has been shown to improve symptoms, extend life span, and reduce pulmonary artery pressure in patients with primary pulmonary hypertension. There have been four cases in which treatment of portopulmonary hypertension with continuous intravenous epoprostenol was followed by the development of progressive splenomegaly, with worsening thrombocytopenia and leukopenia (6). This

© 2006 Elsevier B.V. All rights reserved.

finding may limit the usefulness of epoprostenol in portopulmonary hypertension and influence the timing of transplantation in such patients.

Eprazinone

General Information

Eprazinone hydrochloride is a cough suppressant that is also reported to have expectorant properties.

Drug Administration

Drug overdose

In a retrospective study of 199 cases of accidental or intentional acute poisoning with eprazinone, eprozinol, and zipeprol, collected at the Poison Control Center in Paris from 1975 to 1982, there were seven cases of seizures, all after ingestion of eight times the therapeutic dose. They resolved rapidly and without recurrence with symptomatic treatment (1).

Eprosartan

See also Angiotensin II receptor antagonists

General Information

Eprosartan is a non-biphenyl, non-tetrazole competitive antagonist at angiotensin II type 1 (AT_1) receptors that is chemically distinct from other angiotensin II receptor antagonists (1). It causes dual blockade of AT_1 receptors both presynaptically and postsynaptically, reducing sympathetic nerve activity significantly more than other receptor antagonists.

Organs and Systems

Respiratory

In a multicenter controlled study in patients with hypertension and a history of ACE inhibitor-induced cough, eprosartan significantly reduced the risk of cough by 88% compared with enalapril (2).

Ergot derivatives

General Information

Ergot derivatives include ergotamine tartrate (rINNM), dihydroergotamine (BAN, USAN), ergometrine (rINNM, also called ergonovine), and methylergotamine (rINNM). They are potent alpha$_1$-adrenoceptor and 5-HT receptor antagonists, and have been used to treat migraine (ergotamine, dihydroergotamine) and to stimulate uterine contraction (ergometrine, methylergotamine).

Ergotamine and dihydroergotamine

Ergotamine and dihydroergotamine have been used in preventing migraine attacks and dihydroergotamine in the treatment of hypotension (either orthostatic or caused by spinal or epidural anesthesia). When dihydroergotamine was given intravenously after coronary bypass surgery, despite increased filling pressure there was no rise in cardiac output, and despite increased cardiac work the bypass flow fell significantly. The significant decrease in regional myocardial vascular resistance found after the administration of dihydroergotamine may explain the absence of the expected increase in cardiac output and coronary bypass flow.

The combination of heparin with dihydroergotamine has been used in the prevention of thromboembolic complications. It was claimed that these two components act synergistically, allowing a lower dosage of heparin to be used. However, the lower risk of hemorrhagic complications is certainly not counterbalanced by a lowered risk of ergotism (SEDA-8, 147). Vasospastic reactions after giving heparin with dihydroergotamine seem to occur particularly in traumatized patients or when a limb is injured. Since the risk of vasospasm increases with treatment time, the Swedish Adverse Reactions Committee recommended that the duration of treatment with dihydroergotamine with heparin should not exceed 7 days (SEDA-15, 135).

With daily use of dihydroergotamine by injection, there is an ill-defined frequency of nausea, vomiting, abdominal pain, and diarrhea, but also a high incidence of muscle cramps and some cases of lethargy and peripheral edema (SEDA-17, 171).

An expert European group has re-evaluated the preclinical and clinical data on ergotamine as they relate to treatment of migraine and have tried to reach a consensus on how to use it prudently (1).

Ergometrine

Ergometrine is used in obstetrics, since its oxytocic effects are relatively more marked than its vascular effects. Nausea and vomiting can occur if it is given orally. Slight bradycardia is common, but tachycardia occurs in some patients, and there can be changes in intracardiac conduction and pacemaker function. Very rarely, hypertensive reactions and cardiac arrest have been described and there are two reports of myocardial infarction in healthy women who were smokers (SEDA-18, 160). A newborn infant inadvertently injected with ergometrine and oxytocin developed depression of respiration and convulsions (2).

The "ergonovine provocation test" has been used in the diagnosis of angina pectoris (by producing vasospasm during angiography) but it can cause myocardial infarction and even death (SED-12, 324) (3).

Co-dergocrine

Co-dergocrine mesylate (Hydergine) is a mixture of the methane sulfonates of the dihydrogenated derivatives of the three alkaloids of ergotoxin (dihydroergocornine, dihydroergocristine, and dihydroergocryptine). Dihydrogenation eliminates the vasoconstrictor effects of ergotoxin and enhances its alpha-adrenoceptor antagonist and 5-HT receptor antagonist properties. Co-dergocrine has other pharmacological effects, including inhibition of brain-specific phosphodiesterases, several of which are still poorly described.

Co-dergocrine is claimed to have some effect in brain ageing and has also been promoted as a "metabolic enhancer," mainly because it protects against metabolic alterations induced by hypothermia and ischemia in animals (4).

Many double-blind, controlled trials have been conducted with co-dergocrine in senile dementia, and almost all have reported improvements in scores on at least one psychomotor test scale. However, despite this evidence of short-term efficacy, many skeptical clinicians still consider it to be no better than placebo, and find support from a double-blind, placebo-controlled trial in which a group treated with the recommended dosage of 1 mg tds for 24 weeks did not perform better after treatment than did the placebo-treated group (5). The clinical value of co-dergocrine in patients with claudication and rest pain is poorly documented.

Although the recommended dosage has been tripled over the years (from 0.5 to 1.5 mg tds), significant unwanted effects are rare. Vomiting, blurred vision, skin rashes, nasal stuffiness, bad taste, postural hypotension, and vasospastic reactions are all uncommon (SED-12, 472). Diffuse fibrotic processes (for example retroperitoneal fibrosis), repeatedly reported with other ergot derivatives, such as methysergide and dihydroergotamine, have not been observed with co-dergocrine. In elderly people, co-dergocrine only occasionally causes diarrhea, nausea, gastric pain, orthostatic hypotension, and headache. In 40 children, nasal stuffiness and anorexia were most common adverse effects of co-dergocrine (6).

Organs and Systems

Cardiovascular

Ergot derivatives are powerful vasoconstrictors. The extremities become pale and cold, and arterial spasm in the arms and legs has been demonstrated; even the face can be affected. The condition can develop acutely even after brief use of the drug, and there is real risk of gangrene; if given early, intra-arterial infusion of prostaglandin E_1 can reverse the spasms. Protracted coronary spasm has

© 2006 Elsevier B.V. All rights reserved.

also been reported in some cases (SEDA-14, 122). Renal arterial spasm has occurred after a dose of ergotamine of 10 mg in the form of suppositories given over 60 hours (SED-8, 308) (7), and bilateral papillitis with ischemia of the periaxial fibers has resulted from 2 weeks of maximum-dose treatment. High doses have also led on occasion to mesenteric vascular constriction, ischemic bowel disease, and partial necrosis of the tongue. Arterial stenosis can even result in aneurysm formation (8). The absence of symptoms does not mean that there is no adverse effect; in 30 patients who had taken ergotamine 1–5 mg/day for a year all had lowered systolic blood pressures in the foot.

Arterial spasm induced by ergotamine can be due to overdose, but some patients have an exaggerated response to a therapeutic dose. Interaction with other drugs, leading to potentiation, is a third mechanism. Four patients developed extreme limb ischemia after a therapeutic dose of ergotamine: one even took only a single dose of 1 mg. The symptoms responded to vasodilator therapy after withdrawal of ergotamine, but one needed a minor amputation. All patients were taking antiviral treatment for HIV infection, and ritonavir and indinavir may have potentiated the effect of ergotamine by inhibiting its metabolism (9–12).

Treatment of migraine can lead to subclinical ergotism for a prolonged period, and thence to occlusive peripheral vascular disease; peripheral systolic pressure (and liver function tests) should be monitored in patients taking regular ergotamine (SEDA-15, 135). Tolerance to these vasoconstrictive effects varies widely among individuals; such symptoms as cyanosis of the limbs, syncope, hypotension, and paresthesia have been seen in sensitive subjects after doses of up to 8 mg taken over as little as 10 days. The Swedish drug authorities have recommended that treatment should not be continued for more than 7 days (SEDA-13, 113).

- A 78-year-old woman developed gangrene in three fingertips on the right hand and two on the left after being given dihydroergotamine 10 mg/day as migraine prophylaxis (13). She had had Raynaud's syndrome for at least the previous 5 years and was thought to have a relatively mild form of systemic sclerosis.
- A 44-year-old woman developed claudication and rest pain after gross overuse of ergotamine 100 mg suppositories (up to 6 times a day) for chronic headaches over a period of several years (14). Angiography showed occlusion of both femoral arteries. Intra-arterial prostaglandin E (presumably E_1) followed by chemical sympathectomy normalized the circulation in both the legs.
- A 63-year-old Canadian woman who had been taking ergotamine (dosage unspecified) for migraine for 20 years developed acute ischemia of the right arm, with no palpable pulses below the axilla (15). Angiography showed multiple filling defects in upper limb arteries, partially reversible with intravenous phentolamine. She was given prazosin 2 mg/day and became pain-free after 5 days. Treatment was continued for 3 months and during this time attacks of migraine were treated with sumatriptan without adverse effects. Her pulses were entirely normal after 3 months, as was angiography.

Myocardial infarction has been reported.

- A 27-year-old woman with familial hypercholesterolemia already treated with lipid-lowering drugs developed acute chest pain after a prophylactic intramuscular injection of 0.5 mg ergometrine, given during the late stages of labor (16). Angiography showed three-vessel atherosclerotic disease and occlusion of the left anterior descending coronary artery. Angioplasty with stenting was successful and she made an excellent recovery.
- A 34-year-old woman had a myocardial infarction after being given ergonovine for an atonic uterus after cesarean section (17). Within minutes she became unresponsive, with bradycardia and then asystole followed by ventricular fibrillation during cardiopulmonary resuscitation. An electrocardiogram showed an acute anterior infarct and coronary angiography showed diffuse spasm of the circumflex and left anterior descending arteries, with subtotal occlusion of the latter. The spasm was reversed with intracoronary glyceryl trinitrate but she required ventilation for another 2 days and was eventually discharged 11 days after the infarct, with a borderline left ventricular ejection fraction of 45%.

The authors commented that the latter patient was of Asian origin and that such individuals are thought to have increased susceptibility to the vasoconstrictor effects of ergot derivatives.

The role of arterial spasm as a cause of angina after angioplasty has been studied in two men, aged 45 and 58 years, who had emergency angioplasties for acute coronary thrombosis (18). Although the primary procedures were successful in both cases, ischemic chest pain returned after 4 and 6 months respectively. Perhaps a little surprisingly, in both cases intravenous ergonovine (0.4 mg) was given during coronary angiography, causing severe arterial spasm, which resolved with intravenous isosorbide dinitrate. There was no evidence of restenosis. The authors noted that recurrence of angina does not necessarily imply restenosis, although it is not clear how many cardiologists will repeat this procedure with their own patients.

- A 48-year-old woman developed a cold pulseless right leg and no measurable blood pressure at the right ankle (19). She was a migraine sufferer and had been taking over-the-counter medications, some of which contained ergot derivatives, although the nature and quantity were not specified. Arteriography showed severe stenosis of the superficial femoral artery, with no identifiable tibial vessels. There was an initial improvement with intra-arterial glyceryl trinitrate infusion, and sustained normalization of the circulation in the leg after administration of sodium nitroprusside, nifedipine, prazosin, and heparin. She made a full recovery.

The authors reviewed the pharmacology of the ergot alkaloids and the acute and subclinical ischemic syndromes that they can produce. They pointed out that in some countries, notably in Latin America, ergot-containing formulations are freely available without a prescription.

Acute hypertensive encephalopathy has occurred in a patient given methylergotamine (SEDA-3, 121).

Diverticulum formation in the internal carotid artery occurred in a patient who had taken ergotamine for

© 2006 Elsevier B.V. All rights reserved.

4 years (SEDA-10, 119). Rupture of a splenic artery aneurysm in a 46-year-old woman was ascribed to excessive ergotamine ingestion for migraine (20). The authors thought that significant vasospasm may have led to damage and weakening of the vessel wall and consequently to the development of a false aneurysm. It should be noted that splanchnic aneurysms are occasionally discovered in otherwise healthy people and carry a 5% risk of spontaneous rupture.

Long-term abuse of ergotamine can occasionally cause fibrosis of the cardiac valves (SEDA-18, 160).

Ear, nose, throat

During intranasal administration for migraine, nasal congestion, irritation, and sneezing can occur (21).

Nervous system

The cerebral vasculature can also be vulnerable to ergot-induced vasoconstriction.

- A 54-year-old woman with a 20-year history of migraine used a nasal ergotamine spray one evening during an episode of migraine (22). She used a second dose at 4 p.m. the next day since the migraine had persisted. The following morning she was given subcutaneous sumatriptan 6 mg. Some 30–45 minutes later she developed the symptoms of global amnesia, which resolved by the following morning. Magnetic resonance imaging showed a small infarct in the right thalamus.

It seems likely that the co-administration of two cerebral vasoconstrictors increased the likelihood of such an event.

- A 36-year-old woman developed a "cerebral angiopathy" within 36 hours after starting to take oral metergoline, an ergot derivative prescribed after delivery to suppress lactation (23). This angiopathy was apparently due to severe narrowing of small and medium cerebral arteries; its main features were sudden hypertension, seizures, and variable reversible neurological deficits.

Transient cortical blindness, with severe headache and hallucinations, has been associated with the intravenous injection of methylergometrine 0.2 mg in a postpartum patient reference.

The role of ergotamine and sumatriptan in drug-induced headache has been surveyed in over 2000 patients at a regional headache clinic (24). About 600 had taken ergot derivatives previously and a similar number had used sumatriptan, while nearly 250 had experience of both. Drug overuse was defined as the use of at least one dose of either drug on 18 or more days every month for at least 3 months. By these criteria the rates of ergotamine and sumatriptan overuse were estimated at 14 and 3.5% respectively. Drug-induced headache was much more common among ergotamine overusers than sumatriptan overusers (68 versus 32%).

Sensory systems

Bilateral ischemic optic neuropathy can develop secondary to acute ergotism after administration of ergotamine tartrate (25).

Psychological, psychiatric

Unlike the dopamine-mimetic ergolines, ergotamine is not usually regarded as a drug with major effects on the brain. However, this may not always be true.

- A 75-year-old woman in Arizona developed progressive confusion, auditory hallucinations, and aggressive behavior (26). Her systolic pressure was raised (194 mmHg). She had a history of migraine and many other problems, including hypertension. Her headaches had become more severe over the weeks before admission and she had been gradually increasing her intake of a formulation containing ergotamine 1 mg and caffeine 100 mg: just before the emergence of her psychiatric symptoms she was taking 14 tablets per week. After withdrawal of the ergotamine/caffeine, her mental state and blood pressure returned to normal, without antihypertensive medication, and remained so 12 months later.

Although there has been extensive discussion of the phenomenon of ergotism in medieval and early modern times, its features do not closely resemble this case, perhaps because of the co-administration of caffeine. However, regardless of that, there does seem to be a strong case for a drug effect here.

A syndrome resembling reversible dementia has been described in chronic ergotamine intoxication (SEDA-3, 121).

Gastrointestinal

Nausea and vomiting are common problems with effective doses of ergotamine. Rectal stenosis demanding treatment has several times been described after prolonged use or overuse (27). This pattern of use can also rarely cause reversible gastrointestinal ischemia, presenting as lower abdominal pain (SEDA-17, 146).

- A 50-year-old woman developed ischemic necrosis of the stomach wall after taking up to 5 mg/day of ergotamine tablets for 10 years because of daily headaches (28). The necrosis was seen on the greater curvature and was about 10 cm in diameter. She required laparotomy because of peritonitis and there was a 4 cm area of full-thickness necrosis within the ischemic area. She made a full recovery.
- A necrotic small intestine was resected in a 65-year-old man with ergotamine abuse (29). Histological examination showed hypertrophy of the smooth muscle of the mesenteric arteries resulting from chronic vasospasm. The patient developed postoperatively limb ischemia and tongue gangrene before he died.

Liver

Portal hypertension, presumably due to vasoconstriction, has been reported (SEDA-11, 131).

Skin

Anocutaneous ergotism (characterized by anal ulceration) has been observed in one case after excessive use of ergot suppositories (SEDA-10, 119).

© 2006 Elsevier B.V. All rights reserved.

Serosae

Retroperitoneal fibrosis, as produced classically by methysergide, has been reported after the administration of ergotamine (SEDA-8, 147) and dihydroergotamine (SEDA-17, 170).

Other fibrotic reactions have been reported in patients taking ergot derivatives.

- A 67-year-old man in Germany with Parkinson's disease took co-careldopa and (somewhat unusually) alpha-dihydroergocryptine 45 mg/day, the latter in order to regulate fluctuations on motor function (30). After 2 years he developed a dry cough with dyspnea. Chest X-rays showed severe thickening of the pleura bilaterally with associated effusions. Biopsy confirmed fibrosis. The ergot drug was immediately replaced with pramipexole, eventually at a dose of 3 mg/day. Respiratory symptoms improved markedly within weeks, but there was little change radiologically.

Although this is the first description of such a reaction to this particular drug, it has been well documented with several other dopaminergic ergot derivatives.

Long-Term Effects

Drug dependence

If ergotamine tartrate is used chronically, which is in any case undesirable because of its vascular effects, a vicious cycle can arise, withdrawal headaches leading to the use of ever-increasing doses (SEDA-13, 113). Tolerance can develop to the point at which the doses being used exceed those that are normally regarded as safe. The only possible treatment is to withdraw the drug; the withdrawal symptoms tend to be poorly responsive to other drugs, but they usually abate within 72 hours, after which the patient can be treated with other antimigraine drugs. The best means of preventing ergotamine dependence is to limit the use of ergotamine tartrate to no more than 2 days per week and to ensure that the drug is not used unnecessarily for plain headaches, which have been labeled as migrainous.

Second-Generation Effects

Teratogenicity

Microcephaly occurred in a child whose mother had used ergotamine and caffeine (during the first trimester) and propranolol (during the second) for the relief of migraine (SEDA-13, 114). Although this suggests the possibility of teratogenicity, data in animals are not consistent. However, ergotamine should in any case not be used in pregnancy in view of its oxytocic effects (SEDA-8, 147), which can lead to fetal stress requiring cesarean section (31).

Lactation

Ergotamine does not affect the amount of milk secreted during lactation (32). It has been said that if ergotamine is used during lactation, the infant may have gastrointestinal upsets, cardiovascular instability, and even convulsions, but there is little documented evidence of this.

Susceptibility Factors

Hepatic disease

There are special risks in giving ergotamine in liver disease, since most of the drug is metabolized by the liver. Ergotamine also reduces liver blood flow by vasoconstriction and therefore reduces its own first-pass metabolism.

Other features of the patient

Women taking oral contraceptives and pregnant women are more susceptible to the vasospastic effects of the ergot alkaloids, as are patients in shock, with sepsis, and with Raynaud's disease or Buerger's disease. The risk of severe vascular reactions is increased in the presence of peripheral vascular disease or when sympathomimetic agents are given at the same time.

Drug Administration

Drug overdose

The signs of ergot poisoning initially include dizziness, frontal headache, depression, and leg and low back pain; more severe poisoning results in formication, severe cyanosis of the extremities, muscular twitching, tonic spasms, convulsions, delirium, and ultimately death (33).

Drug–Drug Interactions

Clarithromycin

Clarithromycin has been reported to potentiate the effects of ergotamine.

- A 41-year-old woman presented with pain and pallor in the leg and a sensation of coolness exacerbated by exercise (34). For many years she had been taking a formulation containing ergotamine 1 mg plus caffeine 100 mg, at a dose of one or two tablets daily, for both prophylaxis and treatment of migraine. For 7 days she had also taken clarithromycin (dose is not stated) for a chest infection. Her legs were cool and cyanosed, with no palpable popliteal or foot pulses and an ankle–brachial index of only 0.6 (normal >0.8).

The authors concluded that her symptoms had been precipitated by the introduction of clarithromycin, an inhibitor of CYP isozymes like the other macrolide antibiotics. However, she was also taking omeprazole, another inhibitor, which may have contributed to the problem. All drugs were withdrawn and nifedipine was given, with full recovery within a couple of days.

Ritonavir

Ritonavir has been reported to potentiate the effects of ergotamine.

- A 28-year-old woman was taking triple therapy for HIV infection, including the protease inhibitor ritonavir (35).

© 2006 Elsevier B.V. All rights reserved.

She had also started to take a combined formulation containing ergotamine (0.6 mg/day), phenobarbital (40 mg/day), and belladonna extract (0.4 mg/day). Four days later she noted pain in both legs and all her extremities were cold, pale, and pulseless. She had diffuse arterial spasm in the aorta and all four limbs. Despite intensive vasodilator therapy, she developed bilateral gangrene of the toes, requiring transmetatarsal amputations.

- A 37-year-old woman with AIDS who had been taking ritonavir developed acute dysphasia and right-sided weakness having taken a total of 10 mg of ergotamine in suppository form for severe headaches that were presumed to be migraine (36). Transcranial Doppler and angiography showed multiple stenoses in vessels in the circle of Willis, and an MRI scan showed watershed infarcts in the right and left hemispheres. It was presumed that she had had ergotamine-induced vasospasm due to inhibition of ergotamine metabolism by ritonavir. She was treated with "hemodilution, hypertension and hypervolemia"; the cerebral flow velocities normalized over the next 18 days and the angiographic appearances by day 90. She was left with a slight right expressive dysphasia and weakness in the right leg.

Ritonavir is a very potent inhibitor of CYP3A4, which is responsible for the metabolism of ergotamine, and this interaction obviously led to toxic plasma concentrations of the alkaloid.

Sumatriptan

The combination of ergotamine with sumatriptan has been associated with vasospasm in the cerebral arteries (37).

- A 20-year-old woman developed a severe headache 24 hours after a spontaneous normal delivery. She was given sumatriptan 6 mg subcutaneously followed 24 hours later by three tablets of ergotamine. Shortly after this she had a secondarily generalized tonic-clonic seizure, starting in the left arm, and became hemiplegic. A CT scan showed cerebral edema and angiography showed multiple narrowings of the right vertebrobasilar and middle cerebral arteries. After several further seizures she gradually improved and was clinically normal after 10 days. An MRI angiogram was normal two days later.

The danger of combining two cerebral and coronary vasoconstrictors needs no emphasis.

Ericaceae

See also Herbal medicines

General Information

The genera in the family of Ericaceae (Table 1) include heather, huckleberry, and rhododendron.

Arctostaphylos uva-ursi

Arctostaphylos uva-ursi (bearberry) contains a steroid, sitosterol, and triterpenoids, such as amyrin, betulinic acid, lupeol, oleanolic acid, taraxenol, ursolic acid, and uvaol. The main constituent is a glucoside called arbutin. Other constituents are methylarbutin, ericolin, ursone, gallic acid, and ellagic acid.

Its reputed antibacterial activity is ascribed to the urinary metabolite hydroquinone, which is excreted in the form of inactive conjugates and needs an alkaline urine to be liberated. As the urine of people who consume a Western non-vegetarian diet is usually acidic, it is sometimes suggested that one should alkalinize the urine of bearberry users with sodium bicarbonate. However, as the dosage recommended for this purpose is usually high, this carries well-known risks such as a high sodium load and interference with the renal clearance of certain other drugs.

Table 1 The genera of Ericaceae

Agarista (Florida hobblebush)
Andromeda (bog rosemary)
Arbutus (madrone)
Arctostaphylos (manzanita)
Befaria (befaria)
Calluna (heather)
Cassiope (mountain heather)
Chamaedaphne (leather leaf)
Comarostaphylis (summer holly)
Elliottia (elliottia)
Epigaea (trailing arbutus)
Erica (heath)
Gaultheria (snowberry)
Gaylussacia (huckleberry)
Gonocalyx (brittle leaf)
Harrimanella (harrimanella)
Kalmia (laurel)
Kalmiopsis (kalmiopsis)
Ledum (Labrador tea)
Leiophyllum (leiophyllum)
Leucothoe (dog hobble)
Loiseleuria (loiseleuria)
Lyonia (stagger bush)
Menziesia (menziesia)
Ornithostaphylos (ornithostaphylos)
Oxydendrum (swamp cranberry)
Phyllodoce (mountain heath)
Pieris (fetter bush)
Rhododendron (rhododendron)
Symphysia (symphysia)
Vaccinium (blueberry)
Xylococcus (mission manzanita)
Zenobia (honeycup)

© 2006 Elsevier B.V. All rights reserved.

Adverse effects

The urine of patients taking bearberry can darken on standing.

Toxic reactions to bearberry have not been reported, except for an anomalous case of dyspnea, cyanosis, and skin reactions after the consumption of an aqueous decoction (1).

- A 56-year-old woman who had taken *uva ursi* for 3 years developed reduced visual acuity (2). She had a typical bull's-eye maculopathy bilaterally.

The authors suggested that the effect was due to impaired melanin synthesis.

Reports of carcinogenicity of hydroquinone after prolonged administration of high doses to rats or mice raise a question about the long-term safety of *A. uva-ursi* and other medicinal herbs that contain substantial amounts of arbutin (3).

Gaultheria procumbens

The volatile oil of *Gaultheria procumbens* (wintergreen) leaves consists largely of methyl salicylate (more than 95%).

Adverse effects

Salicylism has been attributed to the use of oil of wintergreen as part of an herbal skin cream for the treatment of psoriasis (4).

- A 40-year-old man became acutely unwell after receiving oil of wintergreen from an unregistered naturopath. Transcutaneous absorption of the methyl salicylate was enhanced in this case owing to the abnormal areas of skin that were covered and the use of an occlusive dressing. The patient developed tinnitus, vomiting, tachypnea, and the typical acid/base disturbance of salicylate toxicity. Decontamination of the skin followed by rehydration and establishment of good urine flow was successful.

Laryngeal edema has been attributed to oil of wintergreen (5).

Methyl salicylate in topical analgesic preparations can cause irritant or allergic contact dermatitis and anaphylactic reactions (6).

In a retrospective study 80 subjects who had taken aspirin tablets ($n = 42$) or topical oil of wintergreen ($n = 38$) were compared (7). The admission plasma salicylate concentrations were generally higher in those who had taken aspirin tablets, but the two highest readings (4.3 and 3.5 mmol/1) belonged to two of the subjects who had taken oil of wintergreen.

Oil of wintergreen in the form of candy flavoring was ingested by a 21-month-old boy who developed vomiting, lethargy, and hyperpnea but recovered rapidly with parenteral fluids and sodium bicarbonate (8).

Methylsalicylate is also an important constituent of the Red Flower Oil formulations that are popular herbal analgesics for topical application in Southeast Asia. Some users take small amounts of the oil orally to enhance its analgesic effects. There are many different brands, which provide variable amounts of declared or undeclared methylsalicylate (up to 0.78 g/ml of oil). A suicide attempt by deliberate ingestion of about 100 ml resulted in severe salicylate poisoning (9).

Ledum palustre

The essential oil of *Ledum palustre* (marsh Labrador tea), which contains flavones, monoterpenoids, and sesquiterpenoids, is a potent irritant of the gastrointestinal tract, kidneys, and urinary tract; other toxic effects include abortion.

Vaccinium macrocarpon

Vaccinium macrocarpon (cranberry, marsh apple) has been used to prevent and treat urinary tract infections, although it is not useful in established infections (10,11). It is supposed to act by preventing adhesion of bacteria to the bladder wall. It may also reduce the risk of formation of some types of urinary stone (12,13).

Adverse effects

Hematologic

Cranberry juice may contain small amounts of quinine, which can cause immune thrombocytopenia.

- After transurethral resection of his prostate, a 68-year-old man developed immune thrombocytopenic purpura (platelet count 1×10^9/l) (14). He had self-medicated with cranberry juice for 10 days before the operation and had also taken amlodipine and aspirin. He had oral petechiae, bleeding gums, hematuria, and bruises. He recovered within 3 days of being given human immunoglobulin and oral prednisolone, and 18 months later his platelet count was still normal.

Drug interactions

Cranberry juice has been reported to enhance the action of warfarin (15)

- After a chest infection a man in his 70s had a poor appetite for 2 weeks and ate next to nothing, taking only cranberry juice as well as his regular drugs (digoxin, phenytoin, and warfarin) (16). Six weeks later his international normalized ratio was over 50, having previously been stable. He died of gastrointestinal and pericardial haemorrhage. He had not taken any over the counter preparations or herbal medicines, and he had been taking his drugs correctly.

The Committee on Safety of Medicines has received several other reports through the yellow card-reporting scheme about a possible interaction between warfarin and cranberry juice.

In one case this effect was suggested to have been due to contamination with salicylic acid, which displaces warfarin from protein binding sites (17).

Erythromycin

See also Macrolide antibiotics

General Information

For some decades erythromycin was the only macrolide antibiotic available, but with the development of new macrolides with remarkable pharmacokinetic and safety features (1), it has met fierce competition and has, at least in some health-care systems, lost its place as the most important macrolide.

Comparative studies

In a direct comparison of clarithromycin with erythromycin stearate, the rate of adverse events was 19% in 96 patients taking clarithromycin and 35% in 112 patients taking erythromycin (2). Most of the adverse events associated with clarithromycin affect the gastrointestinal tract (7%).

In a prospective, single-blind, randomized study of a 7-day course of clarithromycin (7.5 mg/kg bd) and a 14-day course of erythromycin (13.3 mg/kg tds) in 153 children with pertussis, the incidence of treatment-emergent drug-related adverse events was significantly higher with erythromycin than with clarithromycin (62 versus 45%) (3). Three subjects given erythromycin withdrew prematurely because of adverse events: one because of a rash; one with vomiting and diarrhea; and one with vomiting, abdominal pain, and rash.

In a double-blind, randomized, multicenter trial in 302 children, a 10-day course of erythromycin estolate (40 mg/kg/day in two doses) was as safe and effective as amoxicillin (50 mg/kg/day in two doses) in acute otitis media. Treatment-related adverse events occurred in 5.3% of patients given erythromycin and in 7.3% of patients given amoxicillin (4).

General adverse effects

Erythromycin is relatively well tolerated, with the exception of gastrointestinal adverse effects. Cholestasis resulting from the use of all forms of erythromycin is virtually the only serious effect. However, local irritation (affecting the gastrointestinal system, the muscles, or the veins, depending on the route of administration) is common. Erythromycin can increase serum theophylline concentrations and occasionally causes theophylline toxicity. Hypersensitivity reactions are rare, unless cholestasis is to be regarded as allergic. They probably have clinical effects in under 0.5% of treated patients, and consist mainly of maculopapular rashes, pruritus, urticaria, and angioedema; anaphylaxis and acute respiratory distress have also been reported. Fixed drug eruptions, urticaria, and Stevens–Johnson syndrome have also been reported.

Organs and Systems

Cardiovascular

Erythromycin has antidysrhythmic properties similar to those of Class IA antidysrhythmic drugs, and causes an increase in atrial and ventricular refractory periods. This is only likely to be a problem in patients with heart disease or in those who are receiving drugs that delay ventricular repolarization (5). High-doses intravenously have caused ventricular fibrillation and torsade de pointes (6). Each episode of dysrhythmia, QT interval prolongation, and myocardial dysfunction occurred 1–1.5 hours after erythromycin infusion and resolved after withdrawal.

In an FDA database analysis, 346 cases of cardiac dysrhythmias associated with erythromycin were identified. There was a preponderance of women, as there was among those with life-threatening ventricular dysrhythmias and deaths after intravenous erythromycin lactobionate. A sex difference in cardiac repolarization response to erythromycin is a potential contributing factor, since in an in vitro experiment on rabbit hearts, erythromycin caused significantly greater QT prolongation in female than in male hearts (7).

© 2006 Elsevier B.V. All rights reserved.

In 35 women and 28 men erythromycin caused QT interval prolongation after the first few doses of erythromycin (8). Similarly, in a prospective, comparative study in 19 patients with uncomplicated community-acquired pneumonia, a single dose of intravenous erythromycin 500 mg increased the heart rate and prolonged the QT interval. These effects were seen after 15 minutes of infusion and disappeared 5 minutes after the infusion had been stopped (9).

Owing to prolongation of the QT interval, a newborn with congenital AV block developed ventricular extra beats and non-sustained ventricular tachycardia after intravenous erythromycin; the QT interval normalized after withdrawal (10).

- Intravenous erythromycin (1 g 6-hourly by intravenous infusion over 30 minutes) resulted in QT interval prolongation, ventricular fibrillation, and torsade de pointes in a 32-year-old woman (6).

Intravenous administration of erythromycin into peripheral veins relatively commonly causes thrombophlebitis, although the lactobionate form of erythromycin may be less irritating to veins than other parenteral forms (11,12). In a prospective study of 550 patients with 1386 peripheral venous catheters, the incidence of phlebitis was 19% with antibiotics and 8.8% without; erythromycin was associated with an increased risk (13).

Respiratory

Adverse effects involving the respiratory system were reported in 2% of patients taking erythromycin stearate (2).

A beneficial effect of erythromycin on sputum volume has been reported in a patient with severe airways obstruction due to bronchorrhea (14).

Nervous system

In patients without neuromuscular disease erythromycin caused subclinical loss of motor unit contractions, which improved with intravenous edrophonium or neostigmine (15).

Sensory systems

Ototoxicity, resulting in hearing loss, and usually reversible, has been reported in patients treated with erythromycin lactobionate 4 g/day or more or large oral doses of erythromycin estolate (16). Ototoxic reactions have also been seen after the use of esters of erythromycin, such as the ethylsuccinate, stearate, and propionate (17). High parenteral doses of erythromycin have resulted in transient perceptive deafness (18–21). Since renal and hepatic disease was a prominent feature in these patients, ototoxicity was thought to result from high blood concentrations (22). Recovery occurred within a few days after withdrawal. The phenomenon differs from the permanent type of ototoxicity caused by aminoglycosides. Erythromycin should not be given together with other potentially ototoxic drugs and hearing acuity should be monitored during erythromycin therapy, especially in the elderly. Acute psychotic reactions have been related to ototoxicity and high-dose erythromycin therapy (23).

Psychological, psychiatric

Erythromycin has been associated with complications such as confusion, paranoia, visual hallucinations, fear, lack of control, and nightmares. These suspected psychiatric adverse effects were seen within 12–48 hours of starting therapy with conventional doses. Such complications may even be under-reported (23–26).

Gastrointestinal

Erythromycin is a motilin receptor agonist (27–29). This mechanism may be at least partly responsible for the gastrointestinal adverse effects of macrolides.

Pylorospasm and hypertrophic pyloric stenosis is associated with early postnatal erythromycin exposure and has been observed in neonates after 1–2 days of oral erythromycin therapy (30). The prominent gastrokinetic properties of erythromycin have been postulated as the mechanism (31).

- Pyloric stenosis has also been reported in a boy born at 23 weeks gestation, weight 690 g, after treatment of the child with three doses of oral erythromycin 10 mg/kg/day (32).

The use of erythromycin in postexposure prophylaxis for pertussis in 200 infants was followed by an increased number of cases of infantile hypertrophic pyloric stenosis, and all seven cases had taken erythromycin prophylactically (33). A case review and cohort study supported these preliminary findings (34). In a retrospective study in 314 029 children, very early exposure to erythromycin (at 3–13 days of life) was associated with a nearly eightfold increased risk of pyloric stenosis (35). There was no increased risk in infants exposed to erythromycin after 13 days of life or in infants exposed to antibiotics other than erythromycin.

Intravenous erythromycin should be restricted to as few patients as possible. It can cause severe abdominal cramps, probably by a direct action on smooth muscle (36–38).

Liver

Erythromycin can cause two different types of liver damage (39,40). Administration of erythromycin as base or salt can be followed in 0–10% of cases by apparently benign increases in serum transaminases, which may or may not recur on rechallenge. In children, raised transaminases were noted at dosages of 40 mg/kg/day but not 20 mg/kg/day.

Cholestatic hepatitis, which is associated primarily with erythromycin estolate, can be caused by all forms of erythromycin, including the base, estolate, ethylsuccinate, propionate, and stearate (39,41). Although it was originally speculated that a hypersensitivity reaction to the estolate ester rather than to the erythromycin itself was responsible for this adverse reaction (42), erythromycin does inhibit bile flow (43). Most probably the differences in hepatotoxicity between the various erythromycin derivatives are of a quantitative rather than a qualitative nature (44,45), perhaps because of better intestinal absorption of the estolate. Potentially severe but rare cholestatic liver injury occurs in perhaps up to 2–4% of

© 2006 Elsevier B.V. All rights reserved.

treated patients. Erythromycin-induced cholestasis is rare in children under the age of 12 years, but has occurred in infants at 6 weeks of age, in whom it can mimic acute cholecystitis, biliary atresia, or neonatal hepatitis (46).

- A young woman developed severe cholestasis and jaundice after taking erythromycin stearate (47). A second severe episode of jaundice and malaise occurred after treatment with erythromycin succinate 2 years later pointing to erythromycin itself as the culprit.

The syndrome generally starts 10–14 days after the start of therapy, but earlier after re-exposure, sometimes within 12–24 hours (48). At all ages it often begins with abdominal pain, nausea, vomiting, pyrexia, pruritus, and jaundice; fever, rash, leukocytosis, raised serum transaminases, and eosinophilia can also occur. However, it can be ushered in with severe acute upper abdominal pain or right subcostal tenderness, simulating an acute abdomen, or it can resemble obstructive jaundice. Serum bilirubin, alkaline phosphatase, and transaminases are raised. Histological examination typically shows intrahepatic cholestasis and periportal inflammatory infiltration, with lymphocytes, neutrophils, and disproportionate numbers of eosinophils (49). These histological findings could be interpreted as reflecting a hypersensitivity reaction, but this hypothesis has been rejected (43). If erythromycin is promptly withdrawn, the clinical signs often improve rapidly, although prolonged jaundice has been reported.

Urinary tract

Acute renal insufficiency has been observed in a patient with Henoch–Schönlein syndrome (50). Another case presented as interstitial nephritis with acute renal insufficiency (51).

Skin

Topical erythromycin in benzoylperoxide, marketed for acne treatment, must be compounded by a pharmacist and requires subsequent refrigeration, warranting the development of alternative formulations. In a double-blind, parallel-group, multicenter study in 327 patients, a single-use erythromycin in benzoylperoxide combination package was compared with the vehicle alone and the original, reconstituted formulation packaged in a jar. Dry skin was the most frequently reported skin-related adverse event; it occurred in 3.2% of patients who used the preformulated erythromycin in benzoylperoxide and 5.0% of those who used the reconstituted erythromycin in benzoylperoxide (52).

A fixed drug eruption due to erythromycin has been observed (53). In another case skin tests with erythromycin were positive for the immediate and or delayed types of hypersensitivity (54).

- A 27-year-old woman developed urticaria 30 minutes after taking a single dose of erythromycin (55). An identical episode had occurred three years before. Erythromycin-specific IgE was detected in her serum by radioimmunoassay.
- Stevens–Johnson syndrome developed in a 64-year-old man who took erythromycin stearate for non-specific upper respiratory tract symptoms (56). After four doses of 250 mg, he developed a fever and typical lesions in the mouth and conjunctivae and on the lips. He was treated with prednisolone and recovered rapidly.

Second-Generation Effects

Teratogenicity

In a retrospective study there was no evidence of an increased risk of pyloric stenosis among infants born to mothers exposed to erythromycin during pregnancy (57).

Drug–Drug Interactions

Antihistamines

The association of ventricular dysrhythmias with co-administration of erythromycin and terfenadine (58) is thought to be due to inhibition of CYP3A4 by erythromycin. This combination should be avoided.

Erythromycin increases concentrations of astemizole (59). This combination should be avoided.

A double-blind, crossover study of the potential interaction between erythromycin and loratadine in 24 healthy volunteers showed that the AUCs of loratadine and its metabolite descarboethoxyloratadine were increased 40% and 46% respectively by erythromycin, but with no discernible effect on the QT interval (60).

Combined desloratadine 7.5 mg/day plus erythromycin 500 mg qds in 24 healthy volunteers was well tolerated and had no clinically important electrocardiographic effects (61). Although co-administration of erythromycin slightly increased plasma concentrations of desloratadine, this change did not correlate with prolongation of the QT interval, and there was no toxicity.

Benzodiazepines

Erythromycin can increase concentrations of midazolam and triazolam by inhibition of CYP3A4, and dosage reductions of 50% have been proposed if concomitant therapy is unavoidable (59).

Buspirone

Co-administration of erythromycin with the anxiolytic drug buspirone increased the plasma concentration of buspirone (62).

Carbamazepine

Erythromycin can cause acute carbamazepine intoxication, probably by inhibiting its hepatic metabolism (63). Erythromycin may also directly inhibit the conversion of carbamazepine to its epoxide. In a controlled study of the effects of erythromycin on carbamazepine pharmacokinetics in healthy volunteers, the clearance of a single dose of carbamazepine was reduced by 19% during erythromycin treatment (64). In contrast, the single-dose pharmacokinetics of phenytoin were not affected by erythromycin (65,66). After withdrawal of the macrolide, carbamazepine concentrations quickly return to normal (67). If co-administration of erythromycin and carbamazepine cannot be avoided, a dosage reduction of

© 2006 Elsevier B.V. All rights reserved.

carbamazepine of around 25% should be considered, with careful monitoring of serum concentrations (59).

Cilostazol

When erythromycin was given to 16 healthy non-smoking male volunteers taking cilostazol, the C_{max} and AUC of cilostazol increased significantly by 47 and 73% respectively, and the unbound clearance of the major metabolite of cilostazol, OPC-13015, fell by about 50% (68).

Cisapride

- QT interval prolongation and torsade de pointes occurred after co-administration of cisapride and erythromycin 500 mg qds for 1 week in a 47-year-old woman (69).

Digoxin

The interaction of erythromycin with digoxin (70,71) is probably due to inhibition of its presystemic metabolism by inhibition of the growth of *Eubacterium glenum*.

Disopyramide

Disopyramide altered protein binding of erythromycin and this resulted in increased plasma erythromycin concentrations in vitro (72). The interaction between erythromycin and disopyramide was potentially fatal in two cases (73).

Ergot alkaloids

The interaction of erythromycin with ergotamine or dihydroergotamine can cause ergotism, sometimes leading to gangrene, by inhibition of the metabolism of the ergopeptides (74).

Felbamate

Erythromycin (333 mg tds for 10 days) had no effect on the pharmacokinetics of felbamate (3.0 or 3.6 g/d) used as monotherapy in epilepsy (75).

Halofantrine

Erythromycin inhibited halofantrine metabolism in vitro, suggesting that increased cardiotoxicity might be clinically important (76).

Lidocaine

Erythromycin can increase the plasma concentration and toxicity of oral lidocaine, as shown in a crossover study in nine volunteers who took erythromycin orally (500 mg tds) for 4 days and 1 mg/kg of oral lidocaine on day 4 (77).

Oral anticoagulants

Erythromycin can interact with warfarin, resulting in a modest increase in blood concentrations and a rise in the prothrombin time of around 8% (78).

Erythromycin may potentiate acenocoumarol anticoagulant treatment, as reported in a 68-year-old man on stable anticoagulation with acenocoumarol 3 mg/day who took erythromycin ethylsuccinate 1.5 g/day (79).

Quinidine

Erythromycin reduced the total clearance of quinidine, reduced its partial clearance by 3-hydroxylation, and increased its maximal serum concentration in an open study in 30 healthy young volunteers (80).

Quinine

Erythromycin is a competitive in vitro inhibitor of quinine 3-hydroxylation and may therefore interact with quinine (81).

Selective serotonin re-uptake inhibitors (SSRIs)

- A 12-year-old boy developed the serotonin syndrome, which is normally associated with the interaction of two or more serotonergic agents, after the co-administration of erythromycin and sertraline.

This could have been due to erythromycin-induced inhibition of sertraline metabolism by CYP3A (82).

Statins

It has been proposed that the risk of myotoxicity increases when statins are prescribed concurrently with erythromycin (83). There are no data for any pharmacokinetic interaction with fluvastatin or pravastatin, but as in the case of simvastatin the major route of metabolism of these drugs is by CYP3A4 and there is potential for an adverse interaction.

Atorvastatin

When erythromycin was co-administered with atorvastatin, the mean C_{max} and AUC of atorvastatin increased by more than 30% (5,84).

Lovastatin

Rhabdomyolysis with or without renal impairment has been reported in patients taking both erythromycin and lovastatin (85). The exact mechanism is unknown, but lovastatin is extensively metabolized by CYP3A4 and its metabolism may therefore be inhibited by erythromycin. The manufacturers have advised that careful monitoring is required when these two drugs are given together.

Simvastatin

A case-control analysis of 7405 cases and 28 327 controls suggested that concomitant use of simvastatin and erythromycin is associated with an increased risk of cataract (86). Studies in dogs have shown that some statins are associated with cataract when given in excessive doses (87).

Theophylline and other xanthines

Erythromycin can increase the serum concentrations of theophylline by 20–25%. However, patients with an average serum concentration of theophylline under 15 μg/ml will probably only experience a small increase in their serum theophylline concentration during erythromycin therapy, whereas patients with steady-state concentrations above 15 μg/ml deserve careful monitoring and close observation for symptoms of theophylline toxicity during treatment with erythromycin (88,89).

© 2006 Elsevier B.V. All rights reserved.

Tiagabine

Both tiagabine and erythromycin are metabolized by cytochrome P450. In an open, crossover study in 13 healthy volunteers, tiagabine (4 mg bd) and erythromycin (500 mg bd) were co-administered for 4 days (90). Maximum plasma concentration, AUC, and half-life of tiagabine were comparable when tiagabine was administered alone or in combination with erythromycin. The t_{max} was prolonged after administration with erythromycin in women; this effect may be due to a differential effect of erythromycin on gastric emptying. The interpretation of these findings is limited by the rather low doses of tiagabine used in the study and the short time of co-administration.

Erythropoietin, epoetin alfa, epoetin beta, epoetin gamma, and darbepoetin

General Information

Erythropoietin is an endogenous glycosylated protein hormone that is produced mainly in the kidneys and stimulates the production of members of the erythroid series of blood cells. Epoetin is the name that has been given to recombinant forms, of which there are four: epoetin alfa, epoetin beta, epoetin omega, and darbepoetin alfa. Darbepoetin alfa is a supersialylated form of erythropoietin with a longer half-life.

Uses

Recombinant human erythropoietin (epoetin and darbepoetin) provides effective therapy with a very favorable risk–benefit ratio in hemodialysis patients with end-stage chronic renal insufficiency, and in patients with progressive renal insufficiency who are not yet being dialysed (1). It improves cognitive function and the quality of life of patients with chronic uremia (2–5) and is very effective in children with chronic renal graft rejection and anemia (6). It also offers new opportunities for treating anemia in non-uremic patients. In patients with chemotherapy-induced anemia, epoetin increases hemoglobin concentration, reduces transfusion requirements, and improves quality of life (7,8). The response rate to epoetin in patients with multiple myeloma and anemia, which is 55–85% (9), increases when GM-CSF or G-CSF is co-administered (10). Epoetin is also approved for indications such as anemia induced by zidovudine in HIV-infected patients, the prevention of anemia in surgical patients, and anemia of prematurity (10,11). Treatment with epoetin results in a substantial improvement in the rehabilitation and quality of life of patients with cancer, AIDS, and rheumatoid arthritis (12).

Anemia due to prematurity can also be treated with epoetin. However, there are still questions to be answered about its efficacy, dosage regimen, and route of administration (subcutaneously or intravenously) (13,14). A comparison of the efficacy of daily versus less frequent dosing schedules in preterm infants showed that dosage regimens that achieve lower peak serum concentrations over a more prolonged period of time may be more efficacious (14). Although growth retardation in children with renal insufficiency does not improve (15,16), well-being, energy, appetite, and cardiac function are enhanced, and by obviating the need for regular blood transfusions, iron overload, allo-immunization to cellular antigens, and transfusion-transmitted viral infections are avoided (17).

Patients with cancer often develop anemia, and several studies have shown that recombinant human epoetin is a useful alternative to blood transfusion in such patients (18). Response rates of up to about 80% have been reported in patients with cancer-related anemia, especially in patients treated with platinum-based chemotherapy (18). Whether epoetin will improve tumor control after radiotherapy is being investigated (19). Epoetin corrects low hemoglobin concentrations, resulting in a better quality of life and probably improving cure rates in cancer patients undergoing radiotherapy (19). It also relieves symptoms of fatigue in patients with cancer (20,21), increasing hemoglobin and reducing transfusion requirements (22). No acceleration of tumor growth by epoetin has been observed (23). Epoetin has also been used in combination with G-CSF and amifostine or G-CSF and IL-3 as adjunctive treatment for cytopenias complicating myelodysplastic syndrome (24,25). Although these combinations are well tolerated, they promote hemopoiesis only in a subgroup of these patients.

Epoetin combined with parenteral iron is effective and safe for moderate and severe iron deficiency anemia during pregnancy (26), and iron supplementation is often required (27). The use of epoetin in combination with intravenous iron makes collection of larger numbers of autologous erythrocyte units feasible. However, epoetin does not synergize with G-CSF for the mobilization of peripheral blood progenitor cells in healthy donors (28).

Epoetin has been used to reduce allogeneic transfusion needs by increasing the efficacy of autologous transfusion for elective surgery (29). The combination of autologous predonation and epoetin treatment reduces blood requirements during and after orthopedic and cardiac surgery (30). In elective open-heart surgery, 26 of 30 patients who received only iron preoperatively needed blood transfusions compared with one of 30 patients who received iron plus epoetin (30).

While epoetin is not of benefit after autologous bone marrow transplantation, in patients receiving allogeneic bone marrow transplantation epoetin accelerates erythroid engraftment, increases hemoglobin concentrations,

© 2006 Elsevier B.V. All rights reserved.

reduces requirements for erythrocyte transfusions, and shortens the time to transfusion independence (31).

The main limiting factor in obtaining an optimal response to epoetin is the adequacy of the patient's iron stores (32,33); the response is abated in the presence of iron deficiency, occult blood loss, hemolysis, and other hematological diseases (34,35). Other causes of an inadequate response to epoetin include concurrent infection or inflammatory disease (1), aluminium toxicity, vitamin deficiencies, secondary hyperparathyroidism (36,37), and osteitis fibrosa (38,39).

Pharmacokinetics

Subcutaneous epoetin in patients undergoing hemodialysis can maintain the hematocrit at a desired target range using an average weekly dose lower than with intravenous administration (40). Intravenous administration leads to higher initial epoetin concentrations compared with subcutaneous administration. However, after intravenous administration the half-life is only 4–5 hours, compared with 19–22 hours after subcutaneous administration (41).

Observational studies

In a prospective trial in 3012 patients, the clinical benefits and adverse events profiles were similar with once-weekly epoetin compared with historical experience with thrice-weekly dosing (42).

In 194 patients a low dose of epoetin beta before elective surgery was well tolerated and reduced the need for transfusions (43).

Effective epoetin treatment has been reported in a transfusion-dependent beta-thalassemia major patient: there were no adverse effects (44).

In four patients with chronic diffuse gastrointestinal bleeding that was difficult to control, epoetin was successfully used as a hemostatic agent (45).

Placebo-controlled studies

In a double-blind, randomized, placebo-controlled, multicenter study in 80 critically ill patients, epoetin led to a 45% reduction in the number of erythrocyte units transfused. There were no epoetin-related adverse effects (46).

General adverse effects

Both epoetin alfa and beta and darbepoetin alfa are quite well tolerated (47). Common adverse effects are infection, hypertension, hypotension, shunt thrombosis, myalgia, nausea, headache, and chest pain (34,48). After the first few doses of epoetin, flu-like symptoms occur transiently, with an incidence of 5.4–18% (34,49). These can be avoided by injecting epoetin subcutaneously rather than intravenously (31,33,50,51). It has also been suggested that such symptoms can be avoided by dose escalation, starting with an ultra-low dose (49). Subcutaneous injection can cause local reactions, probably due to allergy (52).

Darbepoetin

Darbepoetin alfa is a long-acting form of erythropoietin, with additional sialic acid residues, and does not require such frequent administration as epoetin; its long half-life allows administration once every 1 or 2 weeks (53).

The safety profiles of epoetin and darbepoetin are similar. Adverse effects of darbepoetin include hypertension, injection site pain (generally mild and transient) in the case of subcutaneous administration, cardiovascular events, headache, vascular disorders (vascular access thrombosis), flu-like symptoms, and skin rashes (20,53,54). Adverse effects such as hypertension and thrombophlebitis are observed in uremic patients requiring dialysis but not in patients with hematological malignancies (55).

Organs and Systems

Cardiovascular

In a randomized study of 180 patients with anemia due to hormone-refractory prostate cancer, who were treated with epoetin beta 1000 IU or 5000 IU subcutaneously 3 times a week for 12 weeks, cardiovascular events were more frequent with the higher dosage. Four patients had deep vein thrombosis and two had myocardial infarctions; all were taking the higher dosage. However, only one of the patients with deep vein thrombosis had a high hemoglobin concentration (21).

Hypertension

Epoetin causes or aggravates hypertension in about 20–35% of dialysis patients (56–60). It can be accompanied by encephalopathy or seizures (61). In 44 children with chronic renal insufficiency treated with epoetin 150 U/kg/week, hypertension was mostly observed in patients on hemodialysis (66%) compared with peritoneal dialysis (33%) and predialysis patients (16%) (62).

Several factors contribute to the development of hypertension. One is the loss of the hypoxic vasodilatory response, leading to an increase in peripheral vascular resistance (63), but more important is the rise in blood viscosity, which increases with the hematocrit in both normotensive and hypertensive individuals (64). It is still being debated whether hypertension occurs only in patients with pre-existing hypertension or in normotensive patients as well, but about 30% of all patients require increased or de novo antihypertensive therapy as they respond to erythropoietin treatment (65).

Hypertension after epoetin has mostly been seen in uremic patients (66). However, in two of 44 cancer patients treated with epoetin during cisplatin-containing chemotherapy, epoetin was withdrawn owing to hypertension (diastolic pressure over 100 mmHg) (67).

Hypertensive encephalopathy can arise in connection with the sudden and extreme rises in blood pressure that occur in some patients given epoetin (52,68).

- A 14-year-old child developed hypertensive encephalopathy, a known rare adverse effect of erythropoietin, after 2 months (69).

During an open, uncontrolled study in 22 patients with end-stage renal disease treated with epoetin omega there was one case of hypertensive encephalopathy (70).

© 2006 Elsevier B.V. All rights reserved.

Susceptibility factors

It is not clear why certain patients develop hypertension and hypertensive encephalopathy and others do not, but transfusion-dependent anemic patients with a low hematocrit (<20%) are particularly susceptible, as are those with previous hypertension and seizures. Careful control of blood pressure at the start of epoetin treatment and the use of low doses are therefore advised in patients at high risk.

If epoetin is given preoperatively without autologous predonation, there is an increased risk of hypertension, an increased risk of graft thrombosis and myocardial infarction in cardiac surgery, and an increased risk of venous thromboembolism in orthopedic patients (71).

Because of an increase in cardiac-related deaths, it has been recommended that in patients with congestive heart failure or ischemic heart disease the hematocrit should not be raised above 42% (3).

Mechanisms

One of the possible mechanisms of epoetin-induced hypertension is an imbalance of local endothelial factors, such as endothelium-derived relaxation factor and endothelin (61), a potent vasoactive peptide produced by endothelial cells (13), increased concentrations of which have been observed in adults with an increase in mean blood pressure of more than 10 mmHg. In contrast, in preterm infants receiving epoetin there were no acute effects of epoetin on endothelin-1 concentrations or mean blood pressure (13). When intravenous and subcutaneous epoetin were compared, only intravenous epoetin was accompanied by hypertension (57,61). Plasma concentrations of proendothelin-1 and endothelin-1 increased after infusion of epoetin only in patients with hypertension. In addition the molar ratio of endothelin-1 to proendothelin-1 was significantly higher in patients with hypertension than in patients without (61). The authors suggested that endothelin-1 converting enzyme may play a role in the pathogenesis of epoetin-induced hypertension (61). Studies in rats have confirmed that epoetin stimulates endothelin release and synthesis of vascular tissue (72). There is a relation between the dose of epoetin and postdialysis blood pressure, but not predialysis blood pressure (57). Risk factors for the development or worsening of hypertension are pre-existing hypertension, the presence of native kidney, a rapid increase in hematocrit, a low baseline hematocrit, high dosages of epoetin, and intravenous administration (57).

Epoetin has vascular effects that can cause an imbalance between vasoconstrictor-proproliferative-proatherogenic factors (angiotensin, endothelin, thromboxane) and vasodilator-antiproliferative-antiatherogenic factors (nitric oxide, prostacyclin). These changes may be related to the occurrence or aggravation of pre-existing hypertension in humans and can cause vascular hypertrophy and potentially accelerate the development of atherosclerosis (66).

Adrenomedullin, an endocrine peptide with vasodilatory and natriuretic actions, is increased in patients with hypertension and chronic renal insufficiency. In 54 patients with renal anemia, treated with epoetin 6000 IU once a week, there was a correlation between the progression of renal disease and circulating adrenomedullin; however, there was no relation between adrenomedullin and epoetin-induced hypertension (73).

The induction of hypertension by epoetin has been attributed to increased blood viscosity after a rapid increase in hematocrit and a loss of hypoxia-induced vasodilatation (59). Another pathogenic mechanism for the induction of hypertension by epoetin is enhanced endothelin production by endothelial cells (59).

In 10 normotensive hemodialysis patients with severe anemia treated with epoetin there was increased adrenergic activity (74).

Epoetin-induced hypertension may be associated with an angiotensinogen gene polymorphism; the incidence of hypertension was increased in patients carrying a homozygous T on position 235 of the angiotensinogen gene (75). The authors speculated that erythropoietin causes a rise in blood pressure via the T allele, which influences components of the renin–angiotensin system, thereby stimulating production of angiotensinogen, which leads to hypertension.

Management

Blood pressure should be monitored during treatment (18).

Erythropoietin-induced hypertension can easily be treated by initiating or increasing antihypertensive medication (76). For example, two of 26 pregnant women treated with epoetin for iron deficiency anemia had worsening of mild hypertension, which was managed effectively with methyldopa 250 mg tds (26).

Antiplatelet therapy reduces the incidence of epoetin-induced hypertension in predialysis patients (60).

Vascular disease

There is an increased incidence of peripheral vascular diseases in diabetic patients who receive peritoneal dialysis and epoetin (4). In these patients the time to a first vascular incident is shorter, the number of vascular events is increased, and more hospital days associated with vascular disease have been reported compared with patients receiving peritoneal dialysis without epoetin (4). Significant risk factors for the development of peripheral vascular disease are epoetin therapy, epoetin dose, and smoking (4). Peripheral vascular disease may be related to increased blood viscosity or other changes in blood rheology (4).

Thrombotic events related to epoetin include vascular access thrombosis, renal and temporal vein thrombosis, transient ischemic attacks, and myocardial infarction (66).

Vascular access thrombosis has been reported in up to 26% of patients treated with epoetin alfa (3,34,38). Most of the failures occurred in polytetrafluoroethylene grafts. There was no comparison with patients not treated with epoetin. It has been suggested that the increased risk of extracorporeal circuit clotting and the higher heparin requirements during hemodialysis may not be due to a hypercoagulable state, but rather to an increase in erythrocyte mass and consequently in whole blood viscosity (66).

- A patient with end-stage renal disease treated with epoetin-alfa developed a dural sinus thrombosis (5).

It was postulated that it was caused by polycythemia, because the hematocrit more than doubled in under 2 months, reaching 0.55 (5).

© 2006 Elsevier B.V. All rights reserved.

Nervous system

Several neurological complications of epoetin, such as headache, seizures, visual hallucinations, transient myalgia, and hypertensive leukoencephalopathy, have been described (5,77).

Headache, probably due to intracranial hypertension, has been reported in 15% of patients with renal insufficiency treated with epoetin (23). Analysis of the safety of epoetin in cancer patients is often hampered by toxicity of the concomitant chemotherapy. In a prospective open study, three of 183 anemic cancer patients who did not receive chemotherapy complained of headache, possibly or probably related to epoetin (22). Complaints of dizziness and headache, possible due to epoetin, occurred in two of 44 cancer patients during cisplatin-containing chemotherapy (67).

Seizures have been reported in 2–17% of dialysis patients treated with epoetin (38,78). The mechanism is not known, but is most likely multifactorial, including increased peripheral vascular resistance, reversal of hypoxic vasodilatation, and a direct pressor effect of epoetin mediated by enhanced production of serum endothelin-1 (78). Seizures occur most often during the correction of anemia and are associated with a rapid increase in hemoglobin concentration and poor control of hypertension (38).

Reversible posterior leukoencephalopathy syndrome, in which imaging abnormalities are present in the parieto-occipital regions of the brain, is reversible after blood pressure control and withdrawal of epoetin (59,79). Monitoring of the blood pressure is indicated and the hematocrit should be increased slowly, with a target of not more than 30%. If hypertension and seizures are under control, epoetin therapy can be resumed (59).

Psychological, psychiatric

Visual hallucinations have been reported in patients receiving epoetin (59).

Endocrine

In two patients with non-insulin-dependent diabetes and uremia, glucose control deteriorated after the introduction of epoetin, requiring insulin therapy (80).

Hematologic

Iron deficiency is a common adverse effect (30%) in children with chronic renal insufficiency treated with epoetin, even with iron supplementation (62). In premature infants given enteral epoetin, there was a significant fall in ferritin concentrations despite iron supplementation (81), and there were increased numbers of hypochromic erythrocytes and soluble transferrin receptors (14). This implies that active erythropoiesis in premature infants causes increased iron requirements.

Erythrocytes

Worldwide, 112 cases of pure red cell aplasia have been reported after subcutaneous administration of epoetin alfa (especially Eprex) in patients with chronic renal insufficiency. In these patients, neutralizing anti-erythropoietin antibodies were detected (82–84); these antibodies cross-react with all other erythropoietin products. This adverse effect was probably restricted to patients with renal insufficiency because these patients had used subcutaneous erythropoietin for many years. The incidence was calculated as one in 10 000 patients after 1 year of use of erythropoietin.

In other reports from Canada and the UK, patients typically developed sudden worsening of anemia unresponsive to increasing doses of epoetin alfa or any other form of erythropoietin and became transfusion dependent (85). In patients who develop sudden lack of efficacy or worsening of anemia, typical causes of non-response (for example deficiencies of iron, folate, and vitamin B_{12}, infection or inflammation, blood loss, hemolysis, and aluminium intoxication) should be investigated. If pure red cell aplasia is suspected and no cause can be identified, erythropoietin antibodies should be sought.

The Australian Adverse Drug Reactions Advisory Committee has also received 12 reports of pure red cell aplasia associated with the use of epoetin alfa (Eprex) in patients with renal insufficiency (86). The patients were aged 28–76 years and the duration of epoetin alfa use, when known, was 4–13 months.

Janssen-Ortho Inc, in association with Health Canada, have issued a "Dear Health Professional" letter about the addition of a boxed section to the product monograph of epoetin-alfa (Eprex). The addition recommends that epoetin alfa should be administered intravenously rather than subcutaneously in patients with chronic renal insufficiency. This advice is based on the fact that most of the worldwide reports of pure red cell aplasia in patients treated with epoetin alfa have been associated with subcutaneous administration.

The suggested mechanism for these cases of pure red cell aplasia is an immune reaction that is probably induced by repeated, subcutaneous administration of a foreign protein, a biotechnologically processed erythropoietin. However, no antibodies toward darbepoetin alfa were detected in over 1534 patients treated for 2 years (87).

- A 70-year-old woman with a history of diabetes mellitus and renal insufficiency rapidly developed a severe anemia (with a hemoglobin concentration of 3.5 mmol/l). She had been treated with recombinant erythropoietin (4000 IU/week) for 6 months with an initial favorable response (hemoglobin concentration between 6.8 and 7.5 mmol/l) (82). Her bone marrow showed pure red cell aplasia with early termination of maturation. The dose of recombinant erythropoietin was increased to 8000 IU/week. She required 3 units of packed red cells per month.

This patient had developed antibodies against recombinant erythropoietin. After recombinant erythropoietin was withdrawn, the concentration of antibodies fell slightly. Because of persistent transfusion requirements, she received prednisone (1 mg/kg/day) for 6 months. At that time, antibodies against erythropoietin could not be detected anymore and the hemoglobin concentration was around 5.6 mmol/l.

Leukocytes

In neonates neutropenia has been described after treatment with high doses of epoetin. Neutrophil counts

© 2006 Elsevier B.V. All rights reserved.

increased in these neonates after withdrawal of epoetin (88). Lymphopenia has been described (89), but the fall in lymphocyte count in patients with renal insufficiency is less significant. Pretreatment with imidazole-2-hydroxybenzoate, which inhibits the synthesis of prostaglandins, causes a less marked and delayed reduction of lymphocytes (89). However, neutropenia has not been noted in recent studies (14).

Thrombotic events have been reported in patients given epoetin (90,91), but there have been contradictory results on its effects on blood coagulation and fibrinolysis. There is currently no definitive evidence that epoetin further enhances hypercoagulability in uremic patients (66). In a prospective controlled study, epoetin for elective hip surgery did not activate coagulation and fibrinolysis (92). In 26 patients the effect of epoetin on hemostasis was minimal, with only a clinically insignificant fall in the total amount of protein S (93). In contrast to earlier studies, this study did not show changes in the number of platelets or platelet function. Regular epoetin treatment in 39 hemodialysis patients with anemia did not result in adversely high blood viscosity, and in an overview of data from 3000 patients there was no increase in shunt or fistula occlusion (94).

In a placebo-controlled study of severely anemic patients with low-grade non-Hodgkin's lymphoma, chronic lymphocytic leukemia, or multiple myeloma, a fatal case of pulmonary embolism was thought to have been related to treatment with epoetin beta (95). Thrombotic events, such as vascular access thrombosis, venous thrombosis, and pulmonary embolism, have occurred after treatment with epoetin or darbepoetin alfa (96). It is therefore recommended that a rapid rise in the hemoglobin concentration be avoided and that care should be taken that the hemoglobin concentration does not exceed 12.1 g/dl (7.5 mmol/l) (97).

In 173 renal patients with anemia, in which once-weekly administration of subcutaneous epoetin beta was compared with thrice-weekly administration, there were seven serious adverse events, possible related to epoetin beta (98). There were two cases of arteriovenous fistula thrombosis in the once-weekly group and three in the thrice-weekly group. A transient ischemic attack and a hypertensive crisis occurred in one patient in the once-weekly group.

Treatment of patients with sickle cell anemia has led to disastrous sickling crises (99), and there are at present no clinical data to support the use of erythropoietin in sickle cell disease (100).

Gastrointestinal

Of 183 anemic cancer patients who did not receive chemotherapy in a prospective open study, seven complained of nausea, possibly or probably related to epoetin (22).

Urinary tract

Because the erythrocyte volume increases under the influence of erythropoietin, the clearance achieved by the dialyser can fall, with a consequent increase in creatinine, potassium, and phosphate (101). However, earlier fears that the renal function of predialysis patients receiving epoetin might deteriorate prematurely have not been realized (65).

The use of darbepoetin alfa is associated with an increase in erythrocytes and a reduction in plasma volume, which can lead to reduced efficacy of dialysis (48).

Skin

Generalized skin rash and local swelling at the injection site have been reported after subcutaneous epoetin (8,20), as have urticaria and other skin rashes (48,102). Of 61 patients with malignancies of the oral cavity and oropharynx who were treated with epoetin before perioperative chemoradiation, one had a mild transient skin rash related to epoetin (103).

- Strawberry hemangiomas developed in a premature infant after 1 week of treatment with epoetin (104).

Strawberry hemangiomas are congenital vascular lesions characterized by endothelial hyperplasia during the proliferative phase. The development and proliferation of capillary endothelium requires the presence of angiogenic factors, such as vascular endothelial growth factor. Epoetin has a proliferative effect on endothelial cells and can induce angiogenesis (104,105).

- A rare case of generalized exfoliative dermatitis secondary to epoetin has been described (38). Epoetin was withdrawn and the lesions disappeared spontaneously after 20 days.

Hair

- At the start of treatment with epoetin alpha for anemia, a 60-year-old man with nephrotic syndrome developed reversible total alopecia (106).

Sexual function

- Veno-occlusive priapism occurred in a 25-year-old man with chronic renal insufficiency treated with epoetin. The episodes resolved after the epoetin dosage was reduced (107).

The exact mechanism of this adverse effect is not known. Several cases of priapism have been reported, and it has been hypothesized that androgen therapy probably contributes (107).

Immunologic

Occasionally low-titer antibodies have been reported in patients treated with epoetin (38,108). Neutralizing anti-erythropoietin antibodies have been found in patients with chronic renal insufficiency who develop pure red cell aplasia after subcutaneous administration of epoetin alfa (especially Eprex). This adverse effect was probably restricted to patients with renal insufficiency because they had used subcutaneous erythropoietin for many years. The incidence was calculated as one in 10 000 patients after 1 year of use of erythropoietin (82–84).

There is no evidence of antibody formation to darbepoetin alfa, probably in part owing to the fact that carbohydrate chains are rarely immunogenic (54,109,110). No antibodies to darbepoetin alfa were detected in over 1534 patients treated for 2 years (87).

© 2006 Elsevier B.V. All rights reserved.

An allergic reaction led to early termination of epoetin treatment in one of 26 pregnant women treated with epoetin for iron deficiency anemia (26).

Anaphylaxis has been observed after the administration of epoetin that contained bovine gelatine as a stabilizer (2). Antibovine gelatine IgE antibodies were found. No anaphylactic reaction was observed after the administration of epoetin that contained human serum albumin as a stabilizer in the same patient.

Body temperature

Of 183 anemic cancer patients who did not receive chemotherapy in a prospective, open study, four had fever, possibly or probably related to the use of epoetin (22).

Long-Term Effects

Drug abuse

Epoetin has been abused by athletes, increasing the risk of hypertension and disseminated intravascular coagulopathy (10). In athletes epoetin causes increased blood viscosity, which will further increase during dehydration, leading to risks of myocardial infarction, cerebrovascular accident, or encephalopathy (10). Epoetin induces accelerated fibrinolysis, and so epoetin doping can be detected by analysis of fibrin degradation products in urine (10). In addition, hypochromic macrocytes are increased (10).

Susceptibility Factors

Age

The adverse effects of erythropoietin in neonates are minimal compared with adults. There were no hypertensive effects reported and no effect on development and growth measured at 18–22 months (111). In a multicenter, randomized, double-blind trial in 21 anemic HIV-infected children, who were concomitantly treated with antiretroviral drugs, epoetin was effective and safe (112).

In 30 preterm infants epoetin 300 μg/kg three times a week for 4 weeks reduced transfusion requirements without problems with tolerability (113).

High doses of epoetin in children undergoing long-term hemodialysis is associated with increased heparin requirements during hemodialysis, suggesting that careful monitoring of thrombotic events, especially in small children who need catheters for hemodialysis access, is warranted (114).

Drug Administration

Drug formulations

In the past, subcutaneous epoetin alfa resulted in more pain than epoetin beta, owing to citrate buffer in the product. Although the formulation of epoetin alfa has been changed to a phosphate buffer, discomfort after epoetin alfa is still greater than after epoetin beta (115,116).

Drug administration route

Epoetin can be administered in four ways: intravenously, subcutaneously, orally, and intraperitoneally (37). The subcutaneous route is preferred in patients undergoing dialysis, because subcutaneous epoetin provides better long-term utilization and maintains the same hematocrit with 20% lower dosages than intravenous administration. After intraperitoneal administration the absorption time is prolonged and only 5–10% of the dose is utilized (37). Local reactions occur at the site of injection when epoetin is given subcutaneously (117), and local pain has been reported after the administration of citrate- or phosphate-buffered epoetin (117,118).

After subcutaneous administration the systemic availability of epoetin is not complete (20%) and lower plasma concentrations are observed than after intravenous administration. However, the apparent half-life of epoetin is prolonged after subcutaneous injection, and this allows the use of lower doses to obtain an equivalent hemoglobin concentration (38). Subcutaneous injections are more effective when given thrice weekly rather than once weekly (38).

Patients with a skin-fold thickness of less than 20 mm at the injection site have a mean reduction in the maintenance dose of 36% when treatment is changed from two injections a week to daily injections (119). In patients with a thin layer of subcutaneous fat, the diffusion distance of epoetin to bloodstream is shorter than in patients with a thicker layer of subcutaneous fat. Therefore, the diffusion time in lean patients is shorter and the increase in plasma epoetin concentration is more pronounced but of shorter duration after each injection. More frequent injections of reduced amounts of epoetin creates an absorption curve whose area is more congruent with the area of the therapeutic plasma concentration.

Epoetin can also be given orally in premature infants, resulting in a significant increase in plasma epoetin concentration, increased peak reticulocyte counts, and reduced blood transfusion requirements (62,81).

In children undergoing peritoneal dialysis, epoetin is usually given intraperitoneally, resulting in similar systemic availability and dosages compared with subcutaneous administration. A follow-up study is required to determine if the risk of peritonitis is increased by intraperitoneal epoetin (120).

Drug–Drug Interactions

ACE inhibitors

During treatment of renal hypertension or heart failure with ACE inhibitors the response to epoetin therapy is reduced; this can be avoided by the use of angiotensin-II receptor antagonists instead (39).

Moxifloxacin

Possible synergy between erythropoietin and moxifloxacin was observed in a patient with myelodysplastic syndrome who did not respond to erythropoietin alone (121).

Esmolol

See also Beta-adrenoceptor antagonists

General Information

Esmolol is a beta$_1$-selective adrenoceptor antagonist with an extremely short half-life (about 10 minutes), because of extensive metabolism by esterases in blood, liver, and other tissues.

Organs and Systems

Cardiovascular

Esmolol causes hypotension, sometimes symptomatic, in up to 44% of patients (1–3).

Drug Administration

Drug administration route

Irritation at the infusion site occurs in up to 9% of patients and depends on the duration of the infusion (4).

Drug–Drug Interactions

Digoxin

Esmolol increased digoxin concentrations by 10–20% in healthy volunteers (5).

Morphine

Co-administration of esmolol with morphine resulted in increased steady-state concentrations of esmolol (5).

Esomeprazole

See also Proton pump inhibitors

General Information

Esomeprazole is the *S*-isomer of omeprazole. The pharmacology, pharmacokinetics, efficacy, and safety of esomeprazole have been reviewed (1). Esomeprazole produces acid control comparable to that of currently available proton pump inhibitors. It undergoes less hepatic metabolism than omeprazole, has an oral availability of 89% at a dose of 40 mg, and a half-life of 1.5 hours. Esomeprazole is well tolerated; its common adverse effects are diarrhea, headache, nausea, abdominal pain, respiratory infection, and sinusitis.

To assess symptom control, esomeprazole 20 mg on demand has been compared with placebo on demand (maximum of one dose a day) for 6 months in a multicenter, double-blind study in 342 endoscopy-negative patients with gastro-esophageal reflux disease (2). There was complete resolution of heartburn after 4 weeks of daily esomeprazole therapy. On-demand therapy with esomeprazole was significantly more effective than placebo in controlling symptoms. The frequencies of adverse effects and laboratory profiles were similar in the two groups when adjusted for the time spent in the study.

© 2006 Elsevier B.V. All rights reserved.

To examine the pharmacokinetics and pharmacodynamics of esomeprazole, 12 healthy men took once-daily esomeprazole 5, 10, or 20 mg, or omeprazole 20 mg for 5 days in a crossover study (3). The pharmacokinetics of esomeprazole were time- and dose-dependent. There was greater acid inhibition with esomeprazole than with omeprazole.

Estrogens

See also Individual agents

General Information

For a complete account of the adverse effects of estrogens, readers should consult the following monographs as well as this one:

- Diethylstilbestrol
- Hormonal contraceptives—emergency contraception
- Hormonal contraceptives—oral
- Hormone replacement therapy—estrogens
- Hormone replacement therapy—estrogens + androgens
- Hormone replacement therapy—estrogens + progestogens.

The physiological secretion of endogenous estrogens rises and falls during the monthly cycle; it is much lower before the menarche and after the menopause than during the period of fertility. Any use of estrogens that deviates from this pattern is therefore unphysiological.

Types of estrogen

The primary estrogen in premenopausal women is 17-β-estradiol (E2), which is synthesized by developing ovarian follicles. Estradiol is oxidized to estrone (E1) and then to estriol (E3). Estrone is also produced in peripheral tissues by aromatization of androstenedione, an androgen precursor that is produced by both the ovaries and the adrenal glands; after the menopause, estrone produced in this way becomes the predominant estrogen. All of the estrogens are sulfated and glucuronidated before excretion.

Natural 17-β-estradiol undergoes first-pass metabolism when given by mouth, and other compounds have therefore been preferred for therapeutic purposes. For the estrogen component of the oral contraceptives, mestranol (ethinylestradiol-3-methyl ether) was originally used, but since it was suspected of adverse effects it was by 1969 largely replaced by unesterified ethinylestradiol. 17-α-estradiol has also been synthesized (or extracted from pomegranates) and studied, but it binds much more weakly than the 17-α congener to estrogen receptors. 17-β-estradiol in micronized form, to improve systemic availability, has also been used in various products, especially in Scandinavia.

For estrogen replacement therapy, the less potent estrogens, estrone and estriol, have been widely used, as well as the semi-synthetic compound epimestrol.

In North America, much publicity has for many years been devoted to the supposed merits of "equine estrogens," also known as "conjugated estrogens" (Premarin), described as comprising a natural product extracted from the urine of pregnant mares. However, since pregnant mares were an inadequate source of starting material, these preparations have for a long time apparently been based primarily on synthetic substances (estrone with some equilin), although in some products a small amount of natural material may be present. The Food and Drug Administration in the USA long took the view that sodium estrone sulfate and sodium equilin sulfate were the sole active ingredients of the original product, but this was challenged by the manufacturers, who adduced evidence that dehydroestrone sulfate, and perhaps other components, could play a role. Overall, however, the view seems to be that the effects of Premarin are similar to those of other weak estrogens, whether given singly or in combination.

For injectable formulations used in estrogenic hormone replacement therapy, various esters of beta-estradiol have been most widely used.

Estradiol (E2) (rINN)

As noted above, 17-β-estradiol has hardly been used by the oral route, except in micronized form. The micronized product is also available in the form of an intranasal spray for the treatment of menopausal symptoms; this can give rise to mild irritation, leading to sneezing (1).

Estriol (E3) (rINN) and estrone (E1) (rINN)

Estriol is a very weak estrogen, usually given in oral doses of 1–2 mg/day, which has effects similar to those of ethinylestradiol at about 1/100th of this dosage: that is the vulva and vagina respond, but there is little effect on the endometrium. Similar considerations apply to estrone and to conjugated equine estrogens; most of the activity in the latter is in fact due to the presence of sodium estrone, which appears to be added to most formulations, in view of the limited supply of genuine equine estrogens.

Epimestrol (rINN)

The adverse effects of epimestrol (3-methoxy-17-epiestriol), a very weak estrogen with some ovulation-inducing effects, are largely as one would expect. In one series, hot flushes, insomnia, anorexia, nausea, and vomiting were reported in 1.5%, headache in 3%, and uterine bleeding in 38% (2). Ovarian hyperstimulation is rare but not unknown. As is usual with such treatment, the incidence of the adverse effects reported varies greatly, no doubt

© 2006 Elsevier B.V. All rights reserved.

reflecting differences in the motivation of the patients and the schemes of administration used.

Ethinylestradiol (rINN)
Ethinylestradiol is discussed under hormonal contraceptives.

Fosfestrol (rINN)
Fosfestrol is an unusual agent used in Japan for the treatment of prostatic carcinoma but not accepted by experts in Europe. Described as an estrogen, in European studies it had a high incidence of complications, including fluid retention (16%), myocardial infarction (10%), and thromboembolism (6.3%). A case of adrenocortical insufficiency has now been documented in Japan, involving a 59-year-old man who had taken the drug for 10 years (3).

Quinestrol (rINN)
Quinestrol is an ether of ethinylestradiol. It is stored in body fat and hence acts for weeks or months after a single oral dose; in the event of adverse reactions, this makes prompt termination of exposure impossible.

Non-steroidal estrogens
The non-steroidal estrogens diethylstilbestrol (rINN) and cyclofenine (rINN) are covered in separate monographs.

Uses

Estrogens are used principally for:

- relief of the symptoms of the menopause
- treatment of postmenopausal vaginal atrophy
- contraception, in combination with a progestogen
- hormone replacement therapy, alone or in combination with a progestogen, an androgen, or both.

Hormone replacement therapy should be distinguished from the short-term therapeutic use of estrogen (or hormonal combinations) around the time of the climacteric for the relief of acute (primarily vasomotor) symptoms; such treatment can generally be limited to some 6–12 months although if it is then withdrawn the symptoms may recur (4). Confusion between these two forms of treatment has led to a series of misunderstandings regarding the adverse effects of true hormone replacement therapy.

Oral contraception and hormone replacement therapy are dealt with specifically in separate monographs. Here the general adverse effects of estrogens for any indication are reviewed.

"Equine estrogens" (Premarin)

The controversy regarding the composition of Premarin and what are regarded as its generic equivalents has been outlined above. While still in use for hormone replacement therapy, these products have also been used as a means of reducing unwanted bleeding, for example in uremia (5,6), although their efficacy has been challenged. Estrogens have also been used in the treatment of bleeding in hereditary hemorrhagic telangiectasia (7,8).

General adverse effects

Salt and water retention due to estrogens can cause weight gain and a rise in blood pressure. Changes in liver function tests can occur and jaundice is sometimes seen. Mild gastrointestinal upsets are not unusual. Unwanted endocrine effects include uncomfortable stimulation of the breasts and endometrial bleeding. In men, estrogens produce gynecomastia. Hypersensitivity reactions are rare and include urticaria, edema, and bronchospasm.

Estrogens can be associated with endometrial carcinoma, liver tumors, and breast tumors; they can also promote the further growth of pre-existing estrogen-dependent tumors.

When conjugated estrogens are used to control bleeding they are generally given only in short courses and are therefore well tolerated. As recommendations for control of bleeding involve administration of Premarin on a limited number of occasions (no more than five or seven doses) the usual hormonal problems associated with estrogens will be avoided. Gross hepatic disease is regarded as a contraindication. Headache, flushing, and nausea have been observed after intravenous injections and slow injection is therefore recommended.

Men taking estrogens generally do so in the course of palliative treatment for malignancies (prostatic carcinoma), for which high doses have sometimes been used. Estrogen therapy in men with prostate cancer may be superior to castration in terms of efficacy, but orally administered estrogens are associated with adverse effects: gynecomastia, loss of sexual function, and unacceptable cardiovascular toxicity (9). Low-dose estrogens in combination with anti-androgens or antithrombotic agents may be better tolerated.

Estrogenic effects of non-estrogens

Over the last 50 years, it has been realized that environmental chemicals, such as pesticides and industrial chemicals, can have hormone-like effects in wildlife and humans (10). These chemicals may:

- mimic the effect of endogenous hormones
- antagonize the effect of endogenous hormones
- alter the synthesis and metabolism of endogenous hormones
- alter the synthesis and metabolism of hormone receptors.

There have been reports that aviation crop dusters handling DDT had reduced sperm counts and workers at a plant producing the insecticide kepone had reduced libido, became impotent, and had low sperm counts. Subsequently, animal experiments showed that these pesticides have estrogen-like activity. Man-made compounds used in the manufacture of plastics interfered with experiments on natural estrogens. Some detergents and antioxidants are not themselves estrogenic, but on degradation during sewage treatment can release estrogenic alkyl phenols, such as bisphenol-A, nonylphenol, and phenylphenols. Polycarbonate flasks release bisphenol-A, which can also contaminate the contents of canned food in which polycarbonate coatings are used; bisphenol-A is also used in dental sealants and composites and can leach from teeth into saliva. Polystyrene tubes can release

© 2006 Elsevier B.V. All rights reserved.

nonylphenol. The surfactant nonoxynol is used as intravaginal spermicide and condom lubricant; in animals it is metabolized to free nonylphenol. Other xeno-estrogens include the plasticizers benzylbutylphthalate and dibutylphthalate, the antioxidant butylhydroxyanisole, the rubber additive *para*-phenylphenol, and the disinfectant *ortho*-phenylphenol.

Organs and Systems

Cardiovascular

Estrogens have both wanted and unwanted effects on the cardiovascular system, depending on the manner in which they are used. Hormone replacement therapy is used in the hope of reducing the risk of ischemic heart disease after the menopause. The reduction in risk may be as much as 50% and is attributed variously to vasodilatation mediated by the endothelial production of prostaglandin I_2 (prostacyclin), effects on coagulation factors and endothelial function, and improvements in serum lipids (increased concentrations of HDL cholesterol and reduced concentrations of LDL and total cholesterol) (11), but variable effects on triglycerides. However, estrogens (especially as used in contraception but also postmenopausally) can have a marked effect on clotting factors and renin substrate, increasing the risk of thromboembolism.

The Coronary Drug Project in men taking different doses of estrogens showed a dose-related increase in myocardial infarction and thromboembolic diseases (12).

Respiratory

Allergic bronchospasm occurs very rarely with estrogens (13), but has been reported several times in women with an existing allergic tendency or a history of asthma; some asthmatic women have worse symptoms during the luteal phase of the menstrual cycle. In affected cases, the link with estrogens can be demonstrated by rechallenge.

Nervous system

Various types of headache can occur; in patients with migraine, attacks can be precipitated, usually with prominent visual phenomena.

- In a woman with history of chorea in the distant past, a vaginal cream containing estrogens precipitated an attack.

In a randomized, double-blind, placebo-controlled arm of the Women's Health Initiative, 10 739 postmenopausal women, aged 50–79 years, with prior hysterectomies, were randomly assigned to receive either conjugated equine estrogen 0.625 mg/day or placebo. There was an increased risk of stroke (RR = 1.39; 95% CI = 1.10, 1.77).

Sensory systems

Retinal vein occlusion (14–17), retinal artery occlusion (18), and optic neuritis (19,20) have been described in women taking estrogens.

In older women, estrogens cause a slight rise in intraocular pressure (SED-12, 1031) (21).

Psychological, psychiatric

The effects of estrogens on mood tend to be positive, and improved performance in intellectual tests has been described (SEDA-20, 382) (22); this is in parallel with the known effects of endogenous estrogens. During the menopause some women become depressed and irritable, and the ability of estrogens to correct this has been delineated in various studies, including work with estradiol given transdermally (23). Some workers also claim increased vigilance, and have concluded that this is reflected in encephalographic changes. There is even some evidence of an improvement in mental balance and self-control when estrogens are given to demented and aggressive old people of both sexes (24). However, all of these effects of estrogens on mood or mental performance are only likely to last for as long as the treatment does, and the effects on mood may occur only at the start of treatment; altered mood can follow acute withdrawal.

Endocrine

In postmenopausal women taking long-term mestranol there was a fall in the serum concentration of unbound (free) thyroxine, but it was not associated with hypothyroidism; the serum concentration of thyroid-stimulating hormone was unchanged (25).

Metabolism

Conflicting data concerning the effects of oral contraceptives on carbohydrate metabolism have been presented; the effects are probably clinically insignificant. However, estrogen hormone replacement therapy with a sequential-type product containing mestranol and norethisterone caused significantly impaired glucose tolerance (26).

There is no doubt that with appropriate treatment regimens, altered lipid metabolism due to estrogens can improve (27). In women with familial hypertriglyceridemia or increased triglycerides from other causes, oral estrogens can increase triglyceride concentrations. However, transdermal estrogens can lower triglycerides and generally produce smaller changes in lipoproteins than oral therapy, although it may be that whatever differences are observed merely reflect differing degrees of absorption.

Porphyria can be precipitated by estrogens, and familial porphyria cutanea tarda can become manifest (28).

Metal metabolism

Estrogens increase serum copper concentrations (SED-12, 1030) (29).

Fluid balance

Retention of water and salt and consequent weight gain are common during estrogen therapy. Fluid retention can cause a feeling of abdominal pressure, sensations resembling the premenstrual syndrome, breast tenderness, bloating, and edema. These symptoms can largely be relieved by a mild diuretic, but it is only practicable to use this approach if the estrogen treatment is cyclical and

© 2006 Elsevier B.V. All rights reserved.

the symptoms thus intermittent, since it is undesirable to give diuretics continuously to healthy women over a long period of time.

Hematologic

There is a risk of thrombosis with estrogens, discussed in detail in the monograph on Hormonal contraception. Both superficial and deep complications can occur in either sex. Effects on clotting factors and renin are involved: in one small study, men taking estrogens had increased concentrations of factor VII, factor VIII, and fibrinogen, pointing to a hypercoagulable state and platelet activation (30).

In hormone replacement therapy, the risk of deep vein thrombosis is increased by a factor of 2–4 (31–33). The absolute increase in the treated population as a whole is low, with about one case of venous thromboembolism in 5000 women-years of use of hormone replacement therapy. However, in the subgroup with pre-existing risk factors, such as obesity, varicose veins, smoking, and a prior history of venous thromboembolism or superficial thrombophlebitis, the increase in risk from hormone replacement therapy can be substantial; among these women are those with a genetic predisposition to thrombosis, generally due to some form of thrombophilia, such as deficiency of the coagulation inhibitors protein S, protein C, or antithrombin III. In any of these subjects thrombosis can occur early in hormone replacement therapy. However, this tendency to early occurrence of deep vein thrombosis also seems to be present in all those who take hormone replacement therapy.

The mechanisms of thrombotic complications are multiple. Fibrinolytic activity falls in postmenopausal women when a high dose (250 micrograms/day) of ethinylestradiol is given for 10 days in preparation for prolapse operation (34). On the other hand, long-term administration of mestranol 80 micrograms/day to postmenopausal women for 1 year or longer increased the concentrations of fibrinogen and l-trypsin inhibitor and reduced plasminogen (SED-12, 1030) (35). There is also evidence that even low doses of oral estrogens increase the amount of thrombin generated in vivo.

It has been suggested, on the basis of a case of multiple systemic arterial thrombi in a patient with a prosthetic heart valve, that if estrogens are needed in such individuals they should be combined with anticoagulants. One would be inclined to extend the warning: any woman with a pre-existing risk of thrombosis should be examined very carefully before deciding to give estrogens at all.

The hypercoagulability that can occur with conjugated estrogens has been reported to be less pronounced than with oral contraceptives, but it is not clear that it is less than that seen with other types of estrogen used in hormone replacement therapy (36). The hematological effects of different estrogens are additive; various reports have demonstrated this for ethinylestradiol and diethylstilbestrol (37), which would mean that nothing would be gained by using several estrogens in parallel at reduced doses.

Some work suggests that when estrogens are given parenterally or transdermally rather than orally, the unwanted effects on the clotting process are reduced (38). The most important pharmacokinetic difference is that first-pass metabolism in the liver is avoided in all forms of non-oral therapy, which in the case of estrogens includes percutaneous gels, implants into the abdominal wall or buttocks, transdermal patches, and vaginal tablets, rings, and creams. It may therefore be prudent to use transdermal estrogens or another form of parenteral therapy when seeking to prevent osteoporosis in women with a tendency to thrombosis or hypertension.

For reasons that are not clear, other facets of the blood system are also affected by estrogens. After 6-months treatment with low doses of conjugated estrogens, hemoglobin concentration and mean erythrocyte counts were significantly reduced (39); on the other hand, the hematocrit was significantly increased by high-dose estrogen + androgen at 6 months, while the mean white blood cell count was significantly increased by low-dose estrogen + androgen at 12 months (39).

Mesenteric venous thrombosis has been reported in men taking estrogen therapy for carcinoma of the prostate (SED-12, 1032) (40).

Gastrointestinal

Estrogens can cause dose-related nausea, which is not reduced by using enteric-coated tablets. It has been claimed that there is a significantly lower incidence of nausea with estrogen + androgen than with conjugated estrogens.

Intestinal ischemia has occasionally been attributed to conjugated estrogens (22,41).

There is some reason to distinguish this from the ischemia that can be caused by oral contraceptives, in that it is restricted to the colon, can have a chronic or remitting course, can present with non-specific abdominal and colonic symptoms, can be reversible despite continued use of estrogen, and does not require surgical treatment. The symptoms of intestinal ischemia resolve within days to weeks after withdrawal of the estrogen. However, oral contraceptives have also been reported to cause ischemic colitis.

- A 19-year-old woman developed abdominal cramps, nausea, vomiting, diarrhea, and rectal bleeding (42). She was taking no medications other than Norinyl-2 (norethindrone 2 mg and mestranol 1 mg), which she had taken for 6 months. Just before the onset of the symptoms she had taken dimenhydrinate 100 mg and two ExLax tablets (90 mg of phenolphthalein) for constipation. Colonic X-rays showed impaired mesenteric circulation and bowel ischemia. Her symptoms subsided within 96 hours of withdrawing the oral contraceptive and giving supportive therapy (including intravenous fluid infusion, nasogastric suction, analgesics, and antiemetics). Further radiology showed that the ischemia had resolved.

Estrogens can cause or aggravate constipation (43), but when it occurs it is more likely to be due to the calcium carbonate that many women take as a daily supplement in postmenopausal treatment.

Liver

Changes in liver function tests can occur during estrogen treatment (44). In one comparative study, ethinylestradiol had an unfavorable effect on liver protein synthesis (SED-12, 1030) (45).

© 2006 Elsevier B.V. All rights reserved.

Cholestatic jaundice has often been reported with oral estrogens and is probably related to an effect on the permeability of the canalicular membrane (SEDA-20, 381). Cholestatic jaundice induced by a subcutaneous estrogen implant has also been reported in the absence of any other cause of liver disease (SEDA-20, 381). After removal of the implant the patient's symptoms resolved. The authors' explanation was that fragmentation of the implant had led to release of excessive amounts of estradiol.

The effects of estrogens on liver function differ with the type of estrogen used, problems being particularly associated with 17-substituted steroids. Significant reductions in transaminases, lactate dehydrogenase, and alkaline phosphatase have been found at 6 and 12 months with various forms of estrogen therapy. A reduction in mean bilirubin concentration has been described at 6 months with high-dose conjugated estrogens, and a significant increase in mean bilirubin concentration with low-dose estrogen + androgen at 12 months.

In some studies, women taking estradiol or conjugated estrogens for hormone replacement therapy had no cholestasis or hepatotoxicity, as assessed by rises in serum alkaline phosphatase, bilirubin, or transaminases, whereas these effects did occur with ethinylestradiol.

Pancreas

There is a small but significant risk of acute pancreatitis at 2–78 weeks after the start of hormone replacement therapy; the pain usually abates within 10 days of withdrawal (46).

Urinary tract

In the past, hypernephroma was thought to result from estrogen treatment. However, there is no clear evidence that this is so. There is evidence that older women with an intact uterus become more susceptible to urinary tract infections by taking estrogens (47). This is surprising, since some other studies, admittedly in selected patients, have shown a reduction in such infections when hormone replacement therapy is used. In another study, hormone replacement therapy improved urinary incontinence and nocturia after 6 months in postmenopausal women, without affecting bacteriuria (48).

Skin

Diffuse prickly erythema has been attributed to ethinylestradiol in various oral contraceptive formulations.

- A woman taking an oral contraceptive (Marvelon, ethinylestradiol 30 micrograms + desogestrel 150 micrograms) developed diffuse prickly erythema in an exposed site less than 20 minutes after sun exposure (49). Phototesting showed photosensitivity in the UVB and UVA ranges, but routine patch and photopatch tests with Marvelon were negative. All abnormal findings reversed 4 months after withdrawal of the oral contraceptive, but reappeared when she started using another oral contraceptive (Microgynon 30, ethinylestradiol 30 micrograms + levonorgestrel 150 micrograms). Phototesting was again abnormal. Her symptoms disappeared after withdrawal of the oral contraceptive. Porphyrin production was normal.

Although the estrogen and progestogen were not tested separately in this patient, the photosensitivity was most probably due to the estrogen, because the oral contraceptives that she used contained ethinylestradiol 30 micrograms with different progestogens, and photosensitivity has been described with estrogens (50).

- A 47-year-old postmenopausal woman developed eczematous lesions at the sites of application of an estradiol transdermal system and subsequently at the sites of application of an estradiol gel (51). She was therefore given oral estrogen instead, but this promptly elicited a systemic pruritic rash. The causal link was in all instances confirmed by patch-testing.

Estrogens can cause chloasma (52).

Papillomatous melanocytic nevi can be induced by estrogens (53), and melanocytic lesions can contain large numbers of estrogen and progestogen receptors (54).

When transdermal estrogens are used there can be problems with poor adhesion and skin irritation. The latter occurs more often in hot humid weather and can rarely proceed to edema, induration, a vesicular rash, residual pigmentation, itching, and erythema (55).

Three patients developed erythema nodosum during estrogen replacement therapy (56).

Topical estrogens can reduce skin aging (57), for example with reduced wrinkling and increased firmness in the dermis of perimenopausal women, although it is not clear that the effect is more marked than with oral treatment. Certainly, estrogens augment dermal water content by increasing hyaluronic acid and mucopolysaccharides, improving the structure of elastic fibers, and increase vascularization.

Sexual function

Libido, sexual activity (including masturbation), and orgasm increase in women taking the combination of an estrogen with an androgen, but it is not clear that estrogens alone have any such effect (58,59). Reduced libido and reduced sexual activity are to be expected in men treated with estrogens.

Reproductive system

All estrogens, even less potent ones, can cause endometrial hypertrophy and bleeding in a proportion of users after the menopause; in high doses the complication is common (60). With continuous estrogen therapy, the bleeding is irregular and unpredictable, whereas cyclical use of a combination with a progestogen is likely to produce something resembling normal menstruation, although it generally abates as treatment continues (60).

Estrogens can cause painful tingling and swelling of the breasts, sometimes requiring withdrawal of treatment. Frank gynecomastia can occur in men by exposure to estrogens in a factory environment and has even been described in an elderly man whose wife used an estrogen-containing vaginal lubricant (SEDA-6, 350).

In men, estrogens cause pigmentation of the areola followed by gynecomastia, both during oral treatment and local application (61). Estrogen-induced

© 2006 Elsevier B.V. All rights reserved.

gynecomastia can be prevented in men with prostatic carcinoma by irradiating the breast region before starting therapy.

Immunologic

Estrogens can have adverse immunological effects, which could predispose to infections (62).

The immunological effects of two contraceptive combinations, namely Valette (dienogest 2.0 mg + ethinylestradiol 0.03 mg) and Lovelle (desogestrel 0.15 mg + ethinylestradiol 0.02 mg), have been examined during one treatment cycle (63). Lovelle significantly increased the numbers of lymphocytes, monocytes, and granulocytes. Valette reduced the CD4 lymphocyte count after 10 days and Lovelle did the opposite. Lovelle increased CD19 and CD23 cell counts after 21 days. Phagocytic activity was unaffected by either formulation. After 10 days both contraceptives reduced serum IgA, IgG, and IgM concentrations, which remained low at day 21 with Lovelle but returned to baseline with Valette. Secretory IgA was unaffected by either contraceptive. Neither treatment affected concentrations of interleukins, except for a significant difference between the treatment groups in interleukin-6 after 10 days, which resolved after 21 days. Concentrations of non-immunoglobulin serum components fluctuated; macroglobulin was increased by Valette. However, total protein and albumin concentrations were reduced more by Lovelle than Valette. Complement factors also fluctuated. There was no evidence of sustained immunosuppression with either Valette or Lovelle.

A severe anaphylactic reaction occurred in one patient who was given an intravenous formulation of conjugated estrogens (SED-12, 1033) (64). Some formulations of conjugated estrogens contain foreign (equine) material.

Long-Term Effects

Tumorigenicity

For the sake of simplicity the carcinogenic effects of estrogens in all formulations, including the combined oral contraceptives, are included here.

Knowledge of tumor induction by sex steroids is largely based on interpretation of epidemiological data, with careful exclusion of possible confounding elements. Hepatic tumors have given rise to most concerns, but some evidence also indicates an increased incidence of various other malignancies, including carcinomas of the breast, endometrium, and prostate (65).

The overall incidence of reproductive cancers attributable to oral contraceptive use has been estimated in a modeling analysis (66). The authors assumed a 50% reduction in ovarian and endometrial cancers associated with 5 years or more of tablet use, and used two alternative scenarios for breast and cervical cancer effects. If oral contraceptive use produces a 20% increase in breast cancer before age 50 and the same increase in cervical cancer, then for every 100 000 tablet users there would be 44 fewer reproductive cancers and these users would gain one more day free of cancer. If instead the increase in risk of early breast cancer and of cervical cancer is 50%, oral contraceptive users would have 11 fewer cancer-free days.

Liver tumors

In dealing with liver tumors, it is essential to consider all the various types of sex steroids in a single review since they seem to resemble one another closely in their long-term effects on this organ. The nomenclature used in the literature is unfortunately confusing: most reports differentiate between "hepatic adenoma" and "focal nodular hyperplasia," but the latter term is also sometimes used to cover the whole range. Other terms that have been used are "focal cirrhosis," "regenerative hyperplasia," "hamartoma," "mixed adenoma," and "benign hepatoma," while "peliosis" may constitute a precancerous state.

Androgens and anabolic steroids

There is no essential difference between androgens and so-called anabolic steroids. High doses of either, such as can be used in refractory anemias, have been associated with the induction of benign liver tumors and primary hepatocellular carcinoma. The fact that primary hepatoma, liver adenoma, and peliosis are uncommon conditions and that there is a considerable overlap between the patients concerned and the tiny fraction of the population taking high-dose androgens strongly suggests that the association of both events is more than coincidental (67). Some animal studies and in vitro studies have also pointed to a hepatic carcinogenic effect of anabolic steroids. No cases seem to have been described in sportsmen who have used high-dose androgens or in girls suffering from precocious puberty, but the former at least often use these drugs for relatively short periods; furthermore, such use is likely to be surreptitious and thus poorly documented. Most of the widely used compounds in this class, including methyltestosterone, have been reported to induce liver tumors. The apparent exceptions are the nortestosterone derivatives without 17-alpha substitution. Whether these drugs are indeed safer or whether they have merely been used less often in high doses is not known.

The incidence of liver tumors following the use of androgens and anabolic steroids still cannot be calculated. What is clear is that if these products are used in high doses or over long periods of time (and there is now much doubt about whether they are more than marginally effective in such conditions as osteoporosis and aplastic anemia), techniques such as CT scanning and ultrasonography should be used routinely to ensure early detection of liver lesions.

Oral contraceptives, estrogens, and benign liver tumors

The effects of oral contraceptives on the liver include not only benign liver tumors (focal nodular hyperplasia, hepatic adenoma, and hemangioma) (68) and hepatocellular carcinoma, but also peliosis hepatis (69), sinusoid dilatation (70), and such probably unrelated shorter-term complications as jaundice and gallstones.

However, the causal association between oral contraceptives and certain benign liver tumors has been well documented in humans, and the same association arises with conjugated estrogens (71), diethylstilbestrol, and

© 2006 Elsevier B.V. All rights reserved.

probably antiestrogens. The evidence for the link is based on many case reports, reviewed in SEDA, and on some case-control studies, which first appeared in 1976 and 1981, pointing to a correlation (SED-14, 1450). The relative risk of benign liver tumors in users of conjugated estrogens or oral contraceptives compared with non-users may be about 40:1, although the figure is still low in absolute terms. Animal studies suggest in fact that estrogens, taken alone or in combination with progestogens, can increase the size of pre-existing liver tumors, but do not initiate tumor formation themselves; however, whether these formulations actually induce tumors or promote a latent tendency to tumor development is not of essential importance. Although there is some evidence that liver cell adenomas can regress after oral contraceptives are withdrawn (72), they do not always do so (73).

It is clear that any woman with "pill"-associated liver lesions should avoid all further use of hormonal contraceptives and related products.

Oral contraceptives and malignant liver cancer

Malignant cancer of the liver is still a very rare disease in young women, but case-control studies are possible. Evidence from both sides of the Atlantic suggested from 1987 onwards that there might be a significant relation between oral contraceptives and hepatocellular carcinoma (74–76). However, even the best of these studies had some limitations, for example incomplete data as regards a history of hepatitis or the extent of contraceptive use. One authoritative attempt to estimate the degree of risk was made by the World Health Organization in 1989, matching 122 newly diagnosed cases of primary liver cancer to 802 controls; the relative risk of liver cancer in women who had at any time used combined oral contraceptives was estimated at 0.71; there was no consistent link with months of use or time since first or last use (77). A major examination of the issue appeared in 1992, when it was concluded that the relative risk for sometime users of oral contraceptives was 1.6, rising to 2.0 in those who used the products for more than 10 years (78).

In a review of the earliest studies of hepatocellular carcinoma, it was concluded that oral contraceptives may not interact with other hepatic carcinogens, and that if they do not interact they may not measurably enhance the risk of liver cancer in parts of the world where hepatitis B virus is endemic and hepatocellular carcinoma is common (79). Others have since suggested a positive association between parity or gravidity and hepatocellular carcinoma, which needs to be further explored (80).

Conjugated estrogens

The same association with benign liver tumors arises with conjugated estrogens (71), diethylstilbestrol (q.v.), and probably antiestrogens. The evidence for the link is based on very numerous case reports from the field, reviewed in the Annuals in this series, but also on some case-control investigations. Studies of the latter type first appeared in 1976 and 1981, and both pointed to a correlation (SED-12, 1024). The relative risk of benign liver tumors in users of conjugated estrogens or oral contraceptives compared with non-users may be about 40:1, although the figure is still low in absolute terms.

Uterine tumors

The extent to which tumors of the reproductive tract are associated with hormonal treatment varies greatly with the type of tumor and the type of treatment involved.

Hormonal replacement therapy and endometrial carcinoma

In untreated women, the main risk factors for endometrial carcinoma are age, obesity, nulliparity, late menopause (and possibly early menarche), the Stein–Leventhal syndrome, exposure to exogenous estrogens, radiation, and certain systemic diseases, including diabetes mellitus, hypertension, hypothyroidism, and arthritis (SED-14, 1451) (81). Certain of these risk factors indicate that an altered endocrine state with increased estrogen stimulation is a predisposing cause, and one might thus in theory expect estrogen treatment (and notably hormonal replacement therapy) to increase the risk (SEDA-22, 466).

In women with an intact uterus, the risk of endometrial hyperplasia and cancer increases with increasing dose and duration of estrogen use. Adding a progestogen to estrogen-only therapy for at least 12 days a month greatly reduces this risk. However, it is not clear why the complication develops only in certain users. The risk of developing endometrial cancer during HRT seems to vary individually, perhaps because of genetic rather than exogenous factors. In women with endometrial cancer, women who reported ever taking HRT were more than twice as likely to develop endometrial cancer as women who had never taken it (OR = 2.24; 95% CI = 1.19, 4.23) and among these women the risk of endometrial cancer was higher for women homozygous for the CYP17 T-allele (OR = 4.10; 95% CI = 1.64, 10.3), but not for women with the C-allele. These preliminary findings suggest that CYP17 or other variants in estrogen biosynthesis or metabolism pathways may be markers of susceptibility to endometrial cancer among users of estrogen replacement therapy (82).

Two epidemiological studies published in 1975 first suggested that the use of estrogens during and after the menopause increased the risk of endometrial cancer, and in 1986 the authors of an authoritative review (83) endorsed these findings, concluding that there was an increase in risk among users, relative to non-users, of 4–9 times; the risk increased with both the strength of the medication and the duration of use. A 1990 review of data up to that time suggested that estrogen replacement therapy, continued for over 2 years without concurrent progesterone therapy, was associated with an approximately three-fold increase in the risk of both localized and extrauterine cancer; this risk increased with duration of use and persisted for over 6 years after withdrawal of therapy (84). These studies have been criticized from a methodological point of view, particularly since there is evidence of a detection bias that arises from the increased diagnostic attention received by women with uterine bleeding after estrogen exposure and perhaps also from a greater tendency of women to bleed from a pre-existing tumor when

© 2006 Elsevier B.V. All rights reserved.

estrogens are given (85). It could be that the magnitude of the association between estrogens and endometrial cancer has been greatly overestimated for such reasons, and that the real odds ratio is less than estimated, but it seems unlikely that the risk can be disproved. There is, for example, some older evidence that even when the above-mentioned bias has largely been eliminated, there is still a correlation between the use of estrogens and endometrial carcinoma, the evidence being strongest for the first-generation oral contraceptive products, which contained large amounts of estrogen. One such study still found a six-fold risk among estrogen users compared with non-users (86); long-term users (over 5 years) had a 15-fold risk; there were excess risks for both diethylstilbestrol and conjugated estrogens. Another well-controlled study, from 1986, similarly found increased risks with conjugated estrogens, the greatest increases in risk being associated with a dosage of 0.625 mg/day or greater and duration of use of 10 years or more (87). Although according to this study the risk remained high even among women who had stopped using conjugated estrogens 5 or more years before, one cannot ignore an earlier finding, based on evidence from a large group practice, that a sharp downward trend in the incidence of endometrial cancer occurred in parallel with a substantial reduction in prescriptions for replacement estrogens (88).

Among the many papers that have since then incriminated estrogens, particularly the conjugated estrogens so widely used in North America, some have presented more subtle conclusions. One paper specifically incriminated estrone (89), but this is of course a major component of conjugated estrogens. A case-control study from Buffalo, New York, found that while patients with endometrial cancer and healthy controls had used similar amounts of menopausal estrogens, estrogen users had a significantly higher frequency of low-grade tumors and a correspondingly better survival rate (90). Menopausal estrogens became popular much later in Europe, and relatively little evidence has emerged to complement the US findings. In 1983, however, when Persson in Sweden completed a very large cohort study, he found that while among women treated with estrogens there was no significant increase in endometrial cancer compared with the control population, there was indeed a significantly increased incidence of premalignant lesions among women who had used estrogens alone for more than 3 years (91). A protracted case-control study in a Swiss population pointed in the same direction; the use of HRT for 5 years or more created a mean relative risk of 1.9, and use for 5 years or more a relative risk of 5.1 (CI 2.7, 9.8) (92). This, as well as evidence that progestogens have some protective effect on the endometrium (93), emphasizes the need for prospective studies in different subpopulations taking different types of replacement therapy.

Some helpful evidence comes from related fields. It should be borne in mind, for example, that the question of an increased risk of endometrial hyperplasia and endometrial cancer also arises in patients with estrogen-producing tumors of the ovaries, obesity, and polycystic ovarian syndrome (94) and in patients with breast cancer who are using tamoxifen (95).

During one 3-year study, under 1% of 596 women taking placebo or an estrogen + a progestogen had an abnormal endometrial biopsy. Of women taking an unopposed estrogen, 12% developed typical hyperplasia, 23% complex hyperplasia, and 28% simple hyperplasia. Use of HRT for 15 or more years resulted in a significantly higher relative risk of 1.3 for breast cancer, but was also associated with a significantly lower total mortality (96). The use of combined therapy was not associated with an increased risk of endometrial carcinoma, unless the progestogen was added for less than 10 days each month (97).

Detailed studies may also help to clarify further the risks and the possible interaction of estrogens with other susceptibility factors for endometrial tumors; there is, for example, an impression that the risk is greater in lean than in overweight women, although upper abdominal obesity is thought to reflect a higher risk. Patients who develop endometrial cancer often have an increase in estrogen production, reduced ovulation, and a lower sex hormone binding globulin concentration, resulting in high concentrations of free estrogen. As regards subjects of low susceptibility, the cancer threat may be less in women who have used oral contraceptives earlier.

One can also recognize some correlations between the subtype of tumor and the type of hormonal exposure. Unopposed hyperestrogenism is most likely to be associated with the endometrioid type of endometrial carcinoma, rather than with clear-cell, serous-papillary, and mucinous carcinomas.

Remarkably, the survival curves for women taking estrogens and developing adenocarcinomas are actually better than in women not taking estrogens and not developing adenocarcinomas. In 1822 women with angiographically documented severe coronary artery disease, the mortality among estrogen users was 4% compared with 35% among non-users, suggesting that the benefit of postmenopausal estrogen replacement therapy may be even greater in women with established coronary artery disease than it is in healthy women. A possible explanation is that estrogen replacement therapy in postmenopausal women reduces the risk of coronary heart disease by 5% or more.

Like a history of breast cancer, a history of cancer of the endometrium is commonly regarded as a reason to avoid HRT with estrogens. One study, though limited in duration, provided encouraging evidence that such treatment at least does not adversely affect the rate of recurrence or the survival time (98).

Of 249 women with surgical stage I, II, and III endometrial cancer treated between 1984 and 1998, 130 used estrogen replacement after their primary cancer treatments and half of these used progesterone in addition to estrogen. Among this cohort, 75 matched treatment-control pairs were identified. The hormone users were followed for a mean of 83 months and the non-hormone users for a mean of 69 months. There were two recurrences among the 75 HRT users compared with 11 recurrences in the 75 non-hormone users. Hormone users had a statistically significant longer disease-free interval than untreated women. Whether this is sufficient to conclude that the effect is actually positive is not clear, but no evidence of an increase in risk came to the fore.

© 2006 Elsevier B.V. All rights reserved.

In view of the possibility that HRT can trigger malignancy in the endometrium itself, it is not surprising to find that it has also been reported to do so in endometriosis deposits elsewhere. An adenocarcinoma arose after many years of HRT in abdominal areas of endometriosis in a woman who had undergone hysterectomy and salpingo-oophorectomy 17 years before (99). It is of course known that some 1–2% of endometriosis deposits undergo malignant degeneration, and the link with HRT could therefore have been fortuitous.

The minimum dose of continuously administered norethindrone acetate needed to reduce significantly the incidence of endometrial hyperplasia associated with the use of 17-β-estradiol 1 mg/day has been investigated in a large, controlled, comparative study in 1146 women over 12 months (100). The results suggested that continuous norethindrone acetate at doses as low as 0.1 mg/day is fully effective, at least during the first year of treatment.

The evidence that concurrent use of progestogens reduces the risk of cancer induction needs to be further supplemented; if this beneficial effect of progestogens truly exists, one must still determine how they can best be used. They are widely used, but not consistently, and increase the risk of endometrial cancer both during and after treatment. Some workers have recommended that for partial protection of the endometrium, dosages of medroxyprogesterone acetate of 2.5 mg/day continuously or 5.0 mg/day given for 14 days per cycle are the minimum required to counteract the endometrial effects of continuous therapy with estrogens (101). The added medroxyprogesterone is claimed to have no effect on the efficacy of the estrogen in treating vasomotor symptoms or in preventing osteoporosis. Others have concluded that administration of continuous rather than cyclical estrogen + progestogen therapy is more likely to maintain the beneficial effects of the estrogen and yet protect against the increase in endometrial carcinoma that occurs with estrogen therapy alone (102). However, progestogens have a negative impact on circulating lipids (55); it is possible that this adverse effect is less when using natural progesterone, but this is hardly practicable. The risk of endometrial hyperplasia and endometrial cancer with estrogens given alone must therefore be balanced against this negative impact.

Thus, although our knowledge is still incomplete and needs to be extended, it is highly likely that estrogen replacement therapy given without progestogens considerably increases the risk of endometrial carcinoma. It seems likely that the use of concurrent progestogen treatment reduces the risk, but it is still uncertain how this supplementary treatment can best be administered.

The possibility that the risk of endometrial complications might have been incorrectly estimated and commonly underestimated has been examined with the hypothesis that the method of endometrial examination or sampling is crucial (103). Hysteroscopy was performed in 98 menopausal women with endometrial thickening, and the findings were matched with those of histopathology based on various means of tissue collection, including suction curettage, oriented-streak curettage, hysteroscopically targeted biopsies, or polypectomy and hysterectomy. There was an abnormal endometrium in 35 patients (65% in symptomatic and 22% in asymptomatic women) and there were six carcinomas, 18 polyps, and 11 cases of hyperplasia. Hysteroscopy had a sensitivity of 89% and a specificity of 98%. With blind sampling, tissue collection was too scant to make diagnosis possible in 29% of patients, while in 81% of patients in whom hysteroscopy showed cystic atrophy the pathologist failed to confirm this condition. Moreover, eight endometrial polyps (36%) detected by hysteroscopy were missed when samples were studied in the laboratory. Hysteroscopy with targeted sampling thus appears to be the most effective method for assessing the endometrial lining and detecting unwanted changes.

The endometrial effects of transdermal sequential combination therapy with estradiol and levonorgestrel in various doses has been examined over 1 year in 468 postmenopausal women, who each month used patches that released estradiol for 1 week followed later in the month by combined patches that released both estradiol and levonorgestrel, again for 1 week (104). The dose of estradiol was 50–100 micrograms/day and that of levonorgestrel 15–20 micrograms/day. Endometrial biopsies, obtained from 399 subjects, generally showed good tolerance for all the various combinations tested. However, there were two cases of endometrial hyperplasia at the highest doses, while the lowest dose was associated with less bleeding than the two higher doses and a somewhat different histological pattern.

Oral contraceptives and endometrial cancer

Suggestive case histories raised at an early phase the notion of a possible correlation of oral contraceptives with endometrial cancer. Among cases of endometrial cancer there seemed to be an excess of users of oral contraceptives, particularly of the early high-dose estrogen type. With the virtual demise of these early products, the situation seems to have reversed: a 1983 study from the Centers for Disease Control (CDC) in Atlanta showed that women who had used fixed combinations for oral contraception at some time in their lives had a relative risk of endometrial cancer of only 0.5 compared with never-users (105). The protective effect occurred only in women who had used oral contraception for at least 12 months, and lasted for at least 10 years after withdrawal. The WHO adopted the same view in 1988 in the light of multinational data (106). As in the case of hormonal replacement therapy, the protective effect seems to be due to the progestogen component.

Many studies have also shown a duration-related protective effect of combined oral contraceptives on endometrial cancer, the risk before age 60 being reduced by 38% after 2 years of use and up to a 70% reduction after 12 years (107). This beneficial effect continued for at least 15 years after the end of use. As with ovarian cancer, the CASH study results suggest that the lower-dose combined oral contraceptives have a protective effect similar to that of the higher-dose tablets (108).

Oral contraceptives, cervical neoplasms, and adenosis

A 1988 statistical analysis of data from the Royal College of General Practitioners study in Britain pointed clearly to an association between oral contraceptive use and cervical neoplasms (109); of 47 000 women followed

© 2006 Elsevier B.V. All rights reserved.

since 1965, those who had at some time used oral contraceptives had a significantly higher incidence of cervical cancer than never-users after standardization of other variables, including a history of sexually transmitted disease. The incidence increased with duration of use, attaining four-fold control values after 10 years of use. Other studies (110,111) similarly showed an increased risk with increased duration of use but also with the use of formulations that contained a higher proportion of estrogen or in users with a history of genital infections or abnormal Papanicolaou smears. Benign cervical adenosis and adenomatous polyps have been seen in oral contraceptive users and were prominent in some early reports (SED-11, 857). They often (but not always) disappear when medication is stopped.

By the mid-1980s it was fair to conclude that: (a) oral contraceptive use did not appear to increase the subsequent incidence of abnormal cytology among women who had normal smears at the time they began to use the products; (b) extended oral contraceptive use (over 6 years) appeared to increase by several times the rate of conversion of pre-existing cervical dysplasia to carcinoma in situ. Generally speaking, subsequent data have tended to be compatible with those conclusions, for example pointing to an increased incidence of micro-invasive cervical carcinoma and again stressing the changes in cytology and the extent to which the effect differs with the strength and composition of the product. The average risk figures that emerge are generally in line with those found in a Norwegian study, in which, after correcting for other risk factors, relative rates were found of 1.5 for current users and 1.4 for past users as compared with never-users (112). Clearly, confounding factors, such as differences in sexual activity, age at first coitus, and the number of sexual partners, can confuse the issue and make interpretation more complex (113). In addition, any discussion of the issue must today take into account the current view of the human papilloma virus (HPV) as a sexually transmitted agent that is the main cause of cervical cancer (114), and the possible influence of Herpes simplex virus type 2, smoking, and other known or emergent risk factors.

The most authoritative view on cervical cancer at present is that expressed by the WHO in 1992: "Recent studies suggest that use of oral contraceptives for more than 5 years is associated with a modest increase in relative risk (ranging from 1.3 to 1.8). The extent to which this reflects a biological relationship is uncertain, particularly given the absence of reliable information on the role of possible infectious agents, such as the human papilloma viruses ⋯" (115). In the present state of knowledge, all women taking oral contraceptives over long periods should undergo regular routine screening by cervical cytology to ensure early detection of premalignant and malignant processes.

In 2002 the Chief Medical Officer of the UK Department of Health issued an urgent communication to all Health Professionals that oral contraceptives may contribute to the development of cervical cancer in women with high-risk type HPV, because of an association between an increased risk of cervical cancer and increasing duration of use of oral contraceptives (116). There was a three-fold increase in risk after 5–9 years of oral contraceptive use versus a four-fold increase after 10 or more years in women with HPV, which is sexually transmitted. There are more than 80 HPV, only a few of which are associated with an increased risk of cervical cancer. With the current evidence it is difficult to state what the main precipitating factors for cervical cancer are—the use of oral contraceptives, sexual activity, the type of HPV, or the duration of infection. While cervical screening is not perfect, 80–90% of cervical abnormalities can be detected and treated in women who attend regular screening programmes. The Chief Medical Officer therefore advised that all sexually active women, especially those taking long-term oral contraceptives, should be encouraged to have regular cervical smears.

Oral contraceptives and uterine fibroids

In a long-term, follow-up study in Scandinavia, the risk of fibroids fell consistently with increasing duration of oral contraceptive use (117). A decade earlier, the British Royal College of Physicians study had similarly suggested a protective effect, while an Oxford study had not, but once more the issue is confused by the change in composition of oral contraceptives over the years; more recent papers thus carry the most weight. On the other hand a causal relation between apoplectic leiomyomas and oral contraceptive usage was strongly suggested by Myles and Hart in the light of their study of five histologically distinctive uterine smooth muscle neoplasms with multifocal hemorrhages (118). They thought that effects of hormonal steroids on the blood vessels in pre-existing leiomyomas might be responsible for intimal hyperplasia with or without accompanying thrombi.

Ovarian tumors

Hormone replacement therapy

While the risk that hormone replacement therapy may cause endometrial tumors has been widely discussed, less attention has been given to the possibility that it could increase the risk of epithelial ovarian cancer. Since cancer of the ovary has some risk factors in common with endometrial cancer (notably low parity and obesity), this possible risk needs to be considered, especially in view of the fact that the endometrioid epithelial type of ovarian tumor is histologically so similar to adenocarcinoma of the endometrium.

The issue has been examined in a large Australian case-control study. A total of 793 eligible incident diagnoses of epithelial ovarian cancer in 1990–93 among women living in Queensland, New South Wales, and Victoria were identified. These were compared with 855 eligible female controls selected at random. Standard questionnaires were used to obtain histories. There were no clear associations between the use of hormone replacement therapy overall and the risk of ovarian cancer. However, unopposed estrogen replacement therapy was associated with a significant increase in the risk of endometrioid or clear-cell epithelial ovarian tumors. In addition, the risk associated with estrogen replacement therapy was much larger in women with an intact genital tract than in those with a history of either hysterectomy or tubal ligation. The authors therefore suggested that postmenopausal estrogen replacement may be a risk factor associated with endometrioid and clear-cell tumors in particular.

© 2006 Elsevier B.V. All rights reserved.

The risk of ovarian cancer with various hormonal replacement regimens has been examined in a nationwide study in Sweden in relation to plain estrogen regimens as well as estrogen + sequentially added progestogens or continuously added progestogens (119). Between 1993 and 1995, the investigators enrolled 655 women with histologically verified ovarian cancers and 3899 randomly selected population controls, all aged 50–74. Data on the use of estrogen replacement therapy were collected by postal questionnaires. The risk of ovarian cancer was higher among ever-users than never-users as regards both plain estrogen supplementation (OR = 1.43, 95% CI = 1.02, 2.00) and estrogens with sequentially added progestogens (OR = 1.54, 95% CI = 1.15, 2.05); the increase in risk applied to the serous, mucinous, and endometrioid subtypes. For all cancer types combined, the greatest increases in risk were seen when hormone use exceeded 10 years. The odds ratios after ever use of low-potency estrogens were 1.18 (95% CI = 0.89, 1.55) for oral and 1.33 (95% CI = 1.03, 1.72) for vaginal use. There was no increase in risk among users of continuously added progestogens. In other words, the continuous addition of progestogens appeared to reduce or eliminate the risk.

Oral contraceptives

The results of two major British prospective studies of 1974 and 1976 (120,121) suggested that oral contraceptive treatment was unrelated to the development of benign ovarian tumors; these and other studies also suggested that follicular and lutein cysts are suppressed in women using oral contraceptives. With regard to ovarian cancer, somewhat later data suggested a reduced risk in oral contraceptive users; impressive case-control work from the USA in 1981 seemed to show this protective effect when oral contraceptives had been taken for 4 years or more, the risk of ovarian cancer then being decreased by a mean of some 40%; the effect was even greater when the contraceptives had been used for a longer period (122). Very similarly, in 1988, the results of a multi-country study backed by the WHO suggested that sometime users of combined oral contraceptives had a risk rate that was only 71% of that in non-users, while women who had used oral contraceptives for 5 or more years had about a 50% reduction in risk (106). It should be added, however, that not all reviewers find these trends significant.

A meta-analysis of epidemiological studies of ovarian cancer showed a summary estimated relative risk of 0.64 for ever-use of combined oral contraceptives, implying a 36% reduction in ovarian cancer risk (123). This protective effect increased with increasing duration of oral contraceptive use and continued for at least 10 years after discontinuation. Although most of the oral contraceptives reported in these studies were older, higher-dose formulations, the Cancer and Steroid Hormone (CASH) study included users of tablets containing ethinylestradiol 35 μg or less, and this subgroup of women had a reduced risk of ovarian cancer (108).

With conjugated estrogens, the risk of ovarian cancer was stated in 1977 to increase two- to three-fold (SED-12, 1026), but this conclusion was based primarily on findings in women who had also taken diethylstilbestrol, and it was therefore not generally accepted. A 1982 study in which there was an apparent slight increase in ovarian epithelial carcinoma among American women taking estrogens was similarly open to challenge (SEDA-7, 385) and the link cannot be regarded as having been established (124).

Breast neoplasms

Oral contraceptives

Shortly after the first oral contraceptives were introduced around 1959, the fact that some women noticed acute effects on the breast led to fears that the ultimate consequence might be induction of mammary disorders, particularly tumors; the same concerns were raised about estrogen replacement therapy (125). The debate on this issue has now continued for more than 30 years and it is characterized by contradictions, discrepancies in scientific findings, qualified statements, and controversies and a massive output of data and opinions. The present review will necessarily be confined to some of the highlights of the discussion, presented in Table 1, leading up to a summary of the present situation and the questions that still remain open.

It is clear from the studies reported in Table 1 (126–142) that there is no simple relation between treatment with hormonal oral contraceptives and the incidence of breast cancer. As in the case of other neoplasms, studies are confounded by the influence of many factors, including age, parity, age at first delivery, family history, pre-existent fibrocystic disease, geographical or environmental influences, the ages at which the menarche and menopause have occurred, and progressive changes in the spectrum of contraceptives in use. Information bias can easily mislead. The possible influence of the long latency likely to be involved in any effect has been heavily debated; breast tumors may have been present for many years by the time they become clinically detectable; many tumors induced by oral contraceptives may therefore so far have been missed, but conversely, oral contraceptives must often have been prescribed to women who unknowingly were already suffering from breast cancer. One must also bear in mind the apparently spontaneous increase in the incidence of breast cancer over the last 40 years. Finally, when cancers are found, there is little or nothing to distinguish them histologically from tumors that arise spontaneously (143).

Four meta-analyses have shown no increased risk of breast cancer in women who have ever taken an estrogen, compared with non-users. However, most studies suggest an increased risk of breast cancer among women who take estrogen for 5–10 years or longer. The summary relative risk estimate based on the findings of these studies is 1.32 (95% C1 = 1.16, 1.51) for women who reported long-term use compared with never-users. The increased risk of breast cancer may not persist after estrogen therapy is withdrawn, suggesting that estrogen acts as a promoter rather than a cause of breast cancer (144). In one publication from the Nurse's Health Study, the estimated risk of breast cancer associated with estrogen alone was 1.36 compared with 1.50 for estrogen + progestogen therapy (145). A later analysis from the same cohort showed that women who took unopposed estrogen had a 5% per year increased risk of breast cancer compared with 9% per year in women taking an estrogen + a progestogen. The

Table 1 The possible association of oral contraceptives with breast neoplasms

Type of study	Findings	Source
Review of nine major studies of oral contraceptives	Reduced risk of breast cancer in eight studies; greater effect with higher doses; clinically significant with 2 years of use	(126)
Case-control study	Link between oral contraceptives and breast cancer, but only in those aged 30–34 years; coincidental?	(127)
Prospective epidemiological study	Link between oral contraceptives and breast cancer if used before first full-term pregnancy; high doses→higher risk	(128)
Case-control study	No link between oral contraceptives and breast cancer	(129)
Historical study of breast cancer cases	Four-fold increased risk with injectable estrogens	(130)
Case-control study	No link between oral contraceptives and breast cancer	(131)
Case-control study	Ever-users of oral contraceptives had 1.1 risk compared with never-users; higher doses produce a slightly higher risk; duration of use irrelevant; family history: higher risk; use after age 40: risk increased by 50%	(132)
Editorial	Greater risk if oral contraceptives used long-term in early life?	(133)
Case-control study	Ever-users of oral contraceptives had 0.9 (0.8, 1.2) risk compared with never-users; family history and use of oral contraceptives before first pregnancy irrelevant	(105)
Epidemiological study (extension of Pike, 1981)	Link between oral contraceptives and breast cancer if used before first full-term pregnancy: high doses→higher risk	(128)
Case-control study	Pike's results not confirmed; may be some protective effect of oral contraceptives?	(129)
Case-control study	No link with oral contraceptives	(134)
Case-control study	No link with oral contraceptives, except for a 30% increase if taken before first full pregnancy	(135)
Epidemiological study	No link with oral contraceptives, even in subpopulations	(136)
Epidemiological study	No link with oral contraceptives, even in subpopulations	(137)
Case-control study	Evidence of risk if duration and dosage considered	(138)
International case-control study	Risk doubled by use of oral contraceptives for 12 years; risk increased by duration of use; risk increased by use before first pregnancy; results may only be valid for Swedish women under 40; not seen in older or Norwegian women	(139)
Population-based case control study	No link with oral contraceptives	(137)
Narrative review	No risk	(140)
Systematic review	Greater risk with oral contraceptives in women with a history of fibroadenomas	(141)
Case-control study	Significantly more cases of breast cancer with depot medroxyprogesterone; no link with oral contraceptives	(142)
Population-based, case-control study	12-fold risk increase when young women use oral contraceptives for 12 years or more	(141)
Narrative review	Most studies have found no link with oral contraceptives; no reason for serious concern; possibly slightly higher frequency in industrialized countries	(106)
Narrative review	No increased risk from past use of oral contraceptives in women aged over 45 years; weak link in younger women with long-term use	(115)

most promising marker is the increase in breast density that occurs in 15–50% of women who take replacement estrogen (144).

There are some circumstances in which it is prudent to avoid using oral contraceptives, or in which frequent control of the state of the breasts is essential. These include (a) very long-term use before the first full pregnancy; (b) prolonged use of high-dose formulations; (c) uninterrupted use in women with a family history of breast cancer or with a personal history of fibroadenoma.

Finally, it is clear that the increase in the use of estrogen-containing contraceptives during the last 30 years cannot be held responsible for the current population-wide increase in breast cancer; as the International Committee for Research in Reproduction pointed out in 1989, the overwhelming proportion of the current rise in cases of breast cancer is among women who are too old to have taken oral contraceptives when they were younger. In addition, calculations suggest that even if an adverse effect among younger users of oral contraceptives were proved, it would still only account for a few percent of all breast cancers occurring in Western countries.

Patients with breast cancer who have discontinued estrogens less than 1 year before diagnosis have a significantly higher survival rate (146). Current users of estrogens at breast cancer diagnosis have a survival rate 5 years longer than non-users. However, they also have an increased incidence of breast cancer. This increased survival disappears when corrected for stage at diagnosis, when one can see that estrogen use relates most strongly to early-stage

© 2006 Elsevier B.V. All rights reserved.

tumors. One might therefore expect that these tumors are less aggressive and that they result in an increased survival after diagnosis. The effect of hormone replacement therapy on breast cancer mortality may even be beneficial (147,148). Indicators of biological aggressiveness are the c-er 6 B2 oncoprotein, ploidy, tumor proliferation rate, and the presence of estrogen receptors (149).

Hormone replacement therapy

As far as hormone replacement therapy is concerned (Table 2) one must provisionally conclude, with the authors of a major Canadian study published in 1992, that long-term past use of estrogens is not related to risk, but that current estrogen use increases the risk of breast cancer to a modest degree, and that the addition of progestogens probably does not remove the increased risk resulting from the use of unopposed estrogen (150).

In the Iowa Women's Health Study of postmenopausal women for 11 years, during which 1520 specific breast cancers occurred in the at-risk cohort of 37 105 women, it was concluded that exposure to hormone replacement therapy was associated most strongly with an increased risk of invasive breast cancer with a favorable prognosis. There was a more modest increase in the risk of invasive ductal or lobular carcinoma of the breast (159).

Many clinicians continue to withhold estrogen-based replacement therapy from women who have a history of breast cancer because they fear impairing their prognosis; the evidence is not firm, but experts continue to urge caution in the absence of firm data either way (161). A well-designed study from Finland in 131 such women, two-thirds of whom used HRT, showed no increase in the breast cancer recurrence rate after an average of 2.5 years (162). However, the limited size of the study (and the fact that various different forms of HRT were used) make it difficult to exclude the risk on the basis of these data alone.

Because hyperplastic or fibrocystic changes in the breast may be pre-malignant, there has been a study of 42 women who at breast biopsy had atypical hyperplasia, 74 age-matched women with proliferative fibrocystic changes, and 74 with non-proliferative fibrocystic changes (163). The patients were aged 26–77 years, and had taken predominantly HRT (usually conjugated estrogen) but sometimes oral contraceptives. There was a strong association between exogenous hormone use and the presence of atypical hyperplasia. The authors considered that their results were in line with the theory that there is a continuum between hyperplasia and carcinoma and considered that exogenous hormone use may influence the transition from one to the other in a (still undefined) subset of women.

It is difficult to interpret a Japanese report of a woman aged 62 years who developed a benign fibrous tumor of the breast. The mass, which had been noted 1 year before, progressively enlarged. Bearing in mind that such fibrous tumors of the breast are almost always premenopausal, it may be significant that she had been taking estrogens irregularly for the previous 10 years but had taken them

Table 2 Some studies of the association between hormone replacement therapy and breast neoplasms

Type of study	Findings	Source
Prospective comparative study of users and non-users	Positive link between breast cancer and HRT, provided the menopause was natural	(88)
Cohort study following up long-term users of HRT	Slight increase in breast cancer, possibly accentuated by progestogens; possible methodological problems	(SED-12, 1027) (151)
	Risk increased with HRT by up to 30%	(152)
	Link between HRT and breast cancer uncertain, but Nurse's Health Study suggested a relative risk of 1.36; adding a progestogen reduces the risk	(153)
17 relevant studies of HRT reviewed	Risk increased by 20% with use for over 10 years and 50% with use for over 20 years	(154)
Review	At least 10 acceptable epidemiological papers point to a link between long-term HRT and breast cancer	(155)
Case-control study	No increase in risk among users of combined estrogen + progestogen HRT	(156)
Large case-control study	No increased risk of breast cancer with HRT	(157)
Case-control study	Increased risk among users of any type of HRT for more than 10 years; odds ratio 2.1	(158)
Iowa Women's Health Study	HRT associated most strongly with an increased risk of invasive breast cancer and modest increases in risk of invasive ductal or lobular carcinoma of the breast	(159)
Million Women Study	Current users of HRT more likely than never-users to develop breast cancer	(160)

© 2006 Elsevier B.V. All rights reserved.

intensively during the last year. In addition, there was positive immunohistochemical nuclear staining for estrogen receptor antibodies in stromal cells (164).

By far the largest piece of evidence to emerge on the risk of breast cancer is that from the Million Women Study (160). In all, more than a million women aged 50–64 were recruited into this study between 1996 and 2001 and are being followed up with respect to cancer incidence and deaths. There were 9364 incident invasive breast cancers and 637 breast cancer deaths after an average of 2.6 and 4.1 years of follow-up respectively. Current users of HRT at recruitment were more likely than never-users to develop breast cancer (adjusted RR = 1.66; 95% CI = 1.58, 1.75) and die from it (1.22; 1.00, 1.48). Past users of hormone replacement therapy were not at an increased risk. The risk was significantly increased among current users of formulations containing estrogen only, estrogen + progestogen, and tibolone, but the risk was substantially greater for estrogen + progestogen than for other types of hormone replacement therapy. The risks were significantly increased separately for oral, transdermal, and implanted estrogen-only formulations. In current users of each type of hormone replacement therapy the risk of breast cancer increased with increasing total duration of use. Although the conclusions of this major study are roughly similar to those of the Women's Health Initiative, it has already been challenged on methodological and statistical grounds as presenting an unjustified threat to the continued use of HRT in women who need it (165).

When breast cancers occur in women taking estrogen replacement therapy they are sometimes claimed to be less aggressive than in other women. The effect of the duration or type of replacement therapy on the aggressiveness of such tumors has been studied in 1105 consecutive postmenopausal patients treated for operable breast cancer at the European Institute of Oncology (166). Tumors in women who had been exposed to estrogen replacement therapy were characterized by better stage distribution, a smaller diameter, and less extensive involvement of the axillary lymph nodes; histological grade III tumors were less common. The prognosis was generally better in women who took estrogen replacement therapy for more than 5 years. Tumors with estrogen-positive receptors were more common in the controls, but this tendency was reversed when the comparison was limited to those who had had particularly long exposure. Overall, these findings seem to confirm that prolonged use of estrogen replacement therapy does reduce the degree of aggressiveness of breast cancer, but they still have to be set against the evidence that the incidence of such cancers is increased.

A new approach to the study of the effects of hormone replacement therapy on the breast is to examine breast density, using mammography and the Wolfe classification. In a randomized study of 166 menopausal women, using this technique, there was increased breast density after 6 months of treatment; eight times more commonly in those who took estradiol and norethisterone acetate than in those who took tibolone (167). The significance of this increased density is not clear, but it should for the present be regarded as undesirable, perhaps representing the prodromal phase of more serious complications.

Malignant melanoma

Mortality and incidence rates of malignant melanoma and skin cancer have increased in most Western countries during the last 20 years, clearly for reasons unconnected with oral contraception. However, endocrinological factors can affect the melanocytes and the spread of malignant melanoma. Estrogen receptors have been noted in malignant melanoma cells, and estrogens are known to stimulate melanogenesis, an effect that is enhanced by simultaneous administration of progestogens. Oral contraceptives might therefore have an effect; the fact that chloasma has long been known to occur in some oral contraceptive users is perhaps relevant (168).

One large epidemiological study from California showed that women taking oral contraceptives, particularly long-term users, had a relatively high incidence of malignant melanoma (169). In Australia, there was a significant association with melanoma in women who had used oral contraceptives for at least 10 years before diagnosis (170). In a Canadian study, on the other hand, there was no association between the risk of superficially spreading melanoma or nodular melanoma and the use of either oral contraceptives or menopausal estrogens (SED-12, 1029) (171); however, it was suggested that there might be a risk in some subpopulations. One must be alert for confounding factors: for example, among oral contraceptive users there could be a relatively higher proportion of physically active and sporting women who are more susceptible than the average to expose themselves to sunlight. The results of a case control study in Philadelphia specifically on intraocular malignant melanoma showed that hormonal factors played only a limited role in the causation of this condition (SED-12, 1029) (172).

Pituitary tumors

A 1978 WHO report quoted an unpublished study by March in which pituitary adenomas were found in 26% of women with secondary amenorrhea following the use of oral contraceptives, yet in only 13% of cases who had not used these products (111). The difference was significant, but selection bias might have explained the results.

Second-Generation Effects

Fertility

In 1993, Sharpe and Skakkebaek published a theory that environmental and other forms of exposure of males to estrogens, particularly during fetal life, might explain the increasing incidence of reduced sperm counts and developmental disorders of the male genital system (173). Such exposure could be in part due, for example, to dietary changes in mothers: a low-fiber diet results in a great reabsorption of endogenous estrogens, and there is an increasing use in the diet of soya, which is a rich source of phytoestrogens. The topic goes beyond the scope of this volume, but it is not impossible that baseline exposure to estrogens in the diet or environment could increase the sensitivity of individuals to estrogens that are administered therapeutically or for purposes of contraception.

Teratogenicity

The best-known second-generation effects of estrogens are the genital complications that result from the formerly widespread use in pregnancy of diethylstilbestrol (q.v.), mainly between 1940 and 1975. Although it is difficult to reconstruct medical histories dating back to this period, evidence continues to emerge. The evidence is covered in the monograph on Oral contraceptives.

Hormone replacement therapy is generally given at a time when pregnancy can be excluded, but in principle some of the risks discussed in connection with oral contraceptives would arise if a women taking hormone replacement therapy were to become pregnant. In 1980, an authoritative Scientific Group of the World Health Organization (WHO) surveyed the entire question of the effects of female sex hormones on fetal development and infant health (174), and after 25 years one can conclude that later reports in the literature have almost entirely supported its conclusions.

Congenital abnormalities

Records available in Finland have been used to seek correlations between hormonal treatment (with diethylstilbestrol, estrogens, or progestogens) and adverse effects, including cancers in the mother or infant. A retrospective cohort of 2052 hormone-drug exposed mothers, 2038 control mothers, and their 4130 infants was collected from maternity centers in Helsinki covering the period from 1954 to 1963 (175). Cancer cases were sought in national registers through record linkage. Exposures were examined by the type of the drug (estrogen + progestogen or progestogen only) and by timing (early in pregnancy or only late in pregnancy). There were no statistically significant differences between the groups with regard to maternal cancers, whether total or specified hormone-dependent cancers. However, the total number of malformations recorded, as well as genital malformations in male infants, was higher among exposed children. The number of cancers among the offspring was small, and none of the differences between groups was statistically significant. The authors suggested that their study supported the conclusion that estrogen or progestogen therapy during pregnancy causes malformations among children who were exposed in utero, but not the hypothesis that it causes cancer later in life in the mother; the power to study cancers in offspring was too low to draw firm conclusions. Non-existence of the risk, negative confounding, weak exposure, or a low study power may have explained the negative findings.

Susceptibility Factors

Age

Occasionally, children are exposed unknowingly to estrogens. Precocious puberty has been observed in young girls after contact with hair lotions and other products containing estrogenic compounds (SED-12, 1032) (176,177).

The short-term complications of estrogens are unpleasant rather than dangerous. A questionnaire survey among American pediatric endocrinologists has showed that these effects commonly included weight gain, nausea or vomiting, areolar or nipple pigmentation, headache, and irregular menses (178). However, there seems to have been no methodical follow-up to determine the long-term consequences.

The longer-term consequences have in recent years given rise to rather greater concern. The use of estrogens to arrest excessive growth in height in girls was first reported in 1956 (179). While the estrogen is given continuously, the addition of a progestogen given cyclically around the time of the menarche is customary in order to induce (or permit) menstrual periods and to prevent metropathia hemorrhagica. The estrogen produces a mean reduction in predicted height, provided the treatment is begun at a bone age of 12 years and before the menarche (180). The duration of treatment is from 8 months to 3 years.

There has been an anecdotal report of thrombosis in a girl taking estrogens in addition to older evidence that they can reduce antithrombin activity, which could indeed raise the risk of thrombotic complications (181).

It was long thought that there was no impairment of subsequent fertility or of the pituitary–ovarian axis in tall healthy girls treated with estrogens, but this is now uncertain. In a retrospective cohort study in Tasmania, using medical record reviews and interviews, women who had been treated with estrogen to suppress growth were significantly more likely to be infertile and were more than twice as likely to have ever taken fertility drugs than women who were not treated in this way (182).

Estrogen treatment of girls in whom growth in height tends to be excessive is progressively losing favor. In 2002, after reviewing the possible risks, which in its view could include miscarriage, endometriosis, and ovarian cysts as well as infertility, the USA Physicians' Committee for Responsible Medicine petitioned the FDA to issue appropriate warnings (178).

Sex

Following castration for cancer of the prostate, a high proportion of men have hot flushes, and estrogens can provide relief. In a study in 12 such men, estrogen in a low dose (0.05 mg) or high dose (0.10 mg) given as patches twice-weekly for 4 weeks provided considerable improvement (183). In this dosage, mild painless breast swelling or nipple tenderness was noted in two and five of the 12 men treated with the low- and high-dose patches respectively. Estradiol concentrations increased from 12 pg/ml to 16 and 27 pg/ml with the low-dose and high-dose patches respectively. There were no significant changes in serum testosterone or luteinizing hormone concentrations. This was a small study, and data on the tolerability of this topical treatment in a larger series would be welcome.

There is evidence for a role of estrogen in male bone metabolism, notably from studies in a man with a genetic defect in estrogen receptors and in men with aromatase deficiencies. Estrogen is likely to affect bone turnover in men throughout life, and it has been suggested that older men could have reduced bone resorption in response to estrogen therapy. In a study of this possibility, in 14 men with osteopenia of the femoral neck using micronized estradiol 1 mg/day for 9 weeks, that is a dose that is effective in postmenopausal women, estradiol and estrone concentrations increased significantly by more than 6-fold and 15-fold respectively (184). Concentrations of serum

© 2006 Elsevier B.V. All rights reserved.

hormone binding globulin increased significantly by 17%, but concentrations of total and unbound testosterone fell significantly, by 27% and 34% respectively. Markers of bone resorption showed wide variations both at baseline and during treatment; they were too inconsistent to justify conclusions as to the potential usefulness of the treatment. However, the adverse effects of treatment were minimal, including (as might be expected) breast tenderness and reduced libido, which reversed after treatment.

Hepatic disease

Women with even mild liver disease can have an increased risk of the adverse effects of some estrogens on the liver (185,186). Furthermore, estrogens can potentiate and aggravate the organic complications of liver disease in other systems, for example increased cholesterol or lithogenesis (187,188).

Other features of the patient

Estrogens should be avoided in individuals with current thrombophlebitis or thromboembolism, estrogen-dependent tumors, abnormal genital bleeding without a diagnosis, and pregnancy. They are also contraindicated in apparently healthy women if they have an earlier history of jaundice in pregnancy, hepatic disease, thromboembolism, or porphyria.

Swedish workers have sought to develop a test system to define men who have a higher risk of cardiovascular complications when they take estrogens for cancer of the prostate (189). An investigational battery using exercise stress testing, evaluation of the peripheral circulation, blood volume estimation, chest X-ray, blood tests including hormonal status, lipoproteins, and antithrombin III, and history and physical examination taken by a cardiologist is claimed to make it possible to classify 84% of estrogen-treated patients as individuals with or without a particular risk of a cardiovascular complication and to identify an extremely high-risk subgroup.

Drug Administration

Drug administration route

Intranasal administration

Intranasal estradiol gives results comparable to transdermal estradiol, but substantially higher doses are needed. In 300 postmenopausal women, 17-β-estradiol 300 micrograms/day was as effective as two patches per week delivering 50 micrograms/day (190). Adverse events rates were similar but moderate, and severe mastalgia was significantly less frequent with intranasal estradiol (7.2%) than with the patch (15.5%); 66% of the patients chose to continue the intranasal therapy and 34% the transdermal therapy.

Subcutaneous implants

Implantable formulations of estrogens have been reviewed (191). Subcutaneous implants have as a rule durations of action of 4–12 months, depending on the dosage and formulation used; variations can be due to technical problems, such as disintegration or migration of an implant.

Transdermal patches

Typical patches of estradiol contain 50 micrograms, but there are important differences between the wanted and unwanted effects of the available products, because of the ways in which they are formulated. The wash-out period of estradiol after transdermal administration is about 6 weeks. Transdermal estrogens can also be supplemented periodically by an oral progestogen (192). New topical formulations of estrogens continue to be studied and marketed, although most studies have shown little difference between the various formulations available (193).

The reported incidence of adverse skin reactions to transdermal estradiol varies from 2% to over 25%, depending on the transdermal system, climatic conditions, and individual sensitivity. Of 78 women 29 reported one or more adverse events and eight discontinued prematurely (194). The main reasons for premature withdrawal included problems of adhesion, skin reactions, or undesirable systemic effects, such as headache, breast tenderness, weight gain, leg cramps, and unacceptable withdrawal bleeding.

Poor adhesion and skin irritation, with erythema and itching, are the principal drawbacks of transdermal therapy (195). Skin irritation can be overcome in some cases by changing the application site every day. In a direct comparison of transdermal patches, the duration, severity, and number of skin reactions depended on the individual formulation and excipients.

Allergic contact dermatitis from transdermal estrogen has been described in Korea, where the reaction was found to be due to 17-β-estradiol itself and not to an excipient (196). In some cases, allergic reactions and systemic contact dermatitis are clearly attributable to the patch material or to excipients. Even natural estradiol given in this way can occasionally cause hypersensitivity reactions, as determined by patch tests (197).

All the systemic effects of estrogens can occur with transdermal administration, subject to some modification as a result of the liver being bypassed (198).

Transdermal absorption of estrogen can lead to pseudoprecocious puberty in young girls, and to symptoms in young boys and adult men such as gynecomastia, loss of libido, impotence, and galactorrhea (199–201).

In a randomized, placebo-controlled, crossover study for 12 weeks, the estrogen matrix patch Estraderm MX, which unlike some other patches contains no alcohol, significantly relieved climacteric symptoms in both lower and higher strengths (50 and 100 micrograms of estradiol) (202). Local tolerability was good, but there was a slight increase in estrogen-related adverse effects (breast tenderness, leukorrhea) with the higher dose; there was a 4.8% overall incidence of endometrial hyperplasia in patients with an intact uterus. In women who have local reactions to alcohol, a patch of this type may be helpful.

Other work has confirmed the similar value of two patch formulations, Menorest and Climara; the latter has been reported to cause a much higher incidence of local reactions, but they are mild (203). The Fem 7 patch, which delivers estradiol 50 micrograms/day, was also well tolerated (204). Another effective and well-accepted variant on the patch theme is Demestril, which releases estradiol 25 or 37.5 micrograms/day depending on the formulation used (205). Differences in effect and tolerability between all these various estradiol patches are primarily a question

© 2006 Elsevier B.V. All rights reserved.

of dosage and release rate, but it also seems that acceptance may be better when the drug is incorporated into the adhesive rather than being stored in a separate reservoir. The former type of patch shows better adhesion and is cosmetically more acceptable (206).

When low-dose patch therapy results in breakthrough bleeding it is supposedly more likely to occur in women with large, thin-walled, superficial endometrial vessels (82). If this finding is correct it might also apply to breakthrough bleeding with other forms of hormonal therapy.

Vaginal administration

Because weak estrogens, such as estriol and estrone (the main component of conjugated estrogens), are claimed to act primarily on the lower part of the genital tract, they have long been used topically for atrophic conditions of the vagina and vulva, and are reputed to have useful effects in doses that do not cause marked endometrial or systemic changes. However, everything may in fact be a question of dosage; it could well be that even a low dose of a potent estrogen would have a similarly selective effect. In 159 menopausal women with atrophic vaginitis who used either a conjugated equine estrogen vaginal cream (2 g/day containing conjugated estrogens 1.25 mg) or 17-β-estradiol pessaries 25 μg (one daily for 2 weeks), the two treatments provided equivalent relief of the symptoms of atrophic vaginitis, but at weeks 2, 12, and 24 there were increases in serum estradiol concentrations and suppression of follicle-stimulating hormone in significantly more patients who used the conjugated estrogen cream than in those who used the estradiol pessaries; the patients themselves rated the estradiol treatment more highly (207).

Another effective alternative to the use of weak estrogens is the administration of estradiol from an estradiol-releasing vaginal ring, which offers efficacy, safety, and tolerability with improved comfort and acceptability. The most frequent adverse events were vaginitis, breast tenderness, abdominal pain, pruritus, and vaginal discomfort (208). However, the incidence of these adverse events was similar to those of other estrogen vaginal delivery systems. In women with lower urinary tract symptoms after the menopause an estradiol-releasing vaginal ring was well tolerated and enjoyed better patient acceptance than local estriol (209).

With vaginal creams, used primarily in order to secure a marked local effect in arresting atrophy of the vulva and vagina, the degree of systemic effect can be variable, because of variations from day to day in vaginal vascularization and secretions (198).

Etacrynic acid

See also Diuretics

General Information

Etacrynic acid (ethacrynic acid) is a loop diuretic with similar actions to furosemide and bumetanide. However, it has more adverse effects than the other loop diuretics and offers no clear advantages.

Organs and Systems

Sensory systems

Etacrynic acid is ototoxic after intravenous administration (1–3), an effect that is dose-related. It can sometimes be permanent (3,4). An association with nystagmus has also been reported (3,5). The risk has been estimated to

© 2006 Elsevier B.V. All rights reserved.

be about seven per 1000 injections (6). The risk is increased in renal insufficiency and in patients who are also being given aminoglycoside antibiotics. Animal data suggest that etacrynic acid is more ototoxic than furosemide (7).

Metabolism

Like other diuretics etacrynic acid can impair glucose tolerance in patients with type 2 diabetes mellitus (8). Non-ketotic hyperglycemia has also been reported (9). However, hypoglycemia has also been reported in two patients with uremia (10).

There has been an anecdotal report of hyperuricemia and acute gout in a patient taking etacrynic acid (11).

Electrolyte balance

Etacrynic acid can cause excessive diuresis, natriuresis, and kaliuresis, leading respectively to dehydration and sodium and potassium depletion (12–17).

Mineral balance

Etacrynic acid can cause hypocalcemia and hypomagnesemia (18).

Hematologic

There have been anecdotal reports of agranulocytosis (12,19), hemolytic anemia (20), and thrombocytopenia (16,21).

Gastrointestinal

Nausea, abdominal pain (22), and diarrhea are relatively common with etacrynic acid (23,24), more so than with other loop diuretics. Data from the Boston Drug Surveillance Program showed that intravenous etacrynic acid was associated with an increased incidence of gastrointestinal bleeding (25,26). Overall 20% of the patients treated with etacrynic acid bled, compared with 5% of those who received furosemide. With intravenous etacrynic acid the risk of gastrointestinal hemorrhage was 26%, compared with 10% after oral administration. However, 12 of 28 patients who bled did so before etacrynic acid had been given (27), and it is not clear whether there is a true difference in risk with the different routes of administration.

Liver

Like other diuretics etacrynic acid can precipitate hepatic encephalopathy in the treatment of ascites in patients with hepatic cirrhosis (28). There has been an anecdotal report of focal hepatic necrosis in a patient taking etacrynic acid (29).

Pancreas

There has been an anecdotal report of necrotizing pancreatitis in a patient taking etacrynic acid (30).

Immunologic

Two patients developed a Henoch-Schönlein type of necrotic hemorrhagic rash of the legs and lower part of the body accompanied by histological evidence of vasculitis (31). In both cases the lesions appeared about 2–3 weeks after the start of treatment; in another case a hemorrhagic rash was accompanied by acute gastric and duodenal ulceration (32).

Drug Administration

Drug administration route

Intravenous administration of etacrynic acid causes burning at the site of injection (18).

Drug–Drug Interactions

Aminoglycoside antibiotics

Etacrynic acid potentiates aminoglycoside ototoxicity by facilitating the entry of the antibiotics from the systemic circulation into the endolymph (33). Animal evidence suggests that this effect may be potentiated by glutathione depletion (34). Conversely, neomycin can enhance the penetration of etacrynic acid into the inner ear (35).

Cardiac glycosides

Etacrynic acid potentiates the actions of cardiac glycosides if it causes potassium depletion.

- A patient developed digitalis intoxication and quinidine-induced cardiac dysrhythmias when hypokalemia occurred during etacrynic acid therapy (36).

In rats etacrynic acid inhibited the absorption of digitoxin from the small intestine (37), but an interaction of this sort has not been described in man.

Cefaloridine

Etacrynic potentiated the nephrotoxic effects of cefaloridine in mice, causing renal tubular necrosis (38).

Glucocorticoids

In a survey of the effects of etacrynic acid in 16 646 patients with gastrointestinal bleeding, the risk of major bleeding was increased in patients taking etacrynic acid (4.5% of 111 patients versus 0.2% of 10 637 patients taking no drugs). The risk was further increased in patients taking etacrynic acid plus glucocorticoids (9.1% of 22 patients) (25).

Glyceryl trinitrate

Etacrynic acid inhibited relaxation of large coronary microvessels in response to glyceryl trinitrate in pigs (39). The relevance of this to the clinical use of these drugs is not known.

Lithium

The loop diuretics increase the renal excretion of lithium after single-dose intravenous administration in both animals (40) and man (41). Furosemide has been used to treat lithium intoxication (42). The effect of etacrynic acid

© 2006 Elsevier B.V. All rights reserved.

is larger than those of furosemide and bumetanide (41). However, long-term treatment with furosemide and bumetanide can cause lithium intoxication in some patients (43,44), perhaps by causing sodium depletion and a secondary increase in lithium reabsorption. An adverse interaction of lithium during long-term therapy with etacrynic acid is therefore theoretically likely.

Methotrexate

Etacrynic acid interacts with human serum albumin and modifies its binding properties (45). Since it binds to two binding sites on albumin, the benzodiazepine binding site and the warfarin binding site, it can displace drugs that bind at those sites (46). It competitively displaced 7-hydroxymethotrexate from its binding proteins in vitro (47). The clinical significance of this effect is not known.

Warfarin

Etacrynic acid interacts with human serum albumin and modifies its binding properties (45). Since it binds to two binding sites on albumin, the benzodiazepine binding site and the warfarin binding site, it can displace drugs that bind at those sites (46,48). This has been described for warfarin, whose anticoagulant effect it potentiated (49).

Etamivan

General Information

Etamivan has actions similar to doxapram hydrochloride and has been used as a respiratory stimulant. However, it has a low therapeutic index and the incidence of adverse effects from intravenous etamivan is high. Laryngospasm, sneezing, and substernal chest pain have been among the reactions recorded after intravenous infusion.

Drug Administration

Drug overdose

If it is given too rapidly or in too high a dose; generalized convulsions sometimes occur (1). Epilepsy is a contraindication to etamivan.

Drug–Drug Interactions

Monoamine oxidase inhibitors

Concurrent use of monoamine oxidase inhibitors, which lower the seizure threshold, is a contraindication to etamivan.

Etamsylate

General Information

Etamsylate (formerly also known as cyclonamine) is a synthetic water-soluble non-steroidal drug (diethylamine 2,5-dihydroxybenzenesulphonate), which was shown many years ago to increase platelet adhesion to glass beads. Subsequent clinical studies in animals reported dose-related reduced blood loss after experimental injury associated with etamsylate (1). In a small, randomized, double-blind trial, etamsylate reduced the prolongation of bleeding time and associated blood loss caused by aspirin (2). Treatment with etamsylate does not boost the platelet count or concentrations of coagulation factors (3). Etamsylate improves hemostasis by improving platelet adhesiveness and restoring capillary resistance through enhancement of the expression of P-selectin (4). It has also been suggested that it increases capillary vascular wall resistance (5).

Uses

Etamsylate is licensed for the prophylaxis and treatment of periventricular hemorrhage in neonates, in whom it is apparently effective (6,7). In a multicenter, double-blind, placebo-controlled trial in 330 infants, intraventricular and parenchymal hemorrhages developed in 30/162 infants in the treated group (etamsylate 12.5 mg/kg 6-hourly from within 1 hour of delivery for 4 days), compared with 50/168 in the control group (8). The incidence of intraventricular and parenchymal hemorrhage in survivors was 20/137 after etamsylate and 37/146 in the controls. No adverse effects were attributed to etamsylate. In a double-blind, prospective follow-up of this study, 268 of 276 survivors of the original study were seen at 3.5–4.2 years of age (9). There was no difference between the groups in neuromotor outcome (cerebral palsy) or in the general cognitive index of the McCarthy scales; fewer of the children who were given etamsylate had squints or required surgery for patent ductus arteriosus.

Etamsylate is more widely used to treat menorrhagia, including that associated with use of intrauterine contraceptive devices (10–12), although its efficacy has been challenged. A meta-analysis of drugs available in primary care showed that tranexamic acid was the most effective

© 2006 Elsevier B.V. All rights reserved.

agent available for treatment of menorrhagia, while etamsylate was not associated with significant benefit (13). Guidelines published by the Royal College of Obstetricians and Gynaecologists in the UK stated that "at currently recommended doses, etamsylate is not an effective treatment for menorrhagia" (14). A significant proportion of women with primary menorrhagia turn out to have congenital disorders of coagulation, such as von Willebrand disease, and these cases do not respond to etamsylate (3).

No clinical benefit for patients without bleeding disorders undergoing surgical procedures has been established (15–17), although results in tonsillectomy have yielded conflicting results (18,19).

General adverse effects

Whatever the merits of etamsylate in reducing blood loss in various clinical conditions, it is at least clear that no serious adverse reactions have been attributed to it. A few patients experience nausea, but this is usually avoided by taking the drug after food. Minor adverse effects that have been reported include indigestion, headache, and vertigo (20). Toxicity studies in mice have also shown no adverse effects.

Organs and Systems

Cardiovascular

Modest but transient hypotension has occasionally been observed after intravenous injection, and elderly subjects appear to be more susceptible (21).

Hematologic

Marked leukopenia was reported in one retrospective study in children receiving etamsylate, but a causal link was not firmly established (1,22).

Skin

Skin rashes have occasionally been observed in patients taking etamsylate (23).

Etanercept

General Information

Etanercept is a dimeric fusion protein consisting of two recombinant p75 tumor necrosis factor receptors fused with the Fc portion of human IgG1. It inhibits the binding of tumor necrosis factor alfa to its receptor and thereby neutralizes its biological activity. It has been used in the treatment of moderate to severe active rheumatoid arthritis, ankylosing spondylitis, psoriatic arthropathy, and juvenile rheumatoid arthritis in patients who have failed to respond to previous disease-modifying antirheumatic drugs. The clinical pharmacology and adverse effects of etanercept in patients with rheumatoid disorders have been reviewed (1).

Comparative studies

In a study of weekly oral methotrexate in two different doses (10 or 25 mg) or twice-weekly etanercept in 632 patients, etanercept produced fewer systemic adverse effects than methotrexate, but a higher incidence of injection site reactions (2). Despite theoretical concerns about the development of autoimmune reactions in patients taking etanercept, no evidence of clinical autoimmune disease emerged from this large trial.

General adverse effects

The therapeutic use and safety of etanercept have been reviewed (3). Mild-to-moderate injection site reactions were the most common adverse effects (42–49%), with a frequency 3.8 to 6 times greater than with placebo. Non-neutralizing antibodies to etanercept were rarely detected. Etanercept-treated patients more often developed new antinuclear antibodies or anti-double-stranded DNA antibodies, but no patient developed symptoms suggestive of an autoimmune disease during clinical trials.

Organs and Systems

Respiratory

The typical histological morphology of pulmonary rheumatoid nodules that developed during etanercept treatment has been reported (4,5). Pulmonary granulomas during etanercept treatment can be coincidental and difficult to distinguish from other pulmonary complications, such as relapse of tuberculosis. In two patients with rheumatoid arthritis who underwent lung biopsy for etanercept-associated pulmonary granulomas, there were non-caseating granulomas containing birefringent particulate in one (6) and caseating necrosis in the other (7). Infectious causes were ruled out. After etanercept withdrawal, the lesions resolved completely with steroid treatment in the first patient but persisted over 1 year despite antituberculosis treatment in the other.

Nervous system

Postmarketing warnings about etanercept that have been issued by regulatory agencies and the manufacturers relate to a possible increased risk of demyelinating disorders, such as multiple sclerosis, myelitis, and optic neuritis, in patients with pre-existing or a recent history of demyelinating disorders (SEDA-26, 399). This was in keeping with the results obtained in a placebo-controlled trial of lenercept, another recombinant tumor necrosis factor alfa receptor immunoglobulin fusion protein, in 168 patients with multiple sclerosis; compared with placebo, significantly more patients randomized to lenercept had exacerbation of multiple sclerosis, and exacerbation also occurred earlier (8).

Transverse myelitis of abrupt onset has also been reported (9).

- A 45-year-old woman with resistant rheumatoid arthritis was given etanercept 25 mg twice weekly. Nine days later she developed total acute sensory loss, with flaccid paraplegia, fecal incontinence, and urinary retention. MRI imaging and cerebrospinal fluid analysis were consistent with a diagnosis of transverse myelitis. She also had positive antinuclear and anticardiolipin antibodies. After etanercept withdrawal and treatment with dexamethasone and cyclophosphamide, her motor function improved with no change in sensory function.

Neurological events suggestive of demyelinating disorders in patients treated with tumor necrosis factor alfa antagonists and reported to the FDA's Adverse Events Reporting System have been reviewed (10). These included 17 cases temporarily associated with etanercept and two with infliximab, but complete information was lacking in a number of cases. One additional case with etanercept was more extensively detailed. The first symptoms occurred after a large range of delay after first drug administration (1 week to 15 months; mean 5 months) and mostly included paresthesia, optic neuritis, and confusion. MRI scans in 19 patients showed demyelination in various brain areas in 16. Although a causal relation was not proven, it is noteworthy that most patients improved after withdrawal and one patient had recurrent neurological symptoms after etanercept re-administration. The various hypothetical mechanisms by which tumor necrosis factor alfa antagonists might produce demyelinating events have been discussed elsewhere (11). Briefly, they cause increased peripheral T cell autoreactivity, and their inability to cross the blood–brain barrier may account for exacerbation of central demyelinating disorders.

Endocrine

- Transient hyperthyroidism occurred after 6 months of etanercept treatment in a 37-year-old woman with rheumatoid arthritis (12).

However, a direct causal relation with etanercept was debatable, because there was complete resolution with propranolol and despite continuation of etanercept.

Metabolism

Type 1 diabetes mellitus occurred after 5 months treatment with etanercept for juvenile rheumatoid arthritis in a 7-year-old girl (13). Antiglutamic acid decarboxylase antibodies were positive both before and during treatment, suggesting that etanercept may have prematurely triggered an underlying disease.

© 2006 Elsevier B.V. All rights reserved.

Hematologic

Postmarketing warnings about etanercept that have been issued by regulatory agencies and the manufacturers relate to a possible risk of aplastic anemia and pancytopenia (10 reported cases, of which 5 ended in fatal sepsis) (8).

Etanercept has reportedly caused abrupt exacerbation of the macrophage activation syndrome (14).

- A 22-year-old woman with adult-onset Still's disease developed symptoms suggestive of the macrophage activation syndrome. After initial glucocorticoid treatment, she received two doses of etanercept, and within 6 days her white blood cell count fell from 6.4×10^9/l to 2.5×10^9/l and the neutrophil count from 0.8×10^9/l to 0.2×10^9/l. There was also thrombocytopenia and impaired coagulation and her liver enzymes were raised. A bone marrow aspirate showed delayed myelopoiesis. She received multiple transfusions, intravenous immunoglobulin, and granulocyte-macrophage colony-stimulating factor. The macrophage activation syndrome was diagnosed at that time and she was successfully treated with pulse methylprednisolone and ciclosporin. Epstein–Barr virus infection was subsequently confirmed.

Because soluble tumor necrosis factor alfa receptors are supposedly involved in the macrophage activation syndrome, the authors speculated that the administration of additional soluble receptors may have been the cause of a prolonged and exacerbated syndrome.

Urinary tract

Glomerulonephritis has been discussed as a possible consequence of etanercept treatment in two patients, with biopsy-proven mesangial deposits of IgA in one (15).

Skin

Injection site reactions are very common during the first month of treatment with etanercept. Histological findings in one patient showed a mild transient inflammatory response that did not suggest sensitization (16). The clinical and histological characteristics of these lesions have been analysed in a retrospective review of 103 etanercept-treated patients and in three other patients assessed prospectively (17). Of 103 patients, 21 had injection site reactions (erythema, pain, pruritus, or edema) within the first 2 months of treatment, and typically within 1–2 days after the last injection. In addition, eight patients developed recall reactions while continuing to take etanercept. Skin biopsies and immunohistological analysis of reaction sites in three patients showed an inflammatory infiltrate consistent with a T cell-mediated delayed hypersensitivity reaction.

There have been several descriptions of new cutaneous or pulmonary nodulosis in patients with rheumatoid arthritis treated with etanercept (4,18); concomitant cutaneous vasculitis was also reported in two patients (18). Although this may have been due to the natural history of rheumatoid arthritis or a lack of response to treatment, the short time to the occurrence of cutaneous nodulosis after the start of therapy in some patients implicated the etanercept.

Cutaneous vasculitis can also be the sole cutaneous manifestation of etanercept treatment (19). Purpuric lesions with histological features of leukocytoclastic vasculitis have been reported in a 58-year-old man (20) and a necrotizing vasculitis with eosinophils in a skin biopsy in a woman with rheumatoid arthritis (21). However, it is not known whether this resulted from the deposition of specific immune complexes.

- A 13-year-old girl developed a slowly reversible purpuric rash after 6 weeks of etanercept treatment, and the lesions recurred on re-administration (22). However, further administration of a gradually increasing dose of etanercept, with concomitant high-dose glucocorticoids, and antihistamines, was well tolerated, suggesting that tolerance can be obtained.

One patient who had separate episodes of vascular purpura during each of three sequences of treatment with etanercept, with leukocytoclastic vasculitis during the third episode, later developed similar cutaneous lesions after a third injection of infliximab (19).

Other types of skin reactions that have been described in isolated reports include urticaria-like eruptions with prurigo in two patients with juvenile arthritis (23) and discoid lupus erythematosus in a woman with rheumatoid arthritis (21). Erythema multiforme in three patients and a lichenoid eruption in one were attributed to infliximab; however, one patient had similar lesions after etanercept (24).

Musculoskeletal

Painless orbital myositis has been reported in a 42-year-old woman taking etanercept, but a causal relation was not established (25).

Immunologic

Although patients treated with etanercept commonly develop new antinuclear antibodies or anti-double-stranded DNA antibodies, there were no reports of cutaneous or systemic lupus erythematosus in early clinical trials. However, since then, at least eight cases have been reported, including five patients with a lupus-like syndrome, two with acute discoid lupus, and one with subacute cutaneous lupus erythematosus (26–29). All were women and they developed their first symptoms 6 weeks to 14 months after the first injection of etanercept. Antinuclear and/or anti-DNA antibodies were positive in most of them. Etanercept was withdrawn in all patients with features of systemic lupus erythematosus, and the symptoms resolved within 2–8 weeks. The skin lesions also improved with local glucocorticoids, despite continued etanercept treatment in two patients with discoid lupus or subacute cutaneous lupus erythematosus. This suggests that etanercept-induced autoantibodies are sometimes associated with clinical autoimmune disease.

Infection risk

In contrast to infliximab, etanercept is rarely associated with severe infectious complications. This has been attributed to different mechanisms of tumor necrosis factor alfa neutralization by the two drugs. Indeed, only nine cases of tuberculosis have previously been reported to the FDA from more than 100 000 patients treated worldwide (30). However, severe or uncommon infectious complications (severe viral pneumonia, fatal pneumococcal sepsis due to

© 2006 Elsevier B.V. All rights reserved.

necrotizing fasciitis, osteoarticular tuberculosis) have been described in patients taking etanercept and long-term glucocorticoids (31–33).

Long-Term Effects

Tumorigenicity

There is great concern about the potential development of malignancy after blockade of tumor necrosis factor alfa, and it is biologically plausible. The FDA received reports of 26 cases of lymphoproliferative disorders in patients treated with etanercept ($n = 18$) or infliximab ($n = 8$) over 20 months (34). Although this reporting rate does not exceed the age-adjusted incidence of lymphomas in the USA, spontaneous reporting underestimates the true incidence. In addition, several findings were similar to those reported in patients taking immunosuppressive drugs after transplantation. For example, 81% of the reported cases were non-Hodgkin's lymphomas. Also, the median time to occurrence after the start of anti-TNF-alfa treatment was only 8 weeks. Finally, lymphoma regressed in two patients after withdrawal and without specific cytotoxic therapy. Although the actual incidence of neoplasia was low, additional long-term data that take into account concomitant or previous immunosuppressive treatment are needed before firm conclusions can be reached.

Susceptibility Factors

Age

In eight children with juvenile rheumatoid arthritis, who had failed to respond to disease-modifying anti-rheumatic drugs, high-dose etanercept was well tolerated (35). None withdrew because of etanercept-related adverse events. One child reported transient erythema at the injection site after the first injection. Three had mild transient upper respiratory tract infections. There were no laboratory abnormalities.

Interference with Diagnostic Tests

Troponin concentration

Non-neutralizing antibodies to etanercept have been identified in clinical trials. Although there was no correlation between these antibodies and the development of adverse effects (2), their presence was suggested as a likely explanation of false-positive rises in troponin concentrations in an assay that used mouse antihuman troponin (36).

Ethacridine

See also Disinfectants and antiseptics

General Information

Ethacridine (6,9-diamino-2-ethoxyacridine) is widely used in the local treatment of inflammatory or ulcerative conditions of the skin, particularly crural eczema due to venous stasis. Many publications point to the high frequency of exacerbation involving local allergic reactions and also generalized eczematous reactions (SEDA-11, 474).

Ethacridine has also been given by slow extra-amniotic instillation of 150 ml of a 0.1% solution to induce abortion or delivery in patients with missed abortion or fetal death, and during the second and third trimester without or in combination with drip infusion of oxytocin or dinoprost (prostaglandin $F_{2\alpha}$) (SEDA-11, 474).

In 56 women (18–20 weeks gestation), treated at the Marie Stopes Clinic in Jodhpur, India, who underwent termination of pregnancy with 0.1% ethacridine lactate 150 ml injected into the intrauterine extra-amniotic space and in whom intravenous oxytocin was used to expedite the delivery of the abortus, ethacridine lactate induced successful abortion in 52 cases (1). Abortion failure occurred in the other four cases because of transverse lie of fetus ($n = 2$), cervical dystocia ($n = 1$), and uterine inertia ($n = 1$). In 41 women the abortion occurred at 12–24 hours after induction (mean 20 hours) which was shorter than that of previous reports (29.5–38 hours). There were complications in six cases: three women had cervical tears and three had incomplete expulsion. There was one case each of severe bleeding and vaginal laceration. There were no cases of sepsis. The authors concluded that ethacridine lactate performed better than other instillation abortion methods.

In a prospective, placebo-controlled study, tannin albuminate 500 mg plus ethacridine lactate 50 mg was given to 30 patients with Crohn's disease and chronic diarrhea for 5 days, followed by a 5-day break, and then a further 5 days treatment (2). Stool frequency was significantly reduced, albeit by only a small amount, with an improvement in the consistency of the stools.

Ethambutol

See also Antituberculosis drugs

General Information

Ethambutol is tuberculostatic and acts against *Mycobacterium tuberculosis* and *Mycobacterium kansasii* as well as some strains of *Mycobacterium avium* complex. It has no effect on other bacteria. The sensitivities of non-tuberculous mycobacteria are variable. Ethambutol suppresses the growth of most isoniazid-resistant and streptomycin-resistant tubercle bacilli (1).

The adverse effects of ethambutol are mainly seen in patients taking very high doses, that is over 25 mg/kg/day. Dosages over 25 mg/kg/day should be administered for only about 2 weeks at the beginning of therapy. Treatment can then be continued with 15 mg/kg/day. If initial problems arise and ethambutol is essential, the daily dose should not exceed 10 mg/kg.

© 2006 Elsevier B.V. All rights reserved.

About 80% of an oral dose of ethambutol is absorbed from the gastrointestinal tract. Peak plasma concentrations are reached in 2–4 hours and the half-life is 3–4 hours. Within 24 hours, about 60% is excreted unchanged in the urine. In patients with renal insufficiency, the dose has to be altered (2). There is no indication for ethambutol monotherapy.

General adverse effects

Visual disturbances are the most common adverse effects and also the most important. These include diminished visual acuity, retrobulbar neuritis, retinal pigment displacement, and (rarely) hemorrhages. Gastrointestinal symptoms (abdominal pain or vomiting), and headache, dizziness, mental confusion, and hallucinations are all rarely seen. Adverse effects are more frequent in elderly patients and patients with alcoholism, diabetes, or renal insufficiency. Stevens–Johnson syndrome, toxic epidermal necrolysis (3), purpura-like vasculitis, acute thrombogenic purpura, joint pain, drug fever, tachycardia, and leukopenia have been attributed to allergy. As these reactions often arise during combined treatment with other tuberculostatic drugs, it is difficult or impossible to determine which drug is responsible. Tumor-inducing and teratogenic effects have not been described.

Organs and Systems

Nervous system

Peripheral neuropathy can precede or accompany ocular damage from ethambutol. These symptoms can serve as warning of impending eye damage (4). Loss of sensitivity, with numbness and tingling of the fingers, are relatively rare adverse effects (5). Electroneuromyography in ethambutol-induced neuropathy has confirmed that elderly patients are at increased risk (6). Sensory changes are more severe than motor dysfunction (5).

Sensory systems

Ocular disturbances due to ethambutol are dose-related. Dosages not over 25 mg/kg/day during the first 2 months of treatment and 15 mg/kg/day thereafter are generally accepted as adequate (7). At a dosage of 15 mg/kg/day, which should be regarded as a maximum for maintenance therapy, ocular toxicity developed in only 1.6% of patients (8). Advanced age (9), renal insufficiency, and diabetes can enhance ocular damage.

- The earliest onset of visual disturbance occurred in a 26-year-old man 3 days after beginning combined treatment including 15 mg/kg/day ethambutol, suggesting an idiosyncratic reaction (10).

Biochemical research has shown the importance of zinc metabolism in the retina (9). Zinc is found in high concentrations in the choroid, the retina, and especially the ganglion cells. Retinol dehydrogenase, a zinc-containing enzyme, interferes with the transformation of retinol (vitamin A_1), which is essential for color sensation and conal vision. Furthermore, zinc is involved in the biosynthesis of the specific transport of retinol from the liver to the effector cells. Ethambutol is a chelating agent and makes zinc unavailable for axoplasmic transport, provoking optic or retrobulbar neuritis (11). Patients with zinc blood concentrations below 0.7 μg/ml (reference range 0.9–1.0 μg/ml) before the use of ethambutol are at high risk of ocular disturbances (12).

The onset of visual loss can be sudden and dramatic, with color vision defects in the red–green or blue–yellow spectra, as well as variable field defects. In acute cases, disc edema is accompanied by splinter hemorrhages. Retrobulbar neuritis with ethambutol can be predominantly axial, presenting with reduced visual acuity and central scotoma, or periaxial, with peripheral field defects. In non-acute types the fundi and discs appear normal (13). Visual defects can be unilateral or bilateral.

Visual-evoked potential tests, such as flash electroretinography, flash and pattern visual-evoked responses, flicker fusion thresholds, and visual field perimetry, are reported to be the most reliable methods for early detection of ocular abnormalities (8,11,14). The routine use of visual-evoked potentials in the systematic follow-up of ethambutol-treated patients has been recommended (15).

Color vision and visual acuity should be examined before beginning ethambutol and every 2–4 weeks during treatment, using color tables and reading tests (SED-9, 525). Some recommend computerized perimetry of the central visual fields (SED-10, 581) (16,17). In patients with diabetes with retinopathy monthly monitoring of the fundi and visual acuity are mandatory. Early childhood, when visual examination is difficult or impossible, is a major indication for electroretinography. As a rule, ethambutol is not recommended for children under 5 years of age, because of the difficulty in reliably testing their visual acuity, unless the severity of tuberculosis makes the use of ethambutol necessary (15).

If ethambutol is not withdrawn when visual symptoms occur, optic atrophy or permanent blindness can occur. Patients therefore have to be instructed to interrupt treatment if they experience any visual abnormality. Hydroxocobalamin can accelerate recovery (18).

Metabolism

Blood urate concentrations can be increased because of reduced excretion of uric acid in patients taking ethambutol (19). This is probably enhanced by combined treatment with isoniazid and pyridoxine. Special attention should be paid when tuberculostatic drug combinations include pyrazinamide. However, severe untoward clinical effects are rare, except in patients with gout or renal insufficiency (2,20).

Hematologic

Acute thrombocytopenia, probably due to an immunological mechanism, has been described in a single patient (21).

Liver

Jaundice and non-icteric liver disturbances probably occur in under 0.1% of patients, as long as isoniazid and rifampicin are not given simultaneously (22).

Second-Generation Effects

Pregnancy

Ethambutol in combination with isoniazid in pregnancy has been suspected of causing one case of gastrointestinal malformation, but other factors may have been implicated (SEDA-12, 256).

Teratogenicity

Fetal damage has not been attributed to ethambutol (23).

Fetotoxicity

Toxic effects in the newborn have not been attributed to ethambutol (24).

Lactation

No adverse effects during lactation have been attributed to ethambutol (24).

Susceptibility Factors

Renal disease

In patients with impaired glomerular filtration or any other renal dysfunction, ethambutol dosages have to be altered (25).

Drug–Drug Interactions

Antacids

In 13 patients with tuberculosis, aluminium hydroxide significantly lowered serum ethambutol concentrations during the first 4 hours after a dose; in healthy volunteers, both aluminium hydroxide and glycopyrrhonium, alone or in combination, reduced ethambutol absorption (26).

Isoniazid

The risk of optic neuropathy due to ethambutol may be increased when it is combined with isoniazid.

- A 40-year-old patient underwent unsuccessful cadaver kidney transplantation and was treated with ethambutol and isoniazid (27). Bilateral retrobulbar neuropathy with an unusual central bitemporal hemianopic scotoma developed and ethambutol was withdrawn, but there was only a small improvement. When isoniazid was also withdrawn, there was dramatic improvement in visual acuity.

In another patient taking isoniazid and ethambutol, optic neuropathy improved only when both drugs were withdrawn (28).

Isoniazid 300 mg/day orally for 7 days increased serum ethambutol concentrations at 4, 6, and 8 hours after a daily dose of 20 mg/kg; the cumulative percentage dose excreted was significantly reduced at 4, 6, and 24 hours (29). In another study from the same center, ethambutol 20 mg/kg did not alter the pharmacokinetics of a single dose of isoniazid 300 mg in 10 patients with tuberculosis (30).

Ethanol

General Information

Ethanol (alcohol) is a drug of frequent abuse, and has long-term adverse effects that will not be discussed here. It is sometimes used therapeutically in the following ways:

- topically as an astringent.
- by direct instillation to embolize arteries.
- by direct injection into nerve ganglia or around nerve trunks to destroy them and relieve severe or chronic pain (for example trigeminal neuralgia); however, the results are generally only short-lasting.
- to swab the skin before venepuncture and other surgical procedures.
- as a rubefacient in some liniments.
- to harden the skin to prevent bedsores, and to harden the nipples before breastfeeding.
- to reduce sweating.
- in the treatment of acute methanol poisoning, since ethyl alcohol competes with methyl alcohol (methanol) for hepatic metabolism.

Alcohol is also widely used as a solvent in pharmaceutical preparations.

In 28 children from Argentina there was alcohol intoxication when ethyl alcohol was applied to the abdomen in alcohol-soaked cloths, as a home-remedy for disturbance of the gastrointestinal tract (1). The symptoms and signs included nervous system depression (100%), abdominal erythema (89%), alcoholic breath (86%), miosis (86%), hypoglycemia (54%), convulsions (18%), respiratory depression (18%), mydriasis (14%), acidosis (11%), and death (7%).

A danger of embolization of arteries is reflux of the instilled ethanol and the possibility of embolization of arteries other than the targeted ones. Infarction of the left testis secondary to transcatheter embolization of a malignant left renal tumor with ethanol has been reported (2). Colonic infarction following ethanol embolization of a renal tumor has been attributed to a reflux of ethanol from the renal artery into the aorta (3).

In combination therapy of unresectable hepatocellular carcinoma with transcatheter embolization and percutaneous injection of alcohol in 24 patients, 18 developed transient local pain and a burning sensation after the injection of alcohol, 16 had mild fever, and two had transient hypotension (4).

Organs and Systems

Cardiovascular

Alcohol is one of many drugs that cause or aggravate systemic hypertension. Acute alcohol exposure has an inconsistent effect on blood pressure, but cross-sectional population studies have shown a relation between chronic alcohol consumption and blood pressure, and the prevalence of hypertension up to three times higher in heavy drinkers (5). Although the mechanism of hypertension caused by chronic alcohol consumption is not known, it is suspected that it is partly related to repeated episodes of acute withdrawal, causing increased sympathoadrenomedullary activity, an increase in plasma renin activity, and increased ACTH secretion, which may be sufficient to have a mineralocorticoid effect (6).

Respiratory

In 36 patients with inoperable cancers of the esophagus who were treated by endoscopic injection of alcohol, complications included mediastinitis in one patient and tracheoesophageal fistulas in two (7).

Nervous system

Peripheral nerve block is created by injecting ethanol around the selected nerve. The effect of alcohol on nerve tissue has been examined in animal models and in postmortem specimens from patients who received neurolytic blocks (8,9). In general, alcohol causes destruction of nerve fibers, with subsequent Wallerian degeneration. The basal lamina around the Schwann cell usually remains intact. This leaves a tract available for axon regeneration without the formation of a neuroma. If the cell bodies are completely destroyed, regeneration will not occur. Contact of alcohol with unintended nerve roots underlies many of the more serious complications. Involvement of anterior rootlets sufficient to interrupt motor nerve function will result in muscle weakness or paralysis. Interruption of

© 2006 Elsevier B.V. All rights reserved.

parasympathetic fibers in the anterior roots of the three middle sacral segments can result in bowel and bladder dysfunction and can cause urinary retention and anal sphincter paralysis.

In one study of 82 patients over a 20-year period who received repeated peripheral alcohol nerve blocks for trigeminal neuralgia, although moderate swelling and discomfort were invariable, significant complications occurred in only three of 413 nerve blocks (10):

- avascular necrosis, leading to a sequestrum, possibly due to repeated injections;
- necrosis of the lateral aspect of the nose, attributed to intravascular injection of alcohol;
- pallor and faintness after the injection followed by diplopia, which took 5 months to resolve.

Alcohol relatively commonly causes less serious complications, such as vomiting, headache, and paresthesia, which are but fortunately of limited duration, while loss of proprioception and profound numbness are disconcerting but almost always preferable to the pain that the alcohol injection has relieved (11).

Liver

Injection of ethanol into the liver to treat hepatocellular carcinoma commonly causes severe pain, fever, and hepatic dysfunction; there can also be pleural effusion, pneumothorax, ascites, vasovagal reaction, transient hypotension, myoglobinuria, and portal thrombosis. Fatal massive hepatic necrosis distant from the injection site has also been attributed to this treatment (SEDA-18, 377).

There have been three studies of the effects of percutaneous ethanol injections in the treatment of hepatocellular carcinoma, either alone (12,13) or in combination with transcatheter arterial embolization (14). The procedure was effective and safe and improved long-term survival. Adverse effects were generally mild and of short duration, and commonly included abdominal pain, fever, intoxication (especially among non-drinkers), transient rises in serum transaminases, and chemical thrombosis of the tributary branch of the portal vein. Hepatic infarction has been reported in two patients with hepatocellular carcinoma after percutaneous ethanol injection of the tumors (15). Both patients had previously been treated with transcatheter arterial infusion using a suspension of styrene maleic acid neocarzinostatin, and the liver damage may have occurred through a combination of arterial damage due to the neocarzinostatin and vasculitis caused by flow of the injected ethanol into a portal vein branch.

In an open trial, percutaneous ethanol injections into the liver improved prognosis compared with conservative treatment in 63 patients with cirrhosis and hepatocellular carcinoma who were not suitable for surgery or transcatheter arterial chemoembolization (16). Most of the patients had mild to moderate local pain during or immediately after injection and 29% developed fever.

Urinary tract

When 99% ethanol was instilled into renal cysts under ultrasound guidance in 25 cases, there were 12 complications after puncture, either related to the puncture itself or caused by the ethanol (17). They included flank pain, nausea, causalgia, and a feeling of drunkenness, which occurred immediately after instillation.

Etherified starches

General Information

Etherified starches are synthetic colloids containing over 90% amylopectin, a waxy starch derived from maize, that has been variably etherified. There are two major forms, hetastarch and pentastarch (both BAN and USAN). They are produced synthetically by introducing hydroxyethyl groups into glucose units of starch molecules, followed by acid hydrolysis, which results in a product with a molecular weight of several thousands of daltons. In hetastarch 7 or 8 and in pentastarch 4 or 5 of the hydroxyl groups in each glucose molecule are etherified.

The etherified starches are used in solution as plasma substitutes. They are good alternatives to albumin, because they have an extended shelf-life, carry no risk of transmitting blood-borne diseases, and can be infused into patients who refuse blood products on religious grounds.

The elimination of etherified starches is complex and related to the size of the particles. The smaller molecules, with a molecular weight of less than 50 000 daltons, are excreted unchanged by glomerular filtration. The larger molecules are metabolized to smaller molecules and distributed to various body tissues, where they may undergo hydrolysis in the reticuloendothelial system or enzymatic degradation by amylases.

A detailed histological and immunohistochemical study of deposits of hetastarch in rat tissues has thrown some light on the relation between its adverse effects and its fate in the body (1). Thirteen days after a single intravenous injection the rats were sacrificed and their liver, spleen, lymph node, lung, kidney, and skin were studied. In all these organs anti-etherified starch antibody stained cells that were mainly regarded as mononuclear phagocytes (confirmed by the use of antimacrophage monoclonal antibody ED1). These findings suggested a degree of prolonged tissue storage of either etherified starch or of a degradation product that stains with the antibody, and this may account for persistent complications such as pruritus. However, in this histochemical study there was no mast cell degranulation or accumulation of inflammatory cells.

Nomenclature

Different types of etherified starch are designated by a number that indicates the molecular weight in kilodaltons followed by a number that indicates the degree of substitution of glucose units with hydroxyethyl groups. Thus, etherified starch with a molecular weight of 200 kDa and 62% substitution is designated 200/0.62.

Comparative studies

The efficacy and safety of hetastarch and albumin have been compared in 85 patients with postaneurysmal subarachnoid hemorrhage (2). Of 26 patients who developed clinical symptoms of vasospasm, 14 were treated with hetastarch, while the other 12 received albumin. In all patients who received hetastarch there was significant prolongation of the partial thromboplastin time after transfusion (pretransfusion mean 24 seconds, post-transfusion 33 seconds), while in patients treated with albumin the partial thromboplastin time was not significantly altered. The prolongation of the partial thromboplastin time resulted in increased occult blood loss in the hetastarch-treated patients, requiring blood transfusion in four patients. On the basis of hetastarch-associated coagulopathy and data that show that albumin may be the most effective agent for increasing cerebral blood flow and preventing infarction, the authors stopped using hetastarch in these patients and decided to recommend albumin exclusively.

Some authors have concluded that etherified starches and albumin do not differ with respect to efficacy and adverse effects on coagulation and renal function (3), but etherified starches clearly do have a distinct adverse reactions profile. Some of the problems that they cause, such as anaphylaxis, volume overload, cerebral hemorrhage, and acute renal insufficiency, are sufficient reason to avoid hetastarch when benefit is doubtful, such as ischemic brain infarction (4).

Placebo-controlled studies

Hypervolemic hemodilution with agents such as etherified starches or dextran increases cerebral blood flow and can therefore reduce ischemic tissue damage in the penumbra zones when given within the therapeutic time window. However, the clinical benefit of such therapy has yet to be proven. Since etherified starch is considered to be the safer choice, in particular the recently developed lower molecular weight form (etherified starch 130/0.4), an explorative, randomized, placebo-controlled, safety trial of etherified starch for hypervolemic hemodilution in patients with acute ischemic stroke has been undertaken (5). This was a double-blind, randomized, placebo-controlled, parallel-group, multicenter study in 106 patients with acute ischemic stroke, who were recruited over 3 years. Treatment comprised high-dose hypervolemic hemodilution with either etherified starch 130/0.4 or placebo within 6 hours of the start of symptoms, with a randomization ratio of 2:1 in favor of etherified starch. There were no significant differences between the groups with regard to the incidence of specific adverse events (cardiovascular, bleeding complications, allergic reactions), assessed over days 1–30, or of deaths over days 1–8. The author, on behalf of the Hydroxyethyl Starch in Acute Stroke Study Group in Germany, noted that while the study was not designed to prove efficacy, the global tests of efficacy suggested a slight but insignificant trend toward better functional outcome with etherified starch.

General adverse effects

Transitory hyperamylasemia, chills, and mild increases in body temperature, pruritus, enlargement of the submandibular and parotid glands, and erythema multiforme can occur (6). The risk of anaphylactic reactions to hetastarch is very small (about 5 per million) (7).

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Cardiovascular

In a comprehensive comparison of the pharmacokinetics and pharmacodynamics of dextran and etherified starch (8), the effects of etherified starch on the cardiovascular system have been delineated. The mean arterial pressure, central venous pressure, wedge pressure, cardiac index, left ventricular stroke work index, and stroke output all rise, whereas the pulmonary vascular resistance falls. Oxygen availability to the tissues is improved. The effects of etherified starch on blood viscosity and erythrocyte aggregation, in particular, are more pronounced than with dextran.

Nervous system

The effect of hemodilution with colloids on somatosensory-evoked potentials in non-premedicated volunteers has been reported (9). In seven subjects, blood (20 ml/kg within 30 minutes) was removed and simultaneously replaced by gelatine 3% or etherified starches 6%. After 30 minutes, blood was retransfused. Median and posterior tibial nerve somatosensory-evoked potentials were recorded from the cortex, second cervical vertebra, Erb's point, and first lumbar vertebra. Hemodilution with gelatine or etherified starches or retransfusion did not affect somatosensory-evoked potentials, provided normovolemic conditions were maintained.

Acid–base balance

Two prospective, randomized studies of acid-base changes induced by etherified starches have been reported. In the first study (10), healthy volunteers were given 15 ml/kg of hetastarch 6% or albumin 5% intravenously over 30 minutes. Four weeks later they were given the other colloid. Arterial blood gases and electrolyte parameters were measured at baseline and at 30-minute intervals for 5 hours. There were statistically significant changes in bicarbonate, chloride ion, and albumin concentrations, base excess, and arterial carbon dioxide tension 30 minutes after infusion of hetastarch, but only the albumin concentration changed significantly in the albumin-treated group.

In the second study (11) there were acid–base changes caused by the same two colloids in patients undergoing acute normovolemic hemodilution during gynecological surgery. Two groups of 10 patients were randomly assigned to receive either albumin 5% or etherified starch 6%, containing chloride ion concentrations of 150 and 154 mmol/l respectively. The blood volume was well maintained in both groups. Acute normovolemic hemodilution caused slight metabolic acidosis with hyperchloremia. Plasma albumin concentrations fell after hemofiltration with etherified starches but increased after albumin. The authors concluded that acute normovolemic hemodilution with albumin or etherified starches led to some degree of metabolic acidosis, but not of clinical relevance.

Hematologic

After intravenous administration, hetastarch alters the rheological properties (12) of blood and increases the erythrocyte sedimentation rate (13).

Coagulation

Etherified starch can cause coagulation disorders. Administration of 10% hydroxyethyl starch 200/0.62 to 10 patients with cerebrovascular diseases over 10 days (a loading dose of 500 ml administered once over 45–60 minutes followed by 500 ml/day) had a markedly unfavorable effect on blood coagulation (14). There was a significant 43% increase in activated partial thromboplastin time. Factor VIII:C, von Willebrand ristocetin co-factor, and von Willebrand factor antigen fell during therapy below the limit required for hemostasis (30%), and in some patients below 10%. This was thought to be due to accumulation of large molecules that are difficult to break down and which unfavorably affect rheological and coagulation function.

The pathogenic mechanism that affects factor VIII/vWF complex has not been elucidated. There may be accelerated elimination after attachment of factor VIII/vWF complex to starch molecules. The significant fall in factor XI and factor XII shows that impairment of the intrinsic system of coagulation is not limited to factor VII/vWF complex (14). Even a small volume of 6% etherified starches (average molecular weight 450 kDa; 2.5 litres in 3 days) can cause a significant coagulation disorder (15).

In another study, administration for 24 hours of hetastarch (6%) or human serum albumin to 12 patients with septic shock caused moderate effects on hemostasis (prothrombin time, partial thromboplastin time, and quantitative platelet count). There was no increase in bleeding, and there were no statistically significant differences between these effects and those produced by human serum albumin (16); however, it should be noted that the number of subjects was so small as effectively to preclude a finding of significant difference between the groups studied. The authors' conclusion that hetastarch is a safe and effective volume expander in patients with sepsis and shock needs to be considered cautiously, particularly as the authors pointed out that there is an immediate fall in factor VIII coagulant to about half normal in patients receiving hetastarch. Furthermore, a patient with von Willebrand's disease had a markedly prolonged bleeding time and reduced platelet adhesiveness, although there was no overt bleeding.

- A man of 33 developed von Willebrand's disease shortly after he had been given 3 liters of hetastarch over 3 days after acute sensorineural hearing loss. He had a history of a prolonged activated partial thromboplastin time (APTT), although he had previously undergone bilateral hip arthroplasties with no evidence of abnormal bleeding. He had an episode of epistaxis and experienced weakness and pain in his leg. When hetastarch was withdrawn, it was noted that he had a raised APTT concentration, and reduced concentrations of factors XII and VIII:C. Over the next few months, the von Willebrand's syndrome was reversed, although his factor XII concentration remained reduced (17).

This case is typical of many others. In six patients with cerebral circulatory disturbances who received hemodilution therapy for 9–10 days with etherified starches (molecular weight 200 kDa and a high degree of substitution, 0.62), all the multimers of von Willebrand factor fell to the same extent. This corresponds to type 1 von

Willebrand's syndrome (18). This potential hemorrhagic complication is treatable, since type 1 von Willebrand's syndrome can be controlled with the vasopressin derivative desmopressin.

A survey of formulations containing etherified starch, and particularly Elohes 6% (molecular weight about 200 kDa), carried out by the French Agency for Health Products identified eight cases of acquired von Willebrand disease (19). Three cases were fatal and in two cases there were hematomas with prolongation of the activated cephalin clotting time. All these effects were observed during the administration of Elohes for vasospasm secondary to meningeal hemorrhage due to rupture of a cerebral aneurysm in patients with no relevant previous history. Duration of treatment of more than 4 days appears to be a risk factor. Nine cases of hepatic overload were also reported, and could cause or aggravate portal hypertension. The Agency announced that the product information for products containing hetastarch would be revised, with a contraindication to the use of Elohes in patients with severe hepatic insufficiency, the stipulation of a maximum dose, a restriction on the duration of treatment, and instructions on the monitoring of hemostasis.

Of nine patients with hemostatic disorders, all treated with medium molecular weight etherified starch (Elohes), six developed type I von Willebrand's disease (20). Before the abnormalities in coagulation were discovered, the patients had received a mean dose of pentastarch of 121 ml/kg. The abnormalities resolved each time pentastarch was withdrawn. The authors hypothesized that accumulation of starch probably led to quantitative defects of complex factor VIII and von Willebrand factor by accelerated elimination from the circulation of complexes attached to starch molecules. Because Elohes is highly substituted, it is difficult to break down and is therefore eliminated more slowly. Accumulation of Elohes after repeated administration may explain why its adverse effects on coagulation resemble those of high molecular weight starch, while other medium molecular weight starches affect coagulation much less. The authors recommended that the dose of Elohes should be limited to 33 ml/kg/day and the cumulative dose to 80 ml/kg. Treatment should be given over no more than 3 days and Elohes is contraindicated in patients with coagulation disorders.

Etherified starch shortens the thrombin time by a fibrinoplastic effect. This accelerates the conversion of fibrinogen to fibrin, resulting in a less stable thrombus, which is more susceptible to lysis. The macromolecules in etherified starch induce an acquired von Willebrand's syndrome with reduced concentrations of all three main forms of factor VIII: factor VIII:C, von Willebrand factor, and von Willebrand factor antigen (vWFag).

Platelets

Plasma substitutes in general reduce the platelet count partly by a dilutional effect, even after a single dose. However, there are other mechanisms. In a study of the effects on platelet number and function of etherified starches, given for 10 days to 20 patients with cerebrovascular diseases, both medium- and low-molecular weight etherified starches caused a significant reduction in the number of platelets on the first day, in excess of a dilutional effect. During the course of treatment the platelet number increased, recovering its initial value. The number of large platelets fell disproportionately and significantly. Etherified starch did not affect spontaneous platelet aggregation. The fall in platelets was probably caused by colloid-osmotic shrinkage and increased degradation. There were no signs of impaired platelet function, as determined by spontaneous platelet aggregation (21). Patients suffering from thrombocytopenia or impaired platelet function should be carefully monitored when they are receiving large doses of etherified starches.

Macromolecules may coat the outer membrane of circulating platelets and cause a qualitative functional defect, thus prolonging bleeding time. Minor abnormalities of platelet aggregation have been observed after infusion of low volumes of etherified starches, and platelet defects probably contribute to the hemorrhagic state.

Etherified starch altered hemostasis in vitro in blood taken from patients undergoing abdominal surgery; the effect was more pronounced in patients with blood group O (22). The authors recommended that the intraoperative administration of etherified starches should be restricted in patients with blood group O undergoing surgical procedures with a high risk of bleeding.

Urinary tract

In a patient with normal renal function it is possible that the kidneys present a selective barrier to all but the smallest of starch molecules. The breakdown products are then eliminated by urinary excretion. Etherified starch can be associated with increasing serum creatinine concentrations (23). Associated clinical symptoms and signs include pain in the renal region and swelling of kidney parenchyma. In a study of 25 patients randomly allocated to control and treatment groups (the latter received 10% etherified starch 12 ml/kg) there were differences in renal tubular function in the latter. Those who received etherified starch had increased excretion of alpha$_1$-microglobulin, Tamm-Horsfall protein, and brush border enzyme acetyl-beta-glucosaminidase. There were no significant differences in glomerular function. The findings suggest a primary renal tubular lesion caused by etherified starch (23).

The risk of acute renal insufficiency associated with the use of etherified starch in volume replacement therapy has been critically reviewed (24). The author made the important point that not all etherified starch formulations are the same—they differ widely in physicochemical characteristics. Such differences have consequences for adverse events, including impaired renal function. Furthermore, all volume replacement therapies have potential hazards. The author therefore concluded that etherified starch, in particular products containing etherified starch with a low or medium molecular weight (for example 70, 130, or 200 kDa) and a low degree of substitution (0.4 or 0.5), can be considered for use in patients without pre-existing kidney dysfunction. It is recommended that all formulations of etherified starch, including the latest (molecular weight 130, degree of substitution 0.4), should be used only very cautiously in patients with some degree of renal impairment (plasma

creatinine concentration greater than 365 μmol/l, 3 mg/l) and are probably best avoided for alternative regimens.

Osmotic nephrosis-like lesions have been reported in kidney transplant recipients, attributed to etherified starches that had been used in brainstem-dead patients before organ procurement (25). The incidence of these lesions was not influenced by cold ischemia time, the presence and length of delayed graft function, or the immunosuppressive regimen (including the use of ciclosporin). The lesions had no significant deleterious influence on the occurrence of delayed graft function or on serum creatinine at 3 and 6 months after transplantation. Osmotic nephrosis-like lesions can be long-lasting, since in three patients they were still present at 3 months after transplantation on routine renal biopsy. In patients without osmotic nephrosis-like lesions no kidney was lost, whereas among those with such lesions, seven of 31 were lost. Although there was no obvious short-term detrimental influence on renal function, these lesions might cloud the already difficult interpretation of renal transplant biopsies, especially for ciclosporin-induced nephrotoxicity. The authors recommended avoiding etherified starches in potential organ donors.

Two cases of osmotic nephrosis-like lesions have been reported in which similar changes have been noted, accompanied by evidence of renal insufficiency. The first case occurred after the administration of etherified starch during surgery (26).

- A 67-year-old woman with no history of nephritis was given etherified starch (500 ml) and Ringer's lactate (2.5 litres) for hypotension during surgery. Postoperatively she developed acute renal insufficiency (urine output below 600 ml/day) and her serum creatinine rose to 443 μmol/l, despite fluid challenge. Ultrasound showed no urinary obstruction, no thrombosis in the renal vessels, and normal kidneys. A renal biopsy showed major osmotic nephrosis-like lesions in the proximal tubules, but no lesions suggestive of acute tubular necrosis. Renal function returned to normal within 14 days after surgery.

The authors suggested that the renal insufficiency was due to the perioperative infusion of etherified starch, even though she received a much smaller dose (less than 10 ml/kg) than kidney donors usually receive. They further suggested that nephrotoxicity can occur within a few hours after even low-dose infusion of etherified starches.

- A 20-year-old man from Mali with polymyositis that had not responded to prednisolone, monthly infusions of immunoglobulin, and plasma exchanges with albumin and modified gelatin, was given ciclosporin, which led to marked improvement (27). When he developed hepatic cirrhosis the ciclosporin was withdrawn and glucocorticoids were reintroduced in association with plasma exchanges three times a week with 6% etherified starches and 4% albumin. After seven plasma exchanges (cumulative dose 320 g) his serum creatinine rose to 216 μmol/l without proteinuria or hematuria. Renal biopsy showed diffuse microvacuolization of the tubular epithelial cells (osmotic nephrosis-like lesions). Plasma exchange was restarted with 4% albumin alone, after which his renal function improved and the polymyositis stabilized.

The authors concluded that the most likely cause of renal insufficiency was etherified starch-induced tubulopathy and hypothesized that even low amounts of etherified starch as replacement fluid in plasma exchange can cause renal tubular lesions in patients predisposed for other reasons (such as drugs or renal hypoperfusion) to renal insufficiency. In this context, albumin should be combined with replacement fluids other than etherified starch.

The lesions of osmotic nephrosis involve the proximal and distal tubules. Severe changes in proximal tubules have been described in dogs after complete blood exchange with etherified starches. It is believed that smaller molecules (molecular weight under 50 kDa) are excreted unchanged by glomerular filtration, leading to a large amount of osmotically active small molecules in the ultrafiltrate. As a result of reduced glomerular filtration in these patients, a highly viscous ultrafiltrate, complicated by tubular stasis and osmotic nephrosis of tubular cells, may have been caused by reabsorption of etherified starches, resulting in acute renal insufficiency. In the two cases described in this report, and in the absence of either significant hypotension or oliguria, acute renal insufficiency due to purely prerenal (hypovolemic) causes was improbable (28).

Hetastarch can cause a discrepancy between urinary specific gravity and osmolality (29). High-molecular weight molecules present in the hetastarch solution produced a disproportionate rise in urine specific gravity compared with osmolality. In two patients, the combined effects of acute tubular necrosis secondary to hypotension and abnormal glomerular permeability were thought to have allowed high-molecular weight particles of hetastarch to be excreted in the urine. The hetastarch particles increased the urine specific gravity, but had a correspondingly smaller effect on osmolality. It was not thought that hetastarch itself was nephrotoxic. The authors concluded that in the setting of pre-existing renal disease, hetastarch may increase the urinary specific gravity without unduly affecting the ability of the kidney to concentrate urine. They recommended that urinary osmolality, rather than specific gravity, should be regarded as the preferred method of evaluating the urine after the administration of high-molecular weight colloid solutions.

Hemodilution therapy with etherified starch caused acute deterioration of an already existing nephropathy in two cases (29). The authors suggested, on theoretical grounds, that the deterioration in renal function was likely to have been the result of increased permeability caused by damage to the glomerular basement membrane. Etherified starch molecules are filtered above the physiological renal threshold, and this increases the viscosity of the urine. This can be counteracted by promoting diuresis. The authors managed to avoid precipitating renal insufficiency by ensuring a fluid intake of about 3 l/day. Without an adequate diuresis etherified starches accumulate in patients with renal dysfunction, with consequences that include further damage to the diseased kidneys.

Conclusions have differed as to whether use of etherified starch in brain-dead organ donors influences kidney graft function at 1, 3, and 6 months after transplantation (30–32). In one report (33), during the first 10 days after transplantation there was reduced kidney graft function

© 2006 Elsevier B.V. All rights reserved.

with higher creatininemia or increased requirements for hemodialysis in recipients in those given etherified starch plus gelatin. Some other workers have not confirmed this finding (30,31), but it is not unique. In 69 other brain-dead patients followed up prospectively over a period of 18 months 33% of those who received etherified starch up to 33 ml/kg during the first 8 days after transplantation for colloid plasma volume expansion required extrarenal hemodialysis or hemodiafiltration, compared with 5% in a control gelatin-only group (33). Serum creatinine concentrations were significantly lower in the controls. The results suggested that etherified starch used as a plasma volume expander in brain-dead donors impairs renal function.

Skin

Severe pruritus after infusion of etherified starch is common and troublesome. In skin biopsies taken from 93 patients who had received etherified starches, half of whom had pruritus, immunoelectron microscopy was conducted using an antibody highly specific for etherified starches. After infusion of etherified starches, formation of intracytoplasmic storage vacuoles in the skin was demonstrated in all cases. Dose-related uptake of etherified starches was first detectable in macrophages and afterwards in endothelial and epithelial cells. There were vacuoles that reacted to etherified starches in the Schwann cells of unmyelinated as well as small myelinated nerve fibers, and in endoneural and perineural cells. Neural devacuolization paralleled the clinical improvement in itch (34). The authors of this study suggest that deposits of etherified starches in cutaneous nerves, as a consequence of a high cumulative dose, may account for the itching seen after infusion of etherified starch.

In 481 patients with diseases of the microcirculation of the cochleovestibular system, 149 of whom were treated with etherified starch, 43 (29%) complained of pruritus, compared with only 5.7% of another group of patients who were treated with dextran 40 (35). In more than 40% of the patients pruritus started in normal skin 1–3 weeks after therapy and lasted between 6 weeks and 6 months; the itching was resistant to therapy with antihistamines. Pruritus can be socially embarrassing, particularly when etherified starch has been given in high doses. The resistance of etherified starch-induced pruritus to standard therapy, including antihistamines, glucocorticoids, ultraviolet light, and other measures, has been described in a single case (36). This resistance to treatment is not unusual. Four patients with nausea or tinnitus who received intravenous etherified starch developed severe pruritus, especially on the trunk, without skin eruptions, 1–3 weeks after the start of treatment. The pruritus was refractory to treatment, and neither oral nor topical antihistamines were effective; only ultraviolet phototherapy or topical glucocorticoids gradually alleviated the pruritus after periods ranging from several weeks to 1 year (37).

In a retrospective study of 491 patients treated for various cochleovestibular disorders, 25 of 59 patients (42%) treated with etherified starch complained of pruritus, compared with four of 35 (11%) treated with dextran-40 (38).

Generalized itching occurred in 43 of 149 patients treated with etherified starch for acute or chronic microcirculatory disease causing neuro-otological disturbances (39).

In another retrospective study of 266 patients receiving etherified starch for otological indications 32% developed pruritus, which characteristically appeared as a pruritic crisis. In 55% of the patients the onset of symptoms was after the etherified starch had been withdrawn. The symptoms persisted on average for 8.8 weeks. Pruritus was generalized, but with a predilection for the trunk and genitalia. Coincidental atopic disease or higher age were not predisposing factors. The incidence of pruritus correlated well with the cumulative dosage and also depended on the type and molecular weight of the etherified starch given (6 or 10%, molecular weight 40 or 200 kDa). Light and electron microscopy showed deposits of etherified starch, especially within dermal macrophages and endothelial cells adjacent to nerve fibers (40). The authors suggested that a histamine-independent pathway is probably responsible for pruritus due to etherified starch. Antihistamines had no therapeutic effect on the patients reported.

After etherified starches treatment, vacuoles in the cells of various organs in humans occur, predominantly affecting the mononuclear phagocyte system (41). These vacuoles are indirect evidence for phagocytosis of etherified starch particles. In skin biopsies of patients who had received etherified starch and later suffered from itching, light and electron microscopy, immunohistochemistry, and immunoelectron microscopy using a polyclonal antihetastarch antiserum showed that storage of etherified starch was present in the skin of all patients. This was mainly in dermal macrophages, endothelial cells of blood and lymph vessels, some perineural cells and endoneural macrophages of larger nerve fascicles, some keratinocytes, and Langerhans cells. There were no morphological signs of histamine release from mast cells. The authors concluded that mediators other than histamine, released from hetastarch-affected cells, must be responsible for the itching.

In three patients with persistent pruritus after the administration of etherified starches during and after heart surgery, there was histopathological evidence of storage vacuoles containing etherified starch in the dermis (42). Etherified starch solutions are heterogeneous, containing molecules with a wide range of molecular weights. The smaller molecules (<50 kDa) are rapidly excreted by the kidneys, whereas larger molecules persist intravascularly until they are slowly hydrolysed or taken up by the mononuclear phagocyte system and other cells in various tissues. The mechanism by which storage of etherified starch causes pruritus is not adequately understood. It does not seem to be an allergic reaction mediated by the immune system, as there is usually little or no inflammatory cell infiltration, and the incidence of pruritus is dose-related. Whether macrophages, endothelial cells, keratinocytes, Langerhans cells, or other cells in which the starch molecules are deposited release mediators that induce itching, or whether there is a more direct effect on sensory nerve fibers, is uncertain. In this small series the number of mast cells was increased and mast cells were degranulated on electron microscopy. These features have not been seen in other studies. The

resistance of the pruritus to treatment suggests that it is not simply mediated by histamine and indeed etherified starch does not release histamine (42).

- A 68-year-old woman developed marked and persistent periocular swelling after infusion of etherified starch for sudden hearing loss. In both the affected periocular skin and healthy skin there was lysosomal storage of etherified starches with a specific antibody in histiocytes, endothelial cells, basal keratinocytes, and small nerves. In the periocular skin there was more deposition of etherified starches, in addition to distinct xanthomatous changes and features of lymphedema. In addition, there was a 50% reduction in the pH-dependent activity of the lysosomal alpha-glucosidase in cultured fibroblasts.

This finding is consistent with a heterozygous glycogenosis type II (Pompe's disease) and is of potential pathogenic relevance for the intralysosomal accumulation of etherified starch. It is possible that alpha-glucosidase has a role in the elimination of tissue-stored etherified starch. Patients with reduced alpha-glucosidase activity may be at risk of unusual adverse effects after extraordinary and prolonged tissue storage of etherified starches, especially if it is infused in large quantities. There may be unusual lysosomal accumulation of etherified starches in endothelial cells and macrophages, which may in turn account for the higher risk of pruritus and other unusual adverse effects (43).

In a prospective, randomized, controlled, epidemiological comparison of 6% etherified starch solution (200/0.5) and lactated Ringer's solution, there were no more serious complications with the former than the latter. There was a greater than 10% incidence of pruritus in both groups (44).

In 26 patients who had received etherified starch (varying widely in both dose and duration), storage of etherified starch was dose-related, and fell in all organs over time; tissues deposits were greater in patients with pruritus (45). The authors concluded that tissue deposition is transitory and dose-related, but varies widely between subjects in both severity and duration. In a retrospective postal questionnaire in 100 consecutive intensive care patients who had previously received etherified starch, of 73 patients who replied, 34% had pruritus after discharge, of whom 44% had persistent pruritus that did not resolve with conventional treatments (46). There was a significant relation between the volume of etherified starch infused and the occurrence of pruritus.

In 120 patients who had received plasma substitutes (including 93 who had received etherified starch) skin biopsies showed lysosomal deposits in the histiocytes, some of them also in the cutaneous epithelium and endothelium (47). The extent of lysosomal storage correlated with the amount of etherified starch infused. Consecutive biopsies in some cases showed a slow reduction (over years) of etherified starch deposits in vacuoles. The authors suggested that pruritus after high cumulative doses of etherified starches was closely related to deposition of etherified starch in cutaneous nerves.

In a retrospective study of the dose-relatedness of pruritus caused by etherified starch, 50 consecutive patients were evaluated by questionnaire about 6 months after treatment; 37 returned the questionnaires, of whom 20 reported pruritus, lasting an average of 15 weeks (48). There was significantly more pruritus in patients who had received more than 5 liters of etherified starch compared with those who had received less than 5 liters. The pruritus had a delayed onset and occurred in acute bouts lasting 2–30 minutes. The authors concluded that hetastarch-induced pruritus is dose-related, and that in some cases it can be prolonged and severe.

Reproductive system

Ovarian hyperstimulation syndrome has been attributed to etherified starch (49).

- A 32-year-old Caucasian woman underwent IVF for primary tubal sterility and hyperandrogenemia as reflected by polycystic disease. Follicle formation was stimulated with FSH. The first stimulation cycle had to be discontinued because of threatened ovarian hyperstimulation syndrome. During the second attempt the dose of FSH was reduced to 100 IU/day for 10 days then 150 IU/day for 7 days, when follicles were observed. Ovulation was induced with a reduced dose of HCG (5000 IU). She was given crystalloids, 50 ml of serum albumin 20%, and 500 ml of medium molecular weight etherified starch 10% (HEAS, Fresenius). This was repeated on days 5–8 and 11–15, this time with high molecular weight etherified starch 6% (Plasmasteril, Fresenius), together with other fluids. After 4 days she developed massive ascites, abdominal pain, dyspnea, hemoconcentration, and a leukocytosis of 27×10^9/l. Her girth increased between days 7 and 12, and continuous abdominal paracentesis over 6 days was necessary. Her renal function was supported using diuretics and by a continuous infusion of dopamine. On day 17 she developed increased dyspnea and headache and a pleural effusion. Her anemia was severe (hemoglobin 7.8 g/dl) and nearly all the factors in the intrinsic coagulation cascade were greatly reduced. Disseminated intravascular coagulopathy and primary liver disease were excluded. The pleural effusion contained a high concentration of etherified starch (74% of the plasma concentration). She gradually improved and was discharged on day 36.

The authors concluded that the most likely cause of severe ovarian hyperstimulation syndrome was overinfusion of etherified starch.

Immunologic

Starch derivatives are relatively safer in terms of adverse reactions than other colloid plasma substitutes, but there is an incidence of anaphylactic reactions of 4–6 per million.

- An anaphylactic reaction has been attributed to etherified starches during re-infusion of autologous bone marrow in a man treated for malignant lymphoma (6). The re-infused material had been processed using etherified starches. The patient reported pruritus and carpal spasm. Edema and erythema of the hands were present, together with hypotension and tachycardia. A very small amount of etherified starches was present in the processed bone autograft.

© 2006 Elsevier B.V. All rights reserved.

However, in this case other causes such as dimethylsulfoxide (DMSO) or plasma used while processing the autologous bone marrow for freezing could not be excluded.

- A 43-year-old male non-smoker, with a history of asthma, hypertension, and angina pectoris, was admitted to an intensive care unit for mechanical ventilation for acute severe asthma (50). He was given an inhaled bronchodilator, aminophylline, and prednisolone. His condition improved slowly but he became hypovolemic. Within 60 seconds of a fluid challenge with pentastarch 200 ml he had a severe anaphylactoid reaction.

Patients with allergy and atopy have an exaggerated response to chemical mediators released during adverse reactions. The incidence of allergy, atopy, and asthma in patients who have anaphylactic reactions is substantially greater than in non-reacting controls, which may have explained this incident. This sudden unanticipated severe reaction demanded immediate intervention, and its occurrence in a patient with pre-existing bronchospasm posed problems in maintaining ventilation and oxygenation.

Volume therapy with etherified starches in trauma patients results in a reduction in circulating adhesion molecules, an effect that is not observed with albumin infusion (51). Continuous infusion of pentoxifylline did not have a beneficial modulating action on circulating adhesion molecules. Adhesion molecules appear to play an important role in tissue damage secondary to the inflammatory process. Besides neutrophil- and endothelium-bound adhesion molecules, soluble forms have been detected in the circulating blood in trauma patients. They seem to be markers of endothelial damage, but they may also have other biological functions.

Of 1004 patients assessed at least 14 days after starch administration, using a highly sensitive enzyme-linked immunoadsorbent assay technique, one had a low titer (1:10) of etherified starch-reactive antibodies of the immunoglobulin M (IgM) class. Despite repeated infusions, no clinical reaction could be detected in this patient. The authors concluded that antibodies to etherified starches are extremely rare and that they do not necessarily cause anaphylaxis. This low antigenicity of etherified starches might explain their excellent tolerance, compared with other plasma expanders (52).

The reason for the considerable tolerability of etherified starch may be the raw material: etherified starch is synthesized from amylopectin by attaching hydroxyethyl groups. Amylopectin is very similar to glycogen, but whereas glycogen occurs in the cells of warm-blooded organisms, amylopectin is the lower-branched analogue in cells of plant origin. The human immune system is replete with this molecular structure. This may explain why the etherified starch-induced antibody was directed against the hydroxyethyl group and not against the starch molecule itself.

Second-Generation Effects

Pregnancy

Two healthy, full-term primigravidae with uneventful pregnancies and without a previous history of renal disease developed acute transient non-oliguric renal insufficiency after cesarean section under epidural anesthesia. During the procedure etherified starch 6% (70/0.5) was administered, 500 ml to one patient and 1000 ml to the other, for volume substitution after moderate blood loss (less than 800 ml). Acute non-oliguric renal insufficiency occurred on day 3 after cesarean section in the first patient and on day 2 in the second. Renal function recovered spontaneously.

Drug–Drug Interactions

Metamizole

- After plastic reconstruction with a neurovascular pedicular cutaneous sliding flap a healthy 46-year-old man developed acute renal insufficiency (53). He had received two 500 mg doses of the pyrazolone metamizole and two 500 ml infusions of 6% etherified starches.

A causative link between acute renal insufficiency and etherified starch in this case was tenuous, as it was with the metamizole. Simultaneous administration of the two is not advised.

Ethionamide and protionamide

See also Antituberculosis drugs

General Information

Ethionamide is a synthetic derivative of thio-isonicotinamide. The initial oral dosage for adults is 250 mg/day, slowly increasing up to 15–20 mg/kg/day (maximum 1 g/day).

Protionamide is a pyridine derivative of ethionamide. The dosage is 250–300 mg/day.

Ethionamide and protionamide have often proved to be effective in non-tuberculous mycobacterial infections. Acute rheumatic symptoms and difficulty in the management of diabetes have been reported (1).

Organs and Systems

Nervous system

Mental depression, weakness, drowsiness, and hypotension are not rare in patients taking ethionamide or protionamide (1,2). Other neurological reactions include diplopia, olfactory disturbances, metallic taste, dizziness, paresthesia, headache, and tremor (3).

Psychological, psychiatric

Psychotic reactions have been described in patients taking ethionamide (4,5) and may be exacerbated by alcohol (6).

Endocrine

Goitrous hypothyroidism has rarely been described in patients taking ethionamide (7), with recovery after withdrawal (8). Ethionamide inhibits both the uptake of iodine and its incorporation into trichloroacetic acid-precipitable protein (9).

Metabolism

Thionamides lower the blood glucose concentration and also suppress appetite, which influences carbohydrate intake (10).

Gastrointestinal

Nausea, vomiting, and anorexia reflect gastric intolerance, and ethionamide is best taken with meals (1,2). Protionamide has better gastric tolerance, but patients with a history of stomach ulcer are susceptible to gastric problems (11).

Skin

Severe allergic skin reactions, alopecia, acne, and purpura can occur in patients taking ethionamide (1,12). Other adverse effects include acneiform eruptions, photodermatitis, and hair loss (13).

Sexual function

Gynecomastia, impotence, and menorrhagia have been observed in patients taking ethionamide (7,14).

Second-Generation Effects

Teratogenicity

Ethionamide is teratogenic (15,16), and neither ethionamide nor protionamide should be administered during the first trimester of pregnancy.

Susceptibility Factors

Hepatic disease

Since hepatitis occurs in about 5% of patients treated with ethionamide or protionamide, frequent monitoring of liver function is compulsory (17).

Drug–Drug Interactions

Rifamycins

When thionamides are used in combination with rifampicin, hepatotoxicity is more common and severe (18,19). There was a 13% incidence of hepatotoxicity in patients with multibacillary leprosy treated with dapsone, rifampicin, and protionamide 10 mg/kg/day, and a 17% incidence in 110 patients treated with dapsone, rifampicin, and protionamide 5 mg/kg/day; however, although the lower dose of protionamide did not reduce the incidence of hepatotoxicity, it did reduce its severity (20). Protionamide does not affect the pharmacokinetics of rifampicin (21).

Ethosuximide

See also Antiepileptic drugs

General Information

The main adverse effects of ethosuximide include gastrointestinal disturbances, anorexia, dizziness, fatigue, drowsiness, headache, mood and behavioral disturbances, dyskinesias, and hiccups (1). Skin rashes (including Stevens–Johnson syndrome), systemic lupus erythematosus, scleroderma, nephrotic syndrome, blood dyscrasias, liver dysfunction, and autoimmune thyroiditis are rare.

Organs and Systems

Immunologic

Patients who develop antinuclear antibodies should be watched for the subsequent development of systemic lupus erythematosus (SEDA-19, 67) (SEDA-22, 83).

Ethylene oxide

See also Disinfectants and antiseptics

General Information

Ethylene oxide is a gas that is used in the sterilization of equipment too large for other techniques, and for sterilizing rubber, plastic goods, and other materials that are damaged by heat and not adequately disinfected by other cold methods.

Ethylene oxide is highly toxic. If it is not eliminated after sterilization it can produce severe irritation and burns. In addition, it forms ethylene glycol with moisture and ethylene chlorhydrine with free chlorine atoms. Both products, also irritants, are absorbed by the sterilized object, from which they elute very slowly. The rate of elimination of ethylene oxide and its irritant reaction products depends on a variety of factors, such as the nature and thickness of the material, the duration and temperature of aeration, and the material used for wrapping the sterilized item. Ethylene oxide is also an alkylating agent, a directly acting mutagen and carcinogen.

Exposure

Exposure to ethylene oxide has been reported predominantly in workers in sterilization units, and should be kept as low as feasible. Health personnel working in close proximity to ethylene oxide should be given information about its dangers, and should be informed of the known and

© 2006 Elsevier B.V. All rights reserved.

uncertain risks of exposure. Sterilizing equipment should be regularly checked, proper ventilation established, and alarm systems installed. These procedures must guarantee that the content of ethylene oxide is lower than 1 ppm, and that the content of halogenated ethylene hydrines is lower than 150 ppm on materials that have been sterilized by ethylene oxide at the time of use. The manufacturer of each device or instrument that should be sterilized by ethylene oxide must declare the conditions necessary for sterilization and decontamination (SEDA-11, 479).

Occupational exposure of sterilizing staff to ethylene oxide in hospitals, tissue banks, and research facilities can result during any of the following operations and conditions (1):

- changing pressurized ethylene oxide gas cylinders
- leaking valves, firings, and piping
- leaking sterilizer-door gaskets
- opening sterilizer doors at the end of a cycle
- improper ventilation at the sterilizer door
- improperly ventilated or unventilated air gap between the discharge line and the sewer drain
- removal of items from sterilizers and transfer of sterilized loads to aerators
- improper ventilation of aerators and aeration areas
- incomplete aeration items
- inadequate general room ventilation
- passing near sterilizers and aerators during operation.

In most studies, exposure appears to result mostly from peak emissions during such operations as opening the door of a sterilizer and unloading and transferring sterilized material. Although much smaller amounts are used in sterilizing medicinal instruments and supplies in hospitals and industrially, it is during these uses that the highest occupational exposures have been measured. On the other hand, proper engineering controls and work practices are reported to result in full-shift exposure of less than 0.1 ppm (0.18 mg/m^3) and short-term exposure of less than 2 ppm (3.6 mg/m^3) (1). Regular medical follow-up is advisable for sterilizing staff.

Monitoring exposure

Measurement of the concentration of ethylene oxide in workplace air is commonly used for exposure control. A standard of 1 ppm for workplace air is currently accepted as a threshold limit (SEDA-21, 254).

In 12 workers who were occupationally exposed to ethylene oxide during the sterilization of medical equipment, concentrations of 0.2–8.5 ppm were detected (2). This study also confirmed the relation between the ethylene oxide concentration in ambient air and the amount of *N*-2-hydroxyethylvaline in human globin, which has been used as a biological marker of carcinogenicity.

Disposition

Ethylene oxide is readily taken up by the lung. At steady state, 20–25% of inhaled ethylene oxide reaching the alveolar space is exhaled as unchanged compound and 75–80% is taken up by the body and metabolized. Aqueous ethylene oxide solutions can penetrate human skin.

Ethylene oxide is rapidly and uniformly distributed throughout the body. It is eliminated metabolically by hydrolysis and by conjugation with glutathione and glycol. The half-life has been estimated at 14 minutes to 3.3 hours (3–6). It is excreted mainly in the urine as thioethers; at higher doses, the proportion of thioethers is reduced, while the proportion of ethylene glycol increases.

Ethylene oxide alkylates nucleophilic groups in biological macromolecules. Hemoglobin adducts have been used to monitor tissue doses of ethylene oxide (7).

Local irritant effects

Some communications report irritating effects caused by liberation of residue of ethylene oxide and its reaction products in industrial materials, for example (SEDA-11, 479):

- tracheal stenosis by tracheotomy cannulae
- severe bronchospasm and asthmatic attacks after endotracheal anesthesia by endotracheal tubes
- anaphylaxis in a hemodialysis patient from plastic and rubber connecting tubes in an arteriovenous shunt
- postoperative inflammatory reactions to intraocular lenses
- allergic contact dermatitis
- hemolysis after exposure to plastic tubing sterilized with ethylene oxide.

Organs and Systems

Nervous system

In 12 men who were exposed to ethylene oxide after a sterilizer developed a leak, although the concentrations of ethylene oxide were not monitored, all four operators intermittently smelled the ethylene oxide gas, roughly indicating a concentration of more than 700 ppm (8). All four operators developed neurological disorders. One operator who had been working for only 3 weeks developed headache, nausea, vomiting, and lethargy, followed by major motor seizures. The other three had all been working for more than 2 years and had headache, limb numbness and weakness, increased fatigue, trouble with memory, and slurred speech. Three of them developed cataracts and one required bilateral cataract extractions. Four men, two of whom had not worked directly with the leaking sterilizer, had increased central corneal thickness with normal endothelial cell counts (SEDA-11, 479).

Other reports of neurological dysfunction related to acute and chronic exposure to ethylene oxide have appeared (9–15).

Sensory systems

Of 16 hospital sterilization operators who had been exposed to ethylene oxide and underwent medical and ocular examinations, 14 had lens opacities and 12 had abnormal contrast vision (an abnormality that is nonspecific to cataracts but which often supports the diagnosis) (16).

Hematologic

Epidemiological studies have associated ethylene oxide with hematological diseases (mainly anemia, leukopenia, and leukemia) (SEDA-24, 271). To determine whether occupational exposure to low concentrations of ethylene oxide can cause hematological abnormalities and whether

© 2006 Elsevier B.V. All rights reserved.

blood monitoring could be used as health surveillance, a cross-sectional study was undertaken (17). Blood samples were collected from 47 hospital workers who were exposed to ethylene oxide during a mean period of 6.6 years. Ethylene oxide concentrations were in the range <0.01–0.06 ppm. The control group, individually matched by age, sex, and smoking habits, consisted of 88 workers from the administrative sector who had never been occupationally exposed to ethylene oxide. There were significant differences between the exposed and the control groups in the frequency of workers with low leukocyte counts. There was no significant difference in the absolute mean number of total leukocytes, but there was an increase in the mean number of monocytes and eosinophils and a reduction in the absolute mean number of lymphocytes in the exposed group compared with the controls. There was an increase in the percentage hematocrit and the mean absolute number of erythrocytes and a fall in the mean absolute number of platelets in the exposed group compared with the controls. The mean absolute numbers of eosinophils and erythrocytes were significantly higher, as was the hematocrit, and the mean absolute numbers of lymphocytes and platelets were significantly lower in the subgroups with a higher cumulative dose of exposure. There was a dose relation between cumulative exposure and the absolute mean number of eosinophils. The results of this study suggest that the total leukocyte count and the eosinophil count could be used to monitor for early detection of health problems in ethylene oxide workers.

Immunologic

Dialyser hypersensitivity syndrome (SEDA-11, 219) (SEDA-11, 479) presents as an acute anaphylactic reaction, the symptoms of which range from mild to life-threatening. The cause of the syndrome is unknown, but affected patients appear to have a high incidence of positive radioabsorbent tests to a conjugate of human serum albumin and ethylene oxide used to sterilize artificial kidneys. This conjugate may be the allergen responsible.

Immediate hypersensitivity reactions occurred in six of 600 donors who underwent automated platelet pheresis; skin-prick testing in four of them (but in none of 40 controls) was positive when an ethylene oxide human serum albumin reagent was used (18). Radioallergosorbent testing showed that serum from four of the six donors, but only one of 145 controls, contained IgE antibodies to ethylene oxide-albumin.

Long-Term Effects

Mutagenicity

There is overwhelming evidence that ethylene oxide produces genetic damage in a wide range of organisms and cells, including somatic cells of exposed humans (7,19). Ethylene oxide is a germ-cell mutagen in rodents. In male mice it induces chromosome breakage, leading to dominant lethal mutations and heritable translocations. Sensitive stages appear to be restricted to late spermatocytes and early spermatozoa.

In females, ethylene oxide also induces presumed, dominant, lethal mutations. When females are exposed shortly after mating or during the early pronuclear stage of the zygote, high frequencies of fetal anomalies are induced.

Ethylene oxide was ineffective in inducing morphological-specific locus mutations in spermatogonial stem cells; however, it produced dominant visible and electrophoresis-specific locus mutants in male mice, assumed to be derived from poststem cells.

The effectiveness of ethylene oxide in inducing chromosome breakage in germ cells of male mice is strongly influenced by varying degrees or rates of exposure. Since there was a dose-rate effect for ethylene oxide-induced, dominant, lethal mutations at high concentrations and over long exposure periods, considering the short burst exposure and low TWA exposure in humans, the question of whether significant dose-rate effects also exist at low exposures is unanswered.

Cytogenetic studies have been performed in the peripheral lymphocytes of humans exposed to ethylene oxide (SEDA-12, 574). Several studies in workers in hospital ethylene oxide sterilization units or plants have suggested that these workers have increased frequencies of chromosomal aberrations, including micronuclei and sister chromatid exchanges in peripheral lymphocytes.

The International Agency for Research on Cancer (IARC) Working Group reviewed the published studies of workers exposed to ethylene oxide in hospital and factory sterilization units and in ethylene manufacturing and processing plants (9). The studies consistently showed chromosomal damage in peripheral blood lymphocytes, including chromosomal aberrations in 11 of 14 studies, sister chromatid exchange in 20 of 23 studies, micronuclei in three of eight studies, and gene mutation in one study. In general, the degree of damage is correlated with the degree and duration of exposure. The induction of sister chromatid exchange appears to be more sensitive to exposure to ethylene oxide than is induction of either chromosomal aberrations or micronuclei. In one study, chromosomal aberrations were observed in the peripheral lymphocytes of workers 2 years after cessation of exposure to ethylene oxide, and sister chromatid exchanges 6 months after cessation of exposure. However, in one study, incidental exposure to high concentrations of ethylene oxide did not cause any measurable permanent mutational/cytogenetic damage in lymphocytes of exposed persons (20).

The effects of glutathione-*S*-transferase T1 and M1 genotypes on hemoglobin adducts in erythrocytes and sister chromatid exchange in lymphocytes have been examined in 58 hospital operators of sterilizers that used ethylene oxide and non-exposed workers (21). The results suggested that the glutathione-*S*-transferase T1 null genotype was associated with increased formation of ethylene oxide-hemoglobin adducts in relation to occupational exposure. This suggests that individuals with the glutathione-*S*-transferase T1 null genotype may be more susceptible to the genotoxic effects of ethylene oxide.

Tumorigenicity

Ethylene oxide is carcinogenic, assigned to Group 1 of the IARC (7). There is limited evidence of carcinogenicity in humans, but much evidence in experimental animals, and

© 2006 Elsevier B.V. All rights reserved.

the IARC has classified ethylene oxide in category 1 ("carcinogenic in humans"), based primarily on evidence in animals and genotoxic considerations. The overall evaluation of the Working group of the IARC, updated in 1995, is based on the following supporting evidence.

Ethylene oxide is a directly acting alkylating agent that:

- induces a sensitive, persistent, dose-related increase in the frequency of chromosomal aberrations and sister chromatid exchange in peripheral lymphocytes and micronuclei in bone marrow cells of exposed workers;
- has been associated with malignancies of the lymphatic and hemopoietic systems in both humans and experimental animals;
- induces a dose-related increase in the frequency of hemoglobin adducts in exposed humans and a dose-related increase in the numbers of adducts in both DNA and hemoglobin in exposed rodents;
- induces gene mutations and heritable translocations in germ cells of exposed rodents;
- is a powerful mutagen and clastogen at all phylogenetic levels.

In 1979, three cases of hemopoietic cancer that had occurred between 1972 and 1977 were reported in workers at a Swedish factory where 50% ethylene oxide and 50% methyl formate had been used since 1968 to sterilize hospital equipment (22).

In epidemiological studies of exposure to ethylene oxide, the most frequently reported association has been with lymphatic and hemopoietic cancer. Two populations were studied: people using ethylene oxide as a sterilizing agent and chemical workers manufacturing or using ethylene oxide. Of studies of sterilization personnel, the largest and most informative is that conducted in the USA (23,24). Overall, mortality from lymphatic and hemopoietic cancers was only marginally raised, but there was a significant trend, especially for lymphatic leukemia and non-Hodgkin's lymphoma, in relation to estimated cumulative exposure. For exposure to 1 ppm (1.8 mg/m^3) over a working lifetime of 45 years, a ratio of 1.2 was estimated for lymphatic and hemopoietic cancers. The other studies of workers involved in sterilization in Sweden (25–27) and in the UK (28) each showed non-significant excesses of lymphatic and hemopoietic cancers. An assessment based on epidemiological data showed no increase in leukemia in those who had been exposed to ethylene oxide (29).

Because of the possibility of confounding occupational exposure in the studies of chemical workers exposed to ethylene oxide (20,25,26,28,30–38), less weight can be given to the positive findings. Nevertheless, they are compatible with a small but consistent excess of lymphatic and hemopoietic cancers found in studies of sterilization personnel. Some of the epidemiological studies have shown an additional risk of cancer of the stomach, which was significant only in one study from Sweden (25,26,30).

Second-Generation Effects

Teratogenicity

In animals, ethylene oxide has toxic effects on reproduction and is teratogenic, but the relevance of animal and epidemiological studies to occupational exposure of humans in the environment of sterilization units is unclear (SEDA-12, 576) (39).

Ethylenediamine

General Information

Ethylenediamine is used to improve the solubility of theophylline in the formulation known as aminophylline (theophylline ethylenediamine). Aminophylline is converted to theophylline after oral and intravenous administration.

Ethylenediamine is also used as a stabilizer in creams and ointments.

Ethylenediamine tetra-acetic acid is a chelating agent that is used as an anticoagulant for collecting blood samples and for removing calcium from experimental fluids in laboratories.

Organs and Systems

Respiratory

Asthma has been reported after occupational exposure to ethylenediamine (1).

Skin

Cutaneous reactions have been reported with ethylenediamine (2).

Immunologic

Systemic contact dermatitis is a delayed hypersensitivity skin reaction that results from systemic exposure. Exanthematous systemic contact dermatitis from ethylenediamine has been reported with aminophylline. Disodium edetate (ethylenediamine tetra-acetic acid) has caused contact dermatitis after local application (SEDA-23, 242), and ethylenediamine cross-reacted in a patch test in a patient who had had contact dermatitis with hydroxyzine, an ethylenediamine derivative (SEDA-22, 178). Prior sensitization can occur to ethylenediamine in creams and ointments (SED-14, 485).

Originally described in 1984, baboon syndrome is a form of systemic contact dermatitis involving the buttocks and adjacent skin in a distribution reminiscent of the erythematous buttocks seen in baboons (3). Areas under the underwear, the inner thighs, and the axillae can also be affected. Most cases are caused by oral agents, suggesting that excretion of the antigen may be a factor. In one case systemic

© 2006 Elsevier B.V. All rights reserved.

administration caused a reaction at a site that may have been previously exposed to topical ethylenediamine (2).

- A 64-year-old man developed a pruritic erythematous eruption in the perineal area a few hours after a stress test, during which he received dipyridamole and intravenous aminophylline. He had a morbilliform erythema of the perineal area under his underclothing anteriorly, with still more prominent erythema posteriorly. The measles-like rash lacked epidermal changes of exudation of scaling. A series of 20 standard patch tests were negative, except for a +++ response to ethylenediamine. On being questioned, he remembered using a topical medicament prescribed for his wife on this area in the distant past. He improved uneventfully with time and avoidance.

The authors proposed that the topical medicament had contained ethylenediamine.

- A 30-year-old woman developed a generalized urticarial reaction immediately after the intravenous administration of aminophylline (4). Skin intradermal testing was positive to ethylenediamine. Rechallenge was positive with intravenous aminophylline but negative with diprophylline, which does not contain ethylenediamine.

Most reports of aminophylline hypersensitivity reactions in the English language literature were delayed reactions. However, most of the Japanese cases were immediate reactions. Acetylation is the main metabolic pathway of ethylenediamine. Most Japanese are rapid or intermediate acetylators, while 50% of Caucasians are slow acetylators. This difference suggests an explanation for the different incidences of immediate and delayed reactions to ethylenediamine in Japanese and Caucasians.

Etidocaine

See also Local anesthetics

General Information

Etidocaine is a highly lipid-soluble, long-acting aminoamide. It has a similar toxicity profile to that of bupivacaine and there is an increased risk of life-threatening cardiac events compared with lidocaine (1).

© 2006 Elsevier B.V. All rights reserved.

Etifoxine

General Information

Etifoxine is a non-benzodiazepine drug, licensed in France for psychosomatic manifestations of anxiety.

Organs and Systems

Psychological, psychiatric

The psychomotor and amnesic effects of single oral doses of etifoxine (50 mg and 100 mg) and lorazepam (2 mg) were studied in 48 healthy subjects in a double-blind, placebo-controlled, randomized, parallel-group study (1). Its effects were assessed by a battery of subjective and objective tests that explored mood and vigilance, attention, psychomotor performance, and memory. Whereas vigilance, psychomotor performance, and free recall were significantly impaired by lorazepam, neither dose of etifoxine (50 mg and 100 mg) produced such effects. The results suggested that 50 mg and 100 mg single doses of etifoxine do not induce amnesia and sedation compared with lorazepam.

Etodolac

See also Non-steroidal anti-inflammatory drugs

General Information

Etodolac, a pyranocarboxylic acid, was first marketed in the UK in 1986. By 1988, etodolac had been reported 27 times to the UK Committee on Safety of Medicines as being suspected of causing serious adverse reactions (1). In a French postmarketing safety study in 51 355 patients taking 200–600 mg/day, 10% of patients reported a total of 6236 adverse reactions and 9% dropped out because of adverse reactions, 21 of which were judged severe (2). In another four postmarketing surveillance studies in 8334 patients with rheumatic conditions who took 200–600 mg/day of etodolac for periods ranging from 4 weeks to 1 year, 23% reported adverse events and 9%

stopped taking the drug because of adverse reactions; gastrointestinal events were the most commonly reported (3).

Organs and Systems

Nervous system

Nervous system effects of etodolac include dizziness (4.4%), headache (6.0%), and tinnitus (2.6%).

Hematologic

One case of agranulocytosis, probably induced by etodolac, with the pattern common to the other NSAIDs, has been reported (4).

Gastrointestinal

Animal experiments, as well as endoscopic and ^{51}Cr blood loss studies in man, suggest that the gastric irritancy of etodolac is low (5,6), but such claims have to be regarded with the reservations expressed about all NSAIDs. Etodolac in short-term dosages of 200, 400, and 600 mg bd caused significantly less damage to both the gastric and the duodenal mucosa than aspirin 3.9 g/day (SEDA-12, 85). It had a less damaging effect on the stomach than naproxen in a short-term endoscopic study in rheumatoid arthritis (7). The most frequent adverse effects in 1379 patients in trials were gastrointestinal symptoms: 8.9% of patients had nausea, 5.8% epigastric pain, 5.7% heartburn, and 5.2% indigestion; 1.9% of patients had to be withdrawn because of these adverse effects.

Acute colitis demonstrated by endoscopy and rechallenge was reported in two patients taking etodolac for arthritis (8). Colonic strictures have been described in another report (SEDA-22, 115).

Skin

Skin rashes occur in 3% of patients who take etodolac (SEDA-12, 85).

Susceptibility Factors

Age

The safety profiles of etodolac in elderly and younger patients are similar (SEDA-19, 98).

Drug Administration

Drug formulations

The long-term treatment safety profile of a modified-release formulation of etodolac was similar to that of the standard formulation (SEDA-18, 104).

Drug dosage regimens

In 1986, the UK Drug Safety Research Unit at Southampton published a report on its prescription event monitoring study of etodolac (SEDA-13, 80). Etodolac was rated effective in only 56% of 9109 patients, and the Unit concluded that the average dosage used (400 mg/day) was too low to be effective. Consequently, the adverse reaction figures should be viewed with great caution. Indeed, at an adequate dosage they might actually be unfavorable, since in this study the rate of dyspepsia during the first month was 16 per 1000 compared with 3 per 1000 for piroxicam. After the first month, the rates were similar for etodolac and piroxicam. Few serious events were recorded: exfoliative dermatitis in one patient with psoriatic arthritis and 20 cases of hematemesis or melena.

Etomidate

See also General anesthetics

General Information

Etomidate, a non-barbiturate anesthetic, is considered to be safe, especially in patients with hemodynamic instability. The most common complications of using etomidate are venous sequelae, pain on injection (1), and involuntary muscle movements (SED-11, 211) (2).

Organs and Systems

Cardiovascular

The cardiorespiratory tolerance of etomidate is usually excellent (3), but cardiovascular instability has been described after a bolus dose (4).

© 2006 Elsevier B.V. All rights reserved.

Nervous system

In 104 patients, the frequency of pain on injection of etomidate was 32–53% and was severe in 5–20% of patients (5). The frequency of involuntary movements was 15–35%. The frequency of both pain and involuntary muscle movements was least when fentanyl 2.5 μg/kg was given before etomidate. There was no significant relation between pain and muscle movement. A medium-chain triglyceride and soya bean emulsion formulation has been used for anesthetic induction, in an attempt to reduce the unwanted adverse effects of pain on injection and thrombophlebitis (6).

Myoclonus has been noted, and can be dangerous in open eye surgery (7).

Etomidate produced activation of epileptiform activity, and electrographic seizures during craniotomy in epileptic patients (8). Generalized seizures were noted after etomidate induction in 20% of 30 patients without a history of epilepsy (9). Cerebral excitation can also occur after recovery from etomidate anesthesia, with potential respiratory disturbance (10,11). Caution should be exercised when giving etomidate to patients with a history of seizures (SEDA-18, 113).

When etomidate was given to 12 patients who had seizures of short duration during electroconvulsive therapy conducted previously under propofol anesthesia, mean seizure duration was significantly increased with etomidate anesthesia (12). However, there is no evidence that this observation is associated with an improved psychiatric outcome.

Endocrine

Adrenocortical function has been assessed in a randomized trial after intravenous etomidate in 30 patients who required rapid-sequence induction and tracheal intubation (13). The controls received midazolam. Etomidate caused adrenocortical dysfunction, which resolved after 12 hours.

Cortisol and aldosterone concentrations were reduced by etomidate in adults (14,15), but the clinical relevance was minimal after a single bolus (16). A reduction in cortisol was reported 2 hours after delivery in 40 infants whose mothers received etomidate for cesarean section. There were also nine cases of severe to moderate hypoglycemia in this study, but the changes in blood glucose concentration were not significantly different from those in controls (17).

Hematologic

Hemolysis has been reported after the administration of etomidate (18). It may be related to the use of propylene glycol as a solvent (19,20).

Platelet hyperaggregability after general anesthesia has been reported in patients undergoing vascular surgery. The effect of etomidate and thiopental on platelet function has now been examined in 46 patients undergoing infrainguinal vascular surgery (21). Etomidate caused significant platelet inhibitory effects, whereas the effects of thiopental were minor. This may affect the choice of anesthetic in patients with compromised hemostasis.

Immunologic

Transient erythema has been described, but histamine release does not occur (22).

Etomidate is the induction agent of choice in atopic patients, in whom etomidate, fentanyl, and vecuronium comprise the safest combination of drugs for general anesthesia. However, non-allergic anaphylactic (anaphylactoid) reactions have been observed, even with this combination (23,24), and it can even be life-threatening; one patient also had a myocardial infarction (24).

Drug Administration

Drug formulations

An oral transmucosal formulation of etomidate, which is absorbed over 15 minutes, has been studied in 10 healthy adults at four doses: 12.5, 25, 50, and 100 mg (25). Dose-related drowsiness and light sleep occurred 10–20 minutes after administration. Peak serum concentrations and clinical effects were noted at about 20 minutes, with no clinical effect noticeable by 60 minutes. There was no vomiting and only four patients had transient nausea. Two patients had brief episodes of involuntary tremor with the 100 mg dose. Of note was the increasingly unpleasant taste with increasing dose and the apparent reduction in absorption with higher doses.

Adverse effects

Taiwanese doctors have reported two cases of hepatocellular injury after oral administration of infusions of *B. officinalis* (2).

- One of the two patients had taken 1500 mg of the lower stem and root of *B. officinalis* boiled in water in a suicide attempt. She was admitted with vomiting and headache and later developed gastritis, hematuria, and liver damage. Symptomatic treatment resulted in full recovery.
- A 51-year-old woman consumed 20 pieces of the lower stem and root of *B. officinalis* to treat dermatitis. She developed nausea, vomiting, and dizziness, and had raised liver enzymes. Her liver function recovered 1 month after withdrawal of *B. officinalis*.

When *B. officinalis* was mistaken for a similar plant, *Securinega suffruticosa*, and was cooked in a soup used for muscle aches, lumbago, or as a tonic by 19 patients, 14 developed diarrhea, 10 had nausea and felt cold, nine had sensations of abdominal fullness, and seven vomited (3). Liver enzymes rose and the median times to median peak activities were 3 days for alanine transaminase, 2 days for aspartate transaminase, 5 days for alkaline phosphatase, and 12 days for gamma glutamyltranspeptidase. The liver damage was hepatocellular liver injury rather than cholestatic and marked jaundice did not develop.

Croton tiglium

The oil of *Croton tiglium* (croton) has a violent purgative action and contains tumor-promoting phorbol diesters and triesters.

Adverse effects

Croton oil has been used as a peeling agent in phenol as a carrier; its use in concentrations of 2% and over is almost always associated with depigmentation of the skin and delays in healing in areas other than the thick skin of the lower nose and around the mouth (4).

Croton is also the name given to *Codiaeum variegatum*, a highly decorative potted plant. Handling this plant over a period of 6 months produced contact eczema of the hands in a nursery gardener. Patch tests with croton leaves were positive (5).

Ricinus communis

Castor oil is the fixed oil obtained from the seeds of *Ricinus communis* (castor) by cold expression. The whole beans contain a variety of substances that are not expressed with the oil, including the toxin ricin (6,7).

Adverse effects

When taken by mouth, especially in large doses, castor oil can cause violent purgation with nausea, vomiting, colic, and a risk of miscarriage.

Transdermal exposure to ricin is not serious, since it is not well absorbed through the skin. Oral exposure, for example by ingestion of castor beans, can cause severe gastroenteritis, gastrointestinal hemorrhage, and death due to circulatory collapse. Parenteral injection of ricin is rapidly fatal, as is aerosol exposure; the lethal dose by these routes is 5–10 micrograms/kg (8).

Immunologic

Anaphylaxis has been attributed to consumption of whole castor beans (9).

- A 44-year-old woman chewed a castor bean seed and within minutes developed urticaria, drowsiness, Quincke's edema, and extreme hypotension. Her anaphylactic shock was treated with adrenaline, intravenous glucocorticoids, antihistamines, and intravenous fluids. She quickly recovered and a subsequent blood test demonstrated CAP-RAST to castor beans.

Fetotoxicity

In 498 women who had recently taken castor oil and possibly herbal substances called "sihlambezo" before artificial rupture of membranes, fetal passage of meconium was more common (10). However, in a study of 100 women castor oil had no effect on the rate of meconium-stained liquor (11).

Everolimus

General Information

Everolimus is an immunosuppressive macrolide that also has synergistic actions with ciclosporin and interrupts the proliferative responses of vascular and bronchial smooth muscle cells. In a phase I trial, its safety profile and pharmacokinetics were assessed during a 4-week course of once-daily sequential ascending doses (0.75, 2.5, or 7.5 mg/day) in renal transplant recipients on a stable regimen of ciclosporin and prednisone (1). Pharmacokinetic data showed dose proportionality, a good correlation between trough and AUC concentrations, and moderate accumulation (2.5-fold). Absorption was within 2 hours, and the half-life was 16–19 hours. There was no evidence of a pharmacokinetic interaction of ciclosporin with everolimus. Virtually every patient in this study had at least one adverse event and 43% of patients treated with everolimus 7.5 mg/day had serious adverse events. In all everolimus groups there was an increased incidence of infectious episodes (*Herpes simplex*, upper respiratory infections, pharyngitis, pneumonia, and sinusitis). Similarly, adverse events involving the gastrointestinal system (diarrhea, nausea, and vomiting) were more common. Serum concentrations of triglycerides and total cholesterol increased significantly over time. Individuals treated with everolimus 7.5 mg/day had significant falls in white cell count (–2.6%) and platelet count (–51%); the nadir occurred on day 19 and the cell counts recovered spontaneously without withdrawal of the drug. Serum creatinine concentrations and blood pressure did not change.

Drug–Drug Interactions

Ciclosporin

Both everolimus and ciclosporin are extensively biotransformed by CYP3A and are substrates for P-glycoprotein. However, in a multicenter randomized double-blind study in 101 patients, 1 year after kidney transplantation, who were randomly assigned to receive everolimus 0.5, 1, and 2 mg bd plus ciclosporin and prednisone, the pharmacokinetics of ciclosporin were similar to published values in patients not taking everolimus (2).

Eye-drops and ointments

General Information

Eye-drops and ointments are specialized pharmaceutical formulations intended to produce therapeutic concentrations of the active drug in ocular structures; a lower dose can be used than would be necessary to obtain the same effect by systemic administration. They can cause local adverse effects in the eye due either to the active ingredient or to excipients in the liquid or solid vehicle. The excipients included in modern ophthalmic medicines increase the viscosity of the drug, help to maintain it in solution or suspension, and are thought to stay longer on the exterior of the eye, leading to a longer contact time and possibly greater absorption of the drug than is the case with a simple aqueous solution (1).

Excipients

Methylcellulose is a vehicle used in eye-drops and contact lens solutions (SEDA-1, 369). It is non-irritant and has a good refractive index. A 1% solution is well retained in the conjunctival sac. Corneal cultures have been stimulated by methylcellulose, resulting in increased growth of cells (2); tear-film break-up time was increased four-fold with 2% methylcellulose. Hydroxypropyl methylcellulose is also used as artificial tears for people with dry eyes (3).

Petrolatum-mineral oil ointment is retained longer on the eye than other vehicles. The large molecules of the petrolatum-mineral oil-base ointment are not easily removed by blinking, and a component of the corneal tear film is a non-polar oil. Ointments are oil bases and non-polar, which is why they are readily absorbed by the pre-corneal and conjunctival tear films. To maintain drug contact with the eye, patching is recommended (1).

Polyvinyl alcohol, a synthetic long-chain alcohol, has been used as a component of various ophthalmic drug vehicles. For retaining clear vision and longer drug contact with the eye, polyvinyl alcohol is superior to saline. Polyvinyl alcohol has good drug compatibility and it acts as a wetting agent, lowering surface tension; at a concentration of 1.4% it does not interfere with corneal wound healing (1).

Systemic effects of ophthalmic medications

Of the drug that is administered in eye-drops, 80% diffuses into the general circulation and can have systemic effects, even when low concentrations are used (1). The lacrimal pump is the essential route of diffusion from eye-drops into the systemic circulation, through active cellular absorption in the lacrimal secretory pathways. The active ingredient avoids first-pass metabolism and reaches its site of action directly, resulting in increased systemic availability. All the same, this form of treatment is generally very well tolerated, when one bears in mind the immense volume of eye-drops prescribed by ophthalmologists each day.

Everolimus

General Information

Everolimus is an immunosuppressive macrolide that also has synergistic actions with ciclosporin and interrupts the proliferative responses of vascular and bronchial smooth muscle cells. In a phase I trial, its safety profile and pharmacokinetics were assessed during a 4-week course of once-daily sequential ascending doses (0.75, 2.5, or 7.5 mg/day) in renal transplant recipients on a stable regimen of ciclosporin and prednisone (1). Eye-drops and ointments

General Information

Eye-drops and ointments are specialized pharmaceutical formulations intended to produce therapeutic concentrations of the active drug in ocular structures; a lower dose can be used than would be necessary to obtain the same effect by systemic administration. They can cause local adverse effects in the eye due either to the active ingredient or to excipients in the liquid or solid vehicle. The excipients included in modern ophthalmic medicines increase the viscosity of the drug, help to maintain it in solution or suspension, and are thought to stay longer on the exterior of the eye, leading to a longer contact time and possibly greater absorption of the drug than is the case with a simple aqueous solution (1).

Excipients

Methylcellulose is a vehicle used in eye-drops and contact lens solutions (SEDA-1, 369). It is non-irritant and has a good refractive index. A 1% solution is well retained in the conjunctival sac. Corneal cultures have been stimulated by methylcellulose, resulting in increased growth of cells (2); tear-film break-up time was increased four-fold with 2% methylcellulose. Hydroxypropyl methylcellulose is also used as artificial tears for people with dry eyes (3).

Petrolatum-mineral oil ointment is retained longer on the eye than other vehicles. The large molecules of the petrolatum-mineral oil-base ointment are not easily removed by blinking, and a component of the corneal tear film is a non-polar oil. Ointments are oil bases and non-polar, which is why they are readily absorbed by the pre-corneal and conjunctival tear films. To maintain drug contact with the eye, patching is recommended (1).

Polyvinyl alcohol, a synthetic long-chain alcohol, has been used as a component of various ophthalmic drug vehicles. For retaining clear vision and longer drug contact with the eye, polyvinyl alcohol is superior to saline. Polyvinyl alcohol has good drug compatibility and it acts as a wetting agent, lowering surface tension; at a concentration of 1.4% it does not interfere with corneal wound healing (1).

Systemic effects of ophthalmic medications

Of the drug that is administered in eye-drops, 80% diffuses into the general circulation and can have systemic effects, even when low concentrations are used (1). The lacrimal pump is the essential route of diffusion from eye-drops into the systemic circulation, through active cellular absorption in the lacrimal secretory pathways. The active ingredient avoids first-pass metabolism and reaches its site of action directly, resulting in increased systemic availability. All the same, this form of treatment is generally very well tolerated, when one bears in mind the immense volume of eye-drops prescribed by ophthalmologists each day.

The systemic effects exerted by eye-drops are most pronounced in the case of agonists and antagonists in the autonomic nervous system. For example, beta-blockers in eye-drops can cause bronchospasm, heart failure, syncope, and psychiatric disorders (4–6), especially at high doses and with non-selective beta-blockers, although these adverse reactions are usually related to failure to observe prescribing precautions (1).

Alpha$_2$-adrenoceptor agonist eye-drops can cause hypotension (7).

Except in patients at special risk (children under the age of 30 months and the elderly) parasympathomimetic eye-drops cause few systemic adverse effects (SEDA-16, 543).

Cholinesterase inhibitors, which have curare-like properties, are contraindicated for 6 weeks before general anesthesia.

In the very young and the very old patients atropine eye-drops carry a risk of cardiovascular collapse and neuropsychiatric disturbances (SEDA-16, 543).

Systemic problems can also develop with antimicrobial eye-drops (8) and contact lens products (9,10).

Local adverse effects

Ophthalmic drugs can cause problems of local tolerance, but with variable frequency. They can cause pain on instillation, allergic reactions, delayed healing, punctate keratitis, and disturbances of lacrimal secretion and accommodation. These local problems may be responsible for poor patient adherence to therapy.

Contact dermatitis

Allergic contact dermatitis is the most common dermatological condition that affects the eyelids. Allergic contact dermatitis was found in a retrospective study in 151 (74%) of 203 patients with persistent or recurrent eyelid dermatitis with or without dermatitis elsewhere (11): 46 had protein-contact dermatitis, but only 14 had protein-contact dermatitis without concurrent allergic contact dermatitis; 23 patients had atopic eczema, of whom 16 also had allergic contact dermatitis, protein-contact dermatitis, or both. Other conditions included seborrheic dermatitis, psoriasis, dry eyes, and dermatomyositis or overlapping connective tissue disease. Important sources of contact sensitivity were topical ocular medications, including glucocorticoids, cosmetics, metals, dust mites, animal dander, and artificial nails; only five cases were caused by nail lacquer.

Susceptibility factors

Elderly people are particularly likely to make errors in the administration of ophthalmic medications, resulting in overdosage and adverse toxic effects or underdosage with inadequately controlled glaucoma (12). This may reflect impaired memory, mental confusion, impaired vision, hearing, and mobility, or a combination of these factors. It is wise to assess both adherence to therapy and administration technique to ensure the safe and effective use of ophthalmic formulations in these patients (SEDA-21, 487) (13).

Use of eye-drops

A few simple rules can reduce the incidence of adverse effects of eye-drops and improve adherence to therapy:

- respect the contraindications and precautions applicable to the drug (1);
- start with the lowest possible dose, especially in children and elderly people (12);
- never administer more than 30 µl of an eye-drop at any time, and give it only into the superolateral corner of the eye (13);
- close the medial canthus with the finger after instillation of the eye-drop to minimize systemic absorption (14).

Ezetimibe

General Information

Ezetimibe is a selective potent inhibitor of the intestinal absorption of dietary and biliary cholesterol. A total of 432 patients were included in a pooled analysis of two phase-II studies, both lasting for 12 weeks; ezetimibe was well tolerated, with an adverse events profile similar to that of placebo (1). In 668 patients who took ezetimibe with simvastatin, the adverse effects were similar to those with simvastatin alone (2).

Fabaceae

See also Herbal medicines

General Information

The genera in the family of Fabaceae (Table 1) (formerly Leguminosae) include broom, liquorice, senna, tamarind, and a variety of pulses, such as fava beans, lentil, peas, and vetches.

Cassia species

The leaves and fruits of *Cassia angustifolia* and *Cassia senna* (senna) contain laxative anthranoid derivatives. Mutagenicity testing of sennosides has produced negative results in several bacterial and mammalian systems, except for a weak effect in *Salmonella typhimurium* strain TA102 (1,2). No evidence of reproductive toxicity of sennosides has been found in rats and rabbits (3).

Senna is widely used in fairly low doses without serious problems; it has also been used in a very high dosage form to clear the colon before radiological examination. In this form it is generally well tolerated, but it should not be used if there is any predisposition to colonic rupture.

Adverse effects

The safety and efficacy of senna have been reviewed (4). Its rhein-anthrone-induced laxative effects occur through two distinct mechanisms, an increase in intestinal fluid transport, which causes accumulation of fluid intraluminally, and an increase in intestinal motility. Senna can cause mild abdominal complaints, such as cramps or pain. Other adverse effects are discoloration of the urine and hemorrhoidal congestion. Prolonged use and overdose can result in diarrhea, extreme loss of electrolytes, especially potassium, damage to the surface epithelium, and impairment of bowel function by damage to autonomic nerves. Abuse of senna has also been associated with melanosis coli, but resolution occurs 8–11 months after withdrawal. Tolerance and genotoxicity do not seem to be problems associated with senna, especially when used periodically in therapeutic doses.

Liver

Abuse of senna can cause hepatitis (5,6).

Skin

Occupational allergic contact dermatitis has been attributed to a species of *Cassia* (7,8), as has contact urticaria (9).

Musculoskeletal

Finger clubbing (hypertrophic osteoarthropathy) has been reported in patients who have abused senna (10–15).

Lactation

When a standardized preparation containing senna pods (providing 15 mg of sennosides per day) was given to breastfeeding mothers, the suckling infants were only exposed to a non-laxative amount of rhein, which

remained a factor of 10^{-3} below the maternal intake of this active metabolite (16).

Tumorigenicity
A well-defined purified senna extract was not carcinogenic, when administered orally to rats in daily doses up to 25 mg/kg for 2 years (17).

Drug interactions
An unusual Antabuse-type reaction reported on one occasion seems to have been due to an interaction of metronidazole with the alcohol present in the high-dosage form X-Prep (SEDA-15, 398).

Crotalaria species

Most of the members of the *Crotalaria* (rattlebox) species contain pyrrolizidine alkaloids, such as crotaline and monocrotaline, and therefore have hepatotoxic potential (18). These alkaloids are covered in a separate monograph.

Adverse effects
Pyrrolizidine alkaloids cause obstruction of the hepatic venous system and can lead to hepatic necrosis. Clinical manifestations include abdominal pain, ascites, hepatomegaly, and raised serum transaminases. The prognosis is often poor, death rates of 20–30% being reported. In an outbreak of veno-occlusive disease in the Sarguja district of India, probably caused by consumption of cereals mixed with *Crotalaria* seeds, 28 of 67 patients died (19).

It is prudent to avoid exposing unborn or suckling children to herbal remedies containing pyrrolizidine alkaloids. Animal studies have shown that transplacental passage and transfer to breast milk are possible, and there is a human case on record of fatal neonatal liver injury, in which the mother had used a herbal cough tea containing pyrrolizidine alkaloids throughout her pregnancy.

Cyamopsis tetragonoloba

Guar gum, which is covered in a separate monograph, comes from the endosperm of the seeds of *Cyamopsis tetragonoloba* (cluster bean). It has a small hypolipidemic effect (20) and a small blood glucose-lowering effect (21).

Adverse effects
Guar gum causes abdominal pain, flatulence, diarrhea, and cramps (22). It has been repeatedly associated with esophageal obstruction (23).

Guar gum can cause occupational rhinitis and asthma. Of 162 employees at a carpet-manufacturing plant, in which guar gum is used to adhere the dye to the fiber, 37 (23%) had a history suggestive of occupational asthma and 59 (36%) of occupational rhinitis (24). Eight (5%) had immediate skin reactivity to guar gum. Eleven (8.3%) had serum IgE antibodies to guar gum.

Guar gum reduces the speed but not the extent of absorption of digoxin (25), nitrofurantoin (26), and paracetamol (27). It reduces both the speed and extent of absorption of phenoxymethylpenicillin (25).

Cytisus scoparius

Cytisus scoparius (Scotch broom) contains the toxic alkaloid sparteine and related quinolizidine alkaloids, such as isosparteine and cytisine. Sparteine has been used as a marker of drug metabolism by CYP2D6 (28) and is covered in a separate monograph.

Adverse effects
Inexpert self-medication with a broom tea has resulted in fatal poisoning with clinical symptoms of ileus, heart failure, and circulatory weakness.

It is prudent to avoid broom formulations during pregnancy, not only because sparteine has abortifacient potential but also because of evidence that the plant produced malformed lambs in feeding trials.

Dipteryx species

The seeds of *Dipteryx odorata* (Dutch tonka bean) and *Dipteryx oppositofolia* (English tonka bean) are said to yield 1–3% of the non-anticoagulant coumarin, which is covered in a separate monograph.

Genista tinctoria

Genista tinctoria (dyer's broom) contains 0.3–0.8% of toxic quinolizidine alkaloids, such as anagyrin, cytisine, and *N*-methylcytisine. The last two constituents have peripheral effects similar to those of nicotine, whereas their central activity may be different. Anagyrine is a suspected animal teratogen and cytisine has teratogenic activity in rabbits.

Glycyrrhiza glabra

Glycyrrhiza glabra (licorice) (29) contains a wide variety of chalcones, coumarins, flavonoids, and triterpenoids, some of which mimic the mineralocorticoid actions of aldosterone. The saponin glycoside glycyrrhizinic acid (glycyrrhetinic acid, carbenoxolone) (30) and deglycyrrhizinized licorice (Caved-S) (31) have both been used to treat gastric ulceration, but have been displaced by better drugs.

Licorice is used widely and is found in a variety of sources (32):

Pastis brands
Anisettes (raki, ouzo, Pernod).

Adverse effects

Most individuals can consume 400 mg of glycyrrhizin daily without adverse effects, but some individuals develop adverse effects following regular daily intake of as little as 100 mg of glycyrrhizin (33).

Cardiovascular

In healthy volunteers who took licorice corresponding to glycyrrhizinic acid 75–540 mg/day for periods of 2–4 weeks, there was an average increase in systolic blood pressure of 3.1–14.4 mmHg (34). The increase in blood pressure was dose-related and the authors concluded that as little as 50 g/day of licorice for 2 weeks would have caused a significant rise in blood pressure.

Sensory systems

Five patients who had consumed large amounts (0.1–1 kg) of licorice subsequently had transient visual loss/aberrations (35). Glycyrrhizinic acid in licorice causes vasoconstriction in vascular smooth muscle and the authors therefore speculated that vasospasm of the retinal or occipital artery had caused the problems.

Electrolyte balance

The active ingredients of licorice inhibit the breakdown of mineralocorticoids by inhibiting 11-beta-hydroxysteroid dehydrogenase type 2, and its adverse effects relate mainly to mineralocorticoid excess, with sodium retention, potassium loss, and inhibition of the renin–angiotensin–aldosterone system (36).

In two cases prolonged intake of relatively small amounts of licorice resulted in hypertension, encephalopathy, and pseudohyperaldosteronism (37). Both patients were highly susceptible to the adverse effects of glycyrrhizinic acid because of 11-beta-hydroxysteroid dehydrogenase deficiency.

- A 44-year-old woman developed an irregular heart rhythm and repeated episodes of life-threatening torsade de pointes (38). Her serum potassium was 2.3 mmol/l. Treatment with an infusion of potassium and magnesium promptly restored normal rhythm. The cause of the problem was identified as the patient's habit of consuming large (but not more closely defined) quantities of licorice daily. One year after this episode she was still abstaining from licorice and showed no signs of cardiac disease.
- A 39-year-old woman had a potassium concentration of 2.9 mmol/l at a routine checkup (39). She denied taking any medications except a "cleansing tea" purchased from a health food company. The tea was analysed and found to contain significant amounts of licorice. Her potassium concentration normalized after withdrawal of the product and potassium supplementation.
- A 67-year-old Chinese man developed progressive muscular weakness (40). His medical history was unremarkable, but his urinary potassium excretion was high and he had hypokalemia and low plasma renin activity. He admitted taking a powdered Chinese herbal formulation for about 4 months, which was shown to contain large amounts of glycyrrhizinic acid (336 mg/day). He was treated with spironolactone, and 2 weeks later his potassium values had normalized.

Two patients who used licorice-flavored chewing gum developed severe hypokalemia (32).

- A 21-year-old woman who took licorice about 100 g/day developed a headache, hypertension (190/120 mmHg), and hypokalemia (2.6 mmol/l). She stopped eating licorice and instead used a chewing gum that also contained licorice (daily intake of glycyrrhizinic acid about 120 mg). Three weeks after she stopped using the gum her blood pressure was 110/80 mmHg and plasma potassium concentration 5.3 mmol/l.
- A 35-year-old woman developed pretibial edema and hypokalemia (2.2 mmol/1) after using a licorice-flavored chewing gum (about 50 mg of glycyrrhizinic acid per day). She stopped using the gum and improved within 2 weeks.

In six male volunteers who took glycyrrhizinic acid for 7 days, serum, urinary, and sweat electrolytes values were consistent with a mineralocorticoid-like effect (41). Plasma renin activity was suppressed, and plasma cortisol and aldosterone progressively fell during treatment. The authors proposed that glycyrrhizinic acid initially acts by increasing the effect of endogenous mineralocorticoids, and then when it or its metabolites accumulate it may also have a direct mineralocorticoid-like effect itself.

Lupinus species

Lupinus (lupin) seeds are commonly taken as an appetizer in Southern Europe and the Middle East. Lupin flour has been used as a source of energy and protein (42,43). An extract of *Lupus termis* has been used to treat chronic eczema (44).

Adverse effects

Anticholinergic effects of lupin poisoning have been reported (45).

- A 72-year-old Portuguese woman presented to an emergency department with classic anticholinergic

© 2006 Elsevier B.V. All rights reserved.

signs: sudden onset of nausea and vomiting, blurred vision, generalized weakness, and tachycardia (46). She had taken a herbal product containing lupin seeds in the belief that it would cure her recently diagnosed diabetes mellitus.

Analysis of the product identified the preponderant compound as oxosparteine, which has powerful anticholinergic effects.

Medicago species

Medicago sativa (alfalfa) sprouts are commonly used as a source of protein.

Adverse effects

Skin

Dermatitis has been recorded after the ingestion of infusions made from alfalfa seeds. Dermatitis has also been reported in horse handlers exposed to the straw itch mite, *Pyemotes tritici*, contaminating alfalfa seeds (47).

Immunologic

Prolonged ingestion of alfalfa seeds or alfalfa tablets has been associated with the induction or exacerbation of a lupus-like syndrome in humans, perhaps because of the canavanine alfalfa contains (48,49).

Infection risk

Alfalfa seeds are readily infected and there have been numerous reports of infections arising from the consumption of alfalfa sprouts grown from contaminated seeds. The most common infections are with *Salmonella* species, including *Salmonella enterica* (50), *Salmonella havana* (51), *Salmonella kottbus* (52,53), *Salmonella mbandaka* (54), *Salmonella muenchen* (55), *Salmonella paratyphi* (56), *Salmonella stanley* (57), and other serotypes (58,59). Occasionally, other organisms occur, such as *Listeria* (60) and *Escherichia coli* (61,62).

Melilotus officinalis

Melilotus officinalis (sweet clover) contains coumarin, 3,4-dihydrocoumarin (melilotine), ortho-coumaric acid, ortho-hydroxycoumaric acid, and the ortho-glucoside of ortho-coumaric acid (melilotoside). Withering of the plant leads to enzymatic glycoside hydrolysis and the resulting ortho-coumaric acid is spontaneously transformed to coumarin; the dried herb therefore smells strongly of coumarin (see separate monograph). *M. officinalis* has been used to treat lymphedema and the edema of chronic venous insufficiency.

Myroxylon species

Balsam of Peru is derived from species of *Myroxylon* such as *Myroxylon balsamum* and *Myroxylon pereirae* and has been used in medicinal and cosmetic ointments for centuries. It contains about 25 different substances, including triterpenoids, and can cause allergic reactions. Its sensitizing constituents have been determined (63).

Adverse effects

Balsam of Peru is a topical photosensitizer (SEDA-19, 162) and can cause contact urticaria (64,65). A systemic contact dermatitis has been reported after oral administration (66). In one case an allergic contact dermatitis in a patient sensitive to balsam of Peru caused a primary eruption on the face with secondary purpuric vasculitis-like eruptions on both legs (67).

In 60 patients with positive patch-test reactions to a fragrance mix or *M. pereirae* resin (balsam of Peru) there were positive immediate contact reactions to *M. pereirae* resin in 57% and to the fragrance mix in 12% (68). In a control group ($n = 50$) of eczematous, patch test-negative patients there were positive immediate reactions to *M. pereirae* resin in 58% and to the fragrance mix in 12%. The authors commented that the absence of a significant difference between the fragrance-allergic group and the control group was in keeping with a non-immunological basis for the immediate contact reactions.

Pithecollobium jiringa

Pithecollobium jiringa (jering fruit) is valued in Malaysia and Indonesia as a delicacy and for its antidiabetic properties.

Adverse effects

Acute renal insufficiency is a rare complication of the use of jering. In one case there was dysuria, hematuria, vomiting, abdominal pain, and blue urine (69). In two other cases there was bilateral loin pain, fever, nausea, vomiting, oliguria, hematuria, and passage of sandy particles in the urine (70). Blood urea and serum creatinine were markedly raised. With conservative therapy, which included rehydration with isotonic saline and alkalinization of the urine with sodium bicarbonate, the acute renal insufficiency resolved.

Sophora falvescens

Sophora falvescens (Ku shen) contains a variety of matrine alkaloids, such as aloperine, cytosine, lehmannine, matrine, oxymartine, oxysophocarpine, sophocarpine, sophoramine, and sophoridine, the flavonoid kushenol, and the saponin sophoraflavoside. Ku shen is a Chinese herbal remedy made from the root of *S. falvescens*. And Qing luo yin, a Chinese herbal remedy for rheumatoid arthritis, is a combination of extracts of *Dioscorea hypoglauca*, *Phellodendron amurense*, *Sinomenium acutum*, and *S. flavescens*.

Adverse effects

A herbal record lists the following adverse effects of Ku shen: salivation, abnormal gait, dyspnea, tachycardia (71). In larger doses, nervous system stimulation with muscle spasm and seizures can occur. There have been three reports of adverse reactions such as nausea, vomiting, dizziness, bradycardia, palpitation, ataxia, pallor, sweating, seizures, and dysphasia.

Trifolium pratense

Trifolium pratense (red clover) contains flavones (isorhamnetin, pratensein), phenolic coumarins, phytoestrogens, and demethylpterocarpin. It has been used to treat menopausal symptoms, without good evidence of efficacy (72).

© 2006 Elsevier B.V. All rights reserved.

Adverse effects

The coumarins in red clover may potentiate the effects of oral anticoagulants (73).

Factor VII

See also Coagulation proteins

General Information

Factor VII is the most sensitive of the vitamin K-dependent clotting factors. The mode of action is tissue factor-dependent activation of factors Xa and IXa on the surfaces of activated platelets (1). Factor Xa leads to thrombin generation and hemostasis, by converting fibrinogen to fibrin. This process is limited to the site of injury, since exposure of tissue factor from the subendothelial matrix has a role in the action of recombinant factor VIIa, thereby reducing the risk of thromboembolic events (2).

Recombinant activated factor VII (factor VIIa) is indicated for patients with inhibitors of clotting factors VIII and IX (3–5). It has also been used to good effect preoperatively, in patients with severe thrombocytopenia, and in the treatment of life-threatening bleeding, including bleeding related to anticoagulant therapy or liver failure (3). The usefulness of recombinant factor VIIa for correcting the prothrombin time has been demonstrated in three neonates with liver failure undergoing liver biopsy and central venous catheter placement (6).

A disadvantage of recombinant factor VIIa is the need for frequent administration, because of its short half-life, about 2.7 hours with a clearance of 0.5 ml/kg/minute. The clearance is even faster in patients aged under 15 years. In one child the half-life was no more than 1 hour (7).

In general factor VII is well tolerated, with an incidence of non-serious adverse events of 3.6% (3). The most frequently reported adverse events are hypertension, skin reactions, fever, headache, epistaxis, reduced plasma fibrinogen, and prolonged prothrombin time (3,4).

Animal studies and case reports have suggested that recombinant factor VIIa should reduce the INR in patients taking oral anticoagulants and also has a hemostatic effect (8).

Organs and Systems

Cardiovascular

Thrombophlebitis at the infusion site is a common complication of continuous infusion of various clotting factor concentrates and has been noted after infusion of factor VIIa (9,10). Thrombophlebitis occurred in one of eight hemophiliacs with inhibitors who received continuous infusion of recombinant factor VIIa to allow elective surgery (11). In 25 hemophilia patients with inhibitors, who received recombinant factor VIIa for surgical procedures or spontaneous bleeding, there was one case of thrombophlebitis in 35 continuous infusion courses (12). In most instances, thrombophlebitis can be prevented by parallel infusion of saline or heparin.

- A 38-year-old patient with hemophilia A with factor VIII inhibitors was treated with recombinant factor VIIa for about 1 month and 18 days after the last infusion developed a distal deep venous thrombosis. An effect of the factor VIIa could not be ruled out, but long-term immobilization and severe infection could have contributed (13).

Angina pectoris and tachycardia have been reported after the use of recombinant factor VIIa (3). Among patients who had more than 2400 treatment episodes with recombinant factor VIIa, there were two cases of acute myocardial infarction (14). One of these patients had a history of cardiovascular disease and the other was very overweight and received massive transfusions, human factor VIII, activated prothrombin complex, and finally recombinant factor VIIa to treat severe intra-abdominal bleeding and shock.

Hematologic

Bleeding at sites other than the primary site (oozing at a central line insertion site, hemarthrosis, and epistaxis) has been reported during treatment with recombinant factor VIIa in four patients (7). The authors suggested that local fibrinolysis may have contributed to or actually caused bleeding from central line insertion sites. In three cases they found raised fibrin degradation products and in two cases a 15–35% fall in plasminogen activity.

No causality has been demonstrated between administration of recombinant factor VIIa and arterial thrombotic complications (15,16). However, venous thrombosis has been reported (17).

The risk of disseminated intravascular coagulation and other thrombotic events appears to be less with factor VII than with activated prothrombin complex products (1,18). However, disseminated intravascular coagulation after infusion of recombinant factor VIIa has been reported (19,20).

Urinary tract

In two patients with hemophilia with antibodies to both human and porcine factor VIII, continuous recombinant factor VIIa resulted in hematuria (21). In neither case was a cause of the hematuria found. The author suggested that mucosal bleeds, such as hematuria, are characterized by high fibrinolytic activity locally and may require higher peak concentrations of factor VII to generate sufficient thrombin to achieve and sustain hemostasis. The need for a full thrombin burst could relate to the role of thrombin in the activation of thrombin-activatable fibrinolysis inhibitor.

Immunologic

The development of antibodies against recombinant factor VIIa or hypersensitivity reactions to normal doses of recombinant factor VIIa have not so far been reported (7). No antibodies against recombinant factor VIIa were observed in a group of 222 hemophilia A and 16 hemophilia B patients with inhibitors treated with high doses of factor VIIa (14). However, antibodies to factor VII have been observed in a patient with factor VII deficiency who received 40 times the recommended dose of recombinant activated factor VIIa (3). Another case of low-titer and transient factor VII antibody formation has been reported in a patient with factor VII deficiency (10).

© 2006 Elsevier B.V. All rights reserved.

Drug Administration

Drug administration route

Continuous infusion of recombinant factor VII appears to offer advantages over bolus dosing, with a reduction in the total dose of recombinant factor VIIa by 50–75% (7,22).

Drug–Drug Interactions

Heparin

Small doses of heparin are used for the prophylaxis of infusion-related thrombophlebitis (23). Low molecular weight heparin is added to recombinant factor VIIa to prevent a 50% loss of activity of factor VII within 4 hours of storage (9). In one case, however, there was co-precipitation of reconstituted factor VIIa and low molecular weight heparin in syringes (24). The authors therefore suggested that a parallel saline infusion be used instead of heparin to prevent thrombophlebitis.

Factor VIII

See also Coagulation proteins

General Information

Lyophilized factor VIII has been used as substitution therapy in patients with hemophilia A. Most, but not all, recombinant factor VIII (recFVIII) is structurally and immunologically similar to plasma-derived factor VIII, and it has been well tolerated by patients in clinical trials. A major concern about recombinant factor VIII has been the occurrence inhibitors (1). However, there is evidence that there is no difference in the occurrence of inhibitors between recombinant factor VIII and plasma-derived factor VIII (2).

Highly purified animal coagulation factors, such as porcine factor VIII, continue to be used to good effect in

© 2006 Elsevier B.V. All rights reserved.

patients with hemophilia with high-titer inhibitors. Adverse effects are relatively mild, consisting of fever and rare anaphylactoid reactions (3); platelet aggregation and progressive thrombocytopenia have also been observed (4).

Gene therapy

Trials of gene therapy in hemophilia A and B, to determine safety and efficacy, are under way (5). The hazards of current vectors include the development of inhibitors, as observed in substitution therapy, insertion mutagenesis (for example through disruption of a regulatory gene such as a tumor suppressor gene), and transmission of genes to germ cells (6). In the various phase I trials performed in patients with hemophilia such adverse events have not been observed (6). Other theoretical hazards are immunogenesis, hepatotoxicity, and carcinogenic effects. In particular, retroviral vectors have a considerable carcinogenic potential. Adenoviruses, which do not integrate into the genome and consequently have only a transient effect, are considered to be safer. Also adeno-associated viruses have a low pathogenic potential in humans, as do lentiviruses.

The death of a young patient who took part in a clinical gene therapy study, probably caused by an adverse reaction to the viral vector (7,8), has led to increased interest in the application of non-viral techniques for gene therapy. When factor VIII genes were introduced into autologous skin cells in culture by electroporation, and thereafter implanted in the omentum in six patients with hemophilia A, no adverse events were reported (9).

Organs and Systems

Cardiovascular

Thromboembolic complications developed in two of 81 patients with Von Willebrand disease treated with a high-purity factor VIII/Von Willebrand factor (VWF) concentrate (10). Four cases of venous thrombosis were reported in patients with Von Willebrand disease treated with an intermediate-purity factor VIII/VWF concentrate. Use of pure VWF concentrate without increased factor VIII:C is preferable (11).

Respiratory

In a retrospective study of 29 treatments with porcine factor VIII:C in 18 patients with hemophilia A with inhibitors, the initial bolus administration of porcine factor VIII:C before continuous infusion caused bronchospasm in one patient (12).

Nervous system

- A 71-year-old man with acquired hemophilia and high titers of antibodies to factor VIII developed a fatal thrombotic stroke while receiving porcine factor VIII (13).

Hematologic

Porcine factor VIII, used for the treatment of patients with inhibitors of factor VIII, can cause thrombocytopenia, which is dose-related and occurs during intensive treatment for severe bleeding or surgery (14,15).

During continuous infusion of porcine factor VIII:C in patients with hemophilia A with inhibitors there is a smaller fall in platelet count and fewer other adverse effects than during the period after the initial bolus administration, as was shown in a retrospective study of 29 treatments with porcine factor VIII:C of 18 patients with hemophilia A with inhibitors (13). The authors attributed these differences to the dose of factor VIII:C and the rate of administration.

Skin

Urticaria and periorbital edema after initial bolus administration of porcine factor VIII:C before continuous infusion have been observed in one of 18 patients with hemophilia with inhibitors receiving a total of 29 treatments with porcine factor VIII:C (13).

Immunologic

There has been some concern about the possible effects of factor VIII formulations on the immune system. In vitro experiments with coagulation factor concentrates have shown immunosuppressive effects (16,17), such as the impairment of Fc receptor-mediated phagocytosis and intracellular bacterial killing (18). Inhibition of IL-2 production, an impaired MLR, and impairment of PHA transformation have been demonstrated (19). A fall in the number of T4 lymphocytes has also been found. Whether these findings reflect functional impairment of the immune system is still unclear.

If the modulation of certain immune functions is in fact due to contaminating components in the preparations, one would expect the new generation of factor VIII preparations of very high purity to behave differently. Highly purified factor VIII with a specific activity of 100–150 U/mg protein is now available, as is factor VIII purified by immunoaffinity chromatography using mouse monoclonal antibodies.

In 58 previously treated patients with hemophilia treated with a recombinant factor VIII product for more than 5 years, there were neither allergic reactions to murine or hamster proteins nor any de novo formation of inhibitors of factor VIII (20).

Antibodies to factor VIII (factor VIII inhibitors)

Patients with bleeding disorders are at risk of developing antibodies against the coagulation protein that is absent, present in reduced amounts, or present in an inactive form in their blood. Such coagulation inhibitors make treatment very difficult. Gene deletions, truncations, and inversions of the factor VIII gene give rise to abnormal forms of the factor VIII protein, resulting in failure to induce tolerance against the normal form of factor VIII (21). Starting with factor VIII treatment at an early age is associated with an increased risk of developing inhibitors (22).

Frequency

Inhibitors of factor VIII are the most common and develop in 5–36% of patients with hemophilia A (23,24). Inhibitors of factor IX develop in 1–8% of patients with hemophilia B (24–26). Frequency varies with age (24). Patients with factor VIII inhibitors present clinically either as “high responders” who show a strong anamnestic response and a sharp rise in inhibitor concentrations

© 2006 Elsevier B.V. All rights reserved.

after exposure to factor VIII, or "low responders", who show little or no anamnestic response (27).

Following the introduction of recombinant factor products, the incidence of antibody formation seemed to be higher than in patients using plasma products (28). However, after considering factors such as the number of exposure days, the severity of the disease, and the frequency of prospective monitoring, the prevalence and the incidence of antibody formation for both products were similar.

In two studies of previously untreated patients with severe hemophilia, who were given two different recombinant factor VIII products, the incidence of development of an inhibitor was comparable (about 30%) (29).

In 31 previously untreated and minimally treated children with severe hemophilia A, who received full-length recombinant factor VIII (formulated with sucrose) for home therapy and surgery, there was no difference in the incidence of inhibitor formation compared with other recombinant products or plasma-derived products (2).

Mechanism

Antibody formation in patients with mild and moderate hemophilia most likely results from the presence of structurally abnormal circulating factor VIII, so that administration of exogenous factor VIII leads to the development of antibodies by exposing the immune system to epitopes on factor VIII molecules not previously encountered (30). Data from the UK Haemophilia Centre Directors Organization have shown that 25% of patients who developed antibodies had mild or moderate hemophilia (30). It has been suggested that this high figure can be explained by improved data collection and by changes in clinical practice, namely the switch from lower purity to higher purity or recombinant products and the use of continuous infusion instead of repeated injections (30).

Novel molecular defects, Arg2163His and Phe2101Cys, were held responsible for inhibitor formation in two patients (31).

- Two patients (aged 60 and 73 years) with mild and moderate hemophilia respectively, without a family history of inhibitor formation, were exposed to factor VIII for more than 50 days. An inhibitor developed in both patients after an intermediate factor VIII product was replaced by a high-purity factor VIII product, which was given by continuous infusion during a surgical procedure.

Susceptibility factors

Six cases of factor VIII inhibitor development within the postoperative period have been described (32). Some patients have a greater tendency to develop inhibitors, such as patients with severe hemophilia who were sparingly treated, patients with moderate hemophilia and a family history of inhibitor development, patients who had transient inhibitors in the past, and patients with high-risk mutations in their factor VIII gene (32). It has been suggested that alteration of the immune system, by operative stress or the use of antibiotics, increases the risk of inhibitor development (32). Of 81 patients with Von Willebrand disease, who were treated with high-purity factor VIII/Von Willebrand factor concentrate, two had reduced in vivo recovery, suggesting antibody formation (10).

The formation of inhibitors of factor VIII is not restricted to patients with severe hemophilia. There have been two cases of high-titer factor VIII inhibitors in two children with mild hemophilia A; one occurred after only minimal exposure to factor VIII:C (33).

In 20 previously treated patients with severe or moderate hemophilia A treated with recombinant factor VIII formulated with sucrose, no inhibitors were found (34). The risk of forming inhibitors after treatment with B domain-deleted recombinant factor VIII was comparable to that seen with full-length recombinant products (35,36).

Management

Treatment options for patients with inhibitors are high dosages of clotting factor or recombinant factor VIIa for both hemophilia A and B or, in the case of hemophilia A, porcine factor VIII:C or activated prothrombin complex (37). Regular administration of intermediate or low-dose factor VIII concentrates leads to the rapid disappearance of factor VIII inhibitors in some high responders (27); this is thought to be due to the development of immune tolerance.

This may explain the effectiveness of treating patients with hemophilia who have inhibitors with high doses of factor VIII. Another approach involves the use of prothrombin complex concentrate to treat bleeding episodes in patients with factor VIII inhibitors (38); however, thromboembolic complications related to higher doses of prothrombin complex concentrate have been described, although these are relatively rare (39,40). Thrombotic events are extremely rare when highly purified factor IX is used. Activated prothrombin complex concentrate is also effective in patients with factor VIII inhibitors (41). Serious complications are rare, but disseminated intravascular coagulation has been reported (42).

If the inhibitor activity is under 10 Bethesda units/ml, patients can be treated with increased doses of factor VIII or IX concentrates (43). In addition, patients with hemophilia A with low or intermediate antibody titers can also be treated with porcine factor VIII (43). However, hemorrhagic episodes in patients with antibody activity over 10 Bethesda units/ml may result in life-threatening hemorrhage that cannot be treated by conventional therapy (26,43). Prevention or treatment of clinically significant bleeding episodes in these patients can be achieved by using so-called bypassing therapies, such as recombinant factor VIIa and activated prothrombin complex (23,26,43). Recombinant factor VIIa is both effective and safe in the treatment of inhibitors directed to either factor VIII or IX (44,45).

A less effective method of treating patients with inhibitors is to give them deamino-d-arginine vasopressin (DDAVP), which increases production of intrinsic factor VIII. This has a number of drawbacks, such as tachyphylaxis, flushing, headaches, myocardial ischemia, and fluid retention (46).

It has been recommended that non-hemophiliacs with autoantibodies be treated with porcine factor VIII products (14).

Inhibitor bypassing agents include prothrombin complex concentrates, activated prothrombin complex concentrates (such as FEIBA), porcine factor VIII, and recombinant factor VIIa. During 10 years usage of FEIBA (3.95×10^5 FEIBA units infused) a total of 16 thrombotic events were reported, corresponding to an incidence of 4.05 per 10^5

© 2006 Elsevier B.V. All rights reserved.

infusions. In 13 of these 16 events, known risk factors, such as FEIBA overdose, obesity, and serum lipid abnormalities, were present (47). Antibody reactivity against factor VIIa, which was detected in patients with hemophilia with high-titer antibodies, was a response to treatment with blood products or bypassing agents or due to cross-reactivity. This reactivity might hamper the hemostatic effect (48).

The production process of porcine factor VIII does not incorporate virus-eliminating steps. However, each batch is extensively screened to confirm the absence of viruses. In a pharmacovigilance study of 81 hemophiliacs treated with porcine factor VIII, there were no cases of transmission of porcine viruses (porcine parvovirus, encephalomyocarditis virus, porcine respiratory, and reproductive syndrome virus) (49).

Body temperature

Febrile reactions occurred in two patients after the initial bolus administration of porcine factor VIII:C in a retrospective study of 29 treatments with porcine factor VIII:C in 18 patients with hemophilia A with inhibitors (13).

Drug Administration

Drug formulations

Recombinant factor VIII is stabilized with human serum albumin during purification and in the final product. Although albumin has an excellent safety record and no recombinant antihemophilic factors have been associated with virus transmission, there is still concern about the safety of products that contain human- or animal-derived components (50). A second-generation recombinant factor VIII product has been developed with a modified manufacturing process and a formulation in which the recombinant factor VIII is stabilized by sucrose instead of albumin (50).

Drug contamination

Plasma-derived factor VIII concentrates have been implicated in the transmission of the non-enveloped hepatitis A and parvovirus B19 (28). The virus-inactivating procedures now in use (chemical inactivation, wet-heat treatment, and nanofiltration) should provide coagulation factors without risk of transmitting HIV and with a very high safety for hepatitis virus. Nevertheless, recombinant factor VIII is considered a safer alternative.

Patients with hemophilia have various disturbances of immune function, resulting not only from infections with HIV and hepatitis, but also from chronic exposure to extraneous proteins in clotting factor concentrates (51). Protein contaminants, such as immunoglobulins, fibrinogen, and fibronectin, can depress immune function. It has been postulated that high-purity concentrates in HIV-positive hemophiliacs are associated with better maintenance of $CD4^+$ cells and other indicators of immune function compared with products of intermediate purity (51).

One of 81 patients with Von Willebrand disease treated with a high-purity factor VIII/Von Willebrand factor concentrate was infected with parvovirus B19 after infusion of a solvent/detergent-treated formulation. Parvovirus B19 is not lipid-enveloped and is resistant to treatment by solvent detergent (10).

Parvovirus B19 transmission occurred in a child who had received vapor heat-treated prothrombin complex concentrate (60°C for 10 hours and 80°C for 1 hour) and in another child who received dry-heated factor VIII concentrate (80°C for 72 hours). Both children had severe hemophilia A and were treated for factor VIII inhibitors (52).

Second-generation recombinant factor VIII products, which contain lower amounts of human albumin, and third-generation products, which are free of human proteins and thereby carry a lower risk of pathogen transmission, are on the market.

Drug administration route

Hemophiliacs are traditionally treated with bolus injections of factor VIII. This kind of administration is associated with peak and trough concentrations of these factors, with a risk of bleeding when the concentration of factor VIII falls below a critical concentration (53).

Several studies of continuous infusions of factor VIIa, factor VIII, and factor IX in hemophiliacs undergoing surgery have shown that this mode of administration is safe and effective when steady plasma concentrations of the clotting factors can be achieved (53–56). The total dosage of clotting factor concentrates is reduced, and so continuous infusions are cost-effective (53,56).

Factor IX

See also Coagulation proteins

General Information

Factor IX is used as substitution therapy in patients with hemophilia B. Although the half-lives of recombinant and plasma factor IX products are comparable, the in vivo recovery of recombinant factor IX is 28% lower than a highly purified plasma-derived product. To treat hemorrhage the dosage of recombinant factor IX needs to be 20% higher than plasma-derived products to increase the circulating factor IX activity to 1% per IU of recombinant factor IX given (1).

General adverse effects

Mild adverse effects of factor IX include discomfort at the infusion site, fever, dizziness, allergic rhinitis, and lightheadedness (1).

Gene therapy

Trials of gene therapy in hemophilia A and B, to determine safety and efficacy, are under way (2). Three patients with hemophilia B were treated in a phase I trial with a recombinant adenovirus-associated vector expressing human blood-coagulation factor IX (3). There was no evidence of formation of inhibitory antibodies against factor IX. In a phase I trial with a recombinant adenovirus-associated vector expressing human blood-coagulation factor IX, there was no evidence of germ-line transmission of vector sequences (3).

The hazards of current vectors include insertion mutagenesis, immunogenesis, hepatotoxicity, and carcinogenic effects. In particular, retroviral vectors have a considerable carcinogenic potential. Adenoviruses, which do not integrate into the genome and consequently have only a transient effect, are considered to be safer. Also adeno-associated viruses have a low pathogenic potential in humans, as do lentiviruses.

Organs and Systems

Cardiovascular

Thrombophlebitis at the infusion site is a common complication of continuous infusion of various clotting factor concentrates. Continuous infusion of recombinant factor IX in six patients with hemophilia B undergoing surgery or suffering bleeding was complicated in two cases by thrombophlebitis (4). In most instances, thrombophlebitis can be prevented by parallel infusion of saline or heparin.

Respiratory

Shortness of breath was observed in a young patient with hemophilia B with inhibitors after a number of attempts to induce immune tolerance with a high dose of factor IX:C (5).

Urinary tract

During treatment with extremely high doses of factor IX concentrate, to induce immune tolerance, nephrotic syndrome has been described (6,7). Withdrawal or dosage reduction is of crucial importance for the resolution of nephrosis (6). Renal biopsy in one of these patients showed peripheral capillary wall thickening and deposits throughout the basement membrane (7). In addition minimal interstitial fibrosis and tubular atrophy were present. There were no deposits of factor IX in the glomeruli, which the authors attributed to absence of free factor IX epitope in the tissue (7).

In patients with hemophilia B with antibodies who undergo immune tolerance induction there is a risk of nephrotic syndrome (8).

Skin

A young patient with hemophilia B with inhibitors developed an urticarial rash after several attempts to induce immune tolerance with a high dose of factor IX:C (5). Recombinant factor IX gave rise to urticaria in patients with hemophilia B undergoing surgery (9).

Immunologic

Allergic and anaphylactic reactions due to factor IX inhibitor have been described (SEDA-21, 343) (6). Anaphylactic reactions occur particularly in patients with undetectable concentrations of factor IX, because of major disruptions in the factor IX gene (10). In patients with factor IX inhibitor, IgG1 subclass antibodies have been found, which may activate complement, resulting in allergic reactions (SEDA-21, 343) (10). However, it has also been suggested that allergic reactions to factor IX products are IgE-mediated.

- In two patients with severe factor IX deficiency and high concentrations of factor IX inhibitors who

© 2006 Elsevier B.V. All rights reserved.

developed anaphylaxis to factor IX, RAST and skin test reactions to factor IX were positive (10). After desensitization, the circulating IgE antibodies to factor IX fell.

Treatment with high dosages of clotting factors to induce immune tolerance brings a risk of allergic reactions, as has been observed in a 4-year-old child with hemophilia B (5).

Antibodies to factor IX (factor IX inhibitors)

Patients with bleeding disorders are at risk of developing antibodies against the coagulation protein that is absent, present in reduced amounts, or present in an inactive form in their blood. Such coagulation inhibitors make treatment very difficult.

Inhibitors of factor VIII are the most common and develop in 5–15% of patients with hemophilia A. Inhibitors of factor IX develop in 1–4% of patients with hemophilia B (11,12). Patients with hemophilia B with complete gene deletions or derangement of the factor IX gene are particularly at risk of developing antibodies after the administration of factor IX concentrate (8). In patients with hemophilia B with antibodies, treatment with factor IX concentrate can result in an anaphylactic response.

Anaphylaxis in conjunction with inhibitor development has been described. Patients with hemophilia B with complete gene deletions have the greatest risk of anaphylaxis, with a minimum risk of 26%, whereas the risk in patients with null mutations was 2.4% and nearly zero for mis-sense mutations (13). Predisposing factors for the development of anaphylaxis, besides mutation type, are genetic predisposition and environmental experience, such as the type and frequency of factor IX product (13).

Drug Administration

Drug administration route

Hemophiliacs are traditionally treated with bolus injections of factor IX, which is associated with peak and trough concentrations of these factors, with a risk of bleeding when the concentration of factor IX falls below a critical concentration (14).

Several studies of continuous infusions of factor VIIa, factor VIII, and factor IX in hemophiliacs undergoing surgery have shown that this mode of administration is safe and effective when steady plasma concentrations of the clotting factors can be achieved (14–17). The total dosage of clotting factor concentrates is reduced, and so continuous infusions are cost effective (14,17).

Famciclovir

General Information

Famciclovir is an oral prodrug of penciclovir, a selective antiviral drug with activity against *Varicella zoster* virus, *Herpes simplex* virus types 1 and 2, and Epstein–Barr virus, as well as human hepatitis B virus.

After oral administration, famciclovir is well absorbed (systemic availability 77%), with little intersubject variability, and is rapidly converted to penciclovir. This

© 2006 Elsevier B.V. All rights reserved.

compares favorably with aciclovir, the absorption of which is slow and incomplete, with a highly variable systemic availability of only 10–20%.

Comparative studies

In a study of oral famciclovir versus oral aciclovir, designed to demonstrate equivalence of efficacy of the two drugs in the treatment of mucocutaneous *Herpes simplex* infection in HIV-infected individuals, there was no difference in the incidence or nature of adverse effects in the two groups (1). None of the withdrawals from the trial was considered by the investigator to be related to the study medication.

Placebo-controlled studies

In an integrated safety analysis of 1607 patients who had taken famciclovir for the treatment of *Herpes zoster* or genital herpes, famciclovir was extremely well tolerated with an adverse effect profile similar to placebo (2). Headache, nausea, and diarrhea were the most frequently reported adverse events in those taking both famciclovir and placebo.

In an experimental study of *Herpes simplex* labialis, adverse events (diarrhea and nausea) occurred with similar frequency with famciclovir and placebo (3). No laboratory abnormalities were consistently associated with famciclovir.

In a randomized, placebo-controlled study in 455 patients oral famciclovir (125 or 250 mg tds or 250 mg bd) used to suppress recurrent genital *Herpes simplex* infections, the toxicity profile of famciclovir was comparable to placebo (4). The only serious adverse effects reported as being possibly related to famciclovir were raised bilirubin concentration and lipase activity in one patient after 10 months of treatment with famciclovir 125 mg tds. However, these laboratory abnormalities resolved on therapy after 7 days and did not recur during the rest of the study.

Organs and Systems

Gastrointestinal

Adverse effects associated with famciclovir have been collected in over 6000 patients in two postmarketing surveillance studies (5). Only headache, abdominal symptoms, dizziness, vomiting, and diarrhea were associated with the drug. Two prospective trials have confirmed the low frequency of adverse effects, the more common ones being nausea, headache, vomiting, and diarrhea (6,7).

Sexual function

Prolonged administration of high dosages of famciclovir has been associated with reversible dose-dependent adverse effects on testicular function in rats and dogs. However, in a double-blind, placebo-controlled trial in which 34 men with recurrent genital herpes took famciclovir 250 mg bd for 18 weeks, there were no significant effects on sperm production or function (8).

Famotidine

See also Histamine H_2 receptor antagonists

General Information

Famotidine is a histamine H_2 receptor antagonist. It does not affect drug metabolism and it has been claimed to be free of the antiandrogenic effect of cimetidine; however in one woman who accidentally took double doses of the drug for some months it did cause hyperprolactinemia and breast engorgement (SEDA-18, 372). In other ways it bears a very close resemblance to cimetidine; for example, headache and confusion with intravenous use are reported, as are thrombocytopenia and pancytopenia (SEDA-15, 395).

The effects of famotidine 20 mg bd and omeprazole 20 mg/day for 8 weeks have been compared in the treatment of reflux esophagitis in a randomized trial in 56 patients (1). Omeprazole was more effective in healing esophagitis and providing symptom relief. Adverse events, which were rare, were similar in the two groups, and consisted of nausea, palpitation, abdominal pain, and mild abnormalities of liver function tests.

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Nervous system

Histamine receptor antagonists can cause a variety of reactions involving the central nervous system. These are rare with famotidine.

- Five elderly patients (61–85-years-old) developed acute central nervous system reactions, consisting of confusion, agitation, hallucinations, and disorientation, 24 hours to a few days after starting to take famotidine 40 mg/day (2). These features resolved completely 24–48 hours after withdrawal. Rechallenge was not attempted.

Hematologic

Although it is hard to make a direct comparison between famotidine and cimetidine, since the former has been less extensively used, it is possible that the hematological problems occur more often with famotidine; there have been frequent well-documented reports of both thrombocytopenia and neutropenia, sometimes severe (SEDA-17, 417).

Liver

- Famotidine-induced cholestatic hepatitis has been reported in a previously healthy 13-year-old boy who had taken famotidine 40 mg/day for 30 days for epigastric pain (3). Other possible causes were excluded. He had a gradual and complete recovery 2 months after drug withdrawal.

Musculoskeletal

Rhabdomyolysis has been attributed to famotidine and might reflect its immunomodulating action (SEDA-17, 418).

Immunologic

Vasculitis occurred in a patient taking famotidine who had tolerated cimetidine well (4).

Body temperature

Hyperpyrexia has been attributed to famotidine, but the patient had pre-existing cerebral trauma as a facilitating factor (SEDA-16, 422).

Drug Administration

Drug overdose

After overdosage famotidine has a wide margin of safety; deliberate ingestion of very high doses did not appear to be associated with adverse sequelae (SEDA-21, 363) (5).

Drug–Drug Interactions

Omeprazole

Intragastric acid control by omeprazole 20 mg taken in the morning after variable dosing of over-the-counter famotidine 10 mg has been assessed in 12 healthy volunteers negative for *Helicobacter pylori* (6). Famotidine did not reduce the daytime efficacy of the next-morning dose of omeprazole.

Fazadinium

See also Neuromuscular blocking drugs

General Information

Originally claimed, from animal experiments, to be of rapid onset, short duration, and free from important adverse effects, this non-depolarizing relaxant has been found to be less satisfactory in man. The usual doses are 0.5–0.75 mg/kg, although 1 mg/kg is sometimes advocated for fast intubation (within 1–2 minutes). The duration of action is similar in man to that of D-tubocurarine and pancuronium. Excretion is primarily in the urine (50–80%, mostly in the first 6 hours), although a biliary route has also been suggested. Metabolism occurs, probably to a minor extent, 1–3% being detected in the urine as inactive metabolites.

Organs and Systems

Cardiovascular

Cardiovascular effects account for the relative unpopularity of fazadinium. It has some ganglion-blocking activity (1) and blocks cardiac muscarinic receptors in the therapeutic dose range (2). Its vagolytic potency is about the same as that of gallamine. Fazadinium, like pancuronium, also blocks the reuptake of noradrenaline into sympathetic nerve endings. These actions explain its major cardiac adverse effect, namely significant tachycardia (3), which occurs even with small doses and is persistent.

© 2006 Elsevier B.V. All rights reserved.

It is dose-related (4), the increase in heart rate varying between 30 and 100%, and is associated with a rise in cardiac output and falls in stroke volume and peripheral resistance. Hypertension or hypotension can occur (5,6). If fazadinium is used injudiciously, extreme and dangerous cardiovascular changes can ensue (7).

Immunologic

Histamine release from fazadinium is very uncommon, but hypotension associated with an urticarial rash and two cases of severe bronchospasm and cardiac arrest (in patients who had also received thiopental) have been reported (8) as probably being due to fazadinium.

Immunological investigations combined with positive intradermal tests have been used to confirm fazadinium as the causative agent in a severe reaction (9).

Second-Generation Effects

Fetotoxicity

Placental transfer occurs and, though there may be some fetal uptake, Apgar scores did not appear to be affected (10,11).

Felbamate

See also Antiepileptic drugs

General Information

Felbamate is a broad-spectrum antiepileptic drug, whose use has been drastically curtailed owing to the risks of aplastic anemia and hepatotoxicity.

Benefit to harm balance

The Quality Standards Subcommittee of the American Academy of Neurology and the American Epilepsy Society (1) has reviewed efficacy and safety data to establish recommendations for felbamate use in the light of the risk of aplastic anemia and liver toxicity (SEDA-22, 86). Felbamate was considered to have a favorable benefit to harm balance in patients with Lennox–Gastaut syndrome aged over 4 years who were unresponsive to primary anticonvulsants, in patients over 18 years of age with intractable partial seizures that have not responded to standard antiepileptic drugs in therapeutic concentrations, and in patients who are already taking felbamate and benefit from it for more than 18 months. There are conditions in which the benefit:harm balance is unclear, but for which use may be appropriate under certain circumstances, depending on the nature and severity of the seizure disorder; these include children with intractable partial epilepsy, patients with other generalized epilepsies unresponsive to primary agents, patients who have unacceptable sedative or cognitive effects with traditional antiepileptic drugs, and patients under 4 years with Lennox–Gastaut syndrome unresponsive to other antiepileptic drugs.

Assessment of its benefit to harm balance does not support the use of felbamate in new-onset epilepsy in children and adults, in patients who have significant prior hematological adverse events, in patients in whom follow-up and compliance will not allow careful monitoring, and in patients who are unable to discuss risk/benefits and for whom no parent or legal guardian is available to provide consent.

In patients taking felbamate, the benefit to harm balance should be constantly assessed. Patients should be educated about early signs of liver and bone-marrow toxicity, and about the manufacturers' recommendations. Laboratory monitoring has not been proven efficacious, but the manufacturer and the FDA suggest liver function and hematology testing at baseline and every 1–2 weeks for the first year. After that, the risk of aplastic anemia falls and the need for regular testing is less clear. A registry has been set up by the manufacturers to collect further safety data in patients started on the drug.

An open trial with 3-year follow up has been conducted in 36 patients with catastrophic childhood onset epilepsy (2). The overall responder rate (more than a 50% reduction in seizure frequency) fell with time: 69% at 3 months, 66% at 6 months, 47% at 1 year, and 41% at the end of the study. The most frequent adverse effects were anorexia, weight loss, urinary retention, somnolence, nervousness, and insomnia. Other reported adverse effects include skin reactions (including Stevens–Johnson syndrome), various blood dyscrasias, hepatotoxicity, and systemic lupus erythematosus (3).

Organs and Systems

Nervous system

Central nervous system adverse effects are common with felbamate, and consist mainly of insomnia, headache, impaired concentration, ataxia, dizziness, somnolence, behavioral disturbances, and mood changes. Movement disorders, psychosis, increased seizures, status epilepticus, and withdrawal seizures are less common (SEDA-19, 67) (SEDA-20, 61). The incidence of these effects is increased in the elderly, possibly owing to reduced drug clearance (4), whereas patients with mental retardation may be more prone to behavioral disorders (SEDA-19, 68).

Hematologic

Aplastic anemia affects 1 in 5000, or even 1 in 2000 patients (5), although a more recent estimate is 27–209 per million, compared with 2–2.5 per million in the general population (6). The underlying mechanism is unknown, although a deficiency in free radical scavenging activity may play a role (SEDA-22, 86).

Of 34 cases of aplastic anemia (mean age 41 years, mean time of felbamate exposure 154 days), 20 occurred in combination with other compounds implicated as a possible cause of aplastic anemia and 5 occurred concurrently with viral infections (7). Although 5 patients were taking felbamate monotherapy, 13 of the 34 suffered from autoimmune disease, and 1 was receiving cytostatic therapy. Past allergic or toxic reactions to other anticonvulsants were reported by 65% of the patients and blood dyscrasias by 45%, while 32% had serological evidence of a previous immune disorder. Eight of nine patients tested had experienced at least one episode of aplastic anemia associated with HLA antigens.

Felbamate is currently reserved for patients who are refractory to other drugs after careful consideration of the benefit:harm balance. In some countries the indication has been restricted to refractory Lennox–Gastaut syndrome. It is wise to avoid felbamate in patients with previous blood dyscrasias or autoimmune disorders, especially lupus erythematosus. Before they start to take it, patients should be informed about the potential risks and early symptoms of bone-marrow toxicity, such as bruisability, petechiae, fever of unknown origin, weakness, and fatigue. Hematology tests should be performed at baseline and during treatment, and dose escalation should be slow.

Because felbamate-induced aplastic anemia might be linked to the formation of atropaldehyde, a urine screening test has been developed that indirectly assesses the formation of this toxic metabolite (8). The risk of serious toxicity may also be related to HLA status, and HLA typing is being performed in patients entered in the manufacturer's felbamate registry. The potential value of these tests in reducing the risk of toxicity remains to be established.

Gastrointestinal

Felbamate is commonly associated with anorexia, nausea, and vomiting (9,10). Constipation and abdominal pain also occur. In 36 patients (12 men) aged 11–68 (mean 30) years in whom felbamate dosage was titrated gradually from 300 mg/day to a mean total daily maintenance dose of 1936 mg, the most frequent adverse events were: nausea, vomiting, anorexia, and weight loss (11).

Weight loss can occur. Of 65 patients with intractable seizures who received felbamate for a mean treatment time of 23 (range 6–116) weeks 49 lost weight (12). Among those over 15 years, there was a mean weight loss of 3.2 kg or 4.1% of body weight; 22 lost more than 4 kg, and 7 lost more than 8 kg. Among those aged 15 years or younger there was a non-significant mean weight loss of 0.20 kg or 1.8% of body weight.

However, in another study of 30 children aged 2–17 years with refractory partial seizures, felbamate up to a maximum of 45 mg/kg caused transient weight loss in 57%, maximal after 12 weeks and abating after 20 weeks (13). Anorexia and insomnia occurred in 20% and 16% of the patients respectively.

Liver

Of 23 reported cases of hepatic failure, only 10 (including 5 who died) were considered to be probably related to the drug (7,14). There have also been 20 cases of hepatitis in which no deaths occurred; in five of these a relation to felbamate was unlikely. Overall the incidence of fatal liver toxicity is estimated at 1 per 26 000–34 000. A careful history of past hepatic toxicity with other drugs should be taken and liver function tests are recommended before starting felbamate. Patients should have hepatic function monitored regularly and should be alerted to the signs and symptoms of hepatotoxicity.

Urinary tract

Urolithiasis has been associated with felbamate (15).

- A 15-year-old boy with Lennox–Gastaut syndrome taking felbamate(3000 mg/day), topiramate(200 mg/day), and lorazepam developed painful hematuria, bilateral urethral obstruction, and urinary retention. Kidney, bladder, and urethral stones were found. The stone material was identified as felbamate by chemical analysis. However, as the patient was also taking topiramate the association with felbamate was uncertain.

Susceptibility Factors

It is wise to avoid felbamate in patients with previous blood dyscrasias or autoimmune disorders, especially lupus erythematosus.

Drug–Drug Interactions

Carbamazepine-10,11-epoxide

Felbamate is a metabolic inhibitor and significantly increases blood concentrations of carbamazepine-10,11-epoxide (SEDA-19, 69) (SEDA-20, 61).

Clonazepam

Although felbamate increases the plasma concentrations of clonazepam only slightly, patients taking this

© 2006 Elsevier B.V. All rights reserved.

combination are more vulnerable to central nervous system adverse effects (16).

Gestodene

Felbamate reduces the plasma concentrations of gestodene and may reduce its contraceptive efficacy (SEDA-20, 61).

Phenobarbital

Felbamate is a metabolic inhibitor and significantly increases blood concentrations of phenobarbital (SEDA-19, 69) (SEDA-20, 61).

Phenytoin

Felbamate is a metabolic inhibitor and significantly increases blood concentrations of phenytoin (SEDA-19, 69) (SEDA-20, 61).

The dose dependency and clinical relevance of the inhibition of phenytoin metabolism by felbamate has been examined in 10 patients (17). Phenytoin concentrations increased from 64 μmol/l at baseline to 84 and 107 μmol/l after felbamate 1200 and 1800 mg/day respectively. Owing to adverse effects, a reduction in phenytoin dosage was required in four patients after felbamate 1800 mg/day and in six patients after felbamate 2400 mg/day. Felbamate titration to doses of 3600 mg/day required overall phenytoin dosage reductions of 40% on average (range 20–72%), based on tolerability. Based on these findings, phenytoin dosage should be reduced by 20% when felbamate is added, and further dosage reductions are likely to be required when felbamate dosage is increased. Requirements for dosage reductions may be predicted by clinical signs of phenytoin intolerance, such as mental slowing, nausea, fatigue, and somnolence. The same study showed that in patients taking phenytoin co-medication serum felbamate concentrations are reduced by about 60% compared with those achieved in monotherapy.

Valproate

Felbamate is a metabolic inhibitor and significantly increases blood concentrations of valproic acid (SEDA-19, 69) (SEDA-20, 61).

Felbinac

See also Non-steroidal anti-inflammatory drugs

General Information

Felbinac, an active metabolite of fenbufen, is used as a gel for topical treatment (1).

Organs and Systems

Skin

Felbinac can cause itching, rash, and eosinophilia (SEDA-16, 110).

Reference

Felodipine

See also Calcium channel blockers

General Information

Felodipine is a dihydropyridine derivative with diuretic properties (1). Its diuretic properties are not unique but are shared by other dihydropyridines. Its vasodilator-related adverse effects include flushing, headache, and tachycardia (2,3). Reduced arterial oxygen saturation has been seen in patients given intravenous felodipine for pulmonary hypertension (4,5). Along with amlodipine, but unlike other calcium channel blockers, felodipine may be safer in severe chronic heart failure accompanied by angina or hypertension.

Organs and Systems

Skin

Different skin reactions have been reported with calcium antagonists, and in particular telangiectases in light-exposed areas of the skin with nifedipine and amlodipine (6).

- A 70-year-old woman took felodipine 10 mg/day and enalapril for about 1 year for hypertension. She developed telangiectatic lesions of both sides of the trunk. After excluding other causes, felodipine was withdrawn. After 2 months the lesions slightly abated, but never completely disappeared. The diagnosis was confirmed by histological evidence of enlarged capillaries parallel to the skin surface, in the absence of mast cells.
- Photodistributed telangiectases, made worse by solar radiation have been reported in a 67-year-old man taking felodipine 5 mg/day (7). Rosacea was also present. Felodipine was withdrawn and the telangiectases improved. Rechallenge was not performed.
- A 67-year-old man who had taken felodipine 5 mg/day for 4 years developed facial telangiectatic lesions that worsened with solar exposure for 9 months before felodipine was withdrawn; 2 months later the lesions had markedly diminished (7).

Drug–Drug Interactions

Erythromycin

The metabolism of felodipine is inhibited by erythromycin (SEDA-17, 239).

Grapefruit juice

In 12 elderly people (aged 70 years and over), grapefruit juice increased the AUC of felodipine three-fold and its peak concentration four-fold (8). Blood pressure was lower with grapefruit juice after a single dose of felodipine, but not at steady state. Heart rate was higher with grapefruit juice after both single and multiple doses. Elderly patients should avoid taking grapefruit juice during treatment with felodipine because of this marked and unpredictable interaction.

Fenbendazole

General Information

The antiprotozoal activity of fenbendazole, a benzimidazole derivative, is similar to that of mebendazole; the target seems to be the microtubule protein beta-tubulin. Its adverse effects are comparable to those of mebendazole (1).

Reference

1. Katiyar SK, Gordon VR, McLaughlin GL, Edlind TD. Antiprotozoal activities of benzimidazoles and correlations with beta-tubulin sequence. Antimicrob Agents Chemother 1994;38(9):2086–90.

Fenbufen

See also Non-steroidal anti-inflammatory drugs

General Information

The profile of fenbufen is similar to the profiles of other NSAIDs (1). The dropout rate due to adverse reactions was 12–22% in different studies.

Organs and Systems

Respiratory

Fenbufen can cause a pulmonary alveolitis with rash, dry cough, breathlessness, fever, hypoxia, sometimes eosinophilia, and bilateral alveolar shadowing or infiltrates, which regress after withdrawal (SEDA-12, 85) (SEDA-13, 80) (SEDA-15, 100).

Nervous system

Headache has been reported with fenbufen (2).

Severe encephalitis, with generalized erythema and maculopapular rash on the trunk, has been reported (SEDA-19, 98).

Hematologic

Hemolytic anemia, in some cases with signs of hypersensitivity, has been reported (SEDA-14, 94). Aplastic anemia has been described in two patients (SEDA-18, 104), but both recovered fully after withdrawal.

Liver

The incidence of hepatotoxicity with fenbufen varies greatly. Changes in liver function tests were recorded in 25% patients in an early study (SEDA-4, 68), but were not confirmed later (SEDA-5, 194) (SEDA-6, 96). Abnormalities in the liver function of patients with rheumatoid arthritis may be a non-specific reaction to inflammation; however, hepatotoxicity should be watched for in patients taking fenbufen.

Skin

About 5% of patients have itching, rashes, or erythema multiforme (3). Circulating immune complexes have been found (4). The UK's Committee on Safety of Medicines issued a warning about the high rate of cutaneous adverse reactions with fenbufen and noted that some are followed by severe illnesses (SEDA-13, 72) (SEDA-14, 94) (SEDA-15, 100). Toxic epidermal necrolysis, a life-threatening reaction, has also been reported (SEDA-6, 96) (SEDA-8, 106) and a 1981–85 review on its incidence in France identified fenbufen as the third most common NSAID, after isoxicam and oxyphenbutazone, as a causal factor (5). Another severe skin reaction with laboratory evidence of hepatotoxicity has been described (SEDA-22, 115).

Drug–Drug Interactions

Enoxacin

Many cases of epileptic seizures have been reported in Japan in patients taking a combination of fenbufen and enoxacin (SEDA-12, 85) (SEDA-15, 100).

Quinolones

Fenbufen can cause convulsions, which has mainly been described in patients taking quinolone antibiotics (SEDA-18, 104).

Fenclofenac

See also Non-steroidal anti-inflammatory drugs

General Information

Fenclofenac was withdrawn in the UK after its license was not renewed because of its adverse drug reaction profile (1). Data from the UK's Committee on Safety of Medicines included records of seven deaths and 895 adverse effects in patients taking fenclofenac. Shortly afterwards it was withdrawn in all other countries in which it had been marketed.

Organs and Systems

Skin

Fenclofenac has the second highest incidence of complications and ranks first in the number and severity of skin reactions (2).

Fenfluramines

See also Anorectic drugs

General Information

Although it resembles amfetamine structurally, the appetite suppressant fenfluramine does not produce central nervous system stimulation in therapeutic doses.

Dexfenfluramine, the dextrorotatory isomer, was previously widely marketed as an appetite suppressant in the management of obesity. It appears to be a pure serotonin receptor agonist without the dopaminergic and sympathetic activity of the racemic mixture.

Fenfluramine, dexfenfluramine, and phentermine have been used alone or in combination as an alternative to diet and surgery in the management of obesity. This therapy was halted in 1997 after reports of valvular lesions affecting almost one-third of patients treated with these drugs. The combination of fenfluramine and phentermine is called fen–phen.

General Adverse Effects

Dexfenfluramine

During both short-term and long-term therapy the adverse effects of dexfenfluramine seen with greater frequency than with placebo were tiredness, nausea, diarrhea, and dry mouth (1,2). Mydriasis, depression, withdrawal depression, insomnia, nervousness, headache, and increased urinary frequency have also been reported. So far, published clinical experience suggests that the greater selectivity of the dextrorotatory isomer leads to better tolerability. There has been only one long-term, that is longer than 6 months, trial on which to base this opinion (2). Since weight increase is common after withdrawal of treatment, long-term treatment is likely to be sought and given. Because studies on laboratory animals, including squirrel monkeys, suggest that there is a dose-dependent depletion of serotonin and metabolites along with a persistently reduced number of uptake sites, there has always been concern about a neurotoxic response with both isomers. However, it has also been pointed out that dexfenfluramine was used by more than 5 million patients for 6 years, and the parent compound by more than 20 million patients for 26 years, and yet it has not been associated with any serotonergic-mediated functional nervous system pathology in humans (SEDA-17, 1).

Fenfluramine

The main adverse effects of fenfluramine in two double-blind studies were sedation and drowsiness in addition to abdominal discomfort and dry mouth (3). Very rarely were these severe enough to justify withdrawal. At fairly high doses, the above-mentioned adverse effects became more severe and frequent. Drowsiness and gastrointestinal disturbances, consisting of colicky abdominal pain, were among the outstanding adverse effects in several other studies, most of them double blind; dizziness, light-headedness, and headaches were less frequent but occasionally quite marked (4). Shivering, teeth grinding, and alopecia have occasionally been reported as adverse effects of fenfluramine (4).

Phentermine

Phentermine is a central nervous system stimulant that can increase brain dopamine concentrations and has a structure similar to amfetamine.

Phentermine is indicated only for short-term treatment, and tolerance often develops. Its common adverse effects are dry mouth, insomnia, increased blood pressure, and constipation (5). It is the subject of a separate monograph (p. 2804).

Organs and Systems

Cardiovascular

Spontaneous rupture of a retroperitoneal aneurysm occurred in a 70-year-old woman who had been taking phentermine hydrochloride, 30 mg/day, for about 1 month (6). Other long-term medications included fluoxetine and amitriptyline, and she had no history of coronary artery disease, hypertension, diabetes, or complications of pregnancy. Although it is plausible that phentermine could have contributed to the ruptured aneurysm, other possibilities should be considered, particularly rupture of an anomalous retroperitoneal blood vessel.

Cardiomyopathy

Restrictive cardiomyopathy due to endocardial fibrosis occurred in a 35-year-old woman 5 months after she had started to take fenfluramine 10 mg tds and phentermine 15 mg/day (7). The endocardial findings strongly resembled the valvular lesions associated with the use of fenfluramine–phentermine. Endocardial and valvular fibrosis associated with anorectic drugs is strikingly similar to the plaque material found in patients with carcinoid syndrome and those exposed to methysergide, and all possibly arise from a common mechanism.

Valvulopathy

The fenfluramines and phentermine can cause valvular heart disease (8–10), and this has been reviewed (11). Fenfluramine was voluntarily withdrawn by the manufacturers on 15 September 1997, and the US Department of Health and Human Services issued interim recommendations for people previously exposed to fenfluramine or dexfenfluramine with cardiac valvulopathies (SEDA-22, 3).

The use of fenfluramine or dexfenfluramine alone or in combination with phentermine, in 2524 adult participants in the population-based Hypertension Genetic Epidemiology Network Study, was associated with aortic regurgitation independent of aortic dilatation or fibrocalcification (12). The association between the use of fenfluramine or dexfenfluramine (alone or with phentermine) and aortic regurgitation adjusted for potential confounders was analysed. Nineteen participants, all of whom had hypertension, were being treated with fenfluramine or dexfenfluramine (5 on these agents alone, 14 also with phentermine). Aortic regurgitation was present in 32% ($n = 6$) of those taking fenfluramine/dexfenfluramine versus 6% (162/2505) of the remaining subjects. In multivariate analyses, after adjusting for important confounders, in particular aortic root structure, treatment with fenfluramine or dexfenfluramine was associated with

© 2006 Elsevier B.V. All rights reserved.

aortic regurgitation (OR, 5.2; 95% CI, 1.7–14) and fibrocalcification (OR, 5.2; 95% CI, 1.9–15).

The autopsy findings in the heart and lungs of a patient with pulmonary hypertension associated with fenfluramine and phentermine have been described (13).

- A 36-year-old woman with a body mass index of 47.5 kg/m^2, took fen–phen for 7 months and developed pulmonary hypertension. Her pulmonary arterial pressure was 56 mmHg and echocardiography showed right ventricular dilatation and hypokinesia. She had a cardiopulmonary arrest during right-heart catheterization and died 3 days later. At autopsy, there was right ventricular dilatation with a fibroproliferative tricuspid valve. The pulmonary arteries had fibroproliferative plaques which were more severe and prominent in the upper lobes than in the lower lobes.

More autopsy cases of patients with a history of fen–phen use are warranted to document the frequency of combined cardiac valvular disease and pulmonary hypertension.

Progressive pulmonary hypertension occurred in two patients who took fenfluramine for only 8 months (SEDA-6, 9). The symptoms abated on withdrawal but returned in one patient when rechallenged.

In 1996, in a case-control study, 95 patients from 35 centers in France, Belgium, the UK, and the Netherlands were compared with 355 age- and sex-matched controls (14). The use of anorexic drugs (mainly derivatives of fenfluramine) was associated with an increased risk of primary pulmonary hypertension. Association with recognized risk factors such as a family history of primary pulmonary hypertension, infection with HIV, or the use of intravenous drugs was also confirmed. The absolute risk for obese patients who took anorexic agents for more than 3 months was 30 times higher than in non-users.

Echocardiography with color Doppler in 22 patients aged 25–69 years (19 women and three men) who had taken fen–phen for more than 3 months showed that one patient with newly discovered aortic insufficiency was asymptomatic. Some were taking several other drugs, none of which is known to precipitate valvular heart disease. Echocardiography was normal in 12 cases and abnormal in 10 including significant aortic insufficiency and significant mitral regurgitation. Ten of the patients had significant aortic insufficiency and nine had at least mild mitral insufficiency. The author inferred that fenfluramine was the likely offending agent, because (a) while it is known to cause release of serotonin, phentermine does not; (b) carcinoid tumors, which secrete serotonin and ergotamine, a serotonergic drug, are known to cause valvular heart disease; *and* (c) none of the obese patients who took phentermine and fluoxetine for more than 2 years developed pulmonary hypertension (15) and the author found no valvular heart disease in this cohort either (16). The recommendation that phentermine should be combined with fluoxetine, sertraline, or fluvoxamine as safer alternatives (16) requires prospective studies.

It was suggested that in patients who met the FDA criteria for cardiac valvular abnormalities on echocardiography performed soon after the withdrawal of appetite suppressants, there was a possibility (ranging from as low as 5% to as high as 67%) that the abnormality was a naturally occurring phenomenon and not a consequence of drug use (17). However, various studies have supported earlier reports of an association between fenfluramine or its d-isomer and cardiac valvular regurgitation, although they have differed with regard to the strength and clinical significance of the association (17). Differences in design, including a lack of baseline cardiac evaluation in echocardiographic assessment (9,10,18), have precluded comparisons. Additional evidence linking the use of fenfluramine or dexfenfluramine to cardiac valvular regurgitation has reaffirmed the wisdom of the FDA's decision to withdraw them from the market.

Why was this type of valvulopathy not recognized sooner? Changes in medical practice seem to have played a role as long-term and widespread use of these drugs evolved in the 1990s. Furthermore, cardiac murmurs can be more difficult to detect in obese patients (19).

Prevalence

Although initially a prevalence of up to 30% was estimated, subsequent reports have suggested much lower rates. There are several reasons for this disparity including uncontrolled data and the limitations of echocardiography (20–22). The FDA surveys and the University of Minnesota study reported point prevalences and inherently overestimated the association of appetite suppressants with valvulopathy because a certain percentage of patients have pre-existing valvular lesions. The method of detection also plays a crucial role. Echocardiography is far more sensitive than clinical examination in detecting valvular regurgitation. The issue may also be confounded by lesion regression after withdrawal of therapy (23). Moreover, case-control studies are no substitute for objective evidence of the status of cardiac valves before drug exposure (8). Also the duration of exposure has varied widely in different reports.

Pulmonary hypertension and valvular heart disease associated with anorexigens have been described predominantly in women, which raises important questions about biological and psychological risk factors and ethical practice. Do women respond differently to these drugs because of genetic or physiological factors or are these drugs being prescribed almost exclusively for women? Was it realistic for the regulatory authorities to believe that these drugs would be used only to treat morbid obesity? Most important, what view of the benefit to harm balance of using anorexigenic drugs has allowed women and their physicians to justify the use of potentially lethal drugs to deal with concerns about body image and weight? These questions (24) are pertinent to the current scenario of appetite-suppressant drug-related concerns.

Studies in which baseline echocardiography was carried out before the drug was used showed that the risk of new or prospective valvular heart disease was much lower than implied by previous prevalence studies (8). In 46 patients who used fenfluramine or dexfenfluramine for 14 days or more, the primary outcome was new or worsening valvulopathy, defined as progression of either aortic regurgitation or mitral regurgitation by at least one degree of severity and disease that met FDA criteria. Two patients taking fen–phen developed valvular heart disease. One had mild aortic regurgitation that progressed to moderate regurgitation and the second developed new moderate aortic insufficiency. The authors argued that the referral bias in their study, which required an echocardiogram for inclusion, would have tended to result in a higher incidence of valvular disease.

© 2006 Elsevier B.V. All rights reserved.

In an amended randomized double-blind placebo-controlled comparison of dexfenfluramine with an investigational modified-release formulation of dexfenfluramine, the study medication was discontinued and echocardiographic examinations were performed on 1072 overweight patients within a median of 1 month after withdrawal of treatment (18). These patients, 80% of whom were women, had been randomly assigned to receive dexfenfluramine (366 patients), modified-release dexfenfluramine (352 patients), or placebo (354 patients). The average duration of treatment was 71–72 days in each group. Echocardiograms were assessed blind. Pooling the fenfluramine groups, there was a higher prevalence of any degree of aortic regurgitation (17 versus 12%) and mitral regurgitation (61 versus 54%) with fenfluramine. Analyses carried out using the criteria set by the FDA showed that aortic regurgitation of mild or greater severity occurred in 5% of the patients taking dexfenfluramine, 5.4% of those in the two fenfluramine groups combined, and 3.6% of those in the placebo group. Moderate or severe mitral regurgitation occurred in 1.7 and 1.8% of those taking fenfluramine and 1.2% of those taking placebo. Aortic regurgitation of mild or greater severity, mitral regurgitation of moderate or greater severity, or both occurred in 6.5, 6.9, and 4.5% respectively.

This was an unusual study because patients enrolled for a different purpose were analysed mid-way through the study in response to withdrawal of fenfluramine. Exposure to fenfluramine in this study was relatively short (2–3 months) and the prevalences of mitral regurgitation and aortic regurgitation in this study were much lower than previously described (25).

Although the findings of this study may be reassuring for patients who have taken dexfenfluramine for 2–3 months, they should not preclude the appropriate investigation of a new murmur or new symptoms in any patient with a history of exposure to dexfenfluramine as specified in the American College of Cardiology Guidelines (26).

In 24 women who were evaluated an average of 12 months after starting to take fen–phen, echocardiography showed that all had unusual valvular morphology and regurgitation affecting valves on the right and left sides (27). Eight women also had newly documented pulmonary hypertension. Histopathological findings included plaque-like encasement of the leaflets and chordal structures with intact valve architecture. The histopathological features were like those seen in carcinoid or ergotamine-induced valve disease. As of the end of September 1997, the FDA had received 144 individual spontaneous reports (including the 24 cases reported earlier) involving fenfluramine or dexfenfluramine with or without phentermine in association with valvulopathy, 113 with complete information (28). Of these, 98% occurred in women of whom 2% used fenfluramine alone, 14% used dexfenfluramine alone, 79% used fenfluramine with phentermine, and 5% used a combination of all three; none had used phentermine alone. The median duration of drug use was 9 months (range 1–39 months). Cardiac valve replacement surgery was required in 24% and there was an 11% mortality.

Based on a prospective study carried out in 226 obese subjects (183 women and 43 men) with a mean body mass index of 40 kg/m^2, therapy with fen–phen was associated with low prevalence of significant valvular regurgitation (29). The authors suggested that valvular regurgitation in these subjects may have reflected age-related degenerative changes. However, several limitations of this study have been pointed out: (a) there was no control group and not all the subjects had echocardiography; (b) multiple readers interpreted the echocardiograms, rendering the comparison less accurate; (c) there was inherent inaccuracy in differentiating mild degrees of valvular regurgitation especially using qualitative scoring systems; (d) there was selection bias; and (e) neither direct inspection nor histopathological confirmation of valvular lesions was performed on any patient.

The risk of a subsequent clinical diagnosis of a valvular disorder of uncertain origin has been assessed in a population-based follow-up study using nested case-control analysis of 6532 subjects who took dexfenfluramine, 2371 who took fenfluramine, and 862 who took phentermine (10). The control group comprised 9281 obese subjects who did not take appetite suppressants matched with the treated subjects for age, sex, and weight. No subject had cardiovascular disease at the start of the follow-up for an average duration of 5 years. There were 11 cases of newly diagnosed idiopathic valvular disorders, five with dexfenfluramine and six with fenfluramine. There were six cases of aortic regurgitation, two of mitral regurgitation, and three of combined aortic and mitral regurgitation. There were no cases of idiopathic cardiac valve abnormalities among the controls or those who took phentermine. The 5-year cumulative incidence of idiopathic cardiac valve disorders was 0 per 10 000 among both those who had not taken appetite suppressants (95 CI = 0, 15) and those who took phentermine alone (CI = 0, 77), 7.1 per 10 000 among those who took either fenfluramine or dexfenfluramine for less than 4 months (CI = 3.6, 18), and 35 per 10 000 among those who took either of these medications for 4 months or more (CI = 16, 76). The authors concluded that the use of fenfluramine or dexfenfluramine, particularly when used for 4 months or longer, is associated with an increased risk of newly diagnosed cardiac valve disorders, particularly aortic regurgitation.

The above study was based on information derived from the General Practice Research Database in the UK. Subjects who had been given at least one prescription for dexfenfluramine, fenfluramine, or phentermine after 1 January 1988, and who were 70 years or younger at the time of their first prescription were included. Subjects were considered to have a new cardiac abnormality if they had no history, on the basis of clinical records, of cardiac valvular abnormalities and if there was evidence of a new valvular disorder on the basis of echocardiography or clinical examination after exposure to appetite suppressants. All the data had been recorded before the publication of recent reports of an association between appetite suppressants and cardiac valve disorders (25,27,30–32) or primary pulmonary hypertension (14). Hence, it was possible to exclude the possibility that enhanced awareness of possible serious adverse effects of appetite suppressants had led to closer surveillance of patients who were taking these drugs. Nevertheless, the study did not provide information on the frequency of idiopathic cardiac valve disorders that are asymptomatic or otherwise not clinically diagnosed.

Using the FDA case definition of appetite-suppressant related valvulopathy, the prevalence was 31% (60/191) in a selected group of Mayo Clinic patients at Rochester (33). The most common finding was mild aortic regurgitation. Of asymptomatic patients 28% had abnormal

© 2006 Elsevier B.V. All rights reserved.

echocardiographic findings. This study emphasized the spectrum of diet- or drug-related cardiac disease and the potential for valvulopathy in asymptomatic patients.

In patients who had taken dexfenfluramine (n = 479) or fen–phen (n = 455) continuously for 30 days or more in the previous 14 months, there was an increase in the prevalence of aortic regurgitation compared with 539 control subjects (34). There was no increase in the prevalence of moderate or severe aortic regurgitation in treated patients, and no difference in the prevalence of mitral regurgitation between the untreated and treated groups, irrespective of duration of therapy. All evaluations were carried out using the FDA criteria. The authors were careful to point out that their study was not specifically designed or adequately powered to evaluate specific categories of anorexigen therapy duration.

Further evidence that the prevalence of significant valvular regurgitation is low in patients who take fen–phen has been reported (35). Transthoracic echocardiography was performed in 343 obese patients in a 3-year prospective study that began within 4 months from the withdrawal of fenfluramine and dexfenfluramine from the market. There were 281 women and 62 men, mean age 47 years, and mean body mass index 40 kg/m^2. Using the FDA's criteria, only 21 subjects (6.1%) had significant valvular lesions. Aortic regurgitation was detected in 18 subjects, mitral regurgitation in 3, and both aortic and mitral regurgitation in 1. Significant valvular disease did not correlate with age, sex, initial or final body mass index, drug dose, or the duration of therapy.

Mechanisms and risk factors

The determinants of valvulopathy in patients treated with dexfenfluramine have been investigated: age and blood pressure can also affect the prevalence of regurgitation (36,37), as can duration of exposure (36). Others have found no correlation between valvular disease associated with appetite suppressants and either dose or duration of drug exposure (29).

Cases of severe diffuse multivalvular disease associated with fen–phen have been described (38,39).

- A 52-year-old woman had a transesophageal echocardiogram 1 year before starting to take fen–phen, and had no significant valvular disease. She presented a year later with a new heart murmur and eventually required isolated aortic valve replacement. Pathological evaluation of the excised aortic valve was consistent with that described with fen–phen use.
- A 44-year-old woman who had previously taken appetite suppressants, developed valvular disease consistent with the effects of fen–phen. She had an identical twin who, despite having been treated with the same medication, remained symptom-free and without abnormal echocardiography. Both the patient and her sister took fen–phen for 2 years. However, the patient took a daily dose of fenfluramine of 60–120 mg (and often as much as 240 mg) and phentermine 90 mg (at times 180 mg), whereas her twin sister adhered to the daily amount prescribed (fenfluramine 60 mg and phentermine 24 mg).

The latter case suggests that dosage is important in the production of the valvular pathology. Mitral and tricuspid insufficiency developed in a 36-year-old woman who had taken fen–phen for 24 months (40). Transmission electron microscopy of the mitral and tricuspid valves showed many areas that appeared to contain intracellular, virus-like particles clustered in the cytoplasm, with a mean diameter of 32 nm. Whether this finding was incidental or related to the underlying pathology was uncertain.

There is further evidence, from an uncontrolled observational study in 85 patients, that the dose and duration of administration of fen–phen affects the risk of significant valvular disease (41). The authors suggested that it would be prudent to consider diagnostic echocardiography in patients who have used fen–phen either in a dosage of at least 60 mg/day or for at least 9 months. They also raised concerns that for patients with mild obesity, the prolonged use of larger cumulative amounts may lead to a higher risk of valve regurgitation.

There is further evidence of the relation between the duration of treatment with fen–phen and the prevalence of valvular abnormalities (42). In 1163 patients who had taken anorexigens within the previous 5 years and 672 control patients who had not, valvular abnormalities primarily involved those who had taken anorexigens for more than 6 months, and predominantly resulted in mild aortic regurgitation. The study had some noteworthy limitations: since fenfluramine has been withdrawn from use, a randomized trial was impossible; also the lack of baseline echocardiograms before treatment implies that one cannot be certain that the valvular regurgitation developed subsequent to drug treatment.

Diagnosis

It has been proposed that valvular disease can be attributable to appetite suppressants only if the following criteria are satisfied:

- the macroscopic and microscopic features are consistent with fenfluramine-related valvulopathy;
- clinical, echocardiographic, and intraoperative findings support the diagnosis;
- the history of drug exposure predates the development or exacerbation of valvular dysfunction (43).

It is obvious that these criteria can be applicable only in cases in which cardiac valves are explanted and are available for histopathological studies.

The prevalence and diagnostic value of cardiac murmurs for valvular regurgitation has been determined in 223 patients taking dexfenfluramine for 6.9 months and 189 matched controls. Experienced physicians, non-cardiologists, who were unaware of the echocardiographic findings, took a history and performed cardiac auscultation. Based on their findings the authors recommended that cardiac auscultation should be the screening method of choice for detecting valvular regurgitation in users of anorexigens (44). In this study, the absence of cardiac murmurs predicted the absence of clinically important valvular regurgitation in 93% of dexfenfluramine users. These results support the recommendation by the American Heart Association and American College of Cardiology (45) that asymptomatic users of anorexigens without a cardiac murmur do not warrant echocardiography. The data also suggest that in users of anorexigens with a 10% prevalence of valvular regurgitation and a 10–15% prevalence of cardiac

© 2006 Elsevier B.V. All rights reserved.

murmurs, cardiac auscultation will prevent 85–90% of patients from undergoing unnecessary echocardiography. These implications may apply to all users of anorexigens because the prevalence of valvular regurgitation in recent large series is similar to that in this study (SEDA-24, 4). There are therefore large potential cost savings of cardiac auscultation, by preventing a large proportion of the more than 6 million Americans who are exposed to anorexigens from undergoing initial and follow-up echocardiography or from receiving empiric antibiotic prophylaxis for emergency procedures that preclude further cardiac evaluation.

Effects of withdrawal of therapy on valvulopathy

In a patient who was followed-up for 2 years after withdrawal, multivalvular regurgitation associated with fenfluramine and phentermine may have regressed (23).

- A 44-year-old woman with morbid obesity but no history of cardiac disease developed atypical chest pain. Myocardial infarction was ruled out, and an echocardiogram showed normal chamber sizes and mildly reduced global systolic function. However, moderate to moderately severe aortic regurgitation, mild mitral regurgitation, and moderate tricuspid regurgitation were present. The estimated pulmonary artery pressure was slightly raised. Her only medications were fenfluramine 60 mg/day and phentermine 30 mg/day, which she had taken for the previous 50 weeks, during which time she had lost 40 kg. These drugs were withdrawn and 6 months later an echocardiogram showed improved left ventricular function and a reduction in the severity of all her valvular lesions with no clinically significant change in the estimated pulmonary artery pressure. An echocardiogram obtained 2 years after the initial study showed only trace aortic and tricuspid regurgitation without mitral regurgitation.

In this case, serial echocardiography over 2 years documented regression of multivalvular regurgitation, first discovered while the patient was taking fenfluramine and phentermine. The authors argued that although she was also given lisinopril, the marked degree of improvement in all the valvular lesions after withdrawal of the appetite suppressants was unlikely to be attributable to this alone (46).

The small increase in prevalence of minor degrees of aortic regurgitation and mitral regurgitation in 941 patients treated with dexfenfluramine for 2–3 months was no longer present 3–5 months (median 137 days) after withdrawal (47). Echocardiograms were acquired using a standardized protocol and were assessed blindly.

In 50 patients with fenfluramine-associated valvular heart disease followed by serial echocardiography for 6–24 months after withdrawal of therapy (48), in most cases valvular heart disease either did not change or improved at least by one grade. Mitral and aortic regurgitation improved in some patients, and tricuspid and pulmonic regurgitation improved in most patients after withdrawal. When improvement did occur, regression of regurgitation often involved multiple valves on both the left and right sides of the heart, rather than affecting one valve in isolation. Although most of the patients stabilized or improved, a few had worsening of valvular regurgitation despite withdrawal.

Comparable results were also reported in a larger series in another study (49). Sequential echocardiographic evaluation 1 year after withdrawal of dexfenfluramine showed a significant reduction in aortic regurgitation. There were no significant changes in mitral regurgitation or any other valvular variables. Although these results can be applied only to the population studied (predominantly middle-aged, obese, white women who took dexfenfluramine for 2–3 months), the implications are considerable. Because valvular regurgitation remained stable or improved in most of the patients, surgical referral for patients with severe regurgitation may be delayed. Improvement in valvular regurgitation often occurred within months after drug withdrawal. Watchful waiting with serial echocardiography, prophylaxis against endocarditis, and medical therapy may be a reasonable management strategy in patients with severe regurgitation, minimal symptoms, and no evidence of left ventricular dysfunction (48).

However, reversibility may not occur in all cases (50).

- Cardiac allograft transplantation was carried out from a 35-year-old hypertensive donor with prolonged exposure to fenfluramine and phentermine. There was non-specific mitral valve thickening, with trivial mitral regurgitation and poor approximation of the mitral valve leaflets, due to reduced posterior leaflet mobility. There was no evidence of any other valvular lesion. Examination of the donor heart during cardiac implantation showed three discontinuous lesions along the left atrial surface of the mitral valve annulus and another firm nodular lesion of the annular endocardium. Transplantation of the heart was uneventful and intraoperative transesophageal echocardiography, performed after weaning from cardiopulmonary bypass, showed trivial mitral regurgitation with excellent allograft contractility. The postoperative course was uneventful and the patient was discharged on the eighth postoperative day. Histological examination of the specimen showed a glistening appearance with proliferating myofibroblasts and associated fibrinous vegetations. There was no evidence of acute or chronic inflammation, and Gram staining did not show bacterial or fungal elements. A transthoracic echocardiogram 6 weeks after transplantation showed only trivial mitral regurgitation with improved mobility of the posterior leaflet. Hemodynamic data showed normal allograft function. However, after 6 months of follow-up, Doppler echocardiography showed worsening of mitral regurgitation to moderate severity, but no adverse effects of this hemodynamic load were noted and the patient remained stable.

Although conclusions based on single cases have limitations, they can often provide useful insights and act as catalysts for further studies. This report illustrates a few important features of cardiac valvulopathy associated with anorexigen use. There was no involvement of chordal apparatus and so the pathological changes within the valve leaflets and annulus represented the earliest site of an anorexigen-induced valvulopathy. This opportunity to observe a case of "early" valvulopathy visually and histopathologically offered insight into pathogenesis, and may have been helpful in staging the lesions temporally.

Of 120 patients who had follow-up echocardiography at least twice after stopping fen–phen, 99 met FDA criteria

© 2006 Elsevier B.V. All rights reserved.

for valvulopathy (51). On second echocardiography, 57 of these 99 had no change in valvulopathy, 33 had improved, and 9 had deteriorated; nine patients no longer met FDA criteria for valvulopathy. The authors suggested that physicians must continue to be vigilant with patients who develop valvulopathy after taking fen–phen.

Obesity as a confounding factor in cardiac valvulopathy

It is not clear whether valvular insufficiency is related to the use of appetite suppressants or is simply a consequence of obesity. Obese patients who took dexfenfluramine alone, dexfenfluramine in combination with phentermine, or fenfluramine in combination with phentermine have been compared with a matched group of obese-control subjects who had not taken these medications (9). A total of 1.3% of the controls (3 of 233) and 23% of the patients (53 of 233) met the case definition for cardiac valve abnormalities (OR=23). The odds ratios for such cardiac valve abnormalities were 13 with dexfenfluramine alone, 25 with dexfenfluramine and phentermine, and 26 with fenfluramine and phentermine. This study showed that the prevalence of valvular insufficiency is significantly higher among obese patients who have taken appetite suppressants than among subjects matched for age, sex, and body mass index who did not take such drugs. Since a higher percentage of patients than controls had trace aortic valve insufficiency, the authors questioned whether the case definition threshold for cardiac valve abnormalities in association with appetite suppressants set by the FDA and Centers for Disease Control and Prevention is perhaps too high. In this study the factors that predisposed patients to valvular insufficiency were (a) age at the start of therapy, (b) use of dexfenfluramine, (c) combination of dexfenfluramine with phentermine, and (d) combination of fenfluramine with phentermine. Hence, neither the clinical significance nor the natural history of this type of valvular disease has been defined.

Other epidemiological studies have ruled out the possibility that obesity itself causes a high prevalence of cardiac valvular regurgitation (52–54).

Pulmonary hypertension

Pulmonary hypertension associated with fenfluramine was first reported in the early 1980s. A retrospective study further established the link (55). Subsequently a multicenter case-control study in 95 patients showed a high incidence of pulmonary hypertension in patients who had used fenfluramine or dexfenfluramine (14). Moreover, there was a strong suggestion of a dose–response effect, longer periods of use being associated with a progressive increase in the relative risk of pulmonary hypertension. In 1997, the first case of pulmonary hypertension in association with fen–phen was reported (56). Eight of the 24 patients with valvular disease had newly diagnosed pulmonary hypertension, although in most cases it was attributable to valvular abnormalities (57). It is not clear whether a combination of these agents poses a higher risk in predisposed individuals.

The results of a Belgian study in 35 patients with pulmonary hypertension and 85 matched controls have been published (58). The data were collected when there was no restriction on prescribing of appetite suppressants. Of the patients, 23 had previously taken appetite suppressants, mainly fenfluramines, compared with 5 controls. Moreover, the patients who had been exposed to appetite suppressants tended to be on an average more severely ill and to have a shorter median delay between the onset of symptoms and diagnosis.

Pulmonary artery pressure and cardiac valvular status were determined in a series of 156 mostly asymptomatic patients taking fenfluramine and phentermine (59). The anorexigen was withdrawn when abnormalities were noted. Pulmonary artery pressure was estimated and valvular examination was performed using Doppler echocardiography. There was borderline or mildly elevated pulmonary artery pressure in 21 patients and 31 patients had notable valvular abnormalities. It has therefore been established that asymptomatic patients may have significant echocardiographic abnormalities, representing early lesions.

- A 30-year-old woman who had taken dexfenfluramine for 7 months developed pulmonary hypertension and right heart failure during late pregnancy. She died of septicemia with multiorgan failure 4 days after a cesarean section (60).
- Pulmonary hypertension and multivalvular damage after prolonged use of fenfluramine with phentermine have been reported in a 70-year-old Israeli woman (61).
- Fatal pulmonary hypertension occurred in a 32-year-old man who had been taking phentermine in unknown doses for 4 months (62).

Incidence

The epidemiological association of pulmonary hypertension with aminorex and dexfenfluramine, both with respect to the strength of the association (estimate of relative risk) and its impact on public health, has been investigated (63). Control rates of exposure were used to estimate population exposure prevalences. The estimated odds ratio for the association between pulmonary hypertension and any exposure to aminorex was 98 and for dexfenfluramine 3.7. The strong association between aminorex and pulmonary hypertension projected a fivefold increase in the incidence of pulmonary hypertension, and thus a very noticeable epidemic. In contrast, the association with dexfenfluramine is expected to result in an incidence of only 20% and thus a repeat epidemic seems unlikely.

In a prospective surveillance study of 579 patients with pulmonary hypertension at 12 large referral centers in North America, 205 had primary pulmonary hypertension and 374 had secondary pulmonary hypertension (64). Among the drugs surveyed, only fenfluramine had a significant association with primary pulmonary hypertension compared with secondary pulmonary hypertension (adjusted odds ratio for use for more than 6 months = 7.5; 95% CI = 1.7, 32). The association was stronger with longer duration of use compared with shorter duration of use and was more pronounced in recent users than in remote users. An unexpectedly high (11%) number of patients with secondary pulmonary hypertension had used anorexigens. The high prevalence of anorexigen use in patients with secondary pulmonary hypertension also

© 2006 Elsevier B.V. All rights reserved.

raised the possibility that these drugs precipitate pulmonary hypertension in patients with underlying conditions associated with secondary pulmonary hypertension.

The age-adjusted mortality rates from primary pulmonary hypertension in the years immediately preceding the use of fen–phen were not different from those reported during the years of widespread use among patients aged 20–54 years. This analysis failed to support the hypothesis that the widespread use of fen–phen in the years 1992–1997 increased the incidence of primary pulmonary hypertension. "If the use [of fen–phen] during these years created an epidemic of primary pulmonary hypertension, as some have declared, such an epidemic is not reflected in the mortality database maintained by CDC" (65).

Prognosis

Of 62 patients (61 women) exposed to fenfluramine compared with 125 sex-matched patients with primary pulmonary hypertension, 33 had used dexfenfluramine alone, 7 had used fenfluramine alone, and 5 had used both (66). In 17 cases fenfluramines were taken with amphetamines. Most of the patients (81%) had taken fenfluramines for at least 3 months. The interval between the start of therapy and the onset of dyspnea was 49 months (range 27 days to 23 years). The two groups differed significantly in terms of age and body mass index. Both groups had similar severe baseline hemodynamics, but the percentage of responders to an acute vasodilator was higher in patients with primary pulmonary hypertension. Hence, more patients with primary pulmonary hypertension were treated with oral vasodilators, and long-term epoprostenol infusion was more often used in fenfluramine users. Overall survival was similar in the two groups, with a 3-year survival rate of 50%.

Mechanism and pathophysiology

The mechanism of fenfluramine-associated pulmonary hypertension has been reviewed (SEDA-21, 3). Since only a minority of patients exposed to fenfluramines develop pulmonary hypertension, it has been postulated that a subset may be genetically susceptible. Whether there is a related genetic abnormality in the familial PPH gene located on chromosome 2q (67) or an abnormality of the angiotensin-converting enzyme gene (68) has yet to be explored.

Anorexigenic drugs accumulate in the lung and other tissues, especially in cellular organelles with an internal acid pH, such as lysosomes, where they bind to acidic enzymes. Lipid enzyme inhibition, lysosomal lipidosis, and associated myeloidosis are key events in the pathological cascade (69). Since several stimulants and other psychotropic drugs are cationic amphiphilic compounds that accumulate in the lung, brain, and other tissues, the variety of pathological mechanisms involved in the effects of this group of drugs should be kept in mind during long-term use (70,71).

The hypothesis that nitric oxide deficiency predisposes affected individuals to anorexigen-associated pulmonary hypertension has been tested in a prospective case-control comparison with two sex-matched sets of controls: patients with primary pulmonary hypertension ($n = 8$) and healthy volunteers ($n = 12$) (72). Lung production of nitric oxide and systemic plasma oxidation products of nitric oxide were measured at rest and during exercise, and were lower in patients with anorexigen-associated pulmonary hypertension than in patients with primary pulmonary hypertension. This deficiency may have resulted from increased oxidative inactivation of nitric oxide, as the concentrations of their oxidative products were raised in inverse proportion to nitric oxide. These findings, and earlier evidence from animal studies (73), have given support to the hypothesis incriminating nitric oxide as a determinant of individual susceptibility to anorexigen-associated pulmonary hypertension.

The pressure response to endothelin-1 in the canine circulation has been investigated in isolated perfused dog lung (74). Acute treatment of the isolated lobes with fenfluramine increased pulmonary arterial pressure. Chronic treatment with fenfluramine potentiated the pulmonary vasoconstrictor response to endothelin-1. Based on these findings, the authors proposed that the pulmonary vasculature becomes hyper-reactive to vasoactive substances, such as serotonin and endothelin-1, possibly leading to pulmonary hypertension.

Anorexigen-associated severe pulmonary hypertension is clinically and histopathologically indistinguishable from idiopathic or primary pulmonary hypertension. Analysis of clonality in microdissected endothelial cells of plexiform lesions in two patients with anorexigen-associated pulmonary hypertension showed a monoclonal expansion of pulmonary endothelial cells. Accelerated growth of pulmonary endothelial cells in response to anorexigens in patients with predisposition to primary pulmonary hypertension has been speculated (75).

Hypertension

In a few patients, hypertension was induced or aggravated by fenfluramine. The hypertension disappeared on withdrawal, but could not in all instances be reinduced by rechallenge (76).

Nervous system

The frequent occurrence of sedation, drowsiness, lightheadedness, and headaches has been referred to in the general section above.

Impaired powers of concentration during the first week, insomnia, apathy, tiredness, reduction in general memory, and a feeling of derealization, but not mood elevation, were noted in healthy people who took fenfluramine (SEDA-13, 3) (77).

Of special interest are studies on the effects of fenfluramine on sleep. After administration of 40 or 80 mg of fenfluramine, patients with chronic psychiatric disorders fell asleep normally, but a few hours later were troubled with a peculiar feeling of uneasiness that kept them awake for the rest of the night. The following night, however, they fell asleep more quickly, regardless of the medication. Moreover, one patient had nightmares after taking two tablets a day; when the dosage was reduced to a single tablet in the morning, the nightmares ceased (78). About half of a group of 50 obese women treated for 20 weeks with various doses, increasing gradually up to the maximum tolerated dose of

© 2006 Elsevier B.V. All rights reserved.

160 mg/day and then reduced again, reported of increased dreaming (79). In other studies vivid and disturbing dreams were reported by patients who tools fenfluramine 20–60 mg/day (80,81).

A 43-year-old woman had tightening movements of the head and neck with tongue and throat muscle spasm after a single fenfluramine tablet (82).

With phentermine, adverse effects due to stimulation of the central nervous system are less than with dexamphetamine, although in one study withdrawal because of adverse effects was as high as 16 of 177 patients (9%); 2 of 13 healthy young volunteers withdrew because of unacceptable stimulation (83).

Insomnia is one of the most common adverse effects of phentermine. In a survey in Edinburgh, 20% of the subjects taking phentermine reported insomnia compared with 6% of those taking placebo (4).

Psychological, psychiatric

The effect of fenfluramine is usually not one of stimulation but of calmness or drowsiness. However, in predisposed subjects, it can precipitate psychotic illness. Several published cases illustrate this (84). It is wise to avoid fenfluramine in patients prone to endogenous depression or psychosis.

A schizophreniform-like psychotic disorder was attributed to phentermine in a young woman without a personal or family history of psychiatric disorders (85).

Metabolism

Fenfluramine tends to improve glucose tolerance and to cause small but significant reductions in fasting blood cholesterol and beta-lipoprotein concentrations. Although it has been suggested that metabolic effects may play a role in weight reduction, and that fenfluramine might even be used to reduce blood lipids, the metabolic effects observed are slight and of dubious clinical importance.

Hematologic

Hemolytic anemia has been attributed to fenfluramine (86).

- A 46-year-old woman took fenfluramine for 5 months without incident. Some time later she restarted therapy and after 2 months developed a hemoglobin concentration of 5.1 g/dl, a reticulocyte count of 8.6%, a white cell count of 17.1 $\times$ 10^9/l, and a positive direct Coombs' test, with IgG rhesus antibodies (anti-e and anti-nl). Fenfluramine was withdrawn and the Coombs' test became negative and the patient recovered after prednisolone infusion.

Two other cases are known of anemia in patients who received fenfluramine and propranolol (SED-9, 13).

A clotting disorder has been attributed to fen–phen (87).

- A 35-year-old woman developed calf-pain while taking fen–phen. It resolved when the medications were withdrawn, but her pain returned when fenfluramine was restarted. She had slight rises in aspartate transaminase and lactate dehydrogenase activities and a remarkably shortened prothrombin time. The clot was composed of very thin fibrin fibers. All laboratory abnormalities, including the abnormal fibrin structure, completely resolved when fen–phen was withdrawn.

Thin fibrin fibers are more resistant to lysis and can result from a variety of factors and increase the risk of thrombosis. Whether abnormal fibrin structure and an increased thrombotic tendency play a role in patients who develop fenfluramine-associated pulmonary hypertension and valvular heart disease is a question that deserves further investigation.

Gastrointestinal

Diarrhea, dry mouth, and nausea have been reported (88).

Urinary tract

Phentermine can cause allergic interstitial nephritis (89).

- A 47-year-old mildly obese woman began a weight-reduction program that included anorectic therapy with phentermine and phendimetrazine. She had normal renal function at the start of therapy. After 3 weeks of treatment she fell ill and discontinued treatment. She was subsequently found to have leukocyturia, a rash on her face and chest, and a rise in serum creatinine from 67 to 175 μmol/l (0.8–2.1 mg/dl). Renal biopsy confirmed the diagnosis of acute interstitial nephritis. She was treated with corticosteroids and her renal function returned to normal.

Sexual function

There have been occasional reports of erectile impotence that disappeared on withdrawal. Very high dose regimens of 240 mg/day seem to produce a fairly high incidence of loss of libido, especially in women (90).

Immunologic

Shortly after starting dexfenfluramine 30 mg/day, an 18-year-old woman died of sclerodermal renal crisis (91). Although there have been reports linking long-term fenfluramine use and the development of scleroderma (92,93), this is perhaps the first report implicating dexfenfluramine.

Long-Term Effects

Drug abuse

Fenfluramine has the potential to become a drug of abuse when used in high dosages. Of 438 drug-dependent subjects, 60 gave a history of fenfluramine abuse and experienced euphoria, depersonalization, and perceptual changes after taking up to 400 mg (SED-9, 13). In another report, three of the eight subjects taking fenfluramine 240 mg/day experienced psychedelic states (SED-9, 13). A 28-year-old woman became dependent on fenfluramine at an average dose of 240 mg/day (SEDA-1, 5).

Some cases of toxic psychosis have been reported with abuse doses of phentermine (94).

© 2006 Elsevier B.V. All rights reserved.

Drug tolerance

While tolerance to the anorectic effects of fenfluramine appears to set in after 6–12 months, tolerance to its adverse effects is much more rapid in onset (90).

Drug withdrawal

Depression can occur but is more common during the first few days following sudden withdrawal (SED-9, 12). An explanation for the depression and irritability encountered after sudden withdrawal may be a rapid reduction in 5-hydroxytryptamine through which the central effect of fenfluramine is mediated.

Second-Generation Effects

Pregnancy

In a prospective cohort study of 98 women who had taken fen–phen at the recommended daily dose during the first trimester of pregnancy and 233 women who had not taken it, there was no evidence of an increased risk of spontaneous abortion or of major or minor anomalies in the offspring of women who took fen–phen (95). These findings are similar to those of a previous French Collaborative Study (96). However, the risk to the offspring of women who take fen–phen for more prolonged periods and at higher dosages during pregnancy is unknown.

Drug Administration

Drug contamination

There have been reports of herbal remedies adulterated with fenfluramine. There was public health concern in the UK after the referral of a 44-year-old woman with new-onset hypertension, palpitation, anxiety, and a body mass index of 19 kg/m^2. It became apparent that an alarming number of the local population had been attending a particular Chinese herbalist for weight loss remedies. Most had been taking multiple formulations and described "spectacular" results. Several reported considerable cardiovascular symptoms, but they were reassured that Chinese medicines are natural and can cause no harm. Analysis by gas chromatography showed a high concentration of fenfluramine in two of the products (sold as Qian Er and Ma Zin Dol, presumably mimicking the brand name Mazindol). Fenfluramine was also found in the patients' urine. Subsequently, a student nurse was admitted with severe fenfluramine toxicity which developed 2 hours after her first dose of a herbal slimming remedy (97). Following an investigation of this case the Medicines Control Agency published a report on traditional ethnic medicines and the current law (98). Stringent regulation of traditional medicines, at least to the standards of conventional practice, is urgently needed. The hazards associated with the use of dietary supplements containing ma huang, a herbal source of ephedrine, have also been reported (99).

Drug overdose

A systematic study of fenfluramine poisoning in 96 human subjects (38 in detail) has been reported (100). Convulsions and coma occurred in 75% of those who took more than 15 mg/kg. Increased muscle tone, hyper-reflexia, or clonus were common; one-third had hyperthermia, but less than 10% died of it; symptoms could last for days. Blood concentrations of 240–850 ng/ml were associated with tachycardia, mydriasis, and confusion. Deaths occurred beginning at 650 ng/ml. Early gastric lavage, activated charcoal, diazepam for seizures, chlorpromazine and cooling for malignant hyperthermia, and lidocaine and constant electrocardiographic monitoring for extra beats were recommended.

Drug–Drug Interactions

Fluoxetine

Following the withdrawal of the fenfluramines, alternative combinations have been explored as appetite suppressants. In an open study of a combination of phentermine + fluoxetine in 16 obese patients with binge-eating disorder, in the setting of cognitive behavioral therapy, there were significant reductions in weight, binge frequency, and psychological distress by the end of treatment; however, the patients regained most of the weight within 1 year (101). At follow-up at 18 months there was still a reduction in binge eating in patients who continued maintenance treatment. The results did not support the long-term value of adding phentermine/fluoxetine to cognitive behavioral therapy for binge-eating disorder. It is worth emphasizing that it is not known whether phentermine/fluoxetine is also associated with cardiac valvulopathy. Moreover, the recognition that phentermine is a monoamine oxidase inhibitor (102) raises further concerns about its safety.

Halothane

Following a report of death after an anesthetic in a 23-year-old woman who had been taking fenfluramine, a study was undertaken in rabbits to investigate the possibility of an interaction of fenfluramine with halothane. Electrocardiographic and phonocardiographic changes were recorded in rabbits given the combined treatment, and could not readily be reversed with beta-blockers and resuscitative drugs. It was recommended that fenfluramine be discontinued a week before anesthesia (SED-9, 13).

Monoamine oxidase inhibitors

Fenfluramine can cause acute confusion if it is given together with monoamine oxidase inhibitors (SED-9, 9).

Fenoterol

See also Beta$_2$-adrenoceptor agonists

General Information

Fenoterol is a beta$_2$-adrenoceptor agonist with higher intrinsic activity than salbutamol; it produces a greater maximal effect and has greater systemic effects at higher than conventional doses. It is available as a multidose pressurized aerosol 100 and 200 micrograms/puff and as a nebulizer solution, respules, 4 ml containing 1.25 mg. A formulation for injection is available in some countries.

Like other beta$_2$-agonists fenoterol has been used in premature labor as well as in asthma.

The safety of fenoterol in severe asthma

Debate continues about the safety of fenoterol in the treatment of severe asthma. A sharp rise in asthma mortality in 1977 in New Zealand provoked debate about the safety of beta$_2$-adrenoceptor agonists, especially the short-acting compound fenoterol. This led to the withdrawal of fenoterol in New Zealand and amendment of the American Asthma Guidelines, suggesting caution in the regular use of beta$_2$-adrenoceptor agonists (1). Although there is evidence linking fenoterol to increased morbidity and mortality in asthma (2), the underlying mechanisms were not known. It was suggested that the increase in mortality might be linked to fatal cardiac dysrhythmias, developing under conditions of asthma-induced hypoxia and high doses of beta$_2$-adrenoceptor agonists (3).

In a report the manufacturers have discussed the epidemiological data linking the use of fenoterol to asthma mortality in New Zealand. They pointed out that asthma mortality started to fall in 1979 while fenoterol sales were still increasing. Sales of fenoterol in Austria, Belgium, and Germany were similar to those in New Zealand at the peak of the New Zealand asthma death epidemic, but asthma mortality in the other countries did not rise. The confounding problem that fenoterol was preferentially prescribed for the more severe cases of asthma was

© 2006 Elsevier B.V. All rights reserved.

again mentioned. Researchers who adjust their data appropriately for asthma severity have concluded that the increased risk of death from asthma reported in patients using fenoterol is due to underlying severe disease in the patients using fenoterol. The proponents of the hypothesis have responded by pointing out that four case-control studies all showed a significantly higher death rate in patients taking fenoterol than in patients taking other $beta_2$ agonists. They have acknowledged that there is some evidence of selective prescribing of fenoterol in populations studied in New Zealand and Canada. However, they do not agree that the association between fenoterol and asthma deaths is due to confounding by asthma severity. A third group has concluded that the association between fenoterol and severe life-threatening asthma is explained by the preferential prescribing of fenoterol for patients with more severe disease. They have pointed out that doses of fenoterol (up to 3200 micrograms) or salbutamol (up to 1600 micrograms) failed to produce clinically relevant cardiac dysrhythmias in patients with acute severe asthma. This was despite the fact that the two-fold higher dose of fenoterol caused greater systemic $beta_2$ effects. They have concluded that although epidemiological evidence may implicate fenoterol as a cause of asthma deaths it can only generate a hypothesis. The hypothesis is not substantiated by data from carefully controlled pharmacodynamic and pharmacoepidemiological studies. They have supported the view that excessive use of $beta_2$ agonists, including fenoterol, in severe asthma is a marker of inadequate suppression of the underlying inflammatory process, indicating the need to introduce or optimize the dose of glucocorticoids.

It is interesting to reflect that a similar debate followed the rise in asthma deaths in the UK in the 1960s. Most physicians now accept that excessive use of beta-adrenoceptor agonists in worsening asthma indicates inadequate treatment rather than a toxic effect of the drugs.

Organs and Systems

Cardiovascular

The cardiovascular safety of high doses of inhaled fenoterol and salbutamol has been compared in acute severe asthma (SEDA-21, 183). It was concluded that in adequately oxygenated patients a total dose of 3.2 mg of fenoterol or 1.6 mg of salbutamol given over 60 minutes was safe in terms of cardiovascular effects in acute severe asthma.

Electrolyte balance

In one study, an intravenous infusion of fenoterol 0.5–2.0 micrograms/minute was given to 83 patients (aged 28–34 years) in premature labor (SEDA-22, 189). Pretreatment plasma potassium concentrations were normal (median 4.10 mmol/l; 25–75 percentiles 4.10–4.40 mmol/l). During the first 2 hours the serum potassium fell significantly to 2.88 mmol/l (2.80–3.00 mmol/l), but returned to normal during the first day and then remained in the reference range, despite continuous fenoterol administration. No potassium supplements were given. No clinical abnormalities, including cardiac dysrhythmias, due to hypokalemia were seen.

Liver

Liver damage has been attributed to fenoterol (SEDA-21, 183).

- A 27-year-old woman at 31 weeks of a second pregnancy was admitted in premature labor and treated with intravenous fenoterol 7.5 mg/day. Within 48 hours her liver enzymes were raised. Because the liver function tests became progressively worse and she had epigastric pain and severe nausea, the fenoterol was withdrawn after 9 days. The liver function tests quickly normalized and there appeared to be a clear relation between the administration of fenoterol and the occurrence of liver damage.

Fenproporex hydrochloride

See also Anorectic drugs

General Information

Fenproporex, one of the lesser known anorectic drugs, is structurally related to amfetamine, to which it is rapidly metabolized after oral ingestion. Stimulatory effects, somnolence, and electroencephalographic abnormalities are reported to be the major undesired reactions (1).

Fenspiride

General Information

Fenspiride is a bronchodilator and anti-inflammatory drug. Two in vitro studies have suggested possible mechanisms for these effects.

Functional studies in human isolated bronchi showed that fenspiride causes a shift to the left of concentration effect curves for relaxation induced by isoprenaline and

© 2006 Elsevier B.V. All rights reserved.

sodium nitroprusside. Biochemical studies confirmed that phosphodiesterase type IV (cyclic AMP-specific) and phosphodiesterase type V (cyclic GMP-specific) are the main phosphodiesterase isoforms present in human bronchi. Fenspiride inhibited both isoforms. Fenspiride facilitates relaxation of human bronchial smooth muscle in vitro, and this effect may be due to inhibition of phosphodiesterases IV and V.

In a human lung epithelial cell line, in which histamine increased the intracellular calcium concentration and the formation of eicosanoids, this response was antagonized by the histamine H_1 receptor antagonist diphenhydramine but unaffected by the H_2 receptor antagonist cimetidine. Fenspiride inhibited H_1 receptor-induced calcium increase. Histamine also caused a biphasic increase in arachidonic acid release, which was inhibited by fenspiride. This study suggests a further mechanism that would promote anti-inflammatory and bronchodilator properties.

The findings in several thousand patients treated by 800 general practitioners have been reported (1). There were mild adverse effects in 10% of the patients, but they were not thought to be specific to the drug (gastrointestinal, neurovegetative).

Fenspiride has been used to treat 392 adults with acute respiratory tract infections, most of whom were considered to have a moderate symptom score that improved with 7 days of treatment with fenspiride. Adverse reactions were classified as mild and tolerance was excellent; only 20 of 392 patients discontinued the drug.

Fentanyl

General Information

Fentanyl citrate is a synthetic opioid 1000 times more potent than pethidine. It has a relatively short duration of action, and its effects are rapidly reversed by opioid antagonists (1). It is useful (2) but has typical opioid adverse effects.

The analgesic effect of fentanyl 1.5 μg/kg has been compared with that of tramadol 1.5 mg/kg in 61 patients receiving standardized anesthetics for day-case arthroscopic knee surgery (3). Opioid adverse effects and analgesia were similar in the two groups.

The analgesic effects and adverse effects profiles of subcutaneous fentanyl and subcutaneous morphine have been compared in a double-blind, crossover, 6-day study in 23 patients with cancer pain (4). There were no significant differences in pain scores between the two drugs and no changes in the level of acute confusion (using the Saskatoon Delirium Checklist) or cognitive impairment (in tests of semantic fluency and trail-making tests). Fentanyl caused significantly less constipation. The patients in this study were highly stable and compliant, and the results cannot be generalized.

Organs and Systems

Cardiovascular

A hypertensive crisis occurred in a patient with a previously unknown pheochromocytoma (5).

Respiratory

Even small doses of fentanyl can cause respiratory depression. Delayed respiratory depression can be a particular problem in the elderly, in whom the half-life is approximately three times longer than in younger patients (6). Respiratory depression has been reversed with nalbuphine; doxapram could only antagonize this effect for 2–5 minutes (7). However, the need for prolonged treatment of respiratory depression with naloxone, because of pharmacokinetic variability and/or transdermal drug reservoir, has been emphasized by several authors (SEDA-16, 80) (SEDA-17, 80).

Fentanyl can evoke the pulmonary chemoreflex, as evidenced by 50% of patients in one study and 28% in another, who coughed after the administration of fentanyl through a central line (SEDA-16, 79) (8). The coughing caused by fentanyl is inhibited by terbutaline (SEDA-21, 88).

Cough has been attributed to fentanyl (9).

- A 7-year-old boy with trisomy 21 (Down syndrome) had explosive coughing, 30 seconds after fentanyl 50 μg (2 μg/kg) had been injected and flushed through an intravenous cannula. The cough was unproductive and persisted in spasmodic bursts for a further 2–3 minutes until anesthesia was induced with propofol 60 mg and atracurium 15 mg intravenously. The coughing immediately ceased. A petechial rash in the conjunctivae and periorbital regions was subsequently noted and disappeared by the end of the first postoperative day.

Nervous system

Movement disorders after withdrawal of continuous infusion, without the characteristic autonomic signs of opioid withdrawal, have been reported in children (SEDA-17, 80).

Fentanyl-induced seizures have been reported (10).

Life-threatening complications have included raised intracranial pressure and critically reducing cerebral perfusion (11).

- A 55-year-old man was given fentanyl 0.05 mg for treatment of left chest pain and immediately developed an acute confusional state and fluctuating tetraparesis (12). The symptoms abated 12 hours after withdrawal. A provocation test confirmed that fentanyl 0.1 mg was enough to cause myoclonic and dystonic reactions with increased agitation. Administration of intravenous naloxone 0.8 mg improved the condition.
- A 14-year-old girl developed a dystonic reaction to fentanyl 50 μg given as a general anesthesia for dental extraction; her abnormal movements stopped completely after 3 days (13).

© 2006 Elsevier B.V. All rights reserved.

Fentanyl can displace bilirubin from albumin in neonates, with a risk of kernicterus; other drugs should be used (SEDA-17, 81).

Psychological, psychiatric

Mood alteration during patient-controlled epidural anesthesia with either morphine or fentanyl was compared in a randomized, double-blind study of 52 patients undergoing elective hip or knee joint arthroplasty under general anesthesia (14). Mood was assessed preoperatively and at 24, 48, and 72 hours, using the bipolar version of the Profile of Mood States. Pain intensity postoperatively did not vary with morphine or fentanyl and, as expected, both fentanyl and morphine users had significant somnolence, pruritus, and nausea compared with baseline. With morphine, the mean score for measures of composure/anxiety, elation/depression and clear-headedness/confusion increased, indicating a change toward the more positive pole, but there were negative changes for the fentanyl users' scores for five of the six components of the Profile of Mood States. The difference in test scores between morphine and fentanyl was significant at 48 hours of patient-controlled anesthesia and 24 hours after withdrawal. There was no correlation between mood scores and pain scores, and mood scores with fentanyl fell with increasing plasma concentrations. Previous investigations have shown transient positive feelings with intravenous fentanyl, followed by more negative feelings in the longer term. The authors suggested that the differences in mood between the two groups may have been explained by differences in the lipid solubility and pharmacokinetics of epidural morphine and fentanyl.

Urinary tract

There have been two cases of urinary retention leading to renal pelvocalyceal dilatation as a result of continuous infusion of fentanyl (3 μg/kg/hour) in premature neonates (15). In both cases the problem was resolved by inserting an indwelling catheter.

Skin

A rash has been attributed to fentanyl (16).

- A 70-year-old man with metastatic cancer of the colon was given transdermal fentanyl 50 mg for analgesia. After 10 days he developed an itchy pustular eruption on the trunk and limbs. The lesions subsided on withdrawal of fentanyl. When he restarted transdermal fentanyl 2 months later, the skin lesions reappeared and became more generalized. The pustules were scattered, sparse, and superficial, and included the tongue and buccal mucosa, but not the conjunctivae or genitalia. A history of eosinophilia suggested an immunoallergic origin.

Like other opioids, fentanyl can cause pruritus. Prophylactic intravenous ondansetron 8 mg with hyperbaric bupivacaine 7–10 mg and fentanyl 25 μg significantly reduced the incidence of intrathecal fentanyl-induced pruritus in 125 patients undergoing knee arthroscopy or urological surgery in a randomized, double-blind, placebo-controlled trial (17). The incidence of pruritus was 39% with ondansetron and 68% with placebo.

Musculoskeletal

There have been three reports and a prospective study of muscle rigidity after fentanyl administration in neonates (18,19).

- Two neonates had transient (0.5–2 minutes) chest wall rigidity after intravenous boluses of fentanyl 2 and 4 μg/kg. They were already compromised, one with a respiratory distress syndrome and one with a diaphragmatic hernia.
- A premature male infant of 28 weeks gestation was given an intravenous bolus of fentanyl 3 μg/kg before intubation and this was followed by isolated rigidity of the tongue lasting 20 seconds (18).

In a prospective case series study of 89 preterm and term infants who received fentanyl out of a total of 404 neonatal intensive care patients in one year, eight neonates (9%) had chest wall rigidity (19). The spectrum of neuromuscular activity extends from mild muscle rigidity through abnormal muscle movements (chewing) to tonic-clonic movements. In two cases there was laryngospasm with chest wall rigidity. In all cases low-dose fentanyl (3–6 μg/kg) had been given for analgesia or sedation.

Chest wall rigidity, sometimes lasting for more than 24 hours and causing hypoxia, can occur postoperatively; it can be attenuated with naloxone or neuromuscular blockers (SEDA-22, 98) (20).

Second-Generation Effects

Pregnancy

The efficacy of intrathecal fentanyl and sufentanil for labor analgesia has been studied in 75 nulliparous women in a two-part comparison (21). In the first phase, 20 subjects received varying doses of fentanyl; the ED_{50} of intrathecal fentanyl for 60 minutes of labor analgesia was 18 μg, with a potency ratio of intrathecal sufentanil to intrathecal fentanyl of 4.4. In the second phase, 55 subjects participated in a double-blind, randomized comparison of the efficacy and safety of either intrathecal fentanyl 36 μg or sufentanil 8 μg. Sufentanil gave 25 minutes longer analgesia than fentanyl. There were no significant differences in adverse effects between the two groups: 83% had pruritus and 27% of those given sufentanil and 10% of those given fentanyl had nausea.

In a randomized, double-blind, placebo-controlled study of whether patient-controlled epidural fentanyl could produce effective and safe postoperative analgesia following 25 μg of spinal fentanyl at cesarean section in 36 patients, the fentanyl group used a mean of 23 μg/hour of fentanyl compared with 27 μg/hour in the control group (22). There was pruritus in 15 patients given fentanyl compared with one control; 9 given fentanyl had mild or moderate drowsiness during the operation compared with 8 controls. Postoperative nausea, pruritus, and drowsiness did not differ between the two groups.

In a randomized, controlled trial, 52 patients in labor were randomly given either intrathecal fentanyl 25 μg with saline or fentanyl 25 μg with magnesium sulfate 50 mg as part of a combined spinal-epidural technique

© 2006 Elsevier B.V. All rights reserved.

(21). The incidence of pruritus with fentanyl alone was 65%, significantly lower than with fentanyl plus magnesium sulfate (77%). However, fentanyl plus magnesium sulfate produced significantly better and longer-lasting pain control, potentially reducing postoperative opioid requirements.

Susceptibility Factors

Other features of the patient

When the concentration of α_1-acid glycoprotein is reduced, with reduced binding, highly protein-bound basic drugs, such as fentanyl, should be given with caution in order to avoid high unbound concentrations and unwanted effects (SEDA-17, 81).

Drug Administration

Drug formulations

- A woman suffered sedation, localized erythematous lesions on the hands, and reduced appetite with weight loss after removing transdermal fentanyl patches from her daughter's skin and replacing them without wearing protective gloves (23). She had severe headaches, night sweats, irritability, nausea, and insomnia. When she used gloves, her weight gradually increased and the sedation abated.
- A 57-year-old woman using transdermal fentanyl (75 μg/hour) developed a reduced respiratory rate and bilateral pinpoint pupils when an upper body warming blanket was used as a normal postoperative procedure (24). The resultant increase in skin temperature significantly enhanced skin perfusion, and increased the systemic absorption of fentanyl from the intracutaneous fentanyl depot, leading to symptoms of opioid overdose. She recovered after removal of the fentanyl patch and the intravenous administration of naloxone 60 μg.

Oral transmucosal fentanyl administration, avoiding first-pass metabolism, produces analgesia and sedation in both adults and children undergoing short painful outpatient procedures. The quality of analgesia is good, and the adverse effects are those typical of the opioids. However, an unusual reaction, with agitation and hyperactivity, progressing over a week to delirium, has been reported. Mild impairment of hepatic and renal function, with accumulation of norfentanyl, has been postulated as a possible mechanism (SEDA-20, 77).

Drug additives

Bupivacaine and/or adrenaline

The addition of bupivacaine and/or adrenaline to epidural fentanyl analgesia has also been studied in 100 women after elective cesarean section. All received fentanyl (3 μg/ml) by patient-controlled analgesia (PCA) for 48 hours and were randomly assigned double-blind to receive either bupivacaine 0.01%, ephedrine 0.5 μg/ml, both, or neither (25). Patients who received fentanyl alone made more attempts at PCA than the other groups, suggesting that this regimen was less effective and the higher dose of fentanyl used perhaps contributed to a higher incidence of nausea and urinary retention and to a higher frequency of severe pruritus. The authors suggested that with lower doses of fentanyl there was less rostral spread of the drug and lower concentrations at the brain stem, thus reducing adverse effects. Breast-fed neonates were neurologically assessed at 2 and 48 hours by a pediatrician and, despite the different fentanyl requirements of mothers, neurobehavioral scores were equally high in the different groups.

Bupivacaine

Effective postoperative pain relief can be obtained with a mixture of fentanyl and bupivacaine, which not only provides better analgesia than either drug alone, but also fewer adverse effects. There have been several studies of the efficacy of this mixture, using different doses and routes of administration, the addition of clonidine, and in comparison with morphine.

In a randomized, double-blind study in 56 patients, continuous infusion of fentanyl (1 μg/kg/hour or 0.5 μg/kg/hour) and bupivacaine 0.1 mg/kg/hour, with intravenous morphine PCA as rescue analgesia, produced better pain relief after knee ligament operations than epidural saline combined with intravenous morphine PCA (26). There was a non-significant increase in nausea in the fentanyl group.

In another randomized, double-blind study, 84 parturients requesting epidural analgesia were given either bupivacaine 20 ml only, followed by intravenous fentanyl 60 μg or bupivacaine 20 ml with fentanyl 60 μg followed by intravenous saline (27). The minimum local analgesia concentration (MLAC) of bupivacaine + intravenous fentanyl was 0.064% w/v and the MLAC of bupivacaine + epidural fentanyl was 0.034% w/v. The epidural fentanyl solution significantly increased the analgesic potency of bupivacaine by a factor of 1.88 compared with intravenous fentanyl. This was associated with increased pruritus with epidural fentanyl.

Women scheduled for cesarean section ($n = 32$) were given spinal bupivacaine 10 mg (0.5%) or spinal bupivacaine 5 mg (0.5%) plus fentanyl 25 μg (28). Those given fentanyl had adequate spinal anesthesia for cesarean section with fewer adverse effects (nausea and hypotension). This observation was reproduced by spinal anesthesia with bupivacaine 4 mg plus fentanyl 20 μg, which provided adequate spinal anesthesia for surgical repair of hip fracture in elderly patients, with fewer adverse effects than bupivacaine 10 mg (29).

Bupivacaine, clonidine

Different combinations of fentanyl, bupivacaine, and clonidine were investigated in a multicenter (6 sites) trial of 78 women undergoing elective cesarean section under "spinal block" (30). In some cases, this appeared to imply intrathecal administration, and in others combined intrathecal and epidural administration. Patients received hyperbaric bupivacaine alone, or with 75 μg of clonidine, or with 75 μg of clonidine and 12.5 μg of fentanyl. There were no reported hemodynamic differences between the groups, but sedation and pruritus were significantly more common in those who received fentanyl, occurring in 65% and 25% of

© 2006 Elsevier B.V. All rights reserved.

subjects respectively. Apgar scores and umbilical artery blood pH were unaffected by the drug regimens.

Bupivacaine or ropivacaine

The addition of fentanyl 1 μg/ml to ropivacaine 7.5 mg/ml did not improve nerve blockade by axillary brachial plexus anesthesia in a double-blind, randomized study in 30 patients undergoing orthopedic procedures (31). In another double-blind, randomized study, 60 patients receiving axillary brachial plexus blockade were given 0.25% bupivacaine 40 mg, 0.25% bupivacaine 40 mg plus fentanyl 2.5 μg/ml, or 0.125% bupivacaine 40 mg plus fentanyl 2.5 μg/ml (32). The addition of fentanyl 2.5 μg/ml prolonged sensory and motor blockade without any improvement in the onset of anesthesia and no significant increase in adverse effects. These two studies have reaffirmed the current position of conflicting results in studies of the benefits of adding fentanyl to local anesthetics for peripheral nerve blockade.

Ropivacaine

In a randomized, placebo-controlled study, a mixture of ropivacaine 0.2% and fentanyl 2 μg/ml plus a background infusion of 5 ml/hour was given to 20 patients for postoperative patient-controlled epidural analgesia after gynecological surgery. Another 21 patients were given the same mixture without the background infusion. Both groups were monitored hourly for arterial blood pressure, heart rate, and respiratory rate, and pain, sedation, motor blockade, and sensory levels were monitored every 6 hours (33). There was no difference in pain scores or patient satisfaction scores between the two groups, but the patients who received the background infusion had a higher incidence of adverse effects (71 versus 30%). The authors suggested that there was no additional benefit in using a background infusion.

Fentanyl 2 μg/ml has been used in combination with ropivacaine 2 mg/ml to determine its impact on the quality of postoperative analgesia and the incidence of adverse effects after colonic surgery in 155 patients scheduled for elective colonic surgery in a multicenter, double-blind, randomized study (34). The incidences of hypotension and pruritus in those given fentanyl were significantly increased, although they had better analgesic control. They also had an increased incidence of serious adverse effects affecting the respiratory, cardiovascular, and genitourinary systems.

The ideal combination strength of ropivacaine with fentanyl for postoperative epidural analgesia has been investigated in two studies. In a double-blind, randomized study, 30 patients undergoing lower abdominal surgery received one of three solutions for PCA after a standardized combined epidural and general anesthetic: ropivacaine 0.2% plus fentanyl 4 μg, ropivacaine 0.1% plus fentanyl 2 μg, or ropivacaine 0.05% plus fentanyl 1 μg (35). All three solutions produced equivalent analgesia. Motor block secondary to the ropivacaine was significantly more frequent and intense with ropivacaine 0.2% plus fentanyl 4 μg. Pruritus, nausea, sedation, and hypotension occurred equally often in the three groups and were mild. It was therefore inferred that ropivacaine 0.2% plus fentanyl 4 μg is preferable for analgesia after lower abdominal surgery.

Sufentanil

There was no difference in analgesic efficacy or the incidence of adverse effects when fentanyl 100 μg was compared with sufentanil 20 μg in women in labor who requested epidural analgesia (36).

Bupivacaine or lidocaine

The addition of clonidine or fentanyl to local anesthetics for single shot caudal blocks has been studied in 64 children undergoing bilateral correction of vesicoureteral reflux randomized into four groups (37). The control group received a mixture of 0.25% bupivacaine with adrenaline plus 1% lidocaine; other groups received the same combination plus 1.5 μg/kg of clonidine, or the control combination plus 1 μg/kg of fentanyl, or the control combination plus 0.5 μg/kg of fentanyl plus 0.75 μg/kg of clonidine. The addition of either clonidine or fentanyl significantly prolonged anesthesia, and during recovery the groups receiving local anesthetics alone or with the addition of fentanyl alone had significantly increased heart rates. Two of the children who received extradural fentanyl had a transient reduction in oxygen of saturation to 92% in the first hour of recovery. One of these was from those who received fentanyl alone, while one had received fentanyl plus clonidine. Vomiting occurred only in children exposed to fentanyl (nine of 29 subjects). This is the first report of respiratory depression in children after the caudal administration of fentanyl or clonidine, this adverse effect having been previously described with extradural opioids and clonidine in adults.

Lidocaine

In 100 patients undergoing arthroscopic outpatient surgery minidose spinal lidocaine plus fentanyl (0.5% lidocaine 20 mg plus fentanyl 20 μg) has been compared with traditional spinal anesthesia (1% lidocaine 30 ml with titrated intravenous propofol infusion) (38). The study was randomized and prospective but unblinded. Whereas those given local anesthesia were more likely to have pain requiring analgesic medication before discharge (44 versus 20%), those given spinal anesthesia group were more likely to have nausea (8 versus 22%) or pruritus (8 versus 68%). Both techniques provided a high degree of patient satisfaction, with comparable efficacy both intraoperatively and postoperatively.

Drug dosage regimens

Fentanyl is widely used for obstetric analgesia and the dose–response relation for intrathecal fentanyl has been examined in a randomized study of 84 nulliparous full-term parturients in labor (39). They received intrathecal doses of fentanyl of 5–45 μg and visual analogue scales were used to measure analgesia and adverse effects. The mean duration of anesthesia increased in the dose range 5–25 μg of fentanyl and then reached a plateau. Adequate analgesia was obtained with all doses of fentanyl above 10 μg. Maternal systolic blood pressure was not significantly affected at any dose, although diastolic blood pressure fell significantly at 10–30 minutes after fentanyl. Nausea and vomiting were uncommon, but pruritus was common in all groups and was more severe with higher doses of fentanyl. Fetal heart rate did not change

© 2006 Elsevier B.V. All rights reserved.

significantly with fentanyl at any dose, although the authors acknowledged that they did not undertake continuous fetal heart tracing. They concluded that there is no benefit in using doses of intrathecal fentanyl above 25 μg when fentanyl is used as the sole analgesic agent in labor.

Drug administration route

Opioids have traditionally been given intramuscularly and intravenously. Other methods of administration are oral, subcutaneous, rectal, intrathecal, and extradural. Novel routes include intranasal, inhalational, intra-articular, and transdermal.

Buccal

Oral transmucosal fentanyl citrate has two advantages: it is more acceptable as a flavored lozenge than an oral elixir or tablet would be, especially in children, and 25% goes directly into the systemic circulation without first-pass metabolism (SEDA-20, 77). Its main adverse effect is dose-dependent nausea and/or vomiting, which occurs in 25–50% of patients. In a double-blind, placebo-controlled comparison of oral transmucosal fentanyl citrate (10 μg/kg) and oral oxycodone (0.2 mg/kg) in outpatient wound care procedures in 22 children, there were similar outcomes and no adverse effects in either group (40).

Transdermal

Fentanyl can be used transdermally because of its high solubility in both fat and water, low molecular weight, high analgesic potency, and fewer adverse effects, especially gastrointestinal symptoms (41). It is easy to administer and can be given at 3-day intervals. Transdermal fentanyl has been extensively reviewed in patients with chronic cancer pain (22) and in a review in which the possibilities and techniques available for acute and/or chronic pain relief were considered (42).

Transdermal fentanyl has an adverse effects profile similar to that associated with parenteral administration (SEDA-20, 77). Local erythema and rash have been reported (43), as well as the usual opioid adverse effects. However, an unusual reaction, with progressive agitation to acute delirium, has occurred (SEDA-20, 79).

Local heating and cutaneous hyperthermia of the patch area can cause lethal problems of overdose, owing to increased release and absorption (SEDA-18, 80) (SEDA-19, 83).

Transdermal administration of fentanyl has been extensively reviewed (44). In systemic availability studies, 92% of the fentanyl dose delivered from the transdermal therapeutic system into the skin reached the systemic circulation as unchanged unmetabolized fentanyl (41). Morphine, codeine, and hydromorphone are not good candidates for transdermal administration. Pethidine has a high transdermal permeability but poor analgesic potency. Besides fentanyl, only sufentanil and buprenorphine would be suitable opioids for transdermal administration (45).

There are three techniques used for the transdermal administration of fentanyl. The transdermal therapeutic system (TTS) is a membrane-controlled system designed to release fentanyl at a constant rate for up to 3 days, and is useful in patients with chronic cancer pain (46). There are still limited and predominantly uncontrolled studies that show that TTS fentanyl is useful in chronic pain of neuropathic or somatic origin. An open randomized, crossover trial in 18 patients with painful chronic pancreatitis concluded that TTS fentanyl should not be the first-choice analgesic, because of a high incidence of skin adverse effects and low analgesic effects compared with morphine (47).

TTS fentanyl is not useful in acute or postoperative pain, because of the risk of respiratory depression due to the long delay and decay time, which do not allow adequate dose finding (44). Some patients have acute symptoms of morphine withdrawal, in spite of adequate pain control, when they are converted from morphine to transdermal fentanyl. The mechanism has not yet been determined (48,49).

Transdermal fentanyl was the cause of an opioid overdose when a 77-year-old man with a history of severe arthritis developed respiratory failure after starting epidural diamorphine–bupivacaine mixture for postoperative pain (50). The fentanyl patch was removed, the epidural infusion was stopped, and naloxone was given to counteract the excessive opioid effects.

Fentanyl transdermal delivery systems (FTDS) use an unsealed multilaminate system containing a solid matrix, in which fentanyl is embedded instead of the reservoir designed in the TTS. FTDS is not to be recommended for routine postoperative pain treatment, even though it has a faster onset of action (4–6 hours) after cases of fentanyl toxicity, especially respiratory depression. FTDS has not been investigated adequately in chronic pain and is not expected to be superior to the TTS technique.

Iontophoretic transdermal application of opioids is another technique that is currently being tested. The factors that affect the delivery of opioids like fentanyl and sufentanil by this technique include the physicochemical nature of the drug solution, the voltage used, and the duration and nature of the current used (51,52).

An electrotransport therapeutic system (ETS) for fentanyl has been developed. Preliminary studies show that ETS of fentanyl may be useful for the treatment of acute pain (53).

Transdermal fentanyl has been compared with modified-release oral formulations of morphine among 504 patients with advanced cancer in a multicenter, cross-sectional quality-of-life study using four widely validated scales plus original scales, generated and validated for this study (54). The authors used conversion rates "often reported in the literature" to calculate that the fentanyl group used significantly more opiate (200–300 mg of morphine-equivalent units/day) than the oral morphine users (195 mg/day). Despite this, transdermal fentanyl patients reported fewer and less bothersome adverse effects, although these were not separately identified; 50% reported never having any adverse effects compared with 36% of morphine users without adverse effects, although measures of pain intensity showed no significant difference between the two groups. Subgroup analysis by sex showed that the difference in adverse effects between the two modes of administration was significant only in men. However, it should be noted that the mean ages of

© 2006 Elsevier B.V. All rights reserved.

the two treatment groups were significantly different, a fact that may qualify the reported results.

Transdermal fentanyl avoids the discomfort of injections and reduces fluctuations in drug concentrations. In an open study of transdermal fentanyl patches 50 μg for postoperative pain management in 15 thoracotomy patients, two patients had nausea and one had erythema over the site of application of the patch (55).

Transdermal fentanyl in chronic cancer pain control has been extensively reviewed (22). Data from non-blinded, randomized trials suggest that it is as effective as modified-release oral morphine and that the most common adverse effects include nausea, vomiting, and constipation. The most serious adverse effect reported was hypoventilation, which occurred in about 2% of patients. Skin reactions occurred in 1–3%. A number of non-comparative trials have described the use of transdermal fentanyl for periods of at least a year without serious adverse effects.

In a follow-up study of 78 patients with cancer who participated in a crossover, randomized study of transdermal fentanyl (mean final dose 100 μg/hour) and oral morphine for 4 weeks, the incidences of skin reactions and gastrointestinal symptoms were low (56). Other adverse effects reported were breakthrough pain, light-headedness, and diarrhea. In the original randomized study, which lasted 15 days, there was significantly less constipation with fentanyl than with morphine (57). These results suggest that many patients have stable analgesic requirements with transdermal fentanyl up to the time of death, with no need for additional medication.

In a questionnaire survey of 1005 patients, only 11 had chronic pain from non-malignant disease while taking transdermal fentanyl (58). Their physicians were asked to provide information about their reasons for switching to transdermal fentanyl and were then surveyed until withdrawal of fentanyl because of death, change in analgesic regimen, or serious adverse effects. Modified-release morphine (median dose 90 mg/day) was used in 72% of patients before switching to fentanyl. More than 20% of the cohort had received no continuous opioid medication before the start of transdermal therapy. Most of the patients were switched to fentanyl because of inadequate analgesia or opioid-induced gastrointestinal symptoms. The simplicity of administration and patients' wishes were also contributory factors. Transdermal fentanyl was discontinued primarily because patients died (46%); other reasons included inadequate pain relief (10%), pain relief with another analgesic regimen (10%), adverse effects (5%), rejection of transdermal therapy by the patient (6%), and other unspecified causes, such as pathological fractures and anemia (16%). There were opioid-related adverse effects in 26% of the patients. Serious neurotoxic effects, such as hallucinations (0.2%), withdrawal symptoms (0.1%), or convulsions (0.1%), were rare.

Under controlled conditions, transdermal fentanyl is a useful option for direct conversion from mild to strong opioids in cancer patients. In addition, 25 μg/hour daily incremental steps of transdermal fentanyl can be made by palliative care specialists, if it is required for cancer pain management (59).

Transdermal fentanyl for chronic non-cancer pain control has been studied in two open trials (60,61). In a multicenter, open, randomized study of 256 patients with a history of chronic non-cancer pain, 65% preferred transdermal fentanyl, whereas 28% preferred modified-release oral morphine. Subjective pain control and quality of life were significantly better in the patients who used transdermal fentanyl. Despite a preference for transdermal fentanyl, more patients withdrew because of adverse effects in the first fentanyl period (16%) than in the first morphine period (9%). The difference could have been related to patients' previous experience of morphine, with enhanced tolerance of its adverse effects.

In the second study, 35 patients with severe AIDS-related chronic pain were recruited in a prospective, open, before/after comparison of the analgesic efficacy and adverse effects profile of a stable dose of transdermal fentanyl (25–300 μg/hour) or oral morphine (less than 45 mg/day) for 15 consecutive days (61). Transdermal fentanyl alleviated chronic pain and those who were already dependent on an opioid needed less fentanyl for the same analgesic result.

The long-term use of transdermal fentanyl in patients with chronic non-cancer pain (back pain, leg pain, arthritic pain, trigeminal neuralgia, and intestinal cystitis), which is controversial, has been discussed (62). Transdermal fentanyl was effective and safe and improved quality of life and independent living. However, these case reports were collected by authors closely associated with the company that manufactures transdermal fentanyl patches; a degree of case selectivity and bias might have occurred.

In a prospective study, 64 patients with a recent history of at least one vertebral fracture caused by primary and secondary osteoporosis were recruited from six osteoporosis centers in Germany between December 1999 and April 2001 (63). Transdermal fentanyl 25 μg/hour was the recommended starting dose, with incremental steps of 25 μg/hour if there was insufficient analgesia. Treatment was stopped after less than 28 days in 15 patients (23%). In 10 of these, fentanyl was stopped because of nausea and/or vomiting and/or dizziness. In 49 patients, pain at rest (55% reduction) and on motion (47% reduction) abated significantly from baseline. The starting dose of 25 μg/hour of fentanyl was sufficient in most patients (70%).

The use of transdermal fentanyl in 113 patients with undertreated chronic cancer pain was studied in a non-randomized, uncontrolled, open study for 42 days (64). The mean dose of fentanyl increased from 25 μg/hour to 117 μg/hour between the start and end of the study. By day 3, six patients reported sleepiness and two reported dizziness; five reported nausea and two had vomiting, and by days 21–42 four of the 100 patients who completed the study had severe nausea and vomiting. Non-compliance was not related to the adverse effects of fentanyl, but to insufficient pain control (nine patients) and/or death (three patients).

Epidural

In view of the popularity of fentanyl as an epidural analgesic in labor, its site of action is of some

© 2006 Elsevier B.V. All rights reserved.

interest, and this has been examined in a randomized study in 55 parturients who received 0.125% bupivacaine plus one of three treatments: epidural saline plus intravenous saline; epidural fentanyl (20 μg/hour) plus intravenous saline; epidural saline plus intravenous fentanyl (20 μg/hour) (65). Study treatments were continuously infused, while epidural bupivacaine was patient-controlled. There was a significant reduction (28%) in bupivacaine use with epidural but not intravenous fentanyl, but there was no significant difference in the incidence of adverse effects. This result suggested that the analgesic effects of epidural fentanyl in labor are due to a spinal mechanism, rather than to systemic absorption and a supraspinal effect. However, the authors acknowledged various limitations of their study and commented that they were able to use low doses of fentanyl because of the concomitant use of bupivacaine, which acts synergistically. It is possible that this synergy allows effective analgesia of the visceral afferents at a spinal level without the need for the higher doses that are required for analgesia with fentanyl alone. Higher doses of fentanyl may mask this spinal effect.

In a prospective study of 1030 mixed surgical patients receiving patient-controlled epidural analgesia with 0.05% bupivacaine and fentanyl 4 μg/ml, the incidence of adverse effects was broadly as expected (66): 17% had pruritus, 15% nausea, 13% sedation, 6.8% hypotension, 2% motor block, and 0.3% respiratory depression. Two patients required naloxone for respiratory depression and sedation. Analgesia was terminated electively in 82%, 12% of cases were terminated owing to a displaced catheter, and 3% of cases required anticoagulation, while infection, adverse effects, and inadequate analgesia each accounted for termination of epidural analgesia in 1% of cases. Risk factors for adverse effects were identified as: patient age under 58 years, weight under 73 kg, being female, high fentanyl consumption (over 9 ml/hour), and lumbar placement of the epidural catheter. There was a significant association between patient age and pruritus, and between female sex and nausea, hypotension, and sedation.

The relations between fentanyl and local anesthetics and their adverse effects profiles in epidural analgesia (67) further demonstrate the need for well-controlled, double-blind studies (68,69).

The use of a continuous epidural infusion of lidocaine 0.4% plus fentanyl 1 μg/ml in combination with intravenous metamizol 40 mg/kg provided significantly better analgesia than epidural morphine 20 μg/kg plus intravenous metamizol 40 mg/kg during the first 3 postoperative days in 30 children undergoing orthopedic surgery, without increasing the incidence of adverse effects; however, the difference in beneficial effect was small (70).

Prophylactic nalbuphine 4 mg and droperidol 0.625 mg with minidose lidocaine + fentanyl spinal anesthesia in a randomized, double-blinded, controlled study in 62 patients having outpatient knee arthroscopy provided significantly better analgesia and reduced nausea and pruritus than in another 62 patients who received only nalbuphine 4 mg with minidose lidocaine + fentanyl spinal anesthesia (71).

Intravenous patient-controlled analgesia

In a randomized, double-blind, multicenter trial, 150 postoperative patients who had undergone major surgery received demand doses of fentanyl 20, 40, or 60 μg delivered intravenously by PCA (72); higher doses of fentanyl were associated with improved analgesic effect. Adverse effects were reported in 70 patients; the most commonly reported were nausea and vomiting and most adverse effects were described as mild to moderate. Bradypnea occurred in 6% of patients who received fentanyl 60 μg, in one case sufficiently severe to warrant temporary withdrawal of treatment; respiratory depression and moderate hypoxia occurred in one patient on 40 μg and in one on 60 μg, again requiring withdrawal. Overall, mean respiratory rates in the 60 μg group were significantly lower than in the 20 μg group throughout the study, and at 6 hours after initiation compared with the 40 μg group. One patient developed acute confusion and aggression while receiving fentanyl 40 μg. The authors concluded that 40 μg of fentanyl is an appropriate dose for PCA, as this balances analgesic efficacy against the incidence of adverse effects.

Drug overdose

Accidental overdose can be caused by fentanyl patches.

- A 71-year-old woman was found unconscious, with reduced respiration and miotic pupils, having previously had nausea, dizziness, and drowsiness (73). She had inappropriately applied a fentanyl patch 100 μg/hour a day before the symptoms occurred. She recovered fully after treatment with intravenous naloxone 0.4 mg.
- A 24-year-old woman, with a history of polysubstance abuse and extensive psychiatric history, presented with acute opioid overdose caused by the intentional oral ingestion of a fentanyl patch (Duragesic) (74).

Drug–Drug Interactions

Bupivacaine

Bupivacaine is increasingly being used in combination with fentanyl for obstetric analgesia and has been reported to reduce the incidence of pruritus. In a prospective study, 65 parturients in labor were randomly assigned to receive intrathecal fentanyl (25 μg), intrathecal bupivacaine (2.5 mg), or both as part of epidural anesthesia (75). The group that received both drugs had more prolonged analgesia and significantly less pruritus than those who received fentanyl alone (36 versus 95%). However, the incidence of facial pruritus was not significantly different. The type of analgesia did not affect the outcome of labor, although one patient in the combined treatment group required ephedrine for reduced blood pressure. It was proposed that pruritus is the result of stimulation of mu receptors supraspinally and in the dorsal horn of the spinal cord, and that facial itching is associated with mu receptor activation in the medullary dorsal horn, affecting the trigeminal nerve. Local anesthetics may alter this adverse effect by local neuronal blockade or by direct modulation of mu-opioid receptors. Bupivacaine also promotes opioid binding to kappa-opioid receptors, which reduce pruritus. The failure to relieve facial pruritus suggests a direct effect of fentanyl in the brain stem.

Cimetidine

The hepatic metabolism of fentanyl can be inhibited by cimetidine, leading to respiratory depression and sedation (76,77).

Droperidol

The addition of droperidol 2.5 mg to fentanyl 0.4 mg in 40 ml of 0.125% bupivacaine lowered the incidence of postoperative nausea and vomiting compared with a solution without droperidol or with butorphanol added instead in patients undergoing anorectal surgery in a prospective randomized, single-blind study (78).

Fentanyl plus droperidol (neuroleptanalgesia) was more effective than morphine in relieving anginal pain during unstable angina. However, the patients who received the neuroleptanalgesia also had longer hospital stays, because of significantly more cardiac instability and anginal episodes, and a higher total mortality (79).

Etodimate

Used as a pretreatment for anesthetic induction with etomidate, fentanyl 500 μg produced apnea in all patients, with a 67% incidence of nausea and a 47% incidence of postoperative vomiting (80).

Itraconazole

Oral itraconazole 200 mg did not alter the pharmacokinetics of intravenous fentanyl 3 μg/kg, despite being a strong inhibitor of CYP3A4 in vitro (81). In vitro research suggests that itraconazole should inhibit the elimination of fentanyl, as it has been shown to do to alfentanil. This difference can be accounted for by the higher hepatic extraction ratio of fentanyl (0.8–1.0) compared with alfentanil (0.3–0.5), so that even large changes in the activity of enzymes that metabolize fentanyl significantly affect its pharmacokinetics.

Midazolam

Several adverse effects have been reported with the combined use of fentanyl and midazolam, including chest wall rigidity, making ventilation with a bag and mask impossible (SEDA-16, 79).

In neonates, hypotension can occur (SEDA-16, 80), and respiratory arrest in a child and sudden cardiac arrest have been reported (SEDA-16, 80). However, in one study there were no cardiac electrophysiological effects of midazolam combined with fentanyl in subjects undergoing cardiac electrophysiological studies (SEDA-18, 80).

Monoamine oxidase inhibitors

There is a risk of hypertension, tachycardia, hyperpyrexia, and coma with the concurrent administration of opioids and monoamine oxidase inhibitors (SEDA-19, 83).

Prilocaine

The addition of fentanyl to the local anesthetic prilocaine does not seem to cause major analgesic benefits, but increases the incidence of adverse effects, particularly affecting the nervous system (82).

Propofol

The interaction between propofol and fentanyl has been studied in relation to suppressing the somatic or hemodynamic responses to three types of surgical event—skin incision, peritoneum incision, and abdominal retraction (83). Three of ninety-nine subjects were withdrawn from the study after bradycardia of under 50/minute occurred when intravenous fentanyl (dose not stated) was given to those already anesthetized with propofol. Propofol and fentanyl (concentration range 0.5–9 ng/ml maintained by computer-assisted continuous infusion for at least 30 minutes) had a predictable synergistic effect and caused a fall in systolic blood pressure. After stimulation, the different concentrations of fentanyl required to block somatic responses to surgery in 50% of subjects were 9.7 ng/ml, 15 ng/ml, and 28 ng/ml respectively for skin incision, peritoneum incision, and abdominal retraction. Concentrations required to give a 15% or less increase in post-incision systolic blood pressure were 5.3 ng/ml, 9.7 ng/ml, and 12 ng/ml respectively. At doses of less than 3 ng/ml of fentanyl the hemodynamic response to peritoneal incision or abdominal retraction was inadequate, even when sufficient propofol was present to suppress somatic responses. Somatic response suppression correlated with fentanyl for skin incision, fentanyl and propofol for peritoneal incision, and propofol for abdominal retraction. Prestimulation propofol reduced systolic blood pressure in a concentration-dependent fashion, while post-stimulation fentanyl significantly suppressed increases in systolic blood pressure. This difference in effect was attributed to propofol's mainly sedative and hypnotic effects, while fentanyl is primarily analgesic.

Ritonavir

Ritonavir is an inhibitor of HIV protease and a potent inhibitor of CYP3A4 and CYP2D6. The interaction between ritonavir and intravenous fentanyl has been investigated in 12 healthy volunteers in a double-blind, placebo-controlled, crossover study (84). The volunteers took ritonavir 600 mg on day 1, ritonavir 900 mg and intravenous fentanyl 5 μg/kg on day 2, and ritonavir 300 mg or placebo on day 3. Ritonavir reduced the clearance of fentanyl by 67% by inhibiting its metabolism. This could result in prolongation of fentanyl-induced respiratory depression in a patient with an already compromised cardiorespiratory system.

Ropivacaine

In a prospective, randomized, double-blind study, the analgesic effect and adverse effects profile of epidural ropivacaine (2 mg/ml) alone was compared with three different fentanyl/ropivacaine combinations (fentanyl 1, 2, and 4 μg/ml) for up to 72 hours of postoperative analgesia in 244 patients after major abdominal surgery, most commonly colorectal surgery (85). Hypotension was significantly more common with fentanyl 4 μg (52%) compared with the other three groups (31–34%) in the first 24 hours, but not later. Nausea was not significantly different among the groups, although there was more antiemetic drug use in patients given fentanyl 2 and 4 μg by day 3. Pruritus was significantly more common in patients who received fentanyl 4 μg throughout the whole 72 hours.

© 2006 Elsevier B.V. All rights reserved.

Ropivacaine 2 μg/ml plus fentanyl 4 μg/ml provided the most effective pain relief over the 3 days.

Fentiazac

See also Non-steroidal anti-inflammatory drugs

General Information

Fentiazac, a thiazoleacetic acid derivative, has the same adverse reactions profile as other NSAIDs. Adverse effects in as many as 56% of patients (5-56%), are even more frequent than with phenylbutazone (1).

In 40 patients with rheumatoid arthritis enrolled in a double-blind trial of fentiazac 400 mg/day or sulindac 200 mg/day for 3 months, adverse effects were reported in three patients taking fentiazac (rash, headache, epigastric pain) (2).

Organs and Systems

Nervous system

Adverse effects involving the central nervous system include headache, dizziness, mental confusion, sedation, giddiness, and blurred vision; dysesthesia and oral paresthesia have also been reported (3).

Gastrointestinal

Pyrosis, epigastric pain, nausea, constipation/diarrhea, and occult bleeding are the most frequent gastrointestinal effects of fentiazac (3). Rectal administration can cause both local and systemic adverse effects.

Liver

In one study, seven of 20 patients with rheumatoid arthritis had significant rises in aspartate transaminase and alkaline phosphatase activities (4). Reversible hepatotoxicity occurred in three of 33 patients who took fentiazac during long-term therapy (2).

Feprazone

See also Non-steroidal anti-inflammatory drugs

General Information

Feprazone is an NSAID that is related to phenylbutazone. Feprazone was withdrawn in the UK because of its adverse effects, which resemble those of phenylbutazone. It was designated as a last-resort drug by the Japanese Committee on Safety of Drugs (SEDA-12, 83).

In an 8-week trial in 2693 patients with rheumatoid arthritis and osteoarthritis, 30% reported adverse effects and 11% failed to complete the study. However, two large short-term multicenter studies in general practices in 11 000 patients in Italy reported a very low percentage (1.2–9.8%) of adverse effects (1,2).

Gastrotoxicity, nephrotoxicity, edema, headache, tinnitus, and depression have been attributed to feprazone (3).

Organs and Systems

Hematologic

Thrombocytopenia and immune complex-mediated hemolytic anemia have been reported with feprazone (SEDA-7, 108).

© 2006 Elsevier B.V. All rights reserved.

Skin

Skin reactions (including severe bullous dermatosis) have been attributed to feprazone (SEDA-9, 87). Contact dermatitis has been described with feprazone cream (SEDA-18, 101).

Fexofenadine

See also Antihistamines

General Information

Fexofenadine is the active metabolite of terfenadine. It has antihistaminic but not dysrhythmogenic properties. It is not metabolized by the liver, but eliminated unchanged in the urine. It is efficacious and well tolerated in seasonal allergic rhinitis (1), with positive effects on nasal blockade (2), and in chronic idiopathic urticaria (1,3).

Organs and Systems

Cardiovascular

Fexofenadine is said to have little cardiotoxicity (4). In one study fexofenadine was well tolerated, and there were no statistically significant changes in PR interval, QT interval, QRS complex, or heart rate (5).

There has been a report of ventricular fibrillation during fexofenadine administration in a man with a pre-existing long QT interval (6). However, causality between fexofenadine and the cardiac effects was unclear.

The safety of fexofenadine in children aged 6–11 years with seasonal allergic rhinitis has been assessed in a large double-blind, randomized, placebo-controlled, parallel study (7). There were no statistically significant electrocardiographic effects, suggesting that fexofenadine is both efficacious and well tolerated in children with allergic disease.

Nervous system

The effects of fexofenadine (120, 180, and 240 mg) on performance and sleepiness have been studied in healthy volunteers. There were no changes at any time compared with placebo, and the authors suggested that fexofenadine may prove to be suitable for use by air personnel (8).

Psychological, psychiatric

Even in a high dose (360 mg bd versus the recommended dose of 60 mg bd) fexofenadine had no disruptive effects on psychomotor performance and cognitive function in healthy volunteers (9).

In one study fexofenadine did not alter driving and psychomotor performance when taken in the recommended dosage of 60 mg bd (10).

Skin

Eight episodes of a fixed drug eruption occurred in a 45-year-old man who was taking fexofenadine for seasonal allergies; after withdrawal of fexofenadine the rash did not recur (11).

Drug–Drug Interactions

Azithromycin

The effect of co-administration of azithromycin on plasma concentrations of fexofenadine 60 mg bd has been examined in a randomized third-party-blind, placebo-controlled, parallel-group study in 98 healthy volunteers (5). An initial loading dose of azithromycin (500 mg) was given on day 3, followed by 250 mg od for 4 days. Concomitant azithromycin caused increases in the C_{max} and AUC of fexofenadine (69 and 67% respectively). However, there were no statistically significant increases in the PR, QT, QT_c interval, QRS complex duration, or ventricular rate after administration of fexofenadine with or without azithromycin.

Grapefruit juice

In a non-blinded, randomized, single-dose, crossover study in 24 healthy adults, grapefruit juice reduced the rate of absorption and the systemic availability of oral fexofenadine by 30% (12). However, there were no clinically significant electrocardiographic changes after co-administration of grapefruit juice with fexofenadine compared with fexofenadine alone. The authors concluded that the systemic availability of drugs that do not undergo significant intestinal or hepatic metabolism, such as fexofenadine, may nevertheless be altered when they are given with agents that affect drug transport mechanisms.

St John's wort

St John's wort (*Hypericum perforatum*) is a popular and widely available herbal extract used as a remedy for anxiety, depression, and sleep disorders. Fexofenadine is transported by P glycoprotein in vitro (13) and there is evidence that St John's wort can alter P glycoprotein activity (14). The effects of St John's wort on the pharmacokinetics of fexofenadine have therefore been studied (15). Fexofenadine 60 mg was given orally twice—before a single dose of St John's wort 900 mg and again after 3 weeks treatment with 300 mg tds. A single dose of St John's wort significantly inhibited intestinal P glycoprotein activity and increased the maximum plasma concentration of fexofenadine by 45%. In contrast, long-term St John's wort caused a 35% reduction in the C_{max} of

© 2006 Elsevier B.V. All rights reserved.

fexofenadine and increased its oral clearance. However, the authors concluded that these pharmacokinetic changes alone are unlikely to be clinically significant.

In addition to their effects on P glycoprotein, fruit juices and St John's wort can also inhibit organic anion transporting polypeptides (16). These findings suggest new models of intestinal drug absorption and mechanisms of drug interactions.

Fibrates

General Information

Fibrates reduce plasma triglycerides by inhibiting their hepatic synthesis and increasing their catabolism. They reduce the synthesis of triglyceride–very low density lipoprotein (VLDL) by increasing the beta-oxidation of fatty acids in the liver. They increase triglyceride catabolism by inducing lipoprotein lipase gene transcription and reducing apoC-III gene transcription. Fibrates increase high-density lipoprotein (HDL) cholesterol by increasing apoA-I and apoA-II gene transcription. These effects are due to activation of peroxisome proliferator-activated receptors (PPAR) alpha and induction of the overexpression of genes containing a peroxisome proliferator response element (PPRE) in their promoter (1).

The fibrates include beclobrate, bezafibrate, biclofibrate, binifibrate, ciprofibrate, clinofibrate, clofibrate, dulofibrate, etofibrate, fenirofibrate, fenofibrate, gemfibrozil, lifibrate, nicofibrate, picafibrate, pirifibrate, ponfibrate, ronifibrate, salafibrate, serfibrate, simfibrate, sitofibrate, tiafibrate, timofibrate, tocofibrate, urefibrate, and xantifibrate (all rINNs).

The adverse events of the fibrates are essentially the same with all members of the class and are generally mild or absent during short-term treatment. The observed frequency of adverse effects with a micronized formulation of fenofibrate is comparable to that associated with the usual formulation (SEDA-22, 490).

Organs and Systems

Nervous system

Nervous system adverse effects are rare, constituting 0.5% of all adverse effects (2). Gemfibrozil-induced headache has been reported (3) and occurred in one patient who had taken bezafibrate for 24 hours (4). Peripheral neuropathy has been observed with bezafibrate (SEDA-13, 1324) (5).

Metabolism

Of 70 patients with cutaneous T cell lymphomas, three who were taking gemfibrozil had to have it withdrawn because of increases in serum triglycerides (6).

- A 76-year-old woman with type 2 diabetes taking gemfibrozil for pronounced hypertriglyceridemia had recurrent episodes of hypoglycemia; her insulin requirements fell by 65% and her HbA_{1c} concentration fell from 9 to 6.5% over 5 months (7).

In patients taking fenofibrate and atorvastatin, increased concentrations of plasma homocysteine were attributed to an action of the fibrates themselves and not indirectly via their lipid-lowering effect (8). Concomitant administration of folic acid, at least in part, offset this adverse effect

© 2006 Elsevier B.V. All rights reserved.

(9). The degree of rise in homocysteine differs among the various fibrates. It has been reported with fenofibrate and bezafibrate, and a study of fenofibrate and gemfibrozil substantiated a difference between the drugs (10). Because the concentration of plasma homocysteine depends on renal function, increased plasma homocysteine concentrations could result from renal function impairment caused by fenofibrate. In contrast, gemfibrozil does not affect renal function. This was tested in a crossover study in 22 patients who had hypertriglyceridemia, by giving them gemfibrozil 900 mg/day or fenofibrate 200 mg/day for 6 weeks (11). Lipids were altered similarly, but homocysteine, creatinine, and cystatin C were raised by fenofibrate but not by gemfibrozil. In another report, there was a 57% increase in homocysteine in 26 individuals who took ciprofibrate and a 17% reduction in homocysteine in 12 patients who took bezafibrate.

Fluid balance

Clofibrate has a mild antidiuretic effect (12), and animal studies suggest that this is due to release of antidiuretic hormone (ADH) (13). This effect has been used in the treatment of cranial diabetes insipidus (14).

Hematologic

Leukopenia has been reported with bezafibrate (15), clofibrate (16), and fenofibrate (17).

Gastrointestinal

Abdominal discomfort occurs in 5–10% of all patients taking fibrates. Epigastric fullness, nausea, meteorism, and mild diarrhea have been repeatedly described, and stomatitis has been incidentally mentioned. There are wide discrepancies in the figures given for such complications, ranging as they do from 2 (2) to 20%; the truth appears to be that during the first few days and weeks of treatment, mild discomfort of one sort or another is quite common, although some of it is due to a placebo effect; serious symptoms are most unusual. Bezafibrate is better tolerated than gemfibrozil (18). In a double-blind trial with fenofibrate, the incidence of gastrointestinal adverse effects was not different from that seen with placebo (19). Five of 1213 individuals taking beclobrate complained of diarrhea (20).

Liver

Assurance of good renal and hepatic function is mandatory before beginning treatment with the fibrates (21). Serum transaminase changes are regularly seen and hepatitis occurs (22). Several cases of hepatitis due to fenofibrate have been reviewed (23) and it has also been observed with etofibrate (24). One case of liver failure, probably due to beclobrate, has been reported (SEDA-13, 1324) (25). Liver biopsies showed a lymphoplasmocytic infiltrate in all of five cases of chronic hepatitis associated with fibrates (26).

Biliary tract

Fibrates produce bile that is supersaturated with cholesterol. Although gallstones are common with clofibrate, no excess frequency has been observed with fenofibrate (22). In the WHO study, 59 patients taking clofibrate had to be operated on for gallstones, compared with 24 and 25 respectively in the two placebo groups (27).

Pancreas

Pancreatitis has been attributed to bezafibrate.

- A 75-year-old white woman had fever and raised amylase on three consecutive occasions after taking a tablet of bezafibrate (28). After stopping taking the drug, she remained free of symptoms.

Urinary tract

Unexpected acute renal insufficiency occurred in four patients after uncomplicated cardiac surgery; each was taking a fibrate (29). Renal insufficiency occurred rapidly within 3 days of surgery and was associated with increased concentrations of skeletal muscle-derived creatine kinase. One patient developed myoglobinuria. Presumably, patients taking lipid-lowering drugs are at higher risk of acute renal insufficiency after cardiac surgery, because of rhabdomyolysis. This suggests that patients taking either statins or fibrates should discontinue them before cardiac surgery.

Fenofibrate was the probable cause of rises in serum creatinine concentrations in six patients in one clinic (30). The authors therefore recommended routine serum creatinine monitoring at baseline and at 1 month after starting fenofibrate.

Severe reversible renal insufficiency has been reported with fibrates (31).

Skin

Non-specific rashes have been reported in patients taking fibrates. With fenofibrate, rashes are reported significantly more often than with placebo (32), and occur in some 0.6% of patients (22). In a double-blind trial, the incidence of cutaneous adverse effects was 11% with fenofibrate and less than 1% with placebo; they included hives and urticaria (19). In another study, the difference was 6% (33).

- Chronic radiodermatitis after cardiac catheterization has been observed in a 62-year-old woman taking ciprofibrate. A second catheterization performed when she had stopped taking it did not provoke new lesions (34).

Photosensitivity due to fenofibrate (35) was confirmed by systemic photochallenge (36). Photodermatitis has been associated with cross-reactivity between ketoprofen and fenofibrate; this was thought to be due to chemical similarities between these two drugs (37).

Psoriasis was exacerbated by gemfibrozil in one case (38).

Stevens–Johnson syndrome has been associated with bezafibrate (39) and clofibrate (40).

Musculoskeletal

Rhabdomyolysis is a problem with several lipid-lowering drugs (SEDA-13, 1325) (SEDA-13, 1328) (SEDA-13, 1330) (SEDA-19, 409) (41–43), especially when they are used in combination (44). In individuals with pre-existing renal insufficiency, this can lead to an earlier need for

© 2006 Elsevier B.V. All rights reserved.

chronic dialysis (45). Also, interactions between various hypolipidemic drugs and other drugs sometimes cause rhabdomyolysis (SEDA-18, 426).

Creatine kinase activity increased in five out of 1213 patients taking beclobrate (20). Myopathy during treatment has been reported with gemfibrozil (46) and ciprofibrate (47,48).

Hypothyroidism predisposes to rhabdomyolysis (49,50) and screening of thyroid function has been advocated before starting hypolipidemic drugs (SEDA-21, 458). This notion has been supported by observations in a 69-year-old man taking fenofibrate 200 mg daily (51). The muscular syndrome appears to be a special risk in patients with nephrotic syndrome (SEDA-13, 1325) (52).

- Two women, 55 and 57 years old, with renal insufficiency, had rhabdomyolysis after taking micronized fenofibrate in dosages a little higher than recommended (53). Both had mild hypothyroidism.

Reduced renal function in the elderly appears to be a risk factor for myopathy (SEDA-23, 472).

- A 73-year-old woman had an increase in serum creatinine concentration while she was taking long-acting bezafibrate and again when she was re-challenged by self-medication (54).
- Low-dose bezafibrate was associated with myositis in a patient with mild chronic renal insufficiency (serum creatinine 210 μmol/l) (55). She was a 58-year-old obese diabetic with isolated hypertriglyceridemia.

Sexual function

Erectile dysfunction has been reported in 12% of 339 men treated with fibrate derivatives or statins, compared with 5.6% of similar patients not taking these drugs (57). The mechanism is unknown and should be confirmed in randomized studies.

Gemfibrozil was suspected to have reduced libido in two cases (58,59), an effect that is well-known with clofibrate, and four cases of loss of libido and impotence involving gemfibrozil have previously been reported (SEDA-13, 1325) (60,61).

Immunologic

Vasculitis, Raynaud's phenomenon, and polyarthritis have been reported with gemfibrozil (62).

Allergic reactions have been reported with some fibrates.

- A 61-year-old woman with penicillin allergy suffered generalized urticaria, chest tightness, wheezing, nausea, vomiting, hypotension, and loss of consciousness (63). Two hours earlier, she had taken Eulitop Retard after lunch. She had intense positive responses to intradermal Eulitop Retard and its active component, bezafibrate; skin tests in control subjects were negative. Specific IgE tests (RAST) to Eulitop Retard were negative. The positive skin tests suggested that an IgE mechanism was responsible for this adverse reaction.
- A 69-year-old woman developed a major allergic reaction after taking fenofibrate 300 mg/day for 10 days (64). The clinical features included weakness, hyperthermia, and slight muscular pain. Biological abnormalities were mildly raised muscle enzymes and pancytopenia, which developed rapidly.

Long-Term Effects

Tumorigenicity

It has been suspected that low concentrations of serum cholesterol might be associated with an increased risk of cancer or overall mortality. All fibrates and statins cause cancer in rodents, but the relevance of this finding to man has been questioned (65). In an epidemiological study these risks were almost non-existent after adjusting for confounding factors.

Second-Generation Effects

Fetotoxicity

In pregnant mice given etofylline clofibrate and fenofibrate in doses of 12, 117, and 586 mg/kg orally from day 7 to day 16 of gestation, terminal maternal body weight was significantly reduced by all doses of etofylline clofibrate (66). The low and middle doses of etofylline clofibrate and fenofibrate had no adverse effects on embryofetal development, but the highest dose of etofylline clofibrate significantly reduced fetal weight at term. Postimplantation loss was significantly higher after the highest dose of fenofibrate. There were no teratogenic effects. The significance of these results to human pregnancy is unknown.

Drug–Drug Interactions

Bexarotene

Of 70 patients with cutaneous T cell lymphomas, three who were taking gemfibrozil had to have it withdrawn because of increases in serum concentrations of triglycerides and bexarotene, an RXR-selective retinoid "rexinoid", which is used for all stages of cutaneous T cell lymphoma (6).

Colchicine

Rhabdomyolysis due to the combination of colchicine with gemfibrozil has been reported in a 40-year-old man with amyloidosis and chronic liver disease (67).

Ibuprofen

Acute renal insufficiency occurred in one patient taking ciprofibrate 100 mg/day and ibuprofen 400 mg/day (68). Both drugs are highly protein-bound and contain propionic acid groups. Thus, ibuprofen may displace ciprofibrate.

Statins

The increased risk of myopathy observed during concomitant treatment with statins and fibrates may be partly pharmacokinetic in origin. In interactions between fibrates and statins there may be differences between

© 2006 Elsevier B.V. All rights reserved.

the various fibrates (69). Eleven healthy volunteers took bezafibrate 400 mg/day, gemfibrozil 1200 mg/day, or placebo for 3 days. On day 3, each took a single dose of lovastatin 40 mg. Plasma concentrations of lovastatin, lovastatin acid, gemfibrozil, and bezafibrate were measured for up to 24 hours. Gemfibrozil markedly increased plasma concentrations of lovastatin acid, but bezafibrate did not. The risk of myopathy during concomitant therapy with lovastatin and a fibrate may be smaller with bezafibrate than with gemfibrozil.

In 80 patients with primary mixed hyperlipidemia, gemfibrozil used together with lovastatin resulted in 3% discontinuation because of myositis, but none attributable to rhabdomyolysis or myoglobinuria (70).

Sulfonylureas

Fibrates are highly bound to albumin and displace other similarly bound drugs. This can affect treatment with sulfonylureas. Hypoglycemia occurred in a diabetic patient taking glibenclamide plus gemfibrozil (71).

In 10 healthy volunteers, gemfibrozil 600 mg bd increased the mean total AUC of a single dose of glimepiride 0.5 mg by 23% (range 6–56%) (72). The mean half-life of glimepiride was prolonged from 2.1 to 2.3 hours. This effect may have been caused by inhibition of CYP2C9. However, there were no statistically significant effects on serum insulin or blood glucose variables.

Warfarin

Several interactions between warfarin and hypolipidemic drugs have been described (SEDA-21, 459), including clinically important potentiation of warfarin by bezafibrate (73) and gemfibrozil (74). Two patients developed a significantly increased anticoagulant effect of warfarin while taking fenofibrate (75).

Fibrin glue

General Information

Fibrin glue is a topical tissue adhesive, a two-component system. One component contains highly concentrated fibrinogen, factor VIII, fibronectin, and traces of other plasma proteins. The other component contains thrombin, calcium chloride, and antifibrinolytic agents such as aprotinin. Mixing the two components promotes clotting. Fibrinogen is activated by thrombin in the presence of calcium, and the resultant clot aids hemostasis and tissue sealing and is completely absorbed during wound healing without foreign body reaction or extensive fibrosis. Fibrin glue thus imitates the final stages of coagulation (1) and is used for tissue sealing, hemostasis, and wound healing.

Because of its adverse effects, the original topical fibrin glue, which contained thrombin of bovine origin, has been withdrawn and replaced by a product (Quixil) whose components are all human in origin and not bovine or recombinant. Tranexamic acid is added in order to increase stabilization of the clot. The fibrinogen component is made from pooled plasma and is not highly purified; it therefore contains factor XIII, which also stabilizes the clot. Methods involving precipitation of fibrinogen by cryoprecipitation, polyethylene glycol, or ammonium sulfate have been described and evaluated.

All the components of fibrin glue are subjected to virucidal treatment (solvent/detergent treatment for fibrinogen and nanofiltration for thrombin).

Uses

The primary purpose of using fibrin glue is to reduce blood loss and hence the need for transfusion. It is sprayed on to a surgical field in aerosolized form with a double-barrelled syringe, using either compressed air or nitrogen. Its hemostatic and adhesive properties can be used in any surgical specialty, for example to control bleeding after organ injury (2). Its usefulness is particularly well documented in the fields of cardiovascular surgery (3,4), ENT surgery (5), neurosurgery (6), and thoracic surgery (7).

Fibrin glue has been widely used to treat anal fistulae. In a systematic review of 19 studies the reported success rates ranged from 0 to 100%, which may have been due to differences in patient selection (including fistula aetiology and type), treatment protocols, and follow-up duration (8).

The hemostatic efficacy of fibrin glue in a nasal spray has been studied in 24 patients with hereditary hemorrhagic telangiectasia and epistaxis (9). Fibrin glue produced immediate hemostasis and good healing of bleeding sites, no secondary bleeding, and no inflammation. Adverse events, including local swelling, pain, and slow healing of the bleeding site with atrophy of the nasal mucosa, were more frequent in those who were given foam nasal packing rather than fibrin glue spray.

Fibrin glue has also been used experimentally to deliver a high concentration of drug to a local site, as in the example of the use of losartan to prevent neointimal hyperplasia in pig saphenous artery (10).

Organs and Systems

Nervous system

The use of bovine fibrin glue in neurosurgery was associated with fatal neurotoxicity if the glue came into contact with the cerebrospinal fluid or dura (11,12); this has not been reported with fibrin glue of human origin.

Hematologic

In three patients who underwent cardiovascular surgery subsequent abnormalities in hemostasis, characterized by increased activated partial thromboplastin time, prothrombin time, and bovine thrombin time, and by a markedly reduced concentration of factor V, developed between the seventh and eighth postoperative days after exposure to fibrin glue containing bovine thrombin (13). It was suggested that the glue also contains small amounts of factor V and that this may have caused the abnormalities.

Immunologic

An anaphylactic reaction occurred after the use of bovine fibrin glue as a sealant after mastectomy, probably due to the presence of bovine aprotinin (14).

The use of preparations of fibrin glue containing bovine thrombin resulted in the development of antibovine thrombin antibodies. In a prospective study, 13 of 34 patients developed a thrombin inhibitor and reduced factor V activity (15,16). In another study a factor V inhibitor developed after cardiac surgery (17).

Severe hypotension has been reported after the use of bovine fibrin glue for hemostasis in hepatic injury (18). In one there was cardiac arrest and death. These effects may have been the result of an anaphylactic reaction to one or more components of the glue. Of the three ingredients used to prepare fibrin glue, cryoprecipitate and bovine thrombin are antigenic and potentially the most likely causes of anaphylaxis.

Fish oils

General Information

Omega-3 fatty acids are long-chain polyunsaturated fatty acids. The parent fatty acid of this group is alpha-linolenic acid, an essential fatty acid that the body is unable to synthesize; alpha-linolenic acid can be converted in the body to eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). In animals and man, these acids reduce the production of several compounds that are involved in inflammation and thrombosis, such as eicosanoids (prostaglandins, thromboxanes, prostacyclin, and leukotrienes) and cytokines (interleukin II-1) (1). The extent of the conversion of alpha-linolenic acid to EPA and DHA is unclear. The conversion process appears to be inhibited by a high intake of linoleic acid, another essential fatty acid (2). In addition, alpha-linolenic acid is found in dark green vegetables and the oils of certain nuts and seeds, especially rape seeds and soya beans.

Oily fish and extracted fish oils contain high concentrations of EPA and DHA. Fish oils also contain vitamins A and D. Oil derived from cod, halibut, or shark liver, or from fish body, typically contains about 200 mg/ml of long-chain omega-3 fatty acids. In addition, cod liver oil provides 50 μg/ml of vitamin A and 2 μg/ml of vitamin D. Many fish oil supplements are artificially enriched with omega-3 fatty acids.

The safety of drugs containing EPA and DHA has been reviewed; the reported adverse effects were similar to those in control groups (3). Even 3–7 g/day for several months did not change liver enzyme activities, and there were no bleeding problems. Consumption of fish oils reduces the resistance of LDL to oxidative modification, and this is partly opposed by the addition of vitamin E (4). Belching or eructation with a fishy taste or smell, vomiting, flatulence, diarrhea, and constipation are relatively common.

Organs and Systems

Respiratory

Fish oils can cause exacerbation of asthma in aspirin-sensitive patients (5).

Cod liver oil supplements can cause lipoid pneumonia (6).

Metabolism

In high doses, fish oils can cause a rise in blood glucose concentration in patients with non-insulin-dependent diabetes mellitus (7).

Hematologic

Bleeding times can increase in patients taking fish oils (8), leading to more prolonged and frequent nose-bleeds (9). Fish oil supplements should be used with care in patients with hemophilia and anyone taking high doses of anticoagulants or aspirin.

Gastrointestinal

Of 39 patients with Crohn's disease, treated with an enteric-coated fish oil formulation, 4 were withdrawn because of diarrhea, the only reported adverse effect in this investigation (10).

In 814 patients randomly allocated to fish oils for 18 weeks for the reduction of re-stenosis after percutaneous transluminal coronary angioplasty, gastrointestinal adverse effects, most commonly bloating and burping, were reported in 37% of patients taking fish oils, versus 31% of those taking placebo (11).

Second-Generation Effects

Pregnancy

During early pregnancy, high doses of vitamin A (as found in halibut and shark liver oils) can lead to birth defects (12). Fish oil supplements rich in vitamin A should therefore be avoided by women in the first trimester and those who might become pregnant.

Drug–Drug Interactions

Acetylsalicylic acid

In eight healthy men who took a total of 485 mg of aspirin over 3 days before beginning 2 weeks of fish oil supplementation (4.5 g of n-3 fatty acids/day), aspirin alone prolonged the bleeding time by 34% and fish oil alone prolonged it by only 9%; however, aspirin + fish oil prolonged the bleeding time by 78% (13). Although fish oil alone did not significantly raise aggregation thresholds for collagen, arachidonic acid, or platelet activating factor, it did reduce the extent of aggregation with collagen. When challenged by single or dual agonists, the combination of fish oil and aspirin did not make platelets less sensitive than aspirin alone.

However, in 18 healthy men randomly allocated to N-3 polyunsaturated fatty acids 10 g/day or placebo for 14 days, the addition of a single intravenous dose of acetylsalicylic acid 100 mg did not alter the small effect of polyunsaturated fatty acids on platelet aggregation (14).

In four subjects given a single oral dose of aspirin 37.5 mg before and after a natural stable fish oil daily for 1 week, serum thromboxane A_2 fell by 40% after aspirin alone, but by 62% after fish oil + aspirin, and leukotriene B_4 rose by 19% after aspirin and fell by 69% after fish oil + aspirin; serum prostacyclin fell equally in both cases (15).

In healthy subjects who took either fish oil or olive oil (control) daily for 3 weeks before exposure to aspirin or no aspirin, fish oil had no significant effect on mucosal prostaglandin E_2 or $F_{2\alpha}$ content or on the damaging effect of aspirin on the stomach, despite the fact that fish oil reduced serum triglyceride concentrations significantly (16).

Warfarin

In a placebo-controlled, randomized, double-blind study of the effect of fish oil supplements 3–6 g/day for 4 weeks on the International Normalized Ratio (INR) in 16 patients taking chronic warfarin therapy there was no statistically significant effect on anticoagulation (17).

However, fish oils can affect hemostasis, and there has been an anecdotal report of a possible interaction.

- A 67-year-old white woman who had been taking warfarin for 18 months doubled her dose of fish oil from 1000 to 2000 mg/day. The INR increased from 2.8 to 4.3 within 1 month and fell to 1.6 within 1 week of reduction of the dose of fish oil (18).

5-HT$_3$ receptor antagonists

General Information

The 5-HT$_3$ antagonists, alosetron, granisetron, ondansetron, and tropisetron (all rINNs), are effective antiemetics used in treating cytotoxic-induced and postoperative vomiting.

There have been several reviews of the pharmacology and use of alosetron (1–5). In patients with irritable bowel syndrome, alosetron increases colonic transit time and colonic compliance. It produces significant improvement in abdominal pain, stool consistency, and frequency and

© 2006 Elsevier B.V. All rights reserved.

urgency of defecation in non-constipated women with irritable bowel syndrome, but not in men. Constipation is the most common adverse effect. It occurs more commonly at higher doses and is more common in women, which is consistent with reported bowel function data.

Granisetron and tropisetron appear to have the same safety profile as ondansetron (6). Their adverse reactions include mild rises in transaminases (up to 17%), slight headache (8–42%), transient diarrhea (2–5%), which may be followed during longer-term therapy by constipation, dizziness (5%), and dry mouth (5–17%); the incidence of xerostomia is higher than with metoclopramide. Other reported adverse effects include anorexia, paresthesia, constipation or abdominal discomfort, changes in blood pressure, fever, facial edema, leg cramps, hot flushes, and enlargement of the spleen (7).

Observational studies

Granisetron

In 59 patients who were given intravenous granisetron 1 mg 30 minutes before treatment on days of chemotherapy, the most common adverse effects were headache, somnolence, and weakness (8).

In another open trial the combination of intravenous granisetron (1 mg) plus dexamethasone (10 mg) was effective and well tolerated for antiemetic control in 100 bone-marrow transplant patients receiving highly emetogenic chemotherapy with or without irradiation (9). Adverse effects were mild; headache, diarrhea, and constipation were the most frequent.

Tropisetron

The safety and efficacy of tropisetron in the prevention of chemotherapy-induced nausea and vomiting has been reviewed (10). Tropisetron monotherapy is effective for the control of acute, and to some extent delayed, nausea and vomiting in patients receiving emetogenic chemotherapy. Combining it with dexamethasone increases its efficacy.

The antiemetic efficacy of tropisetron has been confirmed in 22 children (median age 14 years) who received a total of 125 courses of highly emetogenic chemotherapy (11). The only reported adverse effects attributable to tropisetron were mild diarrhea during two treatment courses and dry mouth during three courses.

Comparative studies

Granisetron versus ondansetron

The efficacy and safety of oral granisetron (2 mg od) and oral ondansetron (8 mg tds for 3 days and bd on day 4) in the prophylaxis of nausea and vomiting have been studied in 34 patients receiving hyperfractionated total body irradiation in a randomized, double-blind trial (12). A historical group of 90 patients who received a similar irradiation regimen but no 5HT$_3$ receptor antagonists acted as a control group. Both drugs were safe and effective in preventing nausea and vomiting resulting from irradiation. The most frequent adverse effects were headache and diarrhea.

Oral granisetron (1 mg bd) plus intravenous dexamethasone (10 mg) have been compared with intravenous ondansetron (8 mg tds) plus dexamethasone (10 mg) for the control of nausea and vomiting in a randomized, open trial in 51 patients receiving emetogenic chemotherapy (13). The two combinations were equally effective, and the frequencies of adverse events (none serious) in the two groups were comparable. The most frequent were diarrhea with granisetron and constipation with ondansetron.

The efficacy of converting from intravenous ondansetron to oral granisetron in preventing chemotherapy-induced nausea and vomiting has been assessed in 608 patient interviews (14). There was no difference in the control of nausea and vomiting between the two treatments. Patient adherence to treatment increased from 48 to 78% after the use of oral granisetron. The costs of preventing acute chemotherapy-induced nausea and vomiting also fell, from US$107 to US$65 per treatment.

In a large double-blind study comparison of single-dose oral granisetron versus intravenous ondansetron in the prevention of nausea and vomiting induced by chemotherapy in 1085 patients, the drugs were equally effective and gave rise to a similar frequency of adverse effects, commonly headache, weakness, and constipation (15). Dizziness and blurred vision were reported by significantly more of the patients who received ondansetron.

Granisetron and ondansetron were also effective in controlling nausea and vomiting related to emetogenic chemotherapy in a crossover study in 40 oriental patients (16). Adverse effects were similar to those reported in Western studies, constipation and headache being the commonest. In another placebo-controlled study of the efficacy and safety of granisetron (3 mg), droperidol (1.25 mg), and metoclopramide (10 mg) intravenously for the prevention of nausea and vomiting in 120 parturients undergoing cesarean section under spinal anesthesia, granisetron was the most effective antiemetic (17). The adverse events profiles of all three drugs were similar to that of placebo.

Granisetron versus ramosetron

Oral ramosetron 0.1 mg without water has been compared with oral granisetron 2 mg with water given 1 hour before infusion of chemotherapy in a multicenter, randomized, single-blind, crossover study in 73 patients with cancer (18). The two regimens had similar efficacy in the prevention of chemotherapy-induced anorexia, nausea, and vomiting. The incidence of adverse effects was similar in the two treatment groups. More patients given ramosetron (10%) complained of headache than those given granisetron (1.3%). The other important adverse effects were dry mouth, insomnia, heavy-headedness, and dizziness. In another multicenter, randomized, single-blind study in 194 patients receiving cisplatin chemotherapy for cancer, intravenous ramosetron 3 mg was as effective as intravenous granisetron 3 mg in preventing nausea and vomiting (19). Although the incidence of adverse effects was similar in the two groups, significantly more patients who received granisetron than ramosetron complained of dull headache.

Granisetron versus droperidol

In a randomized trial in 60 patients who underwent elective laparoscopic cholecystectomy the combination of intravenous granisetron 3 mg plus droperidol 1.25 mg

© 2006 Elsevier B.V. All rights reserved.

was more effective in preventing postoperative nausea and vomiting than granisetron 3 mg alone (20). No significant adverse effects were reported in either group.

Granisetron versus droperidol and metoclopramide

The efficacy of intravenous granisetron 40 micrograms/kg, droperidol 20 micrograms/kg, and metoclopramide 0.2 mg/kg have been compared in the treatment of nausea and vomiting after laparoscopic cholecystectomy in a double-blind trial in 120 patients (21). The patients were observed for 24 hours after administration. Granisetron was significantly more effective than the other two drugs. All three drugs were equally well tolerated. The common adverse effects were headache and dizziness.

Ondansetron versus droperidol

Intravenous ondansetron (4 mg at induction of anesthesia and 0.13 mg with each 1 mg bolus of morphine) has been compared with intravenous droperidol (0.5 mg at induction and 0.05 mg with each bolus of morphine) in a double-blind trial in 142 patients (22). The two regimens had similar efficacy in the prevention of postoperative nausea and vomiting. The most important adverse effect was sedation; significantly more patients given droperidol (15%) had excessive sedation than patients given ondansetron (5%).

Ondansetron versus metoclopramide

The antiemetic effect of combined intravenous ondansetron 8 mg, oral dexamethasone 20 mg, and oral lorazepam 0.5 mg was significantly better than that of intravenous metoclopramide 10 mg, dexamethasone 20 mg, and oral lorazepam 0.5 mg in 30 patients receiving chemotherapy for ovarian cancer in a randomized trial (23). All the antiemetics were given 30 minutes before and 6 hours after chemotherapy. Significantly more patients given metoclopramide (40% versus 13%) complained of adverse effects. The most frequent adverse effects with both regimens were sedation and headache.

The antiemetic effects of intravenous metoclopramide 1 mg/kg tds and ondansetron 8 mg/kg tds, alone or in combination with dexamethasone or methylprednisolone, have been compared in an open study in 101 patients receiving several cycles of moderately emetogenic chemotherapy (24). The regimens had similar efficacy in controlling emesis during the first course of chemotherapy. However, ondansetron alone, ondansetron plus glucocorticoids, and metoclopramide plus glucocorticoids were more effective than metoclopramide alone during the next two cycles. All the antiemetic regimens were well tolerated and caused similar frequencies of adverse effects. The most common were headache, constipation, and diarrhea.

Ondansetron or tropisetron versus metoclopramide

In a randomized, double-blind trial in 179 patients undergoing thyroid or parathyroid surgery, premedication with oral tropisetron 5 mg was more effective in preventing postoperative nausea and vomiting in the initial postoperative period (0–2 hours) than either oral ondansetron 16 mg or oral metoclopramide 10 mg when given 1 hour before the operation (25). When the entire 24-hour postoperative period was considered, the incidence of vomiting was lower with ondansetron and tropisetron than with metoclopramide. The adverse effects profiles were similar in the three groups. Common adverse effects were headache, dizziness, pruritus, and visual disturbances.

Placebo-controlled studies

Alosetron

Alosetron (1 mg bd) was well tolerated and effective in alleviating abdominal pain, urgency, and stool frequency in a randomized, double-blind, placebo-controlled trial in 647 women with irritable bowel syndrome (26). Constipation occurred in 30% of patients taking alosetron and 3% of those taking placebo. Laboratory values, including liver function tests, were unchanged by alosetron.

The efficacy of alosetron in the treatment of irritable bowel syndrome has been evaluated in a double-blind, placebo controlled, dose-ranging study in 462 patients (27). In women, but not in men, alosetron 2 mg bd significantly increased the proportion of pain-free days and reduced the visual analogue scale score for diarrhea. Alosetron 0.5–2 mg bd led to significant hardening of stools and reduced stool frequency in the total population. The overall incidence of adverse effects was similar with alosetron and placebo. However, the incidence of constipation was significantly higher during treatment with alosetron 0.5 mg bd and 2 mg bd. There were no changes in laboratory values associated with alosetron.

In a randomized, double-blind, placebo-controlled, crossover trial, alosetron (2 mg bd) delayed left colonic transit in both patients with irritable bowel syndrome ($n = 13$) and healthy volunteers ($n = 12$) (28). In another double-blind, placebo-controlled trial in 25 non-constipated patients with irritable bowel syndrome, alosetron (1 and 4 mg bd) had no significant effect on gastrointestinal transit or rectal sensory and motor mechanisms (29).

Granisetron

Oral granisetron 2 mg has been studied in the prophylaxis of nausea and vomiting following fractionated upper abdominal radiotherapy in a double-blind, placebo-controlled trial in 160 patients (30). Granisetron was significantly more effective than placebo. The common adverse effects attributed to granisetron were diarrhea, weakness, and constipation.

In a crossover study in 90 patients receiving cisplatin-based chemotherapy, prednisolone 50 mg significantly improved the antiemetic effects of granisetron (3 mg intravenously) compared with placebo (31).

Tropisetron

In a randomized, double-blind, placebo-controlled study, intravenous tropisetron 2 mg and 5 mg was effective in preventing emesis in 60 patients who underwent general anesthesia (32). Both doses of tropisetron were equally effective. Adverse effects were not mentioned.

Organs and Systems

Cardiovascular

Hypertension or disturbances of cardiac rhythm can occur with 5HT$_3$ receptor antagonistsT3 antagnists HT, especially in elderly patients (SEDA-20, 316).

© 2006 Elsevier B.V. All rights reserved.

Some patients have electrocardiographic changes, such as prolongation of the QT interval. In a double-blind, placebo-controlled, randomized study of the effects of dolasetron mesylate 0.6–5.0 mg/kg in 80 subjects, there were transient and asymptomatic electrocardiographic changes (small mean increases in PR interval and QRS complex duration versus baseline) in several subjects at 1–2 hours after infusion at doses of 3.0 mg/kg and over (33).

In one trial a patient who took ondansetron had syncope, presumably because of a change in blood pressure (SEDA-18, 370).

Nervous system

Ondansetron can cause extrapyramidal reactions (34). In two cases the reaction did not recur after a reduction in dosage or a change in the infusion time.

Hematologic

Thrombocytopenia has been observed in patients who were given 5 HT3 receptor antagonists, but was probably coincidental, since they were also given cytostatic drugs (35,36).

Gastrointestinal

Constipation is the commonest adverse effect of alosetron. In women with irritable bowel syndrome, alosetron 1 mg bd was more effective than placebo and mebeverine in relieving abdominal pain, discomfort, and diarrhea. The most frequent adverse effect was constipation (1–4). In 30 patients (15 men, 15 women) using scintigraphy to measure bowel transit, alosetron 1 mg bd for 6 weeks caused significantly delayed small bowel and colonic transit times (37). This effect was significantly greater in women. Alosetron 1 mg bd was significantly more effective than placebo in the treatment of diarrhea-predominant irritable bowel syndrome in a multicenter, double-blind, placebo-controlled study in 801 women (38). Constipation was the most frequently reported adverse effect. The tolerability and safety of alosetron 1 mg bd during long-term administration (48 weeks) has been studied in a multicenter, double-blind, placebo-controlled trial in 859 subjects (39). Alosetron was generally well tolerated. The frequencies of adverse events were similar in the two groups, with the exception of constipation, which occurred significantly more often in the treatment group (32% compared with 5%). In most cases (72%) constipation was mild to moderate. There were two deaths in subjects with pre-existing cardiovascular risk factors in the treatment group, but neither was attributed to alosetron. In a dose-ranging, randomized, placebo-controlled, multicenter trial in 320 patients with functional dyspepsia, alosetron 0.5 mg bd and 1 mg bd was better than placebo in symptom control (40). Women had significantly greater responses than men. Constipation was the most commonly reported adverse effect of alosetron (49% compared with 13% in the placebo group). In a randomized, double-blind, placebo-controlled trial in 626 women with diarrhea-predominant irritable bowel syndrome, alosetron 1 mg bd was significantly more effective than placebo in controlling symptoms (41). Constipation was the most common adverse effect of alosetron (25% compared with 5% in the placebo group).

Ischemic colitis has been attributed to alosetron (42).

- A 55-year-old man with irritable bowel syndrome who took alosetron 1 mg bd for 4 days developed symptoms of ischemic colitis, including rectal bleeding, and the diagnosis was confirmed macroscopically and histologically at colonoscopy. The symptoms suggestive of colitis abated on withdrawal of alosetron, but the symptoms of irritable bowel syndrome returned. Colonoscopy 2 weeks later showed a normal colon and biopsies showed normal colonic histology.

The combination of intravenous granisetron (40 micrograms/kg) and dexamethasone (8 mg) was more effective than granisetron alone for prophylaxis of postoperative nausea and vomiting after laparoscopic cholecystectomy in a randomized, double-blind trial in 120 patients (43). There was no difference in the incidence of adverse effects between the two groups. The most frequent were nausea, retching, and vomiting.

Drug Administration

Drug administration route

In a randomized, double-blind study, oral granisetron (1 mg) was more effective than intravenous granisetron (1 mg) in preventing emesis caused by high-dose chemotherapy in 51 patients who underwent peripheral blood progenitor cell or bone-marrow transplantation (44). There was no significant difference in adverse events. The more frequent were headache, diarrhea, extrapyramidal symptoms, and sedation.

Drug–Drug Interactions

Fluoxetine

In an open, non-randomized, crossover study in 12 healthy female and male volunteers alosetron 1 mg bd had no effect on the pharmacokinetics of fluoxetine 20 mg/day (45). Co-administration of the two drugs was well tolerated by all the subjects.

Zenoplatin

Data from a single trial suggest that ondansetron can enhance the nephrotoxicity of the cytostatic drug zenoplatin (SEDA-17, 415).

Flavoxate

See also Anticholinergic drugs

General Information

Flavoxate is an anticholinergic drug that is used to treat bladder detrusor instability. It can cause all the adverse effects that would be expected from its anticholinergic action.

Organs and Systems

Skin

- An 83-year-old man developed a generalized pruritic erythematous reaction with a fever after taking flavoxate 200 mg tds for 6 months in combination with tamsulosin hydrochloride and allylestrenol for prostatic hyperplasia (1). Patch tests with these drugs showed a positive reaction on flavoxate 10% on day 3. Rechallenge with flavoxate caused generalized pruritic erythema with fever.

Flecainide

See also Antidysrhythmic drugs

General Information

Flecainide is a class Ic antidysrhythmic drug. Its clinical pharmacology, clinical use, and adverse effects have been reviewed (1–3).

Comparative studies

In some patients treatment with a class I antidysrhythmic drug converts atrial fibrillation to atrial flutter. Of 187 patients with paroxysmal atrial fibrillation who were treated with flecainide or propafenone, 24 developed atrial flutter, which was typical in 20 cases (4). These patients underwent radiofrequency ablation, which failed in only one case. All the patients continued to take their preexisting drugs, and during a mean follow-up period of 11 months the incidence of atrial fibrillation was higher in patients who were taking combined therapy than in those taking monotherapy. The authors suggested that in patients with atrial fibrillation who developed typical atrial flutter due to class Ic antidysrhythmic drugs, combined catheter ablation and continued drug treatment is highly effective in reducing the occurrence and duration of atrial tachydysrhythmias. They did not report adverse effects.

In 33 patients with symptomatic and inducible supraventricular tachycardias single doses of placebo, flecainide 3 mg/kg, or diltiazem 120 mg plus propranolol 80 mg were used to terminate the dysrhythmia (5). Conversion to sinus rhythm was achieved within 2 hours in 17 patients with placebo, in 20 with flecainide, and in 31 with diltiazem plus propranolol. Time to conversion was shorter with diltiazem plus propranolol (32 minutes) than with flecainide (74 minutes) or placebo (77 minutes). Of those who were given flecainide, two had hypotension and one had sinus bradycardia.

Systematic reviews

A systematic review of 22 studies of the effects of flecainide used for at least 3 months in the treatment of supraventricular dysrhythmias suggested that flecainide is associated with a variety of adverse reactions, many of which are well tolerated, but carries a small risk of serious cardiac events (2%), which can lead to death (0.13%) (SEDA-21, 200).

In a meta-analysis of 122 prospective studies of the use of flecainide in 4811 patients with supraventricular

	Diarrhea	29 (0.7)	50 (2.8)*
	Nausea	71 (1.6)	33 (1.8)

*Significantly different.

dysrhythmias, 21 were placebo-controlled and 37 were comparative studies with other antidysrhythmic drugs (6). The total exposure time was 2015 patient-years, with a mean oral flecainide dose of 216 mg/day. There were eight deaths (total mortality 0.17%, fatality rate per 100 patient-years 0.40; 95% CI = 0.17, 0.78), confirming the earlier finding. Three deaths were non-cardiac (cancer, suicide, urinary sepsis). Of the cardiac deaths, all but two occurred in patients with coronary heart disease. In controls, there was one death. There were prodysrhythmic events in 120 patients taking flecainide (2.7%) and 88 controls (4.8%), 58 (7.4%) of which occurred in patients taking placebo. Non-cardiac adverse effects are listed in Table 1. Thus, flecainide is safe in patients with supraventricular dysrhythmias with no cardiac damage, in contrast to patients with ventricular dysrhythmias after myocardial infarction.

Organs and Systems

Cardiovascular

In a review of 60 original articles detailing 1835 courses of intravenous and/or oral flecainide in both placebo-controlled and comparative studies as well as a large number of uncontrolled studies, unwanted cardiac events occurred in 8% of patients (7). The cardiac events were hypotension (1.3%), heart failure (0.4%), sinus node dysfunction (1.6%), bundle branch block (1.0%), atrial dysrhythmias (1.6%), and ventricular dysrhythmias (1.3%). However, in 8505 patients, 5507 of whom were administered flecainide for more than 4 weeks and most of whom took dosages of 100–300 mg/day, cardiac adverse effects occurred in only about 2% and non-cardiac effects in about 10% (8). The most common cardiac adverse effects were angina pectoris, dysrhythmias, worsening of heart failure, and hemodynamic changes. Of the long-term non-cardiac adverse effects the most common were nausea, vomiting, dizziness, bowel disturbances, headache, and visual disturbances.

Cardiac dysrhythmias

In the wake of the preliminary and final reports of the Cardiac Arrhythmia Suppression Trial (CAST) (9,10), which showed that there was an increased risk of death among patients who took encainide and flecainide after myocardial infarction, there have been many publications in which the implications of these findings have been thoroughly discussed (11–15). The relative risk of death or cardiac arrest due to dysrhythmias in the treated patients was 2.6 and the relative risk due to all causes was 2.4. The risk of non-fatal cardiac adverse effects was no different in treated patients from that in those taking placebo and there was no difference between the groups in the use of other drugs.

Although there is a consensus that encainide and flecainide were associated with an increase in the rate of mortality in CAST, there are still some open questions. First, all the patients recruited to CAST had asymptomatic ventricular dysrhythmias after myocardial infarction, and it is not clear whether the results can be extrapolated to other patients. Secondly, the reasons for the increased mortality in the treated patients are not clear: ventricular dysrhythmias and worsening of left ventricular function are both possible. Thirdly, it is not clear whether the results of CAST in patients with asymptomatic ventricular dysrhythmias after myocardial infarction can also be applied to other Class I antidysrhythmic drugs.

The prodysrhythmic effects of flecainide, by prolongation of the QT_c interval, have been widely discussed (SEDA-15, 175) (16–20). However, overall, cardiac dysrhythmias are less common with flecainide than with other antidysrhythmic drugs of Class I, and the dysrhythmogenic effects of flecainide in patients with supraventricular dysrhythmias may not be great (SEDA-22, 207). When dysrhythmias occur, prolongation of the QT interval is an important mechanism, but in a recent case it was suggested that tachycardia was due to re-entry within the His-Purkinje system (21). In another case flecainide reportedly caused a wide-complex tachycardia due to atypical atrial flutter with 1:1 conduction and aberrant QRS complexes (22). Although drugs of Class Ic, such as flecainide, can slow atrial and atrioventricular nodal conduction in patients with atrial fibrillation or atrial flutter, they do not alter the refractoriness of the atrioventricular node, and this allows 1:1 atrioventricular conduction as the atrial rate slows. This happens despite prolongation of the PR interval.

- Syncope occurred in a patient whose QRS complex duration was prolonged (23).
- In a 67-year-old woman taking flecainide 150 mg bd, widening of the QRS complex occurred during exercise; the effect did not occur at rest or with a dose of 50 mg bd (24).

Hypokalemia can increase the risk of torsade de pointes with flecainide, as with other antidysrhythmic drugs.

© 2006 Elsevier B.V. All rights reserved.

- Torsade pointes has been attributed to mosapride (which is related to cisapride) and flecainide in a 68-year-old man with a plasma potassium concentration of 3.2 mmol/l and prolongation of the QT_c interval from 0.48 to 0.56 seconds (25). His plasma flecainide concentration was just above the target range at 1013 ng/ml, but the mosapride concentration was not reported.

The authors speculated that mosapride may have inhibited the metabolism of flecainide by CYP2D6.

In a retrospective analysis of 24 patients who developed atrial flutter while taking flecainide ($n = 12$) or propafenone ($n = 12$), the electrocardiogram was classified as typical atrial flutter in 13 cases, atypical atrial flutter in eight, or coarse atrial fibrillation in three (26). Counterclockwise atrial flutter was the predominant dysrhythmia. The acute results of ablation suggested that the flutter circuit was located in the right atrium and that the isthmus was involved in the re-entry mechanism. There was better long-term control of recurrent atrial fibrillation in patients with typical atrial flutter (85%) compared with atypical atrial flutter (50%). The authors suggested that patients who develop coarse drug-induced atrial fibrillation may not be candidates for ablation.

Cardioversion

In 24 patients with atrial fibrillation who underwent elective transvenous cardioversion for atrial fibrillation, flecainide reduced the energy requirements for further defibrillation after induction of atrial fibrillation by atrial pacing (27). There were no ventricular dysrhythmias, but transient bradycardia requiring ventricular pacing occurred in two patients. Two patients had transient asymptomatic hypotension after flecainide and one reported transient dizziness and some light-headedness.

Antidysrhythmic drugs increase the pacing threshold, but failure to capture is a rare consequence. It has, however, been reported twice with flecainide (28,29).

Electrocardiographic changes

ST segment elevation in leads II, III, and aVf, resembling an acute inferior myocardial infarction, have been reported with oral flecainide (30). Brugada syndrome is partial right bundle branch block with ST segment elevation in the right precordial leads of the electrocardiogram; it is due to an abnormality of sodium channels and occurs in 0.05–0.1% of the population; some cases are inherited (31). Flecainide can bring out Brugada-type changes on the electrocardiogram (32–34).

Hypotension

Flecainide has been reported to cause acute hypotension after intravenous administration (35).

Respiratory

Interstitial pneumonitis has only rarely been attributed to flecainide (SEDA-16, 181).

- Interstitial pneumonitis with acute respiratory failure was attributed to flecainide in a 59-year-old man with congenital heart disease related to the LEOPARD syndrome, in which there are multiple freckles (Lentigines), Electrocardiographic abnormalities, Ocular hypertelorism, Pulmonic stenosis, Abnormalities of the genitalia, Retarded growth, and sensorineural Deafness (36). A CT scan showed diffuse interstitial injury characterized by thickening of the intralobular septa, with areas of ground-glass pattern. Flecainide was withdrawn and within 2 weeks the changes on CT scan had almost completely disappeared.
- A 75-year-old man, who had taken flecainide 100 mg/day for 22 months, developed fever, headache, and a dry cough (37). A CT scan of the lungs was normal and he responded to prednisone. His symptoms disappeared, but when prednisone was withdrawn they returned, with breathlessness, a dry cough, and weight loss. A chest X-ray showed bilateral patchy opacities and a CT scan subpleural ground-glass opacities and septal thickening. He had impaired lung function, including a reduced diffusion capacity. Biopsy showed diffuse interstitial thickening with lymphocytic and eosinophilic infiltrates. Flecainide was withdrawn and prednisone given, and he made a full recovery within 1 month.
- A 73-year-old man, who had taken flecainide 100 mg/day for 4 months, developed fever, weight loss, breathlessness, and a dry cough (37). A chest X-ray showed patchy infiltrates and a CT scan ground-glass opacities and subpleural septal thickening. He had normal lung function, apart from a reduced diffusion capacity. Flecainide was withdrawn and prednisone given, and he made a full recovery within a few months.

Nervous system

The most common non-cardiac adverse effects of flecainide are on the central nervous system and include dizziness, drowsiness, visual disturbances, headache, nausea, paresthesia, nervousness, and tremor. The incidence of these adverse effects has varied widely (38,39).

Other reported effects of flecainide include dysarthria and visual hallucinations (40), abnormal taste sensations, flushing, a glove-and-stocking type of peripheral neuropathy, and dystonia (SEDA-17, 223).

Sensory systems

Ocular adverse effects of flecainide have included corneal deposits in two patients, due to deposition of flecainide (41). In 38 patients taking flecainide 100–300 mg/day there were brown corneal epithelial deposits in 11 eyes, dryness in eight eyes, and slight blurring of vision on lateral gaze in four patients (42). Four patients had local symptoms, including tearing, itching, and burning. Color vision, contrast sensitivity, and visual fields were all unaffected.

Hematologic

Flecainide can cause neutropenia (43).

Liver

Flecainide can cause increases in the serum activities of transaminases (44). In one case cholestasis and jaundice occurred (45).

Urinary tract

Flecainide can cause acute urinary retention, perhaps due to a local anesthetic effect on the bladder mucosa (46).

© 2006 Elsevier B.V. All rights reserved.

Skin

Flecainide reportedly caused a psoriasiform eruption (47).

Sexual function

Flecainide inhibits sperm motility in vitro (48), but this has not been reported to be of clinical relevance.

Flecainide can cause erectile impotence (49).

Second-Generation Effects

Pregnancy

Flecainide is occasionally used to treat fetal cardiac dysrhythmias by administration to the mother (50,51), although occasionally it can cause adverse effects in the child (SEDA-25, 184) and in the mother (52).

- At 30 weeks of gestation in a 41-year-old woman the fetus had hydrops, ascites, a pericardial effusion, and bilateral hydroceles. A supraventricular tachycardia with 1:1 conduction was treated by giving the mother oral flecainide 150 mg bd. However, during the next few weeks the mother developed evidence of hepatic cholestasis. The dosage of flecainide was reduced to 50 mg bd and the liver damage resolved. The child was born healthy but later required sotalol for a re-entry tachycardia.

Fetotoxicity

- A pregnant woman was given digoxin and flecainide at 29 weeks of gestation for fetal tachycardia and hydrops fetalis (53). The child was delivered spontaneously at 33 weeks and had mild respiratory distress. His electrocardiogram showed bifid P waves, a prolonged PR interval, deep wide Q waves, and raised ST segments. The QT interval was not prolonged. The serum digoxin concentration in the neonate was 1.2 mg/ml. The abnormalities resolved within 3 weeks of birth, despite continued digoxin therapy.

The authors attributed the electrocardiographic abnormalities to maternal use of flecainide.

Susceptibility Factors

Age

Reports of the use of flecainide in children suggest that the risk of adverse effects is low, although these studies have been very small (54–56).

Renal disease

Flecainide is cleared partly by dose-dependent hydroxylation and partly unchanged via the kidneys. Therefore, severe renal impairment and hepatic impairment both cause a reduction in its rate of clearance (57,58). Dosages should be reduced in these circumstances.

Hepatic disease

Flecainide is cleared partly by dose-dependent hydroxylation and partly unchanged via the kidneys. Therefore, severe renal impairment and hepatic impairment both cause a reduction in its rate of clearance (57,58). Dosages should be reduced in these circumstances.

Other features of the patient

Flecainide half-life is prolonged in poor hydroxylators (59) and poor metabolizers may be at an increased risk of adverse effects.

Drug Administration

Drug overdose

There have been a few reports of the effects of overdosage of flecainide (60–65). Various treatments have been used in these circumstances; none is specific.

- A 20-year-old woman took 3–4 g of flecainide and developed circulatory failure unresponsive to pacing, inotropic drugs, and sodium bicarbonate (66). She was then successfully treated with cardiopulmonary bypass for 30 hours. At peak, the plasma flecainide concentration was in excess of 4000 μg/ml, and although this fell during bypass to below 3.5 μg/ml, clinical recovery preceded this fall. Other complications included a coagulopathy with intravascular hemolysis, requiring the use of blood products, and renal insufficiency requiring hemodiafiltration.

The authors proposed that extracorporeal circulatory support had allowed increased perfusion of the liver and therefore more effective metabolism of the flecainide.

- Death has been reported in two patients who took flecainide (67). The postmortem femoral blood flecainide concentrations were 5.4 and 1.2 μg/ml (target range 0.2–1.0).
- Fatal flecainide overdose has been reported in a 65-year-old man who probably took 20 tablets of 100 mg each (68). However, no clinical details were available, because he was found dead. Flecainide was detected in his blood, gastric contents, and liver. *O*-dealkylated flecainide was found in his urine.

Of other fatal cases reviewed in the paper, in only one was there a slightly lower blood concentration of flecainide (7.3 compared with 7.7 mg/kg). The authors proposed that pre-existing cardiac damage could have predisposed this man to a dysrhythmic death.

Drug–Drug Interactions

Amiodarone

The combination of flecainide with amiodarone can result in reduced conduction, predisposing to bundle branch block and dysrhythmias (69,70).

Beta-adrenoceptor antagonists

The combination of flecainide with propranolol results in additive hypotensive and negative inotropic effects (71).

Lipophilic beta-adrenoceptor antagonists are metabolized to varying degrees by oxidation by liver microsomal cytochrome P450 (for example propranolol by CYP1A2 and CYP2D6 and metoprolol by CYP2D6). They can therefore reduce the clearance and increase the steady-state plasma concentrations of other drugs that undergo similar metabolism, potentiating their effects. Drugs that interact in this way include flecainide (72).

© 2006 Elsevier B.V. All rights reserved.

Digoxin

Despite an early report that flecainide might alter the pharmacokinetics of digoxin, this action is minimal and probably of no clinical significance (72). The combination causes a significant increase in the PR interval; but the clinical significance of this is unclear, it may be important for patients with impaired sinus node function (73).

Quinidine

Flecainide is metabolized by CYP2D6, and is subject to polymorphic metabolism. In extensive metabolizers its clearance is reduced by quinine (74). Quinidine reduces the clearance of *R*-flecainide but not that of *S*-flecainide (75).

Verapamil

Although verapamil reduces the clearance of flecainide, this is probably not clinically important (76). However, there is also a pharmacodynamic interaction, since both drugs increase the PR interval and have additive effects on myocardial contractility and atrioventricular conduction (77).

Floctafenine

See also Non-steroidal anti-inflammatory drugs

General Information

Floctafenine is a 4-aminoquinoline NSAID, closely related to antrafenine and glafenine, and its adverse effects profile is similar (1).

Organs and Systems

Urinary tract

Floctafenine has been detected in a urinary calculus (2).

Immunologic

Floctafenine has frequently been associated with anaphylactic reactions (3).

Drug Interactions

Cimetidine

Coma has been reported in a patient taking diuretics and cimetidine, who was given floctafenine (4).

Coumarin anticoagulants

Floctafenine may increase the action of coumarin anticoagulants (5).

Flosulide

General Information

Flosulide is a COX-2 inhibitor.

Organs and Systems

Gastrointestinal

Flosulide caused less damage to the mucosa and was better tolerated than naproxen in a 2-week endoscopic study, but the clinical relevance of endoscopic studies of this sort is debatable (SEDA-14, 79).

Urinary tract

Clinical development of flosulide, a COX-2 selective inhibitor, has been discontinued because of nephrotoxicity (1). Measurement of renal prostaglandin synthesis did not predict the nephrotoxicity of flosulide in single-dose and short-term studies (2).

Floxuridine

See also Cytostatic and immunosuppressant drugs

General Information

Floxuridine is a pyrimidine analogue that is used in regional arterial chemotherapy for primary and metastatic malignancies, delivered using an implantable pump.

Organs and Systems

Gastrointestinal

Nine patients who received hepatic arterial infusion chemotherapy developed gastritis heralded by epigastric pain and tenderness, nausea, vomiting, weakness, and anorexia (1). In 7 patients, 18 gastric ulcers were detected endoscopically. Mucosal damage developed despite prophylactic antiulcer therapy and healed only on withdrawal. In 17 biopsy specimens there were variously inflammatory changes, reactive glandular changes, and cell necrosis, even in patients without ulcers. In addition, there was floxuridine-induced glandular atypia in eight biopsy samples from six patients; the crowded glands

© 2006 Elsevier B.V. All rights reserved.

were distorted and lined by large cells that included bizarre forms with pleomorphic nuclei.

- A patient who received regional intrahepatic chemotherapy from a continuous infusion pump for 31 months developed a gastroduodenal artery–duodenal fistula, and presented with signs and symptoms of upper gastrointestinal bleeding.

Six patients who had received an infusion of floxuridine, either via the hepatic artery or intravenously, developed severe diarrhea (2). In four, the entire ileum or its more distal part was markedly narrowed and in the other two there was thickening or effacement of the mucosal folds in the distal ileum. The symptoms resolved and the radiographic appearances improved after withdrawal.

Biliary tract

The principle of hepatic arterial infusion is based on the fact that hepatic tumors derive much of their blood supply from the hepatic artery, whereas the liver parenchyma receives its supply from the portal venous circulation.

- Acute and chronic cholecystitis has been reported after floxuridine hepatic artery infusion (3). Chemotherapy in this patient was associated with persistent epigastric pain with radiation to the back which was not accompanied by any fever or white blood cell elevation. Cholecystectomy showed a shrunken, thickened fibrotic gallbladder that was filled with thick, pasty, hemorrhagic material. There were no gallstones.

In 27 patients who received intrahepatic floxuridine, total dose 20–41 mg/kg extrahepatic biliary sclerosis was discovered by CT scan and ultrasound, followed by endoscopic retrograde cholangiopancreatography and/or percutaneous cholangiography in three cases (4). Radiological findings included complete obstruction of the common hepatic duct in one case, common hepatic duct stenosis in two cases, common bile duct obstruction in one case, and intrahepatic bile duct dilatation without identifiable obstruction in one case

Fluconazole

See also Antifungal azoles

General Information

Fluconazole is an antifungal triazole that was derived from the older imidazoles. It has a lower molecular weight and is soluble in water. It can be administered orally and parenterally.

Pharmacokinetics

After oral administration, its systemic availability is about 90%; maximum plasma concentrations are seen in 1–2 hours, its half-life is about 30 hours and steady state is reached within 5–7 days. Fluconazole has low protein binding (about 12%), is hardly metabolized, and about 80% of it is excreted in the urine. Hemodialysis reduces plasma concentrations by about half in 3 hours (1–3). Tissue and body fluid penetration is good (2,4–9). The CSF concentration ratio is 0.5–0.9, the resultant concentrations being adequate for the treatment of cryptococcal meningitis (10–12). Penetration into the eye is good (13), and fluconazole has been used successfully in fungal endophthalmitis (14–17). In a patient in whom the concentrations of fluconazole in bile were studied, the concentrations after the first dose were about the same as in serum, but 10–12 hours after the dose, bile concentrations were higher than serum concentrations (18). Sputum concentrations are similar to plasma concentrations. Concentrations in vaginal secretions are slightly lower than in plasma, but persist for longer (19,20).

Like ketoconazole, fluconazole is a potent inhibitor of cytochrome P450, but with much higher specificity for fungal enzymes compared with human enzymes (21,22). Clinical interaction studies and some in vitro studies have suggested that azole antifungal drugs inhibit P glycoprotein. In a cell line in which human P glycoprotein was overexpressed, itraconazole and ketoconazole inhibited P glycoprotein function, with 50% inhibitory concentrations of about 2 and 6 μmol/l respectively; however, fluconazole had no effect (23).

Observational studies

The prophylactic use of oral fluconazole to prevent invasive *Candida* infections in 260 critically ill surgical patients has been investigated in a prospective, randomized, placebo-controlled trial in a single-center, tertiary-care surgical intensive care unit (24). The patients were randomly assigned to receive either oral fluconazole 400 mg/day or placebo. The risk of presumed and proven *Candida* infections in the patients who received fluconazole was significantly less than the risk in those who received placebo. After adjusting for several potentially confounding effects, fluconazole reduced the risk of presumed and proven fungal infection by 55%. There was no difference in death rate between fluconazole and placebo. The authors concluded that enteral fluconazole safely reduced the incidence of fungal infections in this high-risk population.

Comparative studies

Amphotericin

Fluconazole and amphotericin as empirical antifungal drugs in febrile neutropenic patients have been investigated in a prospective, randomized, multicenter study in 317 patients randomized to either fluconazole (400 mg qds) or amphotericin deoxycholate (0.5 mg/kg qds) (25). Adverse events (fever, chills, renal insufficiency, electrolyte disturbances, and respiratory distress) occurred significantly more often in patients who were given amphotericin (128/151 patients, 81%) than in those given fluconazole (20/158 patients, 13%). Eleven patients treated with amphotericin, but only one treated with fluconazole, were withdrawn because of an adverse event. Overall mortality and mortality from fungal infections were similar in both groups. There was a satisfactory response in 68% of the patients treated with fluconazole and 67% of those treated with amphotericin. Thus, fluconazole may be a safe and effective alternative to amphotericin for empirical therapy of febrile neutropenic patients; however, since fluconazole is ineffective against opportunistic molds, the possibility of an invasive infection by a filamentous fungus should be excluded before starting empirical therapy. Similarly, patients who take azoles for prophylaxis are not candidates for empirical therapy with fluconazole.

Conventional amphotericin deoxycholate (0.2 mg/kg qds) and fluconazole (400 mg qds) have been compared in a prospective, randomized study in 355 patients with allogeneic and autologous bone marrow transplantation (26). The drugs were given prophylactically from day –1 until engraftment. There was no difference in the occurrence of invasive fungal infections, but amphotericin was significantly more toxic than fluconazole, especially in related allogeneic transplantation, after which 19% of patients developed toxicity compared with none of those who received fluconazole.

Echinocandins

Caspofungin and fluconazole have been compared in adults with *Candida* esophagitis in a double-blind, randomized trial (27). Eligible patients had symptoms compatible with esophagitis, endoscopic mucosal plaques, and microscopic *Candida*. They were randomized to receive caspofungin (50 mg) or fluconazole (200 mg) intravenously once a day for 7–21 days. Most of them (154/177) had HIV infection, with a median CD4 count of 30×10^6/l. Favorable response rates were achieved in 66 of the 81 patients in the caspofungin arm and in 80 of the 94 patients in the fluconazole arm; symptoms had resolved in over 50% of the patients in both groups by the fifth day of treatment. Drug-related adverse effects were reported in 41% of patients given caspofungin and 32% of those given fluconazole; the most common events in both groups were phlebitis, headache, fever, nausea, diarrhea, abdominal pain, and rashes. Drug-related laboratory abnormalities developed in 29% of patients given caspofungin and in 34% of those given fluconazole. The most frequent laboratory abnormalities included reduced white blood cell count, hemoglobin concentration, and serum albumin concentration, and increased alkaline phosphatase and transaminases. No patient given caspofungin developed a serious drug-related adverse effect; therapy was withdrawn in only one patient (who was receiving fluconazole), because of an unspecified adverse effect.

Placebo-controlled studies

In a randomized, double-blind, placebo-controlled study in Saudi Arabia of oral fluconazole (200 mg/day for 6 weeks) in the treatment of cutaneous leishmaniasis, 106 patients were assigned to fluconazole and 103 to placebo (28). Follow-up data were available for 80 and 65 patients respectively. At the 3-month follow-up, healing of lesions was complete in 63 of the 80 patients who took fluconazole and 22 of the 65 patients who took placebo (relative risk of complete healing, 2.33; 95% CI = 1.63, 3.33). Adverse effects were mild and similar in the two groups.

General adverse effects

Fluconazole is generally well tolerated. The most common adverse effects are nausea and vomiting. Abnormal liver function tests and slight increases in hepatic enzymes have been reported, and there have been anecdotal reports of hepatitis and hepatic failure. Early studies have shown no changes in testosterone concentrations or in the adrenal response to ACTH. Rashes and a few cases of exfoliative skin disorder have been reported (SED-12, 681) and have been seen more frequently in patients with AIDS (29). Alopecia has been reported in a few cases with the use of high doses for prolonged periods of time (SEDA-18, 281). Rare instances of anaphylactoid reactions have been reported (SED-12, 681) (30). Rare instances of hypersensitivity reactions have occurred in other individuals (SEDA-16, 293) (SEDA-17, 320). Tumor-inducing effects have not been reported.

In a study using the UK General Practice Research Database to determine rates of drug-induced, rare, serious adverse effects on the liver, kidneys, skin, or blood, occurring within 45 days of completing a prescription or refill in 54 803 users of either fluconazole or itraconazole, three had illnesses for which a fluconazole-induced cause could not be ruled out; one with thrombocytopenia, one with neutropenia, and one with an abnormal liver function test just after receiving fluconazole (31). The rates were 2.8/100 000 prescriptions (95% CI = 0.8, 10) for serious, adverse blood events and 1.4/100 000 prescriptions (95% CI = 0.25, 8.2) for serious, adverse liver events. These results suggest that fluconazole does not commonly have serious adverse effects on the liver, kidneys, skin, or blood.

Organs and Systems

Cardiovascular

Prolongation of the QT interval is a class effect of the antifungal azoles and has occasionally been reported with fluconazole, with a risk of torsade de pointes.

- A 68-year-old woman with *Candida glabrata* isolated from a presacral abscess developed torsade de pointes after 8 days treatment with oral fluconazole 150 mg/day (32). She had no other risk factors for torsade de pointes, including coronary artery disease, cardiomyopathy, congestive heart failure, or electrolyte abnormalities. The dysrhythmia resolved when fluconazole was withdrawn, but she continued to have ventricular extra beats and non-sustained ventricular tachycardia for 6 days.

© 2006 Elsevier B.V. All rights reserved.

- A 59-year-old woman with liver cirrhosis and *Candida* peritonitis developed long QT syndrome and torsade de pointes after intravenous therapy with 400–800 mg/day of fluconazole for 65 weeks, followed by intraperitoneal administration (150 mg/day) (33). One day after the second intraperitoneal administration, she developed palpitation, multifocal ventricular extra beats, and syncope. In contrast to a normal electrocardiogram on admission, electrocardiography showed polymorphic ventricular extra beats, T wave inversion, alternating T wave amplitude, and a prolonged QT_c interval of 606 ms. Torsade de pointes required cardiopulmonary resuscitation. The fluconazole plasma concentration was 216 μg/ml (usual target range at 400–800 mg/day: 18–28 μg/ml). Fluconazole was withdrawn and all conduction abnormalities reversed fully within 3 weeks.

These patients were not taking any concomitant drugs that prolong the QT interval, suggesting that fluconazole was to blame.

- A 25-year-old woman with worsening endocarditis had a prolonged QT interval at baseline and developed monomorphic ventricular dysrhythmias, which were managed successfully with pacing and antidysrhythmic therapy, including amiodarone (34). Several days later, she was given high-dose fluconazole (800 mg/day) for fungemia and after 3 days had episodes of torsade de pointes.

In this case torsade de pointes developed in the presence of known risk factors—hypokalemia, hypomagnesemia, female sex, baseline QT interval prolongation, and ventricular dysrhythmias.

Nervous system

Central nervous system abnormalities constitute the major dose-limiting adverse effects of fluconazole and are observed at dosages over 1200 mg/day (35).

Dizziness, headache, and seizures were seen in 2–5% of 232 patients with severe systemic fungal infections taking fluconazole (36). In the same group there were three cases each of delirium and dysesthesia (1.3%). A possible effect of the underlying illness has to be considered. In 14 patients treated with fluconazole for cryptococcal meningitis, dizziness was reported in 14% (SED-12, 681).

Two Japanese patients developed clonic convulsions while taking fluconazole 800 mg/day (37).

- A 66-year-old woman with complicated invasive *Candida tropicalis* infection but no renal impairment took fluconazole 800 mg/day. On the 21st day she developed clonic convulsions. The fluconazole trough concentration at the time of the event was 82 μg/ml.
- A 62-year-old man with deteriorating renal and hepatic function after coronary artery bypass surgery was given fluconazole 400 mg bd for a fungal sternal wound infection. On the 15th day he developed seizures. His trough plasma fluconazole concentration was 88 μg/ml. Nineteen days after dosage adjustment to 400 mg qds, he had another seizure. The trough fluconazole concentration was 103 μg/ml, probably because of deteriorating renal function.

In both cases, the seizures abated after dosage reduction. These case reports suggest an association between trough plasma fluconazole concentrations of 80 μg/ml and central nervous system toxicity; they re-emphasize the need for careful monitoring and dosage adjustment of fluconazole in patients with reduced renal function.

Endocrine

Preliminary studies concerning a possible effect on testosterone concentrations and the adrenal response to adrenocorticotropic hormone did not show any changes. However, determinations were performed after only 14 days of fluconazole administration.

- Two critically ill patients, a 77-year-old man with esophageal cancer and a 66-year-old woman with multiple organ failure, developed reversible adrenal insufficiency temporally related to the use of high-dose fluconazole (800 mg loading dose followed by 400 mg/day), as assessed by short stimulation tests with cosyntropin (ACTH) (38). Although anecdotal, these data suggest that the possibility that high-dose fluconazole can cause adrenal insufficiency in already compromised critically ill patients needs to be investigated further.
- A 63-year-old man received high-dose cyclophosphamide for peripheral blood stem-cell harvesting, having been taking fluconazole 200 mg/day (39). On day 3 he developed atrial fibrillation and his blood pressure fell to 78 mmHg. A rapid ACTH stimulation test showed a blunted adrenal response. He was suspected of having adrenal failure, and fluconazole was withdrawn. A rapid ACTH test was normal on day 14. To clarify the association between adrenal failure and fluconazole, he was rechallenged with fluconazole 400 mg/day from day 16 and a rapid ACTH test was performed on day 21; it showed a blunted adrenal response.

Mineral balance

Hypokalemia was observed in only a few patients taking fluconazole, which contrasts with experience with itraconazole (36,40). However, hyperkalemia was reported in one paper (SED-12, 681) (40).

Hematologic

Cytopenias occur but seem to be mild. Occasionally, more marked changes have been described, but these could have been connected with the underlying disease (SED-12, 681) (40,41). In a single placebo-controlled study of fluconazole prophylaxis using a relatively high dose of 400 mg/day, a post-hoc analysis suggested prolongation of granulocytopenia after intensive chemotherapy for hematological neoplasms in the fluconazole group. This may have been due to an interaction with the antineoplastic drug (42).

Leukopenia with eosinophilia has been attributed to fluconazole (43).

- A 75-year-old man with non-Hodgkin's lymphoma and cryptococcal meningoencephalitis developed neutropenia with eosinophilia associated with fluconazole. After 1 week of fluconazole 400 mg/day his total leukocyte count began to fall and his eosinophil count increased. Concurrent medications included levothyroxine, famotidine, and co-trimoxazole. The last two drugs were withdrawn and he was given G-CSF.

© 2006 Elsevier B.V. All rights reserved.

However, his leukocyte count continued to fall and 4 days later reached a nadir of 700 × 10^6/l; the platelet count remained normal. The leukopenia and eosinophilia resolved promptly after withdrawal of fluconazole.

Since the leukopenia and eosinophilia did not resolve until fluconazole was withdrawn, an effect of the compound was plausible. This case and two other reported cases (44,45) emphasize the importance of recognizing fluconazole as a rare but potential cause of bone marrow suppression in patients in whom drug-induced agranulocytosis is suspected.

In one study in patients with AIDS taking prophylactic maintenance fluconazole for cryptococcal meningitis, there was a higher rate of hematological toxicity with fluconazole than with placebo, but this probably reflected the greater proportional and absolute amounts of zidovudine used in the fluconazole group; there was no serious hematotoxicity (SED-12, 682).

Gastrointestinal

Nausea and vomiting are mentioned in most reports of patients taking fluconazole, with an incidence of 10–15% (SED-12, 682) (36,40,41,46,47). Anorexia, mild abdominal pain, and diarrhea have been reported, but none was severe.

Liver

Raised liver enzyme activities have been reported in most studies. In some articles this effect was described as transient, in others as disappearing after withdrawal. The incidence varies from a few percent of cases to 35–45%, but occasionally the effect has been recorded in all cases treated. A temporal relation between these liver function changes and fluconazole treatment has been shown in many cases. Severe liver toxicity has not been reported (SED-12, 681) (21). While asymptomatic rises in transaminases were noted in some children with neoplastic disease who were treated concomitantly with fluconazole in a small study (48), there were no significant changes in a larger study in cancer patients treated with placebo or fluconazole 400 mg (42).

- A 45-year-old woman with protracted cryptococcal meningoencephalitis developed fulminant hepatic failure secondary to high fluconazole serum concentrations, possibly precipitated by renal dysfunction induced by concomitant amphotericin therapy or concomitant therapy with lisinopril, atenolol, or amlodipine (49). Four days after the withdrawal of fluconazole 400 mg/day the serum concentration of fluconazole was 40 μg/ml.

This case points to the potential risks of fluconazole therapy in the setting of renal insufficiency, in particular with higher dosages (400 mg/day and more).

Skin

Rashes of several types occur with fluconazole and are more frequent in immunocompromised patients.

The risk of serious skin disorders has been estimated in 61 858 users of oral antifungal drugs, aged 20–79 years, identified in the UK General Practice Research Database (50). They had received at least one prescription for oral fluconazole, griseofulvin, itraconazole, ketoconazole, or terbinafine. The background rate of serious cutaneous adverse reactions (corresponding to non-use of oral antifungal drugs) was 3.9 per 10 000 person-years (95% CI = 2.9, 5.2). Incidence rates for current use were 15 per 10 000 person-years (1.9, 56) for itraconazole, 11.1 (3.0, 29) for terbinafine, 10 (1.3, 38) for fluconazole, and 4.6 (0.1, 26) for griseofulvin. Cutaneous disorders associated with the use of oral antifungal drugs in this study were all mild.

Pruritus has also been reported (51). A few cases of Stevens–Johnson disease have been reported worldwide (SED-12, 682) (22,46,52), as well as a few instances of fixed-drug eruption (53). In cases of hypersensitivity, desensitization has reportedly been used with success (54).

Fixed drug eruption caused by systemic fluconazole has been reported (55).

- A 36-year-old woman with a history of atopy and recurrent *Candida* vaginitis developed a fixed drug eruption while taking fluconazole 150 mg/day. Local provocation with 10% fluconazole in petrolatum applied at the site of a previous site of fixed drug eruption reproduced the eruption clinically and histopathologically.

Nails

A patient developed a longitudinal band of pigmentation in the diseased nail after fluconazole therapy for onychomycosis at a dosage of 150 mg once a week for 4 weeks (56).

Second-Generation Effects

Teratogenicity

The teratogenic activity of triazole and two triazole derivatives, flusilazole (an agricultural triazole monoderivative fungicide) and fluconazole, has been studied in vitro (57). Rat embryos 9.5 days old (1–3 somites) were exposed in vitro to triazole 500–5000 μmol/l, flusilazole 3.125–250 μmol/l, or fluconazole 62.5–500 μmol/l and examined after 48 hours in culture. There were similar teratogenic effects (abnormalities at the branchial apparatus level and cell death at the level of the branchial mesenchyme) at 6.25 μmol/l and higher for flusilazole and 125 μmol/l and higher for fluconazole. In contrast, there was little effect at the highest concentrations of triazole, suggesting no teratogenic activity. These investigations have confirmed the embryotoxic potential of antifungal triazole derivatives, specifically on the branchial apparatus.

However, teratogenic effects have not been found in humans. The risk of malformations and other outcomes in children exposed to fluconazole in utero has been examined in 165 women who had taken fluconazole just before or during pregnancy, mostly in the form of a single dose of 150 mg to treat vaginal candidiasis (58). Birth outcomes (malformations, low birth weight, and preterm delivery) were compared with the outcomes among 13 327 women who did not receive any prescriptions during their pregnancies. The prevalence of malformation was 3.3% (four cases) among the 121 women who had used fluconazole in the first trimester, and 5.2% (697 cases) in offspring to controls (OR = 0.65; CI = 0.24, 1.77). The risks of preterm delivery (OR = 1.17; CI = 0.63, 2.17) and low birth weight (OR = 1.19; CI = 0.37, 3.79) were not significantly increased in association with fluconazole. Thus, the study showed no increased risk of congenital malformations, low birth weight, or preterm birth in offspring to women

© 2006 Elsevier B.V. All rights reserved.

who had used single doses of fluconazole before conception or during pregnancy.

The potential ability of fluconazole to modulate phenytoin teratogenesis has been studied in Swiss mice (59). Pretreatment with a non-embryotoxic dosage of fluconazole (10 mg) potentiated phenytoin teratogenesis; combined treatment of fluconazole 50 mg with phenytoin resulted in a significant increase in embryo deaths. The mechanism of this teratological interaction remains to be established.

Lactation

Fluconazole is found in breast milk at concentrations comparable with those found in the blood after single or multiple doses (2); this may be of clinical relevance (60).

Susceptibility Factors

Age

In a group of children with fever, neutropenia, and neoplastic disease, there was an increase in renal fluconazole clearance (45). In infants and children, the volume of distribution of fluconazole is significantly higher and falls with age. With the exception of infants, who have a slower clearance rate, children clear the compound more rapidly (61). However, a second larger study reported slower elimination in children under 1 year of age, requiring dosage adjustments (62). Low birth-weight neonates have a particularly low clearance rate, which increases within weeks (63).

The use of fluconazole in 726 children under 1 year of age, reported in 78 publications, has been reviewed (64). They received a wide range of dosages for up to 162 days. Fluconazole was well tolerated and efficacious in the therapy of systemic candidiasis and candidemia in children under 1 year of age, including neonates and very low birth-weight infants. The daily dosage recommended by the manufacturers is 6 mg/kg, to be reduced in patients with impaired renal function in accordance with the guidelines given for adults.

The efficacy and safety of fluconazole in neonates with *Candida* fungemia has been evaluated in a multicenter prospective study (65). Fluconazole was safe and effective even in complicated cases, including infants of very low birth weights. Two of 50 neonates developed raised liver enzymes during fluconazole therapy and two others had raised serum creatinine concentrations. In none of them did these abnormalities necessitate discontinuation of antifungal therapy.

The safety profile of fluconazole has been assessed in 562 children (aged 0–17 years; 323 boys and 239 girls), enrolled into 12 clinical studies of prophylactic or therapeutic fluconazole in predominantly immunocompromised patients (66). Most of the children received multiple doses of fluconazole 1–12 mg/kg, given as oral suspension or intravenously. Overall, 58 children reported 80 treatment-related adverse effects. The most common adverse effects were associated with the gastrointestinal tract (7.7%), the skin (1.2%), or the liver and biliary system (0.5% or three patients). Overall, 18 patients discontinued treatment owing to adverse effects, mainly gastrointestinal. Dosage and age did not affect the incidence and pattern of adverse effects. Treatment-related laboratory abnormalities included transiently raised alanine transaminase (4.9%), aspartate transaminase (2.7%), and alkaline phosphatase (2.3%). Although 99% of patients were taking concomitant drugs, there were no clinical or laboratory interactions. The safety profile of fluconazole was compared with those of other antifungal agents, mostly oral polyenes, by using a subset of data from five controlled studies. Adverse effects were reported by more patients treated with fluconazole (45 of 382; 12%) than by patients treated with comparator agents (25 of 381; 6.6%); vomiting and diarrhea were the most common events in both groups. The incidence and type of treatment-related laboratory abnormalities were similar in the two groups. Fluconazole was well tolerated, mirroring the favorable safety profile seen in adults.

In 34 otherwise healthy infants with oral candidiasis randomized to either nystatin oral suspension qds for 10 days or fluconazole suspension 3 mg/kg in a single daily dose for 7 days, 6 of 19 were cured by nystatin and all of 15 by fluconazole (67). Fluconazole was tolerated without apparent adverse events.

Renal disease

If the creatinine clearance is below 40 ml/minute fluconazole doses should be adjusted (SED-12, 682) (7).

Drug–Drug Interactions

Alfentanil

In a randomized, double-blind, placebo-controlled, crossover study in nine subjects, fluconazole 400 mg reduced the clearance of alfentanil 20 micrograms/kg by 55% and increased alfentanil-induced subjective effects (68).

Amitriptyline

An interaction of fluconazole with amitriptyline has been reported (69).

- A 12-year-old boy with prostatic rhabdomyosarcoma had episodes of syncope periodically over 7 months while taking fluconazole for chemotherapy-induced mucositis. He had taken fluconazole in the past without problems but had also taken a stable dose of amitriptyline for neuropathic pain. On withdrawal of amitriptyline he had no further episodes. The effect was confirmed by readministration.

Concurrent administration of fluconazole probably causes increased exposure to amitriptyline. Three reports of adults have shown increased amitriptyline plasma concentrations with concurrent administration of fluconazole; in one patient, a 57-year-old woman, the QT interval was prolonged and torsade de pointes occurred (70).

Amphotericin

In vitro studies and experiments in animals have given conflicting results relating to potential antagonism between the effects of fluconazole and amphotericin on *Candida* species (71). However, large, randomized, double-blind comparisons of fluconazole with and without amphotericin for 5 days in non-neutropenic patients with

© 2006 Elsevier B.V. All rights reserved.

candidemia showed no evidence of antagonism, but faster clearance of the organism from the blood and a trend toward an improved outcome in those who received the combination (72).

Antacids

Fluconazole absorption after oral administration is not influenced by gastric pH; thus there is no effect of antacids such as co-magaldrox (SED-12, 682) (73).

Antihistamines

The concurrent use of terfenadine with fluconazole can lead to dangerously high terfenadine concentrations, with resulting cardiotoxicity (74). It is suspected that the same may happen with astemizole (75).

Benzodiazepines

The interaction of fluconazole with bromazepam has been studied in 12 healthy men in a randomized, double-blind, four-way, crossover study (76). They received single oral or rectal doses of bromazepam (3 mg) after 4-day pretreatment with oral fluconazole (100 mg/day) or placebo. Fluconazole caused no significant changes in the pharmacokinetics and pharmacodynamics of oral or rectal bromazepam.

Fluconazole increased blood concentrations of midazolam (77) and triazolam (78).

The effects of fluconazole (400 mg loading dose followed by 200 mg/day) on the kinetics of midazolam have been studied in 10 mechanically ventilated adults receiving a stable infusion of midazolam (79). Concentrations of midazolam were increased up to four-fold after the start of fluconazole therapy; these changes were most marked in patients with renal insufficiency. During the study, the ratio of α-hydroxymidazolam to midazolam progressively fell. The authors concluded that in ICU patients receiving fluconazole, reduction of the dose of midazolam should be considered if the degree of sedation is increasing.

In a study of the pharmacokinetics and pharmacodynamics of oral midazolam 7.5–15 mg, switching from inhibition of metabolism by itraconazole 200 mg/day to induction of metabolism by rifampicin 600 mg/day caused an up to 400-fold change in the AUC of oral midazolam (80).

Calcium channel blockers

- Fluconazole enhanced the blood pressure-lowering effects of nifedipine by increasing its plasma concentrations in a 16-year-old patient with malignant pheochromocytoma taking chronic nifedipine for arterial hypertension who was given fluconazole for *Candida* septicemia (81).

Carbamazepime

Fluconazole can cause carbamazepine toxicity, presumably by inhibition of CYP3A4 (82).

- A 33-year-old man on stable therapy with carbamazepine (400 mg tds) for a seizure disorder became stuporose due to carbamazepine toxicity after taking fluconazole 150 mg/day for 3 days. Withdrawal of both drugs resulted in a fall in carbamazepine concentrations (maximum concentration 25 μg/ml) and return of the patient's baseline mental status. Carbamazepine was restarted and the patient had no further adverse events.
- Carbamazepine serum concentrations increased during concomitant fluconazole administration (400 mg/day) in a 38-year-old man (83).

Ciclosporin

Fluconazole can increase concentrations of ciclosporin by inhibiting CYP3A4. In some studies, minimal or no effects were recorded, but in others ciclosporin concentrations were increased by fluconazole. Differences in the dosage and duration of fluconazole treatment could have explained these discrepancies (SED-12, 682) (21,84–87). For example, there was no interaction at a fluconazole dosage of 100 mg/day, but high dosages of fluconazole (400 mg/day or more) increase blood ciclosporin and tacrolimus concentrations (88,89).

The interaction of ciclosporin with fluconazole has been retrospectively evaluated in 19 kidney and pancreas/kidney transplant recipients (90). Both intravenous and oral fluconazole altered the blood concentration of ciclosporin. Five subjects did not have a significant interaction and 15 did. No patient had nephrotoxicity or transplant rejection related to antifungal therapy.

The effects of higher dosages of fluconazole on ciclosporin immunosuppression have been investigated in six renal transplant patients in a prospective, unblinded, crossover study (91). Baseline renal function, ciclosporin AUC, C_{max}, C_{min}, t_{max}, and clearance were compared with those 2, 4, and 7 days after starting fluconazole orally in a dosage of 200 mg/day. From day 8 onwards the ciclosporin dose was reduced by 50% and the above parameters were repeated on day 14. The results are shown in Table 1. On repeated-measures ANOVA only the AUC and C_{max} on day 4 of fluconazole were significantly higher than on day 0. There were no significant changes in ciclosporin clearance and t_{max}. The authors concluded that changes in C_{min} may not be sensitive enough to detect the described interaction and suggested monitoring the AUC near day 4 of treatment to guide ciclosporin dosage adjustments in all patients taking concomitant flucona\zole.

Table 1 Changes in ciclosporin kinetics during co-administration of fluconazole

Parameter	Day 0	Day 4	Day 7	Day 14
AUC (hours.ng/ml)	2887	4750	4052	2330
C_{max} (ng/ml)	701	941	768	498
C_{min} (ng/ml)	207	274	293	174
Clearance (ml/minute/kg)	17	13	12	30
t_{max} (hours)	3.0	2.0	2.5	3.0

Cimetidine

Fluconazole absorption after oral administration is not influenced by gastric pH; thus there is no effect of cimetidine.

Clarithromycin

The effects of fluconazole and clarithromycin on the pharmacokinetics of rifabutin and 25-*O*-desacetylrifabutin

© 2006 Elsevier B.V. All rights reserved.

have been studied in 10 HIV-infected patients who were given rifabutin 300 mg qds in addition to fluconazole 200 mg qds and clarithromycin 500 mg qds (92). There was a 76% increase in the plasma AUC of rifabutin when either fluconazole or clarithromycin was given alone and a 152% increase when both drugs were given together. The authors concluded that patients should be monitored for adverse effects of rifabutin when it is co-administered with fluconazole or clarithromycin.

Cyclophosphamide

Cyclophosphamide is a prodrug that is metabolized by CYP450 enzymes to produce alkylating species, which are cytotoxic, and the extent of cyclophosphamide metabolism correlates with both treatment efficacy and toxicity. In vitro studies in six human liver microsomes showed that the IC_{50} of fluconazole for reduction of 4-hydroxycyclophosphamide production was 9–80 μmol/l (93).

A retrospective study in 22 children with cancers addressed the potential interaction between fluconazole and cyclophosphamide. Children with an established profile of cyclophosphamide metabolism who were not receiving other drugs known to affect drug metabolism were selected; 9 were taking fluconazole and 13 were controls. The plasma clearance was significantly lower in patients taking concomitant fluconazole (2.4 versus 4.2 l/hour/m^2). It is unclear whether this interaction is associated with a reduction in the therapeutic efficacy of cyclophosphamide.

Doxorubicin

The effect of fluconazole on the plasma pharmacokinetics of doxorubicin has been investigated in a randomized, crossover study in non-human primates (94). Fluconazole (10 mg/kg/day) was given intravenously for 4 days before doxorubicin (2.0 mg/kg intravenously). Pretreatment with fluconazole had no effect on the pharmacokinetics of doxorubicin, and the incidence of severe neutropenia (absolute neutrophil count below 0.5×10^9/l) was higher with doxorubicin alone than with the combination of doxorubicin and fluconazole. Thus, fluconazole does not appear to contribute to the marrow-suppressive effects of doxorubicin.

Flucytosine

The concurrent use of fluconazole with flucytosine may have an additive effect (95). This combination could be useful in the treatment of cryptococcal meningitis (21).

HIV protease inhibitors

The pharmacokinetic interaction of fluconazole 400 mg od and indinavir 1000 mg tds has been evaluated in a placebo-controlled, crossover study for 8 days; there was no significant interaction (96).

The effect of fluconazole on the steady-state pharmacokinetics of ritonavir and saquinavir has been studied in patients infected with HIV-1 (97). They received the protease inhibitor (saquinavir 1200 mg tds, $n = 5$, or ritonavir 600 mg bd, $n = 3$) alone on day 1 and then with fluconazole 400 mg on day 2 and 200 mg on days 3–8. The median increase in saquinavir AUC was 50%, and the median increase in C_{max} was 56%. In contrast, fluconazole had no effect on the disposition of ritonavir.

Methadone

An interaction between fluconazole and methadone (a substrate of CYP3A4, CYP2C9, and CYP2C19) has been reported.

- While taking a stable dose of methadone, a 60-year-old man with advanced cancer developed respiratory depression 2 days after receiving intravenous fluconazole for refractory oral candidiasis (98). Intravenous naloxone reversed the respiratory depression.
