PATHOPHYSIOLOGY

The pathophysiologic alterations seen with POAG optic neuropathy are not fully understood. Elevated IOP is clearly associated with damage and eventual death of optic nerves; however, optic neuropathy can still occur in patients with normal IOP. Optic nerve degeneration in the absence of elevated IOP indicates the presence of independent factors that contribute to the death of the optic nerve. The key to understanding the pathophysiology and treatment of POAG relies on an understanding of aqueous humor dynamics and optic nerve anatomy and physiology.[4,5,10,11]

TABLE 58–2. Risk Factors for Glaucoma[2,9,34]

Primary Open-Angle Glaucoma	Primary Angle-Closure Glaucoma
Main Risk Factors • Elevated intraocular pressure • African or Hispanic descent • Family history of glaucoma • Older age • Thinner central corneal thickness	**Risk Factors** • Advancing age • Asian or Eskimo ethnicity • Female gender • Hyperopia • Shallow anterior chamber • Family history of angle-closure glaucoma
Possible Risk Factors • Systemic hypertension • Diabetes • Myopia • Low diastolic perfusion pressures	

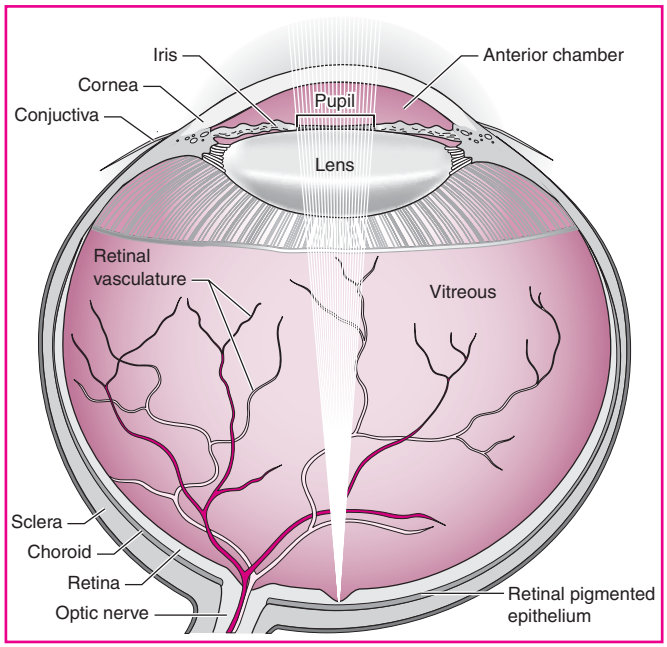

FIGURE 58–1. Anatomy of the eye. (From Lesar TS, Fiscella RG, Edward D. Glaucoma. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 1714, with permission.)

Aqueous Humor

The eye is separated into two segments by the lens: the anterior segment and the posterior segment (Figs. 58–1 and 58–2) The anterior segment of the eye is separated by the iris into the posterior and anterior chambers. The ciliary body, a ring-like structure that surrounds and supports the lens, produces and secretes an optically neutral fluid called aqueous humor through the diffusion and ultrafiltration of plasma. The nonpigmented epithelium of the ciliary body secretes the aqueous humor into the posterior chamber. Aqueous humor formation can be modified pharmacologically through the α- and β-adrenoceptors, carbonic anhydrase, and sodium and potassium activated adenosine triphosphatase of the nonpigmented ciliary epithelium.

After the transport of aqueous humor into the posterior chamber, it flows through the pupil into the anterior chamber where it provides oxygen and nutrition to the avascular lens and cornea. Aqueous humor then exits the anterior chamber through the trabecular meshwork and drains into Schlemm's canal which drains aqueous humor into the episcleral venous system.

Eighty percent of aqueous humor drains through the trabecular meshwork, which is a lattice of connective tissue that surrounds the anterior chamber. The size of the trabecular meshwork can be altered by the contraction or the relaxation of the ciliary muscle. Stimulation of muscarinic receptors on the ciliary muscle causes contraction, which in turn causes the pores of the trabecular meshwork to open, increasing aqueous humor outflow.

A second pathway, uveoscleral outflow, comprises the other 20% of aqueous humor drainage. In the uveoscleral pathway, aqueous humor exits the anterior chamber through the iris root and through spaces in the ciliary muscles, which then drains into suprachoroidal space. Uveoscleral outflow can be pharmacologically modulated by adrenoceptors, prostanoid receptors, and prostamide receptors.[4,10,12–15]

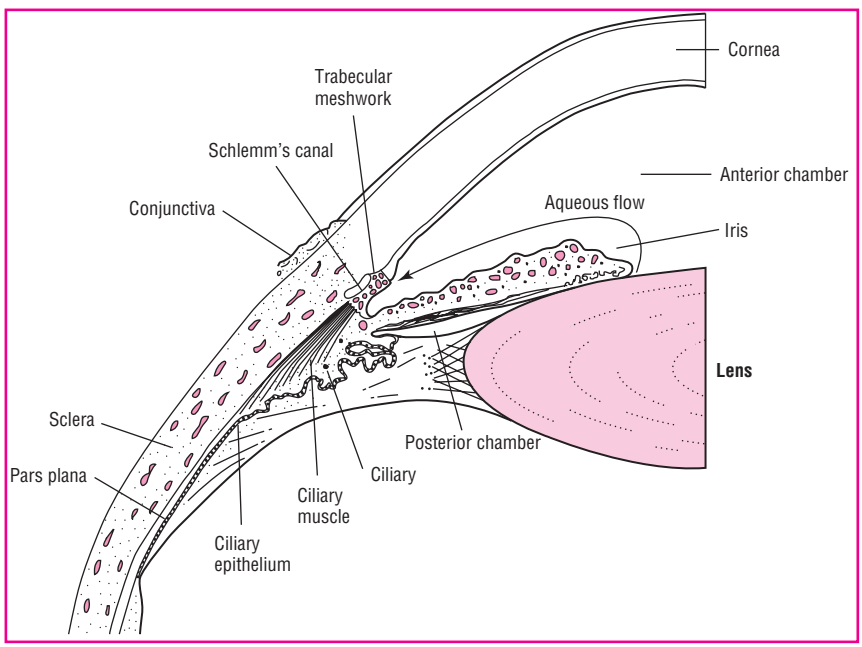

FIGURE 58–2. Anterior chamber of the eye and aqueous humor flow. (From Lesar TS, Fiscella RG, Edward D. Glaucoma. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 1715, with permission.)

Intraocular Pressure

IOP is dependent upon the balance between aqueous humor production and outflow, and is important because the refractive properties of the eye depend on IOP to maintain the curvature of the cornea.[16] The distribution of IOP in the population is 10 to 21 mm Hg and is slightly skewed towards higher values; however, caution should be used in assigning this range as being "normal" for IOP since optic neuropathy can be present in the normal range and can be absent at higher IOPs. Elevated IOP is generally considered to be greater than 21 mm Hg. Optic nerve damage generally is slow and takes several years for noticeable progression between 20 and 30 mm Hg, while an IOP of 40 to 50 mm Hg may lead to rapid optic nerve damage. IOP varies in a cyclic fashion over the 24-hour day. IOP was thought to be lowest at night and at its maximum in the morning; however, more recent evidence suggests that not all individuals follow this pattern. Patients with and without glaucoma may exhibit a rhythm that consists of a peak in IOP right after falling asleep. Nighttime peaks in IOP are detrimental to patients with glaucoma, because systemic blood pressure decreases during the night, leading to a low ocular perfusion pressure. Decreased ocular perfusion pressure can lead to further optic nerve damage, therefore highlighting the importance of IOP control throughout the day.[11,17,18]

IOP is clinically measured by tonometry and can be performed via applanation, indentation, and indirect tonometry.[19] CCT affects the accuracy of IOP measurements. Thin corneas (less than 540 microns) can produce falsely low IOP readings, whereas thick corneas (greater than 555 microns) may produce falsely high readings. The potential consequences of this error in measurement may lead to overtreatment of patients with falsely high IOP and undertreatment of patients with falsely low IOP. The Ocular Hypertension Study demonstrated that CCT is a strong predictive factor for the development of POAG. Patients with corneas less than 555 microns and IOP greater than 25.75 mm Hg had a 36% risk of progressing from ocular hypertension to glaucoma. The CCT should be taken into account when evaluating a patient's IOP.[7] IOP is no longer used as a diagnostic criterion for glaucoma, since the presence of glaucomatous changes can be absent at high IOPs and can be present at lower IOPs. Ocular hypertension is present in about 3 to 6 million people in the United States population; however, less than 10% will have progression to POAG within 5 years.[7] Patients who have a baseline IOP of less than 21 mm Hg with no single measurement greater than 24 mm Hg and meet the criteria for POAG are considered to have normal-tension glaucoma (NTG). Fifteen to forty percent of patients diagnosed with POAG actually meet the criteria for NTG.[2,20]

Optic Nerve

The posterior segment of the eye contains vitreous humor (a clear jelly-like substance), the retina, the retinal vasculature, and the optic nerve head. The retina transforms light energy into neural signals, which are transmitted out of the eye by the retinal ganglion cells. The axons of the retinal ganglion cells converge and exit at the optic nerve head (optic disc) to form the optic nerve (Fig. 58–3). The optic nerve contains one million nerve fibers and synapses at the lateral **geniculate nucleus** of the brain. The optic nerve head is the portion of the optic nerve that is susceptible to elevations in IOP and is visible on funduscopic examination. The optic nerve head is vertically oval and pale yellow with a depression in the center of the optic nerve, called a physiologic cup, which is formed by convergence of the axons. The area surrounding the optic nerve head is the nerve fiber layer, which consists of converging retinal ganglion cell axons. The nutrition of the retina is dependent upon the transport of trophic factors from the retinal cell ganglion axons to their cell bodies.

Glaucomatous changes to the optic nerve head precede visual field loss, making optic nerve head evaluation a useful screening and prognostic tool. The optic nerve head should be assessed for cupping, nerve fiber layer changes, and the presence of splinter hemorrhages using a **slitlamp biomicroscope**. Cupping refers to an increase in the size of the physiologic cup. The cup increases with the loss of retinal ganglion cell axons and the collapse the **lamina cribrosa**. The cup size is expressed as the ratio of the size of the cup to the size of the optic nerve head. A cup-to-disc ratio greater than 0.55 is associated with an increased risk of developing visual field loss. Other findings include atrophy and notching of the nerve fiber layer.[4,5,21,22] The pathophysiology of glaucomatous neurodegeneration has not been completely elucidated. It is unclear whether the optic neuropathy is caused by increased IOP, decreased retinal blood flow, or a combination of these factors.[4,5] Several theories, including autoimmune reactions, excess nitric oxide, and glutamate toxicity have been proposed as to what ultimately causes the retinal ganglion cells to undergo apoptosis.[4,5,23]

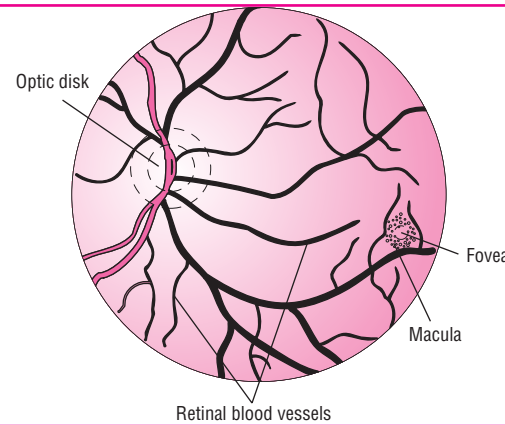

FIGURE 58–3. Normal fundus of the eye and optic disk and cup. (From Lesar TS, Fiscella RG, Edward D. Glaucoma. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 1715, with permission.)

The level of IOP is related to the death of retinal ganglion cell and optic nerve fibers. As optic neurodegeneration progresses over time, the optic nerve becomes more susceptible to high IOP. Increased IOP causes the retinal ganglion cell axons to undergo mechanical stress, alters axonal protein transport, and decreases blood supply to the retina and the optic nerve, leading to tissue ischemia.[4,22,24] Glaucomatous optic neuropathy may also occur independent of increased IOP as illustrated by the fact that 15% to 40% of patients with POAG meet criteria for NTG and 25% to 38% of patients will have progression of their POAG despite control of IOP. Pressure-independent causes of optic neuropathy include abnormal blood flow, systemic hypotension, and abnormal blood coagulability.[11,19] Current glaucoma therapies fail to target IOP-independent glaucoma pathophysiologic factors. However, IOP reduction may still be beneficial, as the rate of visual field progression is decreased in some patients that receive IOP reduction via medical or surgical modalities.[25,26]

Pathophysiology of Angle-Closure Glaucoma

PACG involves a mechanical obstruction of aqueous humor outflow through the trabecular meshwork by the peripheral iris. Two major mechanisms of trabecular meshwork obstruction by the peripheral iris include pupillary block and an abnormality of the iris called iris plateau. Pupillary block is the more common mechanism of obstruction and results from a complete or functional apposition of the central iris to the anterior lens and is associated with mid-dilation. The trapped aqueous humor increases pressure behind the iris causing the peripheral iris to bow forward and obstruct the trabecular meshwork. Plateau iris refers to an anterior displacement of the peripheral iris caused by anteriorly positioned ciliary processes. In this configuration the peripheral iris bunches as the eye dilates. Both of these mechanisms result in the occlusion of aqueous humor outflow, causing IOP elevation at extreme levels that can lead to vision loss in hours to days.[5,9,21,27,28] The degree of obstruction or angle closure can be determined by **gonioscopy**.

The development of PACG is associated with several anatomic risk factors that lead to shallow anterior chambers. PACG patients may have a thick, anteriorly displaced lens that results from myopia or old age. The axial length of the eye is smaller in individuals with PACG, which leads to a lens that is situated more anteriorly than those without PACG.[27,28]

Medications with anticholinergic properties induce mydriasis, which can lead to angle closure in pupillary block and plateau iris. Pupillary block may also be induced by drugs that cause miosis.[12]

PACG can be separated into three categories: acute primary angle closure, subacute primary angle closure, and chronic primary angle closure. Acute PACG is the sudden obstruction of the trabecular meshwork which leads to rapid increases in IOP resulting in pressure-induced optic neuropathy if left untreated. ❷ *Acute PACG is a medical emergency and requires laser or surgical intervention.* Subacute PACG is characterized by self-limiting angle closure that resolves spontaneously. Recurrent attacks or a prolonged acute attack can lead to the development of peripheral anterior **synechia**. Chronic PACG is characterized by the presence of peripheral anterior synechia that partially obstruct the flow of aqueous humor through the trabecular meshwork resulting in an elevated IOP that is similar to what it is seen in POAG.[9,27,28]

Clinical Course

❸ *Patients with ocular hypertension or POAG typically have a slow, insidious loss of vision. This is contrasted by the course of acute PACG which can lead to rapid vision loss that develops over hours to days.* For POAG, only 4% to 8% of patients may progress to legal blindness. It may take 13 to 16 years for a patient to go blind from glaucoma. A patient's quality of life may not be affected until significant visual field loss is present and the

Clinical Presentation of Primary Open-Angle Glaucoma

General
- Adult onset (usually greater than 40 years of age).
- Patients may be unaware they have glaucoma and may be diagnosed during routine eye evaluation.
- POAG is usually bilateral with asymmetric disease progression.

Symptoms
- Patients with severe disease progression may report loss of peripheral vision and may describe the presence of scotomata (blind spots) in their field of vision.

Signs

Ophthalmoscopic examination may reveal:

- Optic nerve head (optic disc) cupping.
- Large cup-to-disc ratio.
- Diffuse thinning, focal narrowing, or notching of the optic nerve head rim.
- Splinter hemorrhages.
- Optic nerve head and nerve fiber layer changes occur before visual field changes can be detected.

Diagnostic Tests
- Gonioscopy: anterior chamber angles are open.
- Applanation tonometry: elevated IOP (greater than 21 mm Hg) may be present; however, a patient can have signs of optic neuropathy without elevated IOP.
- Pachymetry: measures central corneal thickness; thin corneas (less than 540 microns) are considered a glaucoma risk factor.
- Automated static threshold perimetry: evaluates visual fields; useful in diagnosis and determining if there is disease progression.
- Other diagnostic tests: scanning laser polarimetry, confocal scanning laser ophthalmoscopy, and optical coherence tomography.

Clinical Presentation of Acute Angle-Closure Glaucoma

General
- Medical emergency due to high risk of vision loss.
- Unilateral in presentation, but the fellow eye is at risk.

Symptoms
- Ocular pain.
- Red eye.
- Blurry vision.
- Halos around lights.
- Systemic symptoms may develop:
  1. Nausea and vomiting.
  2. Abdominal pain.
  3. Headache.
  4. Diaphoresis.

Signs
- Cloudy cornea caused by corneal edema.
- Conjunctival hyperemia.
- Pupil semi-dilated and fixed to light.
- Eye will be harder on palpation through closed eyelid.

Diagnostic Tests
- Gonioscopy: anterior chamber angles will be closed; peripheral anterior synechiae may be present.
- Applanation tonometry: elevated IOP (greater than 21 mm Hg, but when symptoms are present IOP may be greater than 30 mm Hg).
- Slitlamp biomicroscopy: reveals shallow anterior chamber depth; signs of previous attacks include peripheral anterior synechiae, iris atrophy, glaukomflecken, and pupillary dysfunction.

patient can no longer perform the activities of daily living.[29] Vision loss does not occur until there has been significant loss of the retinal ganglion cells. Peripheral vision is the most susceptible to glaucomatous damage, with central vision being preserved until advanced disease progression has occurred. Visual field abnormalities include **paracentral scotoma**, **nasal scotoma**, and **arcuate scotoma**. Patients may also have problems with depth perception and contrast sensitivity. Peripheral vision may worsen until the patient has tunnel vision and ultimately total field loss. Visual fields can be measured by **perimetry** and can detect defects in the visual field before a patient may notice.[4,5,12]

TREATMENT

Primary Open-Angle Glaucoma

Desired Outcomes and Goals

❹ *The goals of therapy are to prevent further loss of visual function; minimize adverse effects of therapy and its impact on the patient's vision, general health, and quality of life; maintain IOP at or below a pressure at which further optic nerve damage is unlikely to occur; and educate and involve the patient in the management of their disease.* ❺ *Current therapy is directed at altering the flow of aqueous humor, which is the major determinant of IOP.*

General Approach

❻ *Since POAG is a chronic, often asymptomatic condition, the decision of when and how to treat patients is difficult since the treatment modalities are often expensive and have potential adverse effects or complications. The clinician should evaluate the potential effectiveness, toxicity, and the likelihood of patient adherence for each therapeutic modality. The ideal therapeutic regimen should have maximal effectiveness and patient tolerance to achieve the desired therapeutic response.* The American Academy of Ophthalmology (AAO) publishes Preferred Practice Patterns for POAG and POAG Suspect.[2]

Prior to the selection of a therapeutic modality, the target IOP should be determined for each patient. The target IOP ideally represents an IOP range that will slow the progression of optic neuropathy, not simply obtaining an IOP in the range of 10 to 21 mm Hg. Currently, the initial target IOP is an estimate, but it should be modified based on the progression of the disease at each follow-up visit. ❼ *The AAO recommends an initial target IOP to be set at 20% lower than the patient's baseline IOP. The target IOP can be set lower (30% to 50% of baseline IOP) for patients that already have severe disease or have normal-tension glaucoma.*[2,25,26]

Initial IOP control can be achieved by medical, laser, surgical, or a combination of these therapies. The AAO guidelines do not provide a specific recommendation on which therapeutic modality should be selected first, but patients in the early stages of glaucoma should receive treatment. The Early Manifest Glaucoma Trial evaluated the effectiveness of reducing IOP in early untreated POAG. The trial demonstrated that patients who received a topical medication combined with laser therapy had slower progression of glaucoma by an average of 18 months.[30] Initial therapy with laser trabeculoplasty is at least as effective as treatment with a topical β-adrenergic antagonist in preserving visual function and optic nerve head status and can be considered as initial treatment.[2] Even though initial treatment of POAG with surgical trabeculectomy compared to medical therapy has similar visual field outcomes at 5 years, surgical intervention is associated with more eye discomfort and increased risk of cataract development.[20,25,26] Surgical therapy is typically not considered as a first-line therapy.[4] Medical treatment is the most commonly selected therapeutic modality. A well-tolerated ocular antihypertensive at the lowest concentration should be selected as the initial mediation (Table 58–3). If monotherapy alone lowers IOP but does not reach target pressure, then combination therapy or switching to another agent is appropriate. Increasing the concentration or dose frequency can also be tried when possible (Figure 58–4). A uniocular trial can be used to assess the safety and effectiveness of a topical medication prior

TABLE 58–3. Topical Drugs Used in the Treatment of Open-Angle Glaucoma

Drug	Pharmacologic Properties	Common Brand Names	Dose Form	Strength (%)	Usual Dose[a]	Mechanism of Action
β-Adrenergic Blocking Agents						
Betaxolol	Relative β_1-selective	Generic	Solution	0.5	1 drop twice a day	All reduce aqueous production of ciliary body
		Betoptic-S	Suspension	0.25	1 drop twice a day	
Carteolol	Nonselective, ISA	Generic	Solution	1	1 drop twice a day	
Levobunolol	Nonselective	Betagan	Solution	0.25, 0.5	1 drop twice a day	
Metipranolol	Nonselective	OptiPranolol	Solution	0.3	1 drop twice a day	
Timolol	Nonselective	Timoptic, Betimol	Solution	0.25, 0.5	1 drop every day—one to two times a day	
		Timoptic-XE	Gelling solution	0.25, 0.5	1 drop every day[a]	
Nonspecific Adrenergic Agonists						
Dipivefrin	Prodrug	Propine	Solution	0.1	1 drop twice a day	Increased aqueous humor outflow
α_2-Adrenergic Agonists						
Apraclonidine	Specific α_2-agonists	Iopidine	Solution	0.5, 1	1 drop two to three times a day	Both reduce aqueous humor production; brimonidine known to also increase uveoscleral outflow
Brimonidine		Alphagan P	Solution	0.15, 0.1	1 drop two to three times a day	
Cholinergic Agonists Direct-Acting						
Carbachol	Irreversible	Carboptic, Isopto Carbachol	Solution	0.75, 1.5, 2.25, 3	1 drop two to three times a day	All increase aqueous humor outflow through trabecular meshwork
Pilocarpine	Irreversible	Isopto Carpine, Pilocar	Solution	0.25, 0.5, 1, 2, 4, 6, 8, 10	1 drop two to three times a day 1 drop four times a day	
		Pilopine HS	Gel	4	Every 24 hours at bedtime	
Cholinesterase Inhibitors						
Echothiophate		Phospholine iodide	Solution	0.125	Once or twice a day	
Carbonic Anhydrase Inhibitors						
Topical						
Brinzolamide	Carbonic anhydrase type II inhibition	Azopt	Suspension	1	Two to three times a day	All reduce aqueous humor production of ciliary body
Dorzolamide		Trusopt	Solution	2	Two to three times a day	
Systemic						
Acetazolamide		Generic	Tablet	125 mg, 250 mg	125–250 mg two to four times a day	
			Injection	500 mg/vial	250–500 mg	
		Diamox Sequels	Capsule	500 mg	500 mg twice a day	
Dichlorphenamide		Daranide	Tablet	50 mg	25–50 mg one to three times a day	
Methazolamide		Generic	Tablet	25 mg, 50 mg	25–50 mg two to three times a day	

(*Continued*)

TABLE 58–3. Topical Drugs Used in the Treatment of Open-Angle Glaucoma (*Continued*)

Drug	Pharmacologic Properties	Common Brand Names	Dose Form	Strength (%)	Usual Dose[a]	Mechanism of Action
Prostaglandin Analogs						
Latanoprost	Prostaglandin $F_{2\alpha}$ analog	Xalatan	Solution	0.005	1 drop every night	Increases aqueous uveoscleral outflow and to a lesser extent trabecular outflow
Bimatoprost	Prostamide analog	Lumigan	Solution	0.03	1 drop every night	
Travoprost		Travatan	Solution	0.004	1 drop every night	
Combinations						
Timolol-dorzolamide		Cosopt	Solution	Timolol 0.5% Dorzolamide 2%	1 drop twice daily	

[a]Use of nasolacrimal occlusion will increase the number of patients successfully treated with longer dosage intervals.
ISA, intrinsic sympathomimetic activity.
From Lesar TS, Fiscella RG, Edward D. Glaucoma. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 1722, with permission.

to initiation in both eyes; however, uniocular drug trials do not predict the IOP response of the second eye, and the effect of a medication must be assessed independently using baseline IOP measurements. The lack of correlation between IOP of fellow eyes may be explained by asymmetric IOP in each eye or the potential for contralateral IOP lowering of a uniocularly applied medication.[31,32]

Treatment Considerations for the Treatment of Ocular Hypertension

POAG suspects should be considered for topical medication therapy if they can be expected to develop optic nerve damage or they may already have early glaucomatous nerve damage that cannot be reliably diagnosed because of inconclusive exam findings. The Ocular Hypertension Treatment Study demonstrated that a 20% decrease in IOP can reduce the progression from ocular hypertension to POAG over a 5-year period. The incidence of progression to POAG in the treatment (4.4%) and control (9.5%) groups was small, which underscores the importance of selecting patients at high-risk of progressing to POAG.[33] When medical therapy is indicated, a well-tolerated agent should be selected and optimized following the POAG algorithm (Fig. 58–4). The risk-to-benefit ratio of therapy should be reassessed in patients that may require third- or fourth-line agents to control IOP. Surgical or laser intervention are rarely indicated in the treatment of glaucoma suspects.[34]

Nonpharmacologic Therapy

Laser trabeculoplasty uses laser energy aimed at the trabecular meshwork to improve the outflow of aqueous humor and can be used as first-line therapy, especially in patients unable or unwilling to adhere to medical therapy. Laser trabeculoplasty may be used as bridge therapy between medical and surgical intervention, and approximately 50% of laser trabeculoplasty procedures will fail at 10 years. Trabeculectomy is the removal of a portion of the trabecular meshwork to improve aqueous humor outflow. Failure rates of trabeculectomy are less compared to laser trabeculoplasty (20% to 30% failure at 10 years). The most common reason for trabeculectomy failure is scarring of the channel created by the partial removal of the trabecular meshwork. Mitomycin C and fluorouracil are used as antifibrotic agents to decrease scarring at the site of trabeculectomy; however, patients undergoing trabeculectomy are also at increased risk of developing cataracts.[2,4,35]

Ethnicity should be considered with respect to the sequence of surgical or laser therapy in patients that fail maximal medical therapy. The Advanced Glaucoma Intervention Study found that African-Americans who have failed medical therapy had better long-term visual function outcomes if they received argon laser trabeculoplasty, while Caucasians had better long-term visual function outcomes if they received surgical trabeculectomy.[35] Other surgical procedures include cyclodestructive and non-penetrating glaucoma surgery. Patients should be educated about the risks and benefits of laser and surgical intervention. Patients should understand that they may require additional procedures or medical therapy to main long-term IOP control.[2,4]

Primary Angle-Closure Glaucoma

Desired Outcomes and Goals

Therapeutic modalities for PACG are targeted at decreasing IOP. The goals of therapy are to preserve visual function by controlling the elevation in IOP, manage an acute attack of angle closure, reverse or prevent angle closure using a laser and/or surgical intervention, and educate and involve the patient in the management of the disease.[9]

General Approach

The treatment of choice for PACG is laser iridotomy. Medical therapy is used to lower IOP, reduce pain, and reverse corneal edema prior to the iridotomy. IOP should first be lowered

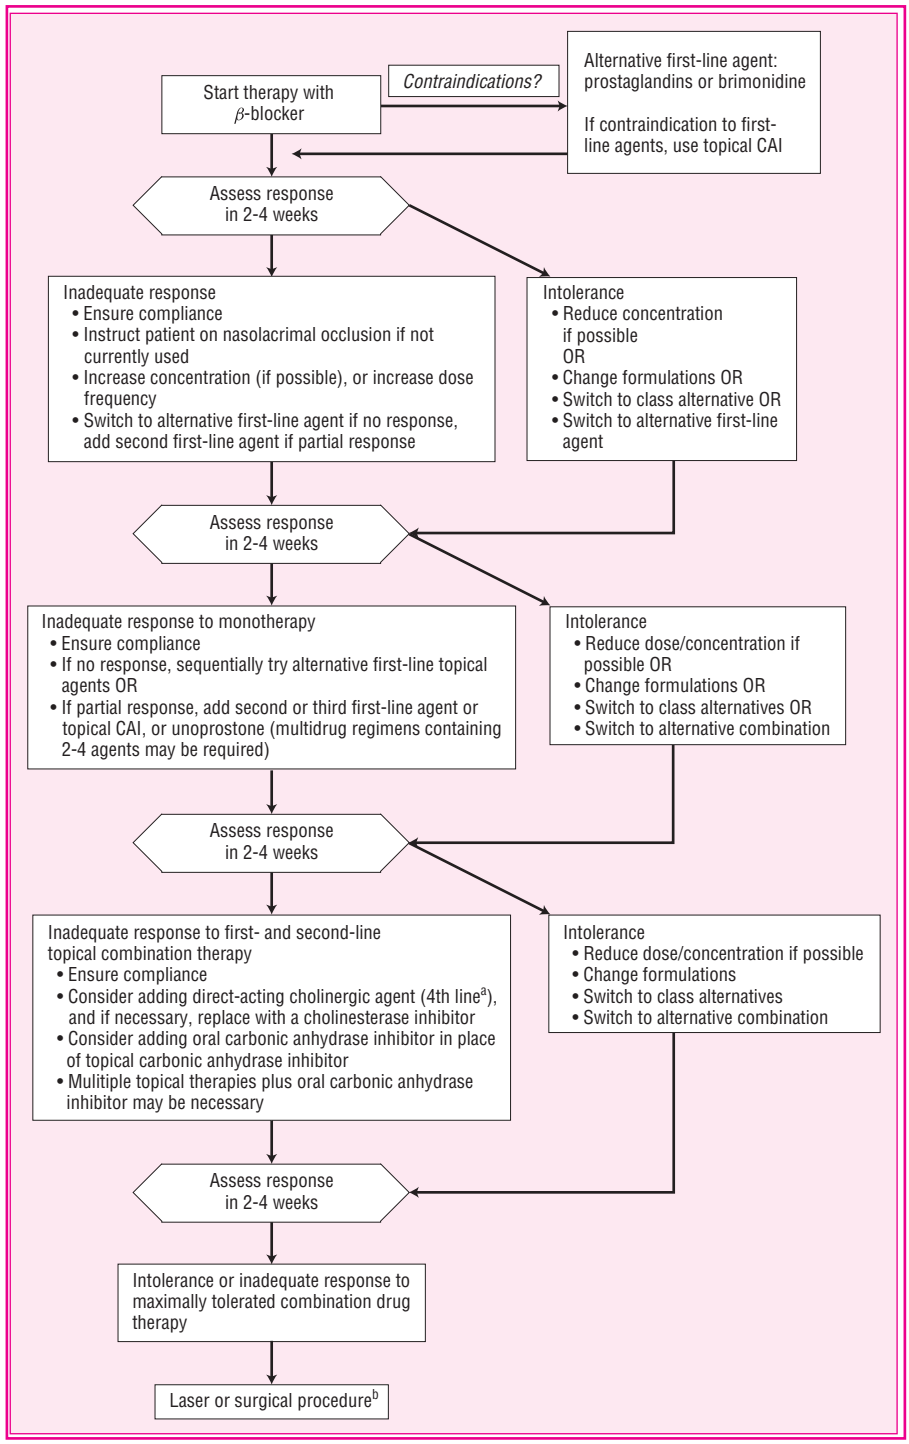

FIGURE 58–4. Algorithm for the pharmacotherapy of open-angle glaucoma.
[a]Fourth-line agents not commonly used any longer.
[b]Most clinicians believe laser procedure should be performed earlier (e.g., after three-drug maximum, poorly adherent patient).
CAI, carbonic anhydrase inhibitor. (From Lesar TS, Fiscella RG, Edward D. Glaucoma. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 1720, with permission.)

with topical β-blockers, topical α-agonists, prostaglandin $F_{2\alpha}$ analogs, systemic carbonic anhydrase inhibitors, or hyperosmotic agents. Once the IOP has been controlled, miotics (i.e., pilocarpine) can be used to break the pupillary block. A topical IOP-lowering agent should be continued to control IOP until laser iridotomy can be performed. Corneal indentation with a cotton-tipped applicator or gonioscopic lens may break pupillary block. If laser iridotomy cannot be performed, incisional iridectomy is used. A topical corticosteroid may be employed to decrease inflammation. The fellow eye is at high risk of having an acute attack and should receive prophylactic iridotomy. Patients with chronic angle closure should also receive laser iridotomy. Acute and chronic angle-closure patients may require chronic medical therapy if the patient has PACG superimposed on preexisting POAG, or synechia formation causes continued increases in IOP.[5,36]

Nonpharmacologic Therapy

Laser iridotomy uses laser energy to cut a hole in the iris to alleviate the aqueous humor build-up behind the iris, resulting in reversal of appositional angle closure. Incisional iridectomy is the surgical removal of a small portion of the iris to allow drainage of aqueous humor trapped in the posterior chamber. Surgical iridectomy is reserved for when laser iridotomy is not possible or indicated.[5,9,36]

Pharmacologic Therapy

Beta-Adrenergic Antagonists

Topical β-adrenergic antagonists (β-blockers) are generally considered first-line agents for the treatment of POAG unless contraindications are present.[10,13] Topical β-blockers decrease IOP by reducing the formation of aqueous humor made by the ciliary body, which results in a 20% to 35% reduction in IOP.[10,13,37] Timolol, levobunolol, metipranolol, and carteolol are non-selective for β_1- and β_2-adrenergic receptors, while betaxolol has β_1-selective properties. All of the topical β-blockers have similar efficacy and adverse-effect profiles. Betaxolol reduces IOP to a lesser extent than the non-selective β-blockers, but may cause less exacerbation of pulmonary disease. Despite the intrinsic sympathomimetic activity demonstrated by carteolol, this does not translate into a clinically significant decrease in pulmonary or cardiovascular adverse effects.

Topical β-blockers are typically administered twice daily. A gel-forming solution of timolol (Timoptic-XE) can be administered once daily. Tachyphylaxis may occur in 20% to 50% of patients on monotherapy with a β-blocker, resulting in the need for a different agent or combination therapy. Patients on concurrent systemic β-blockers may experience less IOP reduction than patients only on topical β-blockers.[10,38]

Ocular medication requires the use of concentrated drug solutions to penetrate the eye. Excess drug drains into the nose via the nasolacrimal duct where it is absorbed into the systemic circulation. β-Blockers can cause significant systemic adverse effects through this pathway, since first-pass hepatic metabolism is bypassed, resulting in pharmacologically significant serum drug concentrations.[39] Bronchospasm is the most common pulmonary effect of topical β-blockers. Pulmonary edema, status asthmaticus, and respiratory arrest have been reported with β-blockers as well. Cardiovascular effects include bradycardia, hypotension, and congestive heart failure exacerbation. As with systemic β-blockers, topical β-blockers have also been reported to cause depression, hyperlipidemia, and mask symptoms of hypoglycemia. Topical β-blockers are generally contraindicated in patients with asthma, chronic obstructive pulmonary disease, sinus bradycardia, second- or third-degree heart block, cardiac failure, and hypersensitivity to the product.[10,23,39–41]

Local side effects are usually tolerable and may be caused by preservatives, therefore switching from one product to another may alleviate the local side effects. Stinging of the eyes upon instillation is the most common adverse effect. Other local adverse effects include conjunctivitis, keratitis, dry eyes, and **uveitis**.[10,13]

Patients prescribed topical β-blockers should be counseled on the nasolacrimal occlusion technique to decrease systemic absorption.

Ocular Hypotensive Lipids

The ocular hypotensive lipids in typical ophthalmology practice are considered first-line alternatives to topical β-blockers because of their superior efficacy and safety profiles. Many clinicians may choose to use the ocular hypotensive lipids as first-line agents, especially in patients that have an initial requirement to lower IOP by more than 25%, or in patients that have relative or absolute contraindications to topical β-blockers. However, latanoprost is currently the only ocular hypotensive lipid drug that has a Food and Drug Administration (FDA) indication for first-line therapy. Bimatoprost and travoprost are indicated by the FDA for patients who are intolerant of other IOP-lowering therapy or insufficiently responsive to another IOP-lowering medication.[10,38]

Latanoprost and travoprost are analogs of prostaglandin $F_{2\alpha}$ and are agonists of the prostanoid FP receptor, which appears to lower IOP by increasing aqueous humor outflow through the uveoscleral pathway. Bimatoprost is a prostamide analog and appears to lower IOP by activating prostamide receptors in the uveoscleral pathway and possibly through increasing outflow through the trabecular meshwork. The exact mechanism is still unclear of how uveoscleral outflow is increased, but stimulation of prostanoid FP receptors and prostamide receptors in the ciliary body cause remodeling of the extracelluar matrix, making it more permeable to aqueous humor, thus increasing aqueous humor outflow through the ciliary muscles.[14,15,42]

Latanoprost, travoprost, and bimatoprost are administered once daily at bedtime and should not be increased to twice daily, as this may decrease effectiveness. These agents lower IOP by 25% to 35% and unlike topical β-blockers, can effectively lower nocturnal IOP, providing IOP control throughout the day and night. The prostaglandin analogs can be used as monotherapy or combination therapy.[10,38] For patients who are non-responsive to latanoprost, switching to brimatoprost may allow some patients to reach their IOP goal, presumably because of the proposed difference in the site of action of each drug.[43,44]

The ocular hypotensive lipids are well tolerated and rarely cause systemic side effects (though headache has been reported). Local effects include conjunctival hyperemia, stinging on instillation, an increase in iris pigmentation, **hypertrichosis**, and darkening of the eyelashes. Increases in iris pigmentation occur most commonly in patients with multi-colored irides on long-term prostaglandin analog therapy. The mechanism of this effect is by its action on melanocytes of the iris, in which the irides become darker because of increased production of melanin in the iris.[45,46] The 12-month incidence of iris pigmentation varies between the agents. Latanoprost appears have the highest incidence of iris pigmentation after 12 months of therapy (5.2% to 25%) compared to travoprost (3.1%) and bimatoprost (1% to 5.5%).[47–52] The increase in pigmentation may be irreversible or may reverse at a very slow rate. Increased iris pigmentation

appears to be only a cosmetic effect, but may affect product selection, especially when choosing monocular therapy. Conjunctival hyperemia or engorgement of conjunctival blood vessels is a common adverse effect caused by a vasodilatory effect on scleral blood vessels. It is most prominent early in therapy and usually subsides over time. While generally a benign adverse effect, patients may have a concern if it affects their cosmetic appearance. Latanoprost has the lowest incidence of hyperemia (14% to 27.6%) compared to bimatoprost (9% to 46%) and travoprost (49.5%).[47–52] The ocular hypotensive lipids should be used with caution in some patients, since they may worsen anterior uveitis and herpetic keratitis. Cystoid macular edema has been reported during treatment with the ocular hypotensive lipids, therefore use caution in patients with intraocular inflammation, **aphakic** patients, **pseudophakic** patients with a torn posterior lens capsule, or in patients with risk factors for macular edema.[10,38]

Patients prescribed ocular hypotensive lipids should be counseled on potential adverse effects and appropriate administration. Patients receiving latanopost therapy should be instructed to refrigerate the dropper bottle until opened. After the bottle has been opened it can be stored at room temperature for 6 weeks.

Alpha$_2$-Adrenergic Agonists

Brimonidine and apraclonidine are α_2-adrenergic agonists that decrease IOP by reducing aqueous humor production. Brimonidine has a higher selectivity to the α_2 receptor than apraclonidine and has a dual mechanism of action by increasing uveosceral outflow.[10,14] Brimonidine may have neuroprotective effects that are being studied in the Low-Pressure Glaucoma Treatment Study.[53] Apraclonidine is often used for the prevention and treatment of post-surgical IOP elevations and no longer commonly used for long-term treatment of POAG because of tachyphylaxis and a high rate of blepharoconjunctivitis. Brimonidine lowers IOP by 14% to 28%. Peak IOP-lowering effect is similar to that of timolol, but the trough IOP-lowering effect is less than with timolol. Brimonidine is usually administered every 8 hours. A 12-hour dosing schedule may be employed by using nasolacrimal occlusion when instilling the drops. Brimonidine-purite 0.1% and 0.15% solution (Alphagan P®) has similar efficacy compared to the brimondine 0.2% solution, because the purite solution's higher pH allows for more drug to penetrate the cornea.[10,13,14]

Apraclonidine and brimonidine cause both local and systemic effects. Local effects of apraclonidine include blepharoconjunctivitis, foreign body sensation, pupillary mydrasis, and eyelid retraction. Brimonidine does not cause the α_1-mediated mydrasis and eyelid retraction, but does cause blepharoconjunctivitis, though at a lesser rate than apraclonidine. The brimonidine-purite solution has a lower incidence of ocular allergy. Systemic effects of both agents include headache, dry mouth, and fatigue.

Brimonidine is typically used as an adjunctive agent in combination with other agents but could be used as a first-line agent as well. The frequency of dosing and local adverse effects may lead to non-adherence in some patients. Patients prescribed brimonidine should be counseled on the nasolacrimal occlusion technique to reduce systemic adverse effects and to improve efficacy.[10,13]

Carbonic Anhydrase Inhibitors

Carbonic anhydrase inhibitors decrease aqueous humor production by inhibition of the carbonic anhydrase isoenzyme II located in the ciliary body. In the eye, carbonic anhydrase catalyzes the conversion of water and carbon dioxide to bicarbonate and hydrogen ion, which is a significant step in aqueous humor production. Carbonic anhydrase inhibitors are available in systemic and topical preparations.[10,13,14]

Topical Carbonic Anhydrase Inhibitors

Dorzolamide and brinzolamide are the only topical carbonic anhydrase inhibitors available and lower IOP by 15% to 24%. Both medications are administered every 8 hours and are used as adjunctive therapy or as monotherapy for patients that cannot tolerate first-line agents. Nasolacrimal occlusion may allow for dosing every 12 hours.[10,13] Recently the European Glaucoma Prevention study found that dorzolamide did not prevent the progression of patients with ocular hypertension to POAG despite a 15% to 22% reduction of IOP over 5 years. Unlike the Ocular Hypertension Treatment Study, a goal IOP reduction of at least 20% was not required for treatment, and surprisingly, the placebo treatment had a clinically significant effect on IOP.[54]

Local side effects include burning, stinging, itching, foreign body sensation, dry eyes, and conjunctivitis. Brinzolamide may have a lower incidence of these side effects since the drug is in a neutral pH solution. Dorzolamide has been reported to cause irreversible corneal decompensation. Taste abnormalities have been reported with each agent. Both topical carbonic anhydrase inhibitors are sulfonamides and are contraindicated in patients with history of sulfonamide hypersensitivity.[10,13]

A combination product of timolol (0.5%) and dorzolamide (2%) (Cosopt™) is available and can be administered twice daily and provides an additive reduction in IOP.

Systemic Carbonic Anhydrase Inhibitors

There are three systemic carbonic anhydrase inhibitors: acetazolamide, dichlorphenamide, and methazolamide. These agents effectively lower IOP by 20% to 30% but are reserved as third-line agents because of their significant adverse effects. They are typically used as bridge therapy from maximal medical therapy to laser or surgical intervention. The systemic carbonic anhydrase inhibitors can also be used to lower IOP in acute angle-closure glaucoma. Acetazolamide has an intravenous formulation that can be utilized in patients having nausea due to the angle-closure attack. Acetazolamide and methazolamide are the best tolerated of the three agents.

The systemic carbonic anhydrase inhibitors are associated with significant adverse effects which include paresthesias of the hands and feet, nausea, vomiting, and weight loss. Patients

can develop systemic acidosis, hypokalemia, hyponatremia, and nephrolithiasis due to the inhibition of renal carbonic anhydrase. Sulfonamide allergy, renal failure, hepatic insufficiency, chronic obstructive pulmonary disease, and decreased serum potassium and sodium levels are all contraindications of systemic carbonic anhydrase inhibitor therapy. Blood dyscrasias from bone marrow suppression have been reported and include agranulocytosis, aplastic anemia, neutropenia, and thrombocytopenia.[10,13]

Cholinergic Agents

Cholinergic agents (also called parasympathomimetics or miotics) were the first class of agents used to treat glaucoma. The class can be divided into direct-acting cholinergic agents and indirect-acting cholinergic agents

Direct-Acting Cholinergic Agents

Pilocarpine directly stimulates the muscarinic (M_3) receptors of the ciliary body which causes contraction of the ciliary muscle. This results in widening of the spaces in the trabecular meshwork, which causes an increase in aqueous humor outflow and reduces IOP by 20% to 30%.

Pilocarpine requires administration four times daily, since the IOP-lowering effect lasts only 6 hours. Pilocarpine is available in 1%, 2%, 4%, 6%, and 8% concentrations. Higher concentrations may be needed for patients with dark irides to obtain adequate IOP reduction. A pilocarpine 4% gel is available and allows for once-daily dosing at bedtime.[10,13,23] In the treatment of acute angle-closure glaucoma, it is important to delay use until IOP has been controlled, because pilocarpine could worsen angle closure by causing anterior displacement of the lens. Once IOP is controlled pilocarpine can be given to break pupillary block by instilling one drop twice in an hour.

The adverse effects of pilocarpine are caused by the induction of miosis. The contraction of the ciliary muscle causes the lens to displace forward, which can lead to accommodation spasm, myopia, and brow ache. Pupillary constriction can also affect night vision. Pilocarpine should be avoided in patients with severe myopia, as it increases the risk of developing retinal detachment. Systemic effects may occur at higher concentrations and include, nausea, vomiting, diarrhea, and bradycardia.

Carbachol stimulates the same muscarinic receptor as pilocarpine and also inhibits acetylcholinesterase, the enzyme that metabolizes acetylcholine. Carbachol is more potent than pilocarpine, but it causes more accommodation spasm and brow ache and may also cause anterior uveitis. Carbachol is rarely used today because of the side-effect profile.

Indirect-Acting Cholinergic Agents

Ecothiophate iodide and denecarium bromide inhibit acetylcholinesterase. Inhibition of this enzyme increases the availability of acetylcholine at the nerve junction, thus increasing the stimulation of the muscarinic (M_3) receptors of the ciliary body. These products are given twice daily and have similar efficacy to pilocarpine in the degree of IOP reduction. The side-effect profile is similar to that of pilocarpine; however, they can deplete systemic cholinesterases and pseudocholinesterases and may cause the formation of cataracts. These agents should be discontinued at least 1 week prior to general surgical procedures. Succinylcholine and some local anesthetics are metabolized by pseudocholinesterases, therefore depletion of this enzyme by ecothiophate or denecarium may lead to toxic effects. These agents are typically used when other topical agents have failed and are limited to use in patients who have had their lenses removed or who have artificial lenses.[10,13]

Hyperosmotics

Glycerin, isosorbide, and mannitol are hyperosmotic agents which increase the osmolality of blood. These agents create an osmotic gradient that draws water from the vitreous humor, thus decreasing IOP. The resulting dehydration of the vitreous humor may cause posterior movement of the lens, which then causes the anterior chamber to deepen, thus opening the anterior angle. If the patient is not vomiting, glycerin (1 to 1.5 g/kg of a 50%) solution and isosorbide (1.5 to 2 g/kg) can be given orally. Isosorbide is preferred in patients with diabetes since it is not metabolized into glucose. If the patient has nausea or vomiting, mannitol (20%) can be given intravenously at a dose of 1 to 2 g/kg over 45 minutes. The hyperosmotic agents are rapid acting, reaching peak effect in 30 to 60 minutes. Headache and thirst are common complaints. Patients that are already dehydrated are at risk of developing central nervous system dehydration which can lead to coma. These agents should be used with caution in patients with renal or cardiovascular disease, as extracellular water is increased.[36]

Non-selective Adrenergic Agonists

Epinephrine and its prodrug, dipivefrine, are rarely used for the treatment of glaucoma and are considered last-line agents because of their systemic side-effect profile. Dipivefrine enhances the corneal penetration. Once it absorbs through the cornea it is enzymatically cleaved to epinephrine. Epinephrine has α- and β-agonist activity and is thought to increase the outflow of aqueous humor through the trabecular meshwork and the uveoscleral pathway. Both products are instilled twice daily and reduce IOP by 15% to 25%. Local adverse effects include mydriasis, conjunctival hyperemia, and ocular irritation. Aphakic patients should not use these medications because they cause a reversible cystoid macular edema. Epinephrine and dipivefrine should not be used in patients with narrow angles since these agents can cause acute angle closure. Systemic side effects include palpitations, increased blood pressure, and arrhythmia, and therefore they should be used with caution in patients with cardiovascular

disease, cerebrovascular disease, and hyperthyroidism. Using the nasolacrimal occlusion technique may decrease systemic effects.[10,13]

SPECIAL CONSIDERATIONS: DRUG-INDUCED GLAUCOMA

Medications have the potential to cause or exacerbate both POAG and PACG; however, PACG is more likely to be exacerbated by medications than POAG. The use of medications with anticholinergic or sympathomimetics properties can precipitate angle closure. Sulfa-based drugs cause swelling of the ciliary body which causes an anterior displacement of the lens resulting in a decrease in anterior chamber depth. Controlled POAG is rarely exacerbated by anticholinergics, sympathomimetics, and sulfa-based drugs unless the patient is concomitantly at risk for angle closure. For uncontrolled or untreated POAG the risks and benefits should be considered before employing these agents. POAG can be exacerbated by corticosteroids. Corticosteroids increase IOP by causing obstruction of the trabecular meshwork with extracellular material. The increase in IOP appears to increase with potency and intraocular penetration. Ophthalmic corticosteroid preparations carry the highest risk of increasing IOP.[12]

OUTCOME EVALUATION

Primary Open-Angle Glaucoma

Evaluate patients 2 to 4 weeks after the initiation or alteration of medical therapy. The clinician should elicit the status of ocular health since the last visit, systemic medical history, medication history, and presence of local and ocular adverse effects of medications. IOP measurement, visual acuity assessment, and slitlamp biomicroscopy should be performed at every POAG follow-up visit. The frequency of visual field and optic nerve evaluation depends on whether IOP is controlled, the length of time IOP has been controlled, and whether there is progression of the disease. Patients who are at target IOP and have no disease progression should have optic nerve head evaluation and visual field testing every 6 to 18 months. Patients with disease progression or who are not at target IOP should receive optic nerve head evaluation every 2 to 12 months and visual field testing every 1 to 6 months.[1] Assess the patient's ability to use topical eye drops.[2,34] Finally, evaluate the patient's adherence to their medical regimen. Non-adherence among patients on topical medical therapy ranges from 5% to 80%. Suspect non-adherence in patients that have visual field and optic nerve progression despite a low IOP measurement, since patients may be more adherent to their medical regimen immediately prior to their visit. Specific patient factors related to the risk of non-adherence have yet to be established, therefore there are few objective measures of adherence. Pharmacy refill histories may be useful in assessing adherence, but do not confirm that the patient is actually taking the regimen as prescribed. Using adherence aids, prescribing the least complex regimen, and educating patients about their glaucoma are ways to reduce non-adherence.[55]

Adjust therapy if patients fail to reach their target IOP. Patients who have achieved target IOP yet have progressive damage of the optic nerve or who have worsening of their visual fields should have further adjustment of their therapy. Evaluate these patients further for possible reasons of continued disease progression. Consider determining the diurnal pattern of IOP and looking for signs of poor ocular perfusion pressure. Establish a lower target IOP. Adjust therapy in patients that are intolerant, non-adherent, or develop contraindications to their drug therapy regimen. Consider increasing the target IOP and reducing drug therapy for patients who have stable disease and who have maintained a low IOP, and closely follow these patients to assess their response.[2,34]

Primary Angle-Closure Glaucoma

Follow-up of angle-closure glaucoma occurs in the postoperative period. Evaluate the patency of the iridotomy and IOP in the postoperative period. Perform gonioscopy and optic nerve head evaluation if not already performed. Treat patients according to POAG guidelines if they have underlying POAG or areas of peripheral anterior synechia with the presence of optic neuropathy.[9]

Application of Ophthalmic Solutions or Suspension

1. Clean hands with soap and water.
2. Avoid touching the dropper tip with your fingers or against your eye to maintain sterility of the product; shake the dropper bottle if the product is a suspension.
3. Tilt head back; pull down the lower eyelid with the index finger.
4. Hold the dropper bottle with the other hand as close as possible without touching the eye. The dropper should be pointing towards the eye with the remaining fingers bracing against the face.
5. Gently squeeze the bottle so that one drop is placed into the pocket.
6. Close your eye for 2 to 3 minutes to allow for the maximum corneal penetration of drug.
7. Use a tissue to wipe away any excess liquid.
8. Replace and retighten the cap to the dropper bottle.
9. Wait at least 5 minutes before instilling another ophthalmic drug preparation.
10. Application of some ophthalmic preparations (suspension and gels) may cause blurring of vision.

Patient Monitoring and Care

1. In undiagnosed patients assess their risk factors for glaucoma and their recommended interval of glaucoma screening.
2. Obtain a thorough history of the patient's prescription, nonprescription, and natural product use. Review for potential drug-drug and drug-glaucoma interactions.
3. Evaluate diagnostic tests (e.g., IOP, visual fields, and optic nerve evaluations) to determine if the patient's current glaucoma therapy is effective.
4. Assess the patient's ability to use ophthalmic preparations.
5. Determine the patient's adherence level to the prescribed medication regimen and factors contributing to poor adherence.
6. Evaluate the patient for systemic and ocular adverse drug reactions and drug allergies.
7. Provide patient education with regard to disease state, drug therapy, and surgical or laser therapy:
   - What causes glaucoma or puts people at risk for glaucoma.
   - Possible complications of glaucoma.
   - How to use ophthalmic preparations appropriately.
   - When to take their medications.
   - Potential adverse drug reactions of medical therapy.
   - Potential benefits and complications of laser or surgical procedures.

Patient Encounter, Part 1

Risk Factor Evaluation and Recommended Frequency of Eye Care

A 65-year-old African-American female with a history of diabetes, mild intermittent asthma, and hypertension presents to your clinic for her yearly check-up. She states that she is concerned about losing her eyesight because her sister has started losing her vision from glaucoma. She states that she has not noticed any changes in her vision.

Meds

Metformin 1,000 mg orally twice a day
Albuterol 2 puffs every 6 hours as needed for wheezing
Lisinopril 10 mg orally daily

- What risk factors does this patient have for glaucoma?
- Based on the available information how often would you recommend that this patient receive a comprehensive eye evaluation?

Patient Encounter, Part 2

The patient was referred to an ophthalmologist for a comprehensive eye evaluation. The ophthalmology report reveals that the patient has an IOP (as assessed by applanation tonometry) of 26 mm Hg. Gonioscopic examination reveals open anterior angles in both eyes. Pachymetry reveals a corneal thickness of 510 microns. Ophthalmoscopy reveals physiologic cupping of the optic discs in both eyes and visual field examination reveals a nerve fiber bundle defect consistent with glaucoma.

- Given this additional information, what additional risk factors does this patient have for glaucoma?
- What is your assessment of the patient's condition?
- Identify the goals of therapy for this patient.
- What pharmacologic and nonpharmacologic treatment modalities are available for this patient?

Patient Encounter, Part 3

Develop a patient-specific care plan for this patient. Be sure to address the patient's drug-related needs, goals of therapy, risks and benefits of potential therapies, and plan for follow-up of therapy. List the monitoring parameters for effectiveness and safety for the chosen therapy. Explain how you would counsel the patient on the chosen therapy, including the administration of an ophthalmic preparation.

59 Allergic Rhinitis

Kristi N. Hofer and Michelle W. McCarthy

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Differentiate between seasonal and perennial allergic rhinitis.
2. Describe the immune-mediated mechanism of allergic rhinitis.
3. List the symptoms of allergic rhinitis.
4. Identify the desired therapeutic outcomes in the management of allergic rhinitis.
5. Recommend appropriate treatment for patients with allergic rhinitis.
6. Educate patients regarding potential adverse effects of the medications used to treat allergic rhinitis.

Key Concepts

❶ Allergic rhinitis may be classified as seasonal or perennial.
❷ Allergic rhinitis is the most common atopic disease in the United States.
❸ In allergic rhinitis, the normal mechanisms by which the nasal mucosa humidifies and filters inspired air are disrupted due to an immunoglobulin E (IgE)–mediated immunologic reaction.
❹ The most common symptoms associated with allergic rhinitis are sneezing, nasal pruritus, rhinorrhea, and nasal congestion.
❺ Goals of allergic rhinitis treatment are to reduce the patient's symptoms, minimize adverse effects, and increase patient productivity (i.e., reduce lost school and work days).
❻ Antihistamines and intranasal corticosteroids are considered first-line therapy for allergic rhinitis, whereas decongestants, mast cell stabilizers, leukotriene modifiers, and systemic corticosteroids are secondary treatment options.
❼ The anti-inflammatory actions of intranasal corticosteroids make them highly effective agents for allergic rhinitis treatment, especially as first-line treatment for patients presenting with persistent or moderate to severe allergic rhinitis.
❽ In allergen immunotherapy, specific allergen extracts (also called *allergen vaccines*) are administered in order to modify or eliminate allergic rhinitis symptoms.
❾ Patients who may benefit from allergen immunotherapy include those who do not tolerate traditional drug therapy (e.g., nosebleeds with intranasal steroids or sedation with antihistamines), suffer from severe symptoms, have comorbid conditions (e.g., asthma or sinusitis), fail drug therapy, or prefer not to take long-term medication.
❿ Consensus-based guidelines indicate that the management of allergic rhinitis in children follows the same principles as those in adults, with special considerations for dose adjustments and adverse effects.

Allergic rhinitis (AR) is a highly prevalent allergen-induced upper airway inflammatory disease that is characterized by chronic hyperreactive airway mucosa with periods of acute exacerbations. ❶ *AR may be classified as seasonal or perennial.* Those with seasonal allergic rhinitis (SAR) experience symptoms primarily during the pollenating seasons of plants (i.e., spring or fall) because they are sensitive to the pollens of grasses, trees, or various weeds. Sufferers of perennial allergic rhinitis (PAR) have year-round symptoms to allergens that have no seasonal

Patient Encounter 1, Part 1

A 28-year-old woman with no significant past medical history presents to your clinic with complaints of sneezing, rhinorrhea, and nasal congestion persisting for the previous 3 weeks. On further questioning, she reports that the symptoms began this spring and worsen when she is outdoors.

- What symptoms are suggestive of AR?
- Would this patient's AR be classified as seasonal or perennial?
- What initial measure(s) would you recommend for this patient?

TABLE 59–1. Environmental Controls to Prevent Allergic Rhinitis

Pollens
- Keep windows and doors closed during pollen season
- Avoid fans that draw in outside air
- Use air conditioning
- If possible, eliminate outside activities during times of high pollen counts
- Shower, shampoo, and change clothes following outdoor activity
- Use a vented dryer rather than an outside clothesline

Molds
- Use similar controls as above
- Avoid walking through uncut fields, working with compost or dry soil, and raking leaves
- Clean indoor moldy surfaces
- Fix all water leaks in home
- Reduce indoor humidity to less than 50% if possible

House dust mites
- Encase mattress, pillow, and box springs in an allergen-impermeable cover
- Wash bedding in hot water weekly
- Remove stuffed toys from bedroom
- Minimize carpet use and upholstered furniture
- Reduce indoor humidity to less than 50% if possible

Animal allergens (if removal of pet is not acceptable)
- Keep pet out of patient's bedroom
- Isolate pet from carpet and upholstered furniture
- Wash pet weekly

Cockroaches
- Keep food and garbage in tightly closed containers
- Take out garbage regularly
- Clean up dirty dishes promptly
- Use roach traps

Other recommendations
- Do not allow smoking around the patient, in the patient's house, or in the family car
- Minimize the use of wood-burning stoves and fireplaces

Adapted from American Academy of Allergy.[3] (From May JR, Smith PH. Allergic Rhinitis. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 1734, with permission.)

variation (e.g., dust mites, mold spores, and animal dander). Symptoms of PAR typically are less severe than those of SAR due to continuous exposure to low-level allergen concentrations.[1]

EPIDEMIOLOGY

❷ *AR is the most common **atopic** disease in the United States*. It affects between 9% and 24% of adults and up to 42% of children.[2,3] More than 80 million Americans experience 7 or more days of nasal-ocular symptoms annually as a result of AR.[3] Additionally, AR is responsible for 3.5 million lost work days and 2 million missed school days annually in the United States.[4] In addition to decreased quality of life from AR symptoms, patients also suffer from disrupted sleep, resulting in fatigue, irritability, memory deficits, excessive daytime somnolence, and depression that further reduce quality of life.[5]

Factors thought to increase the likelihood of AR include positive allergy skin tests and increasing age. Prevalence of AR appears to be higher with increasing socioeconomic status, as well as in nonwhites, those who live in some polluted areas, people with a family history of allergies, those born during pollen seasons, and those who are first-born. Studies in pediatric patients indicate that children's AR risk increases with early introduction of food or formula, heavy maternal smoking during the first year of life, indoor allergen exposure (e.g., animal dander and dust mites), and parental allergic disorders.[6]

Patient Encounter 1, Part 2

The 28-year-old female patient returns to your clinic 1 month later with worsening complaints of AR symptoms. She purchased Afrin (oxymetazoline) intranasal spray at her local pharmacy and has been using it daily for the past 2 weeks. She is reluctant to continue with an intranasal product.

- What treatment regimen would you recommend for this patient? Your plan should include specific nonpharmacologic and pharmacologic interventions.
- What would you advise the patient regarding Afrin (oxymetazoline) intranasal spray use?

PATHOPHYSIOLOGY

❸ *In AR, the normal mechanisms by which the nasal mucosa humidifies and filters inspired air are disrupted due to an immunoglobulin E (IgE)–mediated immunologic reaction* (Fig. 59–1). Following sensitization, repeat exposure to allergens triggers the allergic cascade. This allergic response is categorized as either an early- or a late-phase response. Degranulation of mast cells near the surface of the nasal mucosal epithelium is a critical component of the early-phase response that occurs within minutes of allergen challenge. Histamine is a predominant mediator of the early-phase response. Release of proinflammatory mediators such as histamine, cytokines (e.g., tumor necrosis factor α, and interleukin 4), chemotactic factors (e.g., interleukin 5), and inflammatory mediators such as leukotrienes, prostaglandins, platelet-activating factor, and bradykinin occurs, resulting in nasal obstruction, nasal itching, sneezing, and nasal drainage.

Basophils, neutrophils, eosinophils, and T lymphocytes migrate to the site of the allergen exposure; this action sustains the late-phase response, which occurs hours after allergen challenge. Nasal obstruction is the primary characteristic of the late-phase response; however, sneezing and rhinorrhea persist from the early phase. Cytokines, including cysteinyl leukotrienes and interleukins 4, 5, and 13, are the more significant proinflammatory mediators to perpetuate inflammation and nasal symptoms.[7]

Allergens, or "triggers," differ between PAR and SAR. Common triggers in PAR are dust mites, mold, and animal or

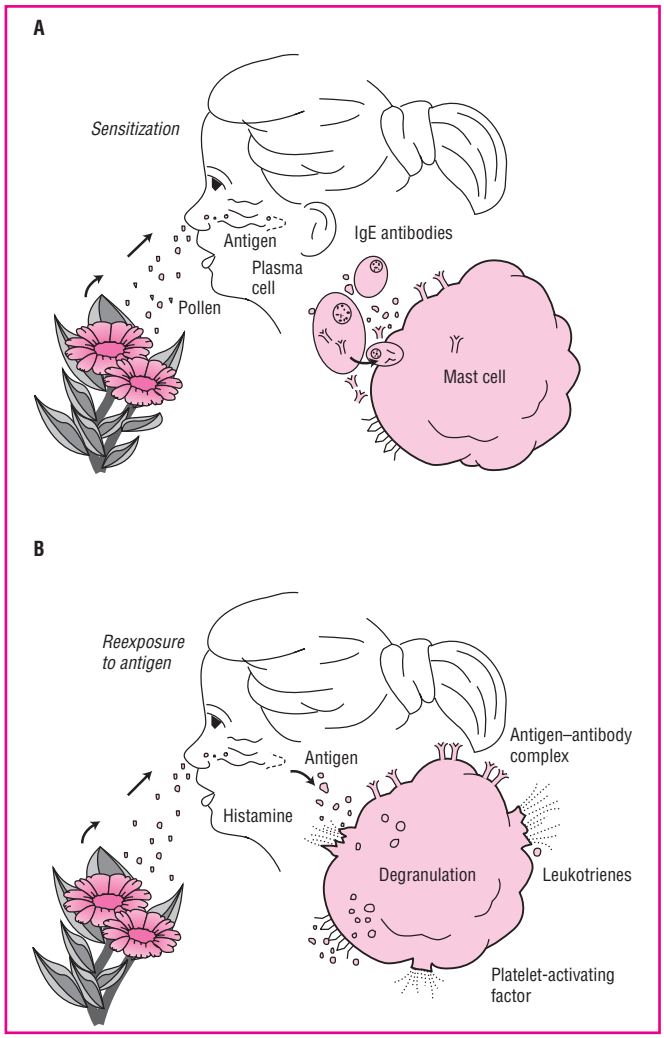

FIGURE 59–1. Allergen sensitization and the allergic response. (From DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005, Figure 93–1, p. 1730.)

cockroach allergens. In SAR, triggers vary depending on the time of year and include plant pollens and outdoor molds. Symptoms develop after the triggers initiate the allergic response.[8]

Patient Encounter 1, Part 3

The patient calls back to the clinic the next day. Her insurance company denied coverage for the antihistamine-decongestant combination and also will not cover these as single-entity products. She requests an alternate prescription.

- What agent(s) do you recommend?

Clinical Presentation and Diagnosis of Allergic Rhinitis[4–6,8]

Typical Symptoms
- Sneezing
- Pruritus (of nose, eyes, throat, and ears)
- Clear rhinorrhea
- Nasal congestion

Other Symptoms
- Chronic cough
- Fatigue
- Irritability
- Malaise
- Recurrent sinusitis
- Sleep disturbances
- Weakness

Signs in Children
- Periorbital "shiners" (edema and darkened tissues)
- "Allergic gape" (chronic mouth breathing)
- "Allergic salute" (open-palm upward nose rubbing that produces nasal crease)
- In severe cases, children may develop facial bone development abnormalities and dental malocclusion.

Diagnosis
- Temporal relationship of symptoms with triggers
- Empirical pharmacologic treatment
- Diagnostic tests optional [e.g., skin test (skin prick or intradermal), serum IgE antibody immunoassay]

TREATMENT

Desired Outcomes and Goals

Although a cure for AR does not exist, therapeutic modalities are aimed at minimizing symptoms. ❺ *Goals of treatment are to reduce the patient's symptoms, minimize adverse effects, and increase patient productivity (i.e., reduce lost school and work days)*. Specifically, therapeutic options may

- Decrease rhinorrhea, sneezing, and nasal pruritus
- Reduce nasal congestion
- Improve quality of life and sleep quality
- Improve productivity
- Prevent complications[5,8]

Nonpharmacologic Therapy

The first step in managing a patient with AR is to recommend lifestyle modifications. Patients should be encouraged to avoid allergens whenever possible (see Table 59–1). This may be difficult, however, especially for those with PAR who have continuous exposure to allergens. In PAR, several environmental adjustments should be made. For example, patients with sensitivity to dust mites should use impermeable covers for

Patient Encounter 1, Part 4

One year later, the female patient returns to your clinic for a routine examination. She reports that she is 8 weeks' pregnant, so she has not been taking her AR medication. She is especially troubled by severe congestion but also reports rhinorrhea and sneezing. She asks you to recommend a medication that will be "safe for her baby." She also would like to breast-feed after her baby is born and wonders if any medications are safe in breast-feeding.

- What do you recommend to manage her symptoms?
- What do you tell her about medication use and breast-feeding?

pillows and mattresses, wash bedding in hot (greater than 130°F) water, and minimize carpeting (i.e., use tile or hardwood floors). The only completely effective measure to eliminate animal dander is to remove the pet from the home. In SAR, outdoor allergens, such as plant pollens and molds, may not be avoided completely. Patients should keep windows and doors closed and use an air conditioner. Since symptoms worsen with increased allergen exposure, patients also should minimize time outdoors, especially during times of high pollen counts (i.e., 11 AM to 3 PM) or certain mold peaks (i.e., late evening and early morning). Despite environmental modifications, patients with significant symptoms of either perennial or seasonal AR often require treatment.[4,8]

Pharmacologic Therapy

Pharmacotherapy has an important role in managing AR symptoms (Table 59–2). Intranasal corticosteroids, systemic and topical antihistamines and decongestants, mast cell stabilizers, and immunotherapy all are beneficial in treating symptoms of AR.[9] ❻ *Antihistamines and intranasal corticosteroids are considered first-line therapy for AR, whereas decongestants, mast cell stabilizers, leukotriene modifiers, and systemic corticosteroids are secondary treatment options*[10–12] (Fig. 59–2). Whenever exposure to allergens can be predicted (e.g., SAR or visiting homes with a pet), medications should be used prophylactically to maximize effectiveness.[11]

H_1 Antihistamines

H_1 antihistamines are the most commonly prescribed medications for AR. H_1 antihistamines bind to and stabilize the H_1 histamine receptor, thereby inhibiting mast cell and basophil mediator release and resulting in reduction of sneezing, itching, rhinorrhea, and ocular irritation. Antihistamines do not prevent histamine release, nor do they bind to already-released histamine. For this reason, maintenance therapy is considered optimal. However, antihistamines are also effective when taken on an as-needed basis.[4,11,12] Antihistamines only minimally reduce nasal congestion, if at all.[8,11–13] Both oral and intranasal antihistamines are classified as first-line therapy in mild to moderate AR.[11,12] Traditionally, antihistamines have been designated by their chemical structure (i.e., ethanolamines, ethylenediamines, alkylamines, piperazines, piperidines, and phenothiazines). Today, H_1 antihistamines are described more commonly as first- or second-generation agents.[13]

First-generation antihistamines (e.g., brompheniramine, chlorpheniramine, clemastine, diphenhydramine, and pyrilamine) were the first to be developed, and most have not been studied in randomized, double-blind, controlled clinical trials.[13] These agents cross the blood-brain barrier and bind to the H_1 receptor, as well as dopamine, serotonin, and cholinergic receptors. These actions result in central nervous system (CNS) adverse effects such as sedation and cognitive impairment, as well as anticholinergic adverse effects (e.g., dry mouth and eyes, constipation, and urinary retention). Patients may develop a tolerance to sedation over a few days, but most of the adverse effects do not subside during treatment.[8] Even with bedtime-only dosing, residual daytime reduction in alertness and performance impairment occur.[14] Due to their adverse-effect profile, first-generation antihistamines should be avoided in patients with high-risk occupations (e.g., pilots and heavy machinery operators), benign prostatic hypertrophy, and elevated intraocular pressure.[4,8] Most first-generation agents have a short half-life that necessitates frequent dosing, often every 4 to 6 hours. First-generation antihistamines are available over the counter (OTC) as either single- or combination-agent products.[8]

Due to the significant adverse effects of the first-generation antihistamines, the second-generation agents were developed. These agents are dosed less frequently than first-generation agents at once or twice daily. The results of several well-designed studies demonstrate that second-generation antihistamines (e.g., cetirizine, fexofenadine, loratadine, and desloratadine) effectively relieve symptoms associated with seasonal or perennial AR.[13] These agents often are referred to as *nonsedating antihistamines.* Larger and more lipophobic than the first-generation agents, second-generation antihistamines penetrate the blood-brain barrier poorly, resulting in decreased CNS adverse effects. Of these agents, cetirizine has the most potential to cause sedation, with 30% greater propensity to occupy CNS H_1 receptors than fexofenadine.[4,13]

Second-generation agents are also more specific to the H_1 receptor, minimizing anticholinergic effects such as constipation and dry mouth.[8] Loratadine became available OTC in December 2002, but the other agents remain available only by prescription. The OTC status of loratadine has had an impact on physician prescribing patterns, as well as resulting in reduced or eliminated insurance coverage of second-generation antihistamines for many patients.[13]

Locally acting antihistamines act more quickly than oral agents but need to be administered intranasally at least twice daily due to the potential for removal by nasal secretions.[13] Azelastine, an intranasal antihistamine, is as effective as systemic antihistamines in the treatment of perennial and seasonal AR.

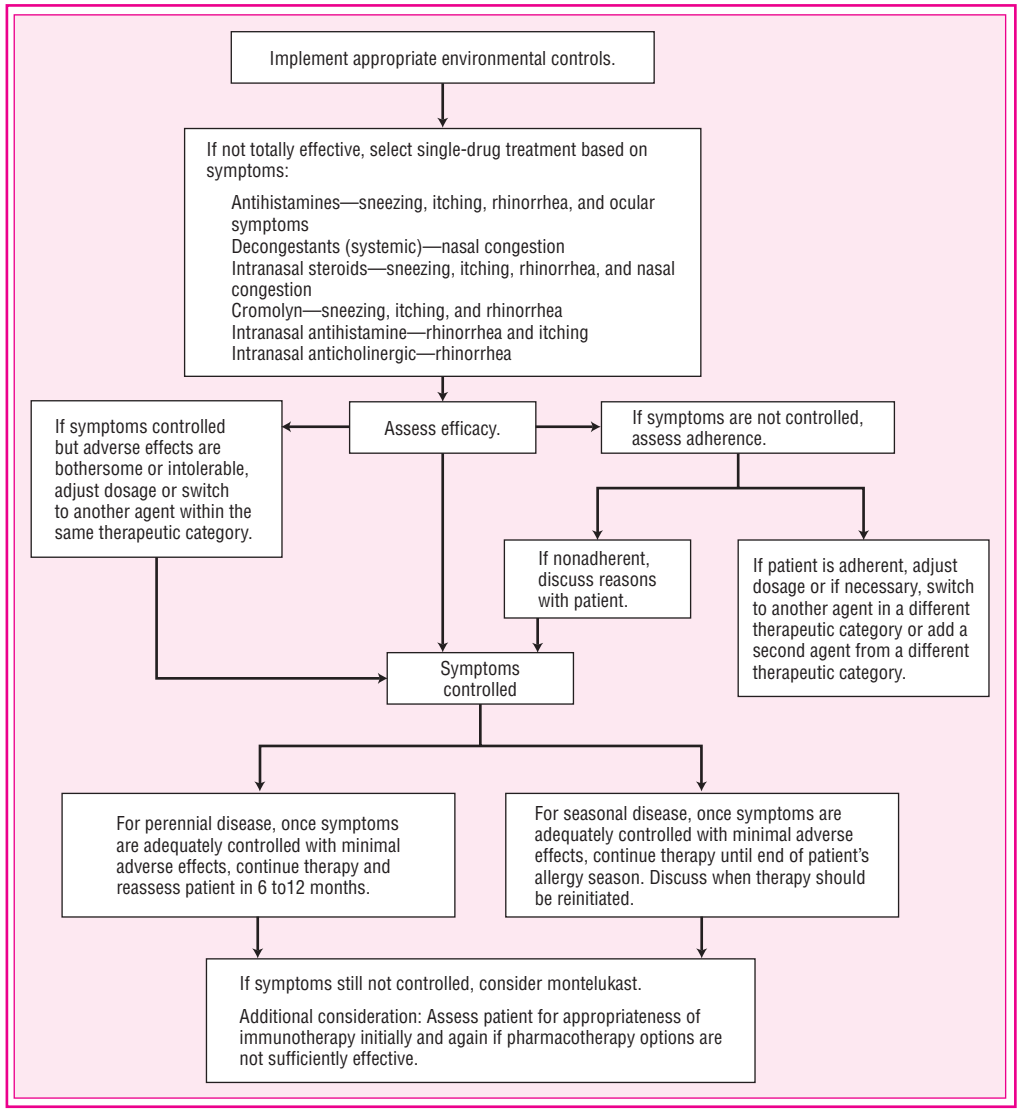

FIGURE 59–2. Treatment algorithm for allergic rhinitis. (From DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005, Figure 93–2, p. 1733.)

Azelastine acts locally to reduce the same symptoms treated by oral antihistamines; it also may reduce nasal congestion to a greater extent. Azelastine is administered twice daily and has a rapid onset of action. Many patients managed with azelastine complain of bitter taste. Drowsiness also has been reported, likely due to systemic absorption.[11–13]

Since comparative data are lacking, H_1 antihistamine selection is based on patient response and preference while minimizing adverse effects and potential drug-drug interactions. Due to the potential for once-daily dosing and a lower incidence of adverse effects compared with first-generation agents, the second-generation agents are prescribed more frequently. However, they are more costly.[12,13]

Intranasal Corticosteroids

❼ *The anti-inflammatory actions of intranasal corticosteroids make them highly effective agents for AR treatment, especially as first-line treatment for patients presenting with persistent or moderate to severe AR.* Intranasal corticosteroids prevent and relieve nasal symptoms associated with early-phase allergic responses such as nasal congestion and itching, rhinorrhea, and sneezing. Additionally, use of intranasal steroids may completely prevent late-phase AR symptoms.[9,10,12] Intranasal corticosteroids reduce inflammatory cell infiltration; decrease the numbers of basophils, eosinophils, neutrophils, and mast cells in the nasal epithelium and nasal secretions; reduce the number of inflammatory mediators from mast cells and other immune cells; decrease capillary permeability; decrease mucus production; and provoke vasoconstriction, resulting in decreased edema.[7]

Currently, six intranasal corticosteroids—beclomethasone, budesonide, flunisolide, fluticasone, mometasone, and triamcinolone—are available commercially. Although all available agents are effective and well tolerated, differences in potency and lipophilicity exist. Fluticasone and mometasone are more potent than the other commercially available intranasal steroids.[9,10] Highly lipophilic agents are associated with a greater degree and faster rate of absorption into the nasal mucosa than less lipophilic agents. The order of lipophilicity from highest to lowest is as follows: mometasone, fluticasone, beclomethasone, budesonide, triamcinolone, and flunisolide.[9]

Intranasal steroids are considered to have a slow onset of action (12–24 hours). Some patients may experience relief within a few days. Maximum treatment response may take up to several weeks to be observed.[9,10,12] To achieve optimal effects, use at regular intervals is recommended.[15] With the exception of beclomethasone and flunisolide, which are administered twice daily, the recommended doses for the intranasal corticosteroids are one to two sprays in each nostril once daily.[15]

Intranasal corticosteroids generally are well tolerated. Local effects such as dryness, burning and stinging, sneezing, headache and epistaxis occur in 5% to 10% of patients regardless of agent or formulation.[9] These adverse effects often resolve with dosage reduction.[10,12] Concerns about adverse effects due to systemic absorption exist with this class of drugs; however, systemic bioavailability is very low (less than 2%) for fluticasone, mometasone, and triamcinolone. Intranasal administration in recommended doses does not appear to affect hypothalamic-pituitary-adrenal axis function.[9,10] Additionally, systemic adverse effects linked to inhaled steroid therapy (e.g., cataract, glaucoma, and dermal thinning) do not seem to occur in patients treated exclusively with intranasal steroids.[10] Slight reductions in growth velocity in children prescribed intranasal steroids have been observed in clinical trials.[9,10,15] The long-term effects, including impact on final adult height and potential for "catchup" growth following discontinuation, have not been studied adequately. Growth of pediatric patients prescribed intranasal steroids should be monitored routinely via stadiometry.[15]

Patients prescribed intranasal steroids should be instructed to shake the product gently before each use and prime the pump before the first use or if not used for more than 1 week. Clear nasal passages before use, and avoid nose blowing for 10 to 15 minutes after use. Rare cases of septal perforation have been reported; therefore, administration of the spray away from the septum should be stressed. Effects are not immediate, and regular use is

Patient Encounter 2, Part 1

A 4-year-old, 20-kg (44 lbs) boy is seen in your practice setting for a routine check-up. His physical examination reveals dark and swollen circles under his eyes, a nasal crease, and mouth breathing. His mother reports that he has suffered from a constant runny and stuffy nose for the past 9 months. She attributed the symptoms to "preschool germs." She reports administering small doses (6.25 mg) of diphenhydramine to him before bedtime two to three times weekly. She states that his symptoms improve following diphenhydramine, but she has a very difficult time arousing him the following morning.

- What signs and symptoms are suggestive of AR?
- Would this patient's AR be classified as seasonal or perennial?
- What treatment regimen would you recommend for this patient? Your plan should include specific nonpharmacologic and pharmacologic interventions, including frequency.
- What monitoring should be performed in the patient? When should the patient be reevaluated?

Patient Encounter 2, Part 2

The patient returns in 1 month for follow-up. He and his mother report improvement in symptoms, and observation reveals less mouth breathing than the month before. The mother discusses her concerns about long-term use of steroids and is not convinced that the plan to monitor growth is sufficient.

- What options are available for the patient?

necessary to experience benefits. If symptoms worsen or do not improve within 3 weeks of treatment, the prescriber should be contacted.[12,15] If symptoms are not controlled with intranasal corticosteroid alone, addition of oral antihistamines may be warranted.[16] Patients with SAR should start therapy before the beginning of the pollen season to achieve maximal benefit.[16]

Decongestants

Decongestants such as OTC pseudoephedrine are sympathomimetic agents that constrict capacitance vessels in the nasal **turbinates.**[17] Decongestants effectively reduce nasal congestion and to some extent rhinorrhea associated with AR.[8,12] The recommended dose of pseudoephedrine is 30 to 60 mg every 4 to 6 hours for a maximum daily dose of 240 mg.[15] Systemic adverse effects such as irritability, dizziness, headache, tremor, tachycardia, and insomnia can occur. Additionally, use is associated with increased blood pressure and intraocular pressure and urinary obstruction.[8,12]

Topical intranasal decongestants (e.g., oxymetolazine, xylometolazine, phenylephrine, and naphazoline) are OTC options that provide prompt relief of nasal congestion. Nasal decongestants are dosed multiple times daily.[15] Tachyphylaxis, rebound congestion, and **rhinitis medicamentosa** may occur with chronic use; therefore, use should be limited to 3 to 5 days.[8,12] These may be used 5 to 10 minutes before administration of intranasal corticosteroids in patients with blocked nasal passages.[15]

Combination Products

Because of their limited effects on allergic symptoms, decongestants often are used in combination with antihistamines.[8] Many antihistamines are available in fixed-dose combinations with pseudoephedrine, which enhances the reduction in nasal congestion and allows for the patient convenience of one tablet. Optimally, therapy should be initiated with an antihistamine alone, adding the adrenergic agent only if nasal congestion does not resolve with antihistamine monotherapy. Use of separate antihistamine and pseudoephedrine also permits independent dose titration.[4,11,12]

Cromolyn

Cromolyn is an OTC nasal spray that inhibits degranulation of sensitized mast cells (i.e., stabilizes mast cells), reducing release of mediators that trigger inflammation and allergic response. Cromolyn also inhibits macrophages, eosinophils, monocytes, and platelets. Studies have demonstrated that intranasal cromolyn is effective in both early and late phases of AR, reducing symptoms of nasal congestion, rhinorrhea, and sneezing. The dose of cromolyn is one spray per nostril four times daily; its frequent dosing interval deters many patients from this treatment option.[18] Patients should use the nasal spray before anticipated allergen exposure and on a regular basis during the season associated with the patient's symptoms.[11] Adverse effects are local, occurring in less than 10% of patients, and include nasal burning, stinging, and epistaxis. No tachyphylaxis has been observed, nor have any drug interactions been reported. These qualities make cromolyn an option for patients with multiple comorbidities and concomitant medications. Cromolyn is an alternative for patients in whom antihistamines are too sedating and impair work and school performance. Additionally, cromolyn helps to prevent AR when taken prior to exposure, such as visiting a home with a pet.[18] Due to its excellent safety profile, cromolyn is a first-line agent in children with AR.[11,12]

Leukotriene Receptor Antagonists

Leukotrienes are inflammatory mediators (similar to histamine) that contribute to the symptoms of the allergic response. Cysteinyl leukotrienes are significant mediators associated with nasal congestion during the late-phase response. Leukotriene receptor antagonists would be expected to block the effects of leukotrienes on nasal congestion, but results of clinical trials have not conclusively demonstrated benefit.[7] Leukotriene receptor antagonists reduce sneezing, rhinorrhea, nasal pruritus and improve the quality of life with rhinoconjunctivitis.[19] Leukotriene receptor antagonists are no more effective than antihistamines at improving nasal congestion.[7] Combination therapy with leukotriene receptor antagonists and antihistamines was more effective than either agent alone but still less effective than intranasal corticosteroids.[19] Although montelukast and zafirlukast are both available commercially in the United States, montelukast is the only leukotriene receptor antagonist indicated for SAR and PAR.[15,20] The recommended dose of montelukast is 4, 5, or 10 mg once daily depending on patient age. Zafirlukast is dosed twice daily, but the ideal dose for AR has yet to be identified. When administered in the evening, montelukast improves nighttime nasal symptoms.[17] Leukotriene receptor antagonists are well tolerated, with headache being the most common adverse effect.[15,20]

Intranasal Anticholinergics

Intranasal anticholinergic agents (e.g., ipratropium) reduce the severity and duration of rhinorrhea but have no effect on other nasal symptoms.[11,12,21] Ipratropium reduces cholinergic hyperreactivity and cholinergically mediated histamine- and antigen-induced secretion. Intranasal ipratropium acts locally, with only minimal systemic absorption. Clinical trials demonstrated that ipratropium bromide 0.3% reduced rhinorrhea in adults and children with PAR.[11,12] Intranasal ipratropium is an option for patients in whom rhinorrhea is refractory to topical intranasal corticosteroids and/or antihistamines.[8,12] Intranasal ipratropium is available only by prescription, and the dose is two sprays nasally two to three times daily.[15] Adverse effects are minimal, but dry nasal membranes have been reported.[11,12]

Systemic Corticosteroids

Systemic corticosteroids, administered orally or by depot injection, are considered last-resort options when all other treatments for SAR are inadequate. Systemic steroids may be used to control rhinitis symptoms in patients with severe PAR or **nasal polyposis.** Data comparing oral and parenteral steroid therapy are lacking; however, oral therapy is preferred due to its low cost

and flexibility in dosing. Due to the risk of adverse effects related to hypothalamic-pituitary-adrenal axis suppression, only short courses (less than 3 weeks) of oral therapy are recommended no more often than every third month. Systemic corticosteroids should be avoided in children and pregnant women.[12,16]

Prescription versus OTC/Self-Treatment

Since many AR treatment options are available OTC, patients often self-treat unless symptoms are intolerable. Additionally, patients without medical insurance or formulary coverage are more likely to purchase OTC agents. Health care providers should ask patients about OTC medication history (i.e., effectiveness of and adverse effects with previously used agents) when selecting AR therapy.

Immunotherapy

Allergen Immunotherapy

Allergen immunotherapy (AIT) is an option in the management of AR, especially in patients who react to limited antigens. ❽ *In AIT, specific allergen extracts (also called allergen vaccines) are administered in order to modify or eliminate AR symptoms.* Patients receive a series of allergen injections beginning with a small quantity of allergen and building up to a maintenance dose. During the upward titration, injections are administered at varied intervals, ranging from several in one day to weekly. Maintenance doses are given every 4 to 6 weeks for 3 to 5 years. Duration of effect is uncertain, but an effect has been noted at least 6 years after discontinuing AIT.[22,23]

The mechanism of AIT is uncertain. It is theorized that AIT modulates allergen-specific T cells, attenuating early- and late-phase allergic responses. Results of clinical trials have demonstrated the effectiveness of AIT in SAR due to grass, ragweed, and birch pollen. AIT is even effective in patients who fail conventional drug therapy. In PAR, a longer duration of AIT is necessary to alleviate symptoms. Despite lengthening therapy duration, AIT may be less effective in patients with PAR than in those with SAR.[22]

In AIT, patient selection is critical. The allergic cause of AR should be verified by history and skin or blood tests. Additionally, the responsible antigen(s) must be identified. ❾ *Patients who may benefit from AIT include those who do not tolerate traditional drug therapy (e.g., nosebleeds with intranasal steroids and sedation with antihistamines), suffer from severe symptoms, have comorbid conditions (e.g., asthma and sinusitis), fail drug therapy, or prefer not to take long-term medication.*[11,22–24]

Local and systemic adverse effects are associated with AIT. Patients may experience pain or subcutaneous nodules at the injection site. In patients who suffer systemic symptoms soon after the injection, the AIT plan should be assessed and may need to be advanced more gradually. Systemic reactions, including anaphylaxis, are most likely to occur during the titration phase. Patients with asthma are at higher risk for systemic and fatal reactions. Patients should be monitored for adverse effects for at least 20 minutes after the antigen injection. Emergency agents, including epinephrine and an injectable corticosteroid, should be readily available.[23,24]

Omalizumab

Clinical trials have indicated that omalizumab, a recombinant humanized monoclonal IgE antibody approved for use in moderate to severe persistent asthma in patients with reactivity to a perennial allergen, is effective in the treatment of SAR.[25–27] Omalizumab inhibits the binding of IgE to mast cell and basophil receptors, resulting in a reduction of allergic mediator release.[25] Additionally, serum free IgE levels are decreased.[25–27] In SAR patients, omalizumab improves quality of life and nasal symptoms and reduces antihistamine needs. The most effective dose in SAR appears to be omalizumab 300 mg administered subcutaneously every 3 to 4 weeks depending on baseline IgE levels.[26,27]

The most common adverse effect with omalizumab is injection-site reaction, reported in 45% of patients in clinical trials. Other adverse effects include viral and upper respiratory tract infections, sinusitis, headache, and pharyngitis. Rare cases of malignant neoplasms and anaphylaxis were reported during clinical trials of omalizumab in asthma. Patients should be monitored for at least 2 hours following the injection so that anaphylaxis and/or injection-site reactions may be managed.[25]

Omalizumab is substantially more costly than other AR treatment options and must be administered in the clinic setting.[28] Comparative trials are needed to determine the role of omalizumab in AR.

Complementary and Alternative Medicines

Complementary and alternative medicine therapies, such as acupuncture, biofeedback, chiropractic manipulation, dietary supplements, herbal therapy, and homeopathic preparations, are used by individuals with allergic rhinitis.[29,30] Use of bromelain, gingko, ginseng, licorice, quercetin, and *Urtica dioica* has been reported, but large-scale studies documenting efficacy are lacking.[31,32] Caregivers should inquire routinely about patients' use of alternative therapies and counsel patients about the lack of validated data to support such practices.[12]

Special Populations

Children

Allergic rhinitis can have a large impact on the health and quality of life of children by causing absenteeism from school, reduced learning, depression, anxiety, and family dysfunction. If left untreated, serious complications such as asthma, sinusitis, nasal polyposis, respiratory infections, and otitis media can occur. ❿ *Consensus-based guidelines indicate that the management of allergic rhinitis in children follows the same principles as in adults, with special considerations for dose adjustments and adverse effects.* Allergen avoidance and environmental control are first priorities. Subsequent treatment recommendations depend on symptom severity. A number of treatment options

are available for pediatric patients with AR. As with adults, second-generation antihistamines and intranasal corticosteroids are first-line treatment options.

First-generation antihistamines are effective, but associated sedation and psychomotor impairment limit chronic use. Efficacy and safety of second-generation antihistamines in children have been demonstrated in clinical trials.[33] Cetirizine is indicated for children 6 months of age and older, loratadine for children 2 years of age and older, and fexofenadine for children 6 years of age and older.[15]

Intranasal corticosteroids are the most effective anti-inflammatory agents used in pediatric patients with allergic rhinitis. Although fewer studies have been conducted in children, results demonstrate that intranasal corticosteroids are effective and well tolerated, with an adverse-effect profile similar to placebo. Mometasone is indicated for children as young as 2 years of age, fluticasone is indicated for children 4 years of age and older, and beclomethasone, budesonide, flunisolide, and triamcinolone are indicated for children 6 years and older.[15] Because concerns regarding effect of intranasal steroids on growth exist, the growth of pediatric patients prescribed intranasal steroids should be monitored routinely via stadiometry.

Azelastine nasal spray is indicated for children 5 years of age and older and is considered an alternative to intranasal corticosteroids in patients with persistent severe symptoms. Intranasal cromolyn, another commonly used agent in children, is indicated in patients 2 years of age and older and has an acceptable safety profile. However, limited efficacy and multiple daily administrations limit its use to mild and early rhinitis or for prophylaxis of a known imminent exposure.

Oral pseudoephedrine should not be used in children under 1 year of age due to safety concerns. Intranasal ipratropium can be used as intermittent therapy for mild rhinitis or as add-on therapy in more severe cases. AIT is recommended for persistent rhinitis, particularly severe disease, because studies have shown that children respond better than adults. Montelukast is indicated for children 2 years of age and older with SAR and for infants 6 months of age and older with PAR. Studies evaluating leukotriene receptor antagonists as monotherapy or in combination with antihistamines have contradictory results.[33]

Pregnancy

Rhinitis symptoms are common during pregnancy and can occur in more than 20% of pregnant women. Approximately one-third of pregnant women experience worsening of AR symptoms during pregnancy. Because the bothersome symptoms of AR affect the quality of life of pregnant women and increase the likelihood of sinusitis, treatment should be optimized during pregnancy. Vasomotor rhinitis of pregnancy results from increased blood flow to the nasal turbinates, increased nasal glandular activity, and relaxation of the nasal vascular smooth muscle from increases in estrogen and progesterone.

As with any other AR patient, avoidance practices are the mainstay of therapy in pregnant AR patients. Elevation of the head of the bed and use of saline nasal spray are helpful in relieving nasal congestion. Intermittent use of intranasal decongestants can be useful for vasomotor rhinitis of pregnancy. Ideally, avoiding all medications during the first trimester, the primary period of organogenesis, is recommended. Cromolyn nasal spray is considered first-line therapy for AR in pregnant patients. The first-generation antihistamines chlorpheniramine and tripelennamine are the recommended antihistamines for use during pregnancy. For women unable to tolerate the first-generation agents, the use of second-generation agents such as loratadine and cetirizine may be considered. No data on adverse effects of azelastine nasal spray in this population are available. Pseudoephedrine is the preferred decongestant during pregnancy. However, an association between use of oral decongestants during the first trimester and infant **gastroschisis**—a rare congenital fissure of the abdominal wall—has been observed. Intranasal steroids may be considered in patients who do not experience adequate symptom relief from antihistamines and decongestants. Because budesonide and beclomethasone have been available for a longer period of time, these may be preferred in pregnancy. AIT is considered safe and effective for pregnant women and may be continued during pregnancy. However, it is not recommended to start AIT during pregnancy nor increase the strength of the allergen.[34]

Lactation

Drug selection in lactating women may be difficult. A number of factors must be considered when responding to questions regarding safety of drugs in nursing mothers. The American Academy of Pediatrics' (AAP) Committee on Drugs provides recommendations on the safety of drugs in lactating women. AR agents considered by the AAP as compatible with breast-feeding include fexofenadine, loratadine, and pseudoephedrine. Limited data are available on the safety of the inhaled corticosteroids in lactating women. However, their low systemic absorption and the classification of systemic (intravenous and oral) prednisone and prednisolone as compatible with breast-feeding should be considered when addressing questions about intranasal corticosteroids in nursing mothers.[35]

OUTCOME EVALUATION

AR is a bothersome and costly disorder affecting large numbers of patients. Clinicians encountering AR patients in their practice settings should be familiar with treatment options. Lifestyle modifications and many pharmacologic agents are effective in reducing symptoms and improving quality of life.

- Educate patients about environmental control measures (see Table 59–1).
- Routinely assess patients for response to treatment and adverse effects.
- Mild or intermittent symptoms are treated with second-generation antihistamines.

- Moderate or frequent symptoms require treatment with an intranasal corticosteroid.
- After 3 months of successful treatment, therapy may be interrupted and started again if symptoms return.
- Patients with severe symptoms or those that persist despite intranasal corticosteroid treatment are treated with a combination of intranasal corticosteroid and antihistamine.
- Investigate for underlying diseases of nonallergic origin (i.e., anatomic abnormalities, chronic sinusitis, or nasal polyps) if combination therapy does not provide sufficient relief.
- For resistant cases of nasal obstruction, evaluate the need for topical decongestants, oral decongestants, or short-course oral steroids.
- Consider intranasal ipratropium for resistant rhinorrhea and immunotherapy for those with symptoms that persist despite treatment.[16]

Patient Care and Monitoring

1. Assess the patient's symptoms to determine if self-treatment is appropriate or evaluation by a physician is necessary. Determine type of symptoms, frequency (seasonal or chronic), and precipitating triggers. Does the patient have any AR-related complications (e.g., nasal polyposis, sinusitis, or otitis media)?
2. Review any diagnostic data (e.g., skin test and serum IgE-antibody immunoassay) to determine to which allergens the patient is sensitized.
3. Obtain a thorough history of nonprescription, prescription, and natural drug product use. Determine which treatments have been helpful in the past.
4. Educate the patient on environmental modifications that may reduce symptoms (see Table 59–1).
5. Is the patient taking antihistamines and/or intranasal steroids? Is the patient experiencing adverse effects (e.g., sedation from antihistamines or nasal itching, burning, or bleeding from intranasal corticosteroids)?
6. Develop a plan to assess the effectiveness of the antihistamine and/or intranasal corticosteroid therapy after 3 months.
7. Determine if long-term therapy is warranted.
8. Assess improvements in symptom control and quality of life, including productivity and sleep.
9. Evaluate the patient for adverse drug reactions.
10. Stress the importance of adherence to the regimen including environment avoidance measures.
11. Provide patient education regarding allergen triggers, avoidance measures, and drug therapy:

- What causes AR?
- Possible complications of AR.
- When to take medications?
- What potential adverse effects may occur?
- What to report to physician (lack of symptom resolution)?

60 Minor Ophthalmic Disorders

Kendra J. Grande

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Differentiate between the various minor ophthalmic disorders based on patient-specific information.
2. Choose an appropriate treatment regimen for an ophthalmic disorder.
3. Discuss the product differences that direct the selection of ophthalmic medications.
4. Assess when further treatment is required based on patient-specific information.
5. Recommend an ophthalmic monitoring plan given patient-specific information, a diagnosis, and a treatment regimen.
6. Educate patients about ophthalmic disease states and appropriate drug and non-drug therapies.

Key Concepts

❶ The clinician must be able to distinguish ophthalmic conditions that lead to significant morbidity, including blindness.
❷ The choice of topical antibiotic in patients who wear contact lenses must cover *Pseudomonas aeruginosa.*
❸ Both acute and chronic bacterial conjunctivitis are self-limiting, except if caused by staphylococci.
❹ Viral conjunctivitis is usually self-limiting, worsening after 4 to 7 days, but then resolving within 2 to 4 weeks.
❺ Nonpharmacologic measures are critical to prevent the spread of viral conjunctivitis.
❻ Use a step-care approach for treatment of allergic conjunctivitis.
❼ Untreated bacterial keratitis is associated with corneal scarring and potential loss of vision. Corneal perforation may cause the loss of the eye.
❽ There is no cure for age-related macular degeneration and the efficacy of most treatments is low.
❾ Dry eye is a chronic condition in which symptoms can be improved with treatment, but it is not usually curable. Patient education is critical.

This chapter provides an overview of common ophthalmic disorders and their treatments. ❶ *Many ophthalmic disorders are benign or self-limited, but the practitioner must be able to distinguish conditions that lead to serious morbidity, including blindness.* Preserving both visual function and cosmetic appearance must be done whenever possible.[1] The clinician must understand when referral is appropriate and the appropriate time frame for follow-up. These vary greatly by condition.

OCULAR EMERGENCIES

Etiology and Epidemiology

Ophthalmic problems encompass 3% to 10% of all emergency department visits.[1] Falls are a frequent cause of traumatic eye injury in the elderly.[2] Corneal abrasions are the most common eye injury in children and are often due to fingernail scratches or objects swung near the eye. Accidental cigarette burns are common in children, but may be a sign of child abuse. Even aggressive eye rubbing may damage the cornea.[3,4]

Health care practitioners must know the proper treatment for ocular emergencies and the time frame for follow-up in order to prevent further morbidity (Table 60–1).

Corneal Abrasions

Clinical Presentation and Diagnosis of Corneal Abrasions[3]

Symptoms
- Photophobia
- Pain with extraocular muscle movement
- Foreign body sensation
- Recent ocular trauma
- Gritty feeling
- Headache

Signs
- Excessive tearing
- Blepharospasm
- Blurred vision

Diagnostic Test
Use sterile fluorescein dye strips and visualize the cornea under a cobalt-blue filtered light; abrasions appear green; ensure that no foreign body remains in the eye

Treatment

Desired Outcomes
- Complete healing of the corneal abrasion with no scarring or vision impairment
- Prevent infection and pain
- Prevent corneal loss or corneal transplant

General Approach to Treatment
The five layers of the cornea contain no blood vessels but are nourished by tears, oxygen, and aqueous humor. Minor corneal abrasions heal quickly. Moderate abrasions take 24 to 72 hours to heal. Deep scratches may scar the cornea and require corneal transplant if vision is impaired. Do not use eye patches to treat corneal abrasion, as they decrease oxygen delivery, increase pain, and increase the chance of infection.[3]

TABLE 60–1. Ophthalmic Emergencies: Time to Follow-up by Ophthalmologist[1]

Immediate Consult Required	Within 24 Hours
Foreign body in eye	Acute angle-closure glaucoma
Acute, painless loss of vision	Orbital cellulitis
Acute chemical burn	Blood in the eye (hyphema)
Blunt trauma to eye	Macular edema
	Retinal detachment
	Sudden congestive proptosis (bulging of eye forward)
	Corneal ulcer
	Corneal abrasion

Corneal Abrasion Prevention[3]
- Wear eye protection during sports
- Wear industrial safety lenses
- Clip fingernails of infants and children
- Remove low-hanging branches and objects
- Tape the patient's eyelids closed or use gels or soft contacts during general anesthesia to prevent lag-ophthalmos
- Carefully fit and place contact lenses

Pharmacologic Therapy

Topical NSAIDs
Topical non-steroidal anti-inflammatory drugs (NSAIDs) decrease pain from corneal abrasion. Available ocular NSAIDs are diclofenac 0.1%, ketorolac 0.5%, nepafenac 0.1%, and bromfenac 0.09%. The usual dose for diclofenac and ketorolac is one drop four times daily; nepafenac is dosed three times daily and bromfenac is dosed twice daily. Use topical NSAIDs with caution in patients with clotting disorders or those who are on systemic NSAIDs or warfarin therapy. Topical administration of NSAIDs may delay wound healing, especially with concurrent topical corticosteroid use.[3,5] Oral analgesics are not well studied for use in corneal abrasion; they may have decreased efficacy. They are less expensive than topical NSAIDs and may be an option for some patients.[3]

Topical Antibiotics
Because an infection slows the healing of a corneal abrasion, prophylactic antibiotics are often used. Studies on the efficacy of this are mixed. Discontinue the use of contact lenses until the abrasion is healed and the antibiotic course complete. ❷ *In contact lens wearers, choose an antibiotic that covers* Pseudomonas aeruginosa, *like gentamicin ointment or solution or a fluoroquinolone.*[3] Antibiotic resistance is an increasing problem. Resistance occurs primarily with older antibiotics, but has been reported for fluoroquinolones as well. Two newer fluoroquinolones, gatifloxacin and moxifloxacin, do not yet have reports of resistance. These agents are more expensive.[6]

Outcome Evaluation

1. Re-evaluate patients in 24 hours.
2. If symptoms worsen, recheck for foreign bodies.
3. If not fully healed, evaluate again in 3 to 4 days.
4. Refer to ophthalmologist if:

- No improvement in 3 days
- Worsening symptoms
- Symptoms do not improve daily
- Symptoms do not improve within a few hours of contact lens removal[3]

Other Ocular Emergencies: Treatment

Traumatic Injuries

Attempt to remove loose foreign bodies by gentle irrigation with artificial tears or sterile saline. If successful, a topical broad-spectrum antibiotic, such as erythromycin, will prevent infection. Some patients may need a short-acting cycloplegic mydriatic-like cyclopentolate or tropicamide to help with pain.[7] Do not use cycloplegic mydriatics in children.[8] If irrigation is unsuccessful, mechanical removal of foreign objects should be completed only by ophthalmologists using a slitlamp. Protect the eye with a metal eye shield or a paper cup taped over the eye while awaiting the ophthalmologist.[7]

Splash Injuries and Chemical Exposure

Instruct patients over the phone to irrigate the eye immediately with water or saline continuously for at least 15 minutes before seeking a clinician. Irrigation dilutes and removes the chemical agent, and is the best way to decrease ocular tissue damage. Patients should then seek immediate care from an ophthalmologist or emergency facility.[7]

Loss of Vision

A variety of disorders may lead to rapid, painless, monocular or binocular vision loss. This may include central retinal artery occlusion, acute narrow-angle glaucoma, trauma, or others. The differential diagnosis is complex and needs to be undertaken by an emergency department or ophthalmologist.[9]

CONJUNCTIVITIS

While no exact numbers are available, conjunctivitis, which is also known as red eye, is one of the most common ophthalmic complaints seen by general clinicians. An inflamed conjunctiva is the most common cause of red eye.[10] Use the differential diagnosis algorithm shown in Fig. 60–1 to determine the proper treatment or need for referral.

Bacterial Conjunctivitis

Etiology

The vast majority of conjunctivitis cases are viral in nature. For acute bacterial **conjunctivitis**, the cause is primarily gram-positive organisms.[11] The primary pathogens in acute bacterial conjunctivitis are *Streptococcus pneumoniae, Staphylococcus aureus,* or *Haemophilus influenzae.*[12]

Staphylococcus, *Moraxella*, or other opportunistic bacteria typically cause chronic conjunctivitis.[10] *Moraxella* infections may cluster in groups of women who share makeup.[12] ❸ *Both acute and chronic bacterial conjunctivitis are self-limiting except if caused by staphylococci.*[13] Because of this, the pathogens are rarely cultured unless the case is unresponsive to treatment. While infection typically begins in one eye, it will often spread to both within 48 hours.[11]

Hyperacute bacterial conjunctivitis is associated with gonococcal infections in sexually active patients. The causative agents are *Neisseria gonorrhoeae* or *N. meningitidis.* Prompt work-up and treatment is required, as corneal perforation occurs in 10% of cases within 48 hours.[12] An ophthalmologist should complete a conjunctival scraping and susceptibility testing.[10]

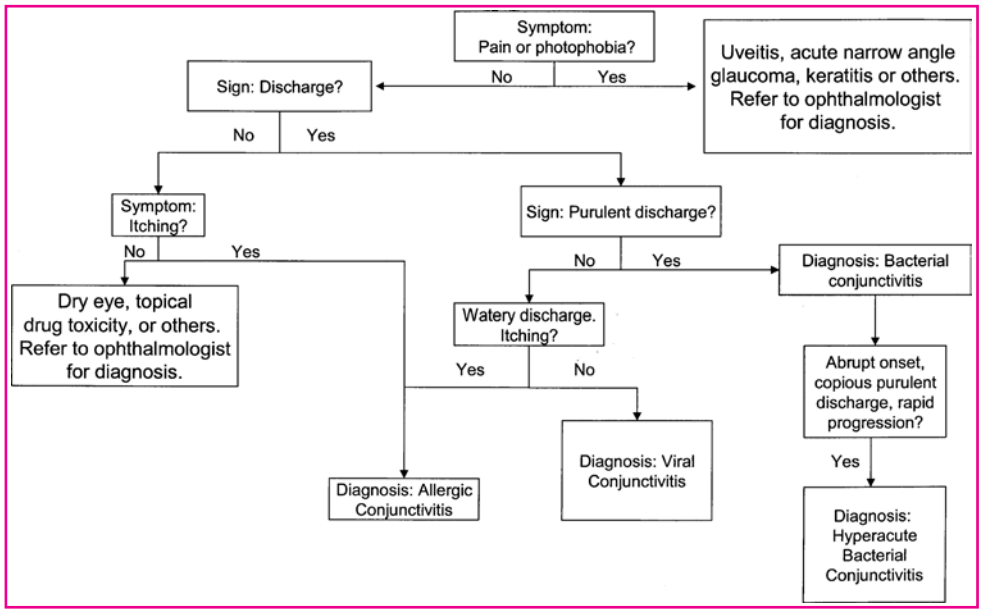

FIGURE 60–1. Differential diagnosis for red eye.

Treatment

Desired Outcomes

- Complete resolution of the bacterial conjunctivitis
- Prevent adverse consequences of the infection
- Preserve functionality of the eye

General Approach to Treatment

Treat acute bacterial conjunctivitis with broad-spectrum antibiotics. Although the condition is usually self-limiting, antibiotic treatment decreases the spread of disease to other people and prevents extraocular infection. Additionally, treatment may help decrease the risk of corneal ulceration or other complications that affect sight. Finally, treatment speeds recovery.[14]

Pharmacologic Therapy

The choice of an antibiotic agent for acute bacterial conjunctivitis is largely empiric. The initial treatment needs to include *Staphylococcus* coverage, but also may be chosen on the basis of cost and side-effect profile.[13,14] In general, ointments are a good dosage form for children. Adults prefer drops because they do not interfere with vision.[14]

Many broad-spectrum topical antibiotics are approved to treat acute bacterial conjunctivitis (Table 60–2). Trimethoprim /polymyxin B solution, polymyxin B with bacitracin ointment, or erythromycin ointment are cost-effective, first-line treatments. The aminoglycosides (tobramycin, neomycin, and gentamicin) are alternatives but have incomplete gram-positive coverage.[14] The aminoglycosides can cause corneal epithelial toxicity. Neomycin often causes allergic reactions. Tobramycin is the best tolerated of the class but is also the most expensive. Sulfacetamide 10% drops show increasing resistance. If infection recurs, use a topical fluoroquinolone like ofloxacin, ciprofloxacin, norfloxacin, gatifloxacin, moxifloxacin, or levofloxacin.[12] Fluoroquinolones are not used first-line for conjunctivitis because they have poor *Streptococcus* coverage and are expensive. Development of resistance is also a concern with fluoroquinolones.[14]

Treat hyperacute bacterial conjunctivitis with a single dose of 1 g of intramuscular ceftriaxone in combination with topical antibiotics.[11]

Patients with chronic bacterial conjunctivitis often have a concurrent case of blepharitis. Add a lid hygiene regimen to topical antibiotic treatment.[12]

TABLE 60–2. Bacterial Conjunctivitis Dosing Guidelines for Topical Ophthalmic Antibiotics[32]

Trimethoprim/polymyxin B solution	1 drop every 3 hours for 7–10 days
Polymyxin B with bacitracin ointment	Apply thin ribbon every 3–4 hours for 7–10 days
Erythromycin 0.5% ointment	Apply a thin ribbon up to six times daily
Tobramycin 0.3% solution	1–2 drops every 4–6 hours
Gentamicin 0.3% solution	1–2 drops every 4 hours
Sulfacetamide 10% solution	1–2 drops every 2–3 hours for 7–10 days
Ofloxacin 0.3% solution	Days 1 and 2: 1–2 drops every 2–4 hours Days 3–7: 1–2 drops four times daily
Ciprofloxacin 3.5 mg/mL solution	Days 1 and 2: 1–2 drops every 2 hours while awake Days 3–7: 1–2 drops every 4 hours while awake
Levofloxacin 0.5% solution	Days 1 and 2: 1–2 drops every 2 hours while awake, up to 8 times per day Days 3–7: 1–2 drops every 4 hours while awake, up to four times per day
Gatifloxacin 0.3% solution	Days 1 and 2: 1 drop every 2 hours while awake up to eight times per day Days 3–7: 1 drop every 4 hours while awake
Moxifloxacin 0.5% solution	1 drop three times a day for 7 days

Outcome Evaluation

Significant improvement of acute bacterial conjunctivitis should be seen within 1 week.[11] Terminate treatment with topical antibiotics when the inflammation is resolved.[12]

Viral Conjunctivitis

Etiology

The most common cause of viral conjunctivitis is adenovirus. It is often called "pink-eye."[10] Viral conjunctivitis infections are easily spread through swimming pools, camps, and contaminated fingers and medical instruments.[14] Patients often present with an upper respiratory tract infection or recent exposure to viral conjunctivitis. While the infection begins in one eye, it will spread to both eyes 50% of the time. ❹ *Viral conjunctivitis is usually self-limiting, worsening after 4 to 7 days but then resolving within 2 to 4 weeks.*[10] Five percent of patients remain contagious 16 days after the appearance of symptoms.[11]

Patient Encounter 1

A 40-year-old woman presents complaining of irritation, redness, and "stickiness" of the right eye for the past 48 hours. Today she woke up with the lids of the right eye stuck together and it took a warm washcloth to get her eye open. Examination reveals a whitish discharge from the right eye and a redness of the left eye. She has worn contact lenses for 6 years.

- What is the probable diagnosis?
- On physical assessment, how do you differentiate between bacterial, viral, and allergic causes?
- What is a reasonable treatment regimen for her?

Treatment

Desired Outcomes

- Complete resolution of the viral conjunctivitis
- Prevent adverse consequences of the infection
- Avoid spreading infection to other patients

Nonpharmacologic Therapy

❺ *Nonpharmacologic measures are critical to prevent the spread of viral conjunctivitis.* Patients should not share towels or other contaminated objects, should avoid close contact with other people and avoid swimming for 2 weeks.[10] The virus remains viable on dry surfaces for more than 2 weeks.[13] Take care in the medical setting to thoroughly decontaminate instruments and wash hands.[11]

Patients may obtain symptomatic relief by using cold compresses and artificial tears.[10] If artificial tear solutions sting, recommend a preservative-free formula.

Pharmacologic Therapy

Topical antivirals are not used to treat adenovirus conjunctivitis. Topical antibiotics are often prescribed for viral conjunctivitis, ostensibly to prevent bacterial superinfection. In reality, this is a case of the patient insisting on a medication to speed healing.[11] Avoid the use of antibiotics for a viral infection.[12] Eliminating superfluous antibiotic use also helps prevent the development of antibiotic resistance.

If patients have a severe subepithelial infiltration, a topical steroid may be required. However, topical steroids may cause serious ocular complications and may worsen herpetic conjunctivitis, which has symptoms similar to viral conjunctivitis. Additionally, the period of virus shedding may be prolonged by up to 50% by topical prednisolone. Only ophthalmologists should prescribe topical steroids.[10]

Outcome Evaluation

Refer patients that do not see improvement within 7 to 10 days to an ophthalmologist to rule out herpetic and other infectious processes.[11] If pain or photophobia occurs, suspect corneal involvement and refer the patient. This typically occurs 10 to 14 days after the onset of conjunctivitis.[13]

Allergic Conjunctivitis

Etiology

Ocular allergy is a broad term that includes several diseases with the hallmark symptom of itching, often accompanied by tearing, conjunctival swelling, and nasal congestion.[14] Seasonal ocular allergy is the most common type of allergic conjunctivitis. This is an IgE-mediated hypersensitivity to pollen or other airborne allergens.[11] Often, the patient's history is positive for atopic conditions such as allergic rhinitis, asthma, or eczema.[14] Perennial allergic conjunctivitis has similar but less severe symptoms and may not be tied to a specific time of year. Finally, **conjunctivitis medicamentosa** is a contact allergy to a topical medication, often an antibiotic.[11]

Pathophysiology

The conjunctiva of the eye is often the first site of contact with an environmental allergen. Mast cell degranulation occurs, resulting in the release of mediators. The earliest mediator is histamine, which causes itching, redness, and swelling. Leukotrienes and prostaglandins cause increased mucus secretion and cellular infiltration along with chemosis, resulting in conjunctival vasodilation. The mast cells also release cytokines, chemokines, and growth factors which trigger inflammatory processes.[15]

Treatment of ocular allergy is aimed at slowing or stopping these processes. Antihistamines block the histamine receptors and some prevent histamine production and/or inhibit mediator release from the mast cells.[15] Mast cell stabilizers inhibit the degranulation of mast cells, preventing mediator release. Some topical agents have multiple mechanisms of action, combining antihistaminic, mast cell stabilization, and anti-inflammatory properties (Tables 60–3 and 60–4).[16]

Treatment

Desired Outcomes

- Relief of current allergic symptoms
- Prevention of future allergic symptoms
- No adverse effects from treatment

Nonpharmacologic Therapy

The primary treatment is removal and avoidance of the allergen.[17] For conjunctivitis medicamentosa, discontinue the offending medication.[11] Apply cold compresses three to four times daily to reduce redness and itching and to provide symptomatic relief.[18]

Pharmacologic Therapy

❻ *Use a step-care approach for the treatment of allergic conjunctivitis.* The first step is a non-medicated, artificial tears solution. The solution dilutes or removes the allergen, providing relief while lubricating the eye. Solutions are applied two to four times daily as needed. Ointments may be used in the evenings to further moisturize the surface of the eye.[17] There are many products on the market. Try a preservative-free formulation if other products sting or burn. Unit-dose preservative-free products are more expensive. Some newer multi-dose products, such as sodium perborate (Purite®), have rapidly dissociating preservatives and are more cost-effective.

If artificial tears are insufficient, the second treatment step is a topical antihistamine or antihistamine/decongestant combination. The antihistamine/decongestant combination is more effective than either agent is alone. Decongestants are vasoconstrictors that reduce redness and seem to have a small synergistic effect with the antihistamine. The only topical

TABLE 60–3. Mechanisms of Action of Ocular Allergy Drugs[15,16,17]

Drug	Mechanisms	Notes
Pheniramine	H_1-receptor antagonist	Available only in combination with naphazoline
Antazoline	H_1-receptor antagonist	Available only in combination with naphazoline
Levocabastine	H_1-receptor antagonist	Downregulates intracellular adhesion molecules, decreasing the inflammatory response; may be used for up to 2 weeks
Olopatadine	Antihistaminic, mast cell stabilizer	
Emedastine	H_1-receptor antagonist; inhibits eosinophil chemotaxis	Superior H_1-receptor binding ability
Ketotifen	H_1-receptor antagonist, mast cell stabilizer, eosinophil inhibitor, platelet-activating factor inhibitor	May inhibit eosinophil chemotaxis
Azelastine	H_1-receptor antagonist, mast cell stabilizer	May inhibit cytokine release
Epinastine	H_1- and H_2-receptor antagonist, mast cell stabilizer, anti-inflammatory	
Nedocromil	Mast cell stabilizer, H_1-receptor antagonist	May inhibit eosinophils
Cromolyn sodium	Mast cell stabilizer	
Lodoxamide	Mast cell stabilizer	May be used for up to 3 months
Pemirolast	Mast cell stabilizer	
Ketorolac	Prostaglandin inhibitor	
Loteprednol	Corticosteroid	Only 0.2% approved for seasonal allergic conjunctivitis

decongestant used in combination products is naphazoline. Topical decongestants burn and sting on instillation and commonly cause mydriasis, especially in patients with lighter-colored eyes. Long-term use leads to rebound congestion or conjunctivitis medicamentosa. Topical decongestant use should be limited to less than 10 days.[17]

There is still debate whether oral antihistamines control ocular allergy as well as topical antihistamines. Topical antihistamines are recommended before oral agent in step therapy because of the increased risk of systemic side effects with oral drugs. Additionally, topical antihistamines provide faster relief of ocular symptoms. Consider oral antihistamines

TABLE 60–4. Dosing and Common Side Effects of Ocular Allergy Drugs

Drug	Dosing[32]	Common Side Effects[17]
Pheniramine	Varies by manufacturer and product	Ocular stinging
Antazoline	Varies by manufacturer and product	Ocular stinging
Levocabastine	1 drop in affected eye(s) four times daily	Ocular stinging, headache
Olopatadine	1–2 drops in affected eye(s) two times daily at 6- to 8- hour intervals	Headache
Emedastine	1 drop in affected eye up to four times daily	Headache
Ketotifen	1 drop in affected eye(s) twice daily	Red eyes (conjunctival injection), headache
Azelastine	1 drop in affected eye(s) twice daily	Ocular stinging, headache, bitter taste
Epinastine	1 drop in each eye twice daily	Ocular stinging, cold symptoms
Nedocromil	1–2 drops in each eye twice daily	Ocular stinging, bitter taste
Cromolyn sodium	1–2 drops in each eye 4–6 times daily	Ocular stinging
Lodoxamide	1–2 drops in affected eye(s) four times daily	Ocular stinging, foreign body sensation
Pemirolast	1–2 drops in affected eye(s) four times daily	Headache, cold symptoms
Ketorolac	1 drop four times a day	Ocular stinging, irritation
Loteprednol	1 drop in affected eye(s) four times daily	Elevated intraocular pressure, cataracts, decreased wound healing, secondary ocular infections, systemic side effects possible

when systemic symptoms are present.[15] Oral antihistamines are reviewed elsewhere in this text.

If insufficient relief is obtained from these products, either a mast cell stabilizer or a multiple-action agent is appropriate.[17] Use mast cell stabilizers prophylactically throughout the allergy season. Full response may take 4 to 6 weeks.

If mast cell stabilizers or multiple-action agents are not successful, a trial of a topical NSAID is appropriate. Ketorolac is the only approved topical agent for ocular itching. NSAIDs do not mask ocular infections, affect wound healing, increase intraocular pressure, or contribute to cataract formation like the topical corticosteroids. However, for allergic conjunctivitis, topical ketorolac is not as effective as olopatadine or emedastine in trials.[15] Full efficacy of ketorolac takes up to 2 weeks. [17]

If all these avenues are ineffective, short-term topical corticosteroids and immunotherapy are the third-line treatments for ocular allergy.[17]

Outcome Evaluation

Monitor patients for relief of symptoms. Ensure an adequate trial of the agent. If no improvement is seen, follow a stepped-care approach to treatment. Refer severe cases that do not respond to an ophthalmologist for short-term topical corticosteroids.

BACTERIAL KERATITIS

Epidemiology

Thirty thousand cases of microbial **keratitis** occur annually in the United States.[18] Microbial keratitis encompasses bacterial, fungal, and *Acanthamoeba* keratitis.[19] Only bacterial keratitis, the most common form, is discussed here.

Pathophysiology

Bacterial keratitis is a broad term for a bacterial infection of the cornea. This includes corneal ulcers and corneal abscesses. The cornea in a healthy eye has natural resistance to infection, making bacterial keratitis rare. However, many factors predispose a patient to bacterial infection by compromising the defense mechanisms of the eye (Table 60–5).[19]

The most common pathogens in bacterial keratitis are *Pseudomonas* (including *Pseudomonas aeruginosa*) and other gram-negative rods, staphylococci, and streptococci. If the keratitis is related to the use of contacts, *Pseudomonas* is the most common cause followed by *Serratia marcescens*. For hospitalized infants and adults on respirators, *Pseudomonas* is the most common.[19]

❼ *Untreated bacterial keratitis is associated with corneal scarring and potential loss of vision. Corneal perforation may occur and the patient may lose the eye.* In virulent organisms, this destruction may occur within 24 hours. Central corneal scarring may result in vision loss even after successful eradication of the organism.

Clinical Presentation and Diagnosis of Bacterial Keratitis[10]

General

The rate of progression of signs and symptoms varies depending on the infecting organism. A differential diagnosis for keratitis must include viral, fungal, and nematodal infections in addition to bacterial causes.[19]

Symptoms

- Photophobia
- Rapid onset of ocular pain

Signs

- Red eye
- Conjunctival discharge
- Decreased vision

Laboratory Tests

Culture if keratitis is severe or sight-threatening. Otherwise, cultures or smears are used only if the corneal infiltrate is chronic or unresponsive to broad-spectrum antimicrobial therapy.[19]

Treatment

Desired Outcomes

- Resolution of infection
- Resolution of corneal inflammation
- Reduced corneal pain
- Restored corneal integrity with minimal scarring
- Restored visual function[19]

TABLE 60–5. Risk Factors for Bacterial Keratitis[19]

Exogenous Factors	**Medications**
Contact lenses	Contaminated ocular medications
Trauma	Topical non-steroidal anti-inflammatory drugs
Previous ocular or eyelid surgery	Anesthetics
Loose sutures	Steroids
Previous corneal surgery	Antimicrobials
Ocular Surface Disease	Preservatives
Misdirection of eyelashes	Glaucoma medications
Abnormal lid anatomy or function	**Corneal Epithelial Abnormalities**
Tear film deficiencies	Herpes zoster ophthalmicus
Ocular infection such as conjunctivitis or blepharitis	Herpes simplex keratitis
Systemic Conditions	Corneal epithelial edema
Diabetes mellitus	Predisposition to recurrent erosion of the cornea
Debilitating illness (malnourishment or respiratory)	
Connective tissue disease	
Substance abuse	
Stevens-Johnson syndrome	
Immunocompromised	
Atopic dermatitis	
Gonococcal infection	
Vitamin A deficiency	

TABLE 60–6. Pharmacologic Therapies for Bacterial Keratitis[19]

Organism	Drug	Topical Dosing
Unknown or multiple organisms	Fluoroquinolones 3 mg/mL	Severe keratitis: loading dose every 5–15 minutes for the first hour, then every 15 minutes to 1 hour around the clock
Gram-positive cocci	Cefazolin 50 mg/mL *or* Vancomycin 15–50 mg/mL	Less severe keratitis may use less frequent dosing
Gram-negative rods	Tobramycin 3–14 mg/mL *or* Gentamicin 3–14 mg/mL *or* Ceftazidime 50 mg/mL *or* Fluoroquinolones 3 mg/mL	Antibiotics may be alternated each hour for ulcers and contact lens wearers as indicated
Gram-negative cocci	Ceftriaxone 50 mg/mL *or* Ceftazidime 50 mg/mL *or* Fluoroquinolones 3 mg/mL	
Non-tuberculous mycobacteria	Amikacin 20–40 mg/mL *or* **Oral** clarithromycin 500 mg every 12 hours	
Nocardia	Amikacin 20–40 mg/mL *or* Trimethoprim 16 mg/mL and sulfamethoxazole 80 mg/mL	

General Approach to Treatment

All cases of suspected bacterial keratitis require prompt ophthalmology consultation to prevent permanent vision loss.[10]

Pharmacologic Therapy

Dosage Considerations

Topical antibiotic drops are preferred. Consider subconjunctival antibiotics if compliance is a concern. Systemic therapy is useful in cases of systemic infection (e.g., gonorrhea) or if the sclera is infected. Reserve ointments for minor cases or adjunctive nighttime therapy.[19]

Drug Choice

Start topical broad-spectrum antibiotics empirically. Use a loading dose for severe keratitis (Table 60–6). Single-drug therapy with a fluoroquinolone is as effective as combination therapy. Resistance is seen with some fluoroquinolones. Because of this, choose a newer fluoroquinolone such as moxifloxacin or gatifloxacin in severe keratitis cases.[6] Fortified antibiotic therapy is an option for severe or unresponsive infections, but may increase toxicity to the cornea and surrounding tissues. Fortified antibiotics must be compounded.[19] All compounded formulations must comply with governmental 797 regulations concerning compounding of drug preparations.

Topical corticosteroids are employed in some cases of bacterial keratitis. The suppression of inflammation may reduce corneal scarring. However, local immunosuppression, increased ocular pressure, and reappearance of the infection are disadvantages to their use. There is no conclusive evidence that they alter clinical outcomes. If the patient is already on topical corticosteroids when the keratitis occurs, discontinue use until the infection is eliminated.[19]

Outcome Evaluation[19]

- Monitor patient symptoms for improvement to determine therapeutic efficacy
- Modify treatment regimen based on results of culture and sensitivity testing, if necessary
- Modify the treatment regimen if the patient does not show improvement within 48 hours
- Gram-negative keratitis will have increased inflammation in the first 24 to 48 hours, even on appropriate therapy
- Taper therapy based on clinical response
- Reculture or biopsy if negative clinical response; discontinue antibiotics for 12 to 24 hours before culture to improve culture results

MACULAR DEGENERATION

Epidemiology and Etiology

Age-related macular degeneration (AMD) is the primary cause of irreversible vision loss in developed countries (Figs. 60–2 and 60–3). The prevalence increases with age.[20] In the United States, 1.75 million people age 40 or older have AMD; another 7 million people are at substantial risk of developing it. Because of the rapid aging of the United States population, it is projected that almost 3 million people will develop AMD by 2020.[21] The causes of AMD are not completely known (Table 60–7).

Pathophysiology

AMD is a deterioration of the central portion of the retina (the **macula**). The macula facilitates central vision and high-resolution visual acuity because it has the highest concentration of photoreceptors in the retina. The loss of central

FIGURE 60–2. Normal vision. (From the National Eye Institute, National Institutes of Health Ref. No. EDS01. Accessed online at: http://www.nei.nih.gov/photo/)

vision leads to irreversible loss of the ability to drive, read, and perform other fine visual tasks like recognize faces.[22] Peripheral vision is preserved, allowing mobility.[20]

Early macular changes are often called age-related maculopathy and are characterized by large **drusen** and pigmentary abnormalities in the macula.[20] Age-related maculopathy accounts for 85% to 90% of all age-related macular changes. Ten to fifteen percent of these patients will develop advanced atrophy and/or develop abnormal blood vessels in and under the retina called **choroidal neovascular membranes**. Patients are then classified as having AMD.[23]

There are two forms of AMD: atrophic (also called the non-exudative or dry form) and neovascular (the exudative or wet form). Ten to twenty percent of patients with the atrophic form will progress to the neovascular form.[23] The neovascular form is responsible for the majority of the cases of blindness; however, vision loss is seen in both forms.[20]

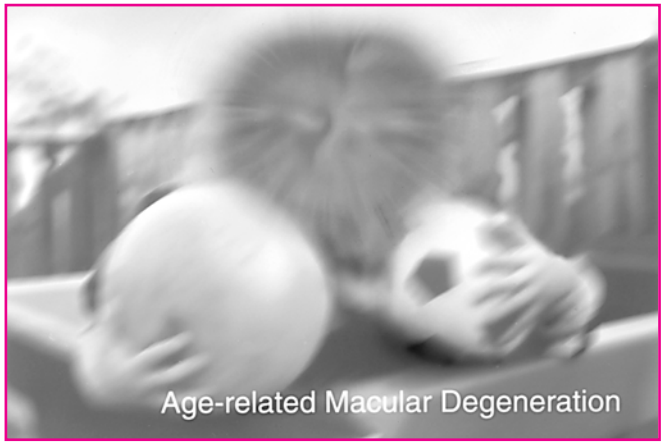

FIGURE 60–3. The scene in Fig. 60–2 as it might be viewed by a person with age-related macular degeneration. (From the National Eye Institute, National Institutes of Health Ref. No. EDS05. Accessed online at: http://www.nei.nih.gov/photo/)

TABLE 60–7. Risk Factors for AMD[20,33]

Definite Risk Factors	Potential Risk Factors
Advancing age (greater than 60 years)	Female gender
Light pigmentation (white ethnicity)	Cardiovascular disease
Cigarette smoking	Hypertension
Family history	Increased body mass index (especially in women)
Low dietary intake of antioxidant vitamins or zinc	Higher dietary fat intake
	Light-colored irides
	Increased exposure to sunlight

Treatment

Desired Outcomes

The primary goal of treatment for AMD is to slow the disease progression. This includes slowing the loss of visual acuity and the progression to legal blindness, along with maintaining contrast sensitivity and slowing the rate of progression to late AMD. The secondary goals are maintaining quality of life for the patient and minimizing the adverse effects of treatment.[22]

Clinical Presentation and Diagnosis of AMD

Symptoms

Age-related maculopathy:

- Mild blurry central vision
- Difficulty reading
- Trouble with color and contrast[23]

Age-Related Macular Degeneration[20,23]

- Painless, progressive moderate to severe blurring of central vision
- Sudden loss or distortion of vision possible

Signs[23]

- Drusen
- Retinal pigment epithelial mottling

Other Diagnostic Tests[20,23]

- Amsler's grid abnormalities indicate fluid in subretinal space (Figs. 60–4 and 60–5)
- Dilated fundus examination shows drusen and pigmentary abnormalities in the macula
- Rapid sequence fluorescein angiography shows leakage in the neovascular form

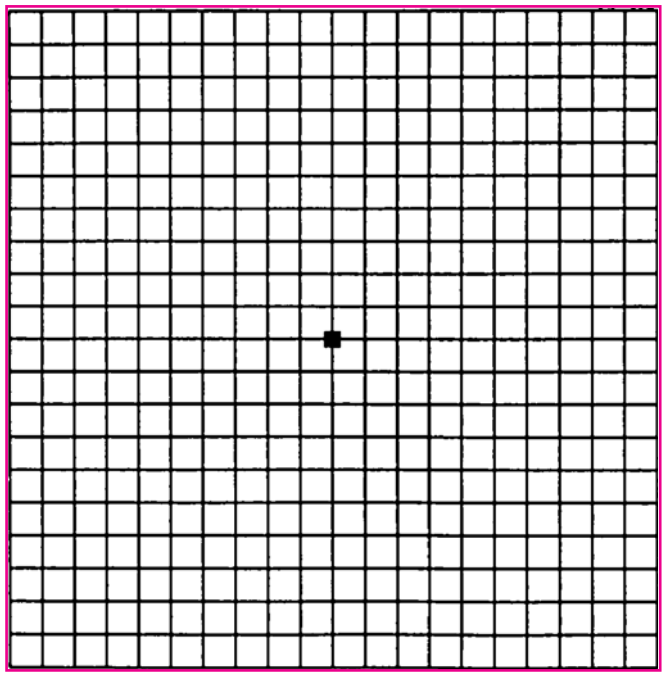

FIGURE 60–4. Amsler's grid distortions in the lines of the grid may be caused by subtle changes in central vision due to fluid in the subretinal space. This is the Amsler's grid as it appears to someone with normal vision. (From the National Eye Institute, National Institutes of Health Ref. No. EC03. Accessed online at: http://www.nei.nih.gov/photo/)

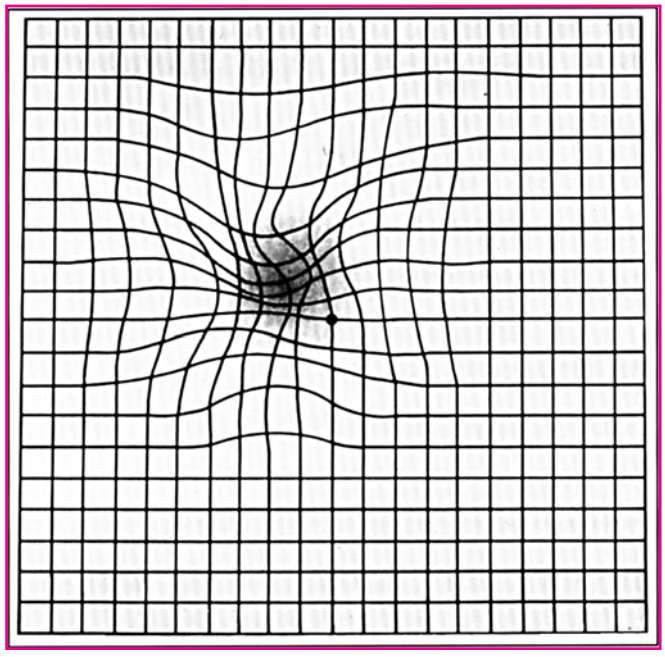

FIGURE 60–5. Amsler's grid as it might appear to someone with AMD. (From the National Eye Institute, National Institutes of Health Ref. No. EC04. Accessed online at: http://www.nei.nih.gov/photo/)

General Approach to Treatment

There is no cure for AMD and the efficacy of most treatments is low. Newer drug developments show promise but no treatment can reverse damage that has already occurred.[23] Early diagnosis is critical. High-risk patients need periodic eye examinations because some patients do not notice any changes, even when neovascularization has occurred.[20]

Nonpharmacologic Treatment

Age-Related Maculopathy and Atrophic Age-Related Macular Degeneration

Drusen ablation may help patients with multiple large drusen in both eyes that have not progressed to neovascular macular degeneration. These laser treatments may lead to resolution of the drusen and improved visual acuity. However, it is not clear if progression to choroidal neovascular membranes and neovascular macular degeneration is reduced.[23] There is a possibility that the laser treatments may induce choroidal neovascularization and retinal atrophy.[22]

Neovascular Age-Related Macular Degeneration

Until recently, the only treatments for neovascular AMD were nonpharmacologic. Thermal laser photocoagulation reduces severe visual loss 2 to 5 years after the procedure, but leads to an immediate and permanent reduction in central vision. There is a 50% chance that leakage will recur in the next 2 years after the procedure.[20,22]

Photodynamic therapy uses non-thermal red light to activate verteporfin, which produces reactive oxygen species that locally damage the neovascular endothelium.[24] Verteporfin treatment reduces the risk of loss of visual acuity and legal blindness over 1 to 2 years. Long-term results are not yet available. Severe photosensitivity for 3 to 5 days after the procedure is common and some patients experience a severe loss of vision. Eventually, most patients have some visual recovery. This procedure requires multiple treatments over time.[22]

Pharmacologic Therapy

Atrophic Age-Related Macular Degeneration

There are no approved pharmacologic treatments for atrophic AMD. The Age-Related Eye Disease Study showed that a supplement containing ascorbic acid 500 mg, vitamin E 400 IU, beta carotene 15 mg, zinc oxide 80 mg, and cupric oxide 2 mg reduced the rate of clinical progression of all types of AMD by 28% in patients with at least intermediate macular degeneration. No benefit was seen in patients with earlier stages of age-related maculopathy; however, the duration of the study may have been insufficient to detect this benefit.[25]

Supplementation is not without risk. For example, beta carotene supplementation in smokers may increase the risk of developing lung cancer.[23] At this time, it is not clear from the

evidence if a patient at high risk but without symptoms of AMD would benefit from supplementation.[26]

Neovascular Age-Related Macular Degeneration

Vascular endothelial growth factor induces **angiogenesis**, increases vascular permeability, and increases inflammation, all of which are thought to contribute to neovascular AMD. A new class of drugs, the vascular endothelial growth factor antagonists, binds to these growth factors in an attempt to suppress neovascularization. Pegaptanib is the only approved drug in this class at this time.[27]

Pegaptanib 0.3 mg is administered as an intravitreous injection every 6 weeks. In clinical studies, patients treated with pegaptanib experienced a slower rate of visual decline than patients treated with a sham injection.[28] Vision loss continued to occur in patients and the drug was less effective in the second year of treatment. Long-term efficacy studies are not available yet.[27]

Outcome Evaluation

Monitor patients for acute and chronic vision changes or loss. The Amsler's grid and frequent eye examinations may detect changes more quickly. The long-term prognosis for AMD is poor. Monitor patients for inability to drive and remove driving privileges as appropriate. Work with patients and family members to plan for lifestyle changes as vision decreases.

DRY EYE

Epidemiology

Dry eye is a frequent cause of eye irritation. A lack of a single diagnostic test for the condition limits the available epidemiologic data. One study estimated the prevalence of dry eye in the United States population age 65 and older at 14.6%, which is approximately 4.3 million Americans.[29]

The risk factors for dry eye are listed in Table 60–8. Of interest, the use of caffeine is associated with a decreased risk of dry eye. Dry eye that is left untreated can cause loss of vision or other morbidities over time.[30]

TABLE 60–8. Risk Factors for Dry Eye[30]

Older age
Female gender
Arthritis
Smoking
Multivitamin use
Estrogen replacement therapy

Pathophysiology

The ocular surface and the tear-secreting glands of the eye are now known to function as an integrated unit. This unit refreshes the tear supply and clears used tears. An autonomic neural reflex loop stimulates secretion of tear fluid and proteins by the lacrimal glands. The sensitivity of the ocular surface decreases as aqueous tear production and tear clearance decreases. This results in a decrease in sensory-stimulated reflex tearing which exacerbates dry eye.[29,30] Over time, wearing contact lenses also desensitizes the cornea by constant stimulation.[12]

Dysfunction may be caused by aging, systemic inflammatory diseases, a decrease in androgen hormones, surgery, ocular surface diseases (such as herpes zoster), systemic diseases, or medications that affect the efferent cholinergic nerves. Decreased tear secretion produces an inflammatory response on the ocular surface called **keratoconjunctivitis sicca**. This inflammation is now a target for new medications that treat dry eye.[29,30]

Conditions that increase the evaporative loss of tears also worsen dry eye. In addition to environmental causes (Table 60–9) an abnormal blink reflex is a common cause of increased evaporative loss.[30]

TABLE 60–9. Associated Conditions That Cause or Worsen Dry Eye[30]

Ocular Conditions	**Local Trauma**
Blepharitis	Orbital surgery
Meibomian gland dysfunction	Radiation
Systemic Diseases	Injury
Sjögren's syndrome	Chemical exposure
Rosacea	**Systemic Medications**
Lymphoma	Diuretics
Sarcoidosis	Antihistamines
Hemochromatosis	Anticholinergics
Amyloidosis	Antidepressants
Human immunodeficiency virus	Systemic retinoids
Hepatitis C	Isotretinoin
Epstein-Barr virus	Hormones
Graft-versus-host disease	Hormone therapy
Rheumatoid arthritis	Cardiac antiarrhythmic
Systemic lupus erythematosus	Diphenoxylate/atropine
Scleroderma	β-Blockers
Neuromuscular diseases	Chemotherapy agents
Bell's palsy	
Parkinson's disease	
Environmental Factors	
Wind	
Reduced humidity	
Air conditioning or heating	
Exogenous irritants or allergens	
Prolonged use of computer or reading	
Contact lenses	
Air travel	
Smoke exposure	

Clinical Presentation and Diagnosis of Dry Eye[30]

General

Many other ocular diseases have similar symptoms. Patients with suggestive symptoms without signs should be placed on a treatment trial. Repeated observations over time may be required for a clinical diagnosis.

Symptoms

- Dry or foreign body sensation
- Mild itching
- Burning
- Stinging
- Photophobia
- Ocular irritation or soreness
- Blurry vision
- Contact lens intolerance
- Diurnal fluctuation
- Symptoms that worsen later in the day

Signs

- Redness
- Mucus discharge
- Increased blink frequency
- Tearing

Other Diagnostic Tests

- The tear break-up time test assesses the stability of precorneal tear film. Break-up times of less than 10 seconds are considered abnormal.
- Ocular surface dye staining assesses the ocular surface and will show blotchy or exposure-zone punctate areas in the dry eye.
- Schirmer's test evaluates aqueous tear production but is not diagnostic for dry eye. Results of 5 mm or less are considered abnormal.
- Assess corneal sensation if trigeminal nerve dysfunction is suspected.
- Evaluate for an autoimmune disorder if significant dry eyes or other signs and symptoms or family history are present.

Treatment

Desired Outcomes

- Relief of the symptoms of dry eye
- Prevention of recurrence
- Prevention of long-term adverse effects from dry eye

General Approach to Treatment

❾ *Dry eye is a chronic condition. Symptoms can be improved with treatment but unless dry eye is secondary to a disease, it is not usually curable. Because of this, patient education is critical and a periodic reassessment of the efficacy of the treatment is appropriate.* If the patient is unresponsive to treatment, refer to an ophthalmologist for additional options. If the dry eye is secondary to a systemic disease, the disease should be managed by the appropriate medical specialist.[30]

Nonpharmacologic Therapy

Behavioral and environmental modifications may significantly improve dry eye, especially in mild cases. Evaluate the patient's environment for air drafts. Consider adding a humidifier in low-humidity areas. Schedule regular breaks from computer work or reading. Lower the computer screen to below eye level to decrease lid aperture. Evaluate medication use and make therapeutic substitutions to medications that do not exacerbate dry eye. Spectacle sideshields or goggles may reduce tear evaporation.[30]

If pharmacologic and other therapies are not sufficient, punctal occlusion or lateral tarsorrhaphy may be an option. Punctal occlusion is the plugging of the punctal drainage sites with collagen (temporary) or Silastic (permanent) plugs. Lateral tarsorrhaphy sutures portions of the lid margins together to decrease evaporative tear loss. These procedures are reserved for severe cases of dry eye secondary to other diseases. [12]

Pharmacologic Therapy

Regardless of the cause, the mainstay of treatment for dry eye is artificial tears. Artificial tears augment the tear film topically and provide relief. If a patient uses artificial tears more than four times daily, recommend a preservative-free formulation. Preservative-free formulations are also appropriate if the patient develops an allergy to ophthalmic preservatives. Artificial tears are available in gel, ointment, and emulsion forms that provide a longer duration of relief and may allow for less frequent instillation. Ointment use is appropriate at bedtime.[30]

Anti-inflammatory agents may be used in conjunction with artificial tears. The only approved agent is cyclosporine emulsion. Administered topically, it is thought to act as a partial immunomodulator suppressing ocular inflammation, but the exact mechanism is unknown. Cyclosporine emulsion increases tear production in some patients. Fifteen minutes should elapse after instillation of cyclosporine before artificial tears are instilled.[31] Use of topical corticosteroids for short periods (e.g., 2 weeks) may suppress inflammation and ocular irritation symptoms. No topical corticosteroid is approved for this indication, however.[30]

The oral cholinergic agonists pilocarpine and cevimeline are used for patients with combined dry eye and dry mouth (e.g., Sjögren's syndrome) or severe dry eye. By binding to muscarinic receptors, the cholinergic agonists may increase tear production. Excessive sweating is a common side effect with pilocarpine and may limit its use (Table 60–10).

TABLE 60–10. Pharmacologic Therapies for Dry Eye[32]

Drug (Brand Name)	Dosing
Pilocarpine 5 mg tablet (Salagen®)	5 mg orally four times daily
Cevimeline 30 mg capsule (Evoxac®)	30 mg orally three times daily
Cyclosporine ophthalmic emulsion 0.05% (Restasis®)	One drop in each eye twice daily

Patient Encounter 2

A 60-year-old woman presents with complaints of redness, burning, and watering of both eyes. She does not have any itching of the eyes or other visible discharge. She has had the symptoms, which are more severe when she arises in the morning, for several years. The symptoms have become worse recently. Your physical examination reveals red and teary eyes.

Her medical history includes osteoarthritis, mild osteoporosis, and hypertension. She also has recurrent sinus infections associated with seasonal allergic rhinitis. She is a medical transcriptionist.

Meds

Metoprolol 100 mg daily
Premarin 0.3 mg daily
Calcium carbonate 1200 mg daily
Ibuprofen 600 mg as needed for joint pain
Loratadine 10 mg as needed for allergies
Senior over-the-counter multivitamin daily

- What is the probable diagnosis?
- What are the other contributing factors that may be worsening her condition?
- What nonpharmacologic interventions might she benefit from?
- What treatment option is best for her?

Outcome Evaluation[29]

- Monitor patient for relief of symptoms
- Periodically reassess the patient's compliance and understanding of the disease
- It may take 6 weeks before improvement is seen with pilocarpine therapy
- Cyclosporine therapy may take up to 6 months for full efficacy
- If a patient presents with visual loss, moderate or severe pain, corneal ulceration, or a lack of response to therapy, refer the patient to an ophthalmologist for prompt evaluation

DRUG-INDUCED OCULAR DISORDERS

Table 60–11 shows some ocular changes due to the use of certain drugs.

Nasolacrimal Occlusion[37]

Use of nasolacrimal occlusion decreases systemic absorption up to 60% and may increase ocular bioavailability of the drug. After instillation of the eye drop, the patient should close the eye and press a finger gently against the nasolacrimal duct (tear duct) for 2 to 3 minutes.

TABLE 60–11. Selected Drug-Induced Ocular Changes

Miosis[34]	**Mydriasis[34]**
Narcotics	Anticholinergics
Barbiturates	Tricyclic antidepressants
Phenothiazines	Sympathomimetics
Decreased Tear Volume[34]	**Corneal Deposits[35]**
Anticholinergics	Amiodarone
Antihistamines	Chloroquine and hydroxychloroquine
Diuretics	Tamoxifen
β-Blockers	Gold
Tricyclic antidepressants	Ibuprofen, naproxen, and indomethacin
Nystagmus[34]	Phenothiazines
Phenytoin	**Cause or Worsen Cataracts[34]**
Barbiturates	Corticosteroids
Increased Tear Volume[34]	**Decreased Blink Rate[34]**
Cholinergic agents	Sedative-hypnotics
Benzodiazepines	Ethanol
Phenothiazines	**Lid and Corneal Edema[34]**
Induce Uveitis[36]	Chlorthalidone
Rifabutin	Oral contraceptives
Bisphosphonates	Ibuprofen
Sulfonamides	Digoxin
Cidofovir	Phenothiazines
Topical metipranolol	
Topical corticosteroids	
Latanoprost

61 PSORIASIS

Rebecca M.T. Law

LEARNING OBJECTIVES

UPON COMPLETION OF THE CHAPTER, THE READER WILL BE ABLE TO:

1. Discuss the etiology of psoriasis including genetic and immune changes.
2. Describe the pathophysiology of psoriasis including types of psoriasis and clinical presentations.
3. Compare and contrast the treatment modalities for psoriasis, including topical and systemic therapies and phototherapy.
4. Recommend an appropriate treatment plan for a patient with psoriasis.
5. Recommend appropriate monitoring parameters for a patient on drug treatment for psoriasis.
6. Provide appropriate counseling information to a patient with psoriasis.

KEY CONCEPTS

❶ Patients with psoriasis have a lifelong illness that may be very visible and emotionally distressing. There is a strong need for empathy and a caring attitude in interactions with these patients.

❷ Psoriasis is a T-lymphocyte–mediated inflammatory disease that results from a complex interplay between multiple genetic factors and environmental influences. Genetic predisposition coupled with some precipitating factor triggers an abnormal immune response, resulting in the initial psoriatic skin lesions. Keratinocyte proliferation is central to the clinical presentation of psoriasis.

❸ Diagnosis of psoriasis is usually based on recognition of the characteristic plaque lesion, and not based on lab tests.

❹ Treatment goals for patients with psoriasis are to minimize signs such as plaques and scales, alleviate symptoms such as pruritus, reduce the frequency of flare-ups, and ensure appropriate treatment of associated conditions such as psoriatic arthritis or clinical depression, and minimize treatment-related morbidity.

❺ Management of patients with psoriasis generally involves both nonpharmacologic and pharmacologic therapies.

❻ Nonpharmacologic alternatives such as stress reduction and the liberal use of moisturizers may be extremely beneficial and should always be considered and initiated when appropriate.

❼ Pharmacologic alternatives for psoriasis include topical agents, phototherapy, and systemic agents including the use of biologic response modifiers.

❽ In initiating pharmacologic treatment, the choice of therapy is generally guided by the severity of disease: topical agents would be appropriate for mild to moderate disease while a systemic agent would be a more appropriate choice for moderate to severe disease. Phototherapy or photochemotherapy are used for patients with moderate to severe psoriasis, generally when topical therapies alone are inadequate. Patient-specific concerns such as existing comorbid conditions (e.g., renal impairment or hepatic disease) must also be taken into consideration in the choice of therapy. Once the disease is under control, it would be important to step down to the least potent, least toxic agent(s) that maintain control.

❾ Rotational therapy (i.e., rotating systemic drug interventions in a sequential manner) is a means to minimize drug-associated toxicities, since systemic agents for psoriasis often have differing toxicities. This may be considered for psoriasis patients who require systemic treatments long-term to manage their condition.

❿ Some biologic response modifiers have proven efficacy for psoriasis; however, there are differences among these agents, including mechanism of action, duration of remission, and adverse-effect profile. In general, due to their immunosuppressive effects, there is an increased risk of infection with most of these agents. The use of live or live-attenuated vaccines during therapy is generally not recommended. Currently, biologic response modifiers are often considered for patients with moderate to severe psoriasis when other systemic agents are inadequate. It has also been

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

recommended that biologic response modifiers be considered as first-line therapy, alongside conventional systemic agents, for patients with moderate to severe psoriasis; however, in practice, cost may be a limiting factor.

Psoriasis is a disease that waxes and wanes. It is a chronic illness that is never cured; however, the signs and symptoms of psoriasis may go into remission (subside totally) and then return again (flare-up, exacerbation, or reactivation). Remission may last for years in some patients, while in others exacerbations may occur every few weeks. Triggers include stress, seasonal changes, and some drugs. Disease flare-ups may also occur at times of life crises. Disease severity may vary from mild to disabling. Thus, management of this condition is necessarily long-term, and management modalities may change according to the severity of illness at the time.

❶ *Patients with psoriasis have a lifelong illness that may be very visible and emotionally distressing. There is a strong need for empathy and a caring attitude in interactions with these patients.*

EPIDEMIOLOGY AND ETIOLOGY

Psoriasis is a common inflammatory skin disorder which is estimated to affect 1.5% to 3% of the Caucasian population.[1,2] It may present at any age.[3,4] Ethnic factors influence disease prevalence. In the United States, prevalence among blacks (0.45% to 0.7%) is lower than in the remainder of the United States population (1.4% to 4.6%).[1] Between 10% and 30% of patients with psoriasis will also have psoriatic arthritis.[5] In 10% to 15% of psoriatic patients with arthritis, joint symptoms actually appear prior to skin involvement.[3] Clinical depression is another frequent comorbid illness in these patients. A recent United States survey showed that 8% to 10% of psoriatic patients aged 18 to 54 years old actively contemplated suicide because of their psoriasis.[6]

❷ *Psoriasis is a T-lymphocyte–mediated inflammatory disease that results from a complex interplay between multiple genetic factors and environmental influences.[1] Genetic predisposition coupled with some precipitating factor triggers an abnormal immune response, resulting in the initial psoriatic skin lesions.* Other risk factors may exacerbate preexisting psoriasis and cause disease flare-ups. Precipitating factors include skin trauma such as a horse-fly bite (known as the **Koebner phenomenon),** an environmental change such as cold weather, stress, a viral or streptococcal infection, or use of a β-adrenergic blocker.[2] Factors exacerbating psoriasis include drugs (e.g., lithium, nonsteroidal anti-inflammatory drugs, antimalarials, β-adrenergic blockers, and withdrawal of corticosteroids), and psoriatic patients commonly have exacerbations during times of stress.[2]

There is a polygenic inheritance pattern which may account for disease susceptibility and expression.[7] Family linkage studies have identified several genetic loci that are potentially responsible: the *PSOR1* gene on chromosome 6p21.3, the *PSOR2* gene on chromosome 17q25, the *PSOR3* gene on chromosome 4q34, the *PSOR4* gene on chromosome 1q21, the *PSOR5* gene on chromosome 3q21, the *PSOR6* gene on chromosome 19p13, the *PSOR7* gene on chromosome 1p, the *PSOR8* gene on chromosome 16q12-13 (which links to both psoriasis and Crohn's disease), and the *PSOR9* gene on chromosome 4q31.[1,4,7,8] There are possibly other genetic loci. *PSOR1* has been considered the major gene locus for psoriasis;[1,4] it appears to be associated with up to 50% of cases of psoriasis.[1]

Studies conducted in twins show a threefold increased risk of psoriasis in monozygotic twins versus fraternal twins.[7] In addition, based on a study in 3,095 families with psoriasis, the calculated lifetime risk of developing psoriasis if no parent, one parent, or both parents have psoriasis was found to be 0.04, 0.28, and 0.65, respectively. If there was already one affected child in the family, the risks were increased to 0.24, 0.51, and 0.83, respectively.[7,9] As many as 71% of patients with psoriasis during childhood have some positive family history.[1] Similarly, psoriatic arthritis is heritable, with a prevalence 19 times higher in first-degree relatives of patients with psoriatic arthritis than in the general population.[7]

PATHOPHYSIOLOGY

❷ *Keratinocyte proliferation is central to the clinical presentation of psoriasis.* **Keratinocytes** are skin cells producing keratin which act as a skin barrier. Increased keratinocyte cell turnover (hyperkeratosis) results in the characteristic thick scaly skin lesions seen in patients with psoriasis.[10,11] Hyperkeratosis results from immune derangements.

The abnormal immune response seen in psoriasis is mediated primarily by T lymphocytes (T cells).[1] In patients with psoriasis, certain types of T cells are overactive and migrate to the skin in large numbers. T cells access the skin by binding to activated endothelial cells via intracellular cell adhesion molecules (ICAM-1).[1,12] These naïve T cells then encounter antigens in the skin, which are presented to the T cells by antigen-presenting cells (APCs), and become activated. There is an LFA-3–CD2 signal which plays an important part in T-cell activation: LFA-3 is the leukocyte-function-associated antigen type 3 found on APCs; CD2 is a cell-surface glycoprotein expressed on T-cell subtypes.[1] When LFA-3 interacts with CD2, there is an increased proliferation of T cells.[13]

Activated T cells begin releasing cytokines including interleukin-2 (IL-2), interferon-γ, (IFN-γ), tumor necrosis factor (TNF-α), and others.[4,13] Cytokine activity leads to a rapid proliferation and turnover of skin cells, triggering the inflammatory process and the development of psoriatic skin lesions.[4,13,14] TNF-α may have a role in disease severity; it upregulates endothelial and keratinocyte expression of ICAM-1,

Patient Encounter, Part 1

A 25-year-old Caucasian man presents with itchy lesions on his scalp, chest, back, elbows, and knees. He says these lesions started about a month ago, and seem to be spreading. Upon examination, the lesions are well-demarcated and are reddish-violet in color—easily distinguished from normal skin. They appeared raised and are covered with loose scales. Removing the scales caused pinpoints of bleeding to show up.

- What information is consistent with psoriasis in this patient?

activates T cells, enhances T-cell infiltration, and augments keratinocyte proliferation.[12]

Treatment of psoriasis is based on an understanding of the underlying pathophysiology. Agents that modulate the abnormal immune response, such as corticosteroids and biologic response modifiers, are important treatment strategies for psoriasis. In addition, topical therapies that affect cell turnover are effective for psoriasis. Clinically, a treatment regimen should always be individualized, taking into consideration severity of disease, patient responses, and tolerability to various interventions.

CLINICAL PRESENTATION

❸ *Diagnosis of psoriasis is usually based on recognition of the characteristic plaque lesion, and not based on lab tests.*

Clinical Presentation of Plaque Psoriasis

General
- Patients have small discrete to generalized confluent lesions over the entire body.

Symptoms
- Patients may complain of severe itching.

Signs
- Lesions are raised and are red to violet in color (commonly known as plaques).
- Lesions have sharply demarcated borders except where confluent.
- Lesions are loosely covered with silvery-white scales, which if lifted off, show small pinpoints of bleeding (Auspitz sign).
- Plaques appear most commonly on the elbows, knees, scalp, umbilicus, and lumbar areas, and often extend to involve the trunk, arms, legs, face, ears, palms, soles, and nails.
- Nail involvement presents as pitting, discoloration ("oil spots"), crumbling, splinter hemorrhages, growth arrest lines, or tissue build-up around the nails.

Clinical Presentation of Other Types of Psoriasis

Inverse psoriasis spares the areas commonly involved in plaque psoriasis and instead appears in intertriginous areas, where scaling is minimal.
Guttate psoriasis presents as a sudden eruption of small, disseminated erythematosquamous papules and plaques, and is often preceded by a streptococcal infection 2 to 3 weeks prior.
Pustular psoriasis may be localized or generalized and may be an acute emergency requiring systemic therapy.
Generalized pustular psoriasis is characterized by disseminated deep-red erythematous areas and pustules, which may merge to become "lakes of pus."
Erythrodermic psoriasis is a generalized, life-threatening condition that presents with erythema, desquamation, and edema, and may require life support measures as well as systemic therapy.
Psoriatic diaper rash is the most common type of psoriasis in children under 2 years old. This usually affects inguinal folds and greater than 90% of psoriatic diaper rash cases may have involvement outside the diaper area.

TREATMENT

Desired Outcomes and Goals

❹ *Since psoriasis is a chronic illness with no known cure, the goals of treatment focus on controlling the signs and symptoms of disease,* including:

- Minimizing or eliminating the signs of psoriasis such as plaques and scales.
- Alleviating pruritus and minimizing excoriations.
- Reducing the frequency of flare-ups.
- Ensuring appropriate treatment of associated conditions such as psoriatic arthritis.
- Avoiding or minimizing adverse effects from topical or systemic treatments used.
- Providing cost-effective therapy.
- Providing guidance or counseling as needed (e.g., stress-reduction techniques).
- Maintaining or improving the patient's quality of life.

General Approach to Treatment

❺ *Management of patients with psoriasis generally involves both nonpharmacologic and pharmacologic therapies.* Pharmacologic alternatives for plaque psoriasis include topical treatments, **phototherapy**, **photochemotherapy**, and systemic therapies alone (orally or by injection). The choice of treatment is usually dictated by the severity of disease.[15–17] In some cases, a combination of treatment options may be preferred. Topical therapies can be used in patients with limited or mild

Patient Encounter, Part 2

Additional relevant information was obtained from the patient, including the following history.

FH
His father and one of his brothers have psoriasis; his only sister has atopic dermatitis

SH
He works as an assistant copywriter in a busy publishing house, and is constantly struggling with multiple deadlines; he is an occasional social drinker and nonsmoker; he is a single father to a 6-year-old boy

PE
He appears anxious and embarrassed about the lesions

VS: Blood pressure 125/70 mm Hg, pulse 72 bpm, respiratory rate 16/minute, temperature 37°C (98.6°F)
CV: Regular rate and rhythm, normal S1, S2; no murmurs, rubs, or gallops
Abd: Soft, nontender; bowel sounds present
Exts: Within normal limits; no joint pains
Skin: Multiple lesions on the scalp, chest, back, elbows, and knees; evidence of excoriation on the chest.

- What risk factors does he have for psoriasis?
- Identify your treatment goals for the patient.

to moderately severe disease. Phototherapy and photochemotherapy are used in moderate to severe disease. Systemic therapies are used for patients with extensive or moderate to severe disease. To minimize drug toxicities in these patients, systemic therapies are often used in rotation, or used in conjunction with topical or phototherapy.[16,17] Biologic agents are becoming incorporated into the same category as other systemic agents and are currently recommended for consideration as first-line therapies alongside conventional systemic agents for moderate to severe disease.[17] However, since there is a significant cost difference, biologic agents are often reserved for cases in whom traditional systemic agents provide inadequate control. There are two recently published treatment guidelines including a general consensus on psoriasis treatments by the American Academy of Dermatology,[16] and a consensus on moderate to severe psoriasis by the Canadian Psoriasis Expert Panel.[17]

Nonpharmacologic Treatment

❻ *Nonpharmacologic alternatives may be extremely beneficial in the patient with psoriasis and complement pharmacologic therapies; thus should always be considered and initiated when appropriate.* These include the following management strategies:[10]

- *Stress reduction techniques*. Psychotherapy including stress management, guided imagery, and relaxation techniques are being used more frequently as adjunctive therapies for patients with psoriasis. Stress reduction has been shown to improve both the extent and severity of psoriasis.
- *Oatmeal baths*. Regular use of oatmeal baths in tepid water may help soothe the itching associated with psoriasis and reduce the need for systemic anti-pruritic agents.
- *Non-medicated moisturizers*. Maintaining adequate skin moisture helps to control the scaling associated with psoriasis. Emollients restore skin pliability, reduce skin shedding, reduce pruritus, and help prevent painful cracking and bleeding.[2] Non-medicated moisturizers may be liberally applied several times daily to help prevent skin dryness. Fragrance-free products should be selected when available.
- *Avoid irritant chemicals on the skin*. Harsh soaps or detergents should not be used. Cleansing should be done with tepid water, preferably using lipid-free and fragrance-free cleansers.
- *Avoid skin trauma*. Sunburns can induce a flare-up of psoriasis. Sunscreens with a sun protection factor of at least 15 should be routinely used when outdoors; often a sun protection factor of 30 is recommended. Avoid scratching the skin, which could lead to excoriations and exacerbate psoriasis. Loose-fitting cotton garments should be worn to minimize skin irritation.

Pharmacologic Treatment

❼ *Pharmacologic alternatives for psoriasis include topical agents, phototherapy, and systemic agents including the use of biologic response modifiers. See Figs. 61–1 and 61–2 for treatment algorithms.*

Patient Encounter, Part 3

The diagnosis is that the patient has new-onset mild to moderate plaque psoriasis.

- What nonpharmacologic alternatives are appropriate for this patient?
- What pharmacologic treatments would be appropriate as initial therapy for this patient?
- Create a care plan for this patient's psoriasis, including statement of the drug-related problems, goals of therapy, patient-specific detailed therapeutic plan, and monitoring plan and follow-up.

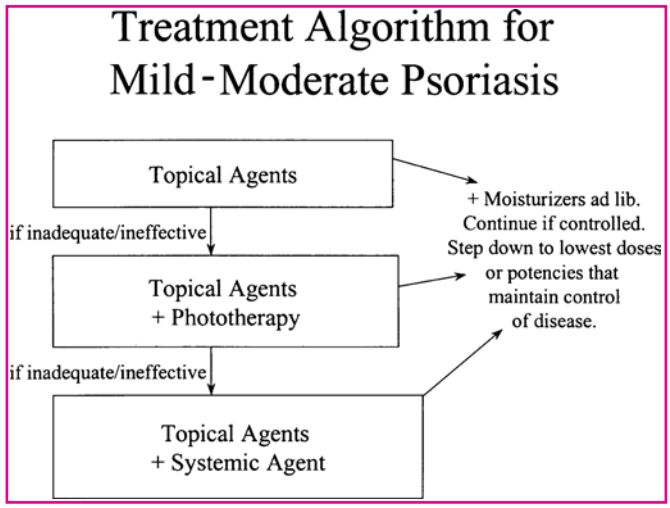

FIGURE 61–1. Treatment algorithm for mild to moderate psoriasis.

Topical Therapy for Psoriasis

❽ *Topical therapy is the initial drug treatment strategy for patients with mild to moderate psoriasis. It is estimated that approximately 70% to 80% of all patients with psoriasis can be treated adequately with use of topical therapy.*[1] Topical therapies include corticosteroids, coal tar products, anthralin, vitamin D_3 analogues such as calcipotriol, retinoids such as tazarotene, and topical immunomodulators such as tacrolimus and pimecrolimus.[18] Vitamin D_3 analogues and topical retinoids all affect keratinocyte functions and the immune response. Currently, these are in wider use than is either anthralin or coal tar preparations.

Topical agents may be incorporated into various vehicles including ointments, creams, gels, lotions, foams, pastes, and shampoos. Ointments provide occlusion which may increase drug penetration and enhance efficacy. Creams and lotions are easier to spread, especially in hairy areas. Gels may have drying and cooling effects in addition to easy spreadability. Foams may have enhanced delivery and/or efficacy in comparison to lotions or creams and become a cosmetically elegant liquid upon skin contact, with good patient acceptance.[18] Shampoos incorporating tar distillates or salicylic acid are useful for scalp psoriasis. Pastes such as Lasar's paste have an inherent stiffness which minimizes the spread of medication and are useful for incorporating drugs such as anthralin. Anthralin, especially in higher concentrations used in short-contact methods, may cause skin irritation and burning if in contact with normal skin. The selection of an appropriate vehicle is often an important consideration.

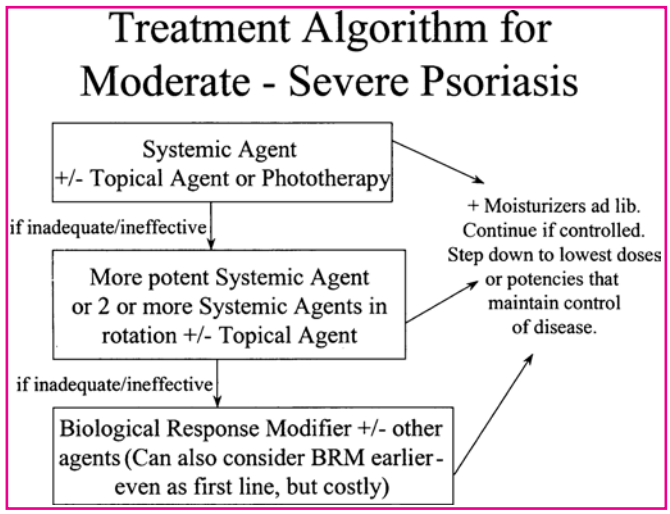

FIGURE 61–2. Treatment algorithm for moderate to severe psoriasis.

For mild to moderate psoriasis, mid-potency corticosteroids such as betamethasone valerate (0.05% to 1%) are most frequently selected first, with escalation to higher-potency corticosteroids if needed, and stepping down to lower-potency corticosteroids when the psoriasis improves. High-potency corticosteroids may be used initially in thicker plaque areas such as palms and soles, but should be considered for short-term use only. These include fluocinonide, clobetasol, halobetasol, and betamethasone dipropionate in optimized base. Low-potency corticosteroids such as hydrocortisone (0.5% to 2%) are appropriate choices if treatment of the face or flexures is necessary. Topical corticosteroids are available as ointments, creams, lotions including scalp lotions, and a few foam products, and should be applied in a thin layer on the skin. Intralesional triamcinolone may be useful for specific lesions such as nail matrix psoriasis. Tachyphylaxis due to down-regulation of steroid receptors can occur with prolonged use, making the treatment regimen ineffective.[2,18] Using a potent corticosteroid for only 1 to 2 days per week ("weekend therapy") has been shown to lengthen the duration of effectiveness.[18] Combining this regimen with calcipotriol used during the week may provide greater efficacy.[18]

It is important to remember that adverse effects of *topical* corticosteroids may be *systemic* in nature and hypothalamic-pituitary-adrenal axis suppression can occur, especially when high-potency corticosteroids are used. Infants and small children may be more susceptible due to their increased skin surface:body mass ratio.[18] Topical corticosteroids may also cause **striae**, skin atrophy, acne, **telangiectasias**, and rosacea.[2,10,18] Atrophy can result in thin, fragile, easily lacerated skin. Striae are caused by tearing of dermal connective tissue and are irreversible.[18] Due to their significant adverse-effect profile, it has been recommended that no topical corticosteroid be used regularly for more than 4 weeks without review and reassessment.[2]

Vitamin D analogues (calcipotriol, calcitriol, and tacalcitol) are also frequently selected as initial pharmacotherapy in the management of mild to moderate psoriasis.[2] These inhibit keratinocyte differentiation and proliferation and may be anti-inflammatory.[2] Unlike corticosteroids, tachyphylaxis does not occur with prolonged use. Clearance of lesions should occur after 4 to 6 weeks of treatment.[2] Lack of response by 8 weeks

indicates treatment failure.[2] These analogues may cause skin irritation leading to erythema, dryness, stinging, or burning. They may also cause hypercalcemia secondary to excessive absorption or use.[2,10,18] Calcipotriol (50 mcg/g) is currently available in the United States and Canada as ointment, cream, and solution. Topical calcitriol has been studied for treatment of psoriasis and appears almost as effective as betamethasone dipropionate in clearance of lesions, with a longer remission period.[2] It is less irritating than calcipotriol and can be used for the face and flexures.[2] Calcipotriol plus betamethasone is available as a combination product in Canada.[10] In contrast, salicylic acid can completely inactivate calcipotriol on contact.[18] Tacalcitol is a newer vitamin D_3 analogue available in the UK.[1]

Keratolytic agents such as salicylic acid are often added to bath oil or shampoos (typically 3% to 4%) for scalp psoriasis.[10] Salicylic acid can also be added to topical corticosteroid preparations to enhance steroid penetration (salicylic acid breaks down keratin).

Coal tar is keratolytic and may have anti-proliferative and anti-inflammatory effects.[2] Coal tar products include crude coal tar and tar distillates (liquor carbonis detergens) available as ointments, creams, and shampoos in various strengths. Preparations containing coal tar may precipitate folliculitis,[10] will stain clothing, and have an unpleasant odor. They are also photosensitizing and can be combined with UVB phototherapy (Goekermann's regimen) to increase treatment response.[19,20]

Anthralin (dithranol) has a direct anti-proliferative effect on epidermal keratinocytes[2] and is generally used only on thick plaque areas. It can be used continuously or as short-contact anthralin therapy (SCAT): 1% to 4% applied for minutes to up to 2 hours.[18] Anthralin, including SCAT with high anthralin concentrations, may be highly irritating, especially if SCAT treatments are misused or used continuously.[10] It is important to remember when compounding anthralin preparations that prescribed concentrations can range from 0.1% (meant for continuous use) to 1% to 4% (meant for short-contact use).[18] Normal skin surrounding the psoriasis plaques should be protected by using non-medicated paste or zinc oxide. People who handle the dry anthralin powder should avoid skin contact (e.g., by wearing gloves while compounding).

Tazarotene is a topical retinoid used for mild to moderate psoriasis and is also effective for acne. It normalizes keratinocyte differentiation and has anti-proliferative and anti-inflammatory effects.[2] Tazarotene is available commercially as a 0.05% or 0.1% gel. It may cause significant skin irritation including erythema, pruritus, and burning, especially upon initial use.[2,10,18] Combining tazarotene use with a topical corticosteroid in an alternate-day regimen or morning corticosteroid–evening tazarotene dosing fashion may minimize skin irritation and steroid-induced skin atrophy, and enhance efficacy.[18] Avoid its use in women of childbearing age unless effective contraception is being used; there is a potential risk of systemic drug absorption[2] and systemic retinoids are known teratogens. Concomitant use of other topical preparations or cosmetics with a strong drying effect should be avoided when possible.[10]

Phototherapy for Psoriasis

Phototherapy or photochemotherapy is used for patients with moderate to severe psoriasis, generally when topical therapies alone are inadequate. Photochemotherapy is the concurrent use of phototherapy together with topical agents[18,21] or systemic drugs.[1,21] Phototherapy of psoriasis involves the use of either ultraviolet A (UVA) or ultraviolet B (UVB). UVA is a longer wavelength, and therapy with UVA is always combined with psoralens (e.g., methoxsalen or trioxsalen), which are used as photosensitizers to increase efficacy (PUVA = psoralens + UVA). There may be an increased risk of skin cancers after prolonged use of phototherapy and risks are greater with PUVA than UVB.[10,21]

There is a bath PUVA and an oral PUVA. Bath PUVA therapies involve soaking in a bath of psoralens liquid for 15 minutes prior to UVA treatment. Oral PUVA involves taking an oral psoralens capsule the day prior to a UVA treatment. Oral psoralens such as methoxsalen cause nausea in many patients. Other adverse effects of PUVA include photosensitivity, which necessitates the use of eye protection and UVA-blocking sunscreen for 24 hours after a PUVA treatment; macular **melanosis** at exposed sites (PUVA **lentigines**); and increased risk of skin cancers, especially squamous cell carcinoma.[21]

PUVA has been used in conjunction with other topical agents to increase treatment efficacy. Calcipotriol when added to a regimen of PUVA may reduce the number of PUVA treatments and the total UVA dosage needed for clearing lesions.[18,22,23] The rate ratio for marked improvement in patients receiving PUVA plus calcipotriol versus PUVA alone was 1.2 in a recent meta-analysis of 11 controlled studies.[24] If calcipotriol and PUVA are used together, calcipotriol must be applied *after* PUVA, since irradiation with UVA will inactivate calcipotriol.[25] Use with other topical agents has been limited. One small study of PUVA with tazarotene in 12 patients with extensive plaque psoriasis showed a statistically significant improvement after 3 weeks;[26] however, UVA doses should be reduced by at least one-third if tazarotene is added, since it increases the risk for immediate pigment darkening caused by UVA.[27] Coal tars are photosensitizing[18] and are not generally used with PUVA,[21] and PUVA plus topical corticosteroids have yielded conflicting results.[21]

UVA can be used with other systemic agents including oral retinoids (RePUVA) and methotrexate. This will be discussed later in greater detail.

UVB treatments are often used alone. However, they have also been given in combination with topical or systemic agents to increase treatment efficacy. Topical regimens include UVB with tazarotene,[21] UVB with crude coal tar (Goekermann regimen),[19–21] UVB with anthralin (Ingram regimen),[21] and UVB with calcipotriol.[21] UVB with tazarotene (a retinoid) may be synergistic; the effect of each agent seems to be enhanced when used together. However, all retinoids can cause skin thinning, which may allow for easier burning to occur. The erythema induction threshold is lowered by about 25%.[21] Therefore, doses of UVB should be reduced by at least one-third when tazarotene is added.[18,21] UVB with crude coal tar is a regimen developed early in the twentieth century which is still considered one of

Patient Encounter, Part 4

The patient's psoriatic condition remains well controlled for about 10 years, then flare-ups become a frequent occurrence. The patient did not respond well to UVB therapy used alone. He is currently presenting with fairly extensive plaque psoriasis, affecting about two-thirds of his body surface area.

Create a care plan for this patient's psoriasis, including statement of the drug-related problems, goals of therapy, patient-specific detailed therapeutic plan, and monitoring plan and follow-up.

the most effective regimens available.[21] However, many patients consider it messy and time-consuming. UVB with short-contact anthralin therapy (SCAT) may not be consistently effective, and UVB with topical steroids may actually shorten the remission period.[22,28]

Several UVB and systemic therapy combinations have shown efficacy. These include UVB with acitretin (ReUVB) and UVB with methotrexate, and will be discussed later.

Systemic Therapy for Psoriasis

❸ *Systemic therapies are seldom used for mild to moderate psoriasis, and are generally reserved for patients with moderate to severe psoriasis.*[17,29] Oral agents include sulfasalazine, acitretin, methotrexate, cyclosporine, mycophenolate mofetil, azathioprine, tacrolimus, and hydroxyurea. Parenteral agents include the biologic response modifiers alefacept, efalizumab, etanercept, infliximab, and many others, currently at various stages of research or approval for psoriasis.

❾ *Rotational therapy (i.e., rotating systemic drug interventions in a sequential manner) is a means to minimize drug-associated toxicities, since systemic agents for psoriasis often have differing toxicities. This may be considered for psoriasis patients who require systemic treatments long-term to manage their condition.* Systemic therapies are optimally used in a rotating fashion to minimize drug toxicities (e.g., methotrexate–acitretin–cyclosporine or methotrexate–PUVA–acitretin).[10]

Sulfasalazine has variable efficacy and is of limited potency. However, its side-effect profile is better than other systemic therapies and it is sometimes tried as an initial systemic agent for moderate to severe psoriasis. Usual doses are 2 to 4 g/day in divided doses.[10]

Acitretin is an oral retinoid that is likely safer than methotrexate or cyclosporine, especially when considering continuous use over many years.[21] The initial dose is 25 mg/day which can be increased to a maximum of 75 mg/day if needed.[17] When acitretin is used concurrently with phototherapy (ReUVB or RePUVA), there appears to be a synergistic treatment effect, and the number and duration of phototherapy sessions needed to achieve clearance is reduced.[21] RePUVA is a well-established treatment regimen for psoriasis.[1] When acitretin is used with calcipotriol, improvement and clearance of lesions may be achieved with significantly lower cumulative acitretin dosages.[21,30] However, acitretin is teratogenic and relatively contraindicated in women of childbearing potential. It must not be used in pregnant women, those with unreliable contraception, or those who intend to become pregnant at any time during or for 3 years after discontinuation of therapy.[10,29] Ethanol should be avoided during therapy and for 2 months after drug discontinuation since it causes the transesterification of acitretin to etretinate, which has a much longer elimination half-life.[10,29] Other side effects include ophthalmologic, neuromuscular, hyperlipidemic, and hepatic enzyme changes.[10,29] Long-term continuous use has caused a syndrome of **disseminated idiopathic skeletal hyperostosis** and mild osteoporosis, found in a few case reports.[21,31]

Methotrexate used in low doses is one of the mainstays of systemic therapy in the treatment of psoriasis. An initial test dose of 2.5 to 5 mg is recommended.[17] If lab values are normal after 1 week, the dose can be increased to a range of 7.5 to 30 mg/wk.[17] This can be given as a single dose or split into two or three doses given 12 hours apart to minimize gastrointestinal side effects. Always titrate to the lowest effective dose for maintenance. There is a significant risk of hepatotoxicity which is greater than that seen in patients with rheumatoid arthritis given similar cumulative doses of methotrexate.[29] In psoriatic patients with no hepatic risk factors, a liver biopsy is recommended when the cumulative dose of methotrexate reaches 1.5 g. In high-risk psoriatic patients, it is preferable to also perform a biopsy during initial therapy with methotrexate.[10,17,29,32] Monitoring PIIINP (the aminoterminal propeptide of type III procollagen) at least three times yearly may reduce the number of repeat liver biopsies required.[10,29] Liver biopsies are not recommended in the elderly, those with limited life expectancy, or those with significant medical problems.[29] Periodic complete blood cell counts, renal and liver function tests, and pulmonary toxicity testing should also be conducted.[10,29]

The combination of methotrexate and UVB seems to be synergistic; responses may occur with lower cumulative doses of both methotrexate and UVB. However, stopping methotrexate may cause rebound[21,33] and there is some concern about photosensitivity.[21] Methotrexate and PUVA have been used together in patients refractory to other treatments; however, there is additive carcinogenesis (especially increasing the risk of squamous cell cancer) and subacute phototoxicity.[21]

Methotrexate has been used successfully with cyclosporine, either concurrently[34] or in rotation. Rotational therapy is particularly effective since it minimizes the serious adverse effects of both agents: hepatotoxicity from methotrexate and hypertension and nephrotoxicity from cyclosporine. Having an overlapping treatment period may not be necessary and patients have been successfully switched after a 1-week washout period.[21,35] This is a very useful combination of systemic agents in the long-term management of this chronic disease.

Cyclosporine is used in low doses whether alone or in combination with other agents. The usual dose range is 2 to 2.5 mg/kg

per day, given orally in two divided doses, for patients with stable generalized psoriasis or for moderate to severe disease. For patients with severe inflammatory flares of psoriasis, or recalcitrant cases who fail to respond to numerous other therapies, or for a highly distressed patient in a crisis situation, the starting dose is higher at 5 mg/kg per day in two divided doses.[29] This dose should not be exceeded[17] and once there is a clear response should be decreased by 0.5 to 1 mg/kg per day at weekly or longer periods, to the lowest effective maintenance dose. If started at 2.5 mg/kg per day, and the response is inadequate, it is recommended to wait at least 1 month before considering a dosage increase. If necessary, the dosage may be increased by 0.5 to 1 mg/kg per day[9,28,35] monthly[17] to a maximum of 5 mg/kg per day.[17] Always titrate to the lowest effective dose for maintenance.[17]

Blood pressure and serum creatinine (SCr) should be assessed prior to beginning cyclosporine therapy to obtain accurate baselines, and should be reassessed biweekly once therapy is started for at least the first 12 weeks of therapy (until values stabilize), and then closely monitored during therapy. If SCr increases to 30% above the patient's baseline, the cyclosporine dosage needs to be decreased and SCr rechecked in a month. If the SCr is still above 30% of the patient's baseline, cyclosporine should be discontinued and only resumed when the SCr returns to within 10% of the patient's baseline. Cyclosporine should also be discontinued for inadequate response after 3 months' use at the maximum dose.[10,36]

The combination of cyclosporine with calcipotriol may be more efficacious than either agent used alone.[21,37] Cyclosporine and SCAT may also be effective.[21,38] However, cyclosporine *should not* be used concurrently with PUVA; there is a well-documented increased risk of squamous cell cancer and the combination may have a negative effect on lesion clearance.[21] The combination of cyclosporine with methotrexate is extremely effective and minimizes toxicity from either agent as discussed. Cyclosporine has also been used successfully with mycophenolate mofetil[38] and etanercept.[29]

Mycophenolate mofetil in doses of 1 to 1.5 g twice daily (maximum dose 3 g/day) is effective as adjunctive therapy in patients with resistant psoriasis on cyclosporine.[29,38] As monotherapy, there may be some benefit in patients with moderate psoriasis and psoriatic arthritis, but not in severe psoriasis.[29]

Hydroxyurea is an older agent still used occasionally today for patients with psoriasis; however, there have been recent precautions about its use in the elderly and cutaneous vasculitic toxicities in patients with myeloproliferative disorders.[29] Toxicity associated with tacrolimus has limited its use in psoriasis. Azathioprine has a slow onset and significant toxicity.[29] Oral corticosteroids are reserved for severe or life-threatening conditions such as severe psoriatic arthritis or exfoliative psoriasis; prolonged oral steroid use should be avoided.[10]

Biologic Response Modifiers

Based on the recent advances in our understanding of the pathogenesis and pathophysiology of psoriasis, there was accompanying research into the development and use of biologic response modifiers for psoriasis and psoriatic arthritis. ⓾ *Some biologic response modifiers have proven efficacy for psoriasis; however, there are differences among these agents, including mechanism of action, duration of remission, and adverse-effect profile. Currently, biologic response modifiers are often considered for patients with moderate to severe psoriasis when other systemic agents are inadequate. It has also been recommended that biologic response modifiers be considered as first-line therapy, alongside conventional systemic agents, for patients with moderate to severe psoriasis;[17] however, in practice, cost may be a limiting factor.* Biologic response modifiers with proven efficacy for psoriasis include alefacept, etanercept, and efalizumab. These agents employ the following targeted immunosuppressive strategies: alefacept inhibits T-cell activation by targeting LFA-3–CD2 and inducing apoptosis in memory T cells,[1] etanercept inhibits T1 cytokines by targeting tumor necrosis factor-α, and efalizumab inhibits T-cell activation by targeting CD11a, the α subunit of LFA-1 (ICAM-1).[1,10,39] Other biologic agents in clinical trials for psoriasis include infliximab, adalimumab, HuMax-CD4, siplizumab, daclizumab, and denileukin diftitox.[10,39] ⓾ *In general, due to their immunosuppressive effects, there is an increased risk of infection with most of these agents. The use of live or live-attenuated vaccines during therapy is generally not recommended.*

The most promising types of biologic response modifiers are monoclonal antibodies, cytokines, and fusion proteins.[1] Monoclonal antibodies may be chimeric (fused mouse and human segments; designated "-ximab"), humanized with intermittent murine sequences (designated "-zumab"), human backbone with monkey sequences, or fully human.[40]

Alefacept is a recombinant fusion protein composed of LFA-3 linked to the constant portion of human IgG.[40,41] Alefacept inhibits T-cell activation by binding to their CD2 sites, thus impairing co-stimulatory signals; and alefacept also interacts with natural killer cells to destroy already activated T cells.[1,10] This agent is useful for moderate to severe chronic plaque psoriasis. About one-third of alefacept-treated patients enter prolonged remissions ranging from 6 to 18 months. Alefacept appears to spare helper T-cell function and does not significantly impair primary or secondary antibody responses (for example, the ability to combat infections or respond to vaccinations). There is a significant risk of malignancy and common side effects include lymphopenia, myalgias and chills, pharyngitis, cough, nausea, and for IM injections pain and inflammation at the injection site.[10,42,43] The dosage recommended is 15 mg IM once weekly for 12 weeks. The regimen may be repeated in 12 weeks if needed, provided the CD4+ T-cell count is normal (defined as greater than or equal to 250 cells/μL).[10]

Etanercept is a fully human dimeric fusion protein composed of human TNF-α p75 receptor fused to the Fc portion of human IgG1.[41] It acts as a tumor necrosis factor-α (TNF-α) inhibitor by binding to and inactivating TNF-α, thus preventing interactions with its cell surface receptors.[41] This agent is useful for chronic moderate to severe plaque psoriasis and for psoriatic

arthritis. In clinical trials, 49% of patients given 50 mg subcutaneously twice weekly showed a 75% improvement in the psoriasis area-and-severity index by 12 weeks.[10,44] The drug appears to be well tolerated; common side effects include injection site reactions, headache, increased respiratory tract infections (colds and sinusitis), and gastrointestinal symptoms.[10,44] There is an increased risk of tuberculosis and hepatitis B reactivation. Serious infections including fatalities have been reported with etanercept and there were reports of worsening congestive heart failure (CHF) and new-onset CHF.[10] Due to rare reports of blood disorders (anemia, aplastic anemia, leukopenia, neutropenia, pancytopenia, and thrombocytopenia), patients are advised to contact their doctor if they experience persistent fever, bruising, bleeding, or paleness.[10] A systemic lupus erythematosus (SLE)-like syndrome has been rarely reported.

Efalizumab is a humanized murine antibody directed against CD11a, the α subunit of leukocyte-function-associated antigen type 1 [LFA-1]. This inhibits T-cell activation, cutaneous T-cell trafficking, and T-cell adhesion to keratinocytes. Efalizumab has a rapid onset of action with symptom improvement seen in about 4 weeks. About 25% of psoriatic patients receiving either 1 or 2 mg/kg per week improved by at least 75% at 12 weeks of treatment.[11,45–47] Treatment should be continued; with cessation of therapy, the median time to relapse is 60 to 80 days. Long-term safety and efficacy are still being evaluated. Thrombocytopenia occurs rarely.[18] Common side effects include headache, fever, chills, nausea, and myalgias, which usually diminish after the first or second weekly dose. Worsening psoriasis may occur during treatment or after drug discontinuation, and there is an increased risk of infection.[11,45–47]

Infliximab is a chimeric human/murine monoclonal antibody against TNF-α. It is approved for reducing the signs and symptoms of psoriatic arthritis and clinical studies in patients with psoriasis are showing benefit. Good responses have been seen in patients with moderate to severe plaque psoriasis receiving infliximab 5 to 10 mg/kg at 0, 2, and 6 weeks. Median time to response was 4 weeks.[48] If the treatment is continued it should be given every 8 weeks thereafter. Infliximab is also approved for rheumatoid arthritis and significant adverse effects from post-marketing experience and clinical trials have included hematologic abnormalities (leukopenia, neutropenia, thrombocytopenia, and pancytopenia), hepatotoxicity (rarely: acute liver failure, jaundice, hepatitis, and cholestasis), hypersensitivity reactions (anaphylaxis, urticaria, and serum sickness), ocular toxicity (optic neuritis and optic neuropathy), and increased infections (tuberculosis, hepatitis B reactivation, *Listeria monocytogenes* infections, fungal infections, and sepsis). There is an increased risk of infection by live vaccines and vaccination with live vaccines while receiving infliximab therapy is not recommended. Patients should be evaluated for active or latent tuberculosis (tuberculosis skin test) prior to therapy.

Adalimumab is a TNF-α inhibitor initially approved for the treatment of rheumatoid arthritis in 2003. It is approved for treatment of psoriatic arthritis and off-label uses and clinical studies in patients with psoriasis are showing benefit. The dosage is 40 mg subcutaneously every 2 weeks. Patients should be evaluated for active or latent TB infection (TB skin test) prior to therapy. There is an increased risk of serious infections (in particular, respiratory infections including pneumonia and tuberculosis, and hepatitis B reactivation), of exacerbation in patients with heart failure, and increased risk of lymphoma. Hematologic abnormalities (pancytopenia, thrombocytopenia, and leukopenia) have been rarely reported. Positive antinuclear antibody titers and a lupus syndrome have been reported. Anti-dsDNA antibody determinations are recommended in patients presenting with lupus-like symptoms during adalimumab therapy. A pruritic urticarial eruption that lessens in severity with each subsequent injection has recently been reported.

Patient Encounter, Part 5

It was decided to begin methotrexate in this patient, rotating with cyclosporine.

- What lab tests would be important to perform prior to starting therapy with methotrexate? With cyclosporine?
- What dosage regimen would be appropriate?
- What monitoring plan would be appropriate?
- What information would be important to provide this patient with?

OUTCOME EVALUATION

- Monitor the patient for clearance of skin lesions. Depending on the agent(s) used and site of lesions it may take 2 to 6 weeks or longer to see a response. Complete clearance may not be achieved for all patients.
- Monitor the patient for specific adverse effects, depending on agent(s) used. Some agents are discussed below, and others are discussed earlier in this chapter.
- Methotrexate: Monitor complete blood cell count and liver function tests at baseline and regularly, and consider liver biopsy prior to treatment and at a cumulative dose of 1.5 g. If available, monitor PIIINP at least three times yearly.
- Cyclosporine: Monitor SCr, blood urea nitrogen, and blood pressure at baseline and reassess biweekly for at least 12 weeks (or longer until values stabilize), then regularly. Adjust doses when needed in response to SCr changes as discussed above.[9,35]
- Acitretin: Monitor serum lipids and liver function tests.
- Topical corticosteroids: Monitor for skin thinning, telangiectasias, and possible hypothalamic-pituitary-adrenal axis suppression.
- Interact with the patient's other health care providers as needed to discuss patient concerns or issues.

Patient Care and Monitoring

With respect to pharmacologic therapies, it is important to:

- Provide patients with an approximate time frame for improvement based on the patient's areas of involvement and type of drug therapy. For example, a statement such as: "There should be less scaling and redness of your scalp lesions and a reduction in the thickly crusted areas within 1 to 2 weeks. You should notice a general improvement in your condition by 6 to 12 weeks. Your palms, soles, elbows, and knees may take longer to clear."[9]
- Provide appropriate advice about drug regimens including how to apply a specific topical agent, how to use a specific systemic agent, and precautions and possible toxicities of any drug therapy, remembering that topical therapies can have significant systemic adverse effects.
- Check the patient profile and talk with the patient to ensure that there are no significant drug interactions with other concurrent medications and therapies.
- Reinforce the importance of adherence to therapies and specific drug regimens.
- Reinforce the importance of regular follow-up with the patient's health care providers including all appointments for follow-up care and lab work (if any).
- Interact with the patient's other health care providers as needed to discuss patient concerns or issues detected including drug interactions, nonadherence, and adverse effects.

SUMMARY

We must remember that psoriasis is a lifelong illness with no known cure and often has a significant psychosocial component. Author John Updike has said about his own psoriatic condition, that "my torture is skin deep" and that "we hate to look upon ourselves," calling himself a "leper."[49,50] This disease may be very visible and emotionally distressing, and can cause significant disability both physically and psychologically, affecting psychosocial functioning and quality of life. Empathy and a caring attitude can go a long way in the care of these patients.[50]

62 Common Skin Disorders

Angie L. Goeser

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiology of common skin disorders.
2. Assess the signs and symptoms of common skin disorders in a presenting patient.
3. List the goals of treatment for patients with common skin disorders.
4. Select appropriate nonpharmacologic and pharmacologic treatment regimens to patients presenting with common skin disorders.
5. Identify adverse effects that may result from pharmacologic agents used in the treatment of common skin disorders.
6. Develop a monitoring plan that will assess the safety and efficacy of the overall disease management of common skin disorders.
7. Create educational information for patients about common skin disorders, including appropriate self-management, available drug treatment options, and anticipated therapeutic responses.

Key Concepts

❶ The development of acne lesions results from four pathogenic factors, which include excess sebum production, keratinization, bacterial growth, and inflammation.

❷ The treatment goals for acne vulgaris are to eliminate existing lesions and prevent new lesions from developing, as well as to decrease discomfort and the incidence of scarring.

❸ Acne is categorized as mild, moderate, or severe based on lesion type and severity and successful treatment approaches are developed based on these categories.

❹ Irritant contact dermatitis results from first-time exposures to irritating substances such as soaps, plants, cleaning solutions, or solvents. Allergic contact dermatitis occurs after an initial sensitivity and further exposure to allergenic substances, including poison ivy, latex, and certain types of metals.

❺ The initial treatment goal of contact dermatitis is identifying the causative substance and eliminating its exposure. The second treatment goal is symptom relief.

❻ Although many factors contribute to the etiology of diaper rash, it is most likely the result of prolonged contact of the skin with urine and feces in the diaper.

❼ The primary goal in the treatment of diaper rash is prevention and is most often accomplished through frequent diaper changes.

❽ When a diaper rash is already present, repairing the damaged skin, relieving discomfort, and preventing infection are important factors to consider when developing an effective treatment regimen.

The skin is the largest organ of the human body. One of its most important functions is to assist the immune system by serving as a barrier that protects underlying structures from trauma, infection, and exposure to harmful environmental elements. The skin also holds in place essential organs and fluids necessary for life. Any significant injury to this outer protective layer may potentially compromise an individual's overall health.

Several thousand skin disorders are currently documented, and many patients will seek the assistance of a health care provider when a problem with their skin develops. Others will utilize methods of self-care to effectively treat their symptoms. Some skin problems, such as mild acne or diaper rash, may be successfully treated with over-the-counter medications and lifestyle modifications. However, if left untreated or treated inadequately, these seemingly simple disorders can worsen and require more advanced care.

As health care providers, it is important to be familiar with the diagnosis and treatment of disorders of the skin. Providing

patients with appropriate nonpharmacologic and pharmacologic therapy options, as well as patient education on methods of treatment and prevention, will assist in the successful resolution of many common skin disorders.

ACNE VULGARIS

Acne vulgaris, an inflammatory skin disorder of the pilosebaceous units of the skin, is the most common dermatologic reason for physician visits in the United States.[1] Although most commonly seen on the face, acne can also present on the chest, back, neck, and shoulders (Fig. 62–1). While generally a self-limiting condition, long-term physical complications of acne may include extensive scarring and psychological distress.[1,3]

EPIDEMIOLOGY

With an estimated 40 to 50 million people affected, acne vulgaris is the number one skin disease in the United States.[4] While acne affects approximately 85% of adolescents and adults aged 12 to 25 years, the disease can develop or recur in adults aged 30 to 50 years.[5] The prevalence of acne among Caucasians, African-Americans, Hispanics, and Asians is similar, with acne occurring more often in males during adolescence and females during adulthood.[6,7]

FIGURE 62–1. A spectrum of acne lesions is seen on the face of a 17-year-old male: comedones, papules, pustules, and erythematous macules and scars at the site of resolving lesions. The patient was successfully treated with a 4-month course of isotretinoin; there was no recurrence over the next 5 years. (From Wolff K, Johnson RA. Disorders of sebaceous and apocrine glands. Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology. 5th ed. New York: McGraw-Hill, 2005: 5.)

PATHOPHYSIOLOGY

❶ *The development of acne lesions results from four pathogenic factors: excess sebum production, keratinization, bacterial growth, and inflammation.*[3]

The pilosebaceous unit of the skin consists of a hair follicle and the surrounding sebaceous glands. An initial acne lesion called a comedo forms when there is a blockage in the pilosebaceous unit.[8]

Sebum is released by the sebaceous glands and naturally maintains hair and skin hydration. An increase in androgen levels, especially during puberty, can cause an increase in the size of the sebaceous gland and the production of abnormally high levels of sebum within those glands. This excess sebum can result in plugged follicles and acne formation.

Keratinization, the sloughing of epithelial cells in the hair follicle, is also a natural process. In acne, however, *hyper*keratinization occurs and causes increased adhesiveness of the sloughed cells. Accumulation of these cells clogs the hair follicle, blocks the flow of sebum, and forms an acne lesion called an **open comedo** or "blackhead."

Propionibacterium acnes (P. acnes), an anaerobic organism, is also found in the normal flora of the skin. This bacteria proliferates in the mixture of sebum and keratinocytes and can result in an inflammatory response producing a **closed comedo** or "whitehead." More severe acne lesions such as pustules, papules, and nodules can also form with inflammatory acne and result in significant scarring if treated inadequately (Fig. 62–2).

TREATMENT

Desired Outcomes and Goals

❷ *While eliminating existing lesions and preventing the development of new lesions are primary goals of acne therapy, secondary goals include relieving pain or discomfort and preventing permanent scarring.*[8] In addition, acne can cause patients a significant amount of stress, anxiety, frustration, embarrassment, and even depression.[10] Because of these psychological symptoms, treatment compliance and patient education on both physical and psychological aspects of this skin disorder are also imperative.

General Approach to Treatment

❸ *Acne is categorized as mild, moderate, or severe based on the lesion type and lesion severity that present* (Table 62–1).

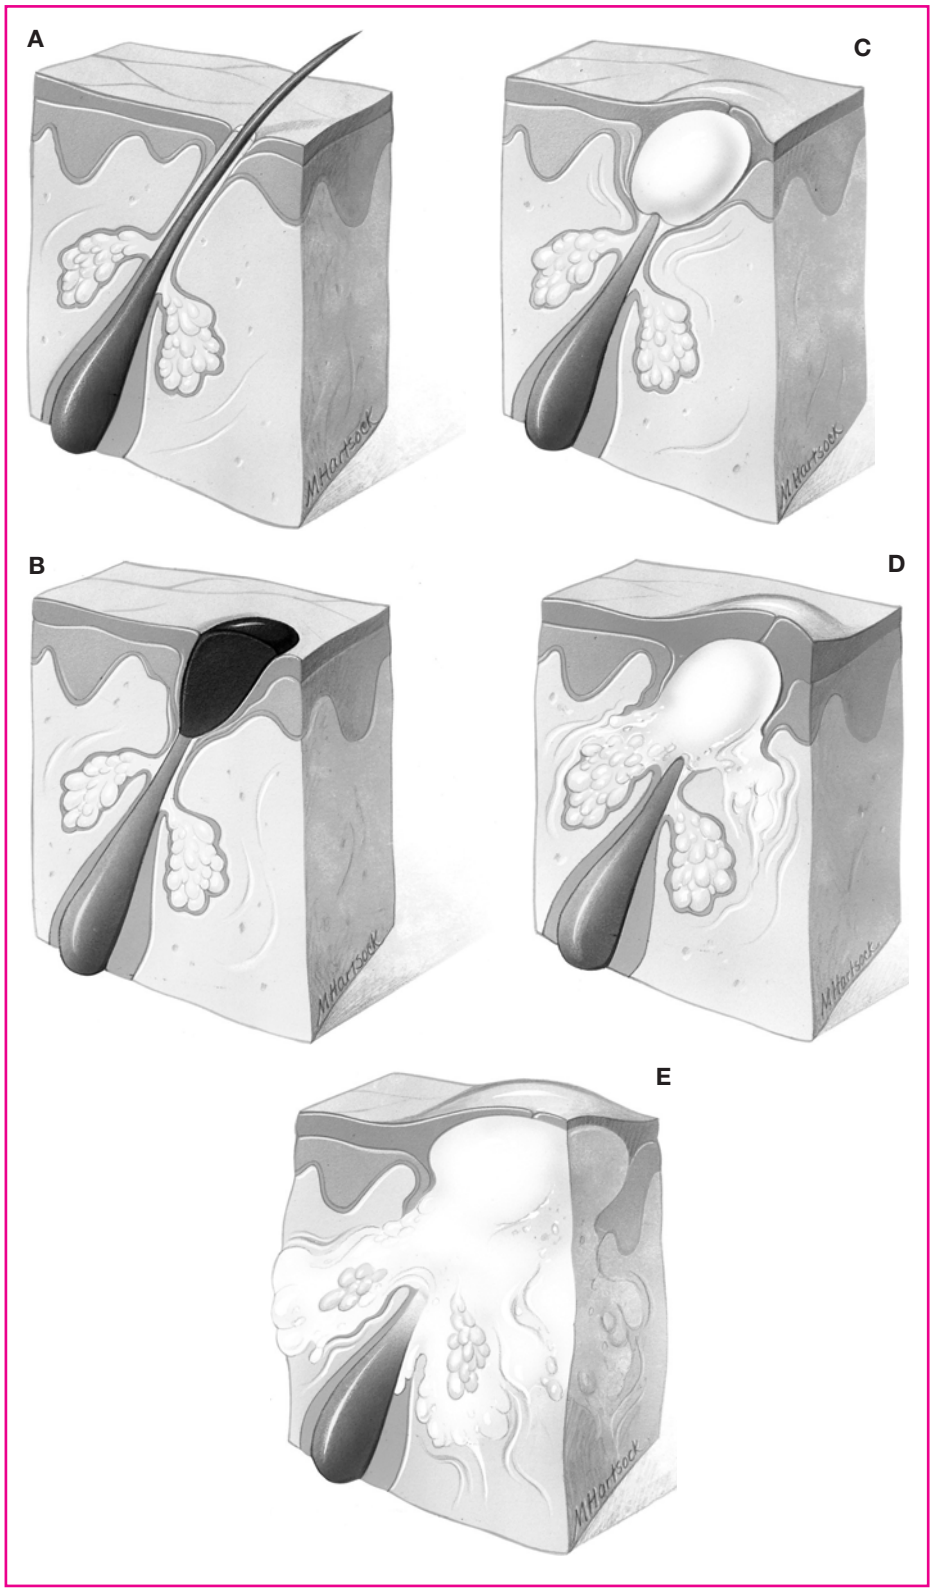

FIGURE 62–2. Stages of acne. *A.* Normal follicle. *B.* Open comedo (blackhead). *C.* Closed comedo (whitehead). *D.* Papule. *E.* Pustule.[9]

TABLE 62–1. Predominance of Acne Lesion Type by Acne Severity

		Typical Frequency of Lesion Type					
Acne Severity	**Predominant Lesions**	**Closed Comedones**	**Open Comedones**	**Papules**	**Pustules**	**Nodules**	**Scarring**
Mild	Noninflammatory lesions (open and closed comedones)	Few to numerous	Few to numerous	Possible	Possible	None	None
Moderate	Inflammatory papules and pustules with some noninflammatory lesions	Few to numerous	Few to numerous	Numerous	Numerous	Few	Possible
Severe	Inflammatory lesions and scarring with some noninflammatory lesions	Few to numerous	Few to numerous	Extensive	Extensive	Extensive	Extensive

From West DP, West LE, Musumeci ML, Micali G. Acne vulgaris. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 1757, with permission.

Successful treatment approaches are developed based on these categories, as well as any previous treatment information presented by the patient. Improvement of symptoms following treatment occurs gradually, sometimes taking 6 to 8 weeks for results to be physically apparent.[8] Patients need to be educated on continual treatment compliance during this time and should not get discouraged if acne lesions appear to worsen before getting better during the initial 2 to 3 weeks of therapy.[11]

Clinical Presentation of Acne

Acne lesions are most often seen on the face, but can also present on the chest, back, neck, and shoulders and are described as either noninflammatory or inflammatory. In addition, severe inflammatory lesions can lead to scarring and hyperpigmentation.

Non-Inflammatory Lesions

Open comedo or "blackhead": a plugged follicle of sebum, keratinocytes, and bacteria that protrudes from the surface of the skin and appears black or brown in color. Although dark in color, blackheads do not indicate the presence of dirt, but rather an accumulation of melanin.

Closed comedo or "whitehead": a plugged follicle of sebum, keratinocytes, and bacteria that remains beneath the surface of the skin. Closed comedos usually appear as small white bumps about 1 to 2 mm in diameter.

Inflammatory Lesions

Papules: solid, elevated lesions less than 0.5 cm in diameter

Pustules: vesicles filled with purulent fluid less than 0.5 cm in diameter

Nodules: lesions greater than 0.5 cm in both width and depth

Cysts: nodules filled with a fluid or semisolid which can be expressed

Scars: inflammatory acne can result in permanent scarring that ranges from small depressed pits to large elevated blemishes

Hyperpigmentation: inflammatory acne may cause hyperpigmentation of the skin that can last for weeks to months

Nonpharmacologic Therapy

There is significant variance in the clinical benefit of many nonpharmacologic interventions for acne vulgaris. Among non-drug treatment alternatives, mild, non-comedogenic facial soap used twice daily, as well as the avoidance of oily skin products and the avoidance of manipulating or squeezing lesions are helpful self-treatment recommendations.

Pharmacologic Therapy

Topical Agents

Benzoyl Peroxide

Benzoyl peroxide is easy to use and recommended as first-line therapy in the treatment of mild to moderate noninflammatory acne. Benzoyl peroxide has a **comedolytic** effect that increases the rate of epithelial cell turnover and helps to unclog blocked pores. It also has antibacterial activity against *P. acnes*, which appears to be the main reason for the effectiveness of this product.[13]

It is available with or without a prescription and remains the most commonly purchased over-the-counter topical treatment for acne.[12] Benzoyl peroxide is available in concentrations ranging from 1% to 10% in various formulations including creams, lotions, gels, and facial washes.

Adverse effects commonly reported with benzoyl peroxide are dryness, irritation, redness, and stinging of the skin. Reducing the incidence of these effects can be achieved by beginning a treatment regimen with the lowest strength of benzoyl peroxide and titrating up to higher effective strengths over several weeks if needed. A disadvantage of benzoyl peroxide is a bleaching effect that tends to discolor hair and fabrics.[12]

A typical regimen for benzoyl peroxide use is to apply the product to clean, dry skin no more than two times a day. The strength and dosage form selected may vary from patient to patient depending on acne severity and the sensitivity of the patient's skin. Since gel preparations are the most potent dosage form, patients with dry or overly sensitive skin should

be recommended a milder cream, lotion, or facial wash.[3] If severe irritation or allergic reaction develops, benzoyl peroxide use should be discontinued.

Retinoids

Retinoids, which are highly effective in the treatment of acne, stimulate epithelial cell turnover and aid in unclogging blocked pores. Retinoids also exhibit anti-inflammatory properties through the inhibition of neutrophil and monocyte chemotaxis.[8] Because of these comedolytic and anti-inflammatory effects, topical retinoids are recommended as first-line treatment for mild to moderate comedonal and inflammatory acne.[3] While success is seen with monotherapy, using a retinoid in combination with benzoyl peroxide or topical antibacterials is also an appropriate and effective therapeutic treatment option.[3] Tretinoin, adapalene, and tazarotene are topical retinoids available for use in the treatment of acne. Table 62–2 describes the strengths and formulations of these agents.

Adverse effects are likely with the use of topical retinoids. Although transient, erythema, irritation, dryness, and peeling at the site of application are all common effects. Photosensitivity can also occur with retinoid use, causing increased skin irritation and redness.[14]

The topical retinoid selected should be used once daily at bedtime, beginning with a low-potency formulation. Increased strengths are then initiated according to treatment results and tolerance. Patients should be advised that a worsening of acne symptoms generally occurs in the first few weeks of therapy, with lesion improvement occurring in 3 to 4 months.[16] The use of topical retinoids should be avoided in children less than 12 years old and in pregnant women.[14]

Antibacterials

Topical antibacterials directly suppress *P. acnes* and are also first-line agents used in the treatment of mild to moderate inflammatory acne.[3,16]

Clindamycin 1% and erythromycin 2% preparations, applied once or twice daily, have similar effects and are the most commonly prescribed topical antibacterial agents.[17] These agents, as well as sodium sulfacetamide, are available in various formulations for the treatment of acne.

Adverse effects are generally mild and include dryness, erythema, and itching.[18] Although rare and seen most often with oral therapy, pseudomembranous colitis can occur with the use of topical clindamycin.[19] As with any antibacterial agent, the possibility of resistance exists with the use of topical erythromycin. However, co-administration of erythromycin and benzoyl peroxide has been shown to decrease the incidence of resistance, as well as to improve symptoms of mild to moderate inflammatory acne.[20]

Azelaic Acid

With antibacterial and anti-inflammatory properties, and the ability to stabilize keratinization, azelaic acid is an effective alternative in the treatment of mild to moderate acne in patients who cannot tolerate benzoyl peroxide or topical retinoids.[3,21] It also has a hypopigmentation effect that may prove effective in patients who are prone to post-inflammatory hyperpigmentation resulting from acne.[22]

Adverse effects are minimal and transient with erythema and skin irritation most commonly reported.[16,21]

Azelaic acid 20% cream should be applied twice daily with improvement of symptoms seen in 1 to 2 months.[21]

Keratolytics

Sulfur, resorcinol, and salicylic acid are not as effective as other topical agents, but can be used as second-line therapies in the treatment of mild to moderate acne.[12]

While these agents may cause less skin irritation than benzoyl peroxide or the topical retinoids, several disadvantages exist. Sulfur preparations produce an unpleasant odor when applied to the skin, while resorcinol may cause brown scaling. And although rare, the possibility of salicylism exists with continual salicylic acid use.[3,12]

TABLE 62–2. Topical Retinoids Available for the Treatment of Acne[15]

Agent	Brand Name	Dosage Form	Dosage	Side Effects
Tretinoin	Retin-A™	0.025%, 0.05%, and 0.1% cream 0.01%, 0.025% gel 0.05% solution	Apply a small amount once daily before bedtime	Skin irritation, dryness, photosensitivity; initially may worsen acne
	Retin-A™ Micro	0.04% and 0.1% gel		Skin irritation, dryness, photosensitivity; initially may worsen acne
Adapalene	Differin®	0.1% cream 0.1% gel	Apply a small amount once daily before bedtime	Same as tretinoin but may be *less* severe
Tazarotene	Tazorac®	0.05% and 0.1% cream 0.05% and 0.1% gel	Apply a small amount once daily before bedtime	Same as tretinoin but may be *more* severe

Oral Agents

Antibacterials

Moderate to severe acne can be effectively treated with oral antibiotics, especially when treatment with topical therapy has failed. Because of their ability to decrease *P. acnes* colonization, oral antibiotics can prevent acne lesions from developing.[8] Improvement of symptoms is generally evident at 6 to 10 weeks, with maximum benefits occurring after 6 months of therapy.[23]

Although tetracycline, doxycycline, and minocycline are the most commonly prescribed oral antibiotics for acne, erythromycin and clindamycin are appropriate second-line agents for use when patients cannot tolerate or have developed resistance to tetracycline or its derivatives.[3] See Table 62–3 for antibiotic dosing guidelines.

Adverse effects with the tetracyclines include gastrointestinal upset; drug interactions with dairy products, antacids, and iron; and phototoxicity. Minocycline can also cause vestibular complications (headache and dizziness) and skin discoloration that is not typical with tetracycline and doxycycline.[16]

Although their effectiveness is similar to the tetracyclines, the use of erythromycin and clindamycin is often limited due to their potential adverse outcomes. Erythromycin has treatment failure due to resistance and a high incidence of gastrointestinal intolerance, while clindamycin causes diarrhea and carries a risk of developing pseudomembranous colitis with long-term use.[3,8]

Isotretinoin

Isotretinoin is effective in up to 80% of patients with severe nodulocystic acne who are unresponsive to other topical and oral treatment regimens.[8,23,24] Isotretinoin works on the four pathogenic factors that contribute to acne development and can produce acne remission for several years.

Adverse effects with the use of isotretinoin are frequent and generally dose-related. About 90% of patients experience drying of the mucosa of the mouth, eyes, and nose.[3] Drying, peeling, and pruritus of the facial skin is also likely. Increases in cholesterol and triglyceride levels have been reported with isotretinoin use; therefore it is recommended to monitor liver function and serum lipids at baseline and 4 and 8 weeks of therapy to identify any complications. Other serious adverse effects from this medication include increased creatine phosphokinase, increased blood glucose, teratogenicity, photosensitivity, muscle pain, suicidality, and depression.[3] Table 62–4 lists the common adverse effects from isotretinoin therapy and management strategies for those symptoms.

Because it is teratogenic and classified as pregnancy category X, the Food and Drug Administration has recently mandated an online registry program called iPledge™ to ensure that females do not become pregnant while taking isotretinoin. Wholesalers, pharmacies, doctors, and patients must be registered in the iPledge™ computer-based system in order to control the distribution, prescribing, and dispensing of isotretinoin. A negative pregnancy test must be obtained and confirmed in the system before a prescription is dispensed to female patients of child-bearing potential. These patients must also commit to using effective measures of birth control during the course of isotretinoin therapy. Contact the program at their web site: https://www.ipledgeprogram.com/.

Initial dose ranges for treatment are 0.5 to 1 mg/kg daily in two divided doses, with beneficial results generally reported at total daily doses of 120 to 150 mg/day.[3]

TABLE 62–3. Oral Agents Used in the Treatment of Moderate to Severe Acne[15]

Drug	Dosage Form	Strength	Regimen	Side Effects
Tetracycline	Tablets, capsules	250, 500 mg	500 mg twice daily before meals Maintenance dose: 500 mg daily	GI upset, phototoxicity, tooth discoloration, drug and food interactions
Doxycycline	Tablets, capsules	50, 100 mg	100–200 mg daily before meals Maintenance dose: 50 mg daily	GI upset, phototoxicity, drug and food interactions
Minocycline	Tablets, capsules	50, 75, 100 mg	50 mg twice daily or 100 mg once daily Maintenance dose: 50 mg daily	GI upset, phototoxicity, drug and food interactions, vestibular toxicity, skin discoloration
Erythromycin	Tablets	250, 500 mg	500 mg twice daily with food Maintenance dose: 500 mg daily	GI intolerance, drug interactions
Clindamycin	Capsules	75, 150, 300 mg	150–300 mg daily Maintenance dose: 150 mg daily	Diarrhea, pseudomembranous colitis
Isotretinoin	Capsules	10, 20, 40 mg	0.5–1 mg/kg/per day in two divided doses Maximum dose: 2 mg/kg per day Cumulative dose: 120–150 mg/day	Dry skin and mucous membranes, muscle and joint pain, elevated liver enzymes and triglycerides, depression, teratogenicity

GI, gastrointestinal.

TABLE 62–4. Isotretinoin's Adverse Effects and Management Strategies

Adverse Effect	Response
Teratogenicity	Contraindicated during pregnancy
Depression	Patient monitoring and counseling; antidepressants
Dryness	
Mouth	Hard candy
Eyes	Eyedrops; avoid contact lenses if possible during treatment course
Nose	Lubricant
Skin	Nondrying gentle skin cleansers; non-comedolytic moisturizers
Lips	Lip moisturizer with sunscreen
Muscle and joint pain	Nonsteroidal anti-inflammatory drugs
Alopecia	Reversible when drug discontinued or dose decreased
Hypertriglyceridemia	Reversible when drug discontinued or dose decreased
Acne flare at start of therapy	Continue therapy
Photosensitivity	Use sunscreens (moisturizing), protective clothing, and sun avoidance

From West DP, West LE, Musumeci ML, Micali G. Acne vulgaris. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 1762, with permission.

Oral Contraceptives

Oral contraceptives are a valuable second-line treatment option for moderate to severe acne in female patients. Oral contraceptives decrease the production of androgens by the ovaries, which in turn leads to a decrease in sebum production.[3,16]

Adverse effects include nausea, weight gain, breast tenderness, and breakthrough bleeding. Oral contraceptives have also been associated with an increased incidence of thromboembolic disease, particularly in women who use tobacco products or have other risk factors for thromboembolism. The development of these complications is significantly reduced when low-dose estrogen formulations of oral contraceptives are used.[3]

Other Agents

Although use is infrequent, several other agents are available as second or third-line treatment options for acne when first-line therapies fail and include the following:[3]

- Corticosteroids
- Chemical peels
- Antiandrogens
- Estrogens
- Gonadotropin-releasing hormone agonists

Figure 62–3 shows useful algorithms for the effective treatment of the various stages of acne.

OUTCOME EVALUATION

Depending on severity, complete resolution of acne may take weeks to months. Monitor patients after 6 weeks of pharmacologic therapy for any improvement of signs and symptoms:[12]

- Decreased number of lesions
- Decreased severity of lesions
- Relief of pain/irritation

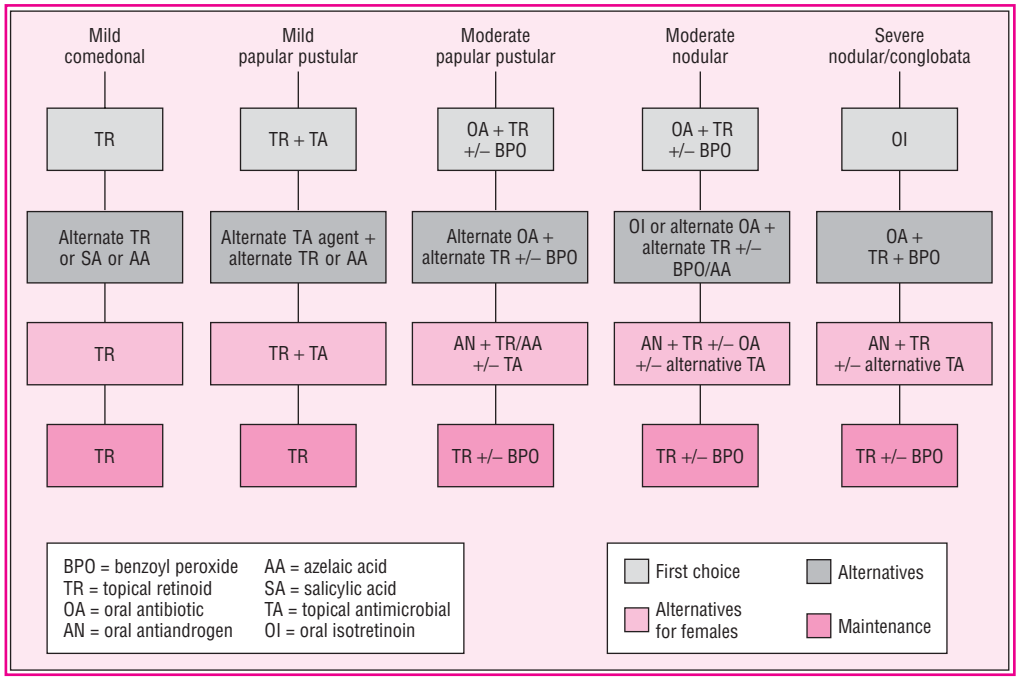

FIGURE 62–3. Algorithms for acne treatment.[3]

Patient Encounter

A 14-year-old female high school student presents to your clinic with complaints of worsening acne. Upon visual examination, you see that she has 4 pustules on her chin, 2 pustules on her forehead, and numerous open and closed comedones on her nose and cheeks. After interviewing the patient, you conclude that her acne lesions are moderately painful and make her feel embarrassed about going to school with so many "zits." She says that she began to have occasional acne at the age of 12, but over the past 6 months symptoms have worsened and states that she always has 4 to 6 lesions present on her face. The patient appears to be a healthy teenager who says that she eats well and is very athletic.

- What reported symptoms support the diagnosis of acne?
- What other information would you obtain from this patient before creating a treatment plan for her?
- Describe your treatment goals for this patient.
- What nonpharmacologic and pharmacologic treatment options are available for this patient?
- Given the information presented, develop a treatment regimen for this patient's acne.

If no improvement is reported or symptoms have worsened, patients should be re-evaluated and a change in the treatment regimen may be necessary.

Educate patients on the possibility of adverse effects. Consider a change in therapy if a patient experiences effects that are not tolerated or are considered a compromise to their health.

Patient Care and Monitoring

1. Assess patient symptoms and the presence of acne lesions. Determine severity of acne: mild, moderate, or severe.
2. Review patient history to determine treatment regimens that have been used in the past, including nonprescription, prescription, and herbal medications.
3. Obtain the patient's allergy status.
4. Develop a treatment plan appropriate for improvement of acne.
5. Discuss any monitoring parameters that may be necessary throughout the course of therapy.
6. Provide patient education on acne and its treatment:
   - What is acne and how does it develop?
   - Describe physical and psychological complications that can result from acne.
   - What drug and non-drug therapies are available for treatment?
   - Describe the possible side effects of drug therapy.
   - Emphasize the importance of treatment regimen compliance to ensure positive results.

FIGURE 62–4. Irritant contact dermatitis. Erythema and edema with spared areas on the back at sites in contact with an irritant in a 30-year-old male. (From Wolff K, Johnson RA. Eczema/dermatitis. Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology. 5th ed. New York: McGraw-Hill, 2005: 20.)

CONTACT DERMATITIS

Contact dermatitis is a term used to describe a condition in which exposure to an offending substance produces inflammation, erythema, and pruritus of the skin.[25] More specifically, contact dermatitis can be divided into either irritant or allergic forms.[25,26] ❹ *Irritant contact dermatitis results from first-time exposures to irritating substances such as soaps, plants, cleaning solutions, or solvents. Allergic contact dermatitis occurs after an initial sensitivity and further exposure to allergenic substances, including poison ivy, latex, and certain types of metal*[27] (Figs. 62–4 and 62–5). Table 62–5 lists agents commonly responsible for irritant and allergic contact dermatitis. While generally occurring on the exposed skin such as the hands and face, contact dermatitis can appear anywhere on the body.[25] Although most cases are easily treated, contact dermatitis remains an uncomfortable and sometimes embarrassing skin condition.

EPIDEMIOLOGY

Contact dermatitis is a common reason for dermatology referrals and constitutes up to 90% of all workers' compensation claims for dermatologic conditions. Although most often seen in adulthood, contact dermatitis can affect all age groups, with females at slightly greater risk than males.[28]

FIGURE 62–5. Allergic contact dermatitis of the hand: chromates. Confluent papules, vesicles, erosions, and crusts on the dorsum of the left hand in a construction worker who was allergic to chromates. (From Wolff K, Johnson RA. Eczema/dermatitis. Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology. 5th ed. New York: McGraw-Hill, 2005: 27.)

PATHOPHYSIOLOGY

Irritant contact dermatitis is not the result of an immunologic process, but rather occurs from direct injury to the skin. An irritating agent comes into contact with the skin, damages the protective layers of the epidermis and can cause erythema, the formation of vesicles, and pruritus.[25,29,30] Symptoms occur within minutes to hours of exposure and begin to heal soon after removal of the offending substance.[27]

TABLE 62–5. Common Agents Causing Contact Dermatitis

Irritant Contact Dermatitis
Soaps
Detergents
Cosmetics
Solvents
Acid, mild or strong
Alkali, mild or strong
Allergic Contact Dermatitis
Plant resins, poison ivy, poison oak, poison sumac
Metals (nickel or gold in jewelry)
Latex and rubber
Cigarette smoke
Local anesthetics (lidocaine, benzocaine)

Clinical Presentation of Contact Dermatitis

Contact dermatitis is generally confined to the area of contact, but in a highly sensitive person, a widespread or even generalized eruption may occur. Contact dermatitis is divided into two forms: irritant and allergic. Both forms may include, but are not limited to:

- Erythema
- Pruritus
- Vesicles
- Papules
- Crusts
- Burning

Irritant Form

The irritant form usually presents within hours of exposure and the rash is often localized. Irritant contact dermatitis may also include fissuring and scaling.

Allergic Form

The allergic form can take several days to present and the condition may extend beyond the borders of the region exposed. Allergic contact dermatitis may also include oozing pustules and skin erosion.

Allergic contact dermatitis is a delayed hypersensitivity reaction.[30] Upon initial exposure, a substance penetrates the skin, binds to a protein and develops into sensitizing antigens. Subsequent exposures to that substance will then elicit an allergic reaction.[25,29,30] Symptoms of allergic contact dermatitis are similar to those of the irritant type, but may take several hours to several days to develop following re-exposure.[25,26]

TREATMENT

Desired Outcomes and Goals

❺ *Identifying the causative substance and eliminating its exposure is the initial treatment goal for contact dermatitis.* Although physical symptoms can develop almost immediately after contact, removal of the offending agent will improve existing symptoms and prevent the occurrence of further complications. ❺ *The second treatment goal is symptom relief.* Since inflammation and pruritus, as well as lesion formation, are likely to result from contact dermatitis, appropriate selection of nonpharmacologic and pharmacologic agents for these symptoms is necessary.

Nonpharmacologic Therapy

In many cases contact dermatitis may not require medical treatment at all. Non-drug therapy for contact dermatitis is

aimed at relieving pruritus and maintaining skin hydration.[27] Effective agents used for this include the following:[25,27]

- Colloidal oatmeal baths
- Cool or tepid soapless showers
- Cool, moist compresses applied to the area for 30 minutes three times a day
- Emollients or lubricants applied to the area after bathing (mineral oil or petrolatum)

Pharmacologic Therapy

Astringents

The drying effect of astringents will decrease oozing from lesions and relieve itching.[25,26] Due to their ability to cause blood vessel constriction, astringents can also decrease inflammation.

Aluminum acetate (Burow's solution), calamine, and witch hazel are safe and effective products available for use.[25] Patients apply solutions as a compress for 15 to 30 minutes two to four times a day.

Adverse effects reported with these agents are minimal and include drying and tightening of the skin. Because of this, their use should be limited to no more than 7 days.[25,26,28]

Topical Steroids

Erythema, inflammation, pain, and itching caused by contact dermatitis can be effectively treated with topically applied corticosteroids. With such a wide range of products and potencies available, an appropriate steroid selection is based on severity and location of the lesions. Table 62–6 shows a list of topical steroids and their potencies. Higher-potency preparations are used in areas where penetration is poor, such as on the elbows and knees. Lower-potency products should be reserved for areas of higher penetration, such as on the face, axillae, and groin. Low-potency steroids are also recommended for the treatment of infants and children.[32,33]

Adverse effects from topical steroids are usually related to the potency of the steroid used, frequency of application, duration of therapy, and the site of application. Skin atrophy, hypopigmentation, striae, and steroid-induced acne are all possible side effects associated with long-term use.[32,33]

Topical steroids are typically applied two to four times daily. As improvement begins, maintenance therapy should be limited to the lowest-strength steroid that continues to control the condition. Once symptoms are completely resolved, use should be discontinued.

Antihistamines

Whether due to their antihistaminic activity or their sedative side effects, pruritus caused by contact dermatitis can be relieved with the use of sedating oral antihistamines such as diphenhydramine or hydroxyzine. Topical antihistamines are available, but use is limited due to their high sensitizing potential.[25,32]

In addition to sedation, many oral antihistamines can cause hypotension, dizziness, blurred vision, and confusion.[28]

Diphenhydramine and hydroxyzine can be safely administered to children older than 2 years and adults. Table 62–7 outlines the recommended doses for these medications.

OUTCOME EVALUATION

With adequate treatment, most cases of contact dermatitis should improve within 7 days. Complete resolution of symptoms may take up to 3 weeks.[12] If a patient experiences severe symptoms associated with fever or difficulty breathing, they should be instructed to seek medical attention immediately. Furthermore, patients should return to their health care provider if any of the following occur:

- Rash has not improved or has worsened after several days of treatment
- Rash has increased in size or has spread to other locations
- Patient is experiencing adverse effects from the treatment regimen

Patient Encounter

A 45-year-old female presents to a pharmacy with complaints of itching and wants a recommendation to treat it. Upon visual examination you see that she has erythematous papules on both legs. After further questioning, you learn that she has recently spent a great deal of time outside at a family picnic. She states that the picnic was in a wooded area near her home and that she and several others went on a short hike that day. She states that she was wearing shorts and "probably" came into contact with the grasses and weeds that lined the hiking trail. The rash appeared the same day as the picnic and she says that it seems to have spread since it first developed. From the information she has presented, you conclude that she has been exposed to poison ivy.

- What information supports the possibility of poison ivy exposure?
- Describe the symptoms that support this diagnosis.
- Determine what the patient has tried to relieve her symptoms.
- What are your treatment goals for this patient?
- What nonpharmacologic and pharmacologic treatment options are available for this diagnosis?
- Given the information presented, develop a treatment regimen for a patient with contact dermatitis.

Patient Care and Monitoring

1. Assess the patient's symptoms. Determine which form of contact dermatitis is present: irritant or allergic.
2. Obtain a thorough patient history. Has there been prior exposure to this agent? If so, what treatment regimens were used in the past to alleviate symptoms?
3. Obtain the patient's allergy status.
4. Develop a treatment plan appropriate for contact dermatitis.
5. Discuss testing that may need to be performed to suggest or confirm the etiologic agent (patch testing).
6. Provide patient education on contact dermatitis and treatment:

   - What is contact dermatitis and how does it develop?
   - List the various types of contact dermatitis.
   - What drug therapies are available for treatment?
   - What are the possible adverse effects of drug therapy?
   - What are symptoms that warrant physician referral?
   - Explain the importance of treatment compliance.
   - Educate the patient about the recognition of agents that may cause contact dermatitis.

DIAPER DERMATITIS

Diaper dermatitis, more commonly known as diaper rash, is a form of irritant contact dermatitis that affects the buttocks, upper thighs, lower abdomen, and genitalia of an estimated 7% to 35% of all infants.[34,35] Onset of occurrence is usually between 3 weeks and 2 years of age, with the most cases reported between 9 and 12 months of age.[36] More than 12 million adults who use diapers for incontinence also have an increased risk of developing diaper dermatitis.[35]

PATHOPHYSIOLOGY

❻ *Although many factors contribute to the etiology of diaper rash, it is most likely the result of prolonged contact of the skin with urine and feces in the diaper.* If a diaper is not changed soon after urination or defecation, the protective layer of the

Clinical Presentation of Diaper Dermatitis

Typical Symptoms

- Erythema is the most common symptom presenting with diaper rash. The rash may begin as light to medium pink with poorly defined edges, but when further developed may become dark red and raised lesions with distinct edges.
- Rashes generally appear in the folds of the skin around the diaper area, thighs, genitals, and buttocks.
- Other typical symptoms include irritation and pruritus.

Atypical Symptoms

Patients presenting with the following symptoms may indicate the need for more aggressive antibiotic or antifungal therapy and should be referred to a primary care physician for further evaluation:

- Rashes not responding to typical creams and concurrent nonpharmacologic treatment
- Rashes extending beyond the diaper region (e.g., upper abdomen or back)
- Formation of papules, bullae, or ulceration
- Excessive oozing
- Presence of genital discharge
- Concurrent fever
- Rashes appearing when diapers have not been used or rashes that fail to improve upon discontinuing diaper usage for extended periods of time (several days or more)
- Bleeding or open skin

TABLE 62–7. Oral Antihistamines Used for Pruritus[15]

Drug	Pediatric Dosage	Adult Dosage
Diphenhydramine (Benadryl®)	*Not recommended for use in infants or neonates* 2–6 years old: 6.25–12.5 mg every 4–6 hours as needed 6–12 years old: 12.5–25 mg every 4–6 hours as needed	25–50 mg every 6–8 hours as needed
Hydroxyzine (Atarax®)	0.6 mg/kg per dose every 6 hours as needed	25 mg every 6–8 hours as needed

skin can break down and make the area more susceptible to irritation and infection from the contents of the diaper.[37] While most mild cases of diaper rash present as erythema, moderate to severe cases can result in the formation of papules, vesicles, and even ulceration. If these cases are not effectively treated, the likelihood of secondary fungal or bacterial infections developing is greatly increased.[34]

TREATMENT

Desired Outcomes and Goals

❼ *The primary goal in the treatment of diaper rash is prevention and is most often accomplished through frequent diaper changes.* ❽ *When a diaper rash is already present, repairing the damaged skin, relieving discomfort, and preventing secondary infections from occurring are important factors to consider when developing an effective treatment regimen.*[37]

Nonpharmacologic Therapy

Most mild cases of diaper rash can be resolved with the use of nonpharmacologic therapies. Keeping the diaper area clean and dry by changing diapers as soon as practically possible is highly effective for treatment and prevention.[34,35] Other nondrug options include:[26,34]

- Washing the area with lukewarm water and mild soap and allowing to completely dry before applying a new diaper
- Keeping diapers loose and well ventilated
- Avoiding plastic pants over diapers
- Allowing infants to take naps on an open diaper or absorbent pad to promote drying and healing

Pharmacologic Therapy

Protectants

Protectants form an occlusive barrier between the skin and moisture from the diaper. Cream and ointment preparations are effective in providing a sufficient barrier in mild, irritant, non-infected diaper rashes. For more severe cases, a paste is the topical agent of choice. Pastes are thicker and often contain additional ingredients (e.g., petrolatum and moisturizers) to help decrease discomfort and promote healing.[36] Zinc oxide is one of the most commonly used topical protectants. In addition to forming an effective barrier against moisture, it has astringent and antiseptic properties that provide added symptom relief.[34]

Protectants are generally applied to the affected area after every diaper change and can be discontinued when the rash resolves. Other available protectants that can be used alone or in combination for the safe and effective treatment of diaper rash include white petrolatum, vitamins A and D, lanolin, and topical cornstarch. Many agents contain a combination of occlusive and protective agents such as Triple Paste® and Calmoseptine®.

Topical Steroids

Because of the increased permeability of their skin, infants are at risk for excessive absorption and toxicity from the use of topical steroids. Although these agents are effective in decreasing inflammation and relieving pruritus, steroid use in infants for the treatment of diaper dermatitis should be limited to only the low-potency preparations.[38]

A thin layer of hydrocortisone cream (0.25% to 1%) applied twice a day for no more than 2 weeks is an appropriate treatment regimen. The use of higher-potency steroids or use extending beyond 2 weeks should be at the discretion of a physician only.

Antifungals

Diaper rashes lasting longer than 48 to 72 hours are at increased risk for the development of fungal infections. These complications are most frequently caused by *Candida albicans* and require treatment with a topical antifungal[35,36] (Fig. 62–6).

Adverse events with the use of topical antifungals are generally limited to local irritation at the site of application.

Nystatin, clotrimazole, and miconazole creams or ointments applied two to four times daily with diaper changes have all shown to be effective in the treatment of candidal diaper rash. Although some of these products are available over the counter, parents and caregivers should be advised to initiate

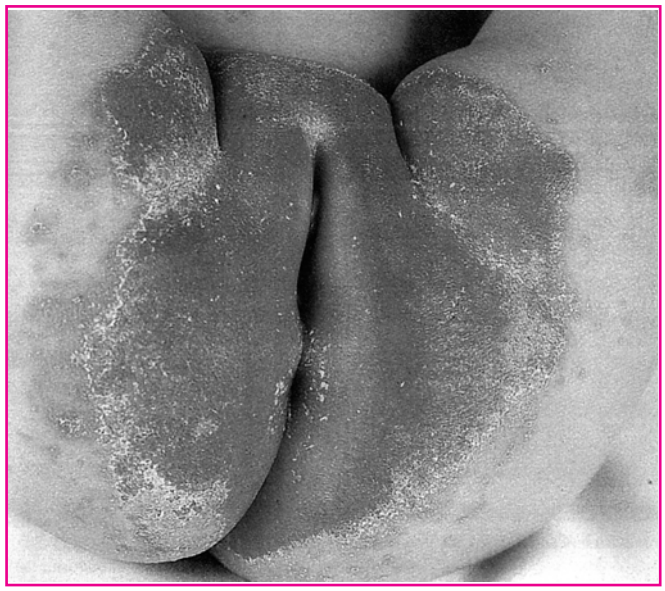

FIGURE 62–6. Candidiasis: diaper dermatitis. Confluent erosions, marginal scaling, and "satellite pustules" in the area covered by a diaper in an infant. (From Wolff K, Johnson RA. Cutaneous fungal infections. Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology. 5th ed. New York: McGraw-Hill, 2005: 721.)

treatment with antifungal agents only after physician recommendation.

Antibacterials

If conventional treatment fails, unresolved diaper rash can also lead to secondary bacterial infections. *Staphylococcus aureus* and *streptococci* are the most likely pathogens responsible for these infections and require treatment with systemic antibiotics.[35–37] While topical protectants may be used as an adjunct in treatment, suspected bacterial infections should always be referred to a physician for accurate diagnosis and the selection of an appropriate antibacterial regimen.[34] Figure 62–7 shows a useful algorithm for the effective treatment of diaper dermatitis.

OUTCOME EVALUATION

Most diaper rashes can be effectively treated in less than 1 week. If symptoms do not resolve or begin to worsen, advise caregivers to seek medical attention to determine the presence of secondary fungal or bacterial infections. In addition, provide educational information on proper diaper hygiene techniques in order to prevent the development of future diaper rashes.

Reference lists and self-assessment questions and answers are available at www.ChisholmPharmacotherapy.com.

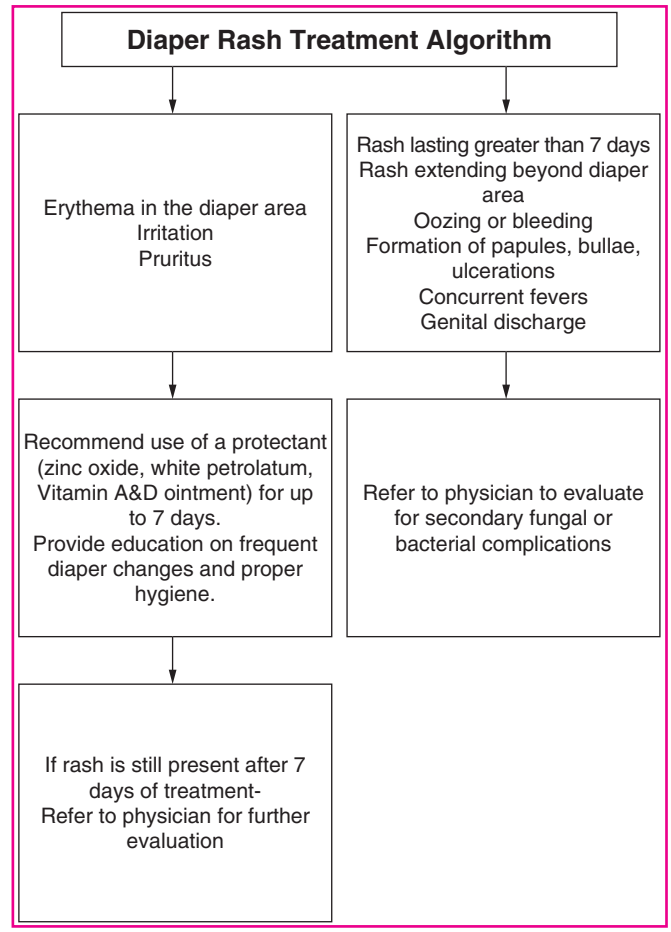

FIGURE 62–7. Diaper dermatitis treatment algorithm.

Patient Encounter

A gentleman presents to a community pharmacy with his 16-month-old daughter who recently developed a rash in her diaper area. He states that besides trying to keep the area clean and dry and changing her diapers more frequently than usual, he has tried to treat it with zinc oxide for the past 2 days. He says the rash is bright red, has persisted for 3 or 4 days and seems to be spreading. Although there is no blistering or oozing, he thinks the rash must be painful because his daughter cries with every diaper change.

- Identify the risk factors present that support the diagnosis of diaper rash.
- Elicit additional information to aid in your assessment of this patient.
- Based on the information obtained, develop a treatment plan for this patient. The plan should include the goals of therapy, nonpharmacologic and pharmacologic treatment options, follow-up instructions, and prevention education.

Patient Care and Monitoring

1. Assess rash symptoms. Determine the level of severity; is there a possibility of a secondary fungal or bacterial infection?
2. Identify signs and symptoms that require immediate physician referral.
3. Inquire about the patient's history, including any similar rashes in the past.
4. Educate the caregiver on the importance of frequent diaper changes and proper hygiene.
5. Obtain the patient's allergy status.
6. Discuss labs that may be necessary if a secondary infection is suspected (e.g., cultures or biopsies).
7. Develop a treatment regimen for the patient, including a plan for assessing improvement of the condition.
8. Provide patient education about diaper rash etiology, treatment, and prevention:
   - What is diaper rash and how does it develop? What exacerbates diaper rash?
   - Symptoms to report to a physician (blistering, oozing, bleeding, changes in the rash, or no improvement in symptoms within 2 to 3 days).
   - Available treatment options, including proper usage instructions and potential side effects.
   - Importance of treatment compliance.
   - Prevention measures.

63 Anemia

Edward C. Li and James M. Hoffman

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Identify common causes of anemia.
2. Describe common signs and symptoms of anemia.
3. Discuss the appropriate diagnostic evaluation to determine anemia type and guide therapeutic decisions.
4. State the desired therapeutic outcomes for patients with anemia.
5. Compare and contrast the various oral and parenteral iron preparations.
6. Explain the optimal use of folic acid and vitamin B_{12} in patients with macrocytic anemia.
7. Evaluate the proper use of epoetin and darbepoetin in anemia patients with cancer and kidney disease.
8. Recommend a specific treatment regimen for anemia considering the underlying cause of anemia and patient-specific variables.
9. Develop a plan to monitor the outcomes of anemia pharmacotherapy.

Key Concepts

❶ Anemia is a reduction below normal in the concentration of hemoglobin in the body that results in a reduction of the oxygen-carrying capacity of the blood.
❷ Common signs and symptoms of anemia include fatigue, lethargy, dizziness, shortness of breath, headache, edema, and tachycardia.
❸ A standard initial laboratory evaluation for anemia includes a complete blood count (evaluation of the serum hemoglobin and hematocrit concentration, white blood cell count, platelets), measurement of the red blood cell count and size, and review of peripheral smear.
❹ The goal of anemia therapy is to increase hemoglobin, which will improve red cell oxygen-carrying capacity, alleviate symptoms, and prevent anemia complications.
❺ The underlying cause of anemia (e.g., blood loss; iron, folic acid, or B_{12} deficiency; or chronic disease) must be determined and used to guide therapy.
❻ In patients with iron-deficiency anemia, appropriate oral iron therapy that delivers sufficient elemental iron should be administered before giving parenteral iron.
❼ Anemia from vitamin B_{12} or folic acid deficiency is treated effectively by replacing the missing nutrient.
❽ Therapy with epoetin or darbepoetin can increase hemoglobin, decrease transfusion requirements, and improve quality of life in cancer and kidney disease patients with anemia.
❾ After treatment, patients should be monitored for symptom resolution, hemoglobin concentration, and adverse effects.

❶ ***Anemia*** *is a reduction below normal in the concentration of hemoglobin in the body that results in a reduction of the oxygen-carrying capacity of the blood.* Some patients with anemia may be asymptomatic initially, but eventually, the lack of oxygen to the tissues will result in fatigue, lethargy, shortness of breath, headache, edema, and tachycardia. Common causes of anemia include blood loss, decreased production of red blood cells (RBCs), increased destruction of RBCs, or some combination of these factors. Determination of the underlying cause of anemia is essential for successful management. Appropriate treatment of anemia will result in an increase in **hemoglobin,** with a corresponding increase in oxygen-carrying capacity and reduction in symptoms.

Patient Encounter, Part 1

A 74-year-old Caucasian woman with a past medical history significant for hypertension and type II diabetes mellitus presents to her primary care physician complaining of shortness of breath and fatigue for the past few days. She denies any recent bleeding manifestations, including bright red blood per rectum, hemoptysis, melena, or epistaxis. She denies any fevers, chills, nausea, vomiting, or recent weight loss. A complete blood count (CBC) was taken and revealed hemoglobin of 9.3 g/dL (93 g/L or 5.8 mmol/L).

- Is this patient anemic? If so, what are possible causes of anemia?
- What additional laboratory assessments are required to make an appropriate therapeutic plan?
- How would the requested laboratory parameter(s) aid your decision making?

EPIDEMIOLOGY AND ETIOLOGY

Anemia is a common condition, and the prevalence of anemia varies widely based on age, gender, race/ethnicity, and comorbid conditions. A study of anemia prevalence in a nationally representative sample of community-dwelling individuals describes how anemia differs across different populations.[1] The prevalence of anemia in children (ages 1–16 years) was 6% to 9%, but the prevalence of anemia increases to approximately 11% in adults over age 65 years and to at least 20% in adults 85 years of age and older. Anemia is generally more common in women, particularly during their reproductive years (ages 17–49 years), when anemia occurs in over 12%, but in less than 2% of men. The same study showed that in the population over age 65, non-Hispanic whites and Mexican Americans had similar prevalence of anemia (9.0% and 10.4%, respectively), but with a prevalence of 27.8%, anemia was significantly more common in non-Hispanic blacks.

Comorbid conditions can increase the risk of anemia substantially. Anemia is especially common in cancer patients receiving chemotherapy and patients with chronic kidney disease (CKD). The incidence of anemia in cancer patients varies based on tumor type and the level of myelosuppression the chemotherapy regimen causes. For instance, serious anemia [hemoglobin 7.9 g/dL or less (79 g/L or 4.9 mmol/L)] occurs in at least 75% of patients who receive a common chemotherapy regimen for lymphoma, but serious anemia may occur in only approximately 10% of patients who receive common chemotherapy regimens for breast cancer.[2] Overall, retrospective reviews demonstrate that with an incidence of 50% to 60%, chemotherapy-induced anemia is most common in patients with lymphomas, lung tumors, and ovarian tumors. Anemia is very common in patients with CKD. For example, one study showed that 60% of patients with serious kidney disease have anemia.[3]

The causes of anemia can be divided into three main categories: decreased production, increased destruction, and blood loss. Drug therapy is the mainstay of treatment for anemias caused by reduced production of erythrocytes and will be the focus of this chapter.

A decrease in erythrocyte production can be multifactorial. A deficiency in nutrients (such as iron, vitamin B_{12}, and folic acid) is a common cause that often is easily treatable. In addition, patients with cancer and CKD are at risk for developing a hypoproductive anemia. Furthermore, patients with chronic immune-related diseases (such as rheumatoid arthritis and systemic lupus erythematosus) can develop anemia as a complication of their disease. Anemia related to these chronic inflammatory conditions is typically termed *anemia of chronic disease.*

PATHOPHYSIOLOGY

Erythropoiesis

Erythropoiesis is a process that starts with a pluripotent stem cell in the bone marrow that eventually differentiates into an erythroid colony-forming unit (CFU-E)[4] (Fig. 63–1). The development of these cells depends on stimulation from the appropriate growth factors, primarily erythropoietin. Other cytokines involved include granulocyte-monocyte colony-stimulating factor (GM-CSF) and interleukin 3 (IL-3). Eventually, the CFU-Es differentiate into **reticulocytes** and cross from the bone marrow into the peripheral blood. Finally, these reticulocytes mature into erythrocytes after 1 to 2 days in the bloodstream. Throughout this process, the cells gradually accumulate more hemoglobin and lose their nuclei.[4]

Hypoproliferative or Decreased-Production Anemias

Nutritional

Deficiencies in nutrients such as folic acid and vitamin B_{12} may hinder this process of erythrocyte maturation.[4,5] Folic acid and vitamin B_{12} are important nutrients required for the formation of DNA. In a setting where these nutrients are decreased, DNA synthesis is inhibited, and consequently, erythrocyte maturation also is inhibited.[4,5] Poor diet can be a contributor to the deficiencies in these

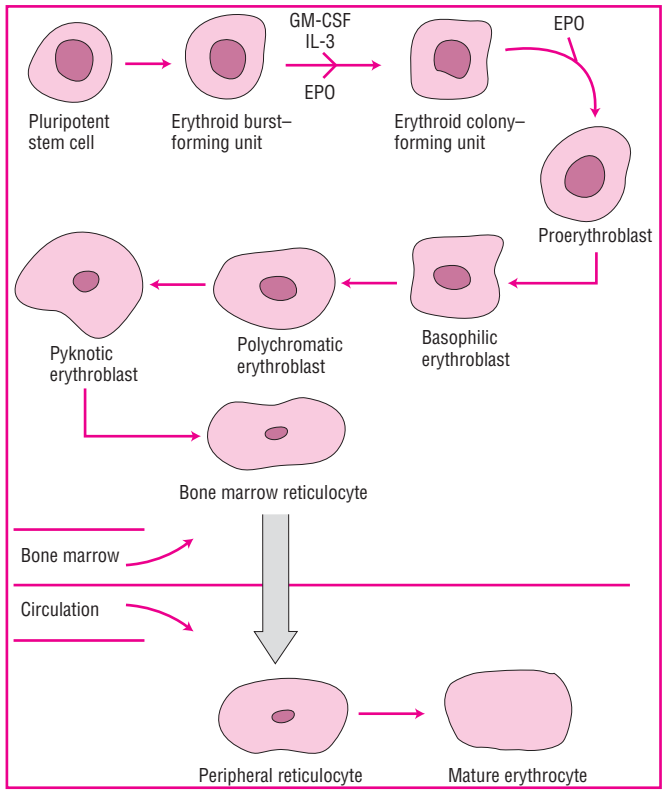

FIGURE 63–1. The process of erythropoiesis.

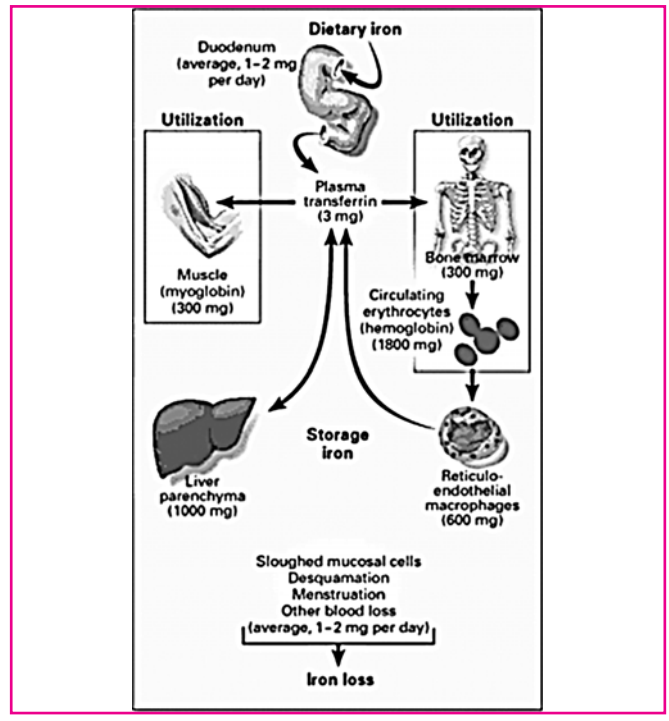

FIGURE 63–2. The distribution of iron use in adults. (From Andrews NC. Disorders of iron metabolism. *New Engl J Med* 1999; 341(26):1986–1995. Used by permission from NEJM. Copyright © 1999 Massachusetts Medical Society. All rights reserved.)

nutrients. Additionally, patients with pernicious anemia are not able to absorb vitamin B_{12} via the gastrointestinal tract because they lack intrinsic factor, a key glycoprotein that binds to vitamin B_{12} and facilitates its absorption in the ileum.[6]

Iron is another vital nutrient in the development of functioning erythrocytes; it is essential for the formation of hemoglobin. Lack of iron leads to a decrease in hemoglobin synthesis and ultimately red blood cells. Normal homeostasis of iron transport and metabolism is depicted in Fig. 63–2.[7] Approximately 1 to 2 mg of iron is absorbed through the duodenum each day, and the same amount is lost via blood loss, desquamation of mucosal cells, or menstruation.

Since there is no true "excretion" of iron from the body, iron-deficiency anemia occurs mostly because of inadequate absorption of iron or excess blood loss. Inadequate absorption may occur in patients who have congenital or acquired intestinal diseases, such as inflammatory bowel disease, celiac disease, or bowel resection. **Achlorhydria** and diets poor in iron also may contribute to poor absorption of iron. In contrast, iron deficiency also may occur in patients who exhibit a higher rate of iron loss from the body. This is manifested in blood loss, either from the gastrointestinal system, menstruation, cancer, or trauma.[7]

Hypoproliferative Marrow

Patients with chronic diseases exhibit a different pathophysiologic mechanism of disease. For example, patients with cancer may suffer from anemia because of chemotherapy and/or the tumor effects itself. Chemotherapy may cause destruction of highly proliferating stem cells, thereby decreasing the production of mature erythrocytes.[8] In addition, tumors can cause anemia via hemorrhage, replacing normal bone marrow with malignant cells, and releasing cytokines that lead to decreased erythropoietin production. Autoimmune hemolysis is also possible.[8]

Decreased Erythropoietin Production or Response

Patients with CKD suffer from a decrease in erythropoietin production because erythropoietin is produced mainly in the kidneys.[4,5] Finally, in patients with anemia of chronic disease, there is a blunted erythropoietin production as well as a diminished response to erythropoietin.[9] Anemia of chronic disease also affects iron homeostasis, causing iron sequestration into storage sites and decreasing the amount available to the rest of the body.[9]

CLINICAL PRESENTATION AND DIAGNOSIS

Clinical Presentation of Anemia

Signs and Symptoms

❷ *Generally, the signs and symptoms of anemia are nonspecific, and may include*:

- Fatigue, lethargy, dizziness
- Shortness of breath
- Headache
- Edema
- Tachycardia

Other findings that may be present in some patients include:

- Dry skin, chapped lips
- Nail brittleness
- Hunger for ice, starch, or clay (termed *pica*)

Past Medical History

Inquire about the following conditions:

- History of blood loss, such as hemorrhoids, melena, or menorrhagia (iron-deficiency anemia)
- Malnourished or recent weight loss (vitamin B_{12} or folate deficiency)
- Alcoholism (folate deficiency)
- Cancer or chronic kidney diseases
- Chronic autoimmune disorders or infections, such as human immunodeficiency virus (HIV) infection or rheumatoid arthritis (anemia of chronic disease)

Physical Examination

These findings aid the clinician in determining the severity of the anemia:

- Orthostatic hypotension and tachycardia secondary to volume depletion.
- Mental status changes and confusion
- Cutaneous changes such as pallor, jaundice, and nail brittleness

Laboratory Evaluation

Table 63–1 describes common tests used to determine the etiology of anemia. A diagnostic and treatment algorithm for anemia is outlined in Fig. 63–3.

1. ❸ *A complete blood count (CBC) is a necessary first step in evaluating a patient with anemia. If the hemoglobin and hematocrit are less that the normal range, the patient is anemic. Subsequent evaluations of red blood cell indices and the peripheral smear often are necessary to determine the etiology (and ultimately, the treatment) of the anemia.*
2. Evaluating the mean corpuscular volume (MCV) is the next step in an anemia work-up. It is classified as microcytic, normocytic, or macrocytic if the MCV is below, within, or above the normal range of 80 to 96 fL/cell, respectively.

Microcytic Anemia and Iron Evaluation

Iron studies (see Table 63–1) should be evaluated in the setting of a low MCV. These include

- Serum iron
- Serum ferritin—the best indirect determinant of body iron stores. It is commonly decreased in patients with iron-deficiency anemia.
- **Total iron-binding capacity (TIBC)—**quantifies the iron-binding capacity of transferrin and is increased in iron-deficiency anemia
- **Transferrin saturation** (serum iron/TIBC)—indicates the amount of transferrin that is bound with iron; it is lower in iron-deficiency anemia.

Macrocytic Anemia

- Evaluate folic acid and vitamin B_{12} levels in the setting of an elevated MCV.
- Further investigation by administering radiolabeled B_{12} (i.e., Schilling test) to determine if lack of intrinsic factor.
- Consider obtaining homocysteine and methylmalonic acid levels.

Normocytic Anemia

- Evaluate reticulocytes and CBC.
- High reticulocyte counts may indicate red blood cells loss via acute blood loss, hemolysis, or splenic sequestration.
- Low reticulocyte counts may indicate a diseased bone marrow (e.g., aplastic anemia, myelodysplasia, or leukemia), especially if the white blood cells and platelets are low.
- High WBC/platelets may be from anemia of chronic disease, malignancy, or chronic kidney disease.

Patient Encounter, Part 2

Additional laboratory parameters are ordered, and the following is observed:

CBC

- *WBC:* 5.50 × 10^3/μL (5.50 × 10^9/L)
- *Hgb:* 9.3 g/dL (93 g/L or 5.77 mmol/L)
- *Hct:* 27.8% (0.278)
- *Plt:* 170 × 10^3/μL (170 × 10^9/L)

Red blood cell indices

- *MCV:* 78 fL/cell
- *MCH:* 26 pg/cell
- *MCHC:* 33.5g/dL (335 g/L)

Others

- *RBC count:* 3 M/μL (3 × 10^{12}/L)
- *RDW:* 15% (0.15)
- *Retic%:* 3% (0.03)

Iron studies

- *Serum iron:* 45 mcg/dL (8.1 μmol/L)
- *Serum ferritin:* 7 mcg/L (15.7 pmol/L)
- *TIBC:* 462 mcg/dL (82.7 μmol/L)
- *Ferritin saturation:* 10% (0.10)

B_{12} and folate

- *Serum folate:* 20 mcg/dL (45 nmol/L)
- *Serum B_{12}:* 675 pg/mL (498 pmol/L)

- Is this a macrocytic or microcytic anemia?
- Specifically, what is the etiology of the anemia?
- What therapy should the patient receive?

TABLE 63–1. Pertinent Laboratory Tests in the Evaluation of Anemia

Test Name	Normal Range	Description/Significance
Complete Blood Count		
Hemoglobin (Hgb)	Males: 14–17.5 g/dL (140–175 g/L or 8.69–10.9 mmol/L) Females: 12.3–15.3 g/dL (123–153 g/L or 7.63–9.5 mmol/L)	Amount of hemoglobin in the blood; signifies oxygen-carrying capacity of the blood and determines if a patient is anemic.
Hematocrit (Hct)	Males: 42–50% (0.42–0.50) Females: 36–45% (0.36–0.45)	The percent of blood that the erythrocytes encompass; also indicates anemia; the hemoglobin is measured, and the hematocrit is calculated.
Red blood cell count (RBC)	Males: 4.5–5.9 × 10^6 cells/mL (4.5–5.9 × 10^{12} cells/L) Females: 4.1–5.1 × 10^6 cells/mL (4.1–5.1 × 10^{12} cells/L)	The number of erythrocytes in a volume of blood; also indicates anemia, but seldom used.
Red Blood Cell Indices		
Mean cell volume (MCV)	80–96 fL/cell	A widely used laboratory value to measure RBC "size"; higher values indicate macrocytosis and lower values indicate microcytosis.
Mean cell hemoglobin (MCH)	27–33 pg/cell	Amount of Hgb per RBC; may be decreased in iron deficiency anemia.
Mean cell hemoglobin concentration (MCHC)	33.4–35.5 g/dL (334–355 g/L)	Hemoglobin divided by the hematocrit; also low in iron-deficiency anemia.
Iron Studies		
Serum iron		
Males:	45–160 mcg/dL (8.1–31.3 µmol/L)	Measures amount of iron bound to transferrin; low in iron-deficiency anemia.
Females:	30–160 mcg/dL (5.4–31.3 µmol/L)	
Serum ferritin	Less than 10–20 mcg/L (22–44 pmol/L)	Ferritin is the protein-iron complex found in macrophages used for iron storage; low in iron-deficiency anemia.
Total iron-binding capacity (TIBC)	220–420 mcg/dL (39.4–75.2 µmol/L)	Measures the capacity of transferrin to bind iron; high in iron-deficiency anemia.
Transferrin saturation (TSAT)	30–50% (0.30–0.50)	Transferrin saturation = (serum iron/TIBC) × 100; a saturation of less than 15% is common in iron-deficiency anemia.
Other Tests		
Red blood cell distribution width (RDW)	11.5–14.5% (0.115–0.145)	A higher value means the presence of many different sizes of RBCs; the MCV is therefore less reliable.
Reticulocyte count		
Males:	0.5–15% of RBCs (0.005–0.025)	Should be elevated in patients who are responding to treatment.
Females:	0.5–2.5% of RBCs (0.005–0.025)	
Folic acid (plasma)	3.1–12.4 ng/mL or mcg/L (7–28 nmol/L)	Used to determine folic acid deficiency.
Folic acid (RBC)	125–600 ng/mL (283–1360 nmol/L)	Used to determine folic acid deficiency.
Vitamin B_{12}	180–600 pg/mL (133–738 pmol/L)	Used to determine vitamin B_{12} deficiency.
Erythropoietin level	2–25 mIU/mL (2–25 IU/L)	Patients may benefit from erythropoietin therapy if they are anemic and erythropoietin levels are normal or mildly elevated.

TREATMENT

Desired Outcomes

❹ *The goal of anemia therapy is to increase the hemoglobin level, which will improve red cell oxygen-carrying capacity, alleviate symptoms, and prevent anemia complications.* Normal hemoglobin values are 14 to 17.5 g/dL (140–175 g/L or 8.69–10.9 mmol/L) for males and 12.3 to 15.3 g/dL (123–153 g/L or 7.63–9.5 mmol/L) for females. It is important to note that continuation of a patient's therapy should be assessed primarily resolution of clinical signs and symptoms. Patients who experience a resolution in their symptoms such as shortness of breath, tachycardia, fatigue, dizziness, and edema may not require aggressive therapy to maintain their hemoglobin values within normal limits. Ultimately, prevention of complications owing to anemia such as hypoxia and cardiovascular sequelae can be avoided if hemoglobin levels are greater than 7 g/dL (70 g/L or 4.34 mmol/L).[10]

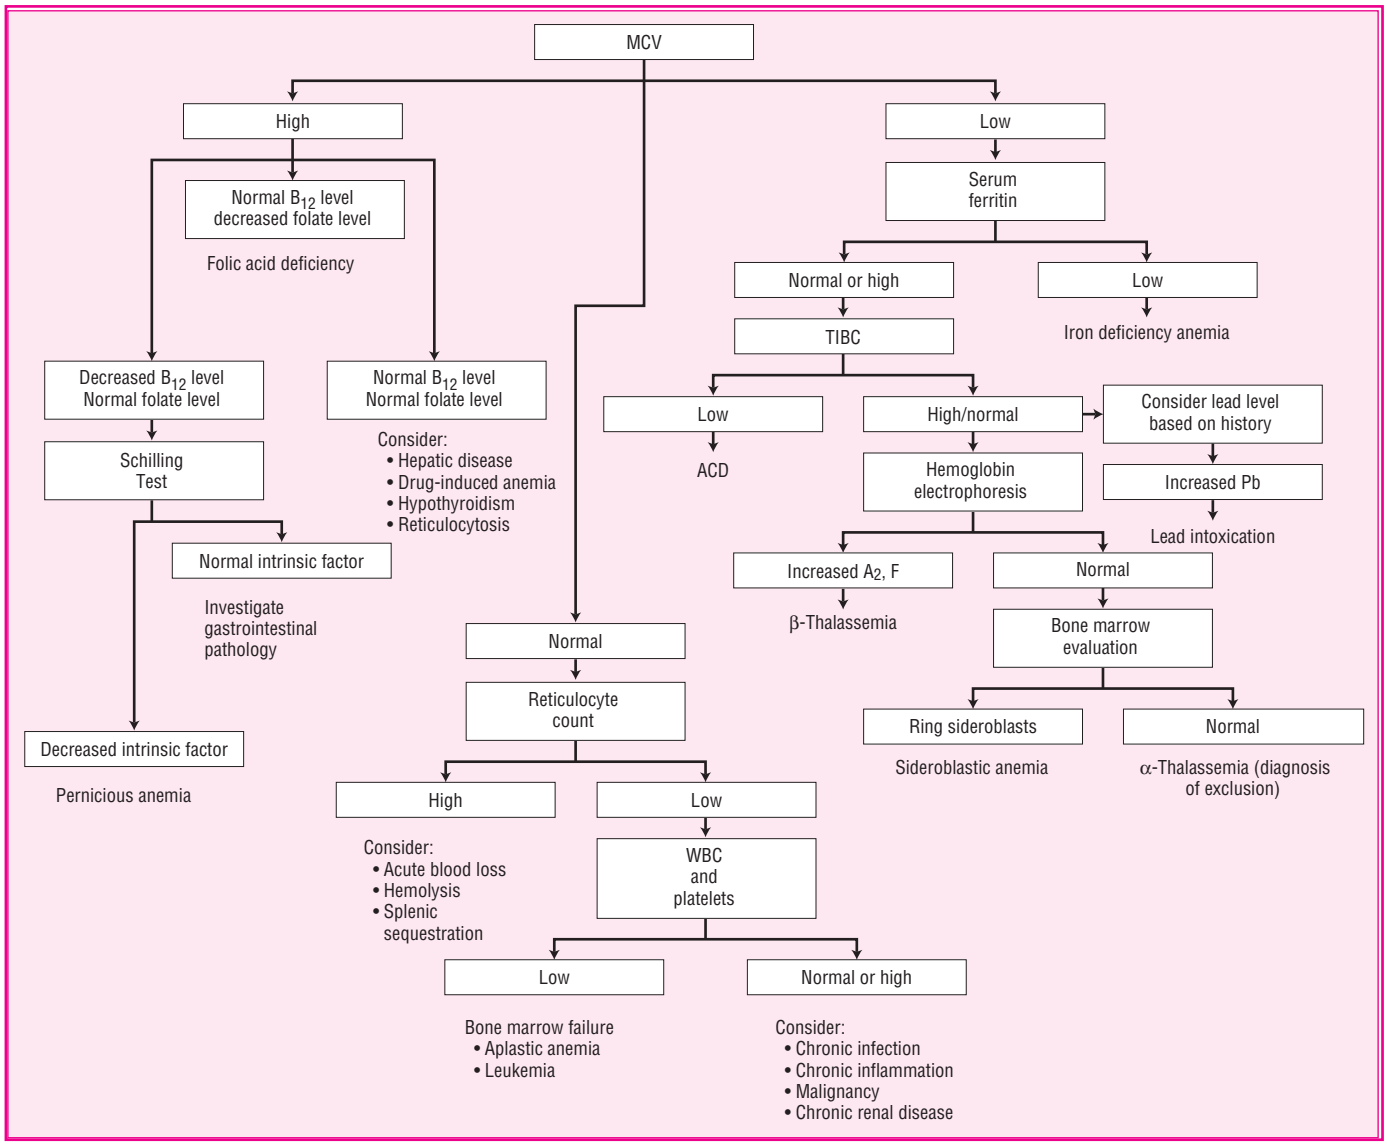

FIGURE 63–3. The anemia evaluation process. MCV, mean corpuscular volume; Pb, lead; TIBC, total iron binding capacity; ACD, anemia of chronic disease.

General Approach to the Anemic Patient

❺ *The underlying cause of anemia (e.g., blood loss; iron, folic acid, or vitamin B_{12} deficiency; or chronic disease) must be determined and used to guide therapy.* As discussed previously, patients should be evaluated initially based on laboratory parameters to determine the etiology of the anemia (see Fig. 63–3). Subsequently, the appropriate pharmacologic treatment should be initiated based on the cause of anemia.

Nonpharmacologic Therapy

The most important nonpharmacologic treatment of anemia is the transfusion of red blood cells. However, because of the risk of infection, immunosuppression, and microcirculatory complications and the high cost of the procedure, the threshold for transfusion has been debated.[11] Generally, only patients requiring immediate correction receive blood transfusions. Determining which patient requires immediate correction is left to the health care provider. Usually, symptomatic patients who present with a hemoglobin concentration of 7 to 8 g/dL (70–80 g/L or 4.34–4.96 mmol/L) are candidates for transfusion.[12]

Other than transfusion, nonpharmacologic therapy plays a limited role in the management of anemia. Certainly, some causes of anemia can be attributed to diets poor in iron, folic acid, or vitamin B_{12}. However, in the United States, nutrient-poor diets are rarely the sole cause of anemia in a patient. Therefore, ingesting a diet that is rich in iron, folic acid, or vitamin B_{12} should be encouraged but should not be the only

TABLE 63–2. Food Sources of Iron, Folic Acid, or Vitamin B_{12}[5]

Nutrient	Food Sources
Iron	Red meat, organ meats, wheat germ, egg yolks, oysters
Folic acid	Green vegetables, liver, yeast, fruits
Vitamin B_{12}	Animal by-products, legumes

modality of treatment. Food sources of iron, folic acid, and vitamin B_{12} are listed in Table 63–2.[5]

Pharmacologic Therapy

Iron-Deficiency Anemia

❻ *The initial treatment of iron-deficiency anemia is oral iron therapy with 200 mg of elemental iron daily for those who are able to tolerate the oral route.* In order to attain this amount of elemental iron daily, many different iron products and salt forms are available. Table 63–3 lists the various salt forms of oral iron available, the amount of elemental iron in each product, and the approximate daily dose of the salt to attain 200 mg of elemental iron daily.

Iron supplementation resolves anemia by replacing iron stores in the body that are necessary for red blood cell production and maturation. If treated properly, a response (via the presence of reticulocytosis) should be seen in 7 to 10 days, and hemoglobin values should rise by about 1 g/dL (10 g/L or 0.62 mmol/L) per week. Patients should be reassessed if hemoglobin does not increase by 2 g/dL (20 g/L or 1.24 mmol/L) in 3 weeks.

Dosing for iron should be divided equally into two to three doses daily. An empty stomach (1 hour before or 2 hours after a meal) is preferred for maximal absorption. After absorption, iron binds to transferrin in the plasma and is transported to the muscles (for myoglobin), liver (for storage), or bone marrow (for red cell production). Iron is not actively excreted from the body but is "lost" through other measures already described.[7] Some studies suggest that iron absorption may be increased by adding ascorbic acid (vitamin C) to the drug regimen.[13] However, administration of iron on an empty stomach and with ascorbic acid may increase the incidence of gastrointestinal (GI) side effects, such as abdominal pain, nausea, and heartburn. Patients who cannot tolerate their iron on an empty stomach may be told to take it with food.

Common toxicities associated with oral iron products include abdominal pain, nausea, and heartburn. Constipation and the presence of dark stools are reported often. Drug interactions may occur with iron products, predominantly owing to iron-drug binding, resulting in decreased absorption of the interacting drug. Examples include fluoroquinolones, tetracyclines, and phenytoin. To avoid this interaction, doses of iron and the interacting drug should be separated by 2 to 4 hours.

Parenteral iron therapy may be appropriate in cases where patients are unable to tolerate the oral formulation because of toxicities or compliance. In addition, those who have documented iron-deficiency anemia and have not responded to

Patient Encounter, Part 3

The patient is diagnosed with iron-deficiency anemia and is started on ferrous sulfate 325 mg orally three times daily to be taken on an empty stomach. Follow-up CBC 1 month later reveals a Hgb of 10 g/dL (100 g/L or 6.2 mmol/L), previously 9.3 g/dL (93 g/L or 5.77 mmol/L). The patient complains of shortness of breath on exertion and constipation. She also admits to taking only one tablet a day because of nausea.

- What hemoglobin level would constitute a therapeutic response in this patient?
- How can nausea secondary to ferrous sulfate be reduced in this patient?
- What changes to this patient's iron therapy do you recommend?

TABLE 63–3. Iron Products (IV and PO) and Elemental Iron Content

Salt Form	Brand Name(s)	Elemental Iron Content per Dose Form
Oral Formulations		
Ferrous sulfate	Feosol	65 mg/325-mg tablet
		60 mg/300-mg tablet
Ferrous sulfate, anhydrous	N/A	65 mg/200-mg tablet
Ferrous gluconate	Fergon	39 mg/325-mg tablet
		37 mg/300-mg tablet
Ferrous fumarate	Feostat	33 mg/100-mg tablet
Polysaccharide-iron complex	Niferex	150 mg/capsule
		50 mg/tablet
Parenteral Formulations		
Iron dextran	InFED	50 mg/mL
Iron sucrose	Venofer	20 mg/mL
Sodium ferric gluconate	Ferrlecit	62.5 mg/5 mL

oral iron therapy (e.g., because of malabsorption) are also candidates for parenteral iron therapy.

Parenteral iron therapy currently is available in three different formulations, which are listed in Table 63–3. Iron dextran was the first parenteral iron formulation to be approved, followed by ferric gluconate, and then iron sucrose. Although these newer agents are only approved by the Food and Drug Administration (FDA) to treat anemia associated with CKD in patients receiving erythropoietin products, they are effective in treating iron-deficiency anemia as well. Iron dextran is FDA approved for treating documented iron deficiency in patients who are unable to tolerate the oral formulation.

The dose of iron dextran can be calculated by the following equation: dose (mL) = 0.0442 (desired Hgb – observed Hgb) × body weight + (0.26 × body weight). The body weight that should be used is lean body weigh for adults and children weighing more than 15 kg and actual body weight for children weighing 5 to 15 kg. The dose in milligrams can be calculated based on a standard concentration of 50 mg elemental iron per milliliter.[14] The prescribing information recommends administering iron dextran in 100-mg aliquots daily until the total dose is achieved. However, anecdotal evidence reports that the total calculated dose can be administered safely over 4 to 6 hours in one day. It is important to note that a test dose (0.5 mL over at least 30 seconds) must be administered to patients who are about to receive their first dose of iron dextran because of the risk of anaphylaxis. Patients should be monitored for signs of anaphylaxis for at least 1 hour after the test dose before administering the total dose. Other adverse effects include arthralgias, arrhythmias, hypotension, flushing, and pruritus.

The use of newer parenteral iron products (e.g., iron sucrose and ferric gluconate) for treating iron-deficiency anemia is controversial; they are FDA approved for the treatment of anemia associated with CKD. It is appealing to use these agents in the setting of iron-deficiency anemia because they are considered "safer" owing to a decreased risk of anaphylaxis. However, the high cost and lack of reimbursement for these agents may preclude their routine use in iron-deficiency anemia patients without kidney disorders.[15]

Patient Encounter, Part 4

Because the patient is not able to tolerate oral iron therapy (constipation and nausea), changing to intravenous iron therapy is appropriate.

- What formulation of intravenous iron therapy should the patient receive?
- Calculate this patient's dose of parenteral iron.
- What adverse effects are associated with parenteral iron?

Vitamin B_{12} and Folic Acid anemia

❼ *Anemia from vitamin B_{12} or folic acid deficiency is treated effectively by replacing the missing nutrient.* Both folic acid and vitamin B_{12} are essential for erythrocyte production and maturation. Replacing these factors allows for normal DNA synthesis and, consequently, normal erythropoiesis.

Vitamin B_{12} (cyanocobalmin) administered both orally and parenterally is equally effective in treating anemia from vitamin B_{12} deficiency. However, use of parenteral cyanacobalamin is the most common method of vitamin B_{12} replacement because it may be more reliable and practical. Subcutaneous or intramuscular administration is appropriate. Vitamin B_{12} is absorbed completely following parenteral administration, whereas oral vitamin B_{12} is absorbed poorly via the GI tract. Furthermore, use of parenteral vitamin B_{12} to treat megaloblastic anemia may circumvent the need to perform a Schilling test to diagnose lack of intrinsic factor.

A typical cyanocobalmin dosing regimen is 800 to 1000 mcg/day for 1 to 2 weeks, followed by 100 to 1000 mcg/day every week until the Hgb/Hct normalizes and maintenance of 100 to 1000 mcg monthly for life. However, a number of dosing regimens exist. In addition, a number of oral vitamin B_{12} preparations are available, including many over-the-counter formulations. A common oral dosing regimen is from 1000 to 2000 mcg/day. If parenteral cyanocobalmin is used initially, oral vitamin B_{12} can be useful as maintenance therapy. Typically, the response to therapy is quick. Neurologic symptoms and megaloblastic cells disappear within a few days, and hemoglobin levels increase after a week of therapy.

Vitamin B_{12} generally is well tolerated and exhibits minimal adverse effects. Injection-site pain, pruritus, rash, and diarrhea have been reported. Drug interactions have been observed with omeprazole and ascorbic acid that decrease oral absorption.

When treating folic acid deficiency, an initial daily dose of 1 mg/day by mouth typically is effective. Absorption of folic acid generally is rapid and complete. However, patients with malabsorption syndromes may require larger doses (up to 5 mg/day). Similar to vitamin B_{12} deficiency, resolution of symptoms and reticulocytosis is prompt, occurring within days of commencing therapy. Hgb will start to rise after 2 weeks of therapy and may take from 2 to 4 months to resolve the deficiency completely. Afterwards, if the underlying deficiency is corrected, folic acid replacement can be discontinued. However, in cases where folic acid is consumed rapidly or absorbed poorly, chronic replacement may be required.

Folic acid is also well tolerated. Some nonspecific adverse effects include allergic reactions, flushing, malaise, and rash. Folic acid has been reported to decrease phenytoin levels by inducing its metabolism.

Anemia of Chronic Disease

Anemia of chronic disease is a term given those with underlying conditions that contribute to or cause anemia in a patient. These chronic diseases can include cancer, chronic

kidney diseases, and other inflammatory disorders. ❽ *In* patients with anemia owing to cancer and chronic kidney disease, therapy with epoetin or darbepoetin can increase hemoglobin, decrease transfusion requirements, and improve quality of life.

Chemotherapy induced Anemia

Studies have shown that in patients with chemotherapy-related anemia, therapy with erythropoietin products (epoetin-alfa and darbepoetin) can increase hemoglobin, decrease transfusion requirements, and improve quality of life.[12] Epoetin is recombinant human erythropoietin, and darbepoetin is structurally similar to endogenous erythropoietin. Both bind to the same receptor to stimulate red blood cell production. Darbepoetin differs from epoetin in that it is a glycosylated form and exhibits a longer half-life in the body. The half-lives of a single subcutaneous injection of epoetin or darbepoetin in patients are roughly 27 and 43 hours, respectively.

The National Comprehensive Cancer Network (NCCN) recommends an anemia work-up for patients with hemoglobin of less than 11 g/dL (110 g/L or 6.8 mmol/L). Patients who are symptomatic or asymptomatic with significant risk factors (e.g., extensive transfusion history, myelosuppressive chemotherapy, etc) may qualify for treatment with erythropoietic agents such as epoetin-alfa or darbepoetin. Data do not support the use of one agent over another; they are both equally effective in treating this type of anemia.[12] Table 63–4 provides dosing recommendations for chemotherapy-related anemia.

The response to erythropoietin products must be monitored closely to prevent adverse effects associated with these agents. The common adverse effects experienced include hypertension and thrombosis. Concomitant drugs with the same adverse-effect profile may increase a patient's risk for these complications. Also, the patient's overall survival may be decreased if the hemoglobin level is titrated to above the recommended 11 to 12 g/dL (110–120 g/L or 6.82–7.44 mmol/L) value. Therefore, it is important to follow the dosing and titration scheme recommended by the NCCN and summarized in Fig. 63–4. Patients should have their hemoglobin evaluated at least every 2 weeks. If in that time period the hemoglobin value rises 1 g/dL (10 g/L or 0.62 mmol/L) or greater, then the dose should be reduced by 25%. In addition, the dose of an erythropoietin agent should be held in patients who have a hemoglobin value equal to or greater than 12 g/dL (120 g/L or 7.44 mmol/L) as a result of treatment. Therapy can be reinitiated once the hemoglobin falls to less than 12 g/dL (120 g/L or 7.44 mmol/L), but the dose should be reduced by 25%.

Patients who do not exhibit at least a 1 g/dL (10 g/L or 0.62 mmol/L) increase in their hemoglobin level after 6 weeks of treatment should have their doses increased by 50%. In addition, if their hemoglobin has not increased by this amount after 12 weeks of therapy, then the drug should be discontinued, and further work-up is required.

Cancer patients also may have concurrent iron deficiency secondary to erythropoietin use ("functional" iron deficiency) or to cancer. Therefore, it is imperative that these patients have iron studies done to assess adequate iron stores needed to drive hematopoiesis. If the patient is determined to have suboptimal iron stores or is iron deficient, then replacement either orally or intravenously may be necessary, in addition to the use of erythropoietin products. The use of iron in these patients is the same as discussed previously under "Iron-Deficiency Anemia."

Chronic Kidney Disease (CKD)

Patients with CKD progress through five stages of disease based on the glomerular filtration rate (GFR).[16] Anemia is a common development in patients with CKD, and anemia evaluation and treatment should be initiated in patients with stage 3 CKD patients (GFR less than 60 mg/dL). Early treatment of anemia in patients with CKD has been associated with slower disease progression and a lower risk of death once patients receive dialysis.[17,18] Therefore, it is essential to evaluate and treat anemia in patients before they progress to stage 5 CKD, which is a GFR of less than 15 mg/dL or dialysis.

To rule out other causes of anemia, a thorough anemia evaluation should be completed in patients with CKD.[19] CKD

TABLE 63–4. Erythropoietin Products and Their Usual Doses for Anemia from Cancer/Chemotherapy and CKD

	Epoetin-alfa (Epogen, Procrit)	Darbepoetin-alfa (Aranesp)
Cancer/chemotherapy dosing regimens	150 units/kg subcutaneously three times per week 40,000 units subcutaneously once every week	2.25 mcg/kg subcutaneously once every week 3 mcg/kg subcutaneously once every 2 weeks; may increase to 5 mcg/kg 200 mcg subcutaneous fixed dose every 2 weeks, may increase to 300 mcg 300–500 mcg every 3 weeks
CKD dosing regimens[a]	50–100 units/kg subcutaneously three times per week	0.45 mcg/kg subcutaneously once every week 0.75 mcg/kg subcutaneously once every two weeks

[a]According to National Kidney Foundation guidelines for the use epoetin in patients with anemia owing to kidney disease, the subcutaneous route is preferred. However, the intravenous route is used commonly in clinical practice.

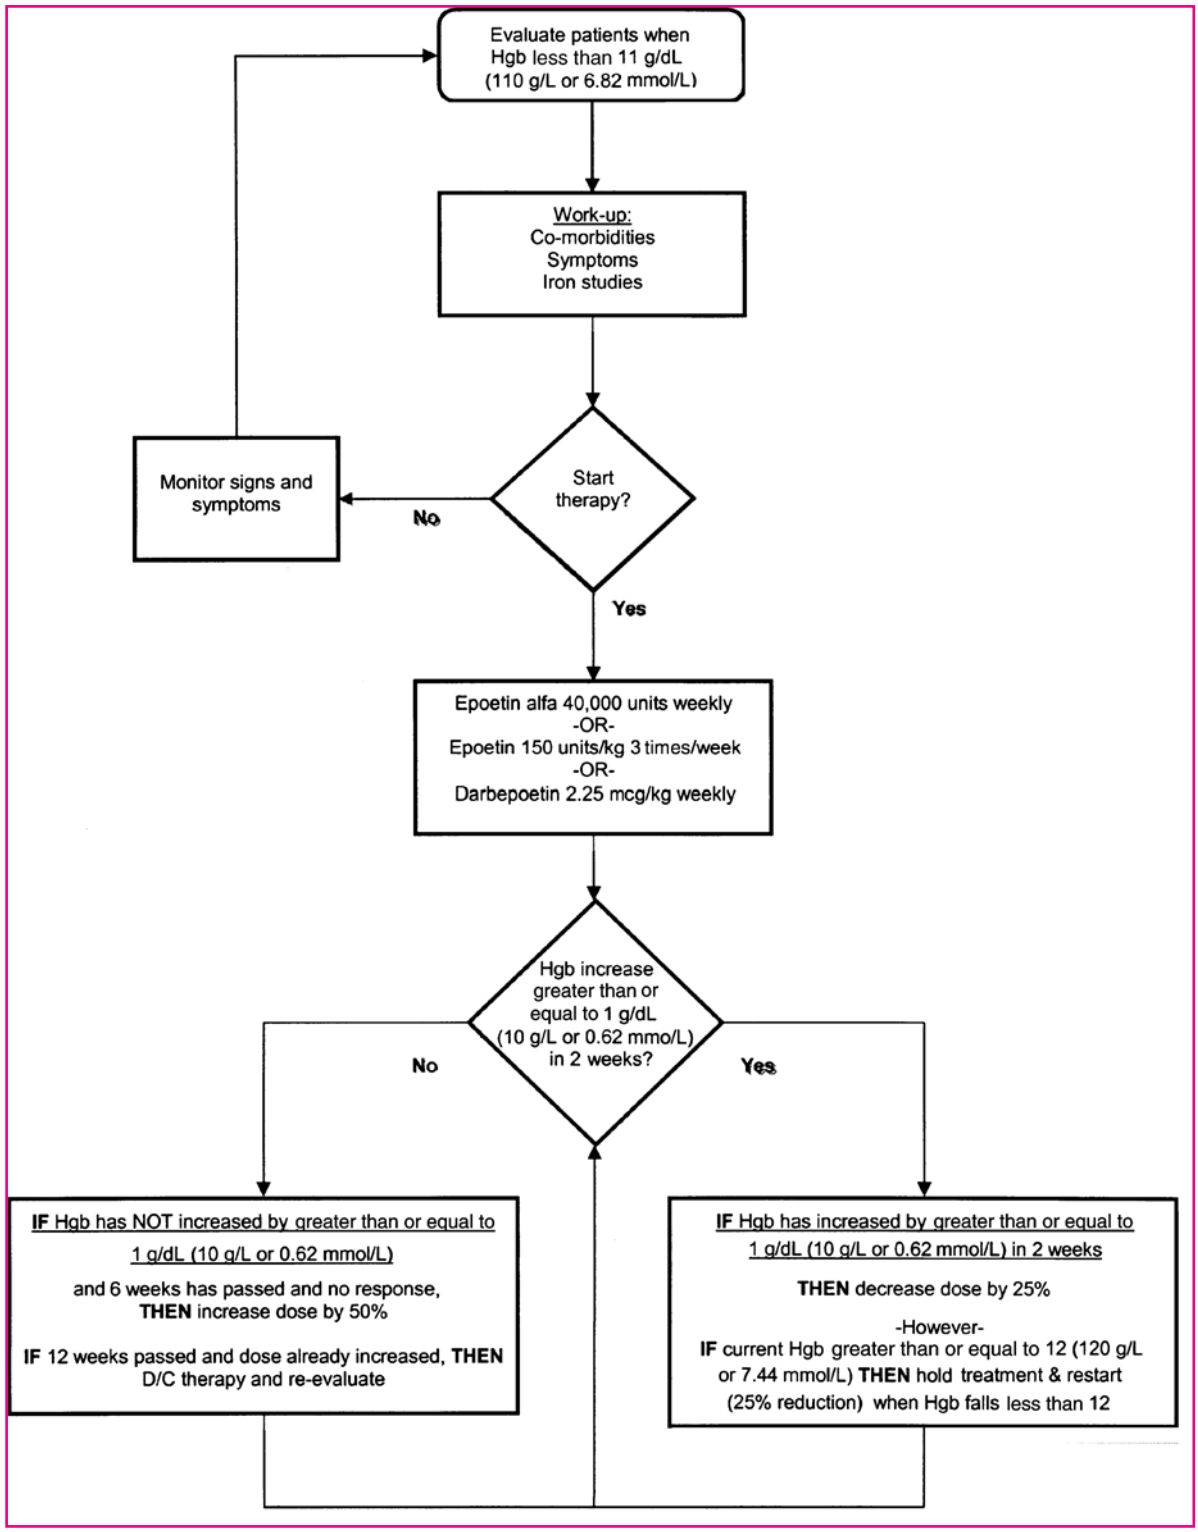

FIGURE 63–4. Summary of treatment guidelines for anemia from cancer/chemotherapy.

anemia typically is a normocytic, normochromic anemia that is due to erythropoietin (EPO) deficiency. Therefore, therapy with epoetin and darbepoetin is effective in treating CKD anemia. The target hemoglobin value in patients with CKD is similar to the target for patients undergoing chemotherapy of 11 to 12 g/dL (110–120 g/L or 6.82–7.44 mmol/L), but the epoetin and darbepoetin doses required for CKD anemia typically are lower than the doses for anemia from cancer/chemotherapy, and subcutaneous administration is the preferred route of administration (Table 63–4). According to the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF-K/DOQI) guidelines, epoetin doses should be increased by 50% if patients do not have an adequate response (less than 2% increase in Hct) after 2 to 4 weeks of therapy and decreased by 25% if the absolute increase in hemoglobin is greater than 3 g/dL (30 g/L or 1.9 mmol/L) or the target hemoglobin is surpassed.

Although EPO deficiency is the primary cause of CKD anemia, iron deficiency is often present, and it is essential to assess and monitor the CKD patient's iron status (NKF-K/DOQI guidelines). Iron stores in patients with CKD should be maintained so that transferrin saturation (TSAT) is greater than 20% and serum ferritin is greater than 100 ng/mL (100 mcg/L or 225 pmol/L). If iron stores are not maintained appropriately, epoetin or darbepoetin will not be effective, and most CKD patients will require iron supplementation. Oral iron therapy can be used, but it is often ineffective, particularly in CKD patients on dialysis. Therefore, intravenous iron therapy is used extensively in these patients. Details of the pharmacology, pharmacokinetics, adverse effects, interactions, dose, and administration of erythropoietin and iron products have been discussed previously.

Other Chronic Diseases

Besides anemia associated with cancer and CKD, anemia of chronic disease can result from inflammatory processes and occurs commonly in autoimmune disorders such as rheumatoid arthritis and systemic lupus erythematosus. In treating these types of anemia of chronic disease, the most important principle is treating the underlying disease. These patients also may have iron deficiency and should be treated in the manner already discussed. Erythropoietin therapy such as epoetin-alfa therapy at a dose of 150 units/kg three times a week also may be used in these patients.

OUTCOME EVALUATION

❾ *After treatment, patients should be monitored for symptom and laboratory value resolution, hemoglobin concentration, and adverse effects.* The goal of anemia therapy is to correct the underlying source of the anemia, normalize the hemoglobin, and alleviate associated symptoms.

- Monitor the CBC to ensure the correct Hgb titration:
- A 1 g/dL (10 g/L or 0.62 mmol/L) per week titration is desirable in patients with iron-deficiency anemia. Reevaluate patients with an increase of less than 2 g/dL (20 g/L or 1.24 mmol/L) in 3 weeks.
- In patients with folic acid deficiency, methylmalonic acid may be normal, and homocysteine may be high. Monitor hemoglobin periodically, and reevaluate patients who fail to normalize hemoglobin levels after 2 months of therapy.
- In patients with vitamin B_{12} deficiency, methylmalonic acid and homocysteine levels may be high. Monitor for resolution of neurologic symptoms (i.e., confusion and paresthesias), if applicable, and Hgb levels periodically until the levels normalize.
- Do not exceed more than 1 g/dL (10 g/L or 0.62 mmol/L) every 2 weeks when using erythropoietin products to increase hemoglobin. Otherwise, decrease the dose of the erythropoietin product.
- Do not exceed Hgb of greater than 13 g/dL (130 g/L or 8.1 mmol/L) because of an increased risk of death and thrombosis in cancer patients.
- Monitor other laboratory tests, such as MCV, iron studies, and presence of reticulocytosis.

Patient Care and Monitoring

1. Identify and treat the underlying cause of anemia.
2. Determine if immediate correction of anemia is required with a transfusion or if chronic therapy can be initiated.
3. Monitor symptoms such as fatigue, shortness of breath, lethargy, headache, edema, and tachycardia for resolution.
4. Monitor the complete blood count monthly.
5. When initiating erythropoietin products, assess the patient's iron status.
6. Monitor side effects of therapy, such as
   - *Oral iron:* nausea, vomiting, abdominal pain, heartburn, constipation, and dark stools
   - *Parenteral iron:* anaphylaxis (test dose required for iron dextran and observe for 1 hour after), injection-site pain/irritation, arthralgias, myalgias, flushing, malaise, and fever
   - *Folic acid:* bad taste and nausea, rash, and allergic reactions
   - *Vitamin B_{12}*: hyperuricemia, hypokalemia, and sodium retention (rare)
   - *Erythropoietin products:* hypertension (monitor blood pressure), thrombosis (e.g., DVT/PE, MI, CVA, and TIA), arthralgias, and headache

ABBREVIATIONS

CBC:	complete blood count

Alma Hamidovic

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Describe the basics of the regulation of hemostasis and thrombosis.
2. Determine which factor-replacement preparation is appropriate in a clinical situation.
3. Calculate an appropriate factor-concentrate dose for a product, given the percentage correction desired.
4. List the complications from hemophilia bleeding episodes.
5. Devise a treatment plan for a patient with a specific variant of von Willebrand's disease.
6. Identify which laboratory tests may aid in the diagnosis of disseminated intravascular coagulation (DIC).
7. Recommend treatment approach for the initial treatment of immune thrombocytopenic purpura (ITP).
8. Identify basic clinical features of thrombotic thrombocytopenic purpura (TTP).
9. List etiologies for neonatal vitamin K deficiency.

Key Concepts

❶ Intravenous factor replacement with recombinant or plasma-derived products to treat or prevent bleeding is the primary treatment of hemophilia.

❷ Type 1 patients unresponsive to desmopressin, patients with types 2 and 3 von Willebrand's disease, and major surgery patients require replacement therapy with plasma-derived intermediate- and high-purity factor VIII virus–inactivated factor VIII concentrates containing von Willebrand factor.

❸ The primary treatment of recessively inherited coagulation disorders is single-donor fresh-frozen plasma (FFP) that contains all coagulation factors.

❹ The cornerstone of the management of disseminated intravascular coagulation (DIC) is aggressive treatment of the underlying primary illness. Supportive measures may be used as necessary; however, owing to the heterogeneity of the DIC etiology, treatment should be guided by predominant symptoms (bleeding or clotting).

❺ Almost all neonates are vitamin K–deficient as a result of (1) insignificant transplacental vitamin K crossover, (2) lack of colonization of the colon by vitamin K–producing bacteria, and (3) inadequate dietary vitamin K intake.

❻ The treatment of immune thrombocytopenic purpura (ITP) is determined by the symptom severity. In some cases, no therapy is needed.

COMPONENTS OF THE HEMOSTATIC SYSTEM

Following endothelial injury, vessel-wall response involves vasoconstriction, platelet plug formation, coagulation, and fibrinolysis regulation. In normal circumstances, platelets circulate in the blood in an inactive form. After injury, platelets undergo activation, which consists of (1) adhesion to the subendothelium, (2) secretion of granules containing chemical mediators (e.g., adenosine diphosphate, thromboxane A_2, thrombin, etc.), and (3) aggregation. Chemical factors released from the injured tissue and platelets stimulate the coagulation cascade and thrombin formation. In turn, thrombin catalyzes the conversion of fibrinogen to fibrin and its subsequent incorporation into plug.

The coagulation system that generates thrombin consists of intrinsic and extrinsic pathways. Both pathways are composed of a series of enzymatic reactions eventually producing thrombin, fibrin, and a stable clot. In parallel with the coagulation, the fibrinolytic system is activated locally. Plasminogen is converted to plasmin, which dissolves the fibrin mesh[1] (Fig. 64–1).

Clinical Presentation and Diagnosis

Hemophilia A and hemophilia B are clinically indistinguishable.

Symptoms

- Ecchymoses
- Hemathrosis* (especially knee, elbow and ankle)
  - Joint pain swelling and erythema
  - Cutaneous warmth
  - Decreased range of motion
- Muscle hemorrhage
  - Swelling
  - Pain with motion of affected muscle
  - Signs of nerve compression
  - Potential life-threatening blood loss, especially with thigh bleeding
  - Mouth bleeding with dental extractions or trauma
  - Genitourinary bleeding
  - Hematuria
  - Intracranial hemorrhage (spontaneous or following trauma), with headache, vomiting, change in mental status, and focal neurologic signs
  - Excessive bleeding with surgery

Hemophilia Is Categorized by Factor Level

Severe: less than 0.01 units/mL (less than 1 IU/dL)
Moderate: 0.01 to 0.05 units/mL (1–5 IU/dL)
Mild: greater than 0.05 units/mL (greater than 5 IU/dL)

*Hallmark of hemophilia; recurrent inadequately managed hemarthrosis leads to chronic deformity and pain.

INHERITED COAGULATION DISORDERS: HEMOPHILIA

Etiology and Epidemiology

Hemophilia A and B are coagulation disorders that result from defects in the genes encoding for plasma coagulation proteins. Hemophilia A (classic hemophilia) is caused by the deficiency of factor VIII, and hemophilia B (Christmas disease) is caused by the deficiency of factor IX. The incidences of hemophilia A and B are estimated at 1 in 5000 and 1 in 30,000 male births, respectively. Both types of hemophilia are evenly distributed across all ethnic and racial groups.[1]

Pathophysiology

The pathophysiology of hemophilia is based on the factor VIII or IX deficiency resulting in inadequate thrombin generation and an impaired intrinsic-pathway coagulation cascade (see Fig 64–1). Factor VIII and IX genes are located on the X chromosome. The hemophilias are recessive X-linked diseases. Generally, affected males carrying either defective allele on their X chromosome do not transmit the gene to their sons. However, their daughters are obligate carriers. Over 800 point mutations, deletions, and inversions have been identified throughout the factor VIII and IX genes. Consequently, hemophilia is not a result of a single genetic mutation. However, inversion at intron 22 of the factor VIII gene accounts for 45% of severe hemophilia A cases. Owing to the high incidence, this mutation is used for carrier and prenatal testing.[2]

Complications of Hemophilia

The severity of bleeding associated with hemophilia correlates with the degree of factor VIII or factor IX deficiency as measured against the normal plasma standard. Table 64–1 summarizes the age at onset and laboratory and clinical manifestations of hemophilia.[3]

TABLE 64–1. Laboratory and Clinical Manifestations of Hemophilia

	Severe (less than 0.01 units/mL)	Moderate (0.01–0.05 units/mL)	Mild (less than 0.05 units/mL)
Age at onset	Less than or equal to 1 year	1–2 years	2 years–adult
Neonatal symptoms			
PCB:	Usually	Usually	Rare
ICH:	Occasionally	Uncommonly	Rare
Muscle/joint hemorrhage	Spontaneous	Minor trauma	Minor trauma
CNS hemorrhage	High risk	Moderate risk	Rare
Postsurgical hemorrhage (without prophylaxis)	Frank bleeding, severe	Wound bleeding, common	Wound bleeding, with factor less than 0.3 units/mL
Oral hemorrhage following trauma, tooth extraction	Usual	Common	Often

Normal range of factor VIII/IX activity level is 0.5–1.5 units/mL (50%–150%). 1 unit/mL corresponds to 100% of the factor found in 1 mL of normal plasma. CNS, central nervous system; ICH, intracranial hemorrhage; PCB, postcircumceisional bleeding.

Treatment

Desired Outcomes

The life expectancy of hemophiliacs was only 8 to 11 years in the 1920s and 1930s. With the development of effective treatment strategies, life expectancy is currently about 65 years, or nearly that of the normal population.

The short-term goals of hemophilia treatment are to:

- Decrease the number of bleeding episodes per year or bleeding frequency
- Normalize or improve clotting factor concentrate levels

The long-term goals of hemophilia treatment are to:

- Maintain clinical joint function.
- Normalize orthopedic joint score.
- Normalize radiologic joint score.
- Maintain quality-of-life measurements.

General Approach to Treatment

❶ *Intravenous factor replacement with recombinant or plasma-derived products to treat or prevent bleeding is the primary treatment hemophilia. Primary prophylaxis* is defined as the regular administration of factor concentrates with the intention of preventing joint bleeds.[4] The rationale for primary prophylaxis is that individuals with factor levels of greater than 0.02 unit/mL (2 IU/dL) rarely suffer from spontaneous bleeds and arthropathy. Therefore, to maintain a trough level above this might convert "severe" hemophilia to "moderate" disease, with the abolition of joint bleeds and the associated arthropathy.[5]

Primary prophylaxis is expensive, but historical cohorts show progressively better outcomes (e.g., joint function and radiologic appearances) with more treatment, and prophylaxis thus is recommended as optimal therapy by the WFH, the World Health Organization (WHO), the U.K. Haemophilia Centre Doctors' Organization, and the National Hemophilia Foundation of the United States. However, a recent Cochrane Review attempting to search for evidence of the benefit of prophylaxis concluded that there were too few trials (only four) to prove benefit.[6]

Nonpharmacologic Therapy

Surgery

Open surgical arthroscopic synovectomy reduces replacement-therapy-resistant disease and repetitive hemarthresis of a single joint. This procedure removes inflamed tissue and joint blood vessels.

Orthotics

Joint prostheses do not deal with the deformities directly. Orthotics in hemophilia serve as an important supportive measure before or after surgery.

Pharmacologic Therapy

Hemophilia A

Primary therapy is based on disease severity and type of hemorrhage.[7] Most patients with mild to moderate disease and a minor bleeding episode can be treated with 1-desamino-8-D-arginine vasopressin [desmopressin acetate (DDAVP)], a synthetic analog of the antidiuretic hormone vasopressin. DDAVP causes release of von Willebrand factor (vWF) and factor VIII from endogenous storage sites. This formulation increases plasma factor VIII levels by three- to fivefold within 30 minutes. The recommended dose is 0.3 mcg/kg intravenously (in 50 mL normal saline infused over 15 to 30 minutes) or subcutaneously or 300 mcg intranasally via concentrated nasal spray every 12 hours. Peak effect with intranasal administration occurs 60 to 90 minutes after administration, which is somewhat later than with intravenous administration. Desmopressin infusion may be administered daily for up to 2 to 3 days. Tachyphylaxis, an attenuated response with repeated administration, may occur after several doses.[8]

Factor VIII Replacement Patients with severe hemophilia may receive primary (before the first major bleed) or secondary (after the first major bleed) prophylaxis, and all hemophiliacs with a major bleed require factor VIII replacement. The therapy may include recombinant (produced via transfection of mammalian cells with the human factor VIII gene) or plasma-derived (concentrate from pooled plasma) factor VIII (Table 64–2). The choice of product and dose are based on the overall clinical scenario because there is no difference in efficacy among various preparations. Newer-generation plasma-derived coagulation factor concentrates are considerably safer owing to advancements in viral testing and inactivation technology. Typically, recombinant factor VIII concentrates are recommended for (1) previously untreated patients, (2) human immunodeficiency virus (HIV)– and hepatitis C virus (HCV) seronegative patients, and (3) mild to moderate hemophiliacs after surgery or trauma when DDAVP is not sufficient.[9]

The severity of hemorrhage and its location are major determinants of percent correction to target, as well as duration of therapy (Table 64–3). Minor bleeding may be treated with a goal of 25% to 30% of normal (0.25–0.30 unit/mL, or 20–30 IU/dL), whereas serious or life-threatening bleeding requires at least 50% of normal activity. Factor VIII is a large molecule that remains in the intravascular space, and estimated volume of distribution, therefore, is approximately 50 mL/kg. Generally, factor VIII levels increase 2% (0.02 unit/mL, or 2 IU/dL) for every 1 unit/kg of factor VIII concentrate infused. The half-life of factor VIII ranges from 8 to 15 hours. Thus, a 1750 units/kg factor VIII bolus would be expected to provide an incremental rise of approximately 50% (0.5 unit/mL, or 50 IU/dL) over baseline (1750 units/70 kg × 0.02 unit/mL). Half the initial dose is given every half-life (every 8–15 hours) to maintain the desired factor VIII level.[10] Although intermittent bolus infusions of factor concentrates have been used successfully, continuous-infusion protocols are being instituted successfully to decrease the overall cost of therapy.

Hemophilia B

Factor IX Replacement Hemophilia B therapy may include recombinant (produced via transfection of mammalian cells with the human factor IX gene) or plasma-derived (concentrate from pooled plasma) factor IX (see Table 64–2). Guidelines for choosing the factor-concentrate formulation for hemophilia B are similar to the guidelines for hemophilia A. However, older-generation factor IX concentrates containing other vitamin K–dependent proteins (e.g., factors II, VII, and IX), called *prothrombin complex concentrates* (PCCs), have been associated with thrombogenic side effects. Consequently, these products are not first-line treatment for hemophilia B.[11]

TABLE 64–2. Factor Concentrates

Brand Name	Product Type	Viral Inactivation or Exclusion Method	Other Contents
Factor VIII concentrates			
Alphanate	Plasma	Solvent detergent, dry heat	Albumin, heparin, vWF
Hemophil M	Plasma	Solvent detergent, monoclonal antibody	Albumin
Humate-P	Plasma	Pasteurization	Albumin, vWF

Hyate:C	Porcine VIII	Freeze-dried	Citrate

APCC, activated prothrombin complex concentrate; PCC, prothrombin complex concentrate; vWF, von Willebrand factor.

TABLE 64–3. Guidelines for Replacement Dosing with Factor VIII and Factor IX

Type of Hemorrhage	Desired Plasma Factor VIII Level (% of Normal)	Desired Plasma Factor XI Level (% of Normal)	Duration of Therapy (Days)
CNS, intracranial, retropharyngeal, retroperitoneal, surgical prophylaxis	80%–100%	80%–100%	Factor VIII: q8–12 hours over 10–14 days Factor IX: q12 hours over 10–14 days
Mild hemarthrosis, musosal (e.g., epistaxis, nosebleed), superficial hematoma	30%	20%–30%	Factor VIII: q8–12 hours over 1–2 days Factor IX: q12–24 hours over 1–2 days

Because it is a small protein, the factor IX molecule passes into the intravascular and the extravascular spaces. Therefore, the volume of distribution of recombinant factor IX is twice that of factor VIII. Consequently, 1 unit of factor IX administered per kilogram of body weight yields a 1% rise in the plasma factor IX level (0.01 unit/mL, or 1 IU/dL). Thus 1750 units of factor IX provides an incremental increase of 50% of normal (0.5 unit/mL, or 50 IU/dL), that is, 1750 units/70 kg × 0.01 unit/mL (1 IU/dL).[12] Additionally, the recovery rate with recombinant factor IX is 20% lower than that with the plasma-derived products. Therefore, initial and subsequent maintenance doses should be adjusted accordingly.

Treatment of Patients with Factor VIII or IX Inhibitors

Factor VIII and IX inhibitors are antibodies that develop in 20% and 12% of hemophilia A and hemophilia B patients, respectively, in response to replacement therapy. These antibodies bind to and neutralize the activity of infused factor concentrates. Although the inhibitors do not increase hemorrhage frequency, their existence challenges the treatment of bleeding episodes. Titers of inhibitors are measured and reported in Bethesda units (BU), and this measurement is used to guide therapy (Fig. 64–2). The therapeutic options for patients with factor inhibitors include recombinant factor VIIa (rFVIIa), prothrombin complex concentrates (PCCs), porcine factor VIII, and gene therapy.[13]

Factor VIIa (rFVIIa) is a bypassing agent designed to generate thrombin only at tissue injury sites, where it binds tissue factor and, in this manner, minimizes the risk of systemic thrombotic events. rFVIIa is used effectively in surgeries and spontaneous bleeds.[14]

PCCs contain the vitamin K–dependent factors II, VII, IX, and X. These agents represent another attempt to bypass the factor at which the antibody is directed (see Fig. 64–2). However, PCCs carry the risk of serious thrombotic complications. Porcine factor VIII is most useful when the inhibitor titer is less than 50 BU (see Fig. 64–2 for dose and frequency). Owing to its similarity to human factor VIII, porcine factor VIII participates in the coagulation cascade. However, most inhibitors have very weak neutralizing activity against it. Porcine factor VIII is a third-line agent (only after factor VIIa and a PCC have failed) owing to a 15% incidence of cross-reactivity.[15]

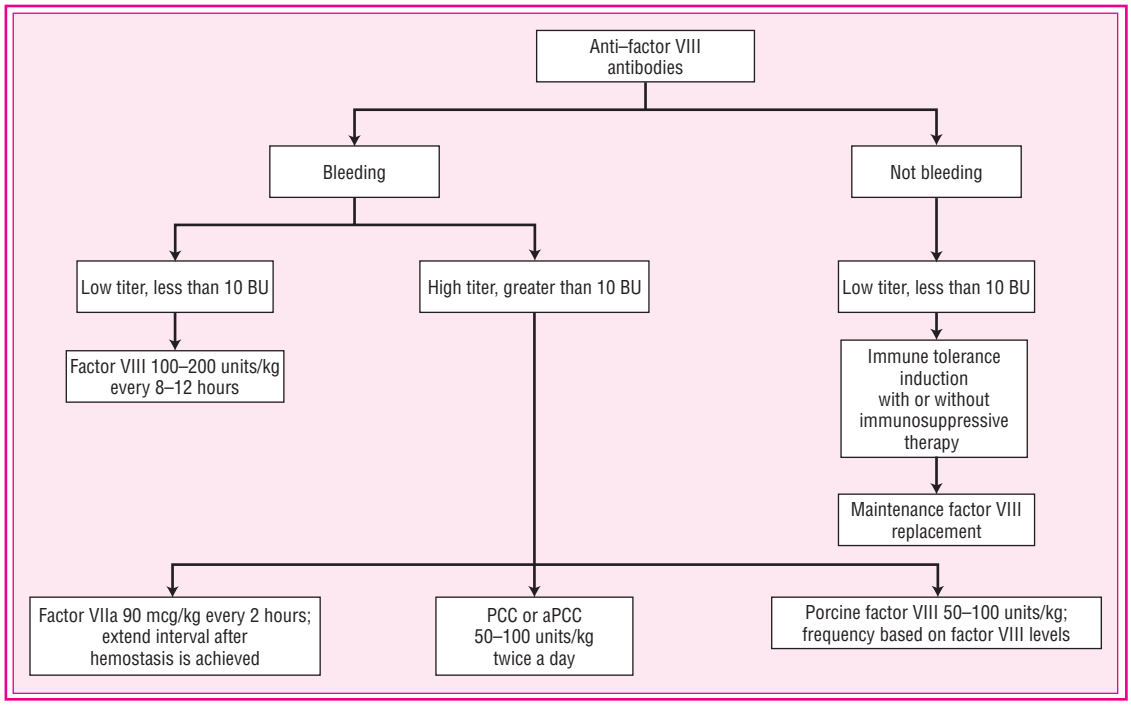

FIGURE 64–2. Treatment algorithm for the management of patients with hemophilia A and factor VIII antibodies. BU, Bethesda unit; PCC, prothrombin complex concentrate; aPCC, activated prothrombin complex concentrate.

Outcome Evaluation

The main goal of hemophilia treatment is to prevent bleeding episodes and their long-term complications. Clinicians should evaluate patients every 6 to 12 months for the following:

- Musculoskeletal status, including joint range of motion and radiologic assessment as indicated
- Number and type of bleeding episodes to assess adequacy of prophylactic treatment and home therapy
- Use of clotting-factor concentrates to check for the development of inhibitors, especially in patients with severe disease and poor treatment responders

VON WILLEBRAND DISEASE

Epidemiology and Etiology

Von Willebrand disease (vWD) is the most common inherited bleeding disorder caused by a deficiency or dysfunction of von Willebrand factor. The disease prevalence is estimated at 30 to 100 cases per million. In contrast to hemophilia, vWD is inherited as an autosomal dominant disorder (although autosomal recessive cases exist), ensuing equal frequency in male and females.[16]

Pathophysiology

Von Willebrand factor (VWF) is a large multimeric glycoprotein with two main functions in hemostasis: to aid the platelet adhesion to injured blood vessel walls and to carry and stabilize factor VIII in plasma. Table 64–4 represents three main vWD phenotypes, their frequency, and genetic transmission.[17]

Treatment

Desired Outcomes

Unlike hemophilia, the bleeding tendency in vWD is less frequent and generally less severe. Consequently, chronic prophylaxis usually is unwarranted. The goal of two mainstay therapeutic options in vWD is:

- To stop spontaneous bleeding as necessary
- To prevent surgical and postpartum bleeding

Nonpharmacologic Therapy

Local measures, including pressure and ice, may be used to control superficial bleeding.

Pharmacologic Therapy

Systemic therapy is used to prevent bleeding associated with surgery, childbirth, and dental extractions and to treat bleeding

Clinical Presentation and Diagnosis

Clinical manifestations vary depending on the sub-type. Patients with mild disease may be asymptomatic into adulthood.

Symptoms

- Bruising
- Mucocutaneous bleeding
  - Epistaxis
  - Oral cavity bleeding
  - Menorrhagia
  - GI bleeding
- Joint and deep tissue bleeding
- Postoperative bleeding

Laboratory Testing

- Normal PT
- Prolonged aPTT
- Platelet count
- Normal von Wilderbrand factor antigen and activity (vWF:Ag)
- Factor VIII coagulation assay (FVIII:C)
- Ristocetin cofactor activity (vWF:RCo)
- vWF multimer analysis (gel electrophoresis)

TABLE 64–4. Classification of von Willebrand Disease

Phenotype	Mechanism of Disease	% Cases	Genetic Transmission
Type 1 vWD	Partial (mild to moderate) quantitative deficiency of vWF and factor VIII	70%–80%	Autosomal dominant
Type 2 vWD	Qualitative abnormalities of vWF	10%–30%	Autosomal dominant
2A	Decreased platelet-dependent vWF function owing to lack of larger multimers		
2B	Increased platelet-dependent vWF function owing to lack of larger multimers		
2M	Defective platelet-dependent vWF functions not associated with multimer defects		
2N	Defective vWF binding to factor VIII		
Type 3 vWD	Severe quantitative deficiency of vWF	1%–5%	Autosomal recessive

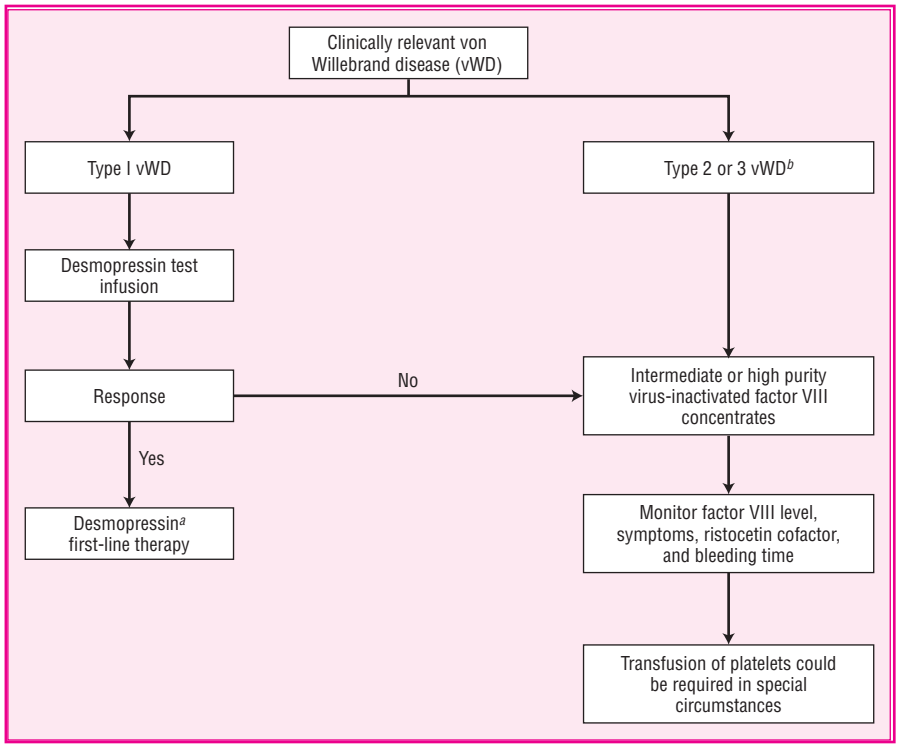

FIGURE 64–3. Guidelines for the treatment of von Willebrand disease. [a]Use factor VIII concentrate for life-threatening bleeding. [b]Some patients with type 2 or 3 von Willebrand disease may respond to desmopressin.

that cannot be controlled with local measures. The two systemic approaches involve using desmopressin, which stimulates the release of endogenous vWF, or administering products that contain vWF. The general approach to the treatment of vWD is depicted in Fig. 64–3.

Most patients with type 1 vWD (functionally normal vWF) and a minor bleeding episode can be treated successfully with desmopressin, which induces secretion of autologous factor VIII and vWF into plasma. The recommended dose is the same as that used to treat mild factor VIII deficiency (0.3 mcg/kg intravenously in 50 mL of normal saline infused over 15 to 30 minutes). This therapy generally is ineffective in type 2A patients who secrete qualitatively abnormal vWF and is controversial in type 2B patients because it may increase the risk of postinfusion thrombocytopenia. Type 3 vWD patients who lack releasable stores of vWF do not respond to DDAVP therapy.[18]

The individual responsiveness to desmopressin is consistent, and a test dose administered at the time of diagnosis or prior to therapy is the best predictor of response. Generally, DDAVP is more effective in vWD than in hemophilia patients, with an average 30% to 50% increase in vWF and factor VIII levels. In patients with an adequate response, desmopressin is first-line therapy because it allows for once-daily administration (elevates plasma levels for 8–10 hours), does not pose a threat in terms of viral transmission, and the cost is substantially less than that of the plasma-derived products. Fibrinolysis inhibitors (50–60 mg/kg of aminocapriotic acid every 4–6 hours or trenexamic acid 10–15 mg/kg every 8–12 hours) and OCs are used successfully in the management of epistaxis and menorrhagia or as adjuvant treatments.

Replacement Therapy

❷ *Type 1 patients unresponsive to desmopressin, patients with types 2 and 3 vWD, and major surgery patients require replacement therapy with plasma-derived, intermediate- and high-purity factor VIII virus–inactivated factor VIII concentrates containing vWF*. The usual dosing guidelines and target levels of replacement-therapy concentrates for control of various types of hemorrhage are provided in Table 64–5. Ultra-high-purity (monoclonal) plasma-derived and recombinant factor VIII concentrates do not contain vWF and should not

TABLE 64–5. Replacement Therapy in von Willebrand Disease[a]

Condition	Therapy
Major surgery	Maintain factor VIII level greater than or equal to 50% for 1 week Prolonged treatment in type 3 patients (greater than 7 days)
Minor surgery	Maintain factor VIII level greater than or equal to 50% for 1–3 days Maintain factor VIII level greater than 20%–30% for an additional 4–7 days
Dental extraction	Single infusion to achieve factor VIII level greater than 50% Desmopressin prior to procedure for type I
Spontaneous or posttraumatic bleeding	Usually single infusion of 20–40 units/kg

[a]The yield of factor VIII after first infusion is similar to that observed in hemophilia A (about 2% increment over baseline amount for every 1 unit/kg of factor VIII infused).

TABLE 64–6. Clotting Factor Deficiency Characteristics

Factor Deficient	Inheritance Pattern	Estimated Incidence	Severity of Bleeding
II (prothrombin)	Autosomal dominant or recessive	Extremely rare	Mild to moderate
V	Autosomal recessive	1:1 million	Mild to moderate
VII	Autosomal recessive	1:500,000	Mild to severe
X	Autosomal recessive	1:500,000	Mild to severe
XI	Autosomal recessive	4% of Askenazi Jews, otherwise rare	Mild to moderate
XII	Unknown	Unknown	No bleeding
XIII	Autosomal recessive	Less than 1:1 million	Moderate to severe

be used in the treatment of vWD. Cryoprecipitate contains considerable amounts of both factor VIII and vWF. However, this product is not a first-line treatment option because it does not undergo viral inactivation.

Outcome Evaluation

The main goal of vWF treatment is to prevent bleeding with surgery or dental procedures. Clinicians should evaluate patients every 6 to 12 months for the following:

- Number and type of bleeding episodes to assess the need for prophylactic treatment.
- Ensure that the factor VII level is greater than or equal to 50% for 1 week prior to major surgery, 1 to 3 days prior to minor surgery, and just prior to a dental extraction.

OTHER CLOTTING FACTOR DEFICIENCIES

Etiology and Epidemiology

Recessively inherited coagulation disorders (RICDs) refer to relatively rare deficiencies in factor II, V, VII, and X–XIII resulting in either decreased clotting factor production or production of a dysfunctional molecule with reduced activity.[19] The clinical severity of bleeding varies and generally is poorly correlated with the factor blood levels. Table 64–6 illustrates these clotting factor deficiencies and some of their characteristics.

Pathophysiology

The other factor deficiencies are rare genetic disorders. Mutations in the gene for the respective clotting factors results in impaired functionality or production of the factor (Table 64–7).

TABLE 64–7. Treatment of Factor Deficiencies

Factor Deficient	Major Surgery	Spontaneous Bleeding
II	1. PCC: 20–30 units/kg 2. FFP: 15–20 mL/kg Target: Greater than 30% until healing complete	1. FFP: 15–20 mL/kg Target: Greater than 30% until healing complete
V	1. FFP: 15–20 mL/kg Target: Greater than 20% until healing complete	1. FFP: 15–20 mL/kg Target: Greater than 20% until bleeding stops
VII	1. rFVIIa: 15–30 mcg/kg q12 hours 2. Concentrate: 30–40 units/kg q12 hours Target: Greater than 20% until healing complete	1. rFVIIa: 15–30 mcg/kg q12 hours 2. Concentrate: 30–40 units/kg q12 hours Target: Greater than 20% until bleeding stops
X	1. PCC: 20–30 units/kg 2. FFP: 15–20 mL/kg Target: Greater than 20% until healing complete	1. PCC: 20–30 units/kg 2. FFP: 15–20 mL/kg Target: Greater than 20% until bleeding stops
XI	1. FFP: 15–20 mL/kg Target: Greater than 20% until healing complete	1. FFP: 15–20 mL/kg Target: Greater than 20% until bleeding stops
XIII	1. Concentrate: 10–20 units/kg 2. FFP: 15–20 mL/kg 3. Cryoprecipitate (1 bag per 10 kg) Target: Greater than 5% until healing is complete	1. Concentrate: 10–20 units/kg 2. FFP: 15–20 mL/kg 3. Cryoprecipitate (1 bag per 10 kg) Target: Greater than 5% until healing is complete

FFP, fresh frozen plasma; PCC, prothrombin complex concentrates.

Clinical Presentation and Diagnosis

Deficient Factor	Main Clinical Symptoms	Laboratory Tests	Other Diagnostic Tests
II	Umbilical cord, joint, and mucosal tract bleeding	Prolonged prothrombin (PT) and activated partial thromboplastin time (aPTT)	Specific assay for prothrombin
V	Mucosal tract bleeding	Prolonged PT and aPTT Normal thrombin time	Specific factor V assay
VII	Mucosal tract, joint and normal aPTT	Prolonged PT	Specific factor VII assay
X	Umbilical cord, joint, and muscle bleeding	Prolonged PT and aPTT Normal thrombin time Prolonged Russel's viper venom	Specific factor X assay
XI	Posttraumatic bleeding	Prolonged aPTT Normal PT Normal thrombin time	Specific factor XI assay
XII	No bleeding	Prolonged aPTT Normal PT Normal thrombin time	Specific factor XII assay
XIII	Umbilical cord, intracranial, and joint bleeding; recurrent miscarriages, impaired wound healing	Normal PT, aPTT, thrombin time, bleeding time	Specific factor XIII assay

Treatment

Desired Outcomes

The main goal of recessively inherited coagulation disorder (RICD) treatment is to prevent and control spontaneous and surgery-related bleeding episodes. Specifically, therapeutic options improve hemostasis via replacement of deficient blood coagulation factors while minimizing the development of immune tolerance.[20]

Nonpharmacologic Therapy

Transfusional Therapies

❸ *The primary treatment of recessively inherited coagulation disorders is single-donor fresh-frozen plasma (FFP) that contains all coagulation factors.* Plasma concentrates of single coagulation factors are not available in the United States. Disadvantages of FFP include the risk of volume overload, especially when repeated infusions are administered in order to improve and maintain **hemostasis,** risk of infections, and risk of inhibitor development. Prothrombin complex concentrates (PCCs) licensed for the treatment of hemophilia B also contain significant levels of vitamin K–dependent factors and may be used off-label for treatment of RICD. Table 64–7 lists the recommended RICD treatment schedules in different clinical scenarios.

Pharmacologic Therapy

Less severe hemorrhages may be treated successfully with antifibrinolytic amino acids alone or in combination with factor replacement therapy. Tranexamic acid (20–25 mg/kg every 8 to 12 hours) and epsilon aminocaproic acid (50–60 mg/kg every 4–6 hours) may be administered intravenously or orally.

ACQUIRED COAGULATION DISORDERS: DISSEMINATED INTRAVASCULAR COAGULATION (DIC)

Etiology and Epidemiology

Disseminated intravascular coagulation (DIC) is a systemic thrombohemorrhagic disorder characterized by an increased propensity for clot formation secondary to a wide variety of clinical conditions (Table 64–8). Central to the etiology of DIC is excessive and unregulated generation of thrombin, leading to an aggressive compensatory **fibrinolysis.** Therefore, clinical manifestations of DIC result from a loss of balance between the clot-promoting (leading to thrombosis) and the clot-lysing (leading to hemorrhage) systems. Although this balance may tip in either direction, presenting as bleeding or clotting, bleeding is most common and is observed in 70% to 90% patients.[21]

TABLE 64–8. Conditions Associated with Disseminated Intravascular Coagulation

Cardiovascular
- Acute myocardial infarction
- Angiopathy
- Aortic aneurysm
- Aortic balloon assist devices
- Giant hemangiomas
- Peripheral vascular disease
- Postcardiac arrest
- Prosthetic devices
- Raynaud's syndrome

Infectious
- Arbovirus
- *Aspergillus*
- *Candida albicans*
- Cytomegalovirus
- Ebola virus
- Gram-negative bacteria
- Gram-positive bacteria
- Herpesvirus
- Histoplasma
- Human immunodeficiency virus
- Influenza
- Kala-azar
- Malaria
- *Mycobacteria*
- *Mycoplasma*
- Paramyxoviruses
- Rocky Mountain spotted fever
- Rubella
- Typhoid
- Varicella
- Variola

Intravascular hemolysis
- Hemolytic transfusion reaction
- Hemolytic uremic syndrome
- Minor hemolysis
- Massive transfusion

Newborn
- Birth asphyxia
- Hypothermia
- Meconium or amniotic fluid aspiration
- Necrotizing enterocolitis
- Respiratory distress syndrome
- Shock

Obstetrics
- Abortion
- Amniotic fluid embolism

Obstetrics (Continued)
- Fatty liver of pregnancy
- Placental abruption
- Preeclampsia/eclampsia
- Retained fetus syndrome

Pulmonary
- syndrome
- syndrome
- Empyema
- Hyaline membrane disease
- Pulmonary embolism
- Pulmonary infarction

Tissue injury
- Burns
- Crush injuries
- Extensive surgery
- Head trauma
- Multiple trauma

Miscellaneous
- Acid-base imbalance
- Acute liver failure
- Amphetamines
- Anaphylaxis
- Autoimmune diseases
- Cholestasis
- Chronic inflammatory diseases
- Collagen vascular disease
- Craniotomy
- Extracorporeal circulation
- Extracorporeal membrane oxygenation
- Fat embolism
- Heat stroke
- Hemorrhagic telangiectasia
- Hepatitis
- Leukemia
- Lightening strikes
- Near drowning
- Organic solvent poisoning
- Paroxysmal nocturnal hemoglobinuria
- Peritoneovenous or pleurovenous shunts
- Polycythemia rubra vera
- Renal vascular disorders
- Severe anoxia
- Snake bite
- Solid tumors
- Transplant rejection

Pathophysiology

Once injured or activated by a toxic substance (e.g., bacterial toxins, placenta chemicals, snake venom, etc.), endothelial cells and monocytes respond by generating tissue factor on the cell surface. This, in turn, leads to the generation of tissue factor–factor VIIIa complexes, followed by unregulated and excessive generation of thrombin, fibrin, systemic **microthrombi** and consumption of coagulation factors, platelets, and regulators (e.g., antithrombin, protein C, and protein S). While bleeding into the subcutaneous tissues, skin, and mucous membranes takes place, microvascular thrombosis exacerbates tissue ischemia and organ damage.[22]

Clinical Presentation and Diagnosis

Clinical manifestations generally are associated with underlying primary illness, as described in Table 64–8.

Signs and Symptoms
- Thrombosis, hemorrhage, or both
- Hemorrhagic bullae
- Peripheral cyanosis
- Petechiae and purpura

Thrombus and End-Organ Dysfunction
- Skin: 70%
- Lungs: 50%
- Kidneys: 50%
- Liver: 35%
- Adrenal: 30%
- Heart: 20%

Laboratory Testing
- Increased D-dimer
- Thrombocytopenia
- Decreased fibrinogen
- Decreased antithrombin
- Decreased protein C and protein S
- Elevated fibrinopeptides A and B
- Increased prothrombin fragments 1 and 2
- Evidence of end-organ dysfunction or failure

Treatment

Desired Outcomes

❹ *The cornerstone of the management of DIC is aggressive treatment of the underlying primary illness. Supportive measures may be used as necessary, but owing to the heterogeneity of DIC etiology, treatment should be guided by predominant symptoms (bleeding or clotting).*[23]

- Replace missing blood components.
- Interrupt coagulation.
- Treat underlying disease.

Pharmacologic Therapy

Anticoagulants

While bleeding is the most frequently observed symptom of DIC, thrombotic events cause most of the mortality. Heparin is an effective anticoagulant with the potential to inhibit thrombin formation and function; however, its use is limited by the potential for bleeding. Clinical trials of heparin in DIC have not shown a consistent benefit. DIC patients most likely to benefit

Patient Encounter, Part 1

A 48-year-old woman was admitted to the intensive care unit with sepsis and hemodynamic instability. Three days earlier, she had undergone an abdominal surgery. After treatment with intravenous antibiotics and fluid administration, the patient was described as stable. Several hours later, the patient's nurse identified extravasation from the intravascular lines and abdominal drains.

- What information is suggestive of DIC?
- What additional information do you need to create a treatment plan for this patient?

from heparin are those with symptomatic thromboemboli, extensive fibrin deposition, persistent coagulation abnormalities despite replacement of hemostatic factors, and solid tumors. Heparin is contraindicated in DIC patients with serious or life-threatening bleeding, such as intracranial bleeding.[24]

Heparin may be given intravenously or subcutaneously, and there is no universally accepted dose. Full-dose heparin therapy in adults is a bolus of 5000 units, followed by a continuous infusion of 1000 units/hour. Since the aPTT is already elevated in individuals with DIC, monitoring full-dose heparin therapy may be difficult, and D-dimer and fibrinogen levels may be better markers of activity. Subcutaneous heparin at a dose of 80 to 100 units/kg every 4 to 6 hours and low-molecular-weight heparins are other, less studied options.[25]

Platelets and Fresh-Frozen Plasma

Treatment with platelet concentrates and plasma is indicated in patients who are bleeding or who require an invasive procedure. In a bleeding patient, the platelet count should be maintained above 50,000/mm^3 (50×10^3/μL or 50×10^9/L), and platelet concentrates should be given at a dose of 1 unit/10 kg of body weight. Fresh-frozen plasma contains all the coagulant factors as well as fibrinogen. Adding fibrinogen to the blood system in a situation where the level of antithrombin is already low may predispose to widespread microvascular thrombosis and aggravate end-organ damage. Non-fibrinogen-containing components are packed red cells, platelet concentrates, and nonclotting protein containing volume expanders such as albumin. If used, **fresh-frozen plasma** (FFP) is dosed at 10 to 15 mL/kg. Both platelet and plasma transfusions should be monitored, and platelet count as well as aPTT should be assessed.

Patient Encounter, Part 2

Meds
- Glyburide 10 mg once daily
- Hydrochlorothiazide 25 mg once daily
- Fluoxetine 20 mg once daily

Labs
- Platelet count: 30,000/mm^3 (30×10^3/μL or 30×10^9/L)
- aPTT: 46 s
- PT: 31 s
- Fibrinogen degradation product level: 380 to 540 g/L
- Plasma antithrombin level: 25%

- Given this additional information, what is your assessment of the patient's emergency?
- Identify your treatment goals for this patient.

Patient Encounter, Part 3: Creating a Care Plan

Based on the information presented, create a care plan for this patient's DIC.

Cryoprecipitate

If FFP cannot maintain fibrinogen concentration above 100 mg/dL (1 g/L) in a symptomatic patient, 1 to 4 units/10 kg of cryoprecipitate may be administered.

Outcome Evaluation

- With each therapeutic option, postinfusion increments (platelets, PT, aPTT, fibrinogen) should be checked within 30 to 60 minutes and every 6 hours thereafter, and the dose should be adjusted accordingly.
- Monitor the patient for relief of symptoms and signs of hemorrhage.

VITAMIN K DEFICIENCY OF THE NEWBORN

Etiology and Epidemiology

Vitamin K is a fat-soluble vitamin cofactor for the activation of factors II, VII, IX, and X in the liver. ❺ *Almost all neonates are vitamin K–deficient at as a result of (1) insignificant transplacental vitamin K crossover, (2) lack of colonization of the colon by vitamin K–producing bacteria, and (3) inadequate dietary vitamin K intake* (especially in breast-fed infants because human milk contains less vitamin K than infant formula or cow's milk). *Vitamin K–deficiency bleeding* (VKDB) refers to bleeding attributable to vitamin K deficiency within first 6 months of life. It occurs in three general time frames: early (0–24 hours), classic (1–7 days), and late (2–12 weeks). Early onset occurs rarely and usually is associated with maternal ingestion of anticonvulsants, rifampin, isoniazid, and warfarin. Classic vitamin K–dependent bleeding usually results from the lack of prophylactic vitamin K administration in

Clinical Presentation and Diagnosis

Symptoms
- Dark melena stools
- Bleeding from the umbilical stump
- Circumcision bleeding
- Bloody vomit
- Blood-stained urine
- Nose bleed
- Petechiae
- Venopuncture site bleed

Laboratory Testing
- Prolonged PT
- Prolonged aPTT
- Elevated abnormal (des-γ-carboxy) prothrombin (PIVKA) II
- Normal thrombin
- Normal platelet count
- Normal fibrinogen

brest-fed infants. The incidence of early and classic disease in the United States is variably reported from 0.25% to 1.7%. Late-onset VKDB is more severe clinically than early-onset or classic disease and has a high incidence (50% to 82%) of intracranial hemorrhage (ICH). The rate of late VKDB ranges from 4.4 to 7.2 per 100,000 births according to reports from Europe and Asia. In addition to breast-feeding, identified risk factors are cystic fibrosis, hepatitis, celiac disease, and α_1-antitrypin deficiency.[26]

Pathophysiology

The levels of vitamin K–dependent coagulation factors are physiologically low in neonates. Absence of vitamin K impairs γ-carboxylation, and the inactive precursors of factors II, VII, IX, and X accumulate in the plasma, unable to bind calcium and cell membranes. Consequently, the precursor levels may decline further, impairing coagulation and potentially leading to VKDB.

Treatment

Desired Outcomes

The main goal of treatment for vitamin K deficiency is prevention and control of VKDB. Specifically, therapeutic options may

- Reduce the incidence of VKDB via prophylaxis
- Improve hemostasis when VKDB occurs

Pharmacologic Therapy

Prophylactic Therapy

Administration of 100 mcg to 1 mg phytonadione intramuscularly at birth is the standard of care in the United States. A single dose corrects the deficiency state and usually does not need to be repeated in an otherwise healthy infant.

VKDB Therapy

Immediate administration of 100 mcg to 1 mg vitamin K subcutaneously or intravenously, followed by administration of FFP as necessary. Vitamin K administration via the intramuscular route may induce hematoma owing to coagulopathy, and intravenous administration should be slow because it has been associated with anaphylaxis. Prothrombin complex concentrate (PCC) at minimum dose of 50 units/kg should be given for life-threatening bleeding.[27,28]

Outcome Evaluation

- Monitor patient for cessation of bleeding.
- Monitor PT and aPTT.
- If evidence of intracranial bleeding is observed, consider transfer to a level III nursery.
- Monitor patient for toxicities such as hematomas and anaphylactic reactions.

PLATELET DISORDERS: IMMUNE THROMBOCYTOPENIC PURPURA

Etiology and Epidemiology

Immune thrombocytopenic purpura (ITP) is one of the most common causes of acquired thrombocytopenia. The estimated incidence is 100 cases per 1 million persons per year, about half of whom are children. ITP is an autoimmune disorder caused by the binding of antibodies (usually IgG) to platelet surface antigens resulting in shortened platelet life span. ITP can occur as an isolated condition or secondary to an underlying disorder. Childhood-onset and adult-onset ITP present very differently. Adult-onset ITP is generally chronic and affects women two to three times more often than men. By contrast, childhood-onset ITP is sudden and usually follows an infectious illness, and both sexes are equally affected. ITP occurs in 1 to 2 of every 1000 pregnancies. In pregnant women with preexisting ITP, both maternal and fetal complications may occur, requiring separate management.[29]

Pathophysiology

IgG autoantibody–coated platelets induce Fcγ receptor–mediated **phagocytosis** by mononuclear macrophages, predominantly in the spleen and liver. Thrombocytopenia develops as a consequence of megakaryocyte inability to increase platelet production and maintain a normal number of circulating platelets. Currently used treatments are directed at different aspects of the antibody production, platelet sensitization, and the clearance and production cycle.[30]

Clinical Presentation and Diagnosis

General

The typical patient is well with the exception of bleeding.

Symptoms

- **Petechiae**
- **Purpura**
- **Ecchymoses**
- Cutaneous bleeding
- Mucosal site bleeding
- Epistaxis
- Gingival bleeding
- Hematuria

Laboratory Testing

- Normal or slightly elevated thrombopoietin
- CBC
- Peripharal blood smear
- Direct antiglobulin test
- *Helicobacter pylori* testing
- Antibody to HIV

Treatment

Desired Outcomes

The main goal of ITP treatment is to maintain the platelet count (greater than 20,000–30,000/mm^3, 20–30 $\times$ 10^3/μL or 20–30 $\times$ 10^9/L) while awaiting spontaneous or treatment-induced remission.[31]

General Approach to Treatment

❻ *The treatment of ITP is determined by the symptom severity (Table 64–9). In some cases, no therapy is needed.* The initial treatment of children with ITP is controversial because more than 70% of cases resolve spontaneously irrespective of pharmacologic intervention. Currently, therapy is indicated in children with platelet counts less than 10,000 to 20,000/mm^3 (10–20 $\times$ 10^3/μL or 10–20 $\times$ 10^9/L) because most intracranial hemorrhages occur when platelets are in this range.[32]

TABLE 64–9. Guidelines for the Initial Management of ITP

Greater than 50,000 platelets/mm^3 (50 $\times$ 10^3/μL or 50 $\times$ 10^9/L)	No treatment
30,000–50,000 platelets/mm^3 (30–50 $\times$ 10^3/μL or 30–50 $\times$ 10^9/L)	Prednisone (1 mg/kg PO qd or no treatment)
Less than 30,000 platelets/mm^3 (30 $\times$ 10^3/μL or 30 $\times$ 10^9/L)	Prednisone (1–1.5 mg/kg per day) Anti-D immune globulin (75 mcg/kg)
Hemorrhage	Platelet transfusion IVIG (1 g/kg per day for 2–3 days) Methylprednisolone (1 g/day for 3 days)

Nonpharmacologic Therapy

Splenectomy generally is considered after 3 to 6 months if the patient continues to require 10 to 20 mg/day of prednisone to keep the platelet count greater than 30,000/mm^3 (30 $\times$ 10^3/μL or 30 $\times$ 10^9/L) or within 6 weeks of diagnosis in patients with platelet counts of less than 10,000/mm^3 (10 $\times$ 10^3/μL or 10 $\times$ 10^9/L) despite treatment. Even though individual patient response cannot be predicted, approximately two-thirds of refractory patients have a favorable response to splenectomy within a couple of days. After splenectomy, approximately 85% of adults attain a stable hemostatic response, and 70% to 80% of children attain complete remission. Within 5 to 10 years, approximately 25% of responding adult patients relapse. Laproscopic splenectomy is preferable to open splenectomy because it speeds the recovery and shortens the duration of hospitalization. The major drawback of splenectomy is bacterial sepsis, occurring at incidence rates of about 1%.

Pharmacologic Therapy

Glucocorticoids

Glucocorticoids may increase platelet production by impairing bone marrow macrophage ability to destroy platelets. Response rate to oral prednisone (1–1.5 mg/kg per day) in adults is 50% to 75% and usually occurs within the first 3 weeks. In children, severe life-threatening bleeding is treated with either high-dose oral (4–8 mg/kg per day prednisone) or parenteral (30 mg/kg per day methylprednisolone) glucocorticoids.

Intravenous Immunoglobulin (IVIG)

IVIG impairs the clearance of platelets coated with IgG by activating inhibitory receptor FcRγIIb. It is generally indicated in emergencies, during pregnancy, and in chronic management of patients refractory to other treatment options. Roughly 85% of adults have a response, but remission usually is not sustained. If treatment is indicated in children, a single dose of IVIG (0.8 g/kg) usually is effective.

Anti-D

Anti-Rh(D) can be used only in Rh(D)-positive patients. It is equal to IVIG in terms efficacy and generally is less expensive. The indications for use of anti-Rh(D) are identical to those for IVIG. Anti-D is especially desirable form of treatment in chronic ITP when the goal is to circumvent long-term exposure to corticosteroids. At doses of 25 mcg/kg per day, anti-Rh(D) may increase the platelet count in about 80% of children with acute and chronic ITP. Substantial numbers of patients treated repetitively with Rh(D) can postpone or avoid splenectomy.

Outcome Evaluation

- Monitor platelet counts as indicated clinically.
- Goal of therapy is to maintain platelet count equal or greater than 30,000/mm^3 (30 $\times$ 10^3/μL or 30 $\times$ 10^9/L).
- Monitor for signs and symptoms of bleeding.

THROMBOTIC THROMBOCYTOPENIC PUPURA

Etiology and Epidemiology

Thrombotic thrombocytopenic purpura (TTP) is a severe systemic disorder characterized by the thrombi formation within the circulation that result in the platelet consumption and subsequent thrombocytopenia. The inherited sub-type is chronic and relapsing and generally occurs in childhood. Acute idiopathic TTP, which occurs in adults, is more common and harder to treat. The estimated annual incidence of TTP is 3.7 cases per million.[33]

Pathophysiology

Endothelial cells normally synthesize vWF in the form of a high-molecular-weight polymer composed of smaller identical multimers. Each multimer is able to bind platelets, and the number of multimers on the vWF polymer is directly proportional to its platelet-binding capacity. Consequently, particularly adherent ultralarge molecules of the factor (ULvWF) are broken down to smaller size by vWF-cleaving proteases by the vWF-cleaving metalloprotease ADAMTS13 to avoid undesired clot formation. TTP results from autoantibody (probably IgG) inhibition of the vWF-cleaving protease ADAMTS13. This, in turn, elevates circulating levels of ultralarge molecules of the factor (ULvWF) leading to inappropriate platelet aggregation. Thrombocytopenia develops as a result of faster rate of platelet aggregation in comparison with megakaryocyte bone marrow production. Hemolytic anemia generally follows as a consequence of red blood cell damage by platelet clumps occluding the microcirculation. Occlusive ischemia of the brain or gastrointestinal tract is common, and renal dysfunction may occur.

Clinical Presentation and Diagnosis

Symptoms

- Flulike prodrome
  - Malaise, fever, headache and sometimes diarrhoea
- Hematologic
  - Purpura
  - Petechiae
  - Ecchymoses
  - Pallor, tiredness, and shortness of breath
- Neurologic
  - Headache, confusion, difficulty speaking, transient paralysis, numbness
- Renal failure

Laboratory Testing

- CBC
- Peripheral blood smear
- Elevated lactate dehydrogenase (LDH)
- Elevated indirect bilirubin level
- Elevated reticulocyte count
- Normal PT and aPTT
- Elevated serum creatinine

Treatment

Desired Outcomes

The main goal of TTP treatment is to prevent end-organ damage.

Nonpharmacologic Therapy

The present standard of treatment for TTP is urgent plasma exchange (PEX). If PEX is unavailable, treatment with plasma infusion and glucocorticoids is indicated until PEX is available.[34]

Plasma Exchange (PEX)

The procedure involves removal of the patient's plasma and its substitution by donor plasma. In this manner, circulating antibody against vWF-cleaving protease is removed. PEX involves placement of two intravenous lines (cannulas) into two separate veins. Blood removed through one cannula is centrifuged to separate the blood cells from the plasma. The blood cells are mixed subsequently with donor plasma and returned via the second cannula to the patient. The goal is to exchange 1 to 1.5 plasma volumes (40–60 mL/kg). The procedure generally is repeated until neurologic symptoms have resolved and a normal LDH and platelet count are maintained for several days. Approximately 85% of patients show both clinical and laboratory response within 3 weeks when PEX is initiated without delay. Although generally considered safe, catheter insertion or catheter infection complications may occur and include hemorrhage, pneumothorax, sepsis, and thrombosis. Allergic reactions to plasma can cause severe hypotension and hypoxia.

Splenectomy

Splenectomy was considered first-line treatment prior to the introduction of PEX. Today, it is reserved for patients with frequently relapsing disease and is performed safely laproscopically with excellent response rates.

Pharmacologic Therapy

Corticosteroids

Corticosteriods are used for their immunosuppressive effect in combination with PEX because they are of no benefit when used alone in this population. The most commonly used agents are methylprednisolone 1 g/day intravenously and prednisone 1 mg/kg per day orally.

Outcome Evaluation

Monitor platelet counts, hemoglobin, and LDH.

Patient Care and Monitoring

1. Obtain a complete history.
2. In a patient presenting with a bleeding or clotting disorder, an initial evaluation should include bleeding time, prothrombin time (PT), activated partial thromboplastin time (aPTT), thrombin time, and platelet count.

- Platelet count
- Activated partial thromboplastin time: aPTT is performed by adding calcium phospholipids and kaolin to citrated blood and measures the time required for a fibrin clot to form. In this manner, aPTT measures the activity of intrinsic and common pathways. Prolongation of aPTT may be due to a deficiency or inhibitor for factors II, V, VIII, IX, X, XI, and XII. It also may be due to heparin, direct thrombin inhibitors, vitamin K deficiency, liver disease, or lupus anticoagulant.
- Prothrombin time: PT is performed by adding thromboplastin (tissue) factor and calcium to citrate-anticoagulated plasma, recalcifying the plasma, and measuring the clotting time. The major utility of PT is to measure the activity of the vitamin K–dependent factors II, VII, and X. The PT is used in evaluation of liver disease, to monitor warfarin anticoagulant effect, and to assess vitamin K deficiency.
- Thrombin time is an assessment of the time required for the appearance of the fibrin clot after thrombin is added to plasma. It may be affected by thrombin inhibitors or fibrinogen abnormalities. Most commonly, thrombin time is used to monitor fibrinolytic therapy.
- Bleeding time indicates how well platelets interact with blood vessel walls to form blood clots by assessing the length of time to arrest the bleeding after a standardized skin cut. The bleeding time is prolonged in thrombocytopenia, fibrinogen disorders, and collagen defects.

3. After a diagnosis is made, institute specific therapy.
4. Monitor resolution of laboratory and clinical symptoms with treatment.

ABBREVIATIONS

ADAMTS13:	vWF-cleaving metalloprotease
BU:	Bethesda units
DDAVP:	1-desamino-8-D-arginine vasopressin (desmopressin acetate)
DIC:	disseminated intravascular coagulation
FFP:	fresh-frozen plasma
HIV:	human immunodeficiency virus
HCV:	hepatitis C virus
ICH:	intracranial hemorrhage
ITP:	immune thrombocytopenic purpura
IVIG:	intravenous immunoglobulin
PCC:	prothrombin complex concentrates
PEX:	plasma exchange
rFVIIa:	recombinant factor VIIa
RICD:	recessively inherited coagulation disorders
TTP:	thrombotic thrombocytopenic purpura
ULvWF:	ultralarge molecules of vWF
VKDB:	vitamin K deficiency bleeding
vWD:	von Willebrand disease
vWF:	von Willebrand factor

65 Sickle Cell Disease

Tracy M. Hagemann and Teresa V. Lewis

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Explain the underlying causes of sickle cell disease and their relationship to patient signs and symptoms.
2. Identify the typical characteristics of sickle cell disease as well as symptoms that indicate complicated disease.
3. Identify the desired therapeutic outcomes for patients with sickle cell disease.
4. Recommend appropriate pharmacotherapy and nonpharmacotherapy interventions for patients with sickle cell disease.
5. Recognize when chronic maintenance therapy is indicated for a patient with sickle cell disease.
6. Describe the components of a monitoring plan to assess effectiveness and adverse effects of pharmacotherapy for sickle cell disease.
7. Educate patients about the disease state, appropriate therapy, and drug therapy required for effective treatment and prevention of complications.

Key Concepts

❶ Sickle cell disease is an inherited disorder caused by a defect in the gene for hemoglobin. Patients may have one defective gene (sickle cell trait) or two defective genes (sickle cell disease).
❷ Although most often seen in persons of African ancestry, other ethnic groups can be affected.
❸ Sickle cell disease involves multiple organ systems.
❹ Prophylaxis against pneumococcal infection reduces death during childhood.
❺ Hydroxyurea has been shown to decrease the incidence of painful crises. However, the patient population that receives hydroxyurea should be monitored carefully.
❻ Chronic transfusion therapy programs have been shown to be beneficial in decreasing the occurrence of stroke in children with sickle cell disease.
❼ Patients with fever greater than 38.5°C (101.3°F) should be evaluated, and appropriate antibiotics should include coverage for encapsulated organisms, especially pneumococcal organisms.
❽ Pain episodes usually can be managed at home. Hospitalized patients usually require parenteral analgesics. Analgesic options include opioids, nonsteroidal anti-inflammatory agents, and acetaminophen. The patient characteristics and severity of the crisis should determine the choice of agent and regimen.

Sickle cells were first identified by physician James Herrick in a 20-year-old medical student from Grenada in 1910.[1] ❶ ***Sickle cell syndrome*** *refers to a collection of autosomal recessive genetic disorders that are characterized by the presence of at least one* ***sickle hemoglobin*** *gene (HbS).*[2,3]

Sickle cell disease (SCD) is a chronic illness that is associated with frequent crisis episodes. Acute complications are unpredictable and potentially fatal. Common symptoms include excruciating musculoskeletal pain, life-threatening pneumonia-like illness, cerebrovascular accidents, and splenic and renal dysfunction.[3] As the disease progresses, patients may develop organ damage from the combination of hemolysis and infarction. Because of the complexity and severity of SCD, it is imperative that patients have access to comprehensive care with providers who have a good understanding of the countless clinical presentations and the management options of this disorder.

EPIDEMIOLOGY AND ETIOLOGY

Sickle cell trait (SCT) is the heterozygous form (HbAS) of SCD in which a person inherits one normal adult hemoglobin (*HbA*) gene and one sickle hemoglobin (*HbS*) gene. These individuals

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

are carriers of the SCT and usually are asymptomatic.[3] Symptomatic disease is seen in homozygous and compound heterozygous genotypes of SCD. **Sickle cell anemia** (SCA) is the homozygous (*HbSS*) state of SCD.[3] It is the most common and severe form of SCD. Compound heterozygosity is seen when individuals inherit one copy of the mutation that causes HbS and one copy of another abnormal hemoglobin gene. One example is *HbSC* genotype, in which a person inherits the genetic mutation for hemoglobin C (HbC) in addition to *HbS*.[2–4] Compound heterozygosity also may include the coinheritance of *HbS* and one of the many different mutations of β-thalasssemia (*HbSβ*^{0}*-thalassemia* and *HbSβ*$^+$*- thalassemia*).[2–4]

SCA affects both males and females equally because it is not a sex-linked disease. ❷ *Nine percent of African Americans possess the SCT and 1 in 600 has HbSS.*[5] Two thousand infants are identified with SCD annually in the United States.[6] For every infant diagnosed with SCD, 50 are identified as carriers.[6] *HbSS* (approximately 45%) is the most common genotypic expression, followed by *HbSC* (approximately 25%), *HbSβ*$^+$*-thalassemia* (approximately 8%), and *HbSβ*^{0} *thalassemia* (approximately 2%). Other variants account for less than 1% of patients.[3,6]

Having the sickle hemoglobin gene protects heterozygous carriers from succumbing to *Plasmodium falciparum* (malaria) infection.[2] The microorganism cannot parasitize abnormal red blood cells (RBCs) as easily as normal RBCs. Consequently, persons with the heterozygous sickle gene (SCT) have a selective advantage in tropical regions where malaria is endemic. The incidence of the sickle gene in a population correlates with the historical incidence of malaria.

The highest incidence of SCD is seen in those with African heritage, but SCD also affects persons of Indian, Saudi Arabian, Mediterranean, South and Central American, and Caribbean ancestry.[6,7] There are more than 200,000 babies born each year in Africa with SCA.[7] The prevalence of SCT in Africa varies across regions, with ranges of 10% to 40% across equatorial Africa, 1% to 2% on the North African coast, and less than 1% in South Africa.[7]

Normal adult hemoglobin (HbA) is composed of two α-globin chains and two β-globin chains ($\alpha_2\beta_2$).[4] A single substitution of the amino acid valine for glutamic acid at position 6 of the β-polypeptide chain is responsible for production of a defective form of hemoglobin called *sickle hemoglobin* (HbS).[2,8] Different genetic mutations encode for other hemoglobin variants such as hemoglobin C (HbC). HbC is produced by the substitution of lysine for glutamic acid at the sixth amino acid position in the β-globulin chain.[4] The α-chains of HbS, HbA, and HbC are structurally identical. The chemical differences in the β-chain are responsible for RBC sickling and its associated sequelae.

SCA is the homozygous (*HbSS*) state of SCD in which individuals inherit the mutant hemoglobin gene (*HbS*) from both parents. The progeny of two carriers will have a 25% probability of having SCD and a 50% risk of being a carrier themselves (Fig. 65–1). β-Thalassemia can be found in conjunction with HbS. Patients with *HbSS* and *HbSβ*^{0}*- thalassemia* do not have normal β-globulin production and usually have a more severe course than those with *HbSC* and *HbSβ*$^+$*-thalassemia.*

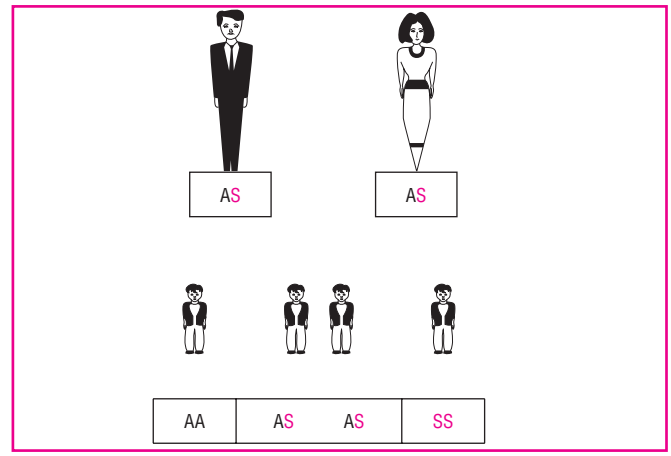

FIGURE 65–1. Sickle gene inheritance scheme for both parents with sickle cell trait (SCT). A, normal hemoglobin; S, sickle hemoglobin. Possibilities with each pregnancy: 25% normal (AA); 50% SCT (AS); 25% sickle cell anemia (SS). (From Chan CYJ, Moore R. Sickle cell disease. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 1856.)

PATHOPHYSIOLOGY

Erythrocyte Physiology

A review of RBC physiology is important to understanding the pathophysiology of SCD. Pediatric RBCs possess normal hemoglobin concentrations of between 9 and 18.5 g/dL (90 to 185 g/L or 5.6–11.5 mmol/L) depending on the age of the child.[9] Adult RBCs contain 12 to 15.5 g/dL (120 to 155 g/L or 7.4–9.6 mmol/L) hemoglobin.[9] The predominant form of hemoglobin is adult hemoglobin or HbA (96%). Other forms of hemoglobin include HbA_2 and fetal hemoglobin (HbF). HbA_2 makes up less than 1% of hemoglobin in newborns. In adults, HbA_2 constitutes approximately 1.6% to 3.5%.[9] Fetal hemoglobin (HbF) is present primarily in fetal RBCs (60% to 90%), whereas adult RBCs contain less than 1% HbF.[9] HbF is the primary oxygen-transport protein in the fetus. Unlike HbA and HbS, HbF does not contain β-chains but rather two γ-globulin protein chains ($\alpha_2\beta_2$).[4] Shortly before birth, fetal hemoglobin undergoes conversion from γ-chains to β-chains. After birth, only a small proportion of red cell clones remain to produce HbF. Certain physiologic conditions, such as severe anemia, hematopoietic stem cell transplantation, and chemotherapy, can caused increased production of HbF. Both water and hemoglobin contents in the RBCs determine the mean corpuscular hemoglobin concentration (MCHC). Passive diffusion and active transport regulate intracellular cation and volume contents, which determine the intracellular viscosity of RBCs. Normal RBCs are biconcave in shape. The elasticity of young erythroid cells enables them to

deform and squeeze through capillaries (Fig. 65–2). As RBCs age, MCHC increases, deformability decreases, and the cells are removed by the reticuloendothelial system.

Impaired circulation, destruction of RBCs, and vascular stasis are three known problems that are responsible primarily for the clinical manifestations of SCD. These pathologic findings are likely due to HbS polymerization and RBC membrane damage (Fig. 65–3).

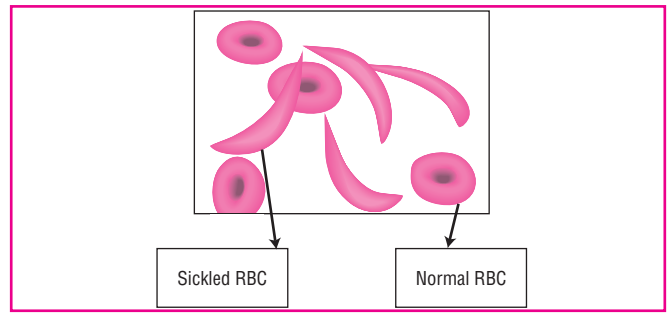

FIGURE 65–2. Elongated sickle-shaped and normal discoid-shaped red blood cells. (From Chan CYJ, Moore R. Sickle cell disease. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 1856.)

Sickle Hemoglobin Polymerization

The primary event in the molecular pathogenesis of SCD involves polymerization of deoxygenated HbS. Since RBCs are packaged with such a high concentration of hemoglobin (32–34 g/dL, 320 to 340 g/L or 19.9–21 mmol/L), it is important

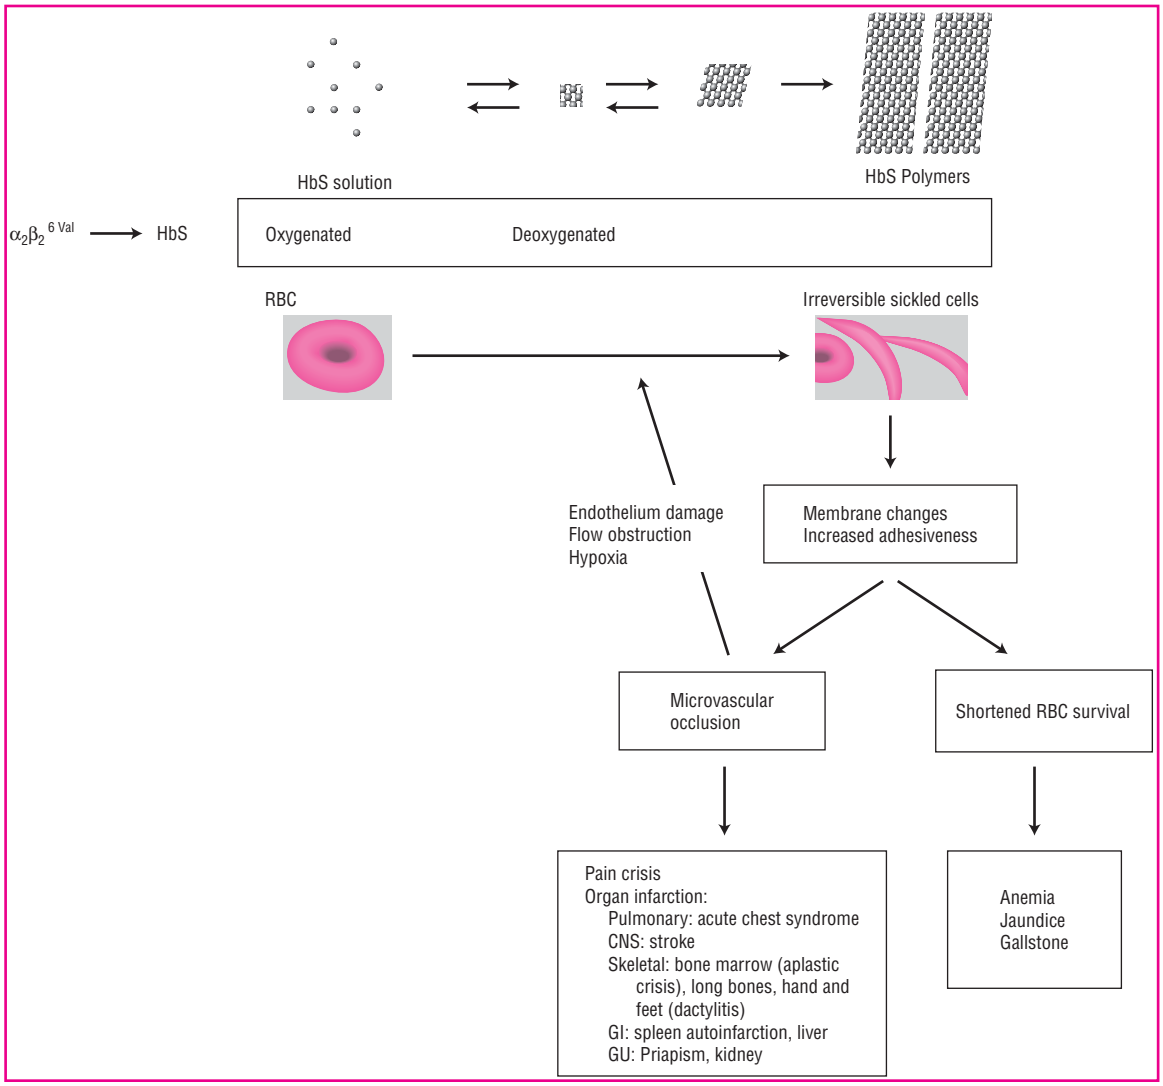

FIGURE 65–3. Pathophysiology of sickle cell disease. (From Chan CYJ, Moore R. Sickle cell disease. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 1857.)

that the proteins be extremely soluble.[8] HbS carries oxygen normally, and when oxygenated, the solubility of HbS and HbA are the same. Once the oxygen is unloaded to the tissues, HbS solubility decreases to approximately 17 g/dL (170 g/L or 10.6 mmol/L). This promotes hydrophobic interactions between the hemoglobin molecules and polymerization.[8] Valine can bind to complementary sites on adjacent globin chains, resulting in intermolecular binding and formation of ropelike fibers that align with others to form a bundle.[2] The deoxy-HbS begins to form semisolid aggregate structures. This distorts the RBC into the characteristic crescent or sickle shape. Polymerization of deoxy-HbS is influenced by the degree of red cell deoxygenation, MCHC, temperature, intracellular pH, intraerythrocytic HbS concentration, and intracellular HbF concentration.[2]

Viscosity of Erythrocytes and Sickle Cell Adhesion

When HbS becomes reoxygenated, the polymers within the RBCs disappear, and the cells eventually return to normal shape. Vasoocclussion is caused by a combination of factors. Repeated assaults on RBCs from sickling and unsickling can lead to cell membrane damage, loss of membrane flexibility, and rearrangement of surface phospholipids. Damage to cell membranes can interfere with ion transport, leading to loss of potassium and water. This creates dehydrated, dense sickle cells and irreversible sickle cells (ISCs). ISC's are the densest cells, and they tend to remain sickled even when oxygenated. Rigid ISCs can become trapped in microvasculature, leading to cell fragmentation and chronic hemolysis and thus contributing to short survival of RBCs. The life span of sickled RBCs is markedly shorter (10–20 days) than that of normal RBCs (100–120 days). As intracellular membrane viscosity of HbS-containing RBCs increases, blood viscosity increases, which further contributes to vasoocclussion.[10] There is also increasing evidence that suggests that sickle cells adhere to vascular endothelium.[2,10] The combined effects of decreased RBC deformability, slow transit through microcirculation, and adhesion to vascular endothelium contribute to obstruction of small and sometimes large blood vessels. The resulting local tissue hypoxia can accentuate the pathologic process of SCD.

Protective Hemoglobin Types

Fetal hemoglobin binds oxygen more tightly than HbA, and it has a decreased propensity to sickling. HbA_2 also possesses this characteristic but to a lesser extent. RBCs that contain HbF sickle less readily than cells without. ISCs are found to have low HbF concentrations. In some patients, higher HbF may ameliorate the disease.

Other Pathophysiologic Effects

Other factors may be responsible for the pathogenesis of some of the clinical features of SCD. Sickle cells can obstruct blood flow to the spleen, leading to functional asplenia, which is loss of splenic function despite having an intact spleen. These patients also may have deficient opsonization. Impaired splenic function can increase the propensity to infection by encapsulated organisms, particularly *Streptococcus pneumoniae*.[11] Additionally, coagulation abnormalities are not uncommon because almost every component of hemostasis is altered in SCD.

CLINICAL PRESENTATION AND DIAGNOSIS

Diagnosis

Table 65–1 shows the clinical features of SCT and SCD. SCD usually is identified by routine neonatal screening programs using hemoglobin electrophoresis, thin-layer isoelectric

TABLE 65–1. Clinical Features of Sickle Cell Trait and Sickle Cell Disease

Condition	Clinical Presentation
Sickle cell trait (*HbAS*)	Generally asymptomatic Females may have frequent urinary tract infections Microscopic hematuria occurs rarely Gross hematuria can occur spontaneously or with heavy intensity exercise Normal Hgb values
Sickle cell anemia (*HbSS*)	Painful vaso-occlusive crises are the hallmark of SCD Chronic hemolytic anemia is common Patients may develop infarction of the spleen, liver, bone marrow, kidney, brain, and lungs Gallstones and priapism also may develop Slow healing lower extremity ulcers may develop usually after infection or trauma Hgb 7–10 g/dL (70–100 g/L or 4.4–6.2 mmol/L)
Sickle hemoglobin C (*HbSC*)	Vaso-occlusive crises are less common and occur later in life Assocated with painless hematuria Aseptic necrosis of bone is a rare occurrence Other complications include ocular disease and pregnancy-related problems Mild anemia (Hgb 10–14 g/dL) (100–140 g/L or 6.2–8.7 mmol/L)
Sickle β^+-thalassemia (*HbSβ^+-thalassemia*)	Milder clincal course than sickle cell disease because of production of HbA Vaso-occulssive crises are rare Aseptic necrosis is a rare occurrence Hgb 10–14 g/dL (100–140 g/L or 6.2–8.7 mmol/L) with microcytosis
Sickle β^0-thalassemia *(HbSβ^0-thalassemia)*	Severity of disease is similar to sickle cell anemia and Vaso-occlussive crises are common No HbA production Hgb 7–10 g/dL (70–100 g/L or 4.4–6.2 mmol/L) with microcytosis

Adapted from DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005, Table 101-1.

focusing, high-performance liquid chromatography, or DNA analysis.[6] All tests are comparable in accuracy.[6] Hemoglobin electrophoresis is recommended by the National Institutes of Health as the method of choice, with isoelectric focusing as an alternative.[11] Positive screening results should be confirmed with a second sample. This should be done before the child is 2 months of age and using a different screening method.[6]

Morbidity and Mortality

Thirty years ago, complications from SCD contributed to high mortality. It was estimated that approximately 50% of patients with SCD did not survive to reach adulthood.[5] Since that time, data suggest improvement in mortality rates for patients with SCD. The median survival age for individuals with HbSS in the United States in 1994 was estimated to be 42 years for men and 48 years for women.[13] Recent reports suggest 85% survival by 18 years of age.[5] Predictors for increased morbidity in children younger than 10 years include having **dactylitis** (**hand-foot syndrome**) before 1 year of age, severe anemia in the second year of life [Hgb concentration less than 7 g/dL (70 g/L or 4.4 mmol/L)], and leukocytosis in the absence of infection (white blood count greater than 15,000/mm^3 [15 × 10^9/L]).[13,14] Infection is the leading cause of death in children younger than 3 years of age.[13,14] For adults, having more symptomatic disease (e.g., acute pain crises, anemic events, **acute chest syndrome**, renal insufficiency, cerebrovascular complications, and pulmonary disease) is associated with increased risk for early death[3,13] (Tables 65–2 and 65–3). Today, with longer survival for SCD, chronic manifestations of the disease contribute to the morbidity later in life (Table 65–4).

TABLE 65–2. Acute Complications of Sickle Cell Disease (SCD)

Infection[a]

Clinical features: SCD carries a high risk for overwhelming sepsis due to functional asplenia and failure to make antibodies against encapsulated organisms; patients should be evaluated for temperature greater than 38.5°C. A low threshold for empiric therapy is recommended.

Pathogens: Streptococcus pneumoniae (most common), *Haemophilus influenzae, Salmonella, Mycoplasma pneumoniae*, *Chlamydia*, and viruses (parvovirus B19)

Evaluation: Physical examination, complete blood count (CBC) with reticulocyte, urinalysis, chest x-ray, and cultures (blood, urine, and throat); lumbar puncture if toxic-looking or presenting with signs of meningitis; needle aspirate in patients with findings suggestive of osteomyelitis

Cerebrovascular Accidents (Stroke)[b]

Clinical features: Incidence is four times higher for HbSS than HbSC. Initial episode most often occurs during the first 10 years of life. "Silent infarcts" as evidenced by changes on magnetic resonance imaging (MRI) have been reported in 21.8% of HbSS and may be associated with increased risk of stroke and decreased neurocognitive function.

Cause: Most common is cerebrovascular occlusion. Other causes include intracranial hemorrhage, cardiac embolisms, infection, and clotting disorders.

Signs and symptoms: Headache, vomiting, stupor, hemiparesis, aphasia, visual disturbances, and seizure; transient ischemic attack is a strong predictor for stroke. Behavioral and performance changes may be present in patients with asymptomatic infarction.

Evaluation: Perform computed tomography (CT) scan and MRI for evaluation of acute event. Perform magnetic resonance angiography for asymptomatic infarction. Perform transcranial Doppler to detect abnormal velocity and identify high-risk patients. Perform electroencephalography if there is a history of seizure.

Acute Chest Syndrome (ACS)[c]

Clinical features: ACS occurs in 15% to 43% of patients and is responsible for up to 25% of deaths. Risk factors include young age, low HbF level, high Hgb and WBCs, winter seasons, and reactive airway disease. Recurrences are up to 80% and can lead to chronic lung disease in adulthood.

Signs and symptoms: New infiltration on chest, x-ray accompanied by fever, cough, dyspnea, chest pain, hypoxia, leukocytosis. Can progress to acute respiratory distress syndrome and death.

Cause: Exact cause remains unknown but pulmonary sickling resulting in infraction is the key element. Proposed etiologies include: infectious *(S. pneumoniae, H. influenzae, Chlamydia, Mycoplasma*, and viral) and noninfectious (fat embolization from bone infarction, hypoventilation secondary to pain, narcotics, etc).

Evlauation: Close monitoring of pulmonary status, blood gases (if indicated), oxygen saturation, chest x-ray, blood and sputum cultures, CBC, bronchoscopy with lavage (if needed)

Priapism[d]

Clinical features: Priapism is defined as a painful and unwanted erection, which is classified as stuttering (less than 3 hours), often multiple prolonged (more than 3 hours). Up to 89% of males with SCD will have at least one episode by age 20. The mean age of the initial episode is 12 years of age. Repeated episodes can cause fibrosis and impotence.

Cause: Sickling in the sinusoids of the penis

Signs and symptoms: Prepubertal children often present with stuttering priapism. Older males can present with prolonged episodes that last for days and should be managed as medical emergencies. Urinary obstruction can occur in severe cases.

Evaluation: Physical examination; monitor duration of episode and for signs of urinary retention.

HbF, fetal hemoglobin; HbSC, sickle-hemoglobin C; HbSS, homozygous sickle hemoglobin; Hgb, hemoglobin; WBC, white blood cell.

TABLE 65–3. Sickle Cell Crisis

Vaso-Occlusive Pain Crisis[a]

Clinical features: Acute painful infarction without changes in Hgb; almost all patients with SCA will have episodes of acute pain. Recurrent acute crises result in bone, joint, and organ damage and chronic pain. Vaso-occlusive crisis most commonly involves the bones, liver, spleen, brain, lungs, and penis. Acute long bone pains may be accompanied by signs of inflammation, making it difficult to differentiate from osteomyelitis. Abdominal involvement may resemble a surgical abdomen. Precipitating factors include infection, extreme weather conditions, dehydration, and stresses.

Signs and symptoms: Deep throbbing pain; local tenderness, erythema, and swelling may be seen. Fever and leukocytosis are common. Dactylitis usually occurs in young infants. Jaundice and increased transaminases present if liver is involved.

Evaluation: Frequent physical examination, complete blood count (CBC), reticulocyte, and urinalysis; based on symptomatology, the following may be needed: needle aspiration to rule out osteomyelitis, abdominal studies (x-ray, computed tomography scan, etc), liver function tests, bilirubin, culture, and chest x-ray.

Aplastic Crisis[b]

Clinical features: Acute decrease in Hgb with decreased reticulocyte count (usually less than 1%); transient suppression of RBC production in response to bacterial or viral infection, most common being parvovirus B19

Signs and symptoms: Headache, fatigue, dyspnea, pallor, and tachycardia; may also present with fever, upper respiratory or gastrointestinal infection symptoms.

Evalution: CBC, reticulocyte count, x-ray, cultures (blood, urine, and throat), parvovirus titers

Acute Splenic Sequestration Crisis[c]

Clinical features: Acute exacerbation of anemia due to sequestration of large blood volume by the spleen. More commonly seen in patients with functioning spleens (e.g., infants and adults with HbSC disease); onset often is associated with viral or bacterial infections; recurrences are common and can be fatal.

Signs and symptoms: Sudden onset of fatigue, dyspnea, and distended abdomen; rapid decrease in Hgb and Hct with elevated reticulocyte count, abdominal pain, splenomegaly, vomiting, hypotension, and shock

Evaluation: Close monitoring of vital signs, spleen size, and oxygen saturation, CBC, reticulocyte, and cultures

TABLE 65–4. Chronic Complications of Sickle Cell Disease (SCD)

System	Complications
Auditory	Sensorineural hearing loss due to sickling in cochlear vasculature with hair cell damage
Cardiovascular	Cardiomegaly, myocardial ischemia, murmurs, and abnormal electrocardiogram; patients with SCD have lower blood pressure (BP) than the normal population; normal BP values for SCD should be used for diagnosis of hypertension ("relative" hypertension); heart failure usually is related to fluid overload
Dermatologic	Painful leg ulcers; failure to heal occurs in 50% of patients; recurrences are common
Genitourinary	Renal papillary necrosis, hematuria, hyposthenuria, proteinuria, nephritic syndrome, tubular dysfunction, chronic renal failure, impotence
Growth and development	Delay in growth (weight and height) and sexual development; decreased fertility; increased complications during pregnancy; depression may be more prevalent than in general population, especially in patients with unstable disease
Hepatic and biliary	Cholelithiasis, biliary sludge, acute and chronic cholecystitis, and cholestasis (can be progressive and life-threatening)
Neurologic	"Silent" brain lesions on magnetic resonance imaging are associated with poor cognitive and fine motor functions; pseudotumor cerebri (case report)
Ocular	Retinal or vitreous hemorrhage, retinal detachment, transient or permanent visual loss; central retinal vein occlusion
Pulmonary	Pulmonary fibrosis, pulmonary hypertension, cor pulmonale
Renal	Hematuria, hyposthenuria (inability to concentrate urine maximally), tubular dysfunction, enuresis during early childhood, acute renal failure can also occur
Skeletal	Aseptic necrosis of ball-and-socket joints (shoulder and hip); prostheses may be needed due to permanent damage; bone marrow hyperplasia resulting in growth disturbances of maxilla and vertebrae
Spleen	Asplenia (autosplenectomy or surgical splenectomy)

From Fixler et al,[47] National Institutes of Health,[6] Dover et al,[48] Kral et al,[52] Vichinsky et al,[58] Gladwin et al,[60] Henry et al,[61] Mukisi-Mukaza et al,[62] Hasan et al,[63] Babalola et al,[64] de Montalembert et al,[65] Hassan et al,[66] and Schatz et al.[67]

Complications

Treatment of SCD is aimed at the preventing and/or minimizing acute and chronic complications, including infection, acute chest syndrome, neurologic damage, and the various forms of sickle cell crises, including vaso-occlusive pain, splenic sequestration, and aplastic crisis. The acute and chronic complications are summarized in Tables 65–2, 65–3, and 65–4.

Signs and Symptoms

Sickle Cell Trait

❸ *SCD involves multiple organ systems, and its clinical manifestations vary greatly between and among genotypes (see Table 65–1).*

- Dehydration during periods when water conservation is necessary
- Microscopic hematuria (presence of blood in the urine)
- Women with SCT also can have frequent urinary tract infections, especially during pregnancy.

Sickle Cell Disease

- Vaso-occlusion
- Hemolytic anemia
- Pneumonia
- Splenomegaly is also a common finding.
- Children younger than 3 years of age can present with dactylitis (hand-foot syndrome), which is painful swelling of the hands and feet.

Sickle Cell Anemia

- Chronic anemia
- Fever and pallor
- Arthralgia
- Scleral icterus
- Abdominal pain
- Weakness
- Anorexia
- Fatigue
- Enlargement of the liver, spleen, and heart
- Hematuria

Serologic Findings

- Low hemoglobin (Hgb) concentration, low HbF, and increased reticulocytes, platelets, and white blood cell (WBC) counts
- The peripheral blood smear demonstrates sickle forms (see Fig. 65–2).

Growth and Development

- Delayed growth and sexual development
- Protuberant abdomen with exaggerated lumbar lordosis, usually an asthenic appearance with rather long extremities and tapered fingers, and frequently a barrel-shaped chest

TREATMENT

Desired Outcomes

Multidisciplinary, regularly scheduled care is required over the lifetime of the SCD patient with the goal of reduction of both complications and hospitalizations. Comprehensive care should include medical, educational, and psychosocial aspects, as well as counseling.

Therapeutic interventions for SCD should be targeted at preventing and/or minimizing the symptoms related to the disease and its complications. The goals of treatment are to reduce or eliminate the patient's symptoms; decrease the frequency of sickle crises, including vaso-occlusive pain crises; prevent the development of complications; and maintain or improve the quality of life through decreased hospitalizations and decreased morbidity. Specific therapeutic options may

- Maintain or increase the hemoglobin level to the patient's baseline
- Increase the HbF concentration
- Decrease the HbS concentration
- Prevent infectious complications
- Prevent or effectively manage pain
- Prevent central nervous system damage, including stroke

General Management

Patients should be educated to recognize the signs and symptoms of complications that would require urgent evaluation. Patients and parents of children with SCD should be educated to read a thermometer properly and to seek immediate medical care when a fever develops or signs of infection occur. With acute illnesses, prompt evaluation is important because deterioration may occur rapidly. Fluid status should be monitored to avoid dehydration or overhydration, both of which may worsen complications of SCD. Patients in acute distress should maintain oxygen saturation at 92% or at their baseline. Any supplemental oxygen requirements should be evaluated.[6,27]

Patient Encounter 1

An 18-month-old girl is presenting for a routine check-up. She was diagnosed with sickle cell anemia at birth, identified through neonatal screening. Today, her hemoglobin is 8.6 g/dL (86 g/L or 5.3 mmol/L) and she is afebrile.

- What acute complications is she at risk for developing?
- What preventative treatment should she receive?
- What additional information do you need to know before creating a plan for this patient?

Nonpharmacologic Therapy

Patients should avoid smoking and excessive alcohol intake. Patients with SCD should maintain adequate hydration and should be educated to avoid extreme temperature changes and to dress properly in hot and cold weather. Physical exertion that leads to complications should be avoided.[6] Regular examinations, including ophthalmic, renal, pulmonary, and cardiac, are required to monitor for organ damage. A treatment overview is shown in Table 65–5.

TABLE 65–5. Management of Sickle Cell Disease

	Options and Comments
Health Maintenance	
Infection prophylaxis	• Pneumococcal vaccines (PCV 7 and PPV 23) • Penicillin prophylaxis for children less than 5 years old • Annual influenza vaccine
Induction of fetal hemoglobin	• Hydroxyurea is the primary agent • Other agents are butyrates (arginine butyrate and sodium phenylbutyrate), decitabine, clotrimazole, and erythropoietin • Combination HbF inducers have been proposed
Chronic transfusion therapy	• Primary indication: stroke prevention in pediatric patients • May also reduce pain crisis and acute chest syndrome • Goal: maintain HbS less than 30%
Future prospects	
Transplantation	• May potentially cure the disease • Most experience is with HLA-matched donors; umbilical cord blood transplantation is being evaluated
Crises and Complications	
Fever and infection	• Broad-spectrum antibiotic: cefotaxime or ceftriaxone (clindamycin for cephalosporin allergy); vancomycin for staphylococcal and resistant pneumococcal organisms
Stroke	• Fluids • Acetaminophen or ibuprofen for fever • Exchange transfusion • Initiate chronic transfusion therapy to prevent recurrent strokes
Acute chest syndrome	• Broad-spectrum antibiotics (include *Mycoplasma coverage*) • Bronchodilator if wheezing or history of reactive airway disease • Fluids • Pain management • Transfusion
Priapism	• Hydration • Pain management • Urology consult for other options (intrapenile injection or surgery)
Aplastic crisis	• Supportive care • Transfusion for severe symptomatic anemia
Sequestration crisis	• Transfusion • Broad-spectrum antibiotic • Splenectomy in severe cases
Pain crises	• Hydration • Analgesics

HbF, fetal hemoglobin; HbS, sickle hemoglobin; HLA, human leukocyte antigen. *From Fixler et al,[47] National Institutes of Health,[6] Dover et al,[48] Pegelow et al,[51] Neumayr et al,[57] Vichinsky et al,[58] Yale,[45] Adamikiewicz et al,[17] Advisory Committee on Immunization Practices,[18] Committee on Infectious Diseases,[16] Sickle Cell Disease Care Consortium,[27] Falletta et al,[19] Kennedy et al,[21] Rodriguez-Cortes,[68] Rabb et al,[69] Charache et al,[70] Nathan,[28] Cokic et al,[71] Gladwin et al,[72] Charache et al,[22] Steinbert et al,[23] National Heart, Lung and Blood Institute,[74] Zimmerman et al,[25] Wilson et al,[26] Najean et al,[74] Atweh et al,[75] Resar et al,[76] Sauntharajah et al,[77] Scothorn et al,[78] Pegelow et al,[79] Russell et al,[80] Adams et al,[81] Harmatz et al,[82] Walters et al,[83] Atkins et al,[32] Brachet et al,[84] Baron et al,[85] Walters et al,[33] Knight-Madden et al,[35] Sullivan et al,[36] Li et al,[86] Mantadakis et al,[37] Dahm et al,[87] Jacob et al,[42] Berde et al,[43] Stinson et al,[44] Christensen et al,[88] and Elander et al.[79]*

Pharmacologic Therapy

Health Maintenance

Immunizations

Children with SCD should receive the required immunizations as recommended by the American Academy of Pediatrics and the Advisory Committee on Immunization Practices.[15] Additionally, influenza vaccine should be administered yearly to SCD patients 6 months of age and older, including adult patients. Any SCD patient who is scheduled for splenectomy should receive the vaccine for meningococcal disease if over 2 years of age.[16]

Because patient with SCD have impaired splenic function, they are less adequately protected against encapsulated organisms such as *S. pneumoniae, Hemophilus influenzae,* and *Salmonella.* ❹ *The use of pneumococcal vaccine in SCD patients has decreased the rates of morbidity and mortality dramatically.* However, there are still groups of SCD children who continue to have high rates of invasive pneumococcal infections.[17] Two pneumococcal vaccines are available. The 7-valent conjugate vaccine (PCV 7: Prevnar) is indicated for infants and children and provides good protection against the seven most common isolates seen in this age range. Administer the first dose of PCV 7 between 6 weeks and 6 months of age, followed by two additional doses at 2-month intervals and a fourth dose at 12 to 15 months of age. The 23-valent polysaccharide vaccine (PPV 23: Pneumovax 23) is indicated for children over 2 years of age. Because PPV 23 is a polysaccharide vaccine, children younger than 2 years of age do not respond well. PPV 23 contains the 23 most common isolates of *S. pneumoniae* seen in older children and adults. Because of the difference serotypes seen in the two vaccines, it is recommended that SCD children receive both vaccines, with a dose of PPV 23 administered after the child turns 2 years of age. The dose of PPV 23 should be separated from the last dose of PCV 7 by at least 2 months. An additional dose of PPV 23 should be considered in children 3 to 5 years of age to ensure antibody response. All adults with SCD also should be vaccinated once with PPV 23. Because some children fall behind on their childhood vaccinations, a catchup schedule is presented in Table 65–6.[16]

TABLE 65–6. Pneumococcal Immunization for Children with Sickle Cell Disease

	Recommended Schedule
Previously Unvaccinated	
Age 2–6 months	**PCV 7 (Prevnar):** 3 doses 6–8 wk apart; then 1 dose at 12–15 months
Age 7–11 months	**PCV 7 (Prevnar):** 2 doses 6–8 wk apart; then 1 dose at 12–15 months
Age greater than or equal to 12–23 months	**PCV 7 (Prevnar):** 2 doses 6–8 wk apart
Age 24–59 months	**PCV 7 (Prevnar):** 2 doses 6–8 wk apart **PPV 23 (Pneumovax):** 2 doses; first dose at least 6–8 wk after last PCV 7 dose; second dose 3–5 years after the first PPV 23 dose
Age 5 years or older	**PCV 7 (Prevnar):** 1 dose **PPV 23 (Pneumovax):** 2 doses; first dose at least 6–8 wk after last PCV 7 dose; second dose 3–5 years (for those age 10 years or younger) or more than 5 years (for those age 10 years or older) after the first PPV 23 dose
Previously Vaccinated	
Age 12–23 months, incomplete PCV 7 series	**PCV 7 (Prevnar):** 2 doses 6–8 wk apart
Age 24–59 months, received four doses	**PPV 23 (Pneumovax):** 2 doses; first dose at least 6–8 wk after last PCV 7 dose; second dose 3–5 y after the first PPV 23 dose of PCV 7
Age 24–59 months, three doses of PCV 7 given before 24 months of age	**PCV 7 (Prevnar):** 1 dose **PPV 23 (Pneumovax):** 2 doses; first dose at least 6–8 wk after last PCV 7 dose; second dose 3–5 years after the first PPV 23 dose
Age 24–59 months, 1 dose PPV 23 given	**PCV 7 (Prevnar):** 2 doses 6–8 wk apart; first dose at least 8 wk after PPV 23 dose **PPV 23 (Pneumovax):** second dose 3–5 years after first PPV 23
Age 5 years or older, received PPV 23	**PCV 7 (Prevnar):** 1 dose 6–8 wk after PPV 23 **If only received 1 dose of PPV 23 (Pneumovax):** Second dose 6–8 wk after PCV 7 *and* 3–5 years (for those age 10 years or less) or more than 5 years (for those age 10 years or older) after the first PPV 23 dose

PCV 7, 7-valent pneumococcal conjugated vaccine; PPV 23, 23-valent pneumococcal polysaccharide vaccine. *From Advisory Committee on Immunization Practices,[18] Committee on Infectious Diseases,[16] and Sickle Cell Disease Care Consortium.[27]*

Penicillin

❹ *Children with SCD should receive prophylactic penicillin until at least the age of 5 years, even if they have been immunized appropriately with PCV 7 against pneumococcal infections.* Penicillin V potassium typically is initiated at age 2 months with a dose of 125 mg orally twice daily until age 3 years and then 250 mg orally twice daily until 5 years of age. The intramuscular use of benzathine penicillin 600,000 units every 4 weeks from age 6 months to 6 years is also an option for noncompliant patients. Penicillin-allergic patients may receive erythromycin 10 mg/kg twice daily. Penicillin prophylaxis usually is not continued in children over the age of 6 years but may be considered in patients with a history of invasive pneumococcal infection or surgical splenectomy.[6,18–20]

Folic Acid

Folic acid supplementation with 1 mg daily generally is recommended in adult SCD patients, women considering pregnancy, and any SCD patient with chronic hemolysis.[6] Because of accelerated erythropoiesis, these patients have an increased need for folic acid. There are conflicting studies in the SCD population, especially among infants and children, but if the child has chronic hemolysis, supplementation is recommended.[21]

Fetal Hemoglobin Inducers

Fetal hemoglobin (HbF) induction in patients with SCD, especially those with frequent crises, has been shown to decrease RBC sickling and RBC adhesion. A direct relationship between HbF concentrations and the severity of disease have been demonstrated in studies.[3]

Hydroxyurea

Hydroxyurea is a ribonucleotide reductase inhibitor that prevents DNA synthesis and traditionally has been used in chemotherapy regimens. Studies in the 1990s also found that hydroxyurea increases HbF levels as well as increasing the number of HbF-containing reticulocytes and intracellular HbF. Other beneficial effects of hydroxyurea include antioxidant properties, reduction of neutrophils and monocytes, increased intracellular water content leading to increased red cell deformability, decreased red cell adhesion to endothelium, and increased levels of nitric oxide, which is a regulator involved in physiologic disturbances.[22]

❺ *Hydroxyurea reduced the frequency of hospitalizations and the incidences of pain, acute chest syndrome, and blood transfusions by almost 50% in a landmark trial in adult SCD patients with moderate to severe disease.* Hemoglobin and HbF concentrations increased, and hemolysis decreased.[22] A follow-up study demonstrated a 40% reduction in mortality over a 9-year period in patients continuing to receive hydroxyurea.[23] Not all patients responded equally, so hydroxyurea may not be the answer for all patients.

The use of hydroxyurea in children and adolescents with SCD has been investigated, and similar results were reported as in adult trials, with no adverse effects on growth and development.[6,24,25]

The most common adverse effect of hydroxyurea in reported studies is myelosuppression. Long-term adverse effects are unknown, but myelodysplasia, acute leukemia, and chronic opportunistic infections have been reported.[26] Hydroxyurea is teratogenic in high doses in animal studies, and this is a concern that should be addressed with patients. Normal pregnancies with no birth defects have been reported in some women receiving hydroxyurea, but close monitoring and weighing risk versus benefit to the patient are vitally important. Hydroxyurea is excreted in breast milk and should be avoided in lactating mothers.[27]

Hydroxyurea should be considered in SCD with frequent vaso-occlusive crises, severe symptomatic anemia, repeated history of acute chest syndrome (ACS), or other history of severe vaso-occlusive crisis (VOC) complications.[6] The prevention of organ damage or reversal of previous damage has not been shown to occur with chronic use of hydroxyurea.

Hydroxyurea is available in 200-, 300-, 400-, and 500-mg capsules. Extemporaneous liquid preparations can be prepared for children who cannot swallow capsules. Doses should start at 10 to 15 mg/kg daily in a single dose, which can be increased

Patient Encounter 2

LK is a 15-year-old girl with history of sickle cell disease (HbS).

PMH
- Cholecystectomy at age 11 years
- Admitted for vaso-occlusive crises five times over the past year
- Acute chest syndrome at age 13 and 14
- Immunizations up to date
- Multiple blood transfusions

FH
Father with SC trait; mother with SCD.

SH
Student in ninth grade. Denies alcohol or drug use. Is sexually active.

Meds
- Lortab 7.5-mg tablets PO q4–6hours prn for pain
- Ibuprofen 600 mg PO three times daily prn for pain
- Folic acid 1 mg PO daily
- The medical team wants to start LK on hydroxyurea.

- Is she a candidate for hydroxyurea?
- What initial laboratory work is required before initiating hydroxyurea?
- Identify treatment goals for hydroxyurea in LK
- What is the initial dose, and how will you monitor for efficacy?
- What patient counseling is needed?
- How will you monitor for toxicity?

after 8 to 12 weeks if blood counts are stable and there are no side effects. Individualize the dosage based on the patient's response and the toxicity seen. With close monitoring, doses can be increased 5 mg/kg per day up to 35 mg/kg daily.[22]

Closely monitor patients for efficacy and toxicity while they are receiving hydroxyurea. Monitor mean corpuscular volume (MCV) because it increases as the level of HbF increases. If the MCV does not increase with hydroxyurea use, the marrow may be unable to respond, the dose may not be adequate, or the patient may be noncompliant.[27] HbF levels also can be monitored to assess response. Assess blood counts every 2 weeks during dose titration and then every 4 to 6 weeks once the dose is stabilized. Temporary discontinuation of therapy is warranted if the hemoglobin level is less than 5 g/dL (50 g/L or 3.1 mmol/L), the absolute neutrophil count is less than 2000/mm^3 (2×10^9/L), platelets are less than 80,000/mm^3 (80×10^9/L), or reticulocytes are less than 80,000/mm^3 (80×10^9/L) if the hemoglobin is less than 9 g/dL (90 g/L or 5.6 mmol/L). Monitor for increases in serum creatinine and transaminases. Once the patient has recovered, hydroxyurea may be restarted with a dose that is 2.5 to 5 mg/kg less than the dose associated with the patient's toxicity. Doses then may be increased by 2.5 to 5 mg/kg daily after 12 weeks with no toxicity.

Administer prophylactic folic acid supplementation to SCD patients receiving hydroxyurea because folate deficiency may be masked by the use of hydroxyurea.

5-Aza-2′-Deoxycytine (Decitabine)

For patients who do not respond to hydroxyurea, 5-azacytidine and 5-aza-2'-deoxycytidine (decitabine) may be useful. Both induce HbF by inhibiting methylation of DNA, preventing the switch from γ- to β-globulin production. Decitabine appears to be safer and more potent than 5-azacytadine. In a small study in adults refractory to hydroxyurea, decitabine 0.2 mg/kg subcutaneously one to three times weekly was associated with an increase in HbF in all patients. Additionally, RBC adhesion was reduced. Neutropenia was the only significant toxicity reported.[6]

Combinations of HbF inducers

Very limited information is available on the use of combination therapy for potentiation of HbF production. Erythropoietin has shown inconsistent results in small numbers of patients. When used with hydroxyurea, erythropoietin has been shown to increase HbF to a greater extent than hydroxyurea alone, and although more studies are needed, this may provide an option for patients who do not respond to hydroxyurea alone.[27]

Chronic Transfusion Therapy

Chronic transfusion therapy is warranted to prevent serious complications from SCD, including stroke and recurrence. ❻ *Especially in children, chronic transfusions have been shown to decrease stroke recurrence from approximately 50% to 10% over 3 years.* Without chronic transfusions, approximately 70% of ischemic stroke patients will have another stroke. Chronic transfusion therapy also may be used to prevent vaso-occlusive pain and ACS, as well as prevent progression of organ damage. Patients receiving chronic transfusion therapy report increased energy levels, improved quality of life, and better exercise tolerance. Patients in whom chronic transfusion therapy should be considered include those with severe or recurrent ACS, debilitating pain, splenic sequestration, recurrent **priapism,** chronic organ failure, transient ischemic attacks, abnormal transcranial Doppler studies, intractable leg ulcers, severe chronic anemia in the presence of cardiac failure, and complicated pregnancies.[6,27]

Several methods of transfusion may be used, including simple transfusion, exchange transfusion, or erythrocytapheresis. The goal of chronic transfusion therapy is to maintain the HbS level at less than 30% (0.30) of total hemoglobin concentration. Transfusions usually are administered every 3 to 4 weeks depending on the HbS concentration. For secondary stroke prevention, current studies have indicated that lifelong transfusion may be required, with an increased incidence of recurrence once transfusions are stopped.[6]

The benefits of transfusion should be weighed against the risks. Risks associated with transfusions include alloimmunization (sensitization to the blood received), hyperviscosity, viral transmission, volume overload, iron overload, and transfusion reactions. Approximately 18% to 30% of SCD patients who receive transfusions will experience alloimmunization, which can be minimized by the use of leukocyte-reduced RBCs or HLA-matched units. Viral transmission is still a concern despite increased screening of blood donors and units. While the risk of contracting acquired immune deficiency syndrome (AIDS) has decreased dramatically, hepatitis C remains a concern. All SCD patients should be vaccinated for hepatitis A and B and should be monitored serially for hepatitis C and other infections. Parvovirus occurs in 1 in every 40,000 units of RBCs and can be associated with acute anemia and multiple sickle cell complications.[6] Iron overload remains a concern among patients maintained on chronic transfusions for greater than 1 year. Counsel patients to avoid excessive dietary iron, and monitor serum ferritin regularly. Chelation therapy with deferoxamine or deferasirox should be considered when the serum ferritin level is greater than 1500 to 2000 ng/mL (1500–2000 mcg/mL). Deferoxamine should be initiated at 20 to 40 mg/kg daily (to a maximum of 1–2 g/day) over 8 to 12 hours subcutaneously and has been associated growth failure.[6] Monitor children receiving deferoxamine for adequate growth and development on a regular basis. Deferoxamines should be initiated at 20 mg/kg daily and is available in a tablet that should be dispersed in water, orange juice, or apple juice and taken orally 30 minutes before food.[30,31] Monitor all chelation patients for auditory and ocular changes on a yearly basis. Exchange transfusions also may be helpful in cases of iron overload.

Sickle cell hemolytic transfusion reaction syndrome is a unique problem in SCD patients. Owing to alloimmunization, an acute or delayed transfusion reaction may occur. Delayed reactions typically occur 5 to 20 days after transfusion. Alloantibodies and autoantibodies resulting from previous

transfusions can trigger the reaction, in which patients develop symptoms suggestive of a pain crisis or worsening symptoms if they are already in crisis. A severe anemia after transfusion also may occur owing to a rapid decrease in hemoglobin and hematocrit, along with a suppression of erythropoiesis. Further transfusions may worsen the clinical picture owing to autoimmune antibodies. Recovery may occur only after ceasing all transfusions and is evidenced by a gradual increase in hemoglobin with reticulocytosis.[6,27]

Allogeneic Hematopoietic Stem Cell Transplant

Allogeneic hematopoietic stem cell transplantation (HSCT) is the only potential cure for SCD. The best candidates are children with SCD who are younger than 16 years of age with severe complications who have an identical HLA-matched donor, usually a sibling. The transplant-related mortality rate is between 5% and 10%, and graft rejection is approximately 10%. Other risks include secondary malignancies, development of seizures or intracranial bleeding, and infection in the immediate posttransplant period.[6,25,32,33]

Experience with HSCT in adult patients with SCD is very limited. Umbilical cord blood and hematopoietic cells from nonmatched donors are alternatives, but use is limited.[6,33]

Acute Complications

Transfusions for Acute Complications

Red cell transfusion is indicated in patients with acute exacerbations of baseline anemia; in cases of severe vaso-occlusive episodes, including ACS, stroke, and acute multiorgan failure; and in preparation for procedures that will require the use of general anesthesia or ionic contrast products. Transfusions also may be useful in patients with complicated obstetric problems, refractory leg ulcers, refractory and prolonged pain crises, and severe priapism. Hyperviscosity may occur if the hemoglobin level is increased to greater than 10 to 11 g/dL (100 to 110 g/L or 6.2–6.8 mmol/L). Volume overload leading to congestive heart failure is more likely to occur if the anemia is corrected too rapidly in patients with severe anemia and should be avoided.[6,27]

Infection and Fever

❼ *Any fever greater than 38.5°C in a SCD patient should be evaluated immediately (see Table 65–2), and the patient should have a blood culture drawn and be started on antibiotics that provide empirical coverage for encapsulated organisms.*[27] Patients who should be hospitalized include:

- Infants younger than 1 year of age
- Patients with a previous sepsis or bacteremia episode
- Patients with temperatures in excess of 40°C (104°F)
- Patients with WBC counts greater than 30,000/mm^3 (30 × 10^9/L) or less than 500/mm^3 (0.5 × 10^9/L) and/or platelets less than 100,000/mm^3 (100 × 10^9/L) with evidence of other acute complications
- Acutely ill appearing individuals

Broad intravenous antibiotic coverage for the encapsulated organisms can include ceftriaxone or cefotaxime. For patients with true cephalosporin allergy, clindamycin may be used. If staphylococcal infection is suspected owing to previous history or the patient appears acutely ill, vancomycin should be initiated. Macrolide antibiotics, such as erythromycin and azithromycin, may be initiated if *Mycoplasma* pneumonia is suspected. While the patient is receiving broad-spectrum antibiotics, their regular use of penicillin for prophylaxis can be suspended. Fever should be controlled with acetaminophen or ibuprofen. Because of the risk of dehydration during infection with fever, increased fluid may be needed.[6,27]

Bone infarcts or sickling in the periosteum usually is indicated by pain and swelling over an extremity. Osteomyelitis also should be considered. *Salmonella* species are the most common cause of osteomyelitis in SCD children, followed by *Staphylococcus aureus.* [27] Select an appropriate antibiotic to cover the suspected organisms empirically.

Cerebrovascular Accidents

Acute neurologic events, such as stroke, will require hospitalization and close monitoring. Patients should have physical and neurologic examinations every 2 hours.[27] Acute treatment may include exchange transfusion or simple transfusion to maintain hemoglobin at around 10 g/dL (100 g/L or 6.2 mmol/L) and HbS concentration at less than 30%. Patients with a history of seizure may need anticonvulsants, and interventions for increased intracranial pressure should be initiated if necessary. Children with a history of stroke should be initiated on chronic transfusion therapy. Adults presenting with ischemic stroke should be considered for thrombolytic therapy if it has been less than 3 hours since the onset of symptoms.[6,27]

Early detection of ischemic stroke can be done with the use of transcranial Doppler ultrasonography. In the Stroke Prevention Trial in Sickle Cell Anemia (STOP) study, screening with this method followed by transfusion significantly reduced the incidence of stroke.[29] Screening is recommended in all patients over 2 years of age.

Acute Chest Syndrome

ACS will require hospitalization for appropriate management of symptoms and to avoid complications. Patients should be encouraged to use incentive spirometry at least every 2 hours. Incentive spirometry helps the patient to take long, slow breaths to increase lung expansion. Appropriate management of pain is important, but analgesic-induced hypoventilation should be avoided. Patients should maintain appropriate fluid balance because overhydration can lead to pulmonary edema and respiratory distress. Infection with gram-negative, gram-positive, or atypical bacterial is common in ACS, and early use of broad-spectrum antibiotics, including a macrolide, quinolone, or cephalosporin, is recommended. Fat emboli, from infarction of the long bones, may lead to ACS. Oxygen therapy should be used in any patient presenting with respiratory distress or

hypoxia. Oxygen saturations, measured by pulse oximeter, should be maintained at 92% or above. Transfusions are indicated often, and patients who present with wheezing may require inhaled bronchodilators.[6,34,35]

The use of corticosteroids is controversial. While they may decrease the inflammation and endothelial cell adhesion seen with ACS, their use also has been associated with higher readmission rates for other complications. Tapered corticosteroids, nitric oxide therapy, and L-arginine are being evaluated for use in ACS in studies.[34,36]

Priapism

Stuttering priapism, where erection episodes last anywhere from a few minutes to less than 2 hours, resolves spontaneously. Erections lasting more than 2 hours should be evaluated promptly. By age 18, approximately 90% of SCD males will have had at least one episode of priapism. Goals of therapy are to provide pain relief, reduce anxiety, provide detumescense, and preserve testicular function and fertility. Initial treatment should include aggressive hydration and analgesia. Transfusion may or may not be helpful but should be considered in anemic patients. Avoid the use of ice packs owing to the risk of tissue damage.[6,27]

Both vasoconstrictors and vasodilators have been used in the treatment of priapism. Vasoconstrictors are thought to work by forcing blood out of the cavernosum and into the venous return. Aspiration of the penile blood followed by intracavenous irrigation with epinephrine (1:1,000,000 solution) has been effective with minimal complications.[37] In severe cases, surgical intervention to place penile shunts has been used, but there is a high failure rate, and the risk of complications, from skin sloughing to fistulas, limits its use.

Pseudoephedrine dosed at 30 to 60 mg/day taken at bedtime has been used to prevent or decrease the number of episodes of priapism.[6] Terbutaline 5 mg has been used orally to prevent priapism with mixed results.[38,39] Leuprolide, a gonadotropin-releasing hormone, also has been used for this indication. Hydroxyurea may be helpful in some patients. The use of antiandrogens is under investigation.[6,27]

Treatment of Acute Complications

Aplastic Crisis

Most patients in aplastic crisis will recover spontaneously. Therefore, treatment is supportive. If anemia is severe or symptomatic, transfusion may be indicated. Infection with human parvovirus B19 is the most common cause of aplastic crisis. Isolate infected patients because parvovirus is highly contagious. Pregnant women should avoid contact with infected patients because midtrimester infection with parvovirus may cause hydrops fetalis and stillbirth.[6,27]

Sequestration Crisis

RBC sequestration in the spleen in young children may lead to a rapid drop in hematocrit, resulting in hypovolemia, shock, and death. Treatment is RBC transfusion to correct the hypovolemia, as well as broad-spectrum antibiotics because infections may precipitate the crisis.[6,27]

Recurrent episodes are common and can be managed with chronic transfusions and splenectomy. Observation is used commonly in adults because their episodes are milder. Splenectomy usually is delayed until after age 2 years of age to lessen the risk of postsplenectomy septicemia. Patients with chronic hypersplenism should be considered for splenectomy.[6,40]

Vaso-Occlusive Pain Crisis

The mainstay of treatment for vaso-occlusive crisis includes hydration and analgesia (see Table 65–7). Pain may involve the extremities, back, chest, and abdomen. ⓢ *Patients with mild pain crises may be treated as outpatients with rest, warm compresses to the affected (painful) area, increased fluid intake, and oral analgesia. Patients with moderate to severe crises should be hospitalized.* Infection should be ruled out because it may trigger a pain crisis, and any patient presenting with fever or critical illness should be started on empirical broad-spectrum antibiotics. Patients who are anemic should be transfused to their baseline. Intravenous or oral fluids at 1.5 times maintenance is recommended. Close monitoring of the patient's fluid status is important to avoid overhydration, which can lead to ACS, volume overload, or heart failure.[6,27]

Aggressive pain management is required in patients presenting in pain crisis. Assess pain on a regular basis (every 2–4 hours), and individualize management to the patient. The use of pain scales may help with quantifying the pain rating. Obtain a good medication history of what has worked well for the patient in the past. Use acetaminophen or a nonsteroidal anti-inflammatory drug (NSAID) for treatment of mild to moderate pain. Patients with bone or joint pain who require intravenous medications may be helped by the use of ketorolac, the only injectable NSAID available. Because of the concern for side effects, including gastrointestinal bleeding, ketorolac should be used only for a maximum of 5 consecutive days. Monitor for the total amount of acetaminophen given daily because many products contain acetaminophen. Maximum dose of acetaminophen for adults is 4 g/day, and for children, five doses over a 24-hour period.[41] Add an opioid if pain persists or if pain is moderate to severe in nature. Combining an opioid with an NSAID can enhance the analgesic effects without increasing adverse effects.[42–44]

Severe pain should be treated with an opioid such as morphine, hydromorphone, methadone, or fentanyl. Moderate pain can be treated effectively in most cases with a weak opioid such as codeine or hydrocodone, usually in combination with acetaminophen. Meperidine should be avoided owing to its relatively short analgesic effect and its toxic metabolite, normeperidine. Normeperidine may accumulate with repeated dosing and can lead to central nervous system side effects including seizures.

Intravenous opioids are recommended for use in the treatment of severe pain owing to a rapid onset of action and ease in titration. Intramuscular injection should be avoided.

TABLE 65–7. Management of Acute Pain of SCD

Principles

- Treat underlying precipitating factors
- Avoid delays in analgesia administration
- Use pain scale to assess severity
- Choice of initial analgesic should be based on previous pain crisis pattern, history of response, current status, and other medical conditions
- Schedule pain medication; avoid as-needed dosing
- Provide rescue dose for breakthrough pain
- If adequate pain relief can be achieved with one or two doses of morphine, consider outpatient management with a weak opioid; otherwise hospitalization is needed for parenteral analgesics
- Frequently assess to evaluate pain severity and side effects; titrate dose as needed
- Treating adverse effects of opioids is part of pain management
- Consider nonpharmacologic intervention
- Transition to oral analgesics as the patient improves; choose an oral agent based on previous history, anticipated duration, and ability to swallow tablets; if sustained-release products are used, a fast-release product is also needed for breakthrough pain

Analgesic Regimens

Mild to moderate pain:

Acetaminophen with codeine
Dose based on codeine—children: 1 mg/kg per dose every 6 hours; adult: 30–60 mg/dose

Hydrocodone + acetaminophen
Dose based on hydrocodone—children: 0.2 mg/kg per dose every 6 hours; adults: 5–10 mg/dose

Anti-inflammatory agents
Use with caution in patients with renal failure (dehydration) and bleeding
Ibuprofen: children: 10 mg/kg every 6–8 hours; adult; 200–400 mg/dose
Naproxen: 5 mg/kg every 12 hours; adult 250–500 mg/dose
Ibuprofen + hydrocodone: Each tablet contains 200 mg ibuprofen and 7.5 mg hydrocodone per tablet; only for older children who can swallow tablets

Moderate to severe pain:

Morphine: 0.1–0.15 mg/kg per dose every 3–4 hours for children; 5–10 mg/dose for adults
Continuous infusion: 0.04–0.05 mg/kg per hour; titrate to effect

Hydromorphone: 0.015 mg/kg per dose every 3–4 hours for children; 1.5–2 mg/dose for adults
Continuous infusion: 0.004 mg/kg per hour; titrate to effect

Intravenous anti-inflammatory agents:
Ketorolac: 0.5 mg/kg up to 30 mg/dose every 6 hours

Patient-controlled analgesics:
Morphine: 0.01–0.03 mg/kg per hour basal; demand 0.01–0.03 mg/kg every 6–10 minutes; 4 hours lock out 0.04–0.06 mg/kg
Hydromorphone: 0.003–0.005 mg/kg per hour basal; demand 0.003–0.05 mg/kg every 6–10 minutes; 4 hours lock out 0.4–0.6 mg/kg

Rescue therapy:
For breakthrough, give $^1/_4$ to $^1/_2$ of the scheduled dose as bolus every 1–2 hours; assess amount of rescue dose used in 8–12 hours and readjust scheduled dose or infusion rate as needed

Other adjunct therapy:
Hydration, heating pads, relaxation, and distraction
Stool softener and/or stimulants for constipation
Antihistamine for itching
Antiemetics for nausea or vomiting

From Yale,[45] Jacob et al,[42] Berde et al,[43] Stinson et al,[44] Christensen et al,[88] and Elander et al.[89]

Analgesia should be individualized and titrated to effect either by scheduled doses or continuous infusion. The use of continuous infusion will avoid the fluctuations in blood levels between doses that is seen with bolus dosing. As needed dosing of analgesia is appropriate only for breakthrough pain or uncontrolled pain. Patient-controlled analgesia (PCA) is used commonly and allows the patient to have control over his or her analgesic breakthrough dosing. As the pain crisis resolves, the pain medications can be tapered. Physical therapy and relaxation therapy can be helpful adjuvants to analgesia.[42–45]

Tolerance to opioids is seen when patients have had continuous long-term use of the medications and can be managed during acute crises by using a different potent opioid or using a larger dose of the same medication. Adverse effects associated with the use of opioids include respiratory depression, itching, nausea and vomiting, constipation, and drowsiness. Patients on continuous infusions of opioids should be on continuous pulse oximeter to assess oxygen saturations. Monitor the patient for oxygen saturations less than 92%. Oxygen should be administered as needed to keep the saturations above 92%. Itching can

Patient Encounter 3

CC: "My right leg and lower back hurt badly."

HPI: CD is a 21-year-old African-American man diagnosed with SCD at birth. He has had repeated pain crises (average of about two per year) and presents today with another. He started feeling ill yesterday, and this morning he woke up with increased pain and a cough.

PMH
Frequent pain crises, acute chest syndrome last year, priapism

FH
Mother with sickle cell trait; father with sickle cell disease. Father died at age 36 from stroke. Has an older brother with SCD and a younger sister with SCT.

SH
CD is a college student. He lives in the dorm. Enjoys basketball.

PE
- Wt 64 kg (141 lbs), ht 6 ft (183 cm), BP 130/80, HR 90, RR 30, temp 40°C (104°F)
- **Lungs:** Decreased breath sounds in bases
- **Skin:** Warm, dry, tender, and increased warmth in right leg, nailbeds dusky, poor capillary refill
- **HEENT:** Sclera slightly yellow

Meds
- Tylenol 3, 2 tablets PO q4–6hours prn for pain
- Pseudoephedrine 30 mg PO twice daily

Allergies: NKDA

Laboratory Data
All within normal limits except
- Hemoglobin: 6.2 g/dL (62 g/L or 3.8 mmol/L)
- Hematocrit: 30% (0.30)
- WBC: 20,000/mm^3 (20 × 10^9/L)
- Total bilirubin: 2.2 mg/dL (37.6 µmol/L)

Based on the information presented, create a care plan for this patient's vaso-occlusive crisis. Your plan should include:

- A statement of the drug-related needs and/or problems
- The goals of therapy
- A patient-specific detailed therapeutic plan
- A plan for follow-up and monitoring to determine whether the goals have been achieved and adverse effects avoided

be managed with an antihistamine such as diphenhydramine. Nausea and vomiting can be treated and managed with the administration of antiemetics such as promethazine or the 5-HT$_3$ antagonists, but the use of promethazine is contraindicated in children younger than 2 years of age. Assess stool frequency in all patients on a continuous opioid, and start stool softeners or laxatives as needed. Excessive sedation is difficult to control, and the concurrent use of an opioid with diphenhydramine or other sedative medications can exacerbate the drowsiness, leading to hypoxemia. A continuous very low dose of naloxone, an opioid antagonist, has been used in some cases where the adverse effects such as itching are unbearable.[46]

OUTCOME EVALUATION

SCD treatment and prevention are considered successful when complications are minimized. The major outcome parameters are a decrease in morbidity and mortality, measured by the number of hospitalizations, and the extent of end-organ damage seen over time. SCD is a chronic disease that cannot be cured, except with transplantation.

Starting with birth, SCD patients should have regularly scheduled health assessments and interventions when necessary. Obtain a urine analysis, complete blood count, liver function tests, ferritin or serum iron level and total iron-binding capacity, blood urea nitrogen (BUN), and creatinine on at least a yearly basis and more often for children younger than 5 years of age to monitor for complications. All SCD patients also should have regular screening of their hearing and vision.

All patients and parents of children with SCD should have a plan for what to do in the event of symptoms of infection or pain. Obtain a medication history when patients are admitted to the hospital. Assess compliance with prophylactic penicillin and childhood immunization schedules in all pediatric SCD patients.

Patient Care and Monitoring

1. Assess the patient's symptoms to determine whether the patient should be evaluated by a physician and/or receive immediate care. Determine the type of symptoms, onset of symptoms, frequency and exacerbating factors. Does the patient have evidence of SCD-related complications?
2. Review any available diagnostic data to determine the severity and status of the patient's SCD. *When was the patient last hospitalized for SCD complications?*
3. Obtain a thorough history of prescription, nonprescription, and natural drug product use. For pain control, determine which treatments have been helpful to the patient in the past. *Is the patient currently taking any medications on a chronic basis?*
4. Educate the patient on lifestyle modifications that may lessen complications. These include maintaining adequate hydration status, avoiding extreme temperature changes, dressing appropriately for hot or cold weather, and avoiding physical exertion, smoking, and excessive alcohol intake.
5. Is the patient up to date on immunizations? Has the patient received his or her annual influenza vaccine? If not, why?

(Continued)

6. Is the patient taking appropriate doses of pain medication to achieve effect? If not, why?
7. Develop a plan to assess the effectiveness of pain medications.
8. Determine if the patient is a candidate for hydroxyurea therapy.
9. Assess improvement in quality-of-life measures, such as physical, psychological, and social functioning and well-being.
10. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.
11. Stress the importance of adherence with the therapeutic regimen, including lifestyle modifications. Recommend a therapeutic regimen that is easy for the patient/parent to accomplish.
12. Provide patient education on disease state, lifestyle modifications, and drug therapy; including:

- Possible complications of SCD, both long and short term
- When to take medications
- What potential adverse effects may occur
- Which drugs may interact with the medication therapy
- Warning signs to report to the physician (e.g., increased or new pain, sudden headache, bleeding or bruising, fever, loss of energy, loss of appetite)

ABBREVIATIONS

ACS:	acute chest syndrome
HbA:	normaladult hemoglobin
HbAS:	one normal and one sickle hemoglobin gene
HbC:	hemoglobin C
HbF:	fetal hemoglobin
HbS:	sickle hemoglobin
HbSβ^0-thalassemia:	one sickle hemoglobin and one β^0-thalassemia gene
HbSβ^+-thalassemia:	one sickle hemoglobin and one β^+-thalassemia gene
HbSC:	one sickle hemoglobin and one hemoglobin C gene
HbSS:	homozygous sickle hemoglobin
Hgb:	hemoglobin
HSCT:	hematopoietic stem cell transplantation
ISC:	irreversibly sickled cell
MCHC:	mean corpuscular hemoglobin concentration
MCV:	mean corpuscular volume
NSAID:	nonsteroidal anti-inflammatory drug
PCA:	patient-controlled analgesia
PCV 7:	7-valent pneumococcal conjugate vaccine
PPV 23:	23-valent pneumococcal polysaccharide vaccine
RBC:	red blood cell
SCA:	sickle cell anemia
SCD:	sickle cell disease
SCT:	sickle cell trait
STOP:	Stroke Prevention Trial in Sickle Cell Anemia
WBC:	white blood cell
VOC:	vaso-occlusive crisis

66 Antimicrobial Regimen Selection

Catherine M. Oliphant and Karl Madaras-Kelly

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Describe how antimicrobials differ from other drug classes in terms of their effects on individual patients as well as on society as a whole.
2. Recognize that antimicrobial resistance is an inevitable consequence of antimicrobial therapy.
3. Identify two guiding principles to consider when treating patients with antimicrobials, and apply these principles in patient care.
4. Differentiate between microbial colonization and infection based on patient history, physical examination, and laboratory and culture results.
5. Evaluate and apply at least six major drug-specific considerations when selecting antimicrobial therapy.
6. Evaluate and apply at least seven major patient-specific considerations when selecting antimicrobial therapy.
7. Select empirical antimicrobial therapy based on spectrum-of-activity considerations that provide a measured response proportional to the severity of illness. Provide a rationale for why a measured response in antimicrobial selection is appropriate.
8. Identify and apply five major principles of patient education and monitoring response to antimicrobial therapy.
9. Identify two common causes of patients failing to improve while on antimicrobials, and recognize other less common but potential reasons for antimicrobial failure.

Key Concepts

❶ An inevitable consequence of exposing microbes to antimicrobials is that some organisms will develop resistance to the antimicrobial.

❷ Antimicrobials are different from other classes of pharmaceuticals because they exert their action on bacteria infecting the host as opposed to acting directly on the host.

❸ Two guiding principles to consider when treating patients with antimicrobials are (1) make the diagnosis and (2) do no harm!

❹ Only bacteria that cause disease should be targeted with antimicrobial therapy, and colonizing flora should be left intact whenever possible.

❺ Bacterial cultures should be obtained prior to antimicrobial therapy in patients with a systemic inflammatory response, risk factors for antimicrobial resistance, or infections where diagnosis or antimicrobial susceptibility is uncertain.

❻ Empirical therapy should be based on patient- and antimicrobial-specific factors such as the anatomic location of the infection, the likely pathogens associated with the presentation, the potential for adverse effects, and the antimicrobial spectrum of activity.

❼ Drug-specific considerations in antimicrobial selection include the spectrum of activity, effects on nontargeted microbial flora, appropriate dose, pharmacokinetic and pharmacodynamic properties, adverse-effect and drug-interaction profile, and cost.

❽ Key patient-specific considerations in antimicrobial selection include recent previous antimicrobial exposures, identification of the anatomic location of infection through physical examination and diagnostic imaging, history of drug allergies, organ dysfunction that may affect drug clearance, immunosuppression, pregnancy, and compliance.

❾ Patient education, deescalation of antimicrobial therapy based on culture results, monitoring for clinical response and

adverse effects, and appropriate duration of therapy are important treatment components.

⑩ Inadequate diagnosis resulting in poor initial antimicrobial selection, poor source control, or the development of a new infection with a resistant organism is a relatively common cause of antimicrobial failure.

The discovery of antimicrobials is among the greatest medical achievements of the twentieth century. Prior to the antimicrobial era, patients who contracted common infectious diseases developed significant morbidity or perished. The discovery of penicillin in 1927, followed by the subsequent discovery of other antimicrobials, contributed to a significant decline in infectious disease–related mortality during the next five decades. However, since 1980, infectious diseases related mortality in the United States have begun to increase, in part owing to increases in antimicrobial resistance.

The discovery of virtually every new class of antimicrobials has occurred in response to the development of bacterial resistance and loss of clinical effectiveness to existing antimicrobials. ❶ *An inevitable consequence of exposing microbes to antimicrobials is that some organisms will develop resistance to the antimicrobial.* Today, there are dozens of antimicrobial classes and hundreds of antimicrobials available for clinical use. However, in many cases, differences in mechanisms of action between antimicrobials are minor, and the microbiologic properties of the agents are similar. ❷ *Antimicrobials are different from other classes of pharmaceuticals because they exert their action on bacteria infecting the host as opposed to acting directly on the host.* Because use of an antimicrobial in one patient affects not only that patient but also other patients if they become infected with resistant bacteria, correct selection, use, and monitoring of clinical response are paramount.

❸ *There are two guiding principles to consider when treating patients with antimicrobials: (1) make the correct diagnosis and (2) do no harm!* Frequently, patients with infections may present with signs and symptoms that are nonspecific for infection and may be confused with other noninfectious disease. Not only is it important to determine if a disease process is of infectious origin, but it is also important to determine the specific causative pathogen of the infection. Antimicrobials vary in their ability to inhibit or kill different species of bacteria, or their ***spectrum of activity.*** Antimicrobials that kill many different species of bacteria are called *broad-spectrum antimicrobials,* whereas antimicrobials that kill only a few different species of bacteria are called *narrow-spectrum antimicrobials.* One might argue that treating everybody with very broad antimicrobial coverage will increase the likelihood that a patient will get better without making a definitive diagnosis. However, counter to this argument is the principle of "Do no harm!" Very broad antimicrobial coverage does increase the likelihood of empirically targeting a causative pathogen; unfortunately, the development of secondary infections caused by selection of antimicrobial-resistant nontargeted pathogens is a common problem. In addition, adverse events are thought to complicate up to 10% of all antimicrobial therapy, and for select agents, the adverse-event rate is much higher.[1] Therefore, the overall goal of antimicrobial therapy should be to cure the patient's infection; limit harm by minimizing patient risk for adverse effects, including secondary infections; and limit societal risk from antimicrobial-resistant bacteria.

EPIDEMIOLOGY AND ETIOLOGY

Infectious disease–related illnesses, particularly respiratory tract infections, are among the most common reasons patients seek medical care.[2] Three of the top 20 prescription medicines dispensed in the United States during 2004 were antimicrobials, with total prescriptions exceeding 220 million.[3] Approximately two-thirds of outpatient antimicrobial use is prescribed for respiratory tract infections, and the Centers for Disease Control and Prevention (CDC) estimate that approximately one-third to one-half of all outpatient antimicrobials are used inappropriately to treat nonbacterial processes.[4] Prescription of antimicrobials in hospitalized patients is also common because up to one-half of all patients receive at least one antimicrobial during hospitalization. In addition, the CDC estimates that almost 2 million **nosocomial** or hospital-acquired infections and 90,000 related deaths occur annually.[5] Generally nosocomial infections tend be associated with more antimicrobial-resistant strains of bacteria. In recent years, there has been a shift in the etiology of some community-acquired infections. Increasingly, infections owing to antimicrobial-resistant pathogens, traditionally nosocomial in origin, are being identified in ambulatory-care settings. Reasons for this change include an aging populace, improvement in the management of chronic comorbid conditions including immunosuppressive conditions, and increases in outpatient management of more debilitated patients. The converging bacterial etiologies and increasing resistance in all health care environments emphasize the need to "make the diagnosis."

PATHOPHYSIOLOGY

Normal Flora and Endogenous Infection

Many areas of the human body are colonized with bacteria—this is known as ***normal flora***. Infections often arise from one's own normal flora (also called an *endogenous infection*). Endogenous infection may occur when there are alterations in the normal flora (e.g., recent antimicrobial use may allow for overgrowth of other normal flora) or disruption of host defenses (e.g., a break or entry in the skin). Knowing what organisms reside where can help to guide empirical antimicrobial therapy (Fig. 66–1). In addition, it is beneficial to know what anatomic sites are normally sterile. These include the cerebrospinal fluid, blood, and urine.

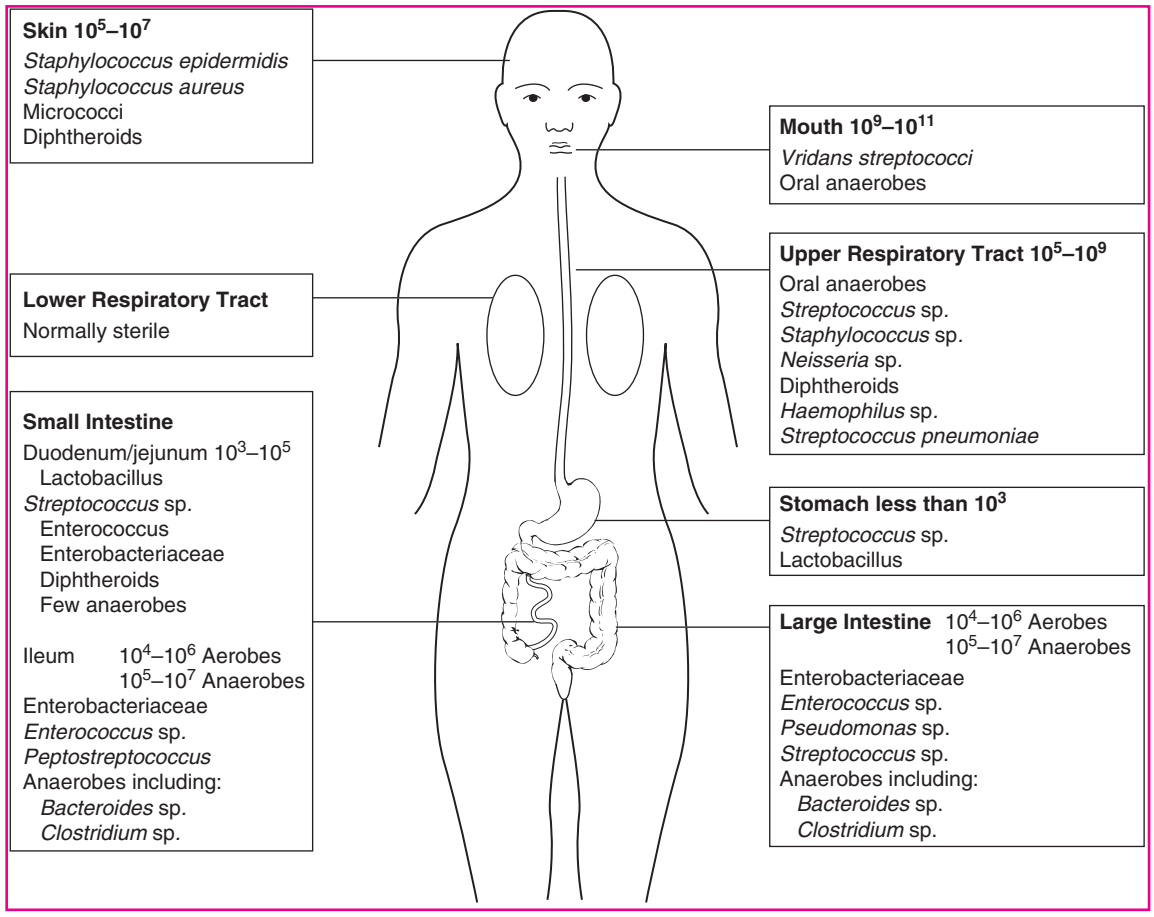

FIGURE 66–1. Normal flora and concentrations of bacteria (organisms per milliliter).

Determining Colonization versus Infection

Infection refers to the presence of bacteria that are causing disease (e.g., the organisms are found in normally sterile anatomic sites or in nonsterile sites with signs/symptoms of infection). *Colonization* refers to the presence of bacteria that are not causing disease. ❹ *Only bacteria that cause disease should be targeted with antimicrobial therapy, and non-disease-producing colonizing flora should be left intact.* It is important to differentiate infection from colonization because antimicrobial therapy targeting bacterial colonization is inappropriate and may lead to the development of resistant bacteria.

Exogenously Acquired Bacterial Infections

Infections acquired from an external source are referred to as *exogenous infections*. These infections may occur as a result of human-to-human transmission, contact with exogenous bacterial populations in the environment, and animal contact. Resistant pathogens such as methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant *Enterococcus* spp. (VRE) may colonize hospitalized patients or patients who access the health care system frequently. It is key to know which patients have acquired these organisms because patients generally become colonized prior to developing infection, and colonized patients should be placed in isolation (per infection-control policies) to minimize transmission to other patients.

Contrasting Bacterial Virulence and Resistance

Virulence refers to the pathogenicity or disease severity produced by an organism. Many bacteria may produce toxins or possess growth characteristics that contribute to their pathogenicity. Some virulence factors allow the organism to avoid the immune response of the host and cause significant disease. Virulence and resistance are different microbial characteristics. For example, *Streptococcus pyogenes,* a common cause of skin infections, produces toxins that can cause severe disease, yet it is very susceptible to penicillin. *Enterococcus faecium* is a highly resistant organism but is frequently a colonizing flora that causes disease primarily in the immunocompromised.

Patient Encounter, Part 1

HPI

A 72-year-old man with a history of congestive heart failure, diabetes, hypertension, and hyperlipidemia presents to the local emergency room with complaints of increasing shortness of breath, cough productive of yellow-green sputum, chest pain, fever, and malaise. He was hospitalized 12 days ago for urosepsis, for which he received 10 days of levofloxacin.

PMH

- Congestive heart failure, diabetes mellitus × 22 years, hypertension, hyperlipidemia
- Chronic renal insufficiency: baseline SCr 1.8 mg/dL (137.3 μmol/L)

FH

- Father died of a myocardial infarction at age 75.
- Mother died of complications after cerebrovascular accident (CVA) at age 87.

SH

- Retired accountant
- Alcohol: 2 to 3 drinks per day

Meds

- Enalapril 10 mg bid
- Metoprolol XL 25 mg daily
- Furosemide 40 mg daily
- Insulin glargine (Lantus) 30 units SC qhs
- Glipizide 10 mg daily
- Atorvastatin 20 mg daily
- Aspirin 81 mg daily
- Home oxygen at 2 L/minute

- What information in the history supports an infectious etiology?
- Is this patient at risk for resistant pathogens? Why?

CLINICAL PRESENTATION AND DIAGNOSIS

Physical Examination

Findings on physical examination, along with the clinical presentation, can help to provide the anatomic location of the infection. Once the anatomic site is identified, the most probable pathogens associated with disease can be determined based on likely endogenous or exogenous flora.

Fever often accompanies infection and is defined as a rise in body temperature above the normal 98.6°F (37°C). Oral and axillary temperatures may underestimate core temperature by at least 1°F, whereas rectal temperatures best approximate core temperatures. Fever is a host response to bacterial toxins. However, bacterial infections are not the sole cause of fever. Fever also may be caused by other infections (e.g., fungal or viral), medications (e.g., penicillins, cephalosporins, salicylates, and phenytoin), trauma, or other medical conditions (e.g., autoimmune disease, malignancy, pulmonary embolism, and hyperthyroidism). Some patients with infections may present with hypothermia (e.g., patients with overwhelming infection). Elderly patients may be afebrile, as may those with

Clinical Presentation

- Review of symptoms consistent with an infectious etiology?
- Signs and symptoms may be nonspecific (e.g., fever) or specific.
- Specific signs and symptoms are beyond the scope of this chapter (see disease-state-specific chapters for these findings).

Patient History

- History of present illness
- Comorbidities
- Current medications
- Allergies
- Previous antibiotic exposure (May provide clues as to colonization or infection with new specific pathogens or pathogens that may be resistant to certain antimicrobials)
- Previous hospitalization or health care utilization (Also a key determinant in selecting therapy because the patient may be at risk for specific pathogens and/or resistant pathogens)
- Travel history
- Social history
- Pets/animal exposure
- Occupational exposure
- Environmental exposure

Physical Findings

- Findings consistent with an infectious etiology?
- Vital signs
- Body system abnormalities (e.g., rales, altered mental status, localized inflammation, erythema, warmth, edema, pain, and pus)

Diagnostic Imaging

- Radiographs (x-rays)
- Computed tomographic (CT) scans
- Magnetic resonance imaging (MRI)
- Labeled leukocyte scans

Non-Microbiologic Laboratory Studies

- White blood cell count with differential
- Erythrocyte sedimentation rate
- C-reactive protein

Microbiologic Studies

- Gram stain
- Culture and susceptibility testing

Patient Encounter, Part 2: Review of Symptoms, Physical Examination, and Laboratory Data

ROS

Patient with malaise, wheezing, dyspnea, cough, chest pain, and chills. No reports of emesis or diarrhea but with decreased appetite.

PE

- **VS:** BP 160/88, P 84, RR 28, T 39.1°C, O_2sat 86%, Ht 6 ft, 0 in, Wt 80 kg
- **HEENT:** Dry mucous membranes
- **Chest:** Rales and rhonchi R greater than L; diminished breath sounds RML and RLL
- **CV:** Tachycardic with regular rhythm; normal heart sounds

Laboratory Data

- WBC 18,800/mm^3, segs 80%, bands 10%, lymphs 10%
- SCr 2.5 mg/dL (190.8 μmol/L)
- Glucose 322 mg/dL (17.9 mmol/L)
- Sputum Gram stain: less than 10 epithelial cells, greater than 25 WBCs, predominance of gram-negative bacilli

Chest X-Ray

Pulmonary infiltrate right middle and lower lobes of right lung

- What findings on physical examination are suggestive of an infectious process?
- What laboratory findings and/or diagnostic studies have been performed to help establish the presence of an infection?
- Are these laboratory and diagnostic studies suggestive of an infection?
- What is your working diagnosis based on this patient encounter?

localized infections (e.g., urinary tract infection).[6] For others, fever may be the only indication of infection. For example, neutropenic patients may not have the ability to mount normal immune responses to infection (e.g., infiltrate on chest x-ray, pyuria on urinalysis, and erythema or induration around catheter site), and the only finding may be fever.

Imaging Studies

Imaging studies also may help to identify anatomic localization of the infection. These studies usually are performed in conjunction with other tests to establish or rule out the presence of an infection. X-rays are performed commonly to establish the diagnosis of pneumonia, as well as the severity of disease (single versus multilobe involvement). CT scans are a type of x-ray that produces a three-dimensional image of the combination of soft tissue, bone, and blood vessels. In contrast, MRI use electromagnetic radio waves to produce two- or three-dimensional images of soft tissue and blood vessels with less detail of bony structures. MRI produce more detailed images of soft tissues and organs than CT scans, whereas CT scans produce more detailed images of bones.

Non-Microbiologic Laboratory Studies

Common non-microbiological laboratory tests include the white blood cell (WBC) count and differential, erythrocyte sedimentation rate (ESR), and determination of the C-reactive protein level. In most cases, the WBC count is elevated in response to infection, but it may be decreased owing to overwhelming or long-standing infection. The differential is the percentage of each type of WBC (Table 66–1). In response to infection, neutrophils leave the bloodstream and enter the tissue to "fight" against the offending pathogens (i.e., leukocytosis). During an infection, immature neutrophils (e.g., bands) are released at an increased rate to help fight infection, leading to what is known as a *bandemia or left shift.* Therefore, a WBC count differential is key to determining if an infection is present. It is important to note that some patients may present with a normal total WBC with a left shift (e.g., the elderly). The erythrocyte sedimentation rate (ESR) and C-reactive protein are nonspecific markers of inflammation. They increase as a result of the acute-phase reactant response, which is a response to inflammatory stimuli such as infection or tissue injury. These tests may be used as markers of infectious disease response because they are elevated when the disease is acutely active and usually fall in response to successful treatment. Clinicians may use these tests to monitor a patient's response to therapy in osteomyelitis and infective endocarditis. These tests should not be used to diagnose infection because they may be elevated in noninfectious inflammatory conditions (e.g., rheumatoid arthritis, polymyalgia rheumatica, and temporal arteritis).

Microbiologic Studies

Microbiologic studies that allow for direct examination of a specimen (e.g., sputum, blood, or urine) also may aid in a presumptive diagnosis and give an indication of the characteristics of the infecting organism. Generally, microbial cultures are obtained with a Gram stain of the cultured material.

A Gram stain of collected specimens can give rapid information that can be applied immediately to patient care. A Gram stain is performed to identify if bacteria are present and to determine morphologic characteristics of bacteria (such as gram-positive or gram-negative or shape—cocci, bacilli). Certain specimens do not stain well or at all and must be identified by alternative staining techniques (*Mycoplasma* spp., *Legionella* spp., *Mycobacterium* spp.) Figure 66–2 identifies bacterial pathogens as classified by Gram stain and morphologic characteristics. The presence of WBCs on a Gram stain indicates inflammation and suggests that the identified bacteria are pathogenic. The Gram stain may be useful in judging a sputum specimen's adequacy. For example, the presence of epithelial

TABLE 66–1. White Blood Cell Count and Differential

Type of Cell	Normal Value	Function	Abnormalities
Neutrophil	Segs 40%–60% Bands 3%–5%	Phagocytic	Leukocytosis • Bacterial infections • Fungal infections • Physiologic stress • Tissue injury (e.g. myocardial Infarction) • Medications (e.g. corticosteroids) Leukopenia • Long-standing infection • Cancer • Medications (e.g., chemotherapy)
Lymphocyte	20–40%	T cells (cell-mediated immunity) B cells (humoral antibody response)	Lymphocytosis • Viral infections (e.g., mononucleosis) • Tuberculosis • Fungal infections Lymphopenia • human immunodeficiency virus
Monocyte	2%–8%	Phagocytic Precursor to macrophage	Monocytosis • Tuberculosis • Protozoal infections • Leukemia

Basophil	Less than 1%		Hypersensitivity reactions

cells on sputum Gram stain suggests that the specimen is either poorly collected or contaminated. A poor specimen can give misleading information with regard to the underlying pathogen and is a waste of laboratory personnel time and patient cost.

Culture and susceptibility testing provides additional information to the clinician to guide appropriate therapy. Specimens are placed in or on culture media that provide the proper growth conditions. Once the bacteria grow on culture media, they can be identified through a variety of biochemical tests. Once a pathogen is identified, susceptibility tests can be performed to various antimicrobial agents. The *minimum inhibitory concentration* (MIC) is a standard susceptibility test. The MIC is the lowest concentration of antimicrobial that inhibits visible bacterial growth after approximately 24 hours (Fig. 66–3). Breakpoint and MIC values determine if the organism is susceptible (S), intermediate (I), or resistant (R) to an antimicrobial. The *breakpoint* is the concentration of the antimicrobial that can be achieved in the serum after a normal or standard dose of that antimicrobial. If the MIC is below the breakpoint, the organism is considered to be susceptible to that agent. If the MIC is above the breakpoint, the organism is said to be resistant. Reported culture and susceptibility results generally do not provide MIC values but report the S, I, and R results.

❺ *In general, bacterial cultures should be obtained prior to initiating antimicrobial therapy in patients with a systemic inflammatory response, risk factors for antimicrobial resistance, or infections where diagnosis or antimicrobial susceptibility is uncertain.* The decision to culture depends on the sensitivity and specificity of the physical findings, diagnostic examination findings, and whether or not the pathogens are readily predictable. Culture and susceptibility testing usually is not warranted in a young, otherwise healthy woman who presents with signs and symptoms consistent with a urinary tract infection (UTI) because the primary pathogen, *Escherichia coli,* is readily predictable. Cultures and susceptibility testing are routine for sterile-site specimens (e.g., blood and spinal fluid), as well as for material presumed to be infected (e.g., material obtained from joints and abscesses). Cultures need to be interpreted with caution. Poor specimen collection technique and processing speed can result in misleading information and inappropriate use of antimicrobials.

Laboratory tests to direct antimicrobial pharmacotherapy. In: In DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 1894.)

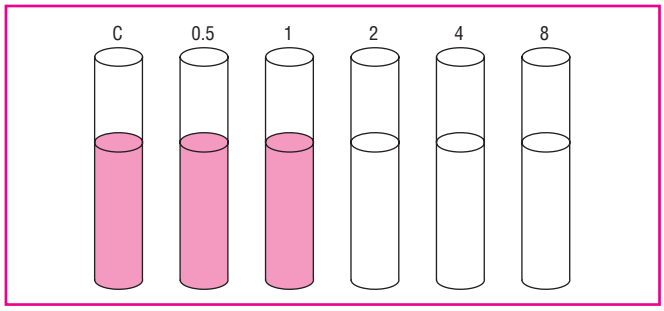

FIGURE 66–3. Macrotube minimal inhibitory concentration (MIC) determination. The growth control (C), 0.5 mg/dL, and 1 mg/dL tubes are visibly turgid, indicating bacterial growth. The MIC is read as the first clear test tube (2 mg/dL). (Reprinted from Rybak MJ, Aeschlimann JR. Laboratory tests to direct antimicrobial pharmacotherapy. In: In DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 1897.)

TREATMENT

General Approach to Treatment, Including Nonantimicrobial Treatment

While selection of antimicrobial therapy may be a major consideration in treating infectious diseases, it may not be the only therapeutic intervention. Other important therapies may include adequate hydration, ventilatory support, and other supportive medications. In addition, antimicrobials are unlikely to be effective if the process or source that leads to the infection is not controlled. ***Source control*** refers to this process and may involve removal of prosthetic materials such as catheters and infected tissue or drainage of an abscess. Source-control considerations should be a fundamental component of any infectious diseases treatment. It is also important to recognize that there may be many different antimicrobial regimens that may cure the patient. While the following therapy sections

Patient Encounter, Part 3: Empirical Selection of Antibiotics

Based on the information presented, select an empirical antimicrobial regimen for this patient. Your plan should include (1) a tentative infectious diagnosis or source, including likely pathogens or resistant organisms, (2) a specific antimicrobial(s) regimen, including drug(s), dose, and route of administration, (3) description of any ancillary treatments, and (4) a rationale for your empirical antimicrobial selection based on drug- and patient-specific considerations.

provide factors to consider when selecting antimicrobial regimens, an excellent and more in-depth resource for selecting antimicrobial regimens for a variety infectious diseases is the *Infectious Diseases Society of America Guidelines*.[7]

Antimicrobial Considerations in Selecting Therapy

❻ *Drug-specific considerations in antimicrobial selection include spectrum of activity, effects on nontargeted microbial flora, appropriate dose, pharmacokinetic and pharmacodynamic properties, adverse-effect and drug-interaction profile, and cost* (Table 66–2).

Spectrum of Activity and Effects on Nontargeted Flora

Most initial antimicrobial therapy is empirical because cultures usually have not had sufficient time to identify a pathogen. ❼ *Empirical therapy should be based on patient- and antimicrobial-specific factors such as the anatomic location of the infection, the likely pathogens associated with the presentation, the potential for adverse effects in a given patient, and the antimicrobial spectrum of activity.* Prompt initiation of appropriate therapy is paramount in hospitalized patients who are critically ill. Patients who receive initial antimicrobial therapy that provides coverage against the causative pathogen survive at twice the rate of patients who do not receive adequate therapy initially.[8]

TABLE 66–2. Considerations for Selecting Antimicrobial Regimens

Drug-Specific	Patient-Specific
Spectrum of activity and effects on nontargeted flora	Anatomic location of infection
Dosing	Antimicrobial history
Pharmacokinetic properties	Drug allergy history
Pharmacodynamic properties	Renal and hepatic function
Adverse-effect potential	Concomitant medications
Drug-interaction potential	Pregnancy or lactation
Cost	Compliance potential

Empirical selection of antimicrobial spectrum of activity should be related to the severity of the illness. Generally, acutely ill patients may require broader-spectrum antimicrobial coverage, whereas less ill patients may be managed initially with narrow-spectrum therapy. While a detailed description of antimicrobial pathogen– specific spectrum of activity is beyond the scope of this chapter, this information can be obtained readily from a number of sources.[9,10]

Collateral damage is defined as the development of resistance occurring in a patient's nontargeted antimicrobial flora that can cause secondary infections. For example, clindamycin is an excellent antimicrobial for treating streptococcal infections. However, many antimicrobials can treat this relatively susceptible pathogen. Clindamycin also readily selects for resistance in a nontargeted organism that may be present in the intestinal tract, namely, *Clostridium difficile*. Collateral damage is manifested because clindamycin is considered to be a major risk factor for *C. difficile*–associated diarrhea.[11] If several different antimicrobials possess activity against a targeted pathogen, the antimicrobial that is least likely to be associated with collateral damage may be preferred.

Single versus Combination Therapy

A common subject of debate involves the need to provide similar bacterial coverage with two antimicrobials for serious infections. Proponents state that double coverage may be synergistic, prevent the emergence of resistance, and improve outcome. However, there are few clinical examples in the literature to support these assertions. Examples where double coverage is considered superior are limited to infections associated with large bacterial inocula and in species that are known to readily develop resistance such as active tuberculosis or enterococcal endocarditis.[12,13] A study of patients with *Pseudomonas aeruginosa* infections, an intrinsically resistant organism, demonstrated that empirical double coverage with two antipseudomonal antimicrobials improved survival.[14] The analysis found that combination therapy increased the likelihood of appropriate empirical coverage; however, once organism susceptibilities were known, there was no difference in outcome between double coverage and monotherapy. In summary, double antimicrobial coverage with similar spectra of activity may be beneficial for selected infections associated with high bacterial loads or for initial empirical coverage of critically ill patients in whom antimicrobial-resistant organisms are suspected. Monotherapy usually is satisfactory once antimicrobial susceptibilities are established.

Antimicrobial Dose

Clinicians should be aware that dosage regimens with the same drug maybe different depending on the infectious process. For example, ciprofloxacin, a fluoroquinolone, has various dosage regimens based on site of infection. The dosing for uncomplicated UTIs is 250 mg twice daily for 3 days. For complicated UTIs, the dose is 500 mg twice daily for 7 to

14 days. Severe complicated pneumonia requires a dosage regimen of 750 mg twice daily for 7 to 14 days. Clinicians are encouraged to use dosing regimens designed for treatment of the specific diagnosed infection because they have demonstrated proven efficacy and are most likely to minimize harm.

Pharmacokinetic Properties

Pharmacokinetic properties of an antimicrobial may be important in antimicrobial regimens. *Pharmacokinetics* refers to a mathematical method of describing a patient's drug exposure in vivo in terms of absorption, distribution, metabolism, and elimination. *Bioavailability* refers to the amount of antimicrobial that is absorbed orally relative to an equivalent dose administered intravenously. Drug-related factors that may affect oral bioavailability include the salt formulation of the antimicrobial, the dosage form, and the stability of the drug in the gastrointestinal tract. Frequently, absorption may be affected by gastrointestinal tract blood flow. All patients that manifest systemic signs of infection such as hypotension or hypoperfusion should receive intravenous antimicrobials to ensure drug delivery. In almost all cases where patients have a functioning gastrointestinal tract and are not hypotensive, antimicrobials with almost complete bioavailability (greater than 80%) such as the fluoroquinolones, fluconazole, and linezolid may be given orally. With antimicrobials with modest bioavailability (e.g., many β-lactams), the decision to choose an oral product will depend more on the severity of the illness and the anatomic location of the infection. In sequestered infections, where higher systemic concentrations of antimicrobial may be necessary to reach the infected source (e.g., meningitis) or for antimicrobials with poor bioavailability, intravenous formulations should be used.

Several points regarding how the antimicrobial distributes into tissue are worth mentioning. First, only antimicrobials not bound to albumin are biologically active. Protein binding is likely clinically irrelevant in antimicrobials with low or intermediate protein binding. However, highly protein bound antimicrobials (greater than 50%) also may not be able to penetrate sequestered compartments, such as cerebral spinal fluid, resulting in insufficient concentration to inhibit bacteria. Second, some drugs may not achieve sufficient concentrations in specific compartments based on distribution characteristics. For example, *Legionella pneumophilia* is a nonenteric gram-negative organism that causes severe pneumonia. The organism is known to survive and reside inside pulmonary macrophages. Treatment with an antibiotic that works by inhibiting bacterial cell wall synthesis, such as a cephalosporin, will be ineffective because it only distributes into extracellular host tissues. However, macrolide or fluoroquinolone antimicrobials, which concentrate in human pulmonary macrophages, are highly effective against pneumonia caused by this organism.

Many antimicrobials undergo some degree of metabolism once ingested. Metabolism may occur via hepatic, renal, or non-organ-specific enzymatic processes. The route of elimination of the metabolic pathway may be exploited for infections associated with tissues related to the metabolic pathways. For example, many fluoroquinolone antimicrobials are metabolized only in part and undergo renal elimination. Urinary concentrations of active drug are many times those achieved in the systemic circulation, making several of these agents good choices for UTIs.

Pharmacodynamic Properties

Pharmacodynamics describes the relationship between drug exposure and pharmacologic effect of antibacterial activity or human toxicology. Antimicrobials generally are categorized based on their concentration-related effects on bacteria. Concentration-dependent pharmacodynamic activity occurs where higher drug concentrations are associated with greater rates and extents of bacterial killing. Concentration-dependent antimicrobial activity is maximized when peak antimicrobial concentrations are high. In contrast, *concentration-independent activity* refers to a minimal increase in the rate or extent of bacterial killing with an increase in antimicrobial dose. Concentration-independent antimicrobial activity is maximized when these antimicrobials are dosed to maintain blood and/or tissue concentrations above the MIC in a time-dependent manner. Fluoroquinolones, aminoglycosides, and metronidazole are examples of antimicrobials that exhibit concentration-dependent activity, whereas β-lactam and glycopeptide antimicrobials exhibit concentration-independent activity. Pharmacodynamic properties have been optimized to develop new dosing strategies for older antimicrobials. Examples include single-daily-dose aminoglycoside or β-lactam therapy administered by continuous infusion. The product labeling for many new antimicrobials takes pharmacodynamic properties into account.

Antimicrobials also can be classified as possessing bactericidal or bacteriostatic activity in vitro. Bactericidal antibiotics generally kill at least 99.9% (3 log reduction) of a bacterial population, whereas bacteriostatic antibiotics possess antimicrobial activity but reduce bacterial load by less than 3 logs. Clinically, bactericidal antibiotics may be necessary to achieve success in infections such as endocarditis or meningitis. A full discussion of the application of antimicrobial pharmacodynamics is beyond the scope of this chapter, but excellent sources of information are available.[15]

Adverse-Effect and Drug-Interaction Properties

A major concern when selecting antimicrobial regimens should be the propensity for the regimen to cause adverse effects and the potential for interaction with other drugs. Patients may possess characteristics or risk factors that increase their likelihood of developing an adverse event, emphasizing the need to obtain a good patient medical history. In general, if several different antimicrobial options are available, antimicrobials with a low propensity to cause specific adverse events should selected, particularly for patients with

risk factors for a particular complication. Risk factors for adverse events may include the coadministration of other drugs that are associated with a similar type of adverse event. For example, coadministration of the known nephrotoxin gentamicin with vancomycin increases the risk for nephrotoxicity compared with administration of either drug alone.[16] Other drug interactions may predispose the patient to dose-related toxicity through inhibition of drug metabolism. For example, erythromycin has the potential to prolong cardiac QT intervals in a dose-dependent manner, potentially increasing the risk for sudden cardiac death. A cohort study of patients taking oral erythromycin found that patients with concomitantly prescribed medications that inhibited the metabolism of erythromycin exhibited a fivefold increase in cardiac death versus controls.[17]

Antimicrobial Cost

A final consideration in selecting antimicrobial therapy relates to cost. It is important to remember that the most inexpensive antimicrobial is not necessarily the most cost-effective antimicrobial. Antimicrobial costs constitute a relatively small portion of the overall cost of care. Frequently, regulatory studies are not designed to identify differences in hospital length of stay, less common adverse events, monitoring costs, collateral damage, or antimicrobial-specific resistance issues, all of which may contribute to medical costs. Careful consideration of antimicrobial microbiologic, pharmacologic, and patient-related factors such as compliance and a variety of clinical outcomes is necessary to establish the cost versus benefit of an antimicrobial in a given patient. If there is no difference or a small difference in these factors, the least costly antimicrobial may be the best choice.

Patient Considerations in Antimicrobial Selection

❸ *Key patient-specific considerations in antimicrobial selection include recent previous antimicrobial exposures, identification of the anatomic location of infection through physical examination and diagnostic imaging, history of drug allergies, pregnancy or breast-feeding status, organ dysfunction that may affect drug clearance, immunosuppression, compliance, and the severity of illness (see Table 66–2)*

Host Factors

Host factors can help to ensure selection of the most appropriate antimicrobial agent. Age is an important factor in antimicrobial selection. With regard to dose and interval, renal and hepatic function varies with age. Populations with diminished renal function include neonates and the elderly. Hepatic function in the neonate is not fully developed, and drugs that are metabolized or eliminated by this route may produce adverse effects. For example, sulfonamides and ceftriaxone may compete with bilirubin for binding sites and may result in hyperbilirubinemia and kernicterus. Gastric acidity also depends on age; the elderly and children younger than 3 years of age tend to be achlorhydric. Drugs that need an acidic environment (e.g., ketoconazole) are not well absorbed, and those whose absorption is enhanced in an alkaline environment will have increased concentrations (e.g., penicillin G).

Disruption of host defenses owing to intravenous catheters, indwelling Foley catheters, burns, trauma, surgery, and increased gastric pH (secondary to antacids, H_2 blockers, and proton pump inhibitors) may place patients at higher risk for infection. Breaks in and entry into the skin provide a route for infection because the natural barrier of the skin is disrupted. Increased gastric pH can allow for bacterial overgrowth and has been associated with an increased risk of pneumonia.[18]

Recognizing the presumed site of infection and most common pathogens associated with the infectious source should guide antimicrobial choice, dose, and route of administration. For example, community-acquired pneumonia is caused most commonly by *S. pneumoniae, E. coli* is the primary cause of uncomplicated UTIs, and staphylococci and streptococci are implicated most frequently in skin and skin-structure infections (e.g., cellulitis).

Patients with a history of recent antimicrobial use may have altered normal flora or harbor resistant organisms. If a patient develops a new infection while on therapy, fails therapy, or has received antimicrobials recently, it is prudent to prescribe a different class of antimicrobial because resistance is likely. Previous hospitalization or health care utilization (e.g., residing in a nursing home, hemodialysis, and outpatient antimicrobial therapy) are risk factors for the acquisition of nosocomial pathogens, which are often resistant organisms.

Antimicrobial allergies are some of the most common drug-related allergies reported and have significant potential to cause adverse events. In particular, penicillin-related allergy is common and can be problematic because there is an approximately 4% cross-reactivity with cephalosporins as well as carbapenems.[19] In general, a patient's medical history should be reviewed to determine the offending β-lactam and nature of the allergic reaction. In some cases, patients with mild or nonimmunologic reactions may receive a β-lactam antimicrobial with low cross-reactive potential. However, patients with a history of physical findings consistent with IgE-mediated reactions such as anaphylaxis, urticaria, or bronchospasm should not be administered any type of β-lactam antimicrobial, including cephalosporins, unless there are no other alternatives. Administration of potentially cross-reactive agents in this situation should occur only under controlled conditions, and some patients may need to undergo desensitization. If the specific medical history relating to a reported allergy cannot be obtained, the patient should be assumed to have had an IgE-mediated reaction and should be managed in a similar manner.

Renal and/or hepatic function should be considered in every patient prior to initiation of antimicrobial therapy. In general, most antimicrobials undergo renal elimination and

exhibit decreased clearance with diminished renal function, and dosing adjustments are found readily in the literature.[20] In contrast, dosing adjustments for antimicrobials that are not eliminated renally are less well documented. Failure to adjust the antimicrobial dose or interval may result in drug accumulation and an increase in adverse effects.

Concomitant administration of other medications may influence the selection of the antimicrobial, dose, and monitoring. Medications that are commonly associated with drug interactions include, but are not limited to, warfarin, rifampin, phenytoin, digoxin, theophylline, multivalent cations (e.g., calcium, magnesium, and zinc), and sucralfate. Drug interactions between antimicrobials and other medications may occur via the cytochrome P-450 system, protein-binding displacement, and alteration of vitamin K–producing bacteria. Interactions may result in increased concentrations of one or both agents, increasing the risk of adverse effects or additive toxicity. A key consideration in selecting antimicrobial regimens starts with obtaining a good patient medical and drug history, recognizing drug-specific adverse-event characteristics, and anticipating potential problems proactively. If it is necessary to use an antimicrobial with a relatively high incidence of adverse effects, informing patients of the risks and benefits of therapy, as well as what to do if an adverse effect occurs, may improve patient compliance and may facilitate patient safety.

Antimicrobial agents must be used with caution in pregnant and nursing women. Some agents are either known or likely to be teratogenic (e.g., metronidazole), and others pose potential threats to the fetus or infant (e.g., quinolones, tetracyclines, and sulfonamides). For some agents, avoidance during a specific trimester of pregnancy is warranted. Pharmacokinetic variables also are altered during pregnancy. Both the clearance and volume of distribution are increased during pregnancy. As a result, increased dosages and/or more frequent administration of certain drugs may be required to achieve adequate concentrations. While a detailed description is beyond the scope of this chapter, this information can be obtained from a number of sources.[21,22]

Compliance is essential to ensure efficacy of a particular agent. Patients may stop taking their antibiotics once the symptoms subside and save them for a "future" infection. If the patient does not complete the course of therapy, the infection may not be eradicated, and resistance may emerge. Self-medication of saved antibiotics may be inappropriate and harmful and may select for resistant organisms. Poor patient adherence may be due to adverse effects, tolerability, cost, and lack of patient education.

OUTCOME EVALUATION

Figure 66–4 provides an overview of patient- and antimicrobial agent–specific factors to consider when selecting an antimicrobial regimen. It further delineates monitoring of therapy and actions to take depending on the patient's response to therapy. The duration of therapy depends on patient response and type of infection being treated.

Patient Encounter, Part 4: Patient Care and Monitoring

Update

The patient was admitted to the hospital with a presumptive diagnosis of health care–associated pneumonia (based on the recent hospitalization). He received intravenous hydration with normal saline, 5 L oxygen via face mask, an insulin infusion to control his glucose, and empirical antimicrobial therapy with piperacillin-tazobactam 2.25 g intravenously every 6 hours and vancomycin 1 g intravenously every 24 hours. All other medications are continued with the exception of the diabetes medications.

After 48 hours of therapy, the following parameters are obtained:

PE

- **VS:** BP 145/82, P 77, RR 22, T 37.9°C, O_2sat 92% on 4 L
- **Repeat chest x-ray:** Increased fluid density in bases, infiltrate unchanged, rales and rhonchi unchanged

Laboratory Data

- WBC 13,200 cells/mm^3
- SCr 1.9 mg/dL (145 µmol/L)
- Glucose 181 mg/dL (10.0 mmol/L)
- Urine and blood cultures × 2: Negative
- Sputum culture: 3+ *P. aeruginosa*

Sensitivity Report

Cefepime	Sensitive
Piperacillin/taz.	Sensitive
Imipenem	Resistant
Gentamicin	Sensitive
Amikacin	Sensitive
Ciprofloxacin	Resistant

- What information suggests improvement in the patient's condition?
- Do any of the antimicrobial doses need to be adjusted for changes in organ function?
- Should antimicrobial therapy be modified based on the culture results?
- Can the antimicrobial therapy be converted from intravenous to oral therapy?

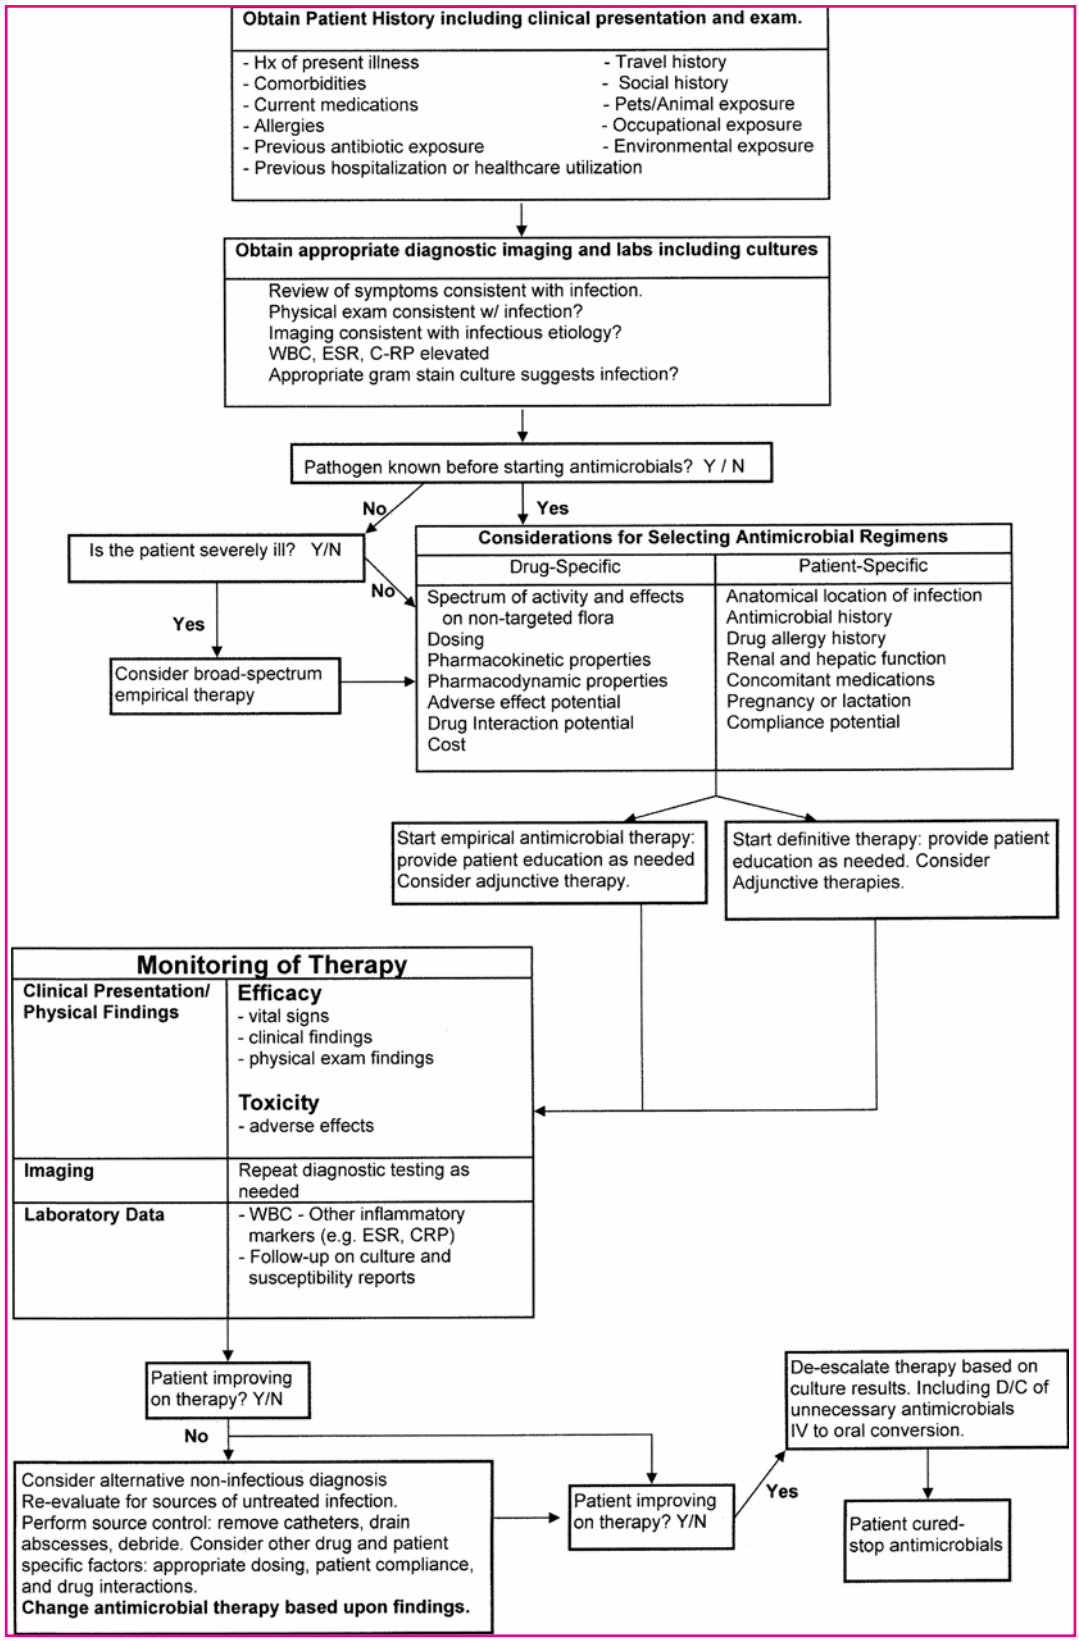

FIGURE 66–4. Approach to selection of antimicrobial therapy.

Patient Care and Monitoring

After selection and initiation of antimicrobial regimen, there are a number of additional patient care and monitoring considerations that should be addressed to improve the likelihood of a successful outcome. ❾ *Patient education, deescalation of antimicrobial therapy based on culture results, monitoring for clinical response and adverse effects, and appropriate duration of therapy are important.*

Patient Education

Provide patient education with regard to appropriate use of antimicrobials (e.g., dose, interval), adverse effects, and drug interactions (which may play a role in therapy failure and increased toxicity).

Therapeutic Monitoring

Monitor for therapeutic response by assessing efficacy and toxicity of the antimicrobial regimen.

- Clinical presentation/physical findings
  - *Efficacy:* Assess vital signs (monitor for return to normal or lack of altered findings, e.g., fever), physical examination findings, patient's subjective impression
  - *Toxicity:* Monitor and assess for adverse effects and evaluate antimicrobial serum concentrations when appropriate to minimize toxicity and improve outcomes
- Diagnostic imaging: Diagnostic testing is disease-state-dependent.
- Laboratory data
  - Monitor and assess laboratory data: WBC count with differential (goal is a reduction in WBC count if elevated initially and resolution of left shift), renal and/or hepatic function (consider need for dosage adjustments), other labs as indicated (e.g., ESR, CRP).
  - Follow up on culture and susceptibility reports with subsequent deescalation of therapy, if possible.
  - Reculture of specimens is not performed routinely except in few cases (e.g., endocarditis) or where a secondary infection is suspected because data may be misleading and lead to the addition of broader or more powerful antimicrobials

Modifying Empirical Therapy Based on Cultures and Clinical Response

If a successful clinical response occurs and culture results are available, therapy should be deescalated. ***Deescalation*** refers to decreasing antimicrobial regimen spectrum of activity to provide coverage against specific antimicrobial-sensitive pathogens recovered from culture. The purpose of deescalation therapy is to minimize the likelihood of secondary infections owing to antimicrobial-resistant organisms. In cases where a specific organism is recovered that has a known preferred agent of choice, therapy might be changed to that specific agent. For example, antistaphylococcal penicillins are considered to be the agents of choice for methicillin-susceptible *S. aureus* owing to their bactericidal activity and narrow-spectrum activity and may be preferable to other antibiotic regimens. In other cases, empirical coverage might be discontinued if a specific suspected pathogen is excluded by culture or an alternative, noninfectious diagnosis is established. In addition, intravenous antimicrobials frequently are more expensive than oral therapy. Therefore, it is desirable to convert therapy to oral antimicrobials with a comparable antimicrobial spectrum or specific pathogen sensitivity as soon as the patient improves clinically.

Failure of Antimicrobial Therapy

While many infections respond readily to antimicrobials, some infections do not. A relatively common question when a patient's condition fails to improve relates to whether the antimicrobial therapy has failed? Changing antimicrobials generally is one of the easiest interventions relative to other options. However, it is important to remember that antimicrobial therapy comprises only a portion of the overall disease treatment, and there may be many factors that contribute to a lack of improvement. ❿ *In general, inadequate diagnosis resulting in poor initial antimicrobial or other nonantibiotic drug selection, poor source control, and the development of a new infection with a resistant organism are relatively common causes of antimicrobial failure.* It is important to remember that an infection-related diagnosis may be difficult to establish and generally has two components: (1) differentiating infection-from non-infection-related disease and (2) providing adequate empirical spectrum of activity if the cause is infectious. Failure of improvement in a patient's condition should warrant broadening the differential diagnosis to include non-infection-related causes, as well as considering other potential infectious sources and/or pathogenic organisms. Another common cause of failure is poor source control. A diagnostic search for unknown sources of infection and removal of indwelling devices in the infected environment or surgical drainage of abscesses should be undertaken if the patient's condition is not improving. Less common but still frequent causes of therapeutic failure include the development of secondary infections. In this case, the patient generally improves but relapses after some period of improvement. The emergence of resistance to a targeted pathogen while on antimicrobial therapy can be associated with clinical failure but usually is limited to tuberculosis, pseudomonads, or other gram-negative enterics. Drug- and patient-specific factors such as appropriate dosing, patient compliance, and drug interactions can be associated with therapeutic failure and also should be considered. A common assumption is that the correct diagnosis was made, but the patient was not treated long enough with antimicrobials. There are certain types of infections (e.g., endocarditis or osteomyelitis) that the standard of care is to treat for prolonged periods of time (i.e., weeks or months). However, the optimal duration

of therapy for many infectious diseases is somewhat subjective. Recently, studies of several infectious processes have suggested that shorter durations of therapy can result in similar clinical outcomes as longer durations of therapy, frequently with fewer complications or secondary infections.[24,25] In this period of extensive antimicrobial resistance, clinicians should keep abreast of recommendations related to shorter duration of therapy.

CONCLUSION

Antimicrobial regimen selection is a complex process involving the integration of a multitude of factors. The guiding principles of make the diagnosis and do no harm must be considered when choosing an antimicrobial for a given patient. In summary, when infection is suspected, rapid and accurate diagnosis should be followed by early intervention that includes administration of appropriately dosed antibiotics with appropriate empirical spectrums. Deescalation to suitable narrow-spectrum antibiotics if susceptibilities are known should occur as soon as possible, and therapy should be stopped as soon as the patient is cured. These fundamental actions improve infectious disease outcomes and minimize collateral damage and adverse effects.

67 Central Nervous System Infections

S. Diane Goodwin and Charles E. Hartis

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Describe the signs, symptoms, and clinical presentation of central nervous system (CNS) infections.
2. Discuss the pathophysiology of CNS infections and the impact on antimicrobial treatment regimens (such as dosing and CNS penetration).
3. List the most common pathogens causing CNS infections, and identify risk factors for infection with each pathogen.
4. State the goals of therapy for CNS infections.
5. Design appropriate empirical antimicrobial regimens for patients suspected of having CNS infections caused by each of the following pathogens (taking age, vaccine history, and other patient-specific information into account), and analyze the impact of antimicrobial resistance on both empirical and definitive therapy: *Neisseria meningitidis* meningitis, *Streptococcus pneumoniae* meningitis, *Haemophilus influenzae* meningitis, *Listeria monocytogenes* meningitis, group B *Streptococcus* meningitis, gram-negative bacillary meningitis, postneurosurgical infection, CNS shunt infection, herpes simplex encephalitis.
6. Modify empirical antimicrobial regimens based on laboratory data and other diagnostic criteria.
7. Discuss the management of close contacts of patients diagnosed with CNS infections.
8. Discuss the role of vaccines and other prophylactic therapies in the prevention of CNS infections.
9. Describe the role of adjunctive agents (such as dexamethasone) in the management of CNS infections.
10. Describe the components of a monitoring plan to assess efficacy and adverse effects of therapy for CNS infections.

Key Concepts

❶ Meningitis is a neurologic emergency that requires prompt recognition, diagnosis, and management to prevent death and residual neurologic defects. Patients with fever, headache, and neck stiffness should be evaluated for meningitis.

❷ Ideally, lumbar puncture to obtain cerebrospinal fluid (CSF) for direct examination and laboratory analysis, as well as blood cultures and other relevant cultures, should be obtained before initiation of antimicrobial therapy. However, initiation of antimicrobial therapy should not be delayed if a pretreatment lumbar puncture cannot be performed.

❸ The treatment goals for central nervous system (CNS) infections are to prevent death and residual neurologic deficits, eradicate or control causative microorganisms, ameliorate clinical signs and symptoms, and identify measures (such as vaccination and suppressive therapy) to prevent future infections.

❹ Prompt initiation of intravenous high-dose cidal antimicrobial therapy directed at the most likely pathogen(s) is essential due to the high morbidity and mortality associated with CNS infections; parenteral (intravenous) therapy is administered for the full course of therapy for CNS infections to ensure adequate CSF penetration throughout the course of treatment.

❺ Empirical therapy should be directed at the most likely pathogen(s) for a specific patient, taking into account age, risk factors for infection (including underlying disease and immune dysfunction, vaccine history, and recent exposures), CSF Gram stain results, CSF antibiotic penetration, and local antimicrobial resistance patterns.

❻ Empirical antimicrobial therapy should be modified on the basis of laboratory data and clinical response.
❼ Close contacts of patients with CNS infections should be evaluated for possible antimicrobial prophylaxis.
❽ The adjunctive agent dexamethasone has been shown to improve outcomes in selected patient populations with meningitis.
❾ Components of a monitoring plan to assess the efficacy and safety of antimicrobial therapy of CNS infections include clinical signs and symptoms and laboratory data (such as CSF findings, culture, and sensitivity data).

The term *central nervous system* (CNS) *infections* describes a variety of infections involving the brain and spinal cord and associated tissues, fluids, and membranes, including meningitis, encephalitis, brain abscess, shunt infections, and postoperative infections (see Glossary). ❶ *CNS infections, such as meningitis, are considered neurologic emergencies that require prompt recognition, diagnosis, and management to prevent death and residual neurologic deficits.* Improperly treated, CNS infections are associated with high rates of morbidity and mortality. Despite advances in care, the overall mortality of bacterial meningitis remains greater than 20%, and at least 10% to 30% of survivors are afflicted with neurologic impairment, including hearing loss, **hemiparesis,** and learning disabilities.[1–3] Antimicrobial therapy and preventive vaccines have revolutionized management and improved outcomes of bacterial meningitis and other CNS infections dramatically.

EPIDEMIOLOGY AND ETIOLOGY

Compared with many other types of infections, CNS infections are less common, with 4 to 6 cases of meningitis reported per 100,000 adults annually.[4] However, the severity of these infections demands prompt medical intervention and treatment. CNS infections can be caused by bacteria, fungi, mycobacteria, viruses, and spirochetes.

Bacterial meningitis is the most common cause of CNS infections. An epidemiologic review of bacterial meningitis in 1995 revealed that *Streptococcus pneumoniae* (pneumococcus) was the most common pathogen (47%), followed by *Neisseria meningitidis* (meningococcus, 25%), group B *Streptococcus* (12%), *Listeria monocytogenes* (8%), and *Haemophilus influenzae* (Hib) (7%).[5] Vaccines directed against bacteria causing meningitis and related infections (such as pneumonia and ear infections) have reduced the risk of infections due to *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* type b dramatically. Prior to the availability of Hib conjugate vaccines, Hib meningitis or other invasive disease was documented in 1 in 200 children by the age of 5 years.[5] Widespread use of the Hib vaccine has reduced the incidence of invasive Hib disease by 99% and has shifted the age distribution of bacterial meningitis to older age groups (from 15 months in 1986 to 25 years in 1995).[1,6] Recent data indicate that routine use of the 7-valent conjugate pneumococcal vaccine in children not only has reduced the incidence of invasive pneumococcal disease in children but also has reduced invasive pneumococcal disease in adults 50 years of age and older by 28%.[7]

Neurosurgical procedures may place patients at risk for meningitis due to bacteria (such as *Staphylococcus aureus*, coagulase-negative staphylococci, and gram-negative bacilli) acquired at the time of surgery or in the postoperative period. In addition to bacteria, other pathogens may cause meningitis in at-risk patients. Immunocompromised patients, such as solid-organ transplant patients and patients living with human immunodeficiency virus (HIV) infection, are at risk for fungal meningitis with *Cryptococcus neoformans* (see Chap. 84). Tuberculosis can spread from pulmonary sites to cause clinical disease in the CNS (see Chap. 67). Life-threatening viral encephalitis and meningitis can occur in otherwise healthy, young individuals, as well as in patients immunocompromised by age or other factors. Because the treatments for different types of CNS infections are often very different, it is important to pay close attention to patients' risk factors when choosing empirical antimicrobial therapy. Patients at extremes of age, those living in close contact with others, and those with immune defects are most susceptible to meningitis. Risk factors for CNS infections can be classified as follows:

- *Environmental*—recent exposures (such as close contact with meningitis or respiratory tract infection, contaminated foods), active or passive exposure to cigarette smoke, close living conditions
- *Recent infection in the patient*—respiratory infection, otitis media, sinusitis, mastoiditis
- *Immunosuppression*—anatomic or functional asplenia, sickle cell disease, alcoholism, cirrhosis, immunoglobulin or complement deficiency, cancer, HIV/AIDS, debilitated state of health
- *Surgery, trauma*—neurosurgery, head trauma, CSF shunt, cochlear implant

Non-infectious causes of meningitis include malignancy, medications, autoimmune disease (such as lupus), and trauma.[8,9] The most common pathogens causing bacterial meningitis, by age group and other risk factors, are found in Table 67–1.

PATHOPHYSIOLOGY

Meningitis is an inflammation of the membranes of the brain and spinal cord (**meninges**) and the cerebrospinal fluid (CSF) in contact with these membranes, whereas encephalitis is an inflammation of the brain tissue. CSF flows through the subarachnoid space, insulating and protecting delicate CNS tissue. CSF is produced within the ventricles of the brain and flows downward through the spinal cord, serving as a continuous flushing mechanism for the CNS.

TABLE 67–1. Most Likely Pathogens and Recommended Empirical Therapy, by Risk Factor, for Bacterial Meningitis[14,24]

Predisposing Factor	Most Likely Pathogens	Recommended Empirical Antibiotic Therapy
Age		
Less than 3 months	Group B *Streptococcus* *Escherichia coli* *Klebsiella pneumoniae* *Listeria monocytogenes*	Ampicillin *plus* cefotaxime or aminoglycoside
3 months to less than 18 years	*Neisseria meningitidis* *Streptococcus pneumoniae* *Hemophilus influenzae*	Cefotaxime or ceftriaxone *plus* vancomycin
18 years to less than 60 years	*Neisseria meningitides* *Streptococcus pneumoniae*	Cefotaxime or ceftriaxone *plus* vancomycin
60 years or older	*Streptococcus pneumoniae* Gram-negative bacilli *Listeria monocytogenes*	Cefotaxime or ceftriaxone *plus* vancomycin *plus* ampicillin
Immunocompromised	*Streptococcus pneumoniae* *Neisseria meningitidis* *Listeria monocytogenes* Gram-negative bacilli (including *Pseudomonas aeruginosa*)	Cefotaxime or ceftriaxone *plus* vancomycin *plus* ampicillin (double antibiotic coverage against *Pseudomonas* if suspected)
Surgery, Trauma		
Postneurosurgical infection	*Staphylococcus aureus* (including MRSA) Coagulase-negative *Staphylococcus* (including MRSE) Gram-negative bacilli (including *Pseudomonas aeruginosa*)	Vancomycin *or* linezolid *plus* ceftazidime or cefepime or meropenem
Penetrating head trauma	*Staphylococcus aureus* (including MRSA) Coagulase-negative *Staphylococcus* Gram-negative bacilli (including *Pseudomonas aeruginosa*)	Vancomycin *or* linezolid *plus* ceftazidime or cefepime or meropenem (double antibiotic coverage against *Pseudomonas* if suspected)
CSF shunt	Coagulase-negative *Staphylococcus* (including MRSE) *Staphylococcus aureus* (including MRSA) Gram-negative bacilli (including *Pseudomonas aeruginosa*)	Vancomycin *or* linezolid *plus* ceftazidime or cefepime or meropenem (double antibiotic coverage against *Pseudomonas* if suspected)

MRSA, methicillin-resistant *Staphylococcus aureus*; MRSE, methicillin-resistant *Staphylococcus epidermidis*.
Adapted, with permission.

Over the past two decades, much has been learned about the pathophysiology of bacterial meningitis and other CNS infections. The blood-brain barrier and blood-CSF barrier are made of specialized tissue capillaries that isolate the brain from substances circulating in the bloodstream or colonizing nearby tissues. To initiate a CNS infection, pathogens must gain entry into the CNS by **contiguous** spread, **hematogenous** seeding, direct inoculation, or reactivation of latent infection. **Contiguous** spread occurs when infections in adjacent structures (such as sinus cavities or the middle ear) invade directly through the blood-brain barrier (such as Hib). **Hematogenous** seeding occurs when a more remote infection causes bacteremia that seeds the CSF (such as pneumococcal pneumonia). Reactivation of latent infection results from dormant viral, fungal, or mycobacterial pathogens in the spine, brain, or nerve tracts. Direct inoculation of bacteria into the CNS is the result of trauma, congenital malformations, or complications of neurosurgery.

Once through the blood-brain barrier, pathogens thrive and replicate due to limited host defenses in the CNS. Figure 67–1 depicts the pathophysiologic changes associated with meningitis. Neurologic tissue damage is the result of the host's immune reaction to bacterial cellular components (such as lipopolysaccharide, teichoic acid, and peptidoglycan) that triggers **cytokine** production, particularly tumor necrosis factor α (TNF-α) and interleukin 1 (IL-1), as well as other mediators of inflammation.[10] Bacteriolysis resulting from antibiotic therapy further contributes to the inflammatory process. **Cytokines** increase permeability of the blood-brain barrier, allowing influx of neutrophils and other host defense cells that contribute to the development of cerebral edema and increased intracranial pressure characteristic of meningitis.[11] The increase in intracranial pressure is responsible for the hallmark clinical signs and symptoms of meningitis: headache, neck stiffness, altered mental status, photophobia, and seizures. Unaltered, these pathophysiologic changes may result in cerebral ischemia and death.

The CNS response to infection is evident by demonstrable changes in the CSF. ❷ *Ideally, lumbar puncture to obtain CSF for direct examination and laboratory analysis, as well as blood cultures and other relevant cultures, should be obtained before*

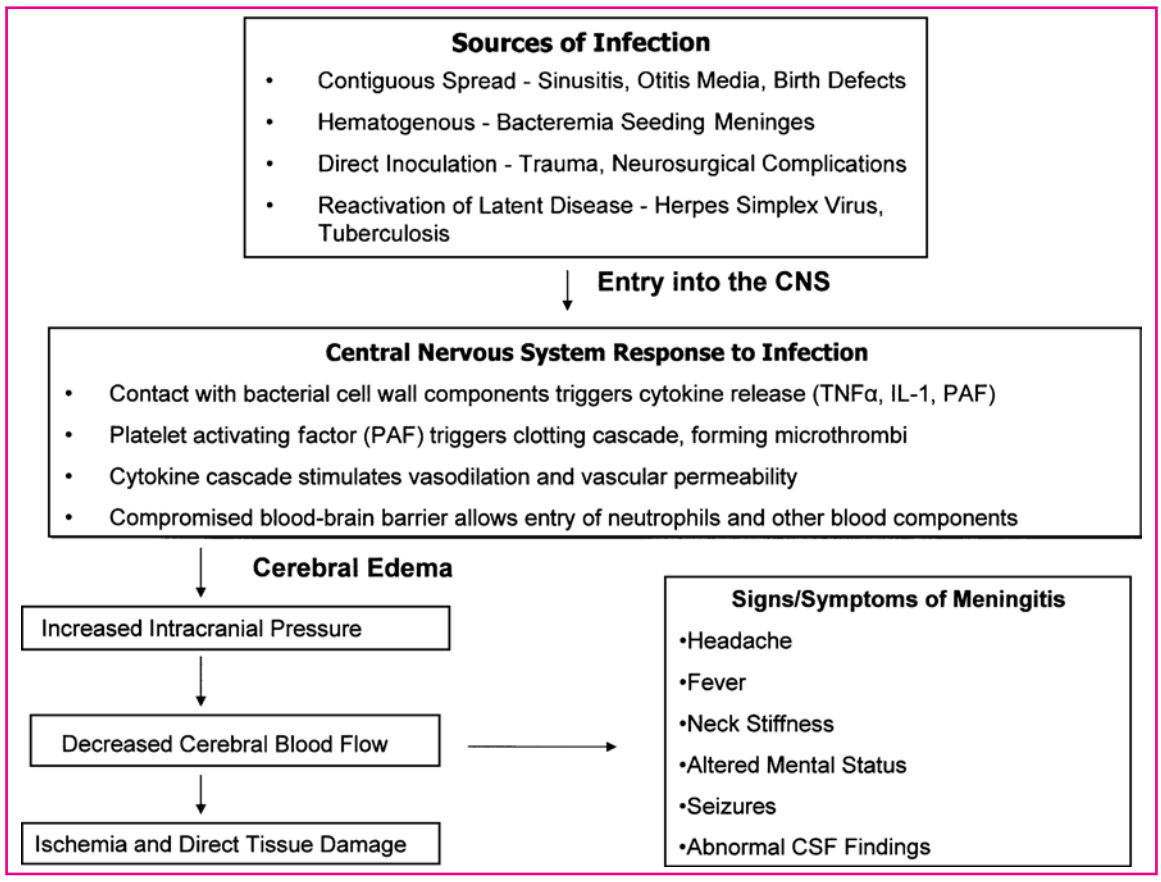

FIGURE 67–1. Pathophysiology of bacterial meningitis.

initiation of antimicrobial therapy. However, initiation of antimicrobial therapy should not be delayed if a pretreatment lumbar puncture cannot be performed.

Normal CSF has a characteristic composition in terms of protein and glucose content, as well as cell count. Table 67–2 lists CSF findings observed in the absence of infection, as well as in patients with bacterial, viral, fungal, and tuberculous meningitis.

CLINICAL PRESENTATION AND DIAGNOSIS

A high index of suspicion should be maintained for patients at risk for CNS infections. Prompt recognition and diagnosis are essential so that antimicrobial therapy can be initiated as quickly as possible. A medical history (including risk factors for infection and history of possible recent exposures) and

TABLE 67–2. Central Nervous System Response to Infection (Cerebrospinal Fluid Findings)[4,15,24]

	Normal CSF	Bacterial Infection	Viral Infection	Fungal Infection	Tuberculosis
WBC (mm^3, $\times 10^9$/L)	Less than 5 (less than 0.005)	1000–greater than 5000 (1.0–greater than 5.0)	100–1000 (0.1–1)	100–400 (0.1–0.4)	50–500 (0.05–0.5)
WBC differential (%, predominant cell type)	Greater than 85% monocytes	At least 80% PMNs	50% lymphocytes (PMNs early)	Greater than 50% lymphocytes	Greater than 80% lymphocytes (PMNs early)
Protein (mg/dL, mg/L)	20–45 (200–450)	Greater than 100 (greater than 1000)	50–100 (500–1000)	100–200 (1000–2000)	40–150 (400–1500)

CSF stain	Negative	Positive Gram stain (60%–90%)	Negative	Positive India ink stain (*Cryptococcus*)	Positive acid-fast bacilli stain

PMNs, polymorphonuclear neutrophils.

Clinical Presentation and Diagnosis of CNS Infections

General

- Evaluate patient risk factors and recent exposures.
- Evaluate other possible causes: space-occupying lesion (which may or may not be malignant), drug-induced CNS disease, autoimmune disease, and trauma.[8,9]

Signs and Symptoms[2]

- 95% of patients with bacterial meningitis have two of four of the following: headache, fever, neck stiffness, and altered mental status.
- Headache (87%)
- Nuchal rigidity (stiff neck) (83%)
- Fever (77%)
- Nausea (74%)
- Altered mental status (i.e., confusion, lethargy, and obtundation) (69%)
- Focal neurologic defects (including positive **Brudzinski's sign** and **Kernig's sign**) (33%)
- Seizures
- Malaise, restlessness
- Photophobia
- Skin lesions (diffuse petechial rash observed in 50% of patients with meningococcal meningitis)
- Signs and symptoms in neonates, infants, and young children: nonspecific findings, such as altered feeding and sleep patterns, vomiting, irritability, lethargy, bulging fontanel, seizures, respiratory distress, and petechial/purpuric rash[12]
- Predictors of an unfavorable outcome: seizures, focal neurologic findings, altered mental status, papilledema, hypotension, septic shock, and pneumococcal meningitis[3]

Laboratory Tests[4,13,14]

- CSF examination via lumbar puncture (LP, spinal tap); contraindicated in patients with cardiorespiratory compromise, ncreased intracranial pressure and papilledema, focal neurologic signs, seizures, bleeding disorders, abnormal level of consciousness, and possible brain herniation [a computed tomographic scan (CT) should be performed before LP if there is a question of a CNS mass to avoid potential for brain herniation] (Table 67–2 for specific CSF findings):
  - Elevated opening pressure (may be decreased in neonates, infants, and children)
  - Cloudy CSF
  - Decreased glucose
  - Elevated protein
  - Elevated WBC count (differential provides clues to offending pathogen)
  - Gram stain (adequate for diagnosis in 60% to 90% of patients with bacterial meningitis)
  - Culture and sensitivity (positive in 70% to 85% without prior antibiotic therapy, positive in less than 20% who have had prior therapy)
  - If CSF Gram stain and/or culture is negative, rapid diagnostic tests (such as latex agglutination) may be useful; these tests are positive even if bacteria are dead.
  - **Polymerase chain reaction** (**PCR;** DNA amplification of the most common bacterial meningitis pathogens) may be useful to help exclude bacterial meningitis.
  - Elevated CSF lactate and C-reactive protein
- Blood cultures (at least two cultures, one "set"; positive in 66%)
- Scraping of skin lesions (such as rash) for direct microscopic examination and culture
- Other cultures should be obtained as clinically indicated (such as sputum).
- WBC count with differential
- Fungal meningitis: CSF culture, CSF and serum cryptococcal antigen titers, microscopic examination of CSF specimens
- Tuberculous meningitis: CSF culture, PCR evaluation (preferred), and acid-fast stain

physical examination yield important information to help guide the diagnosis and treatment of meningitis.

TREATMENT

Goals of Therapy

The introduction of antibiotic therapy and vaccines has reduced dramatically the mortality associated with bacterial meningitis.[15] Prior to these advances, bacterial meningitis was almost universally fatal, and those few patients who survived often suffered from debilitating residual neurologic deficits, such as permanent hearing loss. Although significant improvements have been made, the fatality rate of pneumococcal meningitis remains above 20% likely due to its occurrence in debilitated patient populations.

❸ *The treatment goals for CNS infections are to prevent death and residual neurologic deficits, eradicate or control causative microorganisms, ameliorate clinical signs and symptoms, and identify measures to prevent future infections (such as vaccination and suppressive therapy).* These goals should be accomplished with minimal adverse drug reactions and interactions. Surgical debridement should be employed, if appropriate (as in postneurosurgical infections and brain abscess). Supportive care, consisting of hydration, electrolyte replacement, antipyretics, antiemetics, analgesics, antiepileptic drugs, and wound care (for surgical wounds), is an important adjunct to antimicrobial therapy, particularly early in the treatment course.

Treatment Principles

❹ *Prompt initiation of intravenous high-dose cidal antimicrobial therapy directed at the most likely pathogen(s) is essential due to the high morbidity and mortality associated with CNS infections.* Although there are no prospective studies that relate

timing of antibiotic administration to clinical outcome in bacterial meningitis, a longer duration of symptoms and more advanced disease before treatment initiation increase the risk of a poor outcome.[3,13,16] Two retrospective studies reported that initiation of antibiotic therapy as soon as possible after bacterial meningitis is suspected or proven (even before hospitalization) reduces mortality and neurologic sequelae, as long as antibiotics were started before a score of 10 was reached on the **Glasgow coma scale**.[17,18] Rapid sterilization of CSF is very important; delayed CSF sterilization after approximately 24 hours of antibiotic therapy increases the risk of neurologic sequelae, including moderate to profound hearing loss.[19,20] If dexamethasone is to be used (see Key Concept 8), it should be administered prior to or at the same time as the first dose of antibiotic therapy.

Meningitis occurs in an area with limited host defenses. Bacterial replication occurs rapidly in the absence of complement and specific antibodies directed toward common bacterial pathogens.[21] High-dose parenteral bactericidal antibiotic therapy is required to treat meningitis effectively. Data from animal studies and patients demonstrate better outcomes when bactericidal antibiotic therapy (versus bacteriostatic therapy) is used to sterilize the CSF.[22] However, successful treatment of meningitis has been reported with bacteriostatic agents. High doses of parenteral therapy are required to achieve CSF antibiotic concentrations adequate to rapidly sterilize the CSF and reduce the risk of complications. The presence of infection in the CSF reduces the activity of some classes of antibiotics. For example, the decreased pH of CSF associated with meningitis significantly reduces the activity of aminoglycoside antibiotics.[23]

Antimicrobial pharmacokinetics and pharmacodynamics must be considered when designing treatment regimens for CNS infections. Ability of antibiotics to reach and achieve effective concentrations at the infection site is the key to treatment success. In experimental models of meningitis, maximum bactericidal activity is achieved when CSF concentrations exceed the minimum bactericidal concentration (MBC) of the infecting pathogen by 10- to 30-fold.[12] In general, low-molecular-weight lipophilic antibiotics that are un-ionized at physiologic pH and not highly protein bound penetrate best into CSF and other body tissues and fluids.[21,23] In addition to drug characteristics, integrity of the blood-brain barrier determines antibiotic penetration into CSF. The CSF penetration of most, but not all, antibiotics is enhanced by the presence of infection and inflammation. Sulfonamides, trimethoprim, chloramphenicol, rifampin, and most antitubercular drugs achieve therapeutic CSF levels even without meningeal inflammation.[24] Most β-lactams and related antibiotics (i.e., carbapenems and monobactams), vancomycin, quinolones, acyclovir, linezolid, and colistin achieve therapeutic CSF levels in the presence of meningeal inflammation.[24] Amino-glycosides, first-generation cephalosporins, second-generation cephalosporins (except cefuroxime), clindamycin, and amphotericin do not achieve therapeutic CSF levels, even with inflammation, but clindamycin does achieve therapeutic brain tissue levels.[24]

An adequate duration of therapy is required to treat meningitis successfully (Table 67–3). ❹ *Parenteral (intravenous) therapy is administered for the full course of therapy for CNS infections to ensure adequate CSF penetration throughout the course of treatment.* Antibiotic treatment (and dexamethasone, if used as a treatment adjunct) reduces the inflammation associated with meningitis, which, in turn, reduces the penetration of some antibiotics into the CSF. To ensure adequate antibiotic concentrations throughout the treatment course, parenteral administration is continued for the full treatment course. Carefully selected patients who have close medical monitoring and follow-up may be able to receive a portion of their parenteral meningitis treatment on an outpatient basis.[13,25] A management algorithm for adults with suspected bacterial meningitis, as recommended by the Infectious Diseases Society of America (IDSA), is summarized in Fig. 67–2.

Empirical Antimicrobial Therapy

After expeditious work-up (i.e., evaluation of risk factors, clinical signs and symptoms, and laboratory data) and diagnosis, prompt and aggressive antimicrobial therapy is initiated. Appropriate empirical treatment is of the utmost importance in patients with suspected CNS infections. In most patients, a diagnostic lumbar puncture will be performed before beginning antibiotics, but this never should delay initiation of antimicrobials. ❺ *Empirical therapy should be directed at the most likely pathogen(s) for a specific patient, taking into account age, risk factors for infection (including underlying disease and immune dysfunction, vaccine history, and recent exposures), CSF Gram stain results, CSF antibiotic penetration, and local antimicrobial resistance patterns.* Results of the CSF Gram stain may be used to help narrow empirical therapy for bacterial meningitis. In the absence of a positive Gram stain, empirical therapy should be continued for at least 48 to 72 hours, when meningitis may, in most cases, be ruled out by CSF findings inconsistent with bacterial meningitis, negative CSF culture, and negative PCR evaluations. A repeat lumbar puncture may be useful in the absence of other findings. Table 67–1 outlines recommendations for empirical antibiotic therapy for bacterial meningitis by most likely pathogen(s) and patient risk factors.

Impact of Antimicrobial Resistance on Treatment Regimens for Meningitis

Development of resistance to β-lactam antibiotics, including penicillins and cephalosporins, has significantly impacted the management of bacterial meningitis. Approximately 17% of United States pneumococcal CSF isolates are resistant to penicillin, and 3.5% of CSF isolates are resistant to cephalosporins.[26] The Clinical and Laboratory Standards Institute (CLSI) has set a lower ceftriaxone susceptibility breakpoint for pneumococcal CSF isolates (1 mg/L) than for isolates from non-CNS sites (2 mg/L). Increasing pneumococcal resistance to penicillin G

TABLE 67–3. Pathogen-Based Definitive Treatment for Central Nervous System Infections

Pathogen	Recommended and Alternative Antimicrobial Therapy (Adult Doses; Pediatric Doses)	Adverse Effects/Safety Monitoring	Duration (Days)
Neisseria meningitidis	***Standard Therapy***		*7*
Penicillin MIC 0.1 mg/L	Penicillin G 4 million units IV every 4 hours *or*	Hypersensitivity (rash, anaphylaxis), diarrhea	
	Ampicillin 2 g IV every 4 hours	Hypersensitivity (rash, anaphylaxis), diarrhea	
	Alternative Therapies		
	Ceftriaxone 2 g IV every 12 hours *or* Cefotaxime 2 g IV every 4 hours	Ceftriaxone only: LFT elevation, **pseudocholelithiasis**	
Penicillin MIC 0.1–1 mg/L	***Standard Therapy***		
	Ceftriaxone *or* cefotaxime		
	Alternative Therapies		
	Moxifloxacin 400 mg IV every 24 hours *or*	Nausea/vomiting/diarrhea, dizziness, headache, QT prolongation	
	Meropenem 2 g IV every 8 hours *or*	Rash, hypersensitivity, diarrhea	
	Chloramphenicol 1–1.5 g IV every 6 hours	Rash, diarrhea, seizures, anemia, gray baby syndrome, hypersensitivity, neurotoxicity (last choice due to toxicities)	
Streptococcus pneumoniae	***Standard Therapy***		10–14
Penicillin MIC 0.1 mg/L	Penicillin G *or* ampicillin		
	Alternative Therapies		
	Ceftriaxone *or* cefotaxime *or* chloramphenicol		
Penicillin MIC 0.1–1 mg/L (ceftriaxone/cefotaxime-sensitive strains)	***Standard Therapy***		
	Ceftriaxone *or* cefotaxime		
	Alternative Therapies		
	Cefepime 2 g IV every 8 hours *or* meropenem		
Penicillin MIC 2 mg/L or greater	***Standard Therapy***		
	Vancomycin 15 mg/kg IV every 8–12 hours (with dosing based on serum levels) *plus* ceftriaxone *or* cefotaxime	Vancomycin: rash, red man's syndrome (if infused too quickly) nephrotoxicity, neutropenia, thrombocytopenia	
	Alternative Therapies		
	Moxifloxacin		
Cefotaxime/ceftriaxone MIC at least 1 mg/L	***Standard Therapy***		
	Vancomycin plus ceftriaxone *or* cefotaxime		
	Alternative Therapies		
	Moxifloxacin		
Haemophilus influenzae	***Standard Therapy***		*7*
β-Lactamase-negative	Ampicillin		
	Alternative Therapies		
	Ceftriaxone *or* cefotaxime *or* cefepime *or*		
	Moxifloxacin *or* chloramphenicol		
β-Lactamase-positive	***Standard Therapy***		
	Ceftriaxone *or* cefotaxime		
	Alternative Therapies		
	Cefepime *or* moxifloxacin *or* chloramphenicol

TABLE 67–3. Pathogen-Based Definitive Treatment for Central Nervous System Infections *(Continued)*

Pathogen	Recommended and Alternative Antimicrobial Therapy (Adult Doses; Pediatric Doses)	Adverse Effects/Safety Monitoring	Duration (Days)
Listeria monocytogenes	***Standard Therapy*** Ampicillin *or* penicillin G *plus* gentamicin (5 mg/kg per day, dosing based on serum levels) ***Alternative Therapies*** Trimethoprim-sulfamethoxazole (TMP-SMX) 10–20 mg/kg TMP IV per day in divided doses every 6–8 hours *or* meropenem	Gentamicin: nephrotoxicity, ototoxicity TMP-SMX: Rash, Stevens-Johnson syndrome, bone marrow suppression, nausea/vomiting, hepatotoxicity	At least 26
Streptococcus agalactiae (group B *Streptococcus*)	***Standard Therapy*** Ampicillin *or* penicillin G ***Alternative Therapies*** Ceftriaxone *or* cefotaxime		14–21
Enterobacteriaceae	***Standard Therapy*** Ceftriaxone *or* cefotaxime ***Alternative Therapies*** Aztreonam 2 g IV every 6–8 hours Moxifloxacin *or* meropenem *or* TMP-SMX *or* ampicillin	 Phlebitis, fever, rash, headache, confusion, seizures	21 (longer duration may be required for neonates)
Pseudomonas aeruginosa	***Standard Therapy*** Cefepime *or* Ceftazidime 2 g IV every 8 hours *or* meropenem (addition of aminoglycoside should be considered) ***Alternative Therapies*** Aztreonam *or* ciprofloxacin 400 mg IV every 8–12 hours (addition of aminoglycoside should be considered)	 Hypersensitivity, rash, anemia, neutropenia, eosinophilia, LFT elevation Nausea/vomiting/diarrhea, dizziness, headache, rash, confusion, seizures	At least 21 days
Staphylococcus aureus Methicillin-susceptible	***Standard Therapy*** Nafcillin *or* oxacillin 1.5–3 g every 4 hours ***Alternative Therapies*** Vancomycin *or* meropenem	 Rash, nausea/vomiting/diarrhea, acute interstitial nephritis Hepatotoxicity, red-orange discoloration of body fluids, skin rash, hepatic enzyme induction	3–4 weeks (4–6 weeks if shunt involved)
Methicillin-resistant	***Standard Therapy*** Vancomycin *plus* Rifampin 600 mg PO or IV daily if shunt involved ***Alternative Therapies*** Linezolid 600 mg IV every 12 hours *or* TMP-SMX	 Thrombocytopenia, neutropenia, nausea/vomiting/diarrhea, LFT elevation	
Staphylococcus epidermidis	***Standard Therapy*** Vancomycin *plus* rifampin 600 mg PO or IV daily if shunt involved ***Alternative Therapies*** Linezolid		3–4 weeks (4–6 weeks if shunt involved)
Herpes simplex virus	***Standard Therapy*** Acyclovir 10 mg/kg IV every 8 hours (adults) Acyclovir 20 mg/kg IV every 8 hours (neonates) ***Alternative Therapy*** Foscarnet 120–200 mg/kg IV per day in divided doses every 8–12 hours	 Nephrotoxicity, crystalluria, nausea/vomiting, neurotoxicity, phlebitis Nephrotoxicity, electrolyte imbalances, nausea/vomiting, headache, penile ulceration, thrombophlebitis, seizures	14–21 (21 for neonates)

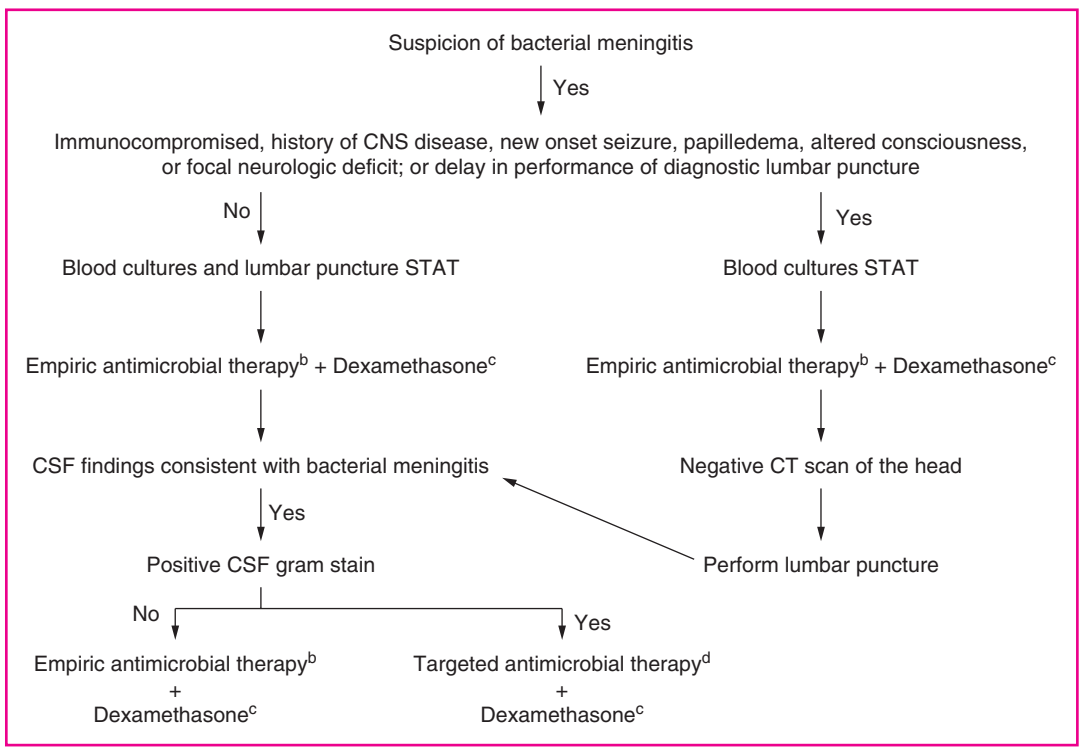

FIGURE 67–2. Management algorithm for adults with suspected bacterial meningitis.[a] [a]Management algorithm is similar for infants and children with suspected bacterial meningitis. [b]See Table 67–1 for empirical treatment recommendations. [c]See text for specific recommendations for use of adjunctive dexamethasone in adults with bacterial meningitis. [d]See Table 67–3 for pathogen-based definitive treatment recommendations. (Adapted, with permission, ref. 14.)

has changed empirical treatment regimens to the combination of a third-generation cephalosporin plus vancomycin. Recognition of relative and high-level resistance to *N. meningitidis* in the laboratory, as well as in clinical treatment failures, has led to greater use of third-generation cephalosporins for empirical therapy of meningococcal meningitis.[16] Previously, ampicillin was the cornerstone of treatment for *H. influenzae* meningitis. Now, treatment of suspected or proven β-lactamase-mediated Hib meningitis requires a third-generation cephalosporin. Increasing rates of methicillin-resistant *S. aureus* (about one-third of staphylococcal CSF isolates) and coagulase-negative staphylococci require the use of vancomycin for empirical therapy when these pathogens are suspected.[26] Global and local resistance patterns should be taken into account when designing empirical treatment regimens for bacterial meningitis.

Pathogen-Directed Antimicrobial Therapy

❻ *Empirical antimicrobial therapy should be modified on the basis of laboratory data and clinical response.* If cultures or other diagnostics, such as CSF Gram stain or antigen or antibody tests indicate a specific pathogen, therapy should be adjusted quickly as needed to ensure adequate coverage for the offending pathogen(s). Table 67–3 outlines recommended definitive pathogen-directed treatment regimens, recommended treatment duration, and key adverse effects that should be monitored during antibiotic therapy for meningitis. Treatment considerations for selected pathogens causing CNS infections are summarized below.

Neisseria meningiditis Meningitis

N. meningiditis most commonly causes CNS infections in children and young adults. An estimated 1400 to 2800 cases of meningococcal meningitis occur annually in the United States, with a mortality of about 10%.[27] From 11% to 19% of survivors of meningococcal meningitis experience long-term sequelae, including hearing loss, limb loss, and neurologic deficits.[27] Nearly all meningococcal disease is caused by five serogroups: A, B, C, Y, and W-135. In the United States, serotypes B, C, and Y each are responsible for approximately 30% of cases.

Meningococcal meningitis is observed most commonly in individuals living in close quarters (such as college students and military personnel). Although infants younger than 1 year of age are at highest risk, nearly 60% of cases occur in patients over 11 years of age.[27,28] *N. meningitidis* colonizes the nasopharynx and usually is transmitted via inhaled respiratory droplets from patients or asymptomatic carriers. A subclinical bacteremia typically ensues, seeding the **meninges.** Meningococcal disease is often (~50%) associated with a diffuse petechial rash, and patients may experience behavioral changes. Patients may develop fulminant meningococcal sepsis, characterized by shock, disseminated intravascular coagulation (DIC), and multiorgan failure.[16,28] Meningococcal sepsis has a poor prognosis and carries a mortality rate of up to 80%.[16] Patients with suspected meningococcal infection should be kept on respiratory isolation for the first 24 hours of treatment.[4]

Traditionally, high-dose penicillin G was the treatment standard for meningococcal disease. However, increasing penicillin resistance requires that third-generation cephalosporins now be used for empirical treatment until in vitro susceptibilities are known.[23] Patients with a history of type I penicillin allergy or cephalosporin allergy may be treated with vancomycin. Treatment should be continued for 7 days, after which no further treatment is necessary.

Prevention of meningococcal disease by vaccination is a key to reducing the incidence of meningococcal meningitis. College freshmen living in dormitories, military recruits, patients undergoing splenectomy, and patients with complement deficiency should receive the meningococcal vaccine.[27] Both the older polysaccharide meningococcal vaccine and the new quadrivalent conjugate meningococcal vaccine protect against four of the five serotypes causing invasive disease (A, C, Y, and W-135). Meningococcal vaccines do not protect against serotype B, which causes more than 50% of the cases of meningococcal meningitis in children younger than 2 years of age.[29] Either of the two available meningococcal vaccines can be used in outbreak situations, with protective antibodies measurable within 7 to 10 days. A possible advantage of the new conjugate vaccine is that it is believed to provide a longer duration of immunity than the older polysaccharide vaccine, although clinical studies to validate the duration of protection are not yet completed. The CDC Advisory Committee on Immunization Practices and the American Academy of Pediatrics recommend that all adolescents 11 to 12 years of age receive a dose of the new quadrivalent conjugate vaccine (currently approved by the Food and Drug Administration for patients 11–55 years of age). Until broader indications for the conjugate vaccine are licensed, the polysaccharide vaccine is available for patients 2 to 10 years of age, as well as patients over 55 years of age.

❼ *Close contacts of patients with meningococcal infections should be evaluated for antimicrobial prophylaxis.* Close contacts include members of the same household, individuals who share sleeping quarters, day-care contacts, and individuals exposed to oral secretions of meningitis patients. After consultation with the local health department, close contacts should receive prophylactic antibiotics to eradicate nasopharyngeal carriage of the organism. Household contacts of patients with meningococcal meningitis have a 400- to 800-fold increased risk of developing meningitis.[28] Prophylactic antibiotics should be started as soon as possible, preferably within 24 hours of exposure (and within 14 days, after which the benefit is significantly reduced). Recommended regimens, all of which are 90% to 95% effective, for adults include rifampin 600 mg orally every 12 hours for 2 days, ciprofloxacin 500 mg orally for one dose, or ceftriaxone 250 mg intramuscylarly for one dose. Regimens for children include rifampin 5 mg/kg orally every 12 hours for 2 days (less than 1 month of age), rifampin 10 mg/kg orally every 12 hours for 2 days (greater than 1 month of age), or ceftriaxone

125 mg intramuscularly for one dose (less than 12 years of age).[27,28] It is not known if close contacts who have been vaccinated will benefit from prophylaxis. Patients with meningococcal meningitis who are treated with antibiotics other than third-generation cephalosporins also should be considered for prophylaxis to eradicate the nasopharyngeal carrier state.[29]

Streptococcus pneumoniae Meningitis

S. pneumoniae is the most common cause of meningitis in adults and in children younger than 2 years of age. Pneumococcus is associated with the highest mortality observed with bacterial meningitis in adults (20% to 30%), and coma and seizures are more common in pneumococcal meningitis.[1–3] Patients at high risk for pneumococcal meningitis include the elderly, alcoholics, splenectomized patients, patients with sickle cell disease, and patients with cochlear implants. At least 50% of pneumococcal meningitis cases are due to a primary infection of the ears, sinuses, or lungs.

High-dose penicillin G traditionally has been the drug of choice for the treatment of pneumococcal meningitis. However, due to increases in pneumococcal resistance, the preferred empirical treatment now includes a third-generation cephalosporin in combination with vancomycin.[13] All CSF isolates should be tested for penicillin and cephalosporin resistance by methods endorsed by the CLSI. Once in vitro sensitivity results are known, therapy may be tailored (Table 67–3). Patients with a history of type I penicillin allergy or cephalosporin allergy may be treated with vancomycin. Treatment should be continued for 10 to 14 days, after which no further maintenance therapy is required. Antimicrobial prophylaxis is not indicated for close contacts.

Administration of vaccines to high-risk individuals is a key strategy to reduce the risk of invasive pneumococcal disease. The 23-valent pneumococcal vaccine targets serotypes that account for over 90% of invasive disease in high-risk patients. However, the 23-valent vaccine does not produce a reliable immunologic response in children younger than 2 years of age or nor does it reduce pneumococcal carriage. The 7-valent pneumococcal protein-polysaccharide conjugate vaccine introduced in 2000 targets the 7 most common serotypes in children and provides protection (94% reduction) against invasive pneumococcal disease (such as sepsis and meningitis) in children younger than 5 years of age.[30] Widespread administration of the 7-valent conjugate vaccine to children has also contributed to a 28% reduction in invasive pneumococcal disease in adults.[7] Unlike the 23-valent vaccine, the 7-valent vaccine reduces carriage and transmission.

Haemophilus influenzae Meningitis

Prior to the introduction of the Hib conjugate vaccine, *H. influenzae* type b was the most common cause of bacterial meningitis in the United States.[5] Routine inoculation of pediatric patients against Hib since 1991 has reduced the incidence of invasive Hib disease (i.e., meningitis and sepsis) in children younger than 5 years of age by 99%,[6] with mortality from Hib meningitis now less than 5%.[2] The Hib vaccine is also recommended for patients undergoing splenectomy. Hib meningeal disease often is associated with a parameningeal focus such as a sinus or middle ear infection. Increases in β-lactamase-mediated resistance have changed the empirical treatment of choice from ampicillin to third-generation cephalosporins (e.g., ceftriaxone and cefotaxime). Treatment should be continued for 7 days, after which no further maintenance therapy is required.

Close contacts of patients with H. influenzae *type B meningitis should be evaluated for antimicrobial prophylaxis.* The risk of Hib meningitis in close contacts may be up to 200- to 1000-fold higher than in the general population.[24] Invasive Hib disease, including meningitis, should be reported to the local health department and the Centers for Disease Control and Prevention (CDC). Prophylaxis to eliminate nasal and oropharyngeal carriage of Hib in exposed individuals should be initiated after consultation with local health officials. Rifampin (600 mg/day for adults; 20 mg/kg per day for children, maximum of 600 mg/day) is administered for 4 days.[12] Rifampin prophylaxis is not necessary for individuals who have received the full Hib vaccine series. Exposed, unvaccinated children between 12 and 48 months of age should receive one dose of vaccine, and unvaccinated children 2 to 11 months of age should receive three doses of vaccine, as well as rifampin prophylaxis.[12] Because of prior vaccine shortages, it cannot be assumed that all children have been vaccinated. Further, some children have not received all childhood vaccines because of parental fears regarding vaccine safety.

Listeria monocytogenes Meningitis

L. monocytogenes is an intracellular gram-positive bacillus that has been reported to contaminate certain foods, such as soft cheese, unpasteurized milk, raw meats and fish, processed meats, and raw vegetables. Bacteria from contaminated foods colonize the gastrointestinal tract, pass into the bloodstream, and overcome natural cellular immune responses to cause infection. *L. monocytogenes* meningitis, usually observed in patients at extremes of age and in immunocompromised patients with depressed cellular immunity (including patients with leukemia, solid-organ transplants, and HIV/AIDS), has an overall mortality rate of up to 30%.[31,32]

Only a limited number of antibiotics show bactericidal activity against *Listeria*. The combination of high-dose ampicillin or penicillin G and an aminoglycoside is synergistic and bactericidal against *Listeria*. A total treatment course of at least 3 weeks is required. Because of concerns about the risk of nephrotoxicity with an extended treatment course of aminoglycosides, patients are treated with combination therapy for 10 days and may finish out the remainder of their treatment with ampicillin or penicillin alone.[31] In penicillin-allergic patients, trimethoprim-sulfamethoxazole is the agent of choice due to documented in vitro bactericidal activity against *Listeria*, as well as good CNS penetration. Vancomycin and cephalosporins

are not effective treatments for *Listeria* meningitis. Prophylaxis is not needed for close contacts, nor is suppressive therapy indicated. Patients with severe depression of cell-mediated immunity should be advised to avoid foods that may be contaminated with *Listeria.*

Group B *Streptococcus* Meningitis

Infection with group B *Streptococcus* (such as *S. agalactiae*) is the most common cause of neonatal sepsis and meningitis. One of every 4 to 5 pregnant women is a carrier of group B *Streptococcus* in the vagina or rectum. Group B streptococci can be acquired during childbirth after exposure to infected secretions from the mother's birth canal or rectum. Neonates born to women who are carriers are at very high risk (1 of every 100–200 babies) of developing invasive group B streptococcal disease, including sepsis and meningitis.[33] Neonatal meningitis is associated with significant morbidity and mortality. Synergistic treatment with penicillin or ampicillin, plus gentamicin, for 14 to 21 days is recommended for the treatment of group B streptococcal meningitis.[13]

To reduce the risk of clinical group B streptococcal disease in neonates, pregnant women should be screened at 35 to 37 weeks' gestation to determine if they are carriers of group B streptococci.[33] Intrapartum antibiotics (e.g., penicillin or ampicillin) are recommended for pregnant women with the following characteristics: group B streptococcal carrier state detected at screening, history of group B streptococcal bacteriuria at any time during pregnancy, and history of delivery of infant with invasive group B streptococcal disease.[33]

Gram-Negative Bacillary Meningitis

Meningitis caused by enteric gram-negative bacilli is an important cause of morbidity and mortality in populations at risk, including those with diabetes, malignancy, cirrhosis, immunosuppression, advanced age, parameningeal infection, and/or a defect allowing communication from skin to CNS (such as neurosurgery, congenital defects, or cranial trauma).[24]

The optimal treatment for gram-negative bacillary meningitis is not well defined. The introduction of extended-spectrum cephalosporins has improved patient outcomes significantly. While the third-generation cephalosporins ceftriaxone and cefotaxime provide good coverage for most **Enterobacteriaceae,** these antibiotics are not active against *P. aeruginosa*. Ceftazidime, cefepime, and carbapenems have been shown to be effective in pseudomonal meningitis.[21,23] Addition of an aminoglycoside may improve treatment results; however, CNS penetration of aminoglycosides is extremely poor, even in the setting of inflamed **meninges.** Intrathecal or intraventricular administration of aminoglycosides may be useful, but intraventricular antibiotics have been associated with increased mortality in neonates.[21,34] Intrathecal therapy is accomplished by administering the antibiotic into the CSF via lumbar puncture, whereas intraventricular therapy is usually administered into a reservoir implanted in the ventricles of the brain.

Initial therapy of suspected or documented pseudomonal meningitis should include an extended-spectrum β-lactam (e.g., ceftazidime, cefepime, or meropenem) plus an aminoglycoside (preferably tobramycin or amikacin). Although the carbapenem imipenem-cilastatin has similar activity to these β-lactams, its use is not recommended in meningitis because of the risk of seizures. Aztreonam, high-dose ciprofloxacin, and colistin are alternative treatments for pseudomonal meningitis. Local therapy (i.e., intrathecal or intraventricular therapy) may be indicated in patients with gram-negative bacillary meningitis (especially infections caused by multidrug-resistant *P. aeruginosa*) or in patients who fail to improve on intravenous antibiotics alone. Given the differences in local hospital resistance patterns, administration of pathogen-directed treatment is very important after microbiology results become available. Therapy for gram-negative bacillary meningitis should be continued for at least 21 days.

Postoperative Infections in the Neurosurgical Patients and Shunt Infections

Patients who undergo neurosurgical procedures or have invasive or implanted foreign devices (such as CSF shunts, intraspinal pumps or catheters, or epidural catheters) are at risk for CNS infections. Key pathogens in postneurosurgical infections include coagulase-negative staphylococci, *S. aureus*, streptococci, propionobacteria, and gram-negative bacilli, including *P. aeruginosa*. Clinical signs and symptoms may be similar to those of other CNS infections, and there also may be evidence of malfunction of implanted hardware or visible signs of a postoperative wound infection.

Empirical therapy for postoperative infections in neurosurgical patients (including patients with CSF shunts) should include vancomycin in combination with either cefepime, ceftazidime, or meropenem. Linezolid has been reported to reach adequate CSF concentrations and resolve cases of meningitis refractory to vancomycin.[35] However, data with linezolid are limited. The addition of rifampin should be considered for treatment of shunt infections. When culture and sensitivity data are available, pathogen-directed antibiotic therapy should be administered. Removal of infected devices is desirable; aggressive antibiotic therapy (including high-dose intravenous antibiotic therapy plus intraventricular vancomycin and/or tobramycin) may be effective for patients in whom hardware removal is not possible. [36]

Brain abscesses are localized collections of pus within the cranium. These infections are difficult to treat due to the presence of walled-off infections in the brain tissue that are hard for some antibiotics to reach. In addition to appropriate antimicrobial therapy (a discussion of which is beyond the scope of this chapter), surgical debridement is often required as an adjunctive measure. Surgical debridement also may be required in the management of neurosurgical postoperative infections.

Viral Encephalitis and Meningitis

Viral encephalitis and meningitis may mimic bacterial meningitis on clinical presentation but often can be differentiated by CSF findings (Table 67–2). The most common viral pathogens are enteroviruses, which cause approximately 85% of cases of viral CNS infections.[24] Other viruses that may cause CNS infections include arboviruses, herpes simplex virus, cytomegalovirus, varicella-zoster virus, rotavirus, coronavirus, influenza viruses A and B, West Nile virus, and Epstein-Barr virus. Viral CNS infections are acquired through **hematogenous** or neuronal spread.[24] Most cases of enteroviral meningitis or encephalitis are self-limiting with supportive treatment.[37] However, arbovirus, West Nile virus, and Eastern equine virus infections are associated with a less favorable prognosis.

In contrast to other viral encephalitides, herpes simplex virus (HSV) type 1 and 2 encephalitis is treatable. Although rare (1 case per 250,000 population per year in the United States), HSV encephalitis is a serious, life-threatening infection.[38] Over 90% of HSV encephalitis in adults is due to HSV type 1, whereas HSV type 2 predominates in neonatal HSV encephalitis (greater than 70%).[39] HSV encephalitis is the result of reactivation of a latent infection (two-thirds of cases) or a severe case of primary infection (one-third). Without effective treatment, the mortality rate may be as high as 85%, and survivors often have significant residual neurologic deficits. High-dose intravenous acyclovir is the drug of choice, given for 2 to 3 weeks at a dose of 10 mg/kg intravenously every 8 hours in adults and for 3 weeks at a dose of 20 mg/kg intravenously every 8 hours in neonates.[39] Foscarnet 120 to 200 mg/kg per day divided every 8 to 12 hours for 2 to 3 weeks is the treatment of choice for acyclovir-resistant HSV isolates.[40]

Adjunctive Dexamethasone Therapy

❽ *The adjunctive agent dexamethasone has been shown to improve outcomes in selected patient populations with meningitis.* Dexamethasone inhibits the release of proinflammatory **cytokines** and limits the CNS inflammatory response stimulated by infection and antibiotic therapy.

Clinical benefit in reducing neurologic deficits (primarily by reducing hearing loss) has been observed in infants and children with *H. influenzae* meningitis, as well as other pathogens causing meningitis, if dexamethasone is initiated prior to antibiotic therapy.[1,13] The American Academy of Pediatrics recommends dexamethasone (0.15 mg/kg intravenously every 6 hours for 2 to 4 days) for infants and children at least 6 weeks of age with Hib meningitis and consideration of dexamethasone in pneumococcal meningitis.[13,41] Dexamethasone should be initiated 10 to 20 minutes before or no later than the time of initiation of antibiotic therapy; it is not recommended for infants and children who have already received antibiotic therapy because it is unlikely to improve treatment outcome in these patients. There are insufficient data to make a recommendation regarding the use of adjunctive dexamethasone therapy in neonatal meningitis.

In adults, a significant benefit was observed with dexamethasone over placebo in reducing meningitis complications, including death, particularly in patients with pneumococcal meningitis.[42] The IDSA recommends dexamethasone 0.15 mg/kg intravenously every 6 hours for 2 to 4 days (with the first dose administered 10 to 20 minutes before or with the first dose of antibiotics) in adults with suspected or proven pneumococcal meningitis.[13] Dexamethasone is not recommended for adults who have already received antibiotic therapy. Some clinicians would administer dexamethasone to all adults with meningitis pending results of laboratory tests.

There is concern regarding administration of dexamethasone to patients with pneumococcal meningitis caused by penicillin- or cephalosporin-resistant strains, for which vancomycin would be required. Animal models indicate that concurrent steroid use reduces vancomycin penetration into the CSF by 42% to 77% and delays CSF sterilization due to reduction in the inflammatory response.[23] Treatment failures have been reported in adults with resistant pneumococcal meningitis who were treated with dexamethasone, but the risk-benefit of using dexamethasone in these patients cannot be defined at this time. Animal models indicate a benefit of adding rifampin in patients with resistant pneumococcal meningitis whenever dexamethasone is used.[21,23]

OUTCOME EVALUATION

Monitor patients with CNS infections continuously throughout their treatment course to evaluate their progress toward achieving treatment goals, including relief of symptoms, eradication of infection, and reduction of inflammation to prevent death and the development of neurologic deficits. These treatment goals are best achieved by appropriate parenteral antimicrobial therapy, including empirical therapy to cover the most likely pathogens, followed by directed therapy after culture and sensitivity results are known. ❿ *Components of a monitoring plan to assess efficacy and safety of antimicrobial therapy of CNS infections include clinical signs and symptoms and laboratory data (such as CSF findings, culture, and sensitivity data).*

During the patient's treatment course, monitor clinical signs and symptoms at least three times daily. Trends are more important than one-time assessments. Expect fever, headache, nausea and vomiting, and malaise to begin to improve within 24 to 48 hours of initiation of antimicrobial therapy and supportive care. Evaluate the patient for resolution of neurologic signs and symptoms, such as altered mental status and nuchal rigidity, as the infection is eradicated and inflammation is reduced within the CNS. Expect improvement and subsequent resolution of signs and symptoms as the treatment course continues. At the time of hospital discharge, arrange outpatient follow-up for several weeks to months depending on the causative pathogen, clinical treatment course, and patient's underlying comorbidities. Specifically evaluate patients for the presence of residual neurologic deficits.

Monitoring of laboratory tests is important in patients receiving treatment for CNS infections. Monitor CSF and blood cultures so that antimicrobial therapy can be tailored to the etiologic organisms. Follow-up cultures may be obtained to prove

eradication of the organism(s) or treatment failure. Although repeat LP generally is not performed, consider repeat LP for patients who do not respond clinically after 48 hours of appropriate antimicrobial therapy, especially those with resistant pneumococcus who receive dexamethasone.[13] Other candidates for repeat LP include the following: those with infection with gram-negative bacilli, prolonged fever, and recurrent meningitis. Repeat the LP in neonates to determine the duration of therapy. Repeat LP also may be performed to relieve elevated intracranial pressure. Expect repeat blood cultures to become negative quickly during therapy and the serum WBC count to improve and normalize with appropriate antimicrobial therapy.

Evaluate antimicrobial dosing regimens to ensure efficacy of the treatment regimen. Trough vancomycin concentrations of 15 to 20 mg/L are recommended for the treatment of CNS infections.[13] Monitor patients for drug adverse effects, drug allergies, and drug interactions. The specific safety monitoring plan will depend on the antibiotic(s) used (Table 67–3). Play close attention to concomitant medications in patients on rifampin for treatment or prophylaxis. Rifampin is a potent inducer of hepatic metabolism and may reduce the efficacy of other drugs metabolized by the cytochrome P-450 3A enzyme pathway.

Patient Encounter

JD is a 17-year-old high school senior who visited her sister at her college dormitory for 1 week prior to her sister leaving for winter break. JD now presents to the emergency department with a 2-day history of headache and fever. Physical findings and laboratory values include temperature of 38.3°C (101°F) and WBC count of 14,400/mm^3 (14.4 × 10^9/L), with 90% PMNs. Examination reveals nuchal rigidity and a petechial truncal rash. JD reports light sensitivity and nausea with vomiting. She has tried over-the-counter analgesics and antipyretics with no relief from her headache or fever.

- What signs and symptoms consistent with meningitis are present in JD?
- What clues to causative pathogen are present in JD?
- What is the empirical regimen of choice for JD?
- How are laboratory data (including culture & sensitivity data) used to refine empirical antibiotic regimen?
- Which drugs are recommended for prophylaxis of close contacts of patients with meningitis?

Patient Care and Monitoring

1. Assess the patient's signs, symptoms, and risk factors for meningitis. Do these offer any clues to the offending pathogen?
2. Determine if the patient can undergo an immediate LP or if the LP should be delayed until a CNS mass lesion can be ruled out. If the LP is delayed, blood cultures should be drawn and appropriate empirical antimicrobial therapy initiated immediately.
3. Based on patient-specific data, local resistance patterns, and other relevant data, design an appropriate empirical antimicrobial regimen directed at the most likely pathogens; empirical regimens should consist of high-dose intravenous cidal therapy.
4. Determine if adjunctive dexamethasone therapy is indicated; if so, start steroid therapy 15 to 20 minutes before the first dose of antimicrobial therapy.
5. Provide supportive care for patients with CNS infections, including hydration, electrolyte replacement, antipyretics, analgesics, and antiepileptic drugs.
6. Monitor culture and sensitivity data from the microbiology laboratory to determine whether any refinements are needed in the patient's treatment regimen. Design a therapeutic plan to finish out the patient's course of therapy for acute meningitis.
7. Monitor the patient's response to therapy (i.e., clinical signs/symptoms and laboratory data), as well as the development of complications, including seizures and hearing loss. Dexamethasone therapy may reduce antibiotic penetration, so antimicrobial drug dosing may have to be increased (especially vancomycin) to achieve adequate CSF levels. Serum levels of vancomycin should be measured and doses titrated to ensure adequate CNS concentrations. Evaluate whether intraventricular or intrathecal antibiotics are indicated.
8. Perform ongoing surveillance for adverse drug reactions, drug allergies, and drug interactions.
9. Determine whether prophylaxis is indicated for close contacts of patients with CNS infections. Close contacts should be located for patients with suspected meningococcal or Hib meningitis. After consultation with the local health department, antibiotic prophylaxis should be provided promptly to these individuals to avoid secondary disease.
10. Evaluate whether the patient is a candidate for finishing out his or her course of parenteral treatment on an outpatient basis. If so, the importance of close medical follow-up and medication compliance should be stressed to the patient and his or her family.
11. Consider how to minimize the patient's risk of contracting the current (and other) CNS infections in the future; administer appropriate vaccines after recovery from the acute infection.
12. Arrange for patient follow-up after discharge from the hospital. Continue to monitor for neurologic sequelae for several months after completion of treatment, and educate the patient and family in this regard. Serious complications that may occur include, among others, hearing loss, **hemiparesis,** quadriparesis, muscular hypertonia, ataxia, seizure disorders, mental retardation, learning disabilities, and obstructive hydrocephalus.

ABBREVIATIONS

AIDS: acquired immune deficiency syndrome

68 Lower Respiratory Tract Infections

Diane M. Cappelletty

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. List the common pathogens that cause community-acquired pneumonia, aspiration pneumonia, ventilator-associated pneumonia (early versus late onset), and health care–associated pneumonia.
2. Explain the host defenses that protect against infection.
3. Explain the pathophysiology of pneumonia.
4. Recognize the signs and symptoms associated with community-acquired pneumonia and ventilator-associated pneumonia.
5. Identify patient and organism factors required to guide the selection of a specific antimicrobial regimen for an individual patient.
6. Design an appropriate empirical antimicrobial regimen based on patient-specific data for an individual with community-acquired pneumonia, aspiration pneumonia, and ventilator-associated pneumonia or health care–associated pneumonia (early versus late onset).
7. Design an appropriate antimicrobial regimen based on both patient- and organism-specific data.
8. Develop a monitoring plan based on patient-specific information for a patient with community-acquired pneumonia and health care– or ventilator-associated pneumonia.
9. Formulate appropriate educational information to be provided to a patient with pneumonia.

Key Concept

❶ There are five classifications of pneumonia: community-acquired, aspiration, hospital-acquired, ventilator-associated, and health care–associated.
❷ The etiology of bacterial pneumonia varies in accordance with the type of pneumonia.
❸ *Streptococcus pneumoniae* is the most common bacterial pathogen associated with community-acquired pneumonia.
❹ The signs and symptoms and severity of pneumonia are needed not only to diagnose the patient but also to assess response to therapy.
❺ The goal of therapy is to eliminate the patient's symptoms, minimize or prevent complications, and decrease mortality.
❻ Treatment of community-acquired pneumonia is predominantly empirical.
❼ Empirical selection of antimicrobial therapy for ventilator-associated, health care–associated, and hospital-associated pneumonia is broad spectrum; however, once culture and susceptibility information are available, the therapy should be narrowed (deescalation) to cover the identified pathogen(s).
❽ Duration of therapy should be kept to the shortest amount of time possible.
❾ Monitoring response to therapy is essential for determining efficacy, identifying adverse reactions, and determining the duration of therapy.
❿ Prevention of pneumococcal disease through the use of vaccination is a national goal.

Pneumonia is inflammation of the lung with consolidation. The cause of the inflammation is infection, which can result from a wide range of organisms. ❶ *There are five classifications of pneumonia: community-acquired, aspiration, hospital-acquired, ventilator-associated, and health care–associated.* Patients who develop pneumonia in the outpatient setting and have not been in any health care facilities, which include wound care and hemodialysis clinics, have *community-acquired pneumonia* (CAP). *Aspiration* is of either oropharyngeal or gastrointestinal contents. *Hospital-acquired pneumonia* (HAP) is defined as pneumonia that occurs 48 hours or more after admission.[1,2] *Ventilator-associated pneumonia* (VAP) requires endotracheal intubation for at least 48 to 72 hours before the onset of

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

pneumonia.[2,3] The newest category is *health care–associated pneumonia* (HCAP), which is defined as pneumonia occurring in any patient hospitalized for at least 2 days within 90 days of the onset of the infection; residing in a nursing home or long-term care facility; having received intravenous antibiotic therapy, wound care, or chemotherapy within the last 30 days of the onset of the infection; or having attended a hemodialysis clinic.[2,4,5]

EPIDEMIOLOGY AND ETIOLOGY

Etiology and Mortality Rates

❷ *The etiology of bacterial pneumonia varies in accordance with the type of pneumonia.* Table 68–1 lists the more common bacterial pathogens associated with the various types or classifications of pneumonia. *Streptococcus pneumoniae* is a component of the nasopharyngeal flora in up to 50% of healthy adults and may colonize the lower airways in individuals with chronic bronchitis.[6,7] It possesses many virulence factors that enhance its ability to cause infection in the respiratory tract. ❸ Therefore, *it is not surprising that S. pneumoniae is the predominant bacterial pathogen associated with CAP.* The second most common pathogen is one of the atypical organisms, *Mycoplasma pneumoniae*. Colonization with nontypeable *Hemophilus influenzae* comes and goes in about 80% of the population, and the incidence of permanent colonization increases in chronic obstructive pulmonary disease (COPD) patients and those with cystic fibrosis. Therefore, the likelihood of nontypeable *H. influenzae* causing pneumonia increases in COPD patients. *Moraxella catarrhalis* is a more common cause of pneumonia in the very young and the very old. *Chlamydia pneumoniae* and *Legionella pneumophila* are less frequent causes than the other bacterial and atypical organisms.

Viruses are a common cause of CAP in children (~65%) and much less common in adults (~15%).[8] Viruses often associated with pneumonia in adults include influenza A and B and adenoviruses, whereas less common causes include rhinoviruses, enteroviruses, cytomegalovirus, varicella-zoster virus, herpes simplex virus, and others. In children, viral pneumonia is caused more commonly by respiratory syncytial virus, influenza A virus, and parainfluenza virus. The viruses associated with CAP in adults are much less common causes of pneumonia in children.

Mortality associated with CAP depends on the severity of the illness and the age of the patient. In elderly patients admitted to the hospital with severe pneumonia, the mortality rate is up to 40%.[9–12] In the outpatient setting (mild to moderate disease), the mortality rate is less than 5%.[13]

Pneumonia owing to aspiration of oral contents is caused by a variety of anaerobes (*Bacteroides* spp., *Fusobacterium* spp., *Prevotella* spp., and anaerobic gram-positive cocci), as well as *Streptococcus* spp. *M. catarrhalis* and *Eikenella corrodens* may be involved, but much less frequently.[14,15] When gastric contents are aspirated, then enteric gram-negative bacilli and *Staphylococcus aureus* are more commonly the pathogens.[15]

HAP, VAP, and HCAP may be caused by a wide spectrum of organisms such as those listed earlier for CAP or enteric gram-negative bacilli, *Pseudomonas aeruginosa, Acinetobacter* spp., or *S. aureus* (both methicillin-susceptible and methicillin-resistant). Rarely are viruses or fungi a cause of these institution-associated pneumonias. The number of infections caused by multidrug-resistant bacteria is increasing significantly in hospitalized patients.[16–21]

TABLE 68–1. Common Bacterial Pathogens by Type of Pneumonia

Type of Pneumonia	Common Bacterial Pathogens
Community	Typical: *S. pneumoniae, H. influenzae, M. catarrhalis* Atypical: *M. pneumoniae, C. pneumoniae, Legionella pneumophila*
Aspiration	Oral contents: Anaerobes, *viridans* streptococci Gastrointestinal contents with pH increase: Enteric gram-negative bacilli
Hospital	(Early onset no risk factors for resistant pathogens)
Ventilator	*S. pneumoniae,* MSSA, *E. coli, K. pneumoniae, M. pneumoniae,*
Health care	*C. pneumoniae*
Hospital	(Late onset and/or risk factors for resistant
Ventilator	pathogens)
Health care	MRSA, extended-spectrum β-lactamase-producing *K. pneumoniae, P. aeruginosa, Acinetobacter* spp.

PATHOPHYSIOLOGY

Local Host Defenses

Local host defenses of both the upper and lower respiratory tract, along with the anatomy of the airways, are important in preventing infection. Upper respiratory defenses include the mucociliary apparatus of the nasopharynx, nasal hair, normal bacterial flora, IgA antibodies, and complement. Local host defenses of the lower respiratory tract include cough, mucociliary apparatus of the trachea and bronchi, antibodies (IgA, IgM, and IgG), complement, and alveolar macrophages. Mucus lines the cells of the respiratory tract, forming a protective barrier for the cells. This minimizes the ability of organisms to attach to the cells and initiate the infectious process. The squamous epithelial cells of the upper respiratory tract are not ciliated, but those of the columnar epithelium of the lower tract are. The cilia beat in a uniform fashion upward, moving particles up and out of the lower respiratory tract.

Particles larger than 10 microns are trapped efficiently by mechanisms of the upper airway and are removed from the nasopharynx either by swallowing or by expulsion. The mucociliary apparatus of the trachea and bronchi, along with the sharp angles of the bronchi, often are effective at trapping and eliminating particles that are 2 to 10 microns in size. Particles in the range of 0.5 to 1 micron may consistently reach the alveolar sacs of the lung. Microorganisms fall within this size range, and if they reach the alveolar sacs, then infection may result if alveolar macrophages and other defenses cannot contain the organisms.

Aspiration

Aspiration of the oropharyngeal or gastric contents may lead to aspiration pneumonia or chemical (acid) pneumonitis. Risk factors for aspiration include

- Dysphagia
- Change in oropharyngeal colonization
- Gastroesophageal reflux
- Decreased host defenses

Dysphagia can be caused by stroke or other neurologic disorders, seizures, alcoholism, and aging.[14] Oropharyngeal colonization may be altered by oral/dental disease, poor oral hygiene, tube feedings, or medications. This could result in a higher number of anaerobic organisms in the oral cavity or colonization with enteric gram-negative bacilli.[14] Gastroesophageal reflux (GER) occurs in all individuals to a degree, but those with GER disease (GERD) have it more frequently. Acid suppression is an important factor in the treatment of GERD, which may allow enteric gram-negative bacilli to colonize the gastric contents. Finally, impaired mucus production or cilia function, decreased immunoglobulin in secretions, and altered cough reflex may increase the likelihood of infection following aspiration. The infection can result in a necrotizing pneumonia or lung abscess.

HAP, VAP, HCAP

Risk factors for the development of HAP fall into four general categories:

- Intubation and mechanical ventilation
- Aspiration
- Oropharyngeal colonization
- Hyperglycemia

Intubation and mechanical ventilation increase the risk of HAP/VAP 6- to 21-fold.[2,22] VAP also may be related to colonization of the ventilator circuit.[23] Risk of aspiration is increased in these patients owing to the supine positioning of the patient, the presence of the endotracheal tube preventing closure of the epiglottis over the glottis, enteral feedings, gastroesophageal reflux, and medications.[23] Oropharyngeal colonization is affected by the use of antibiotics, oral antiseptics, and poor infection-control measures, which may decrease normal commensal flora and allow pathogenic organisms to colonize the oral cavity. Hyperglycemia may promote infection directly or indirectly; two proposed mechanisms are inhibiting phagocytosis and providing additional nutrients for bacteria.

Once breakdown of the local host defenses occurs and organisms invade the lung tissue, an inflammatory response in generated either by the organisms causing tissue damage or by the immune response to the presence of the organisms. This inflammatory response either can remain localized in the infected tissue or can become systemic. The role of the alveolar macrophages is twofold. First is to engulf the organisms

Patient Encounter 1, Part 1

A 73-year-old woman presents to your clinic complaining of difficulty breathing and shortness of breath. Her physical examination reveals that she is alert and oriented × 3, has decreased breath sounds on the left side compared with the right, and has rales in the left lower lobe. Her temperature is 37.4ºC, respiratory rate is 20 breaths per minute, and blood pressure is 110/76 mm Hg.

- What are her signs and symptoms of pneumonia?
- What are the top two organisms that could be causing the pneumonia?
- What additional information do you need to know before creating a treatment plan for this patient?

Patient Encounter 2, Part 1

A 52-year-old man was admitted to the hospital for abdominal surgery. He developed complications postoperatively and was intubated 6 days ago. The nurses note an increase in the amount and purulence of his sputum. Attempts yesterday and today to wean the patient off the ventilator have failed. He is sedated but does respond to commands. His temperature is 38.4ºC, his blood pressure is 120/84 mm Hg, and his white blood cell (WBC) count is 14.2/mm^3 with a cell differential of 76% neutrophils, 4% bands, 16% lymphocytes, and 4% monocytes.

- What are his signs and symptoms of pneumonia?
- What are the top three organisms that could be causing the pneumonia?
- What additional information do you need to know before creating a treatment plan for this patient?

and contain the infection. Second is to process the antigens for presentation in order to generate a specific immune response by either the cell-mediated system or the humoral system or both. The macrophages release cytokines in the area of the infection, which results in an increase in mucus production, constriction of the local vasculature and lymphatic vessels, and attraction of other immune cells to the site. The increase in mucus is associated with symptoms such as cough and sputum production. If tumor necrosis factor α (TNF-α) and interleukins 1 (IL-1), and IL-6 are released systemically, then the symptoms become more severe and include hypotension, organ dysfunction, and/or a septic or septic-shock clinical presentation.

CLINICAL PRESENTATION AND DIAGNOSIS

Several scoring systems are available for assessing the severity of the pneumonia: the Pneumonia Severity Index (PSI), Confusion, Urea, Respiratory Rate, and Blood Pressure (CURB), and CURB-65 (those 65 years and older).[9,24] Some of the characteristics evaluated with these models include but are not limited to age, comorbidities, blood pressure, mental status, respiratory rate, and organ function. These models are used by physicians to help determine the severity of illness, prognosis (mortality risk), and need for hospitalization and then to help guide the selection of antimicrobial therapy along with the use of published guidelines.[9,13,24]

TREATMENT

Desired Outcomes

❺ *The goal of antibiotic therapy is to eliminate the patient's symptoms, minimize or prevent complications, and decrease mortality*. Potential complications secondary to pneumonia include further decline in pulmonary function in patients with underlying pulmonary disease, prolonged mechanical ventilation, bacteremia/sepsis/septic shock, and death. In addition, using an agent with the narrowest spectrum of activity that covers the suspected pathogen without having activity against organisms not involved in the infection is preferred. This is to minimize the development of resistance.

Presentation of Community-Acquired or Aspiration Pneumonia

General

Patients may experience nonrespiratory symptoms in addition to respiratory symptoms. With increasing age, both respiratory and nonrespiratory symptoms decrease in frequency.

❹ Symptoms

- Respiratory: cough (productive or nonproductive), shortness of breath, difficulty breathing
- Nonrespiratory: fever, fatigue, sweats, headache, myalgias, mental status changes

❹ Signs

- Temperature may increase or decrease from baseline, but most often it is elevated. The temperature may be sustained or intermittent.
- Respiratory rate is often increased. Cyanosis, increased respiratory rate, and use of accessory muscles of respiration are suggestive of severe respiratory compromise.
- Breath sounds may be diminished. Rales or rhonci may be heard.
- Confusion, lethargy, and disorientation are relatively common in elderly patients.

Diagnostic Tests

- Chest x-ray should reveal single or multiple infiltrates.
- Oxygen saturation should be over 90%, as determined by pulse oximetery.
- Arterial blood gases are beneficial primarily in patients with severe pneumonia.

Laboratory Tests

- The WBC count may or may not be elevated. In elderly patients, a drop in WBCs also can be a sign of infection. The differential should show a predominance of neutrophils if a bacterial infection is present. The presence of bands also could be an indicator of bacterial infection. Elevated lymphocytes are an indication of viral infection.
- Blood urea nitrogen (BUN) and serum creatinine are needed to dose antibiotics appropriately and to minimize or prevent drug toxicity (especially in the elderly patient).

Microbiology Tests

- Sputum Gram stain should demonstrate the presence of WBCs and the absence of squamous epithelial cells. It may or may not show a predominance of one type of organism.
- Sputum culture and susceptibility are not obtained in the outpatient setting. The value of culturing is debated owing to the rapidity in which *S. pneumoniae* dies in transport media and the inability to reliably or routinely culture atypical organisms.
- **Bronchoscopy** may be performed to improve the ability to diagnose pneumonia. Tracheal secretions often are better specimens than sputum owing to the lack of oral contamination.
- Serology (IgM and IgG) is useful in determining the presence of atypical organisms such as *Mycoplasma* and *Chlamydia*.
- Urinary direct fluorescence antigen (DFA) is used to diagnose *L. pneumophila*.
- Polymerase chain reaction (PCR) is being used more frequently to detect the DNA of respiratory pathogens.
- Blood cultures must be obtained in all patients hospitalized with pneumonia to comply with Joint Commission on Accreditation of Healthcare Organizations (JCAHO) pneumonia guidelines. Positive blood cultures are present in about 1% to 20% of patients with CAP.

Presentation of Severe Community-Acquired or Aspiration Pneumonia

General

In approximately 10% of patients, community-acquired pneumonia will be severe enough to require intensive care or mechanical ventilation.

❹ Symptoms

- Respiratory: cough (productive or nonproductive), shortness of breath, difficulty breathing
- Nonrespiratory: fever, fatigue, sweats, headache, myalgias, mental status changes

❹ Signs

- Temperature may increase or decrease from baseline, but most often it is elevated. The temperature may be sustained or intermittent.
- Respiratory rate greater than 30 breaths per minute. Cyanosis and use of accessory muscles of respiration along with the increased respiratory rate are suggestive of severe respiratory compromise.
- Hypotension (systolic blood pressure less than 90 mm Hg or diastolic blood pressure less than 60 mm Hg)
- Requirement for vasopressors
- Breath sounds may be diminished. Rales or rhonci may be heard.
- Urine output less than 20 mL/hour or less than 80 mL over 4 hours.
- Confusion, lethargy, and disorientation are relatively common in elderly patients.

Diagnostic Tests

As stated in the clinical presentation of community-acquired or aspiration pneumonia.

Laboratory Tests

As stated in the clinical presentation of community-acquired or aspiration pneumonia.

Microbiology Tests

As stated in the clinical presentation of community-acquired or aspiration pneumonia.

General Approach to Treatment

Designing a therapeutic regimen for any patient with any type of pneumonia begins with three general categories of consideration:

1. Patient-specific factors that will affect therapy
2. The top one to three organisms likely causing the infection and resistance issues associated with each organism
3. What antimicrobials will cover these organisms and not be too broad or narrow in spectrum, will penetrate into the site of infection, and what they cost

Patient factors that need to be considered include age, renal function, drug allergies and/or drug intolerances, immune status (e.g., diabetes, neutropenia, or immunocompromised host), cardiopulmonary disease, pregnancy, medical insurance and prescription coverage, and prior antibiotic exposure(s) (what agents and when).

The most common pathogens vary with the type of pneumonia, and they are listed in Table 68–1. *M. pneumoniae* lacks a cell wall; therefore, β-lactam drugs have no activity against

Diagnosis of Ventilator-Associated Pneumonia

Clinical Strategy

- Chest x-ray should reveal a new infiltrate *plus* two of the following:
  - Temperature greater than 38ºC
  - Leukocytosis or leukopenia
  - Purulent secretions
- Semiquantitative cultures are obtained to identify the pathogen(s).
  - **Tracheal aspirates** grow more organisms than invasive quantitative cultures and often result in overuse of antibiotics.
- The major limitation of the clinical strategy is the consistent overprescribing of antibiotics.

Bacteriologic Strategy

- Uses quantitative culture of endotracheal aspirates, **bronchoalveolar lavage** (BAL), or **protected specimen brush** (PSB).
  - Greater than or equal to 10^6 cfu/mL for endotracheal aspirates
  - Greater than or equal to 10^4 to 10^5 cfu/mL for BAL
  - Greater than or equal to 10^3 cfu/mL for PSB
- The advantage of this method is that it separates colonization from infection better than culturing tracheal aspirates.
- The limitation is the potential misinterpretation of negative culture results. These samples should be obtained prior to antibiotics being started.

Recommended Diagnostic Strategy

- Combination of the preceding two methods.
- Obtain either a quantitative or semiquantitative culture of a lower respiratory sample. Initiate empirical broad-spectrum antibiotic therapy.
- Days 2 and 3: Check culture results, and assess clinical response to therapy: temperature, WBCs, chest x-ray, oxygenation, purulent sputum, hemodynamic changes, and organ function.
- Assess clinical improvement at 48 to 72 hours:
  - Improvement and culture negative—stop antibiotics.
  - Improvement and culture positive—narrow antibiotic therapy.
  - No improvement and culture negative—consider other pathogens, complications, or other diagnosis.
  - No improvement and culture positive—change antibiotic therapy and consider other pathogens, complications, or other diagnosis.

Patient Encounter 1, Part 2: Medical History, Physical Examination, and Diagnostic Tests

The 73-year-old woman presents again to your clinic complaining of difficulty breathing and shortness of breath. Her daughter also states that she is easily confused and that this is not normal for her.

PMH
- Chronic obstructive pulmonary disease (COPD) for 15 years
- Hypertension for 4 years, currently controlled

FH
Father died of lung cancer at the age of 68 years; mother died of natural causes.

SH
Smoked 2 packs per day for 23 years, quit 15 years ago. Does not drink alcohol. She lives with her daughter.

Allergies: NKDA

Meds
- Lisinopril 10 mg PO qd
- Ipratropium bromide 4 puffs 4 times per day
- Flunisolide 3 puffs 2 times per day
- Albuterol 2 puffs prn

ROS
(+) difficulty breathing and shortness of breath; (–) chest pain, N/V/D, weight loss, change in appetite.

PE
- **VS:** BP 110/76, P 82, RR 22, T 37.4°C
- **CV:** RRR, normal S_1, S_2; no murmurs, rubs, or gallops
- **Lungs:** Decreased breath sounds on the left side compared with the right and rales in the left lower lobe
- **Abd:** Soft, nontender, nondistended; (+) bowel sounds, no hepatosplenomegaly, heme (–) stool
- **Neuro:** Oriented to name and place but not to date. She is easily confused by questions asked of her.

Diagnostic Tests
- Chest x-ray: left lower lobe infiltrates
- Oxygen saturation 92% on room air

Labs
Unavailable in the clinic.

- Given this additional information, what is your assessment of the patient's condition?
- Identify your treatment goals for the patient.

Patient Encounter 2, Part 2: Medical History, Physical Examination, and Diagnostic Tests

The 52-year-old man who developed complications after abdominal surgery was intubated 6 days ago. The nurses note an increase in the amount and the purulence of his sputum. Attempts yesterday and today to wean the patient off the ventilator have failed. He is sedated, but he does respond to commands.

PMH
- Small bowel obstruction, surgery 8 days ago
- Hypertension for 15 years, currently controlled

FH
Father died of acute MI at the age of 68 years; mother, age 72, years is alive, with hypertension and hypothyroid

SH
No tobacco use; drinks 2 beers per night. He lives with his wife; occupation—carpenter.

Allergies: Penicillin—hives

Meds
Lisinopril 40 mg PO qd

PE
- **VS:** BP 120/84, P 78, T 38.4°C
- **CV:** RRR, normal S_1, S_2; no murmurs, rubs, or gallops
- **Abd:** Soft, nontender, nondistended; (+) bowel sounds, no hepatosplenomegaly, incision looks good and is healing.

Diagnostic Tests
- Chest x-ray: left middle and lower lobe infiltrates
- Oxygen saturation 98% on ventilator

Labs
- WBCs 18.2 cells/mm^3 with a cell differential of 72% neutrophils, 8% bands, 16% lymphocytes, and 4% monocytes
- BUN 10 mg/dL (3.57 mmol/L), SCr 0.9 mg/dL (79.56 µmol/L)
- Sputum Gram stain: many gram-negative bacilli, many WBCs
- Sputum culture is pending.

- Given this additional information, what is your assessment of the patient's condition?
- Identify your treatment goals for the patient.

this organism. The atypical organisms have not changed in recent years with respect to antibiotic resistance. β-Lactamase production in *H. influenzae* has remained relatively steady over the last 5 to 10 years, and the rate is approximately 35%.[25] *S. pneumoniae* is developing resistance mechanisms against many classes of antimicrobials, and these mechanisms include

- Alteration of the penicillin-binding proteins (PBPs) inactivating β-lactams
- Efflux or methylation of the ribosome inactivating macrolides
- Ribosome protection (*tetM* gene) inactivating tetracyclines
- Alteration of DNA gyrase or topoisomerase IV inactivating fluoroquinolones

Resistance to commonly prescribed antimicrobials such as the penicillins and macrolides/azalides increased dramatically in the late 1980s through the middle to late 1990s. Table 68–2 provides resistance information collected nationally from 1999 to 2004 using the Tracking Resistance in the US Today (TRUST) surveillance database.[26] In 2004, the average national rate of resistance to penicillin and macrolides was approximately 18% and 25%, respectively. Susceptibility results alone do not account for clinical success or failures when treating pneumonia.

TABLE 68–2. Percentage of Resistance for Various Antimicrobials Against S. pneumoniae

Antimicrobial	1999	2000	2001	2002[a]	2003	2004
Penicillin	14.7	16.0	16.9	18.4	17.3	18.6
Azithromycin	22.7	23.4	27.5	27.5	27.5	25.0
Ceftriaxone[a]	3.4	3.8	3.0	1.7	1.5	1.4
Levofloxacin	0.6	0.5	0.8	0.9	0.9	1.1
Trimeth-sulfa	NA	NA	NA	26.1	23.9	21.2
Tetracycline	NA	NA	NA	NA	NA	13.5

[a]Separation of ceftriaxone into nonmeningitis interpretation versus meningitis. Numbers presented are nonmeningitis.
NA, not available.

Therefore, despite the 18% and 25% resistance to penicillin and macrolides, the clinical failure rate is less than this. Owing to the empirical treatment of CAP in the outpatient setting, establishing a meaningful clinical failure rate with any therapy is difficult to do. No studies have been performed that established a correlation between clinical failure rates with a particular antimicrobial agent and the percentage of resistant bacterial pathogens.

For HCAP, HAP, and VAP, the risk of infection from a multidrug-resistant (MDR) pathogen is relatively high. The number and type of organisms that are MDR vary from hospital to hospital, making it more difficult to generate guidelines for treatment. Therefore, the treatment recommendations may be too broad or too narrow for any given institution. Treating patients with HCAP, HAP, or VAP is more complex than treating patients with CAP. There are many factors to consider, and one of these relates the timing of infection to the most likely pathogens. Early-onset infection is less likely to be caused by MDR pathogens than late-onset infection. In early-onset infection, community pathogens such as pneumococcus, *Legionella*, and *Mycoplasma* need to be considered, as well as some of the hospital pathogens. Patients developing late-onset pneumonia are at increased risk of having a resistant pathogen or MDR pathogen such as staphylococci, enteric gram-negative bacilli, *Pseudomonas*, and *Acinetobacter*. Another issue is how HCAP and HAP are studied compared with VAP. Most of the studies were performed using patients who were intubated. Therefore, the body of literature supporting the treatment recommendations is greatest for VAP and not for HCAP or HAP. The evidence-based guidelines generated by the American Thoracic Society were derived from VAP and applied to HCAP and HAP.

Risk factors for developing an infection caused by a resistant pathogen generally are related to the prior use of antibiotics, insertion of catheters or other invasive devices, and hospitalization in a unit contaminated/colonized with resistant organisms. The following is a more complete list of factors influencing infection from a resistant organism:

- Antimicrobial therapy in preceding 90 days
- Current hospitalization of at least 5 days
- High occurrence of antibiotic resistance in the community or in the specific hospital unit
- Presence of risk factors for HCAP:
  - Hospitalization for 2 days or more in the preceding 90 days
  - Residence in a nursing home or extended-care facility
  - Home infusion therapy (including antibiotics)
  - Peritoneal or hemodialysis within 30 days
  - Home wound care
  - Close contact family member with MDR pathogen
- Immunosuppressive disease and/or therapy

Once these issues are addressed, antimicrobial therapy can be selected and initiated. The patient- and drug-related categories are common to all types of pneumonia, but the organisms vary with the type of pneumonia. Guidelines have been generated by experts in the field for all types of pneumonia. These guidelines were generated to provide practitioners with evidenced-based therapeutic options for the management of patients with pneumonia.

Pharmacologic Therapy for Community-Acquired Pneumonia (CAP)

❻ *Treatment of community-acquired pneumonia is predominantly empirical.* As a way of incorporating an evidence-based approach to antibiotic selection, several different organizations have generated guidelines for the treatment of bacterial or atypical CAP in adults. Two of the most commonly used or cited guidelines are from the Infectious Diseases Society of America (IDSA), and the American Thoracic Society (ATS).[27,28] These two guidelines are similar in their organization and slightly different with respect to recommended therapies. Both differentiate patients into two broad categories of outpatient and inpatient and then further divide the groups by comorbid conditions and location in the hospital, respectively. These guidelines use patient-specific data along with predominant pathogen information to design appropriate empirical antimicrobial regimens. Table 68–3 summarizes these therapeutic options. If influenza virus is the cause, supportive care is the best medical intervention available; antiviral agents against influenza are not very effective.

Adult Outpatient Previously Healthy

First-line therapeutic options for treating previously healthy adults include use of a macrolide (e.g., erythromycin or clarithromycin) or an azalide (e.g., azithromycin) or doxycycline or a respiratory fluoroquinolone (e.g., levofloxacin, gatifloxacin, or moxifloxacin).[27,28] The issue with using a respiratory fluoroquinolone as first-line therapy in these patients is the broad-spectrum activity of these agents beyond *S. pneumoniae, M. pneumoniae, C. pneumoniae,* and *H. influenzae,* which are the predominant pathogens associated with CAP. If a patient has failed therapy with a macrolide, azalide, or doxycycline, one has to consider why the patient failed. The most common reasons are either medication adherence issues or the presence of resistant organisms. If a resistant organism is suspected, then use of one of the respiratory fluoroquinolones is warranted.

TABLE 68–3. Summary of Community-Acquired Pneumonia Treatment

Adult outpatient otherwise healthy	***Monotherapy:***
Empirical coverage against *S. pneumoniae, M. pneumoniae, C. pneumoniae,* & *H. influenzae*	azithromycin, clarithromycin, erythromycin, doxycycline, telithromycin, gatifloxacin, levofloxacin, moxifloxacin
Adult outpatient comorbidities	***Combination therapy:***
Empirical coverage against *S. pneumoniae, M. pneumoniae, C. pneumoniae,* & *H. influenzae*	high-dose amoxicillin, high-dose amoxicillin-clavulanate, or cefpodoxime, or cefprozil, or cefuroxime *plus* azithromycin or clarithromycin or telithromycin
	Monotherapy:
	gatifloxacin, levofloxacin, moxifloxacin
Adult inpatient (non-ICU)	***Combination therapy:***
Empirical coverage against *S. pneumoniae, H. influenzae M. pneumoniae,* & *C. pneumoniae*	cefotaxime, or ceftriaxone, or ampicillin-sulbactam, or ertapenem *plus* azithromycin or clarithromycin or telithromycin
	Monotherapy:
	gatifloxacin, levofloxacin, moxifloxacin
Adult inpatient ICU (no Pseudomonas)	***Combination therapy:***
Empirical coverage against *S. pneumoniae, L. pneumophila, H. influenzae,* enteric GNB, & *S. aureus*	cefotaxime or ceftriaxone *plus* azithromycin, or clarithromycin or gatifloxacin, or levofloxacin, or moxifloxacin
Adult inpatient ICU (Pseudomonas is a concern)	***Combination therapy:***
Empirical coverage against *P. aeruginosa, S. pneumoniae, L. pneumophila, H. influenzae,* enteric GNB, & *S. aureus*	cefepime, or ceftazidime, or piperacillin-tazobactam, or imipenem, or meropenem *plus* or ciprofloxacin levofloxacin or an aminoglycoside
	If an aminoglycoside is chosen, then add azithromycin or levofloxacin or gatifloxacin or moxifloxacin.
Pediatric outpatient	***Monotherapy:***
Empirical coverage against *S. pneumoniae, M. pneumoniae,* & *C. pneumoniae*	high-dose amoxicillin, or high-dose amoxicillin-clavulanate, or intramuscular ceftriaxone, or azithromycin, or clarithromycin
Pediatric inpatient (non-ICU)	***Combination therapy:***
Empirical coverage against *S. pneumoniae, H. influenzae, M. pneumoniae,* & *C. pneumoniae*	intravenous cefuroxime, or cefotaxime, or ceftriaxone or ampicillin-sulbactam plus azithromycin, or clarithromycin
Pediatric inpatient ICU	***Combination therapy:***
Empirical coverage against *S. pneumoniae, L. pneumophila, H. influenzae,* enteric GNB, & *S. aureus*	cefotaxime, or ceftriaxone plus azithromycin, or clarithromycin

Adult Outpatient with Comorbid Conditions

The comorbid conditions that can affect therapy and outcomes in patients with CAP include diabetes mellitus, COPD, congestive heart failure, and renal failure.[27,28] If the patient has not received antibiotics in the past 3 months, then clarithromycin or azithromycin is the recommended first-line therapy by the IDSA. If the patient has received antibiotics in the last 3 months, then the IDSA recommends using either a respiratory fluoroquinolone alone or a combination of an oral β-lactam and an advanced macrolide/azalide (e.g., clarithromycin/azithromycin). The ATS recommends combination therapy or monotherapy with a respiratory fluoroquinolone for all patients with comorbidities. The β-lactam agents recommended include high-dose amoxicillin, high-dose amoxicillin-clavulanate, cefpodoxime, cefprozil, and cefuroxime.

Missing from the recommendations for treating any outpatient is telithromycin, which is a ketolide antibiotic. Telithromycin was approved after the guidelines were generated. Telithromycin is similar in spectrum of activity to clarithromycin and azithromycin in that it covers primarily the respiratory pathogens and not gram-negative bacilli. At present, it is maintaining activity against macrolide-resistant *S. pneumoniae*. It is approved for the treatment of mild to moderate CAP and is a viable option in the treatment of pneumonia in these patients.

Adult Inpatient Not in the ICU

In patients admitted to the hospital with CAP, the severity of illness generally is increased (caused either by the organism itself or by underlying comorbidities in the patient), and the pathogens are essentially the same as in the outpatient setting. Recommendations by both organizations include using either a respiratory fluoroquinolone alone or a combination of an intravenous β-lactam and either an advanced macrolide/azalide (e.g., clarithromycin/azithromycin) or doxycycline. The recommended β-lactams include cefotaxime, ceftriaxone, ampicillin-sulbactam, and ertapenem.[27,28] Therapy should be initiated within the 4 hours of presentation to the emergency room or hospital. Conversion to oral therapy should occur within 48 to 72 hours for most patients, and discharge from the hospital should be within 5 days if there are no complications.

Adult Inpatient in the ICU

Patients admitted to the intensive-care unit (ICU) have severe pneumonia, and the etiology includes *S. pneumoniae* and *H. influenzae* as in the other categories; however, the incidence of *Legionella pneumophila* increases in this setting and should be included in the organism differential. In addition, enteric gram-negative bacilli and *S. aureus* are more frequently the cause of the pneumonia. The recommendations are to treat with an

intravenous third-generation cephalosporin plus either clarithromycin or azithromycin or a respiratory fluoroquinolone. This combination therapy minimizes the risk of treatment failure owing to a resistant pathogen and also provides coverage against all the potential pathogens.[27,28]

If *P. aeruginosa* is suspected (e.g., patient comes from a long-term care facility or has had a recent hospitalization), then the antimicrobial treatment must include *P. aeruginosa* as well as the organisms listed earlier. Recommended regimens double-cover the *Pseudomonas* and include the use of an antipseudomonal β-lactam (e.g., cefepime, ceftazidime, piperacillin-tazobactam, imipenem, or meropenem) plus either ciprofloxacin/levofloxacin or an aminoglycoside. If an aminoglycoside is chosen, then either intravenous azithromycin or a respiratory fluoroquinolone should be added to cover *S. pneumoniae* and the atypical organisms.[27,28]

Influenza

Influenza viruses A and B can cause pneumonia in pediatric and adult patients. Amantidine and rimantidine are available oral agents with activity against influenza virus type A. If started within 48 hours of the onset of the first symptoms, they reduce the duration of the illness by about 1.3 days. Oseltamivir and zanamivir also are oral agents and are active against both type A and B viruses. These agents also reduce the duration of the illness by about 1.3 days if initiated within 40 to 48 hours of the first symptoms.[29] For active infection beyond the first 48 hours, none of these agents is effective in treating the infection, and supportive care is the best treatment for these patients.

Aspiration

If a patient aspirates his or her oral contents and pneumonia develops, then anaerobes and *Streptococcus* spp. are the primary pathogens. Antibiotics active against these organisms include penicillin G, ampicillin/sulbactam, clindamycin, and metronidazole.

Pediatric Outpatient

If viral pneumonia is diagnosed, then treatment is often supportive (i.e., maintaining hydration and administration of antipyretics) because we have very few effective antiviral agents. The bacterial pathogens are the same as for adults with *S. pneumoniae* as the predominant pathogen, then *M. pneumoniae*, and then the other organisms. Resistance issues with these organisms are similar to those seen in adult patients. Fluoroquinolones and tetracyclines should not be used in children. High-dose amoxicillin, amoxicillin-clavulanate, intramuscular ceftriaxone, azithromycin, and clarithromycin all are potential agents for use in children.

Pediatric Inpatient

If the child is not admitted to the ICU, then the CDC recommends the use of intravenous cefuroxime, cefotaxime, ceftriaxone, or ampicillin-sulbactam plus a macrolide or azalide. If the child is admitted to the ICU, then only the third-generation cephalosporins (e.g., cefotaxime and ceftriaxone) plus a macrolide or azalide should be administered.[30]

Patient Encounter 1, Part 3: Creating a Care Plan

Based on the information presented, create a care plan for this patient's pneumonia. Your plan should include (1) the goals of therapy, (2) a patient-specific detailed therapeutic plan, and (3) a plan for follow-up to determine whether the goals have been achieved and adverse effects avoided.

Pharmacologic Therapy for HCAP/HAP/VAP

Nosocomial pneumonia is the term used to describe patients who developed pneumonia in an institutional setting. This has since been replaced by the terms *health care–associated pneumonia, hospital-associated pneumonia,* and *ventilator-associated pneumonia.* ❼ *Empirical selection of antimicrobial therapy for ventilator-associated, health care–associated, and hospital-associated pneumonia is broad spectrum; however, once culture and susceptibility information are available, the therapy should be narrowed (deescalation) to cover the identified pathogen(s).* Two factors important to the empirical selection of antibiotics for these types of pneumonia are onset time after admission and risk factors for MDR organisms. If it is early onset (less than or equal to 5 days since admission) and there are no risk factors for MDR organisms, then the most frequent pathogens include *S. pneumoniae, H. influenzae*, MSSA, and enteric gram-negative bacilli. Recommendations for therapy include third-generation cephalosporins such as ceftriaxone or cefotaxime; a respiratory fluoroquinolone such as gatifloxacin, levofloxacin, or moxifloxacin; ampicillin-sulbactam, or ertapenem.[31] If it is late-onset pneumonia and/or there are risk factors for MDR organisms, then the pathogen list includes *P. aeruginosa*, extended-spectrum β-lactamase-producing *Klebsiella pneumoniae, Acinetobacter* spp., and MRSA. Empirical antibiotic selection must cover *P. aeruginosa*, which often then covers the other gram-negative pathogens. Available antibiotics include cefepime, ceftazidime, imipenem, meropenem, piperacillin- tazobactam, ticarcillin-clavulanate, levofloxacin, ciprofloxacin, gentamicin, tobramycin, and amikacin. Empirical therapy could include any of the β-lactams, carbapenems, or fluoroquinolones alone or in combination with one of the aminoglycosides. If MRSA is suspected, then either vancomycin or linezolid should be added to the empirical regimen.

Currently, there is debate over whether or not double coverage for *Pseudomonas* is required. In vitro studies have shown that aminoglycosides exhibit synergistic killing against gram-negative bacilli when combined with β-lactams. Dosing of the aminoglycosides depends on the patient's renal function.

TABLE 68–4. Empirical Therapy for Late-Onset HAP, HCAP, or VAP

Antibiotic	Dosage Based on Normal Renal and Hepatic Function
Cefepime	1 g IV q8hours or 2 g IV q12hours
Ceftazidime	2 g IV q8hours
Imipenem	500 mg IV q6hours or 1 g IV q8hours
Meropenem	1 g IV q8hours
Piperacillin-tazobactam	4.5 g IV q6hours or 3.375 g IV q4hours
Ticarcillin-clavulanate	3.1 g IV q6hours
Levofloxacin	750 mg IV/PO q24hours
Ciprofloxacin	400 mg IV q8hours or 750 mg PO q8hours
Gentamicin or Tobramcyin[a]	5–7 mg/kg IV q24hours
Amikacin[a]	20 mg/kg IV q24hours
Vancomycin[b]	15–20 mg/kg q12hours
Linezolid	600 mg IV/PO q12hours

[a]Trough concentrations ideally should be nondetectable; less than 1 mcg/mL (2.09 µmol/L) for gentamicin and tobramycin and less than 4–5 mcg/mL (6.84–8.55 µmol/L) for amikacin are potentially acceptable.
[b]Trough concentrations should be between 5 and 20 mcg/mL.

A high-dose once-daily regimen (e.g., 4–7 mg/kg gentamicin or tobramycin or 15–20 mg/kg amikacin) can be used in patients with good renal function. Most of the studies enrolled patients with estimated creatinine clearances of at least 70 mL/minute (1.17 mL/s). Meta-analyses have shown high-dose once-daily regimens to be as efficacious and less toxic than divided daily dosing.[32–36] Divided daily dosing (e.g., 1–2 mg/kg gentamicin or tobramycin or 7.5 mg/kg amikacin) has been used since the 1970s, and the dosing interval is based on the patient's renal function so that the trough concentration is less than 1 mcg/mL.

In addition to obtaining a synergistic effect, another reason for double coverage when treating VAP, HAP, or HCAP is to broaden the coverage empirically to increase the likelihood of covering the majority of resistant pathogens. VAP is the most studied of these types of pneumonias and is often the most severe. Studies have demonstrated an increase in mortality when inadequate therapy is initiated for VAP. Crude mortality ranges from 35% to 92% with inadequate therapy compared with 25% to 47% with adequate therapy.[16]

❼ *Once a pathogen or pathogens have been identified, therapy should be narrowed to cover only those pathogens.* Use of broad-spectrum antibiotics for prolonged durations increases the risk of colonization with MDR pathogens.

Patient Encounter 2, Part 3: Creating a Care Plan

Based on the information presented, create a care plan for this patient's pneumonia. Your plan should include (1) the goals of therapy, (2) a patient-specific detailed therapeutic plan, and (3) a plan for follow-up to determine whether the goals have been achieved and adverse effects avoided.

Duration of Therapy

❽ *The duration of therapy for pneumonia should be kept as short as possible* and depends on several factors: type of pneumonia, inpatient or outpatient status, patient comorbidities, bacteremia/sepsis, and the antibiotic chosen. If the duration of therapy is too prolonged, then it can have a negative impact on the patient's normal flora in the respiratory and gastrointestinal tracts, vaginal tract of women, and the skin. This can result in colonization with resistant pathogens, *Clostridium difficile* colitis, or overgrowth of yeast. In addition, the longer antibiotics are administered, the greater is the chance for toxicity from the agent as well as an increase cost.[16]

For treating outpatient CAP, two antibiotics are approved for a 5-day duration of therapy, levofloxacin (the 750-mg dose) and azithromycin. The duration of therapy for all other therapies is 7 to 10 days. For treatment of CAP in patients admitted to the hospital, the duration depends on whether or not blood cultures were positive. In the absence of positive blood cultures, the duration of therapy is 7 to 10 days. If blood cultures were positive, then the duration of therapy should be 2 weeks from the day blood cultures first became negative.

The duration of therapy cited in the literature for HCAP, HAP, or VAP ranges from 10 to 21 days. Shortening the duration of therapy is acknowledged as beneficial because of the colonization, toxicity, and cost issues. The Clinical Pulmonary Infection Score (CPIS) has been used to determine when to end therapy for VAP. Luna and colleagues used the CPIS and found that patients who survived VAP and were treated with adequate therapy improved clinically within 3 to 5 days.[37] This was support for shortening the duration of therapy to 6 days. Another study found that when the CPIS was 6 or less, patients were at low risk of VAP or resistant pathogens, and treatment only needed to be for 3 days.[38]

OUTCOME EVALUATION

For CAP, outcomes include preventing hospitalization, shortening the duration of hospitalization, and minimizing mortality. For patients admitted to the hospital, if antibiotics are initiated within 4 hours of presentation, the duration of hospitalization is decreased compared with when antibiotics are started after 4 hours.[39]

Improvement in symptoms should occur within 48 to 72 hours after initiation of therapy for most patients with CAP. Response to therapy could be slowed in patients with underlying pulmonary disease such as moderate to severe asthma, COPD, or emphysema. In patients not responding to therapy with no underlying factors that would suggest a slowed response to therapy, then other infectious and noninfectious reasons must be considered. The infection could be caused by a pathogen not covered by the initial therapy, a drug-resistant isolate could be present, or more severe infection could be present (nonpulmonary), and the patient should be

reevaluated. Noninfectious reasons to consider include pulmonary embolus, congestive heart failure, carcinoma, lymphoma, intrapulmonary hemorrhage, and certain inflammatory lung diseases.

Outcome parameters for VAP, HAP, and HCAP are similar to those with CAP. Clinical improvement should occur within 48 to 72 hours of the start of therapy. If a patient is not responding to therapy, then, again, consider infectious and noninfectious reasons. Infectious explanations are the same as for CAP, but noninfectious reasons are not. They include atelectasis, acute respiratory distress syndrome (ARDS), pulmonary embolism or hemorrhage, cancer, empyema, or lung abscess.

PREVENTION

⑩ *Prevention of pneumococcal disease by use of vaccination is a national goal.* Vaccination is used to prevent or minimize the severity of pneumonia caused by *S. pneumoniae* or the influenza virus.

The influenza vaccine is available in two forms, injectable and nasal inhalation. The injectable is an inactivated vaccine (containing killed virus). The flu shot is approved for use in people older than 6 months of age, including healthy people and people with chronic medical conditions. The nasal-spray flu vaccine is made with live, weakened flu viruses that do not cause the flu (live attenuated influenza vaccine). This formulation is approved for use in healthy people 5 to 49 years of age who are not pregnant. The ability of the flu vaccine to protect a person depends on two key factors: the age and health status of the person getting the vaccine and the similarity or "match" between the virus strains in the vaccine and those in circulation. Given these factors, the vaccine has been shown to be effective. The influenza vaccine is recommended for the following groups of people[40]:

1. *People at high risk for complications from the flu:*
   - People 65 years of age and older
   - People who live in nursing homes and other long-term care facilities that house those with long-term illnesses
   - Adults and children 6 months of age and older with chronic heart or lung conditions, including asthma
   - Adults and children 6 months of age and older who needed regular medical care or were in a hospital during the previous year because of a metabolic disease (such as diabetes), chronic kidney disease, or weakened immune system (including immune system problems caused by medicines or by infection with HIV/AIDS)
   - Children 6 months to 18 years of age who are on long-term aspirin therapy
   - Women who will be pregnant during the influenza season
   - All children 6 to 23 months of age
   - People with any condition that can compromise respiratory function or the handling of respiratory secretions (i.e., a condition that makes it hard to breathe or swallow, such as brain injury or disease, spinal cord injuries, seizure disorders, or other nerve or muscle disorders)
2. *People 50 to 64 years of age.* Comorid conditions are present in nearly one-third of people 50 to 64 years of age in the United States, and this places them at increased risk for serious flu complications. Therefore, vaccination is recommended for all persons aged 50 to 64 years.
3. *People who can transmit flu to others at high risk for complications.* Any person in close contact with someone in a high-risk group should get vaccinated. This includes all health care workers, household contacts, and out-of-home caregivers of children 0 to 23 months of age and adults 65 years of age and older.

There are two pneumococcal vaccines, a 7-valent conjugated vaccine for children younger than 6 years of age and a 23-purified-capsular polysaccharide antigen vaccine for adults. The 23 capsular types in the vaccine represent at least 85% to 90% of the serotypes that cause invasive pneumococcal infections among children and adults in the United States.[41] After vaccination, an antigen-specific antibody response, indicated by a twofold or greater rise in serotype-specific antibody, develops within 2 to 3 weeks in 80% or more of healthy young adults.[42]

Patient Care and Monitoring

⑨ *Monitoring response to therapy is essential for determining efficacy, identifying adverse reactions, and determining the duration of therapy.*

1. Assess the patient's symptoms and status (i.e., inpatient, outpatient, or intubated) to determine the type of pneumonia and comorbid conditions. Does the patient have moderate to severe asthma, COPD, or emphysema or is a current smoker?
2. Review any available diagnostic data to determine severity of the disease.
3. Obtain a history of prescription and nonprescription medication use, as well as allergies and drug intolerances, noting the severity of the reaction.
4. What are the top two to three organisms associated with the type of pneumonia the patient has?
5. Select an appropriate empirical antibiotic regimen for the patient, ensuring that the doses are correct for renal function.
6. Develop a plan to assess the effectiveness of the antibiotic therapy after 24 to 72 hours. If the patient is not improving, then reevaluate the diagnosis and pathogen list, and make appropriate changes to therapy. Develop a plan to assess the effectiveness of the antibiotic therapy again at the end of therapy. When can conversion from intravenous to oral therapy occur?
7. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.
8. For patients who meet the qualifications, discuss the value of vaccination against *S. pneumoniae*.

However, immune responses may not be consistent among all 23 serotypes in the vaccine.[42] Those who should receive the polysaccharide vaccine include

1. *All adults 65 years of age or older.*
2. *Anyone over 6 years of age who has a long-term health problem such as*
   - Heart disease
   - Lung disease
   - Sickle cell disease
   - Diabetes
   - Alcoholism
   - Cirrhosis
   - Leaks of cerebrospinal fluid
3. *Anyone over 6 years of age who has a disease or condition or is taking any drug that lowers the body's resistance to infection, such as*
   - Hodgkin's disease
   - Lymphoma, leukemia
   - Kidney failure
   - Multiple myeloma
   - Nephrotic syndrome
   - HIV infection or AIDS
   - Damaged spleen, or no spleen
   - Organ transplant
   - Long-term steroids
   - Certain cancer drugs
   - Radiation therapy
4. *Alaskan Natives and certain Native American populations.*

The conjugated pneumococcal vaccine is recommended for all children aged 2 to 23 months and for certain children aged 24 to 59 months. If there are underlying health issues such as diabetes mellitus or cardiopulmonary disease, then children 24 to 59 months should receive this vaccine as well. The seven capsular types in the vaccine represent at least 85% to 90% of the serotypes that cause invasive pneumococcal infections among children in the United States.[41]

69 Upper Respiratory Tract Infections

Heather L. VandenBussche

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. List the most common bacterial pathogens that cause acute otitis media, acute bacterial rhinosinusitis, and acute pharyngitis.
2. Explain the pathophysiologic causes of and risk factors for acute otitis media, bacterial rhinosinusitis, and acute pharyngitis.
3. Identify clinical signs and symptoms associated with acute otitis media, bacterial rhinosinusitis, and streptococcal pharyngitis.
4. List treatment goals for acute otitis media, bacterial rhinosinusitis, and streptococcal pharyngitis.
5. Develop an appropriate antibiotic regimen for each infection based on patient-specific data.
6. Recommend appropriate adjunctive therapy for a patient with acute otitis media, acute bacterial rhinosinusitis, or streptococcal pharyngitis.
7. Create a monitoring plan for a patient being treated for each infection using patient-specific information and prescribed therapy.
8. Educate patients about upper respiratory tract infections and proper use of antibiotic therapy.

Key Concepts

❶ Antibiotic resistance patterns affect treatment options for bacterial upper respiratory tract infections.

❷ The majority of uncomplicated acute otitis media infections resolve spontaneously without significant morbidity.

❸ Antibiotic therapy for acute otitis media should be reserved for children who are most likely to benefit from therapy: those under 2 years of age and those with severe disease.

❹ Proper diagnosis of bacterial upper respiratory tract infections is crucial to identify patients who require antibiotics to avoid unnecessary antibiotic use.

❺ Amoxicillin and amoxicillin-clavulanate are first-line antibiotics for acute otitis media.

❻ Antibiotic therapy for sinusitis should be reserved for patients with moderate persistent symptoms, clinical decompensation, or severe symptoms.

❼ Empirical antibiotic selection for acute bacterial rhinosinusitis should incorporate patient risk factors for bacterial resistance.

❽ Amoxicillin and amoxicillin-clavulanate are first-line antibiotics for acute bacterial rhinosinusitis.

❾ The goals of therapy for streptococcal pharyngitis are to eradicate infection, reduce symptoms and infectivity, and prevent complications.

❿ Penicillin is the drug of choice for streptococcal pharyngitis, but cephalosporins may be appropriate alternative first-line agents owing to increasing failure rates after penicillin therapy.

Upper respiratory tract infection (URI) is a term that refers to various upper airway infections, including otitis media, sinusitis, pharyngitis, and rhinitis. Most URIs are viral and often self-limited. Over 1 billion viral URIs occur annually in the United States, resulting in millions of physician office visits each year.[1] Excessive antibiotic use for URIs has contributed to the significant development of bacterial resistance. Guidelines have been established to reduce inappropriate antibiotic use for viral URIs.[2] This chapter will focus on acute otitis media, sinusitis, and pharyngitis because they are frequently caused by bacteria and require appropriate antibiotic therapy to minimize complications.

OTITIS MEDIA

Otitis media, or inflammation of the middle ear, is the most common reason for prescribing antibiotics in children. It usually occurs after a viral infection of the nasopharynx and can be subclassified as acute otitis media or otitis media with

Patient Encounter 1, Part 1

A 15-month-old girl presents to the pediatric clinic with 2 days of fever (38.9°C), runny nose, and fussiness. Her mother states that she is more irritable than usual and cries many times throughout the night. She is not as interested in eating today. She attends day care and has a 5-year-old brother who recently had a cold. Physical examination reveals erythema and bulging of the right tympanic membrane and the presence of middle ear fluid. The left tympanic membrane is obscured with cerumen.

- What information is suggestive of AOM?
- Does the child have risk factors for AOM?
- Is there any additional information you need to know before recommending a treatment plan?

effusion. **Acute otitis media** (AOM) is a symptomatic middle ear infection that occurs rapidly along with effusion, or presence of fluid. **Otitis media with effusion** (OME) is the presence of fluid in the middle ear without symptoms of acute illness. It is important to distinguish between AOM and OME because antibiotics are only useful for treatment of AOM. Effusions can be present for up to 6 months after an acute episode.

Epidemiology and Etiology

Otitis media is most common in children between 6 months and 2 years of age but can occur in all age groups, including adults. By 12 months of age, 75% of children have had at least one episode of otitis media, and up to 20% have recurrent infections.[3,4] At least 13 million antibiotic prescriptions are written annually in the United States for otitis media, resulting in $2 billion in direct costs.[5] Many risk factors (Table 69–1) predispose children to otitis media and can be associated with microbial resistance, such as day-care attendance, prior antibiotic exposure, and age younger than 2 years.[3,4,6]

Bacteria frequently are isolated from middle ear fluid in children with AOM, but viruses also play a predominant role.

TABLE 69–1. Risk Factors for Otitis Media[3,4,6]

Viral respiratory tract infection/ winter season	Native American or Inuit ethnicity
Day-care attendance[a]	Low socioeconomic status
Siblings	Pacifier use
Male gender	Lack of breastfeeding
Tobacco smoke exposure	Young age at first diagnosis[a]
Allergies	Immunodeficiency
Anatomic defects such as cleft palate	Gastroesophageal reflux
Positive family history/genetic predisposition	

[a]Risk factors for infection with a resistant pathogen (day-care attendee, age under 2 years, recent antibiotic use in previous 3 months).

Streptococcus pneumoniae traditionally has been the most common organism, responsible for 25% to 50% of cases.[5,7] Nontypeable *Hemophilus influenzae* and *Moraxella catarrhalis* cause 15% to 30% and 3% to 20% of cases, respectively. Recent data suggest that the microbiology of AOM is shifting toward a prevalence of *H. influenzae* owing to routine childhood immunization with pneumococcal conjugate vaccine.[8] Bacteria that are less frequently associated with AOM include *Streptococcus pyogenes*, *Staphylococcus aureus*, and *Pseudomonas aeruginosa*. Viruses such as respiratory syncytial virus, influenza virus, rhinovirus, and adenovirus are isolated from middle ear fluid with or without concomitant bacteria in over half of AOM cases.[9,10] Lack of improvement with antibiotic therapy is often a result of viral infection and subsequent inflammation rather than antibiotic resistance.

❶ *Bacterial resistance has significantly affected treatment guidelines for AOM.* Penicillin-resistant *S. pneumoniae* (PRSP) encompasses both intermediate resistance (minimum inhibitory concentrations between 0.1 and 1.0 mcg/mL) and high-level resistance (minimum inhibitory concentration of 2.0 mcg/mL and higher). Approximately 35% of respiratory pneumococcal isolates are penicillin-resistant owing to altered penicillin-binding proteins, and almost half are highly penicillin-resistant.[11] PRSP are also commonly resistant to other drug classes, including sulfonamides, macrolides, and clindamycin, and increasingly resistant to fluoroquinolones. Although inappropriate use of antibiotics for URIs has led to increased resistance rates, treatment for pneumococcal AOM is necessary because infection caused by *S. pneumoniae* is unlikely to resolve spontaneously. β-Lactamase production occurs in 30% and nearly 100% of *H. influenzae* and *M. catarrhalis*, respectively.[12] Although infections caused by these organisms are more likely to resolve without treatment, they must be considered in cases of treatment failure.

Pathophysiology

Multiple factors play a role in the development of AOM. Viral infection of the nasopharynx impairs eustachian tube function and causes mucosal inflammation, impairing mucociliary clearance and promoting bacterial proliferation and infection. Children are predisposed to AOM because their eustachian tubes are shorter, more flaccid, and more horizontal than adults, which make them less functional for drainage and protection of the middle ear from bacterial entry. Clinical signs and symptoms of AOM are the result of host immune response and damage to cells caused by inflammatory mediators such as tumor necrosis factor and interleukins that are released from bacteria.[4]

❷ *The majority of uncomplicated AOM cases resolve spontaneously without significant morbidity.* Untreated AOM improves by day 2 or 3 of illness in 80% of children without increasing the risk of complications.[13] Antibiotics improve ear pain in only 7% of children between days 2 and 7 of therapy and significantly improve recovery in children younger than

2 years of age and in those with severe AOM symptoms.[5,14,15] ❸ *Therefore, antibiotics should be reserved for children most likely to benefit from therapy.* Delayed antibiotic therapy in older children and those with less severe disease does not result in more infectious complications, such as mastoiditis or meningitis, when compared with routine initial antibiotic treatment.[14] Use of this approach or use of a safety-net antibiotic prescription that parents fill 2 days later only if the child is not better can reduce antibiotic use for AOM dramatically without increasing complications.[16]

Viscous middle ear effusions caused by allergy or irritant exposure may contribute to impaired mucociliary clearance and AOM in susceptible individuals.[4] OME occurs chronically in atopic children, and effusion can persist for months after an episode of AOM. Children with chronic OME usually require **tympanostomy tube** placement to reduce complications such as hearing and speech impairment and recurrent otitis media.

Clinical Presentation and Diagnosis

It is important to differentiate AOM from OME because they are treated dramatically differently. Patients with AOM usually have cold symptoms, including rhinorrhea, cough, or nasal congestion before or at diagnosis.

Symptoms

- Young children: ear tugging, irritable, poor sleeping and eating habits
- Older patients: ear pain (mild, moderate, or severe), ear fullness, hearing impairment

Signs[5,7]

- Fever: present in less than 25% of patients; often in younger children
- Middle ear effusion
  - Otorrhea (middle ear perforation with fluid drainage): uncommon
  - Bulging tympanic membrane
  - Limited or absent mobility of tympanic membrane
- Distinct erythema of tympanic membrane
- Opaque or cloudy tympanic membrane obscuring or reducing visibility of middle ear

Laboratory Tests

Gram stain, culture, and sensitivities of ear fluid if draining spontaneously or obtained via **tympanocentesis** (not performed routinely in practice)

Complications

- Infectious: mastoiditis, meningitis, osteomyelitis, intracranial abscess
- Structural: perforated eardrum, **cholesteatoma**
- Hearing and/or speech impairment

Diagnosis[5]

- Certain AOM: Requires *all* the following:
  - Rapid onset of signs and symptoms
  - Middle ear effusion findings with **pneumatic otoscopy** (as above)
  - Inflammation indicated by either otoscopic evidence (distinct erythema) or otalgia
- Uncertain AOM: Not all three criteria are present.
- Severe AOM: Moderate to severe ear pain or fever of 39°C or greater.
- Nonsevere AOM: Mild ear pain and fever of less than 39°C in past 24 hours.

Patient Encounter 1, Part 2

On further questioning, you discover that the child is allergic to penicillin. She developed a nonurticarial rash last year during treatment for pharyngitis. She has not received antibiotics since that time, and this is her first ear infection.

Immunizations: Up to date

Meds

Acetaminophen drops 120 mg PO every 4 to 6 hours as needed for fever or pain

ROS

(+) nasal congestion and rhinorrhea, (–) vomiting, diarrhea, or cough

PE

- **Gen:** Irritable child but consolable
- **VS:** Blood pressure 100/60 mm Hg, pulse 120 beats per minute, respiratory rate 18 breaths per minute, temperature 38.6°C
- **HEENT:** As noted before

- Identify your treatment goals for this child.
- Given this information, what nonpharmacologic and pharmacologic therapy do you recommend?

Treatment

Desired Outcomes

Therapy for AOM focuses on symptom relief and prevention of complications. The goals of treatment are to alleviate ear pain and fever, if present; eradicate infection; prevent sequelae; and minimize unnecessary antibiotic use.

General Approach to Treatment

❸ ❹ *Treatment of AOM depends on patient age, illness severity, and the certainty of diagnosis.* Children younger than 2 years of age have a higher incidence of penicillin-resistant pneumococcal infections and have higher clinical and bacteriologic failure rates and complications when not treated initially with antibiotics as compared with older children.[5,15] Patients with severe illness, defined by degree of fever and

pain severity, have lower spontaneous recovery rates than those with nonsevere disease.[14,15] Current guidelines recommend stratifying patients based on these criteria, along with certainty of diagnosis, in order to identify those most likely to benefit from antibiotic therapy.[5]

Nonpharmacologic Therapy

Watchful waiting and safety-net antibiotic prescriptions are approaches being used more frequently to attenuate microbial resistance and avoid unnecessary adverse events and costs of antibiotics. Observation is practiced extensively in Europe and involves monitoring for 48 to 72 hours after diagnosing AOM to see if spontaneous resolution will occur. Observation or delayed antibiotic therapy should be considered only in otherwise healthy children without recurrent disease (Fig. 69–1) and only if proper follow-up and good communication exist between clinicians and the parent/caregiver.[4,5,16]

Other nondrug approaches include the use of external heat or cold to reduce postauricular pain and surgery. Tympanostomy tubes are most useful for patients with recurrent disease or chronic OME with impaired hearing or speech. Adenoidectomy may be necessary for children with chronic nasal obstruction, but tonsillectomy is rarely indicated.

Pharmacologic Therapy

Antibiotic Therapy

When antibiotic therapy is needed, many factors influence initial drug selection. Clinicians must consider drug factors such as antimicrobial spectrum, likelihood of clinical response, incidence of side effects, drug interactions, and cost, as well as patient factors, including risk factors for bacterial resistance, allergies, ease of dosing regimen, medication palatability, and presence of other medical conditions. Studies in uncomplicated AOM have not revealed significant differences between antibiotics in clinical response rates that can be confounded by spontaneous resolution. Bacteriologic response varies among antibiotics and does not always correlate with clinical response. Two recent well-designed trials that performed tympanocentesis at baseline and at days 4 to 6 of treatment found significantly less clinical improvement with azithromycin than with amoxicillin-clavulanate (p less than 0.05) with even larger differences in bacteriologic eradication (p less than 0.01).[17,18] These studies are important because they only included patients with bacteriologically proven AOM and assessed bacteriologic cure separately from clinical resolution, highlighting that clinical success does not equal bacteriologic success.

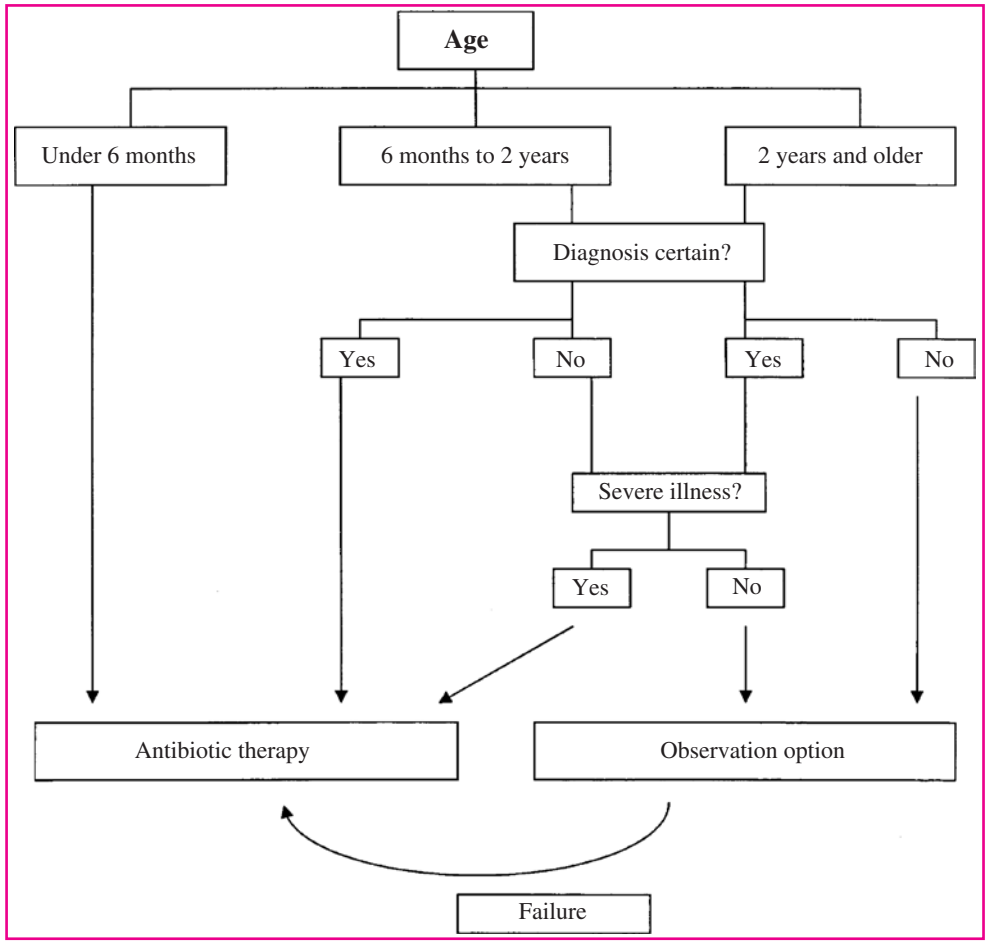

FIGURE 69–1. Treatment algorithm for initial antibiotics or observation in children with suspected or certain uncomplicated AOM.[5]

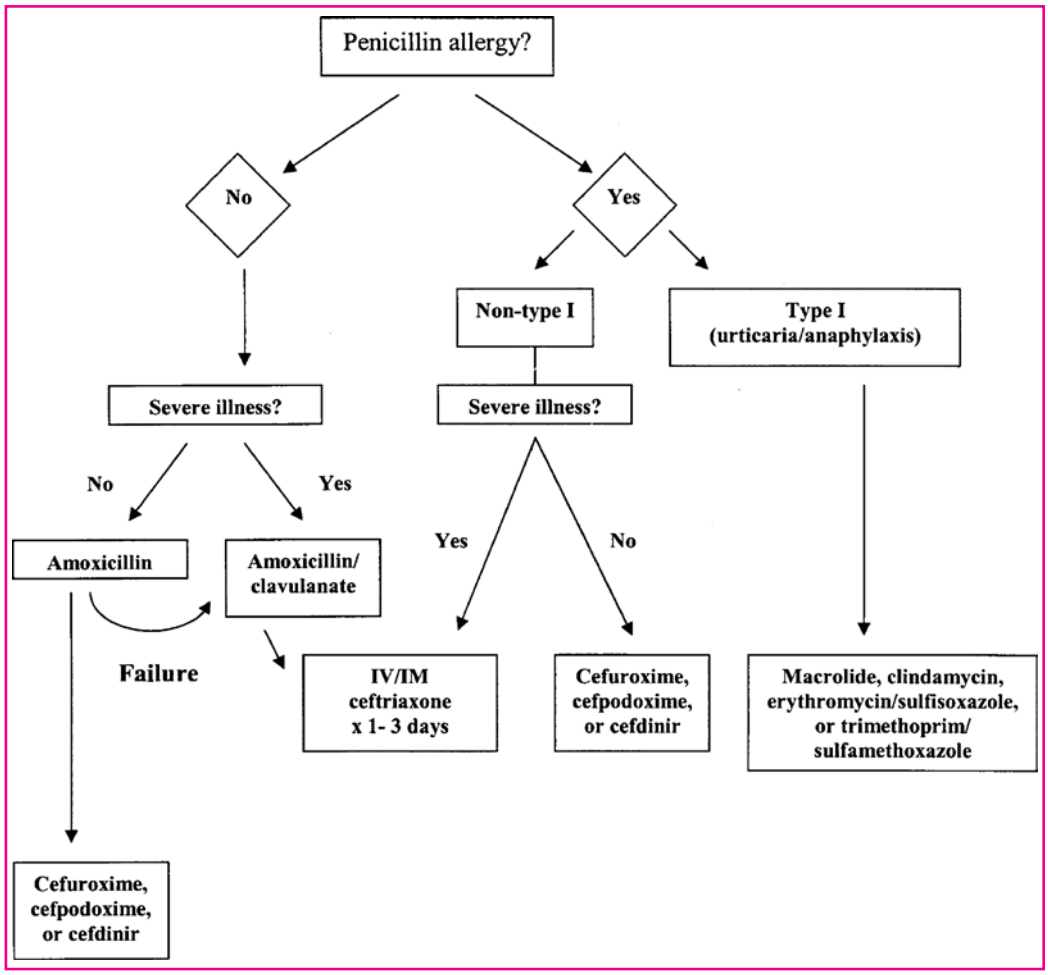

FIGURE 69–2. Treatment algorithm for uncomplicated AOM in children 2 months to 12 years of age.[5,6]

Guidelines from the American Academy of Pediatrics and the American Academy of Family Physicians are available for children between 2 months and 12 years of age with uncomplicated AOM (Fig. 69–2) and are based on published trials and expert opinion.[5] ❺ *Amoxicillin remains the drug of choice in most patients because of its proven effectiveness in AOM when used in sufficient doses for PRSP, as well as its excellent safety profile, low cost, good-tasting suspension, and relatively narrow spectrum of activity* (Table 69–2). High-dose amoxicillin (80–90 mg/kg per day) is preferred over conventional doses because higher drug levels are achieved in middle ear fluid to overcome pneumococcal resistance without substantially increasing adverse effects.[19] ❺ *In cases of severe illness or when coverage for β-lactamase-producing organisms is desired, high-dose amoxicillin-clavulanate is the preferred agent.* Pneumococcal resistance to trimethoprim-sulfamethoxazole and macrolides is problematic and strikingly common in PRSP, making these agents less desirable for most patients.[6,20,21] Patients with penicillin allergies require alternative first-line therapy (see Fig. 69–2). Children who have received an antibiotic in the previous month are more likely to harbor resistant organisms and also should receive alternative therapy.[6] A single dose of intramuscular ceftriaxone is effective for children who cannot tolerate oral medications, but a 3-day course may be preferred because of increasing pneumococcal resistance and failure of single doses.[22] Ototopic antibiotics are an alternative to systemic agents for AOM in patients with tympanostomy tubes.[23]

If there is a lack of improvement or worsening with initial therapy during the first 48 to 72 hours, antibiotic selection must be reassessed, and other contributing diseases must be excluded[5,6] (see Fig. 69–2). Tympanocentesis can help to guide therapy in difficult cases.

Duration of therapy, like drug selection, depends on patient age and disease severity. Standard 10-day oral therapy is more effective than shorter courses for uncomplicated AOM in children younger than 2 years of age and those with recurrent infections, as well as in older patients with severe illness.[5,24] Exceptions to the 10-day regimen are for azithromycin and ceftriaxone. In older children with mild or moderate illness, antibiotic therapy is needed only for 5 to 7 days.

TABLE 69–2. Antibiotics[a] for the Treatment of AOM[5,7]

Drug	Usual Dose and Schedule	Common Adverse Effects	Relative Cost[b]	Comments
Amoxicillin	80–90 mg/kg per day in 2–3 doses (adult: 875 mg twice daily)	Nausea, vomiting, diarrhea, rash	$	Drug of choice for AOM; experts recommended high-dose over conventional doses (40–45 mg/kg per day)
Amoxicillin-clavulanate	80–90 mg/kg per day in 2–3 doses (adult: 875 mg twice daily)	Nausea, vomiting, diarrhea, rash, diaper rash	$$$–$$$$	More diarrhea than amoxicillin, Augmentin ES formulation preferred owing to lower daily clavulanate component
Cefuroxime axetil	30 mg/kg per day in 2 doses (max 1 g/day with suspension; adult: 250 mg twice daily)	Nausea, vomiting, diarrhea, rash, diaper rash	$$$	Suspension gritty and bitter tasting, not interchangeable with tablets (less bioavailable)
Cefdinir	14 mg/kg per day in 1–2 doses (adult: 300 mg twice daily or 600 mg once daily)	Diarrhea, rash, vomiting, diaper rash, yeast infections	$$$	Preferred oral cephalosporin (good taste); separate from Al or Mg antacids and Fe supplements by 2 hours
Cefpodoxime proxetil	10 mg/kg per day in 2 doses (adult: 200 mg twice daily)	Diarrhea, diaper rash, vomiting, rash, yeast infections	$$$	Suspension is bitter tasting
Ceftriaxone	50 mg/kg IM or IV for 1–3 days (max 1 g/dose)	Injection site pain, swelling, or erythema, diarrhea, rash	$$$–$$$$	3-day regimen preferred for PRSP; avoid in children under 2 months
Azithromycin	10 mg/kg × 1 day, 5 mg/kg per day × 4 days; 10 mg/kg per day × 3 days; or 30 mg/kg single dose (adult dose 500 mg × 1,250 mg × 4 days; 500 mg/day × 3 days)	Nausea, vomiting, diarrhea, abdominal pain	$$	Separate from Al or Mg antacids by 2 hours; diarrhea/vomiting more common with single-dose regimen; 3- or 5-day courses preferred; increasing pneumococcal resistance; many failures with *H. influenzae* infection
Clarithromycin	15 mg/kg per day in 2 doses (adult: 250 mg twice daily)	Diarrhea, vomiting, rash, abnormal taste, abdominal pain	$$	Many drug interactions (inhibits cytochrome P-450 3A4); suspension cannot be refrigerated and has metallic taste; same microbiologic issues as azithromycin
Erythromycin-sulfisoxazole	50 mg/kg per day of erythromycin component in 3–4 doses	Nausea, vomiting, abdominal pain, diarrhea, rash	$$	Many drug interactions (like clarithromycin), contraindicated in children under 2 months; increasing pneumococcal resistance
Trimethoprim-sulfamethoxazole	8–10 mg/kg per day of trimethoprim component in 2 doses	Nausea, vomiting, anorexia, rash, urticaria	$	Increasing pneumococcal resistance; contraindicated in children under 2 months
Clindamycin	20–30 mg/kg per day in 3–4 doses (adult: 300 mg four times daily or 450 mg three times daily)	Nausea, diarrhea, *C. difficile* colitis, anorexia	$	Oral liquid has very poor taste; only for pneumococcal infection

[a]Other FDA-approved antibiotics for AOM not included in AAP/AAFP guidelines: cefaclor, cephalexin, cefprozil, cefixime, loracarbef, and ceftibuten.
[b]Approximate cost per course: $ (under $25), $$ ($25–$50), $$$ ($50–$100), $$$$ (over $100).

Adjunctive Therapy

Pain is a central feature of AOM but is often overlooked in disease management. If pain is present on presentation, analgesics or topical anesthetics can be used to alleviate otalgia. Acetaminophen and ibuprofen are commonly used over-the-counter agents for mild to moderate pain. While studies have not demonstrated superior therapeutic advantages of one agent over the other,[25] ibuprofen has a longer duration of effect but is not used routinely in children younger than 6 months of age because of increased toxicity concerns. Alternating ibuprofen with acetaminophen is not recommended owing to a lack of safety and efficacy data on combination therapy and the potential for dosing confusion and error. Topical anesthetic drops such as benzocaine (Auralgan®) provide pain relief within 30 minutes of administration and may be preferred over systemic analgesics when fever is absent. **Myringotomy** provides immediate relief but is performed rarely. Other medications such as decongestants, antihistamines, and corticosteroids have no role in the treatment of AOM and can, in some cases, prolong effusion duration.[26,27] Data are lacking on the safety and efficacy of complementary and alternative treatments.

Prevention

Immunizations may prevent AOM in certain patients, but data are conflicting. Influenza vaccine is more effective in preventing AOM in children older than 2 years of age than in younger patients perhaps owing to impaired immune response and immature host defense in infants and toddlers.[28,29] Pneumococcal conjugate vaccine is protective against infection by vaccine serotypes only with a limited overall benefit for AOM.[30] Antibiotic prophylaxis is no longer recommended for otitis-prone children because of increasing resistance. Avoidance or minimization of risk factors associated with otitis media, such as tobacco smoke and bottle feeding, is advised, but the effects of these interventions remain unproven.

Outcome Evaluation

Improvement of signs and symptoms (i.e., pain, fever, and tympanic membrane inflammation) should be evident by 72 hours of therapy. Children can appear clinically worse during the first 24 hours of treatment but often stabilize during the second day with defervescence and improved eating and sleeping patterns. If clinical improvement is not seen, or if the patient worsens, reevaluation must occur to determine the proper diagnosis and treatment. Counsel patients and caregivers regarding common antibiotic adverse events such as rash, diarrhea, and vomiting that may prompt additional medical attention.

Presence of middle ear effusion in the absence of symptoms is not an indicator of treatment failure. Children who complete therapy and are otherwise healthy should be reevaluated after 3 months for the presence of effusion that requires a hearing evaluation. Preschool-aged and younger children may need reexamination 3 to 6 weeks after therapy because speech and hearing impairment is more difficult to assess in this age group.

Patient Care and Monitoring

1. Assess the patient's signs and symptoms. Are they consistent with acute otitis media?
2. Review diagnostic information to determine if acute infection is present. Are all three diagnostic criteria present? Was the proper method used for diagnosis (pneumatic otoscopy)?
3. Does the patient require antibiotic therapy, or is observation an appropriate option?
4. Obtain a complete medication history, including prescription drugs, nonprescription drugs, and natural product use, as well as allergies and adverse effects.
5. Determine what medication should be used for pain, if present.
6. If applicable, determine which antibiotic to use and the duration of therapy.
7. Develop a plan to assess effectiveness of the chosen therapy and course of action to take if the patient does not improve or worsens.
8. Provide patient education on
   - What to expect from prescribed medication, including potential adverse effects
   - Avoidance of antihistamines and decongestants
   - Signs of treatment failure
9. Stress the importance of adherence to therapy, including antibiotic resistance concerns.
10. Determine the need for influenza and pneumococcal vaccinations.
11. Educate the family regarding risk factors for otitis media.

SINUSITIS

Sinusitis, or inflammation of the paranasal sinuses, is better described as **rhinosinusitis** that also involves inflammation of contiguous nasal mucosa, which occurs in virtually all cases of viral respiratory infections. Acute rhinosinusitis is characterized by symptoms that resolve completely in less than 4 weeks, whereas chronic rhinosinusitis typically persists as cough, rhinorrhea, or nasal obstruction for more than 90 days. Acute bacterial rhinosinusitis (ABRS) refers to an acute bacterial infection of the sinuses that can occur independently or be superimposed on chronic sinusitis. The focus of this section will be on ABRS and appropriate treatment.

Epidemiology and Etiology

Rhinosinusitis is one of the most common medical conditions in the United States, affecting about 1 billion people annually.[1] It is caused mainly by respiratory viruses such as rhinovirus, influenza virus, and respiratory syncytial virus but also can be due to allergies or environmental irritants. Only 0.5% to 2% of

TABLE 69–3. Risk Factors for Acute Bacterial Rhinosinusitis[31,33]

Viral respiratory tract infection/winter season	Anatomic defects (e.g., septal deviation)
Allergic or nonallergic rhinitis	Intranasal medications or illicit drugs
Tobacco smoke exposure	Immunodeficiency
Dental infections or procedures	Swimming/diving
Cystic fibrosis or ciliary dyskinesia	Mechanical ventilation
Nasogastric tubes	Traumatic head injury
Aspirin allergy, nasal polyps, and asthma	Female gender

viral rhinosinusitis in adults is complicated by secondary bacterial infection, but this occurs in 5% to 13% of children.[31,32] Upper respiratory infections of less than 7 days' duration usually are of viral etiology, whereas more prolonged disease or disease with severe symptoms often is caused by bacteria. Risk factors for ABRS include prior viral respiratory infection, allergic rhinitis, anatomic defects, and certain medical conditions[31,33] (Table 69–3). Clinicians often inappropriately prescribe antibiotics for clinically suspected rhinosinusitis that usually is self-limiting and infrequently is complicated by bacterial disease. Antibiotics are useful only in shortening the course of ABRS.

Bacterial pathogens that cause sinusitis are similar to those that cause acute otitis media. *S. pneumoniae* and *H. influenzae* are responsible for 50% to 60% of cases in all patients, with an additional 20% of cases caused by *M. catarrhalis* in children.[31,33] Risk factors for drug-resistant pathogens are also similar to those in AOM.[1] Other pathogens that cause sinusitis include *Streptococcus pyogenes* (up to 5%), anaerobic bacteria such as *Bacteroides* and *Peptostreptococcus* spp. (up to 9% of adults), and *Staphylococcus aureus* (up to 5% of adults).[31] Chronic infections are commonly polymicrobial with a higher incidence of anaerobes, gram-negative bacilli, and fungi.

Pathophysiology

Rhinosinusitis is caused by mucosal inflammation and local damage to mucociliary clearance mechanisms usually as a result of viral infection or allergy. Increased mucus production and reduced clearance of secretions can lead to blockage of the sinus ostia, or the opening of the sinuses to the upper airway. This environment is ideal for bacterial growth and promotes a cycle of local inflammatory response and mucosal injury characterized by increased concentrations of interleukins, histamine, and tumor necrosis factor.[31,33] Factors that contribute to bacterial invasion include nose blowing, reduced local immunity, viral virulence, and nasopharyngeal colonization with bacteria.[31] Damage to the host defense system perpetuates bacterial overgrowth and persistence of infection. Despite bacterial illness, there is a 50% to 70% spontaneous resolution rate for ABRS.[34–36]

Clinical Presentation and Diagnosis

Sinusitis symptoms typically last 7 to 10 days after a viral infection and are caused by activation of the immune system and parasympathetic nervous system.

Acute Signs and Symptoms[31,32]

- *Adults:* Nasal congestion or obstruction, nasal/postnasal discharge or purulence, facial pain or pressure (especially unilateral in a sinus area), diminished sense of smell, fever, cough, maxillary dental pain, fatigue, ear fullness or pain
- *Children:* Nasal/postnasal drainage, congestion, persistent cough (particularly at night), fever, pharyngitis, ear discomfort, halitosis, morning periorbital edema or facial swelling, fatigue, facial or tooth pain

Complications

Orbital cellulitis or abscess, periorbital cellulitis, meningitis, cavernous sinus thrombosis, ethmoid or frontal sinus erosion, chronic sinusitis, and exacerbation of asthma or bronchitis

❹ Diagnosis[31,34]

- *Clinical diagnosis:* Most common method; a viral URI that has not resolved after 10 days or worsens after 5 to 7 days *and* with signs and symptoms of acute infection (as above).
- *Radiographic studies:* Useful for assessing presence of abscess or intracranial complication.
- *Paranasal sinus puncture:* "Gold standard"; not performed routinely but can be useful in complicated or chronic cases.
- *Laboratory studies/nasopharyngeal cultures:* Not recommended for routine diagnosis.

Treatment

Desired Outcomes

The goals of treatment for ABRS are to eradicate bacteria and prevent serious sequelae. Specific aims are to relieve symptoms, normalize the nasal environment, use antibiotics when appropriate, select effective antibiotics that minimize resistance, and prevent development of chronic disease or complications.

General Approach to Treatment

Initial management of rhinosinusitis focuses on symptom relief for patients with mild disease lasting less than 10 days. Routine antibiotic use is not recommended for all patients because viral sinusitis is self-limiting and bacterial infection resolves spontaneously in many cases. ❻ *Antibiotic therapy should be reserved for persistent, worsening, or severe ABRS: patients with mild to moderately severe symptoms based on clinical judgment that have persisted for greater than 10 days or worsened after 5 to 7 days and patients with severe disease regardless of duration.*[31,34] Empirical selection is often employed and should target likely pathogens because sinus cultures are rarely obtained.

Nonpharmacologic Therapy

Ancillary treatments such as humidifiers, vaporizers, and saline nasal sprays or drops are used to moisturize the nasal canal and impair crusting of secretions along with promoting ciliary function. Although many patients report benefit from such therapies, there are no controlled studies that support their use.[32,34,36]

Pharmacologic Therapy

Adjunctive Therapy

Supportive medications that target symptoms of viral URIs are used widely in patients with rhinosinusitis, particularly in the early stage of infection. There is a lack of evidence supporting their use in ABRS, but they may provide temporary relief in certain patients.[32,36,37] Analgesics can be used to treat fever and pain from sinus pressure. Oral decongestants relieve congested nasal passages but should be avoided in children younger than 2 years of age and patients with ischemic heart disease or uncontrolled hypertension. Intranasal decongestants can be used for severe congestion in most patients 6 years of age or older, but use should be limited to 3 days or less to avoid rebound nasal congestion. Antihistamines should be avoided because they thicken mucus and impair its clearance, but they may be useful in patients with predisposing allergic rhinitis or chronic sinusitis. Similarly, intranasal corticosteroids usually are reserved for patients with allergies or chronic sinusitis, but they may be beneficial as monotherapy or with antibiotics in ABRS.[38,39]

Antibiotic Therapy

Although many clinical studies have been performed evaluating antibiotics for ABRS, no randomized, double-blind, placebo-controlled studies have used pre- and posttreatment sinus aspirate cultures as an outcome measure. Despite this, antibiotics appear to resolve symptoms more quickly and reduce failure rates and complications compared with no treatment.[35–37] Since diagnosis usually is based on clinical presentation and not sinus aspirate cultures, clinicians must attempt to differentiate ABRS from viral rhinosinusitis. ❻ *Therefore, it is important to limit antibiotic use to cases where infection is unlikely to resolve without causing prolonged disease: patients with mild to moderate symptoms that persist for 10 days or worsen over 5 to 7 days and patients with severe symptoms.*[31,34]

Treatment guidelines developed by the Sinus and Allergy Health Partnership reflect antibiotic choices that are likely to result in favorable clinical and bacteriologic outcomes based on pathogen distribution, spontaneous resolution rates, and nationwide resistance patterns.[31] ❼ *These guidelines (Figs. 69–3 and 69–4) stratify therapy based on severity of disease and risk of infection with resistant organisms, defined as mild disease in patients with prior antibiotic use within 4 to 6 weeks. Other risk factors for resistance include day-care attendance or frequent*

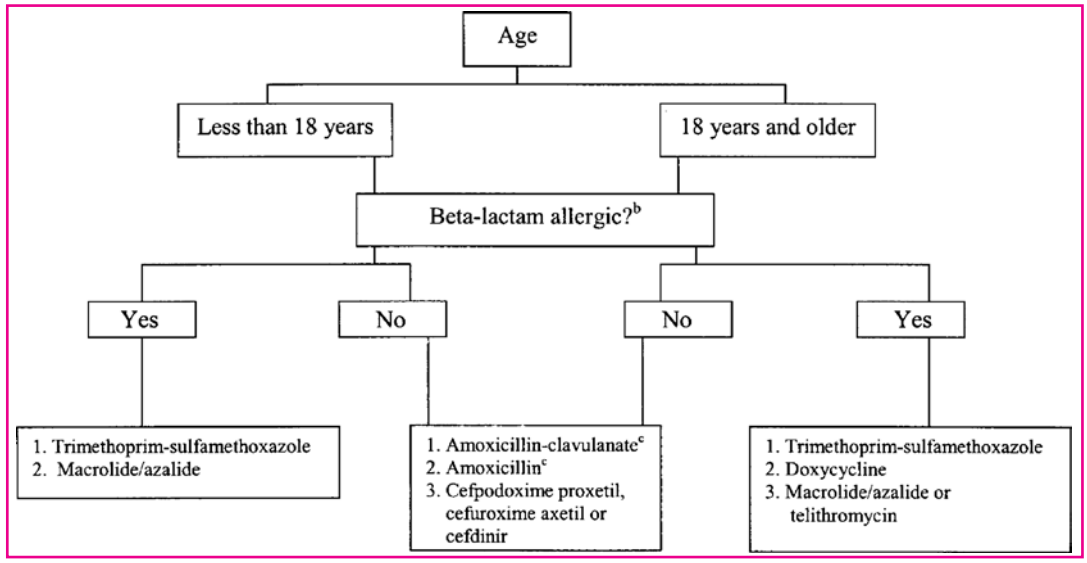

FIGURE 69–3. Treatment algorithm[a] for acute bacterial rhinosinusitis in patients with mild disease without recent antibiotic exposure.[31] [a]Antibiotics are listed in order of predicted efficacy based on predicted clinical and bacteriologic efficacy rates, clinical studies, safety, and tolerability. Doses can be found in Table 69–4. [b]Cephalosporins should be considered for patients with non-type I hypersensitivity to penicillins; they are more likely to be effective than the alternative agents. [c]High doses (90 mg/kg per day) are recommended for most children, especially those with day-care contacts or frequent infections.

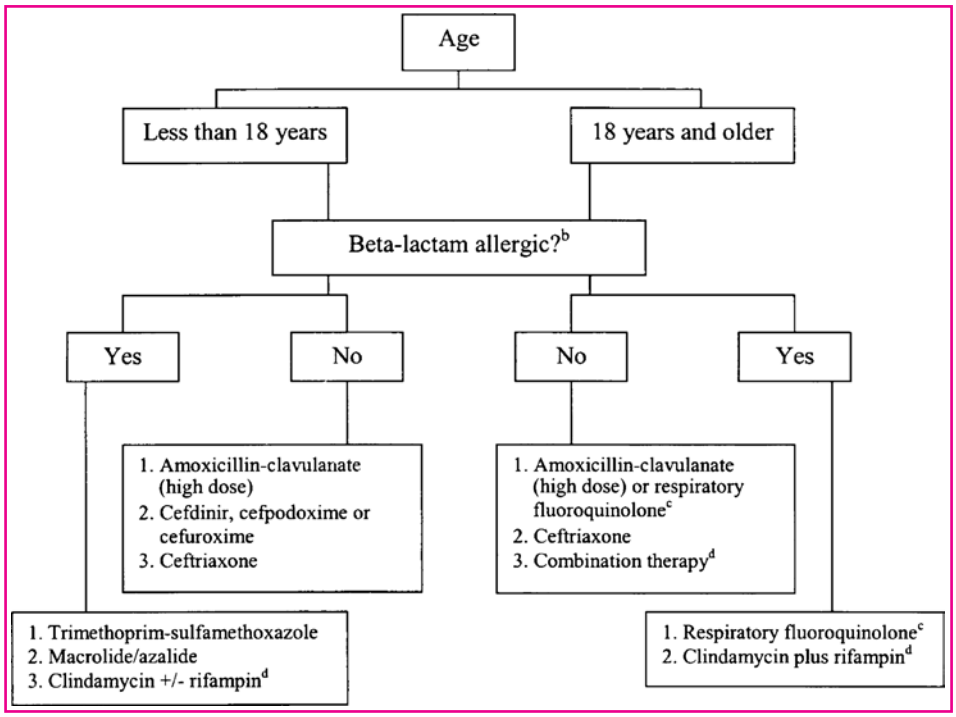

FIGURE 69–4. Treatment algorithm[a] for acute bacterial rhinosinusitis in patients with mild disease and recent antibiotic exposure or moderate disease.[31] [a]Antibiotics are listed in order of predicted efficacy based on predicted clinical and bacteriologic efficacy rates, clinical studies, safety, and tolerability. Doses can be found in Table 69–4. [b]Cephalosporins should be considered for patients with non-type I hypersensitivity to penicillins; they are more likely to be effective than the alternative agents. [c]Respiratory fluoroquinolone = gatifloxacin, levofloxacin, moxifloxacin. [d]Combination therapy should provide gram-positive and gram-negative coverage. Examples are high-dose amoxicillin or clindamycin plus rifampin or cefixime. There are no published clinical studies to support such combinations.

exposure to children in day care and recurrent disease. Severe disease requires evaluation and treatment in conjunction with specialized physicians such as otolaryngologists.

Antibiotic therapy (Table 69–4) is targeted against *S. pneumoniae,* but consideration must be given to other pathogens such as *H. influenzae*, *M. catarrhalis*, and PRSP. ❽ *Patients with mild disease and no prior antibiotic exposure should receive initial therapy with amoxicillin or amoxicillin-clavulanate.* Amoxicillin is effective for most mild infections and can be used in high doses to cover PRSP. It is less expensive and better tolerated than amoxicillin-clavulanate, which provides expanded coverage against β-lactamase-producing bacteria. Patients who are allergic to penicillins can be treated with an appropriate cephalosporin; severe penicillin allergies require treatment with alternative agents that may be less effective based solely on microbial resistance trends and not clinical data[11,20,31,36] (see Fig. 69–3). Initial therapy for patients with moderate symptoms or those with recent antibiotic exposure includes high-dose amoxicillin-clavulanate or a respiratory fluoroquinolone[31,32] (see Fig. 69–4).

Failure to respond to initial therapy after 3 days requires patient reevaluation to consider changing therapy to cover pathogens not treated with the initial choice. Antibiotics traditionally have been given for at least 10 to 14 days, with up to 21 days needed for resolution in some patients.[31] Recent data suggest that 5-day treatment courses of some fluoroquinolones and telithromycin are as effective as longer courses in adults with uncomplicated acute maxillary sinusitis.[40] Treatment success is influenced by medication adherence to the prescribed regimen, where once- or twice-daily agents are preferred over multiple daily doses.

Outcome Evaluation

Clinical improvement should be evident by 72 hours of therapy, as demonstrated by defervescence, reduction in nasal congestion and discharge, and improvements in facial pain or pressure and other symptoms. Patients should be monitored for common adverse events and referred to a specialist if clinical response is not obtained with first- or second-line therapy. Referral is also important for recurrent or chronic sinusitis or acute disease in immunocompromised patients. Surgery may be indicated in complicated cases.

PHARYNGITIS

Pharyngitis is an acute throat infection caused by viruses or bacteria. Other conditions, such as gastroesophageal reflux, postnasal drip, or allergies, also can cause sore throat and must be distinguished from infectious causes. Acute pharyngitis is responsible for 1% to 2% of adult physician visits and 6% to 8% of pediatric visits but generally is self-limited without serious sequelae.[41,42] Antibiotics are prescribed in 50% to 70% of cases in adults and children because of the inability to

TABLE 69–4. Antibiotics[a,b] for the Treatment of Acute Bacterial Rhinosinusitis[31,32]

Drug	Adult Dose	Pediatric Dose[c]	Comments
Amoxicillin	1.5–4 g/day in 2–3 doses	90 mg/kg per day in 2 doses	Lacks coverage against β-lactamase producers
Amoxicillin-clavulanate	1.75–4 g/day in 2–3 doses	90 mg/kg per day in 2 doses	Broad coverage particularly with high doses; Augmentin XR (2 g every 12 hours) targeted toward PRSP
Cefdinir	600 mg/day in 1–2 doses	14 mg/kg per day in 1–2 doses	Preferred oral liquid cephalosporin owing to palatability
Cefpodoxime proxetil	200 mg twice daily	10 mg/kg per day in 2 doses	
Cefuroxime axetil	250–500 mg twice daily	15–30 mg/kg per day in 2 doses	
Ceftriaxone	1 g IM/IV every 24 hours	50 mg/kg IM/IV every 24 hours	Experts recommend a 5-day treatment course
Trimethoprim-sulfamethoxazole	160/800 mg (1 DS tablet) twice daily	8–10 mg/kg per day of trimethoprim component in 2 doses	Considerable pneumococcal resistance limits use of this agent
Azithromycin	500 mg × 1 day, 250 mg/day × 4 days; 500 mg/day × 3 days; 2 g × 1 dose	10 mg/kg × 1 day, 5 mg/kg per day × 4 days; 10 mg/kg per day × 3 days	Increasing pneumococcal resistance and limited *H. influenzae* activity; single-dose regimen has high incidence of nausea, vomiting, and diarrhea
Clarithromycin	500 mg twice daily or 1 g once daily (XL only)	15 mg/kg per day in 2 doses	XL tablets reported to have fewer gastrointestinal problems and taste disturbances than twice-daily preparation
Telithromycin	800 mg once daily × 5 days	Not available	Improved pneumococcal coverage over macrolides; can cause blurred or double vision and difficulty focusing; cost and other side effects similar to clarithromycin-azithromycin
Doxycycline	100 mg twice daily	Avoid in children under 8 years	Can cause photosensitivity, gastrointestinal problems, tooth staining in young children; many drug-drug interactions (antacids, iron, calcium)
Gatifloxacin	400 mg once daily	Not available	Common fluoroquinolone side effects are nausea, vaginitis, diarrhea, dizziness; many drug-drug interactions (antacids, iron, calcium); tendon rupture, photosensitivity, QT prolongation possible; cost similar to amoxicillin/clavulanate
Levofloxacin	500–750 mg once daily (750 mg × 5 days)	Not available	
Moxifloxacin	400 mg once daily	Not available	
Clindamycin	150–450 mg 3–4 times daily	20–40 mg/kg per day in 3–4 doses	No gram-negative coverage; use in combination

[a]Refer to Table 69–2 for more information on antibiotics.
[b]Other FDA-approved antibiotics for ABRS not included in the Sinus and Allergy Health Partnership or AAP guidelines: cefaclor, cefprozil, cefixime, ciprofloxacin, erythromycin, loracarbef.
[c]Maximum dose not to exceed adult dose.

Patient Care and Monitoring

1. Assess the patient's signs and symptoms. Are they consistent with ABRS?
2. How long have the patient's symptoms been present? If symptoms are mild and present for fewer than 10 days, viral sinusitis is likely. Persistent moderate or acute severe symptoms are more indicative of bacterial infection.
3. Does the patient require antibiotic therapy? Avoid antibiotic use in viral disease.
4. Obtain a complete medication history, including prescription drugs, nonprescription drugs, and natural product use, as well as allergies and adverse effects.
5. Determine what adjunctive therapies should be used for symptoms, such as pain and congestion.
6. If applicable, determine which antibiotic to use and the duration of therapy.
7. Develop a plan to assess effectiveness of the chosen therapy and course of action to take if the patient does not improve or worsens.
8. Provide patient education on
   - What to expect from the antibiotic and other medications, including potential adverse effects
   - Avoidance of antihistamines, if appropriate
   - Signs of treatment failure
   - Role of viral infections in sinusitis and how to prevent disease transmission
9. Stress the importance of adherence to therapy, including antibiotic resistance concerns.

easily distinguish between viral and bacterial pathogens and fear of untreated streptococcal illness.[42,43]

Epidemiology and Etiology

Viruses most commonly cause pharyngitis, usually as part of an upper respiratory infection, and include rhinovirus, coronavirus, adenovirus, influenza virus, parainfluenza, and Epstein-Barr virus. *S. pyogenes*, or group A *Streptococcus,* is the most common bacterial cause of acute pharyngitis, responsible for 15% to 30% of cases in children and 5% to 10% of adult infections.[41,44] Infection is most common in late winter and early spring and is spread easily through direct contact with contaminated secretions. Clusters of infection are common within families, classrooms, and other crowded areas. Less common causes of bacterial pharyngitis are *Corynebacterium diphtheriae*, groups C and G streptococci, and *Neisseria gonorrhoeae*. This section will focus on group A streptococcal disease in which antibiotic therapy is indicated.

Pathophysiology

Pharyngeal colonization with group A streptococci occurs in up to 20% of children and is a risk factor for developing streptococcal pharyngitis after a break in mucosal integrity.[45] Clinicians should recognize that the symptoms of streptococcal pharyngitis usually are self-limited and resolve within 2 to 4 days of onset without treatment.[44] Historically, untreated or inappropriately treated disease caused acute **rheumatic fever,** potential permanent heart valve damage, and complications such as peritonsillar abscesses. Delayed antibiotic therapy given up to 9 days after symptom onset can prevent these sequelae, so proper diagnosis is important to minimize unnecessary antibiotic use for viral disease and complications of untreated streptococcal infection.[44,45]

Patient Encounter 2

A 7-year-old boy presents to the pediatrician with a sore throat and fever of 39.2°C for 24 hours. His mother reports that other children in his class have had "strep throat" recently. He also complains of pain on swallowing and is not eating or drinking very much. He does not have any other symptoms and has no known drug allergies. Physical examination reveals pharyngeal and tonsillar erythema with exudates and painful cervical lymphadenopathy.

- Does this child have streptococcal pharyngitis?
- Is antibiotic therapy indicated? If so, what agent should be initiated and for how long?
- What education should be provided to his mother regarding treatment?

Clinical Presentation and Diagnosis

Children between 5 and 15 years of age have the highest incidence of streptococcal pharyngitis. Parents and adults with significant pediatric contact are also at increased risk.

Signs and Symptoms of Streptococcal Pharyngitis[44,45]

- Sudden onset of sore throat with severe pain on swallowing
- Fever
- Headache, abdominal pain, nausea, or vomiting (especially in children)
- Pharyngeal and tonsillar erythema with possible patchy exudates
- Tender, enlarged anterior cervical lymph nodes
- Swollen and red uvula
- Soft palate petechiae
- Scarlatiniform rash
- General absence of conjunctivitis, hoarseness, cough, rhinorrhea, discrete ulcerations, and diarrhea (suggestive of viral etiology)

Diagnosis[41,45]

- Throat swab and culture: "Gold standard"; results within 24 to 48 hours
- Rapid antigen detection test: 80% to 90% sensitivity; results within minutes
- These tests should be performed *only* if there is a clinical suspicion of streptococcal pharyngitis.

Treatment

Desired Outcomes

❾ *The goals of therapy for streptococcal pharyngitis are to eradicate infection in order to prevent complications, shorten the disease course, and reduce infectivity and spread to close contacts*. Sequelae that can be prevented by antibiotic use are peritonsillar or retropharyngeal abscess, cervical lymphadenitis, and rheumatic fever. There is no evidence that antibiotic use has an impact on the incidence of poststreptococcal **glomerulonephritis.**

Pharmacologic Therapy

❹ *Antibiotics should be used only in cases of laboratory-documented streptococcal pharyngitis associated with clinical symptoms in order to avoid overtreatment*[45,46] (Fig. 69–5). Effective therapy (Table 69–5) reduces the infectious period from approximately 10 days to 24 hours and shortens symptom duration by 1 to 2 days.[41] ❿ *Treatment guidelines recommend penicillin as the drug of choice owing to its narrow antimicrobial spectrum, documented safety and efficacy in eradicating streptococci from the nasopharynx, and low cost.*[41,45] Historical studies proving that antibiotics prevent rheumatic fever used intramuscular procaine penicillin, but other antibiotics can eradicate nasopharyngeal streptococci and presumably are effective for

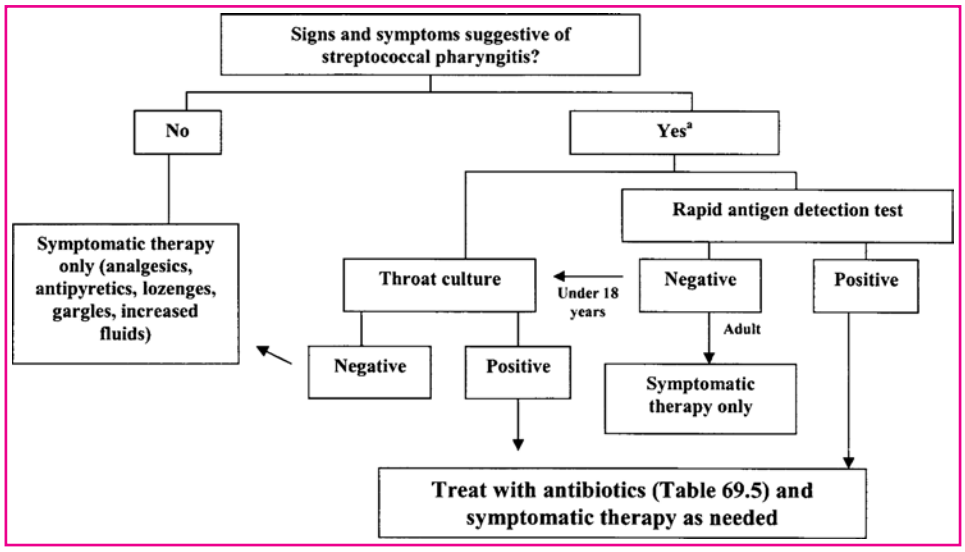

FIGURE 69–5. Treatment algorithm for management of pharyngitis in children and adults.[45,46] [a]Rapid antigen detection tests (RADTs) are preferred if the test sensitivity exceeds 80%.

preventing rheumatic heart disease.[45] ⑩ *Recent data suggest that cephalosporins are more effective than penicillin in producing bacteriologic and clinical cure and can be considered as first-line therapy alternatives in children and adults.*[47,48] Possible reasons for improved cephalosporin efficacy include the copresence of β-lactamase-producing organisms that inactivate penicillin, improved eradication of commensal streptococci by penicillin that are protective against group A streptococcal disease, and improved pharyngeal tissue penetration of cephalosporins. Usual duration of therapy is 10 days, but evidence is mounting that 5-day courses of certain cephalosporins are just as effective for bacterial eradication as 10 days of penicillin.[49,50]

Antibiotic resistance plays a smaller role in pharyngitis therapy compared with other URIs. ❶ *Penicillin resistance has not yet been documented in group A streptococci, but resistance and clinical failures occur more frequently with tetracyclines, trimethoprim-sulfamethoxazole, and to a lesser degree macrolides.* As such, patients with penicillin allergies should be treated with a first-generation cephalosporin (if non-type I allergy), a macrolide/azalide, or clindamycin. Recurrent infections caused by reinfection, poor adherence to therapy, or true penicillin failure can be treated with amoxicillin-clavulanate, clindamycin, or penicillin G benzathine.[45]

Outcome Evaluation

Antibiotics relieve symptoms over 3 to 5 days, and after the first 24 hours of therapy, patients can return to work or school if improved clinically. Follow-up cultures are not recommended to test for bacterial eradication. Lack of improvement or worsening of symptoms after 72 hours of therapy requires reevaluation. Recurrent symptoms following an appropriate treatment course should prompt reevaluation for possible retreatment.

TABLE 69–5. Antibiotics[a] for the Treatment of Streptococcal Pharyngitis[44,45]

Drug	Adult Dose	Pediatric Dose	Duration	Comments
Penicillin V	250 mg 3–4 times daily or 500 mg twice daily	250 mg 2–3 times daily 500 mg twice daily (over 12 years)	10 days	Drug of choice but increasing reports of treatment failures
Penicillin G benzathine	1.2 million units	600,000 units (if under 27 kg)	1 IM dose	Useful for nonadherence or emesis; painful injection
Amoxicillin	250–500 mg 3 times daily 750 mg daily being studied	40–50 mg/kg per day in 3 doses	10 days	Preferred over penicillin V for young children (more palatable)
Cephalexin	250–500 mg 4 times daily	25–50 mg/kg per day in 4 doses	10 days	Consider in penicillin allergy (if non-type I reaction)
Cefadroxil	500 mg twice daily	30 mg/kg per day in 2 doses	10 days	
Cefuroxime axetil	250 mg twice daily	20 mg/kg per day in 2 doses	10 days	
Cefdinir	300 mg twice daily or 600 mg once daily	14 mg/kg per day in 1–2 doses	5–10 days	Broad spectrum; expensive
Azithromycin	500 mg once daily	12 mg/kg once daily	5 days	Increasing resistance
Clindamycin	150 mg 4 times daily	20–30 mg/kg per day in 3 doses	10 days	Useful for recurrent infections

[a]Other FDA-approved agents include amoxicillin-clavulanate, cefixime, cefaclor, cefprozil, cefpodoxime, erythromycin, clarithromycin, and others.

Patient Care and Monitoring

1. Assess the patient's signs and symptoms. Are they consistent with streptococcal pharyngitis? Are symptoms of viral infection present?
2. Perform laboratory testing to confirm the presence of group A streptococci.
3. Does the patient require antibiotic therapy? Avoid antibiotic use in viral disease.
4. Obtain a complete medication history, including prescription drugs, nonprescription drugs, and natural product use, as well as allergies and adverse effects.
5. Recommend antipyretic or analgesic therapy, if needed.
6. If applicable, determine which antibiotic to use and the duration of therapy.
7. Develop a plan to assess effectiveness of chosen therapy and course of action to take if the patient does not improve or worsens.
8. Provide patient education on
   - What to expect from the antibiotic, including potential adverse effects
   - Avoidance of close contacts for 24 hours
   - Signs of treatment failure
9. Stress the importance of adherence to therapy, including antibiotic resistance concerns.

ABBREVIATIONS

ABRS: acute bacterial rhinosinusitis
AOM: acute otitis media
OME: otitis media with effusion
PRSP: penicillin-resistant *Streptococcus pneumoniae*
URI: upper respiratory tract infection

70 Skin and Soft Tissue Infections

A. Christie Graham and Randy Wesnitzer

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Discuss characteristics of the skin that render it resistant to infection.
2. Describe the epidemiology, etiology, pathogenesis, clinical manifestations, diagnostic criteria, and complications associated with skin and soft tissue infections.
3. Identify the desired therapeutic outcomes for patients with skin and soft tissue infections.
4. Recommend appropriate empirical and definitive antimicrobial regimens when given a diagnosis, physical examination, and laboratory findings.
5. Monitor chosen antimicrobial therapy for safety and efficacy.

Key Concepts

❶ Impetigo is a skin infection that most commonly afflicts young children. It is caused by group A streptococci or *Staphylococcus aureus* and is characterized by the development of numerous blisters that rupture and form crusts. Dicloxacillin, cephalexin, and topical mupirocin are considered the antibiotics of choice for treatment of impetigo.

❷ Folliculitis, furuncles, and carbuncles refer to the inflammation of one or more hair follicles, often attributed to infection with *S. aureus.* Treatment depends on severity and may involve local heat, incision and drainage, and/or oral or topical antibiotic therapy.

❸ Erysipelas is a superficial infection of the upper dermis and superficial lymphatics. It is distinguished clinically from cellulitis by its well-defined borders and slightly raised lesions. It is usually caused by β-hemolytic streptococci and treated with penicillin.

❹ Cellulitis is a bacterial infection of the dermis and subcutaneous tissue. *S. aureus* and β-hemolytic streptococci are the most common causes of acute cellulitis in otherwise healthy hosts. Persons who are immunocompromised, have vascular insufficiency, or use injection drugs are at risk for polymicrobial cellulitis.

❺ The antibiotics of choice for treating methicillin-sensitive *S. aureus* (MSSA) infections are penicillinase-stable penicillins and first-generation cephalosporins.

❻ Community-acquired methicillin-resistant *S. aureus* (CA-MRSA) is becoming an increasingly common pathogen in cellulitis. CA-MRSA can be distinguished from health care–associated MRSA (HA-MRSA) by its genetic dissimilarity, host population, drug susceptibility patterns, and toxin production.

❼ Immediate surgical débridement and intravenous broad-spectrum antibiotics are key to reducing the mortality associated with necrotizing fasciitis.

❽ The pathogenesis of diabetic foot infection stems from three key factors: neuropathy, angiopathy, and immunopathy. Aerobic gram-positive cocci, such as *S. aureus* and β-hemolytic streptococci, are the predominant pathogens in acutely infected diabetic foot ulcers. However, chronically infected wounds are subject to polymicrobial infection and require treatment with broad-spectrum antibiotics.

❾ Prevention is key in the management of pressure sores. Mild superficial pressure sore infections may be treated with topical antimicrobial agents. Systemic antibiotics are indicated for pressure sores associated with spreading cellulitis, osteomyelitis, or bacteremia.

❿ Every patient receiving antimicrobial therapy for skin and soft tissue infections must be monitored for efficacy and safety. Efficacy typically is manifested by reductions in temperature, white blood cell count, erythema, edema, and pain that begin within 48 to 72 hours. To ensure safety, dose antibiotics according to renal and hepatic function as appropriate, and monitor for and minimize adverse drug reactions, allergic reactions, and drug interactions.

Infections of the skin and soft tissues are encountered frequently in both acute- and ambulatory-care settings. They can range in severity from mild, superficial, and self-limiting to life-threatening deep tissue infections that require intensive care, surgical intervention, and intravenous (IV) broad-spectrum antibiotics. They are sometimes associated with severe complications, including osteomyelitis, glomerulonephritis, and septic shock. This chapter will cover the epidemiology, pathogenesis, clinical manifestations, and pharmacologic management of the more common and severe bacterial skin and soft tissue infections (SSTIs).

PATHOPHYSIOLOGY

Intact skin generally is resistant to bacterial, fungal, and viral infection. In addition to providing a mechanical barrier, its relative dryness, slightly acidic pH, colonizing bacteria, frequent desquamation, and sweat (which contains IgG and IgA) prevent invasion by various microorganisms.[1] Conditions that predispose a patient to SSTIs include (1) high bacterial load (greater than 10^5 microorganisms), (2) excessive skin moisture, (3) decreased skin perfusion, (4) availability of bacterial nutrients, and perhaps most important, (5) damage to the corneal layer of the skin.[2]

IMPETIGO

Epidemiology and Etiology

Impetigo, which stems from the Latin word for "attack," is a common skin infection worldwide. ❶ *It predominately afflicts children between 2 and 5 years of age but may occur in any age group.*[3] *β-Hemolytic streptococci and Staphylococcus aureus are the most common causative pathogens.*[3,4] It is a superficial infection and is spread easily, especially in settings of poor hygiene and crowding and particularly during the summer months. The offending microorganisms colonize the skin surface and then invade through abrasions, insect bites, or other small traumas. The scabby, crusty eruption of impetigo ensues. These lesions may occur anywhere on the body but are most common on the face and extremities.

Clinical Presentation and Diagnosis

Impetigo lesions are numerous, well localized, and **erythematous.** They develop either as small, thin-walled blisters (impetigo contagiosum) or as larger blisters (bullous impetigo).[3–5] The blisters rupture easily, leaving behind a **friable** crust reminiscent of cornflakes. The lesions of impetigo are rarely painful but are **pruritic**. Scratching the lesions can spread the infection to other areas of the body.

Treatment

Desired Outcomes

The primary goal of therapy for impetigo is resolution of infection. A secondary goal is prevention of glomerulonephritis (although extremely rare) secondary to group A *Streptococcus* (GAS).

Nonpharmacologic Treatment

Because impetigo is rarely painful, there is often a delay in seeking medical attention. However, the lesions will resolve with time and increased hygiene. Soaking the lesions with soap and water and the use of skin emollients to dry skin areas may reduce spread of the lesions.

Pharmacologic Treatment

Because GAS historically has been the primary causative organism, penicillin has been the mainstay of therapy. ❶ *However, the incidence of S. aureus impetigo is increasing, so oral penicillinase-stable penicillins or first-generation cephalosporins are now preferred.*[3] Erythromycin is an alternative choice when penicillin allergy is a concern. *Topical mupirocin may be used alone when there are few lesions.*[3]

FOLLICULITIS, FURUNCLES, AND CARBUNCLES

See Table 70–1.

LYMPHANGITIS

Epidemiology and Etiology

Simply stated, lymphangitis is an inflammation of a lymphatic channel. Lymphangitis begins when a local skin infection is not contained. The infection spreads into the lymphatic channel and is carried to the regional lymph nodes. Most cases are attributed to GAS.

Clinical Presentation and Diagnosis

Lymphangitis is characterized by red linear streaks that extend from the infection site toward the regional lymph nodes.[5,7] The lymph nodes become tender and swollen. If left unchecked, lymphangitis may lead to a complicating bacteremia.

Treatment

Pharmacologic Treatment

In uncomplicated cases, prompt oral antibiotic therapy with amoxicillin or a first-generation cephalosporin halts the progression of lymphangitis. Clindamycin may be used if the patient has a significant β-lactam allergy. Intravenous antibiotics (penicillinase-stable penicillins, first-generation cephalosporins,

TABLE 70–1. Folliculitis, Furuncles, and Carbuncles[3,5,6]

	Folliculitis	Furuncles	Carbuncles
Epidemiology/ etiology	❷ *Folliculitis is a superficial inflammatory reaction involving the hair follicle.* The most familiar form of folliculitis is acne. It can be infectious, caused by microorganisms such as *Staphylococcus aureus, Pseudomonas,* and *Candida*. It is also sometimes chemically induced.	*Also known as boils, furuncles might be described as a deep form of folliculitis. A furuncle is a bacterial infection that has spread into the subcutaneous skin layers but still only involves individual follicles.* Furuncles occur primarily in young men. DM and obesity are other predisposing factors. *Staphylococci are the most common cause.*	*Carbuncles share all the characteristics of furuncles. However, a carbuncle is larger and involves several adjacent follicles and may extend into the subcutaneous fat.* Carbuncles are most common in diabetics and tend to from on the neck and back.
Presentation and diagnosis	Folliculitis presents as small, pruritic, erythematous **papules**. Location of the lesions and a good patient history are often all that are required in the diagnosis of folliculitis. While the papules may be cultured and Gram stains or potassium hydroxide stains done to help determine causative agent, it is not generally required because folliculitis often resolves spontaneously within a few days.	Furuncles most commonly develop on the face, neck, axilla, and buttock. A furuncle typically starts as a small, red, tender nodule. Within in a few days, the nodule becomes painful and pustular. Typically, a furuncle will spontaneously discharge pus, heal, and leave a small scar.	These are larger than a furuncle and exquisitely painful. All carbuncles and furuncles that are large or associated with cellulitis or fever require incision and drainage in order to resolve.
Desired outcomes	The goals of therapy for folliculitis, furuncles, and carbuncles are resolution of infection with no or minimal scaring. A secondary goal of therapy for larger furuncles and all carbuncles is to minimize the risk of endocarditis or osteomyelitis by reducing bloodstream invasion.		
Non-pharmacologic treatment	❷ *Warm compresses are generally sufficient.*	*Moist heat is indicated to facilitate drainage. Large furuncles require incision and drainage.*	*Incision and drainage are indicated.*
Pharmacologic treatment	❷ Often resolves spontaneously. *A topical antibiotic or antifungal may be used to control the spread of infection but generally is unnecessary.* For staphylococcal or streptococcal folliculitis, antibiotic ointments such as mupirocin might be administered three times daily. Antifungal shampoo can be used for **dermatophytes.**	*Carbuncles and furuncles that have surrounding cellulitis and fever or are located midline on the face must be treated systemically with an antibiotic that will cover Staphylococcus, such as dicloxacillin, cephalexin, or erythromycin.* Treatment should continue until acute inflammation has resolved, usually a 5–10-day course.	

or clindamycin) and hospitalization are warranted for patients displaying signs of systemic illness or bacteremia.[7]

CELLULITIS AND ERYSIPELAS

Epidemiology and Etiology

Cellulitis and erysipelas are bacterial infections of the skin. Although separate entities, there is some clinical difficulty in distinguishing the two. ❸❹ *Cellulitis is a bacterial infection of the dermis and subcutaneous tissue, whereas erysipelas is a more superficial infection of the upper dermis and superficial lymphatics.* Although both can occur on any part of the body, about 90% of infections involve the leg.[8,9] Another 7.5% of cases involve the arm or face. Erysipelas is most common in the young and the elderly. Typically, both infections develop after a break in skin integrity, resulting from trauma, surgery, ulceration, burns, tinea infection, or other skin disorder. However, they may occur after an inapparent break in the skin, and the skin may appear previously intact.[3,10] In rare cases, cellulitis develops from blood-borne or contiguous (from adjacent tissues) spread of pathogens.[5,10]

Etiologic microorganisms vary according to the area involved, host factors, and exposures. ❹ *In otherwise healthy adults, S. aureus and GAS are the most common causative bacteria.* ❸ *GAS is the causative pathogen in approximatey 65% of erysipelas cases.*[9] ❹*Persons who are immunocompromised, have vascular insufficiency, or use injection drugs are at risk for polymicrobial cellulitis.*[3]

Clinical Presentation and Diagnosis

The manifestations of and diagnostic criteria for erysipelas and cellulitis are presented in Table 70–2. Once diagnosed, cellulitis is grouped into uncomplicated or complicated presentations depending on patient characteristics and severity of

TABLE 70–2. Presentation of Erysipelas and Cellulitis[3,9–12]

Symptoms

The infected area is described as painful or tender. In the case of erysipelas, the patient may complain of "burning pain" at the lesion site.

Signs

Both erysipelas and cellulitis are manifested by rapidly spreading areas of redness, edema, and heat. Vesicles containing clear fluid may appear on the skin. Lymphangitis and regional lymphadenopathy may be observed.

Important clinical differences between erysipelas and cellulitis exist:

- In erysipelas, low-grade fever and flulike illness are common prior to development of the lesion. The lesion is fiery red, raised above the level of surrounding skin, and has well-defined borders.
- In cellulitis, the lesion is not raised and has poorly defined margins.

Laboratory Tests

Leukocytosis may be present.

Cultures and sensitivities:

- Blood cultures are only positive about 4% of the time but should be obtained for complicated cases. Cultures aspirated from the lesion have an organism isolation rate of less than 20% but also may be considered.
- Abscess drainage and débrided tissue, if obtainable, can be cultured and will yield the causative organism(s) up to 90% of the time.

Imaging Studies

Imaging studies may identify abscess formation, gas in the soft tissues, or osteomyelitis.

infection. Complicated infections are those in which there are systemic signs and symptoms of infection (i.e., fever, chills, leukocytosis, and hypotension); the patient is immunocompromised, bacteremic, or has vascular insufficiency; polymicrobial infection is suspected; or the cellulitis is spreading rapidly, involves a large area of the body, or is chronic. Persons with complicated cellulitis often are hospitalized and require IV antibiotics. Otherwise, cellulitis is classified as uncomplicated and treated with oral antibiotics on an outpatient basis.[12]

Complications of Cellulitis

The causative pathogen(s) of cellulitis can enter the circulation, causing a bacteremia and occasionally sepsis. The mortality rate associated with complicated cellulitis requiring hospitalization is approximately 5%. Patients with multiple comorbid conditions, congestive heart failure, or severe obesity tend to be at higher risk. If the circumference of an extremity is cellulitic, compartment syndrome becomes a concern, and a surgical consult may be required. Infrequently, cellulitis can progress to necrotizing fasciitis, a life-threatening condition that will be discussed later in this chapter.[13]

Recurrent cellulitis can be problematic as well. About 30% of patients hospitalized with cellulitis will develop a recurrent episode within 3 years. Vascular and lymphatic insufficiencies increase the risk of recurrences.[10,11,13]

Treatment

Desired Outcomes

The goals of therapy for cellulitis and erysipelas are rapid and successful eradication of the infection and prevention of related complications.

Nonpharmacologic Treatment

Nonpharmacologic treatment includes elevating and immobilizing the involved limb to decrease associated swelling. For cellulitis, sterile saline dressings should be placed on any open lesions to cleanse them of **purulent** materials. Surgical débridement is indicated occasionally for severe infection. If an abscess is present, drainage is imperative to achieving clinical cure.[10]

Pharmacologic Treatment

❸ *Penicillin is the treatment of choice for erysipelas.* In uncomplicated cases, a 5-day course is as effective as a 10-day course.[3] Other agents that are acceptable for treatment include clindamycin, erythromycin, cephalexin, and dicloxacillin.

❺ *Currently, β-lactams active against penicillinase-producing strains of S. aureus (commonly known as methicillin-sensitive S. aureus, or MSSA) are the drugs of choice for acute bacterial cellulitis in otherwise healthy individuals.*[10] ❻ *However, there is a rapidly increasing prevalence of cellulitis caused by community-acquired methicillin-resistant S. aureus (CA-MRSA) in this population.* Treatment of these infections is problematic secondary to the organism's resistance to many antibiotics and the lack of well-studied, orally administered agents active against it.[14]

❻ *CA-MRSA can be distinguished from health care–associated MRSA (HA-MRSA) by its genetic dissimilarity, host population, drug susceptibility patterns, and toxin production.* While acquisition of HA-MRSA is associated with well-defined risk factors (i.e., history of prolonged hospital or nursing home stay, past antimicrobial use, indwelling catheters, pressure sores, surgery, or dialysis), risk factors for acquisition of CA-MRSA are not well established.[14]

CA-MRSA is susceptible to more antibiotics than HA-MRSA. Like HA-MRSA, CA-MRSA typically is sensitive to vancomycin, linezolid, daptomycin, tigecycline, and quinupristin/dalfopristin, but it also may be sensitive to clindamycin, doxycycline, minocycline, and/or trimethoprim-sulfamethoxazole (TMP-SMX).[14]

Of the latter four agents, clindamycin has the most data supporting its use. However, the clinician must be aware of inducible clindamycin resistance. For CA-MRSA isolates determined to be resistant to erythromycin but sensitive to clindamycin, an additional laboratory analysis, known as the *erythromycin-clindamycin D-zone test,* is conducted to assess for inducible clindamycin resistance.[15] Isolates for which the D-zone test indicates inducible resistance should not be treated with clindamycin.

With regard to the clinical effectiveness of TMP-SMX and the tetracyclines, anecdotal evidence and small trials support their use in the treatment of CA-MRSA cellulitis. However, large randomized, controlled trials are needed to confirm their place in therapy.[16,17]

Finally, CA-MRSA produces the virulent Panton-Valentine leukcocidin toxin. It destroys leukocytes, causes severe tissue damage and necrosis, and has been associated with both necrotizing skin infections and pneumonia.[14]

In addition to being at risk for staphylococcal and streptococcal cellulitis, immunocompromised patients are also at risk for disease caused by resistant gram-negative, anaerobic, and low-virulence organisms (i.e., *S. epidermidis*). Empirical broad-spectrum antimicrobial coverage, including coverage for resistant organisms such as HA-MRSA and *Pseudomonas* spp., is appropriate for severe cellulitis and/or systemic illness. The clinician should be diligent in attempting to isolate a causative pathogen in these individuals.[3]

Injection drug use also predisposes individuals to polymicrobial cellulitis. The antecubital region of the arm is usually the site of infection. *S. aureus,* the most common isolate, is frequently associated with abscess formation. Because some injection drug users lick their needles to "clean" them, antibiotics with anaerobic coverage should be used. Occasionally, *Candida* spp. are isolated, and the patient may require antifungal therapy.[18]

Table 70–3 lists some recommended antibiotic regimens for the treatment of cellulitis. The duration of therapy for uncomplicated cellulitis typically ranges from 7 to 10 days. For complicated cellulitis, begin therapy with IV antibiotics and switch to oral once the patient is afebrile and skin findings begin to resolve. Typically, this is done after 3 to 5 days. The complete duration of therapy can range from 10 to 14 days and longer in cases where abscess, tissue necrosis, underlying skin wounds, or delayed response to therapy are involved.[10]

TABLE 70–3. Empirical Antimicrobial Therapy for Cellulitis[3,6,10]

Host Factors	Probable Etiologic Bacteria	Mild Infection or Step-Down Therapy[a] (Oral Antibiotic Therapy)	Moderate–Severe Infection[a] (IV Antibiotic Therapy)
Previously healthy	MSSA GAS CA-MRSA	Dicloxacillin 500 mg every 6 hours Cephalexin 500 mg every 6 hours CA-MRSA suspected or allergy to PCNs: TMP-SMX DS 1–2 tabs every 12 hours[b] Clindamycin 300 mg every 6 hours[c] Doxycycline 100 mg every 12 hours[b]	Nafcillin 1–2 g every 4 hours Cefazolin 1–2 g every 8 hours CA-MRSA suspected or allergy to PCNs: Vancomycin 15 mg/kg every 12 hours Clindamycin 600 mg every 8 hours[c] TMP-SMX 2.5 mg/kg (TMP component) every 12 hours[b] Doxycycline 100 mg every 12 hours[b] Linezolid 600 mg every 12 hours Daptomycin 4 mg/kg daily
Injection drug use	MSSA GAS Gram-negatives Anaerobes CA-MRSA[d]	Amoxicillin-clavulanate 500 mg every 8 hours Fluoroquinolone + clindamycin 300 mg every 6 hours TMP-SMX DS 1–2 tabs every 12 hours + clindamycin 300 mg every 6 hours	Ampicillin-sulbactam 3 g every 6 hours Piperacillin-tazobactam 3.375 g every 6 hours Ceftriaxone 1 g daily + clindamycin 600 mg every 8 hours Ertapenem 1 g daily
Immune compromise, DM	MSSA HA-MRSA[e] Gram-negatives *Pseudomonas* spp.	Amoxicillin-clavanate 500 mg every 8 hours Fluoroquinolone[f] + clindamycin 300 mg every 6 hours	Piperacillin-tazobactam 3.375–4.5 g every 6 hours[g] Imipenem-cilastatin 500 mg every 6 hours[g] Cefepime 2 g every 8–12 hours[g] + metronidazole 500 mg every 8 hours Cefatazidime 2 g every 8 hours[g] + clindamycin 600 mg every 8 hours Fluoroquinolone[f] + clindamycin 600 mg every 8 hours Tigecycline 100 mg load, then 50 mg every 12 hours

[a]Doses given are for adults with normal renal function. IV therapy can be switched to oral therapy (as for mild infection) when the patient is afebrile and signs of infection are resolving.
[b]Limited clinical data exist for the treatment of MRSA infections.
[c]CA-MRSA isolates resistant to erythromycin should be evaluated for inducible clindamycin resistance.
[d]If CA-MRSA suspected, regimen must include an agent with activity against this organism.
[e]If HA-MRSA suspected, regimen must include vancomycin, daptomycin, linezolid, or tigecycline.
[f]Ciprofloxacin and levofloxacin exhibit activity against *Pseudomonas aeruginosa*.
[g]*Pseudomonas aeruginosa* generally is susceptible to this agent.

Patient Encounter, Part 1

A 56-year-old man presents to the emergency room with complaints of right lower leg pain and redness. Examining his leg, you notice that he has erythema and edema extending from his ankle to proximal tibia. The area feels warm. On questioning, the patient states that the redness started approximately 2 days ago. He has felt feverish over the previous 48 hours but did not check his temperature. He has had no other symptoms. He states that he bumped his shin on the bed frame last week and sustained a bruise but no apparent breaks in the skin. His vital signs at the clinic reveal a temperature of 38.3°C, pulse 102 beats per minute, blood pressure 110/72 mm Hg, and respiratory rate 20 breaths per minute. The physician diagnoses this patient with cellulitis.

- What clinical manifestations are suggestive of cellulitis?
- What additional information do you need before developing a therapeutic plan for this patient?

NECROTIZING FASCIITIS

Epidemiology and Etiology

Necrotizing fasciitis (NF) is an uncommon, rapidly progressive, life-threatening infection of the subcutaneous tissue and fascia. Its associated mortality rate is approximately 25% and is nearly 70% in patients who present with septic shock.[3,19] NF can affect any age group. Although the risk of NF is higher in patients with underlying diseases (specifically diabetes, alcoholism, cardiac disease, and peripheral vascular disease), healthy hosts can become infected as well.[20]

NF typically erupts after an initial trauma, which can range from a small abrasion to a deep penetrating wound. The infection begins in the fascia, where bacteria replicate and release toxins that facilitate their spread.[21]

There are two types of NF, distinguishable by microbiology, source, and severity of illness. Type I (~70% of cases) is polymicrobial and typically involves anaerobes (i.e., *Bacteroides* or *Peptostreptococcus*), **facultative anaerobes** (i.e., β-hemolytic streptococci), and Enterobacteriaceae (e.g., *Escherichia coli*, *Enterobacter*, or *Klebsiella*).[5] Type I infections develop in the following clinical settings: after surgery or deep penetrating wounds involving the bowel; from decubitous ulcer, perianal, or vulvovaginal infection; or from the injection site in an injection drug user (IDU).[3,5]

Type II NF is generally a monomicrobial infection caused by invasive GAS. Occasionally *S. aureus* is implicated. Type II often occurs after minor trauma, such as an insect bite or abrasion.[3] It is more severe than type I because invasive strains of GAS produce toxins that induce erythema, systemic toxicity, multiorgan failure, and shock.[22]

Patient Encounter, Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH
Hypertension. He is not aware of any other illnesses.

FH
Father died of stroke at age 72. Mother, age 79, is alive with diabetes and a history of breast cancer. One brother, age 59, is alive and healthy.

SH
Works as a college professor. Married. Three grown children. Denies tobacco use. Drinks approximately 4 glasses of wine on weekends. Denies illicit drug use.

Meds
Atenolol 100 mg by mouth daily, multiple vitamin 1 tablet by mouth daily

Allergies: No known drug allergies

ROS
(+) pain and swelling in the right lower extremity; (–) headache, chest pain, shortness of breath, cough, nausea, vomiting, diarrhea, and weight loss

PE
- **General:** Patient is in no acute distress. He weighs 72 kg (158 lbs) and is 5 ft, 9 in tall.
- **Chest:** Lungs bilaterally clear to auscultation.
- **CV:** Regular rate, rhythm. No murmurs/rubs/gallops.
- **Exts:** Right lower extremity with erythema and edema from the ankle to just below the knee. Warm to the touch. LLE within normal limits.

Labs
White blood cell count 17.3 × 10^3/μL, serum creatinine 0.8 mg/dL (70.7 μmol/L)
The patient is diagnosed with cellulitis and admitted to the medical floor.

- What are the most likely causative organisms in this case of cellulitis?
- What are the goals of therapy for this patient?
- What nonpharmacologic interventions would you recommend for him?
- What antimicrobial therapy would you recommend? Include drug, dosage, route, interval, and duration of therapy.
- How would you monitor your selected regimen for safety and efficacy?
- If the MRSA rate at your hospital is 75% (mostly CA-MRSA), would you change your pharmacologic recommendation? If so, how?

Clinical Presentation and Diagnosis

Patient outcomes rely on the clinician's ability to recognize NF early in the course of disease. This is often difficult because early disease tends to be indistinguishable clinically from cellulitis. The clinical presentation of NF is presented in Table 70–4.

Complications

NF is perhaps the most devastating SSTI. Left untreated, it can invade the muscles and circulation, resulting in myonecrosis and septic shock, respectively. Half the NF cases caused by GAS are accompanied by GAS toxic shock-like syndrome. The syndrome is endotoxin-mediated, manifested by hypotension and multiorgan dysfunction, and is fatal in 30% to 70% of those afflicted.[5,19] Amputation is required in up to 50% of patients with extremity infections.[23] Once the patient recovers from acute NF, he or she often requires skin and/or muscle grafting and consequent physical rehabilitation depending on the amount and types of tissue removed during surgical intervention and the duration of hospital stay.[24]

Treatment

Desired Outcomes

The goals of therapy for NF include eradication of infection and reduction of related morbidity and mortality.

Nonpharmacologic Treatment

After resuscitation and hemodynamic stabilization, *prompt surgical intervention is key in the treatment of NF. Delayed operative débridement increases mortality.*[21] Some clinicians recommend hyperbaric oxygen (HBO) as an adjunct treatment of NF, although its use is controversial. Clinical data supporting the use of HBO in NF are inconsistent, with some trials showing reduced mortality rates and others showing no benefit.[25]

TABLE 70–4. Presentation of Necrotizing Fasciitis[3,21]

Symptoms
Early: Severe pain that is disproportionate to clinical signs and extends beyond the margins of the infected area.
Late: Area may become numb secondary to muscle and nerve involvement.
Signs
Early: Skin is erythematous, edematous, and warm; the clinical presentation is similar to that of cellulitis.
Intermediate (within 24–48 hours): Blisters and bullae indicate severe skin and tissue ischemia.
Late: The skin becomes violaceous and progressively gangrenous; hemorrhagic bullae may be present. Septic shock may ensue.
Laboratory Tests
Leukocytosis, thrombocytopenia, and elevated serum creatinine may be present.
Deep tissue specimens obtained during surgical irrigation and débridement should be sent for Gram stain, culture, and sensitivity.[3]
Imaging Studies
MRI and CT scans may reveal fluid and gas along fascial planes.
Typically, imaging studies are avoided when making a diagnosis because they may delay surgical intervention and increase mortality.

Pharmacologic Treatment

Broad-spectrum IV antibiotic therapy should be initiated immediately in patients with NF regardless of suspected type. Often a high-dose β-lactam/β-lactamase inhibitor or carbapenem is used in combination with clindamycin. Although the latter agents are active against gram-positive aerobes and anaerobes, clindamycin still should be added to decrease bacterial toxin production, thereby limiting tissue damage.[3]

If GAS is identified as the sole causative organism from deep tissue culture, antimicrobial therapy can be narrowed to high-dose IV penicillin G plus clindamycin. Antibiotic therapy should be continued until further operative débridements are unnecessary, the patient displays substantial clinical improvement, and fevers have abated for at least 48 to 72 hours.[3]

CLOSTRIDIAL MYONECROSIS

Another important necrotizing skin and soft tissue infection is clostridial myonecrosis (gas gangrene). Clostridial myonecrosis can develop spontaneously but most often occurs after trauma. *Clostridium perfringens* is the most common causative pathogen.

The infected area initially may be tense, painful, and pale. The color changes rapidly, becoming bronze and then purplish red. Bullae filled with reddish blue fluid appear. Gas in the tissue is uniformly present and detected by imaging studies or as crepitus. The infection quickly becomes systemic, and the patient may present with shock and multiple-organ failure. The management of clostridial myonecrosis, like NF, requires aggressive surgical débridement and appropriate antibiotics, generally high-dose penicillin plus clindamycin.[5]

DIABETIC FOOT INFECTIONS

Epidemiology and Etiology

Foot ulcers and related infections are among the most common, severe, and costly complications of diabetes mellitus (DM). Fifteen percent of all patients with DM develop at least one foot ulcer, resulting in direct health care expenditures of approximately $9 billion annually in the United States.[26,27] Diabetic foot ulcers and wounds are highly susceptible to infection. Related skin, soft tissue, and bone infections account for 25% of all diabetes-related hospitalizations.[28] More than half of all nontraumatic lower extremity amputations (LEAs) performed each year in Western nations are linked to diabetic foot infection; 80,000 LEAs are performed annually in the United States alone.[29,30]

Pathophysiology

❽ *The pathogenesis of diabetic foot infection stems from three key factors:* ***neuropathy,*** *angiopathy, and immunopathy.*[29,30] Neuropathy, the most prominent risk factor for diabetic foot ulcers, develops when continuously high blood glucose levels damage motor, autonomic, and sensory nerves. Damage to motor neurons that supply the small intrinsic muscles of the foot causes deformation, resulting in altered muscular balance, abnormal areas of pressure on the tissues and bones, and repetitive injuries. Damage to autonomic neurons results in the shunting of blood through direct arteriole-venous communications, thereby decreasing capillary flow. The secretion of sweat and oil is also diminished, producing dry, cracked skin that is more prone to infection. Finally, damage to sensory neurons produces a loss of protective sensation so that the patient becomes unaware of injury or ulceration.

Angiopathy of large (macroangiopathy) and small (microangiopathy) vessels is also the result of high blood glucose concentrations. Angiopathy results in ischemia and skin breakdown.

Finally, persons with diabetes have altered immune function that predisposes them to infection. Although their humoral immune responses remain intact, leukocyte function and cell-mediated immunity are compromised in poorly controlled disease. Achieving and maintaining tightly controlled blood glucose levels can wholly or partially reverse diabetic immunopathy.

Infected diabetic foot ulcers typically contain a multitude of microorganisms. ❽ *Aerobic gram-positive cocci, such as S. aureus and β-hemolytic streptococci, are the predominant pathogens in acutely infected diabetic foot ulcers. However, chronically infected wounds are subject to polymicrobial infection.* The clinician should suspect the involvement of gram-negative (Enterobacteriaceae and *P. aeruginosa*) and possibly low-virulence pathogens (including enterococci and *S. epidermidis*) in chronic or necrotic wounds. Foul-smelling, necrotic or gangrenous wounds are also commonly infected with anaerobic bacteria. Patients recently hospitalized or treated with broad-spectrum antibiotics are at risk for infection with antibiotic-resistant organisms, including MRSA and vancomycin-resistant enterococci (VRE).[31]

Clinical Presentation and Diagnosis

Not all diabetic foot ulcers are infected. However, infection is often difficult to detect when perfusion and the inflammatory response are limited in the diabetic patient. The common signs and symptoms (i.e., pain, erythema, and edema) of infection may be absent.[32] Still, the diagnosis of diabetic foot infection depends mostly on clinical evaluation.

Purulent drainage from the ulcer is indicative of infection. When pus and inflammatory symptoms are not present, the clinician must be astute to more subtle findings. These include delayed healing, increase in lesion size, prolonged exudate production, malodor, and tissue friability. Abnormal granulation tissue also may be present, as evidenced by color change (from bright red to dark red, brown, or gray) and increased bleeding. The ability to probe the ulcer to the underlying bone is highly indicative of osteomyelitis.[32]

Diabetic foot infections are classified into four categories based on clinical presentation using the PEDIS scale (perfusion, extent/size, depth/tissue loss, infection, sensation). Grade 1 signifies no infection; grade 2, involvement of skin and subcutaneous tissue only; grade 3, extensive cellulitis or deeper infection; and grade 4, systemic inflammatory response syndrome.[33] Grade 2 infections are classified as non-limb-threatening infections, whereas grades 3 and 4 infections are limb-threatening.[30,31] Table 70–5 provides detailed information regarding the grades.

Imaging studies, such as x-ray and magnetic resonance imaging (MRI), can identify osteomyelitis. Blood cultures should be obtained from all patients with signs and symptoms of systemic illness. Deep tissue cultures may help to direct therapy. Bone also may be sent for culture in cases of osteomyelitis. Superficial cultures are unreliable and should be avoided.

Complications

Spreading soft tissue infection and osteomyelitis are often the first complications that develop from diabetic foot infection. Some patients develop bacteremia and sepsis.

TABLE 70–5. Clinical Classification of a Diabetic Foot Infection

Infection Severity	PEDIS Grade	Clinical Manifestations of Infection
Uninfected	1	Wound lacking purulence or any manifestations of inflammation
Mild	2	Presence of at least two manifestations of inflammation (purulence or erythema, pain, tenderness, warmth or **induration**), but any cellulitis/erythema extends no more than 2 cm around the ulcer, and infection is limited to the skin or superficial subcutaneous tissues; no other local complications or systemic illness
Moderate	3	Infection (as above) in a patient who is systemically well and metabolically stable but who has at least 1 of the following characteristics: cellulitis extending greater than 2 cm, lymphangitic streaking, spread beneath the superficial fascia, deep tissue abscess, gangrene, and involvement of muscle, tendon, joint, or bone
Severe	4	Infection in a patient with systemic toxicity or metabolic instability (e.g., fever, chills, tachycardia, hypotension, confusion, vomiting, leukocytosis, acidosis, severe hyperglycemia, or **azotemia**).

From ref. 31, with permission.

The most feared complication of infected diabetic foot ulcers is LEA. Diabetic patients are approximately 40 times more likely to require an amputation than nondiabetics.[34] Morbidity and mortality rates are high following amputation. Mortality ranges from 40% to 80% after 5 years, generally secondary to comorbid conditions, including heart and renal disease.[28,30]

Treatment

Desired Outcomes

The goals of therapy for diabetic foot infection are eradication of the infection and avoidance of soft tissue loss and amputation.

Prevention

Comprehensive foot care programs can reduce the rate of diabetic foot ulcers and associated LEAs by 45% to 85%.[29] Periodic foot examinations with monofilament testing and patient education regarding proper foot care, optimal glycemic control, and smoking cessation are key preventative strategies. Custom orthotic footwear and prophylactic reconstructive foot surgeries also may be effective in reducing the incidence of foot ulcers.[26]

Nonpharmacologic Treatment

The nonpharmacologic treatment of diabetic foot ulcers may include **off-loading,** chemical or surgical débridement of necrotic tissue, wound dressings, hyperbaric oxygen, vascular or orthopedic surgery, and the use of human skin equivalents.[30]

Pharmacologic Treatment

The severity of a patient's infection, based on the PEDIS scale, guides the selection of empirical antimicrobial therapy. While most patients with grade 2 diabetic foot infections can be treated as outpatients with oral antimicrobial agents, all grade 4 and many grade 3 infections require hospitalization, stabilization of the patient, and broad-spectrum IV antibiotic therapy.[31]

Multiple antibiotic options exist for the treatment of diabetic wound infections. Table 70–6 provides both general treatment strategies and specific, though not all-inclusive, antibiotic recommendations. The duration of therapy correlates with infection severity. Grade 2 infections require 7 to 14 days of therapy, whereas grade 3 to 4 wounds necessitate treatment durations of 14 to 28 days. If osteomyelitis is present, treatment should continue for at least 6 weeks.[31]

TABLE 70–6. Empirical Pharmacologic Treatment of Diabetic Foot Infection[31]

Infection Severity	PEDIS Grade	General Approach to Empirical Pharmacologic Treatment	Examples of Empirical Regimens[a]
Uninfected	1	None. Avoid treating uninfected diabetic foot ulcers.	Not applicable.
Mild	2	Oral, narrow-spectrum antibiotic therapy with activity against *Staphylococcus aureus* and streptococcal species. Include coverage for MRSA (HA- or CA-MRSA) according to patient history and resistance patterns in the area.	MRSA not suspected: Cephalexin 500 mg by mouth every 6 hours Dicloxacillin 500 mg by mouth every 6 hours HA-MRSA suspected: Linezolid 600 mg by mouth every 12 hours Vancomycin 1 g IV every 12 hours Daptomycin 4 mg/kg IV daily CA-MRSA suspected: Clindamycin 300 mg by mouth every 6 hours[b] TMP-SMX DS 1–2 tablets by mouth every 12 hours[c] Doxycycline 100 mg by mouth every 12 hours[c]
Moderate to severe	3–4	Parenteral, broad-spectrum antibiotic therapy. Generally select drugs with activity against gram-positive, gram-negative, and anaerobic bacteria (especially if wound is malodorous). Include coverage for MRSA (HA- or CA-MRSA) according to patient history and resistance patterns in the area.	Ceftriaxone 2 g IV daily + clindamycin 600 mg IV every 8 hours Piperacillin-tazobactam 3.375–4.5 g IV every 6 hours Imipenem-cilastatin 500 mg IV every 6 hours Ceftazidime 2 g IV + clindamycin 600 mg IV every 8 hours Fluoroquinolone[d] + clindamycin 600 mg IV every 8 hours Tigecycline 100 mg IV load, then 50 mg every 12 hours[e] If MRSA suspected: vancomycin, linezolid, daptomycin, dalfopristin/quinupristin are indicated, in addition to gram-negative and anaerobic coverage as required. Tigecycline is appropriate as monotherapy in polymicrobial SSTI that involves MRSA.[e]

[a]Doses given are for adults with normal renal function.
[b]CA-MRSA isolates resistant to erythromycin should be evaluated for inducible clindamycin resistance.
[c]Limited clinical data exist for the treatment of MRSA infections.
[d]Ciprofloxacin and levofloxacin exhibit activity against *Pseudomonas aeruginosa*.
[e]Tigecycline is not currently approved for the treatment of diabetic foot infections.

INFECTED PRESSURE SORES

Epidemiology and Etiology

Pressures sores, also known as *decubitous ulcers* or *bedsores,* affect 1.5 to 3 million Americans annually.[35] The cost of healing pressure sores can be substantial, with current estimates ranging from $2000 to $70,000 per wound.[35] Although the prevalence of pressure sores is highest in long-term care facilities, 57% to 60% of *new* pressure sores actually develop in the hospital, most commonly in intensive-care and orthopedic patients. Elderly patients and those with spinal cord injuries are most at risk.[36]

A pressure sore is a chronic wound that results from continuous pressure on the tissue overlying a bony prominence. This pressure impedes blood flow to the dermis and subcutaneous fat, resulting in tissue damage and necrosis.[37,38]

Pressure sore infections develop from breaks in skin integrity and contamination from dirty areas of close proximity. Pressure sore infections generally are polymicrobial.[39]

Clinical Presentation and Diagnosis

Approximately two-thirds of all pressure sores occur on the sacrum and heels. The remaining third occur predominately on the elbows, ankles, trochanters, ischia, knees, scapulas, shoulders, or occiput.[35] Pressure sores are classified according to the extent of tissue destruction.[40] The staging of pressure sores is presented in Table 70–7.

Bacterial colonization of pressure sores is common. Because infection impairs wound healing and may require systemic antimicrobial therapy, the clinician must be able to distinguish it from colonization. Table 70–8 describes the clinical presentation of infected pressure sores.

TABLE 70–7. Staging of Pressure Sores[40]

Stage I
Affected area of skin may feel warm (or cool) and boggy (or firm) when compared with the skin on an opposing area of the body. The patient may complain of pain or itching in the area.
Lightly pigmented skin: Persistent area of reddened skin.
Heavily pigmented skin: Persistent area of red-, blue-, or purple-toned skin.
Stage II
Partial-thickness skin loss of the epidermis and/or dermis.
Superficial ulceration presents clinically as an abrasion, blister, or shallow crater.
Stage III
Full-thickness skin loss involving damage to, or necrosis of, subcutaneous tissue that may extend down to underlying fascia.
The ulcer presents clinically as a deep crater with or without undermining of adjacent tissue.
Stage IV
Full-thickness skin loss with extensive damage or necrosis of muscle, bone, or supporting structures (e.g., tendon, joint, or capsule). Undermining and sinus tracts also may be present.

TABLE 70–8. Presentation of Infected Pressure Sores

Symptoms
Because many high-risk patients lack sensation, pain may not be a primary symptom.
Signs
Infection generally is diagnosed when erythema and edema of the surrounding skin, purulent drainage, malodor, or delayed wound healing are present.
Patients with bacteremia develop fever, chills, confusion, and/or hypotension.
Laboratory Tests
Deep tissue cultures may help to direct therapy. Bone also may be sent for culture in cases of osteomyelitis. Superficial cultures are unreliable and should be avoided.
Imaging Studies
Imaging studies, such as CT, MRI, or bone scan, can be used to detect osteomyelitis and to determine the depth and extent of tissue destruction.

Complications

Tens of thousands of Americans, including 1 of every 12 persons with spinal cord injury, die each year as a result of complications relating to pressure sores.[41] Most complications are infectious. The most common is osteomyelitis, which is present in approximately 38% of infected pressure sores.[37] Less frequently, NF, clostridial myonecrosis, and sepsis can occur.

Treatment

Desired Outcomes

The goals of therapy for infected pressure sores include resolution of infection, promotion of wound healing, and establishment of effective infection control.[38]

Prevention

❾ *Prevention is the most humane and cost-effective component in the management of pressure sores.* Key prevention strategies include monitoring of high-risk patients, reducing skin exposure to pressure and moisture, and promoting good nutritional status.

Careful monitoring and preventative care of high-risk patients can begin once these patients are identified. Intrinsic, or host-related, risk factors for the development of pressure sores include age greater than 75 years, limited mobility, loss of sensation, unconsciousness or altered sense of awareness, and malnutrition. Extrinsic, or environmental, risk factors include pressure, **friction, shear stress,** and moisture.[37,42]

Turning and repositioning the patient at least every 2 hours can reduce skin pressure and prevent pressure sores. However, because this level of care is unattainable in most hospital and nursing-home environments, multitudes of pressure-reducing mattresses have been manufactured. Although these can help to decrease pressure on susceptible areas, they do not negate the need for position changes.[37,42]

Maintaining a clean, dry environment can prevent skin **maceration** and subsequent tissue damage. This can be

TABLE 70–9. Antimicrobial Therapy for Infected Pressure Sores[36–38]

Mild Infection (Topical or Oral Antibiotics)[a]	Moderate to Severe Infection (Parenteral Antibiotics)[a]
Topical	Cefoxitin 1–2 g every 8 hours
Silver sulfadiazine 1% cream	Piperacillin-tazobactam 3.375–4.5 g every 6 hours[b]
Combination antibiotic ointments	Imipenem-cilastatin 500 mg every 6 hours[b]
Oral	Ertapenem 1 g daily
Amoxicillin-clavulanate 500 mg every 8 hours	Fluoroquinolone[c] + clindamycin 600 mg every 8 hours
Fluoroquinolone[c] + clindamycin 300 mg every 6 hours	
MRSA suspected:	
Regimen should include vancomycin, daptomycin, quinupristin/dalfopristin or linezolid.	

[a]Doses given are for adults with normal renal function.
[b]*Pseudomonas aeruginosa* is generally susceptible to this agent.
[c]Ciprofloxacin and levofloxacin exhibit activity against *Pseudomonas aeruginosa*.

accomplished with frequent changes of bed sheets and clothing, thorough drying of skin after bathing, and prompt disposal of incontinent stool or urine.[37]

Malnutrition is a significant but reversible risk factor. High-protein diets have been shown in multiple studies to improve wound healing in patients with pressure sores.[37]

Nonpharmacologic Treatment

Pressure relief, adequate nutrition (high-protein diet), and surgical débridement or abscess drainage are the mainstays of nonpharmacologic treatment.[38]

Pharmacologic Treatment

❾ *Systemic antibiotics are indicated for pressure sores associated with spreading cellulitis, osteomyelitis, or bacteremia.* Because the infections usually are polymicrobial, antibiotic therapy should target gram-positive, gram-negative, and anaerobic bacteria. The duration of treatment is generally 10 to 14 days, unless osteomyelitis is present.[38]

Mild superficial infections, such as those that present clinically with delayed wound healing or minimal cellulitis, may be treated with topical antimicrobial agents.[37] Table 70–9 lists some frequently used systemic and topical antibiotics.

INFECTED BITE WOUNDS

Epidemiology and Etiology

Fifty percent of Americans will be bitten by an animal at least once during their lifetimes. Although most of these injuries are minor, approximately 20% will require medical treatment.[3]

Dogs cause approximately 80% of all bites. These bites most commonly involve the extremities, and young children are particularly at risk.[43,44] Approximately 15% to 25% of dog bites become infected.[44]

Cat bites are the second most common animal bite, most often occurring in women and elderly individuals. Most involve the hand. Because cats have long, thin teeth that cause puncture wounds, their bites are more likely to become infected than a dog bite. Approximately 50% of cat bites become infected.[43,44]

Human bites are third most common and the most serious.[44] Before the availability of antibiotics, up to 20% resulted in amputation. Currently, human bite–associated amputation rates remain at 5%, secondary to vascular compromise and infectious complications.[43]

There are two types of human bite injuries. Occlusal injuries are inflicted by actual biting, whereas clenched-fist injuries are sustained when a person's closed fist hits another's teeth. Of the two, clenched-fist injuries typically are more prone to infectious complications.[43,44]

Bite-wound infections generally are polymicrobial. On average, five different bacterial species can be isolated from an infected animal bite wound.[3] Both the normal flora of the biter's mouth and that of the bite recipient's skin can be implicated. The bacteriology of the cat and dog mouth is quite similar. *Pasteurella multocida*, a gram-negative aerobe, is one of the predominant pathogens, isolated in up to 50% of dog and 75% of cat bites. *S. viridans* are the most frequently cultured bacteria from human bite wounds.[3,43] Table 70–10 provides a comprehensive list of cat, dog, and human bite-wound pathogens.

TABLE 70–10. Etiology and Presentation of Infected Bite Wounds[43,44]

Bacterial Pathogens

Dog and cat: *Pasteurella multocida,* staphylococci, streptococci *Moraxella* spp., *Eikenella corrodens, Capnocytophaga canimorsus, Actinomyces, Fusobacterium, Prevotella,* and *Porphyromonas* spp.

Human: *Viridans* streptococci, *Staphylococcus aureus, Eikenella corrodens, Hemophilus influenzae,* and β-lactamase-producing anaerobic bacteria.

Signs and Symptoms

The onset of infectious symptomatology is typically 12–24 hours after the bite.

Pain at the wound site is common.

Erythema, edema, and purulent or malodorous drainage at the wound site are manifestations of infected wounds. The patient may be febrile.

Limited range of motion may be present, especially if the hand is bitten.

Laboratory Tests

Leukocytosis may be present.

The clinician should obtain anaerobic and aerobic wound cultures only if the wound appears clinically infected.

Imaging Studies

X-rays should be obtained if the bite is on the hand, could have damaged bone or joints, or if an embedded object or tooth fragment is suspected.

Clinical Presentation and Diagnosis

The clinical presentation of infected bite wounds is presented in Table 70–10.

Complications

Complications of infected bite wounds include lymphangitis, abscess, septic arthritis, tenosynovitis, and osteomyelitis. Bites to the hand are particularly complication-prone.[43,44]

Treatment

Desired Outcomes

The goals of therapy for an infected bite wound are rapid and successful eradication of infection and prevention of related complications.

Nonpharmacologic Treatment

Thorough irrigation with normal saline is the first step in the care of an infected bite wound. The wound should be elevated and immobilized. Surgical closure may be advocated, especially for facial wounds. Wounds that are infected, at higher risk for infection, or older than 24 hours should be left open because premature closure can lead to disastrous infectious complications.[43]

Pharmacologic Treatment

Most bite wounds require antibiotic therapy only when clinical infection is present. However, prophylactic therapy is recommended for wounds at higher risk for infection. These include human bites, deep punctures, bites to the hand, and bites requiring surgical repair.[43]

❾ *The most effective agent for the treatment (and prophylaxis) of human and animal bite-wound infections is amoxicillin-clavulanate.* Alternatives for patients with significant penicillin allergies include either a fluoroquinolone or TMP-SMX in combination with clindamycin. Doxycycline also may be prescribed. The durations of prophylaxis and treatment generally are 3 to 5 and 10 to 14 days, respectively.[3]

If the wound is associated with significant cellulitis and edema, systemic signs of infection, or possible joint or bone involvement, hospitalization and IV antibiotics (typically ampicillin-sulbactam 3 g IV every 6 hours) should be initiated. Bone and joint infections will require longer durations of therapy of up to 6 weeks.[44]

Rabies and Tetanus

Patients with animal bite wounds may require rabies prophylaxis.[43,44] If the bite is from a bat, a wild animal, a domestic animal that has or is suspected to have rabies, or an unavailable animal, the patient should receive rabies immune globulin and vaccine immediately.[45]

Crush injuries and those greater than 1 cm in depth are at risk for tetanus. A tetanus and diptheria toxoid booster (Td) should be administered to any patient who has not received one in 5 or more years. A Td and tetanus immune globulin are indicated in those patients who have not previously received at least three Td boosters or whose immunization history is unknown.[43,44]

OUTCOME EVALUATION

❿ *Patients receiving antibiotic therapy for SSTIs require monitoring for efficacy and safety. Efficacy typically is manifested by reductions in temperature, white blood cell count, erythema, edema, and pain. Initially, signs and symptoms of infection may worsen owing to toxin release from certain organisms (i.e., GAS); however, they should begin to resolve within 48 to 72 hours of treatment initiation.* If no response, or worsening infection is noted after the first 3 days of antibiotics, reevaluate the patient.[3] Lack of response may be due to a noninfectious or nonbacterial diagnosis, a pathogen not covered by or resistant to current antibiotic therapy, poor patient adherence, drug or disease interactions causing decreased antibiotic absorption or increased clearance, immunodeficiency, or the need for surgical intervention.[46] ❿ *To ensure the safety of the regimen, dose antibiotics according to renal and hepatic function as appropriate, and monitor for or minimize adverse drug reactions, allergic reactions, and drug interactions.*

❿ Patient Care and Monitoring

Choosing antibiotic therapy for SSTIs:

1. To select the most effective *empirical* antibiotic agent(s) for SSTIs, review the following:
   - The diagnosis
   - Clinical manifestations and severity of illness (to assess the need for IV versus oral therapy)
   - Past medical history, chronic disease states (to determine suspected pathogens)
   - Patient's ability to adhere to the regimen (if outpatient treatment indicated)
2. To ensure the safety of your selected antibiotic agent(s), review the following:
   - Current medications (over the counter, prescription, and alternative) for potential drug interactions
   - History of medication allergies and adverse effects
   - Current laboratory analyses to determine renal and hepatic function
   - Chronic disease states or acute conditions that could be worsened by certain antimicrobial agents (e.g., QT prolongation or acute renal failure)
   - Other disease modifiers that may preclude use (e.g., pregnancy, child)

(*Continued*)

Monitoring antibiotic therapy for SSTIs:

1. Ensure that antimicrobial therapy is effective by monitoring for
   - Resolution of local and systemic signs and symptoms of infection
   - Resolution of laboratory evidence of infection
2. Narrow antibiotic coverage when possible with the use of culture and sensitivity data.
3. Assess patient adherence.
4. Ensure that antimicrobial therapy is safe by monitoring for and treating (as appropriate)
   - Common and severe adverse effects
   - Drug interactions

Patient education regarding antibiotic therapy for SSTIs:

1. It is imperative to take the antibiotic as prescribed and to finish the therapy.
2. If no symptomatic improvement is noted within 3 days, contact your health care provider.
3. Many antibiotics cause diarrhea. If it is severe, contact your health care provider.
4. Consider health initiatives to improve wound healing, such as smoking cessation and glycemic control.

71 Infective Endocarditis

Ronda L. Akins

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Differentiate the causes and development of infective endocarditis (IE).
2. Identify the clinical presentation and laboratory evaluation for IE.
3. Assess diagnostic criteria used to evaluate a patient suspected of having IE.
4. Describe the most likely causative organisms of IE, particularly in specific patient populations.
5. Develop appropriate pharmacologic treatment recommendations for patients with IE.
6. Define appropriate patient populations requiring prophylactic treatment, and differentiate appropriate drug regimens.
7. Devise a monitoring plan for patients with IE to determine treatment efficacy and discern any adverse effects.

Key Concepts

❶ For infective endocarditis to develop, the occurrence of several factors is required. These factors involve alterations to the endocardial surface that allow for bacterial adherence and eventual infection.

❷ Persistent fever is the most common symptom present in patients with IE.

❸ Blood cultures are the essential laboratory test for IE because continuous bacteremia occurs in over 80% of patients. Without blood culture results, appropriate treatment would be difficult to establish.

❹ Echocardiograms are used for detecting the presence of a vegetation. Either a transthoracic echocardiogram (TTE) or a transesophegeal echocardiogram (TEE) may be used depending on certain patient characteristics.

❺ Choosing the appropriate antimicrobial therapy is crucial to achieve adequate organism kill.

❻ An extended treatment course of 4 to 6 weeks (in most cases) is required to achieve an adequate cure.

❼ The overall goal of therapy is to eradicate the infection and minimize/prevent any complications.

❽ In an effort to prevent the development of IE, prophylactic treatment generally is recommended for patients with high risk factors.

❾ Monitoring the patient's clinical course is necessary to assess the effectiveness of therapy, detect the potential development of bacterial resistance, and determine outcome.

Infective endocarditis (IE) is a serious infection affecting the lining and valves of the heart. While this disease is mostly associated with infection of the heart valves, the septal defects may become involved as well. Infections also occur in patients with prosthetic or mechanical devices, such as mechanical heart valves or who are intravenous drug users (IVDUs). Bacteria is the primary cause of IE; however, fungi and atypical organisms also can be responsible pathogens.

Typically IE is classified into acute or subacute. This difference has been based on the progression and severity of the disease. Acute disease is more aggressive, characterized by high fevers, elevated white blood cell (WBC) counts, and systemic toxicity, with death occurring within a few days to weeks. This type of IE often is caused by more virulent organisms, particularly *Staphylococcus aureus*. Subacute disease typically is caused by less virulent organisms, such as *viridans* streptococci, producing a slower and more subtle presentation. It is characterized by weakness, fatigue, low-grade fever, night sweats, weight loss, and other nonspecific symptoms, with death occurring in several months.

Successful management of patients with IE is based on proper diagnosis, treatment with adequate therapy, and

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

monitoring for complications, adverse events, or development of resistance. The treatment and management of IE are best determined through identification of the causative organism. IE has varied clinical presentations; therefore, patients with this infection may be found in any medical subspecialty (i.e., medicine, surgery, critical care, etc.).

EPIDEMIOLOGY AND ETIOLOGY

Despite IE being a fairly uncommon infection, in the United States, there are about 10,000 to 20,000 new cases annually, and IE accounts for approximately 1 case per 1000 hospital admissions.[1] Although the exact number of cases is often difficult to determine owing to the diagnostic criteria and reporting methods for this disease, it continues to rise. IE is now considered the fourth leading cause of serious infectious disease syndromes following urosepsis, pneumonia, and intraabdominal sepsis.[2] Men are affected more commonly than women at a ratio of 1.7:1. Although IE occurs at any age, more than 50% of cases occur in patients older than 50 years.[1] IE in children continues to be uncommon unless they have underlying structural defects often involving surgical repair or catheter-related bacteremia.[1] With the increased use of mechanical valves, **prosthetic-valve endocarditis** (PVE) now accounts for approximately 7% to 25%.[3] Patients who are IVDUs are also at an increased risk for IE, with an estimated number of cases of 150 to 2000 per 100,000 persons per year, most being younger adults.[3] Additionally, other patients at high risk for IE include patients with any congenital or structural cardiac defects, including valvular disease; long-term hemodialysis; diabetes mellitus; poor oral hygiene; previous endocarditis; hypertrophic cardiomyopathy; and mitral valve prolapse with regurgitation.[4–6]

Although almost any type of organism is capable of causing IE, the majority of cases are caused by gram-positive organisms (Table 71–1). These consist primarily of streptococci, staphylococci, and enterococci. Consideration of gram-negative, fungal, and other atypical organisms must be taken into account, particularly in certain patient populations.

TABLE 71–1. Etiologic Agents in Infective Endocarditis

Agent	Percent of Cases
Streptococci	60–80
Viridans group streptococci	30–40
Other streptococci	15–25
Enterococci	5–18
Staphylococci	20–35
Coagulase-positive	10–27
Coagulase-negative	1–3
Gram-negative aerobic bacilli	1.5–13
Fungi	2–4
Miscellaneous bacteria	Less than 5
Mixed infections	1–2
Culture-negative	Less than 5–24

Patient Encounter, Part 1

A 56-year-old man with a history of diabetes and coronary artery disease presents to the emergency room with complaints of weakness, fever, and chills. On interviewing the patient, you determine that he went to the dentist about 3 weeks ago and since that time has lost about 5 lb. The patient reports that the symptoms began about 1 to 2 weeks ago. He denies any use of alcohol or illicit drugs but admits to smoking about $^1/_2$ pack of cigarettes per day.

- What information would make you suspect IE?
- Does he have any risk factors for IE?
- What additional information would you like to know before deciding on an empirical treatment for this patient?

PATHOGENESIS AND PATHOPHYSIOLOGY

❶ *For infective endocarditis to develop, the occurrence of several factors is required. Typically, there must be an alteration of the endothelial surfaces of the heart valves to allow for organism attachment and colonization.* These alterations may be produced by an inflammatory process such as rheumatic heart disease or by injury from turbulent blood flow. Platelets and fibrin now deposit on the damaged valves, forming a **nonbacterial thrombotic endocarditis** (NBTE). At this point, bacteria through hematogenous spread (i.e., bacteremia) adhere to and colonize the nidus, forming a **vegetation**. Further deposits of platelets and fibrin cover the bacteria, providing a protective coating that allows for the development of a suitable environment for continued organism and vegetation progression, often producing an organism density of 10^9 to 10^{10} **colony-forming units** (CFU) per gram. This sequence of events is summarized in Fig. 71–1.

Acquisition of PVE differs in early stages, where direct inoculation may occur during surgery instead of through hematogenous seeding. The prosthetic valve also has a greater propensity for organism colonization than native valves. However, in late PVE, the process of colonization and vegetation formation is similar to native valve IE, as described earlier.[7]

Classically, vegetations typically are located on the line along valve closure on the atrial surface of the atrioventricular valves (tricuspid and mitral) or on the ventricular surface of the semilunar valves (pulmonary and aortic) (Fig. 71–2). The vegetations can vary significantly in size from only millimeters to several centimeters and may be single or multiple masses. Often, destruction of underlying tissue occurs and may cause

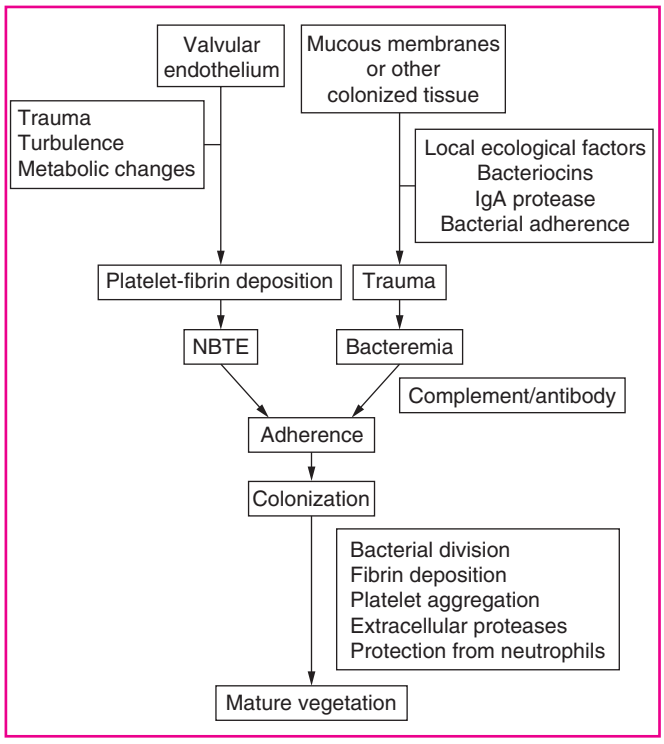

FIGURE 71–1. Pathogenesis of infective endocarditis. (From Scheld W. In: Atlas of Infectious Diseases: External Manifestations of Systemic Infections. Philadelphia: Current Medicine, Inc. Copyright © 1997. Used with permission.)

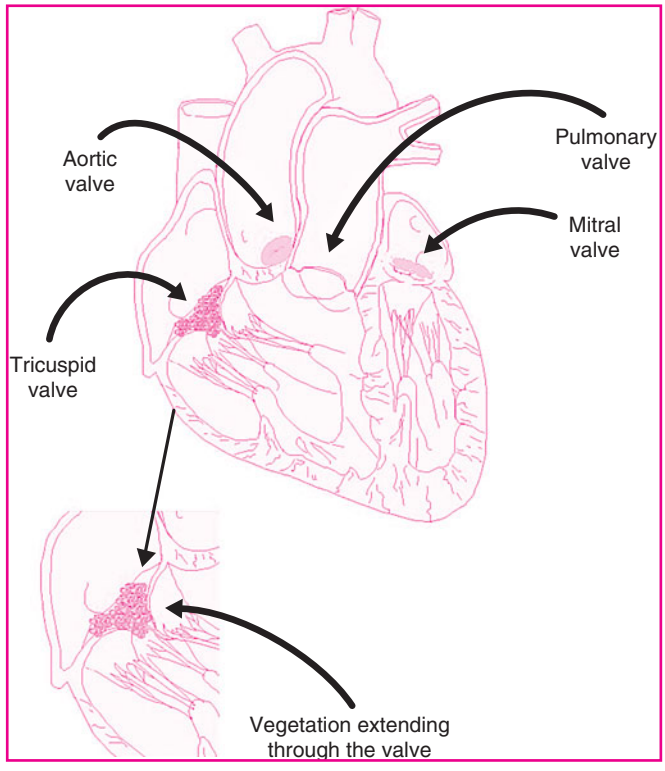

FIGURE 71–2. Diagram of the heart indicating common sites of infection.

perforation of the valve leaflet or rupture of the chordae tendinae, interventricular septum, or papillary muscle. Valve ring abscesses may occur, resulting in fistulas penetrating into the myocardium or pericardial sac, particularly with staphylococcal endocarditis.

Embolic events are also common. Embolization occurs as portions of the friable vegetation break lose and enter the bloodstream. These infected pieces are called *septic emboli.* Pulmonary abscesses are formed commonly as a result of septic emboli from right-sided IE (tricuspid and mitral valves). However, left-sided IE (pulmonary and aortic valves) is more likely to have an embolus travel to any organ system, especially the kidneys, spleen, and brain. Along with emboli, immune complex deposition may occur in organ systems, causing extracardiac manifestations of the disease. This commonly occurs in the kidneys, producing abscesses, infarction, or glomerulonephritis. Immune complexes or emboli also may produce skin manifestations of the disease, as seen with petechiae, Osler nodes, and Janeway lesions, or within the eye (e.g., Roth spots).

CLINICAL PRESENTATION AND DIAGNOSIS

The clinical presentation for IE is quite variable and often nonspecific. ❷ *A fever is the most frequent and persistent symptom in patients but may be blunted with previous antibiotic use, congestive hear failure, chronic liver or renal failure, or infection caused by a less virulent organism (i.e., subacute disease).*[3] Other signs and symptoms that also may occur are listed in the Clinical Presentation box with some discussed further in detail below.

Heart murmurs are heard frequently on auscultation (over 85% of cases), but a new murmur or change in murmurs is only found in 5% to 10 % or 3% to 5 %, respectively.[1] Additionally, over 90% of patients who have a new murmur will develop congestive heart failure, which is a major cause of morbidity and mortality. Splenomegaly and mycotic aneurysms also are noted in many cases of IE.

This disease is also characterized by the following peripheral manifestations that are found in up to one-half of patients with IE, although recently the prevalence has been decreasing[8]:

- *Petechiae* are very small (usually less than 3 mm) pinpoint flat red spots beneath the skin surface caused by microhemorrhaging. They occur in 20% to 40% of chronic IE, often found on the buccal mucosa, conjunctivae (Fig. 71–3*A*) and extremities[1] (Fig. 71–3*B*).
- *Splinter hemorrhages* appear as small dark streaks beneath the finger- or toenails and occur most commonly proximally with IE, typically occurring as a result of local vasculitis or microemboli (Fig. 71–3*C*).
- *Clubbing* of the finger tips typically occurs in long-standing illness and is present in approximately 10% to 20% of patients.[1]

Current Medicine, Inc. Copyright © 1997. Used with permission.)

- *Osler nodes* are small (usually 2–15 mm), painful, tender subcutaneous nodules located on the pads of the fingers and toes (Fig. 71–3*E*) caused primarily by either septic emboli or vasculitis. These nodes are rare in acute disease but are also nonspecific for IE despite occurring in 10% to 25% of all patients.[1]
- *Janeway lesions* are small, painless hemorrhagic macular plaques on the palms of the hands or soles of the feet due to septic emboli and more commonly associated with acute *S. aureus* IE (Fig. 71–3*F*).
- *Roth spots* are rarely occurring (in less than 5% of IE cases), oval-shaped retinal hemorrhages with a pale center near the optic disc (Fig. 71–3*D*).

Laboratory Studies

❸ *Blood cultures are the essential laboratory test for the diagnosis and treatment of IE. Typically, patients with IE have a low-grade consistent bacteremia, with approximately 80% of cases having less than 100 CFU/mL in the bloodstream.*[1] *Blood culture results are critical for determining the most appropriate therapy.* Three blood culture sets should be drawn within the initial 24 hours to determine the etiologic agent. Approximately 90% of the first two cultures will yield a positive result. If a positive blood culture is not obtained from a patient with suspected IE, the microbiology laboratory should be notified and cultures requested to be monitored for growth of fastidious organisms for up to 1 month.

❹ *Another important tool aiding in the diagnosis of IE is the echocardiogram. This imaging tool is used to visualize vegetations. Two methods of the echocardiogram are used: the transthoracic (TTE) and the transesophegeal (TEE).* The TTE has been used since the 1970s; however, it is less sensitive (58% to 63%) than the TEE (90% to 100%).[8] Despite the TEE being more sensitive, use of the TTE for patients with suspected native-valve IE usually is sufficient.[9,10] The TEE may be used as a secondary test for patients whose TTE was negative and in whom a high clinical suspicion of IE exists. Additionally, a TEE is often preferred in patients who have complicated disease, including left-sided IE, prosthetic valves, or perivalvular extension of the vegetation.[2,10] Echocardiograms also may be employed to assess the need for surgical intervention or to determine the possible source of emboli.[9,11]

Additional nonspecific tests for IE may be performed. These include hematologic parameters to determine whether the

❷ ❸ ❹ Clinical Presentation of IE

General
Patients typically present with nonspecific and variable sign or symptoms.

Symptoms
Complaints from patients may include

- Fever
- Chills
- Night sweats
- Weakness
- Dyspnea
- Weight loss
- Myalgia or arthralgias

Signs
- Fever is the most common sign of IE.
- New or changing heart murmur
- Embolic phenomena (emboli affect the heart, lungs, abdomen, or extremities)
- Skin manifestations (e.g., petechiae, splinter hemorrhages, Osler nodes, Janeway lesions)
- Splenomegaly
- Clubbing of extremities

Laboratory Tests
- Blood cultures are the most important laboratory assessment for persistent bacteremia, which occurs commonly in IE. A minimum of three blood culture sets should be collected during the initial 24 hours.
- Hematologic tests for anemia (normochromic, normocytic)
- WBC count may be elevated in acute disease but could be normal in subacute IE.
- Nonspecific findings such as thrombocytopenia, elevated erythrocyte sedimentation rate or C-reactive protein, and abnormal urinalysis (i.e., proteinuria or microscopic hematuria)

Other Diagnostic Tests
An echocardiogram (TTE or TEE) should be performed on any patient with suspected IE to detect the presence of vegetations.

patient is anemic, which occurs in a majority of patients. The white blood cells (WBCs) may be elevated, particularly in acute disease. However, in a subacute infection, the WBCs may be normal. An erythrocyte sedimentation rate (ESR) also may be obtained to determine the presence of inflammation, although this test is highly nonspecific and almost always elevated in IE.

DIAGNOSTIC CRITERIA

A definitive diagnosis of IE would consist of a biopsy or culture directly from pathologic specimens from the endocardium. However, this would be a highly invasive test. Therefore, diagnosis of IE relies on clinical presentation as well as laboratory and echocardiogram results. To guide this clinical diagnosis, criteria have been established to assess major and minor criteria for IE[12,13] (Table 71–2*A*). Depending on the number of major or minor criteria a patient demonstrates, he or she will be classified as either having definite or possible endocarditis or a rejected diagnosis of IE (Table 71–2*B*).

CAUSATIVE ORGANISMS

Gram-positive bacteria are the most common organisms that produce IE. Streptococci and staphylococci species account for the majority of cases at more than 80%.[14] *Viridans* group streptococci are the primary pathogens in IE. However, more recently, staphylococci have been increasing in prevalence as a causative organism. Other gram-positive, gram-negative, atypical, and fungal organisms are less common but still must be considered in certain patient populations.

Streptococci

Streptococci causing IE are most commonly a group of species called *viridans* group streptococci. The most common of this group are *S. salivarius, S. mutans, S. mitus,* and *S. sanguis*. This group of bacteria, considered normal flora in the human mouth, is α-hemolytic, and typically, most clinical microbiology laboratories do not differentiate the exact species. These organisms may cause bacteremia after dental procedures, which can lead to the development of IE in at-risk patients. *Viridans* group streptococci are also the predominant pathogen of IE associated with mitral valve prolapse and native valves and in children.[15,16] Another streptococci species that is commonly associated with IE is *S. bovis*, classified as group D streptococci, found in the gastrointestinal tract. However, owing to the similarities of these streptococci, including microbiologic susceptibility, treatment is similar regardless of the species.

Infective endocarditis caused by these streptococci typically has a subacute clinical course. The current cure rate is often over 90% unless complications occur, which is the case in more than 30% of patients.[17] The majority of *viridans* streptococci remain very susceptible to penicillin, with most strains having a **minimum inhibitory concentration** (MIC) of less than 0.125 mcg/mL.[15,18] Organisms with decreased susceptibilities are increasing. Therefore, antibiotic susceptibilities need to be assessed in order to determine the most appropriate treatment regimen.

Staphylococci

Staphylococcal endocarditis is increasing in prevalence, causing a minimum of 20% to 30% of all cases of IE, with the majority (80%–90%) being due to *S. aureus* (also known as

TABLE 71–2. Modified Duke Criteria for IE

2A. Definitions of Modified Duke Criteria

Major criteria
- Blood culture positive for IE
  - Typical microorganisms consistent with IE from two separate blood cultures:
    - *Viridans* streptococci, *Streptococcus bovis*, HACEK group, *Staphylococcus aureus*, or community-acquired enterococci in the absence of a primary focus, or
  - Microorganisms consistent with IE from persistently positive blood cultures, defined as follows:
    - At least two positive cultures of blood samples drawn greater than 12 hours apart, or
    - All of three or a majority of four separate cultures of blood (with first and last sample drawn at least 1 hour apart)
  - Single positive blood culture for *Coxiella burnetii* or antiphase I IgG antibody titer greater than 1:800
- Evidence of endocardial involvement
- Echocardiogram positive for IE [TEE recommended in patients with prosthetic valves, rated at least "possible IE" by clinical criteria, or complicated IE (paravalvular abscess) TTE as first test in other patients], defined as follows:
  - Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant, or on implanted material in the absence of an alternative anatomic explanation, or
  - Abscess, or
  - New partial dehiscence of prosthetic valve
  - New valvular regurgitation (worsening or changing of preexisting murmur not sufficient)

Minor criteria
- Predisposition, predisposing heart condition or injection drug use
- Fever, temperature greater than 38°C
- Vascular phenomena, major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway's lesions
- Immunologic phenomena: glomerulonephritis, Osler's nodes, Roth's spots, and rheumatoid factor
- Microbiological evidence: positive blood culture but does not meet a major criterion as noted above[a] or serological evidence of active infection with organism consistent with IE

2B. Modified Duke Criteria for the Diagnosis of Infective Endocarditis

Definite IE
- Pathologic criteria
  - (1) Microorganisms demonstrated by culture or histologic examination of a vegetation that has embolized, or an intracardiac abscess specimen, or
  - (2) Pathologic lesions; vegetation or intracardiac abscess confirmed by histologic examination showing active endocarditis
- Clinical criteria[b]
  - (1) Two major criteria, or
  - (2) One major criterion and three minor criteria, or
  - (3) Five minor criteria

Possible IE
- (1) One major criterion and one minor criterion, or
- (2) Three minor criteria

Rejected
- (1) Firm alternate diagnosis explaining evidence of infective endocarditis, or
- (2) Resolution of infective endocarditis syndrome with antibiotic therapy for less than or equal to 4 days, or
- (3) No pathologic evidence of infective endocarditis at surgery or autopsy, with antibiotic therapy for less than or equal to 4 days, or
- (4) Does not meet criteria for possible infective endocarditis, as above

[a]Excludes single positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis.
[b]See above for definitions of major and minor criteria.
TEE, transesophageal echocardiography; TTE, transthoracic echocardiography.
From Li JS, Sexton DJ, Mick N, et al. Proposed modifications to the Duke criteria for the diagnosis of infective endocardits. Clin Infect Dis. 2000; 30:633–638, with permission. University of Chicago Press. © 2000 by the Infectious Diseases Society of America. All right reserved.

coagulase-positive staphylococci).[17,19] This increase in staphylococci has been attributed primarily to expanded use of venous catheters, more frequent valve replacement, and increased IVDU.[20] Coagulase-negative staphylococci (CNS) also cause IE; however, these organisms typically infect prosthetic valves or indwelling catheters.[21]

S. aureus historically was considered community-acquired[17]; however, more recently, almost half the cases are nosocomial in origin.[22] A key issue to consider is that any patient who is bacteremic with *S. aureus* is at an increased risk of developing IE. *S. aureus* also may infect "normal" heart valves (no prior detected valvular disease) in a third of cases.[17,20] Therefore, it is imperative to assess these patients adequately for the presence of vegetations. Any heart valve may be affected; however, when the mitral or aortic valve is involved, it often results in extensive systemic infection with a mortality rate of approximately

20% to 65%.[14,17] When treating *S. aureus* IE, one must consider whether the isolate displays methicillin resistance, the location of the infection (right or left side), presence of prosthetic valves, and history of IVDU. Despite significant resistance to penicillinase-resistant penicillins (e.g., methicillin and nafcillin), most isolates remain susceptible to vancomycin. However, there is an increasing incidence of *S. aureus* with reduced susceptibility to vancomycin, as well as a limited number of vancomycin intermediately resistant or fully resistant isolates.[23–25] Fortunately, at this point they are not widespread enough to affect empirical antibiotic selection. Susceptibility reports should be assessed to ensure antibiotic activity.

The predominant coagulase-negative organism causing IE has been *S. epidermidis*. However, in the past few years, an increase in isolation of another coagulase-negative species (*S. lugdunensis*) has been noted.[26–28] Typically, coagulase-negative IE has a subacute course with numerous complications. Treatment (with or without surgical intervention) usually is successful. On the other hand, *S. lugdunensis* produces a more virulent infection and, despite similar antibiotic susceptibilities, has a much higher mortality rate.[26,28,29]

Enterococci

Enterococci are normal flora of the human gastrointestinal tract and sometimes found in the anterior urethra. Historically, enterococci were considered part of the streptococci genus but now are separated despite similarities, such as group D classification and causing subacute disease. Frequently affected patients are older males who have undergone genitourinary manipulations or younger females who have had obstetric procedures. Although enterococci are a less common cause of IE, there are two predominant species: *E. faecium* and *E. faecalis*. *E. faecalis* is the most common and the more susceptible of the strains. However, enterococci overall are more intrinsically resistant, with enterococcal IE representing one of the most problematic gram-positive infections to treat and cure. Frequently, enterococci display resistance to multiple antibiotics, including penicillins, vancomycin, aminoglycosides, and some of the newer agents (e.g., linezolid or quninupristin/dalfopristin).[30]

Gram-Negative Organisms

Gram-negative IE is much less common (approximately 2%–4%) but typically is much more difficult to treat than gram-positive infections. Fastidious organisms, such as the HACEK group, tend to be seen most commonly, causing 3% of all IE.[31] This group consists of *Haemophilus* spp. (primarily *H. paraphrophilus*, *H. parainfluenzae,* and *H. aphrophilus*), *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens,* and *Kingella kingae*. The clinical presentation of IE by these organisms is subacute, with approximately 50% of patients developing complications. These complications primarily are due to the presence of large, friable vegetations and numerous emboli and the development of acute congestive heart failure that often requires valve replacement.[31,32] It is important to allow cultures sufficient incubation time (often 2–3 weeks) in order to isolate these organisms. Often these organisms may not be isolated on culture and thus present as **culture-negative** IE.

Other gram-negative organisms, such as *Pseudomonas* spp., have been noted to cause IE, especially in IVDUs and patients with prosthetic valves. Additionally, IE caused by *Salmonella* spp., *Escherichia coli*, *Citrobacter* spp., *Klebsiella* spp., *Enterobacter* spp., *Serratia marcescens*, *Proteus* spp. and *Providencia* spp. also has been reported.[1]

Gram-negative IE typically has a poor prognosis with high mortality rates (as high as 83%).[1,] Treatment usually consists of high-dose combination therapy, with valve replacement often a necessity in many patients.

Culture-Negative

Negative blood cultures are reported in approximately 5% of confirmed IE cases, often delaying diagnosis and treatment.[3,33,34] Sterile cultures may be the result of previous antibiotic use, subacute right-sided disease, slow growth of fastidious organisms, nonbacterial endocarditis (e.g., fungal or intracellular parasitic infections), noninfective endocarditis, or improper collection of blood cultures. If nonbacterial or fastidious organisms are suspected, additional testing is essential. The choice of treatment regimen depends on patient history and risk factors.

Other Organisms

Numerous bacteria, including gram-positive bacilli, unusual gram-negative bacteria, atypical bacteria, and anaerobes, as well as spirochetes, have been reported in IE.[31] However, infections caused by these organisms are rare. Some of the more common organisms include *Legionella*, *Coxiella burnetii* (Q fever), and *Brucella*. These rare organisms occur primarily in at-risk patients such as those who have a prosthetic valve or are IVDUs. A comprehensive discussion of these organisms is not feasible for this chapter; for further information, other references sources should be examined. Treatment of these organisms is very difficult, and cure rates are low. Therefore, consulting an infectious diseases specialist is warranted.

Fungi

Fungal endocarditis is quite uncommon but has significant mortality, typically affecting patients who have had cardiovascular surgery, received a prolonged course of broad-spectrum antibiotics, have long-term catheter placement, are immunocompromised, or are IVDUs.[8,35] Survival rates have remained

poor, at approximately 15%, but improvements (approximately 30%) have been reported owing to advances in diagnosis and treatment.[35] The poor prognosis has been attributed to large vegetations, propensity for organism invasion into the myocardium, extensive septic emboli, poor antifungal penetration into the vegetation, and low toxic-to-therapeutic ratio and lack of cidal activity of certain antifungals.[35,36] The two most commonly associated organisms are *Candida* spp. and *Aspergillus* spp. Lack of clinical studies makes treatment decisions difficult. Typically, combination and/or high-dose therapy in conjunction with surgery is required.

TREATMENT

Therapeutic Considerations

Treatment of IE often is complicated and difficult. Numerous factors involving the vegetation influence the effectiveness of the antimicrobial agents. The vegetation consists of a fibrin matrix (as discussed earlier) that provides an environment where organisms are relatively free to replicate unimpeded, allowing the microbial density to reach very high concentrations (10^9–10^{10} CFU/g). Once the organism density has reached this level, the organisms are virtually in a static growth phase. These factors hinder host defenses, as well as the ability of antimicrobials to produce sufficient kill. This is seen often with β-lactams and glycopeptides because their effectiveness can be significantly affected by the bacterial inoculum.

❺ *Selection of an appropriate antimicrobial agent must combine characteristics such as the ability to penetrate into the vegetation, the ability to achieve adequate drug concentrations, and the ability to be minimally affected by high bacterial inoculum in order to achieve adequate kill rates.* ❻ *To accomplish this, antimicrobials typically have to be given parenterally at high doses with an extended treatment course of 4 to 6 weeks (in most cases).* Other desirable drug characteristics include bactericidal and synergistic activity.

Empirical Therapy

❼ *The overall goal of therapy is to eradicate the infection and minimize/prevent any complications.* Patients with suspected IE should be evaluated for risk factors that may provide some indication as to the most likely organism causing the infection. If no risk factors can be determined, empirical therapy primarily should cover gram-positive organisms. Generally, if streptococci are suspected, empirical treatment should consist of penicillin plus gentamicin. However, if staphylococci or enterococci are suspected; empirical treatment should consist of vancomycin plus gentamicin. It is important to monitor the patient's response to therapy closely until cultures and susceptibilities are determined to ensure adequate treatment.

Patient Encounter, Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH

- Type II diabetes mellitus since age 48. He admits that his diet prevents his diabetes from being well controlled.
- Coronary artery disease
- Cardiac pacemaker since 1998

FH

Father had a history of diabetes and died at age 72 with end-stage renal disease; mother died at age 75 from complications of a broken hip.

SH

Smokes about $^1/_2$ pack of cigarettes per day. Denies any use of alcohol of illicit drugs.

Meds

- Metformin 850 mg orally three times daily
- Sotalol 80 mg orally twice daily

Allergies: No known drug allergies

ROS

Recent weight loss of 5 lb, decreased appetite, significant fatigue × 2 weeks

PE

- **Vital Signs:** 168/89 mm Hg, P 88 beats/minute, RR 19 breaths/minute, T 38.5°C
- **Cardiovascular:** Slight tachycardia, positive murmur
- **Abdomen:** Obese, soft, nontender, nondistended; (+) bowel sounds

Labs

Within normal limits, except WBC = 16.4×10^3 cells/mm^3

- Given this additional information, what is your assessment of the patient's condition?
- Identify your empirical treatment recommendations for this patient.
- What other information would be beneficial to obtain?

Specific Therapy

The American Heart Association recently published new guidelines for the management of IE, including specific treatment recommendations.[5] A summary of these treatments for the most common organisms (streptococci, staphylococci, and enterococci) is provided in Tables 71–3 through 71–6. However, for more detailed information (including dosing, length of treatment, etc.) for these organisms or less common organisms, refer to the complete guidelines.[5] These guidelines include primary and alternative regimens, as indicated in the treatment tables under strength of recommendation.

Streptococci

Most isolates are highly susceptible to penicillin; therefore, penicillin G remains the regimen of choice. However, ceftriaxone may be used as an alternative agent if the patient is allergic or resistance is suspected to penicillin. Typically, the length of treatment is 4 weeks and remains the most common regimen. However, a shorter course (i.e., 2 weeks) may be employed for a patient with uncomplicated IE due to highly penicillin-susceptible strains with no extracardiac infection or whose creatinine clearance is greater than 20 mL/minute. If the shorter length of therapy is chosen, gentamicin should be added to the previous regimens for the entire course (i.e., 2 weeks). Recommended therapies for highly penicillin-susceptible *viridans* streptococci are summarized in Table 71–3.

As penicillin MICs increase (greater than 0.12 mcg/mL but less than or equal to 0.5 mcg/mL) for *viridans* group streptococci,

TABLE 71–3. Therapy of Native-Valve Endocarditis Caused by Highly Penicillin-Susceptible *Viridans* Group Streptococci and *Streptococcus bovis*

Regimen	Dosage[a] and Route	Duration (wks)	Strength of Recommendation[g]	Comments
Aqueous crystalline penicillin G sodium ***or*** ceftriaxone sodium	12–18 million units/24 hours (h) intravenous (IV) either continuously or in 4 or 6 equally divided doses 2 g/24 hours IV/intramuscular (IM) in 1 dose *Pediatric dose*[b]: penicillin 200,000 units/kg per 24 hours IV in 4–6 equally divided doses; ceftriaxone 100 mg/kg per 24 hours IV/IM in 1 dose	4 4	IA IA	Preferred in most patients 65 years of age or older or patients with impairment of eighth cranial nerve function or renal function
Aqueous crystalline penicillin G sodium ***or*** ceftriaxone sodium ***plus*** gentamicin sulfate[c]	12–18 million units/24 hours IV either continuously or in 6 equally divided doses 2 g/24 hours IV/IM in 1 dose 3 mg/kg per 24 hours IV/IM in 1 dose *Pediatric dose:* penicillin 200,000 units/kg per 24 hours IV in 4–6 equally divided doses; ceftriaxone 100 mg/kg per 24 hours IV/IM in 1 dose; gentamicin 3 mg/kg per 24 hours IV/IM in 1 dose or 3 equally divided doses[e]	2	IB	2-week regimen not intended for patients with cardiac or extracardiac abscess or for those with creatinine clearance of less than 20 mL/minute, impaired eighth cranial nerve function, or *Abiotrophia*, *Granulicatella*, or *Gemella* spp. infection; gentamicin dosage should be adjusted to achieve peak serum concentration of 3–4 mcg/mL and trough serum concentration of less than 1 mcg/mL when 3 divided doses are used; nomogram used for single daily dosing[d]
Vancomycin hydrochloride[f]	30 mg/kg per 24 hours IV in 2 equally divided doses not to exceed 2 g/24 hours unless concentrations in serum are inappropriately low *Pediatric dose:* 40 mg/kg per 24 hours IV in 2–3 equally divided doses	4	IB	Vancomycin therapy recommended only for patients unable to tolerate penicillin or ceftriaxone; vancomycin dosage should be adjusted to obtain peak (1 hour after infusion completed) serum concentration of 30–35 mcg/mL and a trough concentration range of 10–15 mcg/mL

Minimum inhibitory concentration less than or equal to 0.12 mcg/mL.
[a]Dosage recommended are for patients with normal renal function.
[b]Pediatric dose should not exceed that of a normal adult.
[c]Other potentially nephrotoxic drugs (e.g., nonsteroidal anti-inflammatory drugs) should be used with caution in patients receiving gentamicin therapy.
[d]See Nicolau DP, Freeman CD, Belliveau PB, et al. Experience with a once-daily aminoglycoside program administered to 2184 adult patients. Antimicrob Agents Chemother 1995; 39:650–655.
[e]Data for once-daily dosing of aminoglycosides for children exist, but no data for treatment of IE exist.
[f]Vancomycin dosages should be infused during course of at least 1 hour to reduce risk of histamine-release "red man" syndrome.
[g]IA, condition with evidence and/or general agreement that a procedure or treatment is useful and effective, based on data from multiple randomized clinical trials; IB, condition with evidence and/or general agreement that a procedure or treatment is useful and effective-based on data from a single randomized trial or nonrandomized studies.

Patient Encounter, Part 3: Additional Laboratory and Diagnostic Tests

Blood cultures
All cultures are positive for *viridans* group streptococci.

Labs
Within normal limits.

Echo
3-mm vegetation on the tricuspid valve.

- Given this additional information, are there any changes in your assessment of the patient?
- How would you tailor your treatment based on these new data?
- What would be your treatment goals, including length of treatment?
- What other information would be beneficial to have?

treatment doses are increased, and 4 weeks of treatment is suggested. In addition, combination therapy with gentamicin is recommended during the first 2 weeks. In patients who are allergic or intolerant to either of the β-lactams, vancomycin is an alternative treatment option. Additionally, in patients with resistant strains of *viridans* group streptococci (MIC greater than 0.5 mcg/mL), treatment should employ antimicrobial agents for enterococcal IE (precise agents determined by the susceptibility report).

Patients with PVE caused by penicillin-susceptible strains of *viridans* streptococci require treatment for 6 weeks with penicillin G or ceftriaxone with or without gentamicin during the initial 2 weeks of therapy. However, if the organism demonstrates less susceptibility to penicillin (MIC greater than 0.12 mcg/mL), a combination therapy with penicillin G or ceftriaxone plus gentamicin should be given for the entire 6 weeks. Vancomycin remains the primary alternative if the patient is allergic to β-lactams (e.g., penicillins, cephalosporins, etc.).

Staphylococci

It is important to determine (1) whether the isolate is methicillin-susceptible or methicillin-resistant and (2) whether the patient has a prosthetic valve. For patients with no prosthetic material, methicillin-susceptible staphylococci treatment should consist of a penicillinase-resistant penicillin (e.g., nafcillin or oxacillin) with or without gentamicin, and for methicillin-resistant strains, therapy should consist of vancomycin (see Table 71–4). Combination therapy with aminoglycosides, when used in these patients, typically is given only during the first 3 to 5 days of therapy. In the absence of prosthetic material, some treatment guidelines do not recommend combination therapy against MRSA. However, many clinicians may combine either gentamicin or rifampin with vancomycin if the patient is unresponsive to monotherapy.

Increasing resistance of staphylococci necessitates the expanded use of alternative therapies. A recent clinical study suggests that daptomycin may be a viable alternative to standard therapy (i.e., penicillinase-resistant penicillin for MSSA or vancomycin for MRSA) in staphylococcal IE.[37] The Food and Drug Administration (FDA), based on this study, has approved an indication of daptomycin for the treatment of right-sided IE or bacteremia caused by *S. aureus*. Recommended dosing for these indications are 6 mg/kg per day (unless renal adjustments are necessary).[37] Another retrospective study reported daptomycin safe and well tolerated, with 77% of patients achieving clinical resolution.[38] Additionally, other antibiotics, such as linezolid and quinupristin/dalfopristin, have been used in patients who were unresponsive to standard therapy, although they have had variable response rates.[39–41] These therapies often are reserved for patients who have been unresponsive to traditional therapy (e.g., β-lactams or vancomycin) or for organisms that remain susceptible to these agents when resistant to traditional therapy.

For staphylococcal PVE, treatment length increases significantly, typically requiring a minimum of 6 weeks (see Table 71–5). For MSSA, a penicillinase-resistant penicillin is still employed, as well as vancomycin for MRSA. However, with either regimen, the addition of both gentamicin for first 2 weeks and rifampin for the entire length of treatment is recommended.

Enterococci

For enterococci, it is imperative to determine species and antibiotic susceptibilities. If the organism is susceptible to penicillin and vancomycin, treatment may consist of high-dose penicillin G, ampicillin, or vancomycin plus gentamicin (see Table 71–6). Treatment length is usually 4 to 6 weeks, with the aminoglycoside used over the entire course. As resistance develops to penicillin, ampicillin and vancomycin remain treatment options. Once the isolate becomes resistant to ampicillin, vancomycin is considered the treatment of choice.

If the isolate is determined to be vancomycin-resistant, it is most important to know the exact species because some of the treatment options, such as quinupristin/dalfopristin, are not active against *E. faecalis*. Currently, the treatment options for vancomycin-resistant enterococci (VRE) are not well established by clinical studies or patient experience. The treatment recommendations for vancomycin-resistant *E. faecium* include linezolid or quinupristin/dalfopristin for a minimum of 8 weeks. However, newer agents, such as daptomycin, may provide another option for treatment for either enterococci species (*E. faecium* and *E. faecalis*). Additionally, guidelines suggest the use of imipenem-cilistatin plus ampicillin or ceftriaxone plus ampicillin for the treatment of *E. faecalis* with a minimum of 8 weeks of therapy. Consultation with an infectious diseases specialist is recommended.

TABLE 71–4. Therapy for Endocarditis Caused by Staphylococci in the Absence of Prosthetic Materials

Regimen	Dosage[a] and Route	Duration (wks)	Strength of Recommendation[f]	Comments
Oxacillin-Susceptible Strains				
Nafcillin or oxacillin[b]	12 g/24 hours IV in 4–6 equally divided doses	6	IA	For complicated right-sided IE and for left-sided IE, 6-week treatment; for uncomplicated right-sided IE, 2-week treatment
with optional addition of gentamicin sulfate[c]	3 mg/kg per 24 hours IV/IM in 2 or 3 equally divided doses *Pediatric dose*[d]*:* nafcillin or oxacillin 200 mg/kg per 24 hours IV in 4–6 equally divided doses; gentamicin 3 mg/kg per 24 hours IV/IM in 3 equally divided doses	3–5 days		Clinical benefit of aminoglycosides has not been established
For penicillin-allergic (nonanaphylactoid type) patients: cefazolin	6 g/24 hours IV in 3 equally divided doses	6	IB	Consider skin testing for oxacillin-susceptible staphylococci and questionable history of immediate-type hypersensitivity to penicillin; cephalosporins should be avoided in patients with anaphylactoid-type hypersensitivity to β-lactams; vancomycin should be used in these cases[d]
with optional addition of gentamicin sulfate	3 mg/kg per 24 hours IV/IM in 2 or 3 equally divided doses *Pediatric dose:* cefazolin 100 mg/kg per 24 hours IV in 3 equally divided doses; gentamicin 3 mg/kg per 24 hours IV/IM in 3 equally divided doses	3–5 days		Clinical benefit of aminoglycosides has not been established
Oxacillin-Resistant Strains				
Vancomycin hydrochloride[e]	30 mg/kg per 24 hours IV in 2 equally divided doses *Pediatric dose:* 40 mg/kg per 24 hours IV in 2–3 equally divided doses	6	IB	Adjust vancomycin dosage to achieve 1 hour (peak) serum concentration of 30–45 mcg/mL and trough concentration of 10–15 mcg/mL (see text for vancomycin alternatives)

[a]Dosages recommended are for patients with normal renal function.
[b]Penicillin G 24 million units/24 hours IV in 4 to 6 equally divided doses may be used in place of nafcillin or oxacillin if strain is penicillin-susceptible (minimum inhibitory concentration less than or equal to 0.1 mcg/mL) and does not produce β-lactamase.
[c]Gentamicin should be administered in close temporal proximity to vancomycin, nafcillin, or oxacillin dosing.
[d]Pediatric dose should not exceed that of a normal adult.
[e]For specific dosing adjustment and issues concerning vancomycin, see Table 71–3 footnotes.
[f]IA, condition with evidence and/or general agreement that a procedure or treatment is useful and effective, based on data from multiple randomized clinical trails; IB, condition with evidence and/or general agreement that a procedure or treatment is useful and effective, based on data from a single randomized trial or nonrandomized studies.

Gram-Negative Organisms

Identification of the exact isolate is crucial in gram-negative IE because treatment decisions depend on which organism is isolated. Therapy usually is targeted to the most susceptible antibiotics. Combination therapy (usually the addition of an aminoglycoside) is used commonly. For example, *Pseudomonas* spp. are treated with an antipseudomonal (e.g., piperacillin, cefepime, imipenem, etc.) plus high-dose aminoglycoside (typically tobramycin 8 mg/kg per day). However, exact dosing of antibiotics depends on the organism isolated. Length of treatment usually is a minimum of 6 weeks.

HACEK Group

The HACEK group is difficult to isolate, often taking weeks for identification. If one of these organisms is suspected (e.g., subacute disease, embolism, large vegetations, etc.), it is important to initiate appropriate empirical treatment. The preferred regimen is ceftriaxone (or another third- or fourth-generation cephalosporin), followed by ampicillin-sulbactam. However, for patients who are intolerant of these treatments, ciprofloxacin may be used. The length of treatment typically is 4 weeks for these organisms.

TABLE 71–5. Therapy for Prosthetic Valve Endocarditis Caused by Staphylococci

Regimen	Dosage[a] and Route	Duration (wks)	Strength of Recommendation[d]	Comments
Oxacillin-Susceptible Strains				
Nafcillin or oxacillin	12 g/24 hours IV in 4–6 equally divided doses	6 weeks or longer	IB	Penicillin G 24 million units/24 hours IV in 4 to 6 equally divided doses may be used in place of nafcillin or oxacillin if strain is penicillin-susceptible (MIC less than or equal to 0.1 mcg/mL) and does not produce β-lactamase; vancomycin should be used in patients with immediate-type hypersensitivity reactions to β-lactam antibiotics (see Table 71–3 for dosing guidelines); cefazolin may be substituted for nafcillin or oxacillin in patients with non-immediate-type hypersensitivity reactions to penicillins
plus rifampin	900 mg per 24 hours IV/orally (PO) in 3 equally divided doses	6 weeks or longer		
plus gentamicin sulfate[b]	3 mg/kg per 24 hours IV/IM in 2 or 3 equally divided doses *Pediatric dose*[c] *:* nafcillin or oxacillin 200 mg/kg per 24 hours IV in 4–6 equally divided doses; rifampin 20 mg/kg per 24 hours IV/PO doses; in 3 equally divided doses; gentamicin 3 mg/kg per 24 hours in 3 equally divided doses	2		
Oxacillin-Resistant Strains				
Vancomycin hydrochloride	30 mg/kg per 24 hours IV in 2 equally divided doses	6 weeks or longer	IB	Adjust vancomycin to achieve 1 hour (peak) serum concentration of 30–45 mcg/mL and trough concentration of 10–15 mcg/mL
plus rifampin	900 mg/24 hours IV/IPO in 3 equally divided doses	6 weeks or longer		
plus gentamicin sulfate	3 mg/kg per 24 hours IV/IM in 2 or 3 equally divided doses *Pediatric dose:* vancomycin 40 mg/kg per 24 hours IV in 2 or 3 equally divided doses; rifampin 20 mg/kg per 24 hours IV/PO in 3 equally divided doses (up to adult dose); gentamicin 3 mg/kg per 24 hours IV/IM in 3 equally divided doses	2		

[a]Dosages recommended are for patients with normal renal function.
[b]Gentamicin should be administered in close proximity to vancomycin, nafcillin, or oxacillin dosing.
[c]Pediatric dose should not exceed that of a normal adult.
[d]IB, condition with evidence and/or general agreement that a procedure or treatment is useful and effective, based on data from a single randomized trial or nonrandomized studies.

Culture-Negative

Treatment for culture-negative IE presents a significant dilemma. Therapeutic regimens are guided by specific isolated organisms. When cultures fail to identify a specific organism, decisions regarding treatment should cover the most common causative organisms. If the patient is unresponsive to this initial treatment, then additional coverage for less common organisms is warranted. An infectious diseases specialist should be consulted for managing a patient with this type of infection.

Fungi

Treatment of fungal IE is exceptionally difficult. There is a significant lack of studies to identify and recommend the most appropriate therapy. Currently, amphotericin B is the most common treatment. However, valve replacement surgery is often considered an adjunct therapy. Intravenous antifungal therapy requires high doses for a minimum of 8 weeks of treatment. Oral azoles (e.g., fluconazole) are used as long-term suppressive therapy to prevent relapse. The exact role of some

TABLE 71–6. Therapy for Native-Valve or Prosthetic-Valve Enterococcal Endocarditis Caused by Strains Susceptible to Penicillin, Gentamicin, and Vancomycin

Regimen	Dosage[a] and Route	Duration (wks)	Strength of Recommendation[e]	Comments
Ampicillin sodium ***or***	12 g/24 hours IV in 6 divided doses	4–6	IA	Native valve: 4-week therapy recommended for patients with symptoms of illness less than or equal to 3 months; 6-week therapy recommended for patients with symptoms greater than 3 months
Aqueous crystalline penicillin G sodium	18–30 million units/24 hours IV either continuously or in 6 equally divided doses	4–6	IA	Prosthetic valve or other prosthetic cardiac material: minimum of 6 weeks of therapy recommended
plus gentamicin sulfate[b]	3 mg/kg per 24 hours IV/IM in 3 equally divided doses *Pediatric dose[c]:* ampicillin 300 mg/kg per 24 hours IV in 4–6 equally divided doses; penicillin 300,000 units/kg per 24 hours IV in 4–6 equally divided doses; gentamicin 3 mg/kg per 24 hours IV/IM in 3 equally divided doses	4–6		
Vancomycin hydrochloride[d]	30 mg/kg per 24 hours IV in 2 equally divided doses	6	IB	Vancomycin therapy recommended only for patients unable to tolerate penicillin or ampicillin
plus gentamicin sulfate	3 mg/kg per 24 hours IV/IM in 3 equally divided doses *Pediatric dose:* vancomycin 40 mg/kg per 24 hours IV in 2 or 3 equally divided doses; gentamicin 3 mg/kg per 24 hours IV/IM in 3 equally divided doses	6		6 weeks of vancomycin therapy recommended because of decreased activity against enterococci

[a]Dosages recommended are for patients with normal renal function.
[b]Dosage of gentamicin should be adjusted to achieve peak serum concentration of 3–4 mcg/mL and a trough concentration of less than 1 mcg/mL. Patients with a creatinine clearance of less than 50 mL/minute should be treated in consultation with an infectious diseases specialist.
[c]Pediatric dose should not exceed that of a normal adult.
[d]See Table 71–3 for appropriate dosage of vancomycin.
[e]IA, condition with evidence and/or general agreement that a procedure or treatment is useful and effective, based on data from multiple randomized clinical trials; IB, condition with evidence and/or general agreement that a procedure or treatment is useful and effective, based on data from a single randomized trial or nonrandomized studies.

of the newer antifungals (e.g., voriconazole and caspofungin) is unknown, but they should provide a viable option.[42,43]

Surgery

Surgical intervention has become an integral therapy in combination with pharmacologic management of IE. Valve replacement is the predominant intervention, and it is used in a minimum of 25% for all cases of IE.[1] Surgery may be indicated if the patient has unresolved infection, ineffective antimicrobial therapy (often associated with fungal IE), more than one episode of serious emboli, refractory congestive heart failure, significant valvular dysfunction, a mycotic aneurysm requiring resection, local complications (perivalvular or myocardial abscesses), or a prosthetic valve infection associated with a pathogen that demonstrates higher antimicrobial resistance (e.g., staphylococci, gram-negative organisms, and fungi).[36,44,45] Often a patient's hemodynamic status (i.e., blood pressure, heart rate, pulmonary artery pressure, etc.) is used to determine when surgical intervention is warranted.[46] Despite appropriate medical management and cure, a significant number of people who develop native-valve

Patient Encounter, Part 4: Additional Laboratory

Susceptibility Report

Drug	Penicillin	Ceftriaxone	Vancomycin

- Given this additional information, are there any changes in your assessment of the patient?
- Do you need to adjust your treatment regimen based on these data?
- Would your treatment goals, particularly length of treatment, change?

Patient Encounter, Part 5: Create a Care Plan

Based on this patient's information, create a care plan for the management of his IE. Be sure to include (1) a statement regarding treatment requirements and/or possible problems, (2) goals of therapy, (3) a patient-specific plan, including preventive plans, and (4) a follow- up plan to assess whether the goals have been met and to determine whether the patient experienced any adverse effects.

endocarditis require valve replacement surgery. Involvement of the aorta is considered an indication for surgery in over 70% of patients with PVE.[46]

Prophylaxis

℞ *Certain conditions have been associated more commonly with IE due to preexisting cardiac disease in the presence of a transient bacteremia. In an effort to prevent the development of IE, prophylactic treatment generally is recommended for these at-risk patients.* Although there are no well-controlled clinical studies of these recommendations, it is thought that if antibiotics are given just prior to a procedure, the number of bacteria may be decreased in the bloodstream and prevent the bacteria from adhering to the valves.

Cardiac conditions in which prophylaxis is recommended include presence of prosthetic valves, prior infective endocarditis, congenital cardiac abnormalities, rheumatic heart disease or any other valvular dysfunction, hypertrophic cardiomyopathy, and mitral valve prolapse with valvular regurgitation or thickening/redundancy of the valve leaflets.[6] While many patients have other cardiac dysfunction, only patients with these conditions are considered to be at a high risk of developing IE. No prophylaxis is advised in other patients.

Transient bacteria may be set loose by many types of dental and surgical procedures. All dental procedures, including routine cleaning, may cause gingival bleeding, which can introduce bacteria into the bloodstream. *Viridans* group streptococci are the primary bacteria targeted for prophylaxis in this circumstance. On the other hand, prophylaxis for gastrointestinal or genitourinary surgeries primarily targets enterococci.

The American Heart Association guidelines include suggested antibiotic regimens for each type of procedure.[6] Recommended regimens for dental, oral, respiratory tract, and esophageal procedures are listed in Table 71–7. These guidelines recommend a single oral or intramuscular/intravenous dose initiated shortly before the procedure. The regimen for dental/oral procedures consists primarily of a penicillin as first choice, with clindamycin for penicillin-allergic patients. For gastrointestinal or genitourinary procedures,

TABLE 71–7. Prophylactic Regimens for Dental, Oral, Respiratory Tract, or Esophageal Procedures

Situation	Agent	Regimen[a]
Standard general prophylaxis	Amoxicillin	Adults: 2 g; children: 50 mg/kg orally 1 hour before procedure
Unable to take oral medications	Ampicillin	Adults: 2 g intramuscularly (IM) or intravenously (IV) Children: 50 mg/kg IM or IV within 30 minutes before procedure
Allergic to penicillin	Clindamycin or	Adults: 600 mg; children: 20 mg/kg orally 1 hour before procedure

[a]Total children's dose should not exceed adult dose.
[b] Cephalosporins should not be used in individuals with immediate-type hypersensitivity reaction (urticaria, angioedema, or anaphylaxis) to penicillins.
From Dajani AS, Taubert KA, Wilson W, et al. Prevention of bacterial endocarditis. Recommendations by the American Heart Association. JAMA 1997; 277:1794–1801, with permission. Copyright © 1997, American Medical Association. All rights reserved.

penicillin (e.g., amoxicillin or ampicillin) remains the primary agent, with the addition of gentamicin in high-risk patients or vancomycin for penicillin-allergic patients with gentamicin added for high-risk patients. A second prophylactic dose is not recommended. However, if an infection develops at the procedure site, additional antibiotics (i.e., a therapeutic course) may be required.

OUTCOME EVALUATION

Monitoring for successful therapy is critical in this serious infection to prevent complications, prevent resistance development, and decrease mortality. Routine assessment of clinical signs and symptoms, as well as laboratory tests (i.e., repeat blood cultures), microbiologic testing and serum drug concentrations, must be performed.

Resolution of signs and symptoms typically occurs within a few days to a week in most cases. Monitor the patient daily for febrile episodes, as well as other vital signs, with expected normal values within 2 to 3 days of initiating antimicrobial therapy.[3] Persistent signs or symptoms could be indicative of inadequate treatment or development of resistance.

Blood cultures are the primary laboratory evaluation to assess response to therapy. Typically, with appropriate treatment, they should become negative within 3 to 7 days. Use subsequent blood cultures if the patient appears not to be responding to therapy or on completing treatment to confirm eradication of infection. Evaluate all susceptibility reports to assess antimicrobial therapy.

Additionally, the patient needs to be counseled on the necessity of prophylactic antibiotics prior to any dental or surgical procedure in order to prevent recurrent infections. This is critical in patients with risk factors that predispose them to developing IE, such as prosthetic heart valves, other valvular defects, or previous IE.

Develop a follow-up plan to determine whether the patient has achieved a cure, which includes a clinical evaluation of signs/symptoms, repeat blood cultures, and possibly a repeat echocardiogram. The patient also should be assessed for any adverse events. This should be performed usually within a few weeks after the completion of therapy.

CONCLUSION

When presented with a patient with infective endocarditis, it is imperative to have an accurate diagnosis and treat appropriately. Mortality can be significant depending on the organism and the patient's comorbidities. However, outcomes can be improved through diligent care and monitoring.

⑨ Patient Care and Monitoring

1. Assess the patient's symptoms and/or laboratory results to determine if the empirical therapy is effective. Is the patient's fever resolving? Is the patient's WBC decreasing?
2. Review available microbiologic cultures and sensitivity to assess whether the initial antimicrobial regimen needs to be tailored?
3. Review any additional diagnostic tests to determine if treatment may be needed to prevent/minimize complications (e.g., emboli, congestive heart failure).
4. Evaluate therapeutic serum drug concentrations as appropriate (e.g., vancomycin and gentamicin).
5. Monitor serum creatinine in order to make appropriate renal adjustments of the antimicrobials as necessary.
6. Assess any repeat blood cultures and vital signs to determine continued treatment effectiveness.
7. Evaluate the patient for occurrence of any adverse drug reactions and possible drug allergies and/or drug interactions.
8. Develop a plan if the patient is going to continue therapy at home. Once defervescence has occurred, the patient may complete therapy outside the hospital by receiving the antimicrobials from an outpatient infusion center or through a home health agency.
9. Develop a follow-up plan to assess the resolution of infection once the patient has completed therapy. Assessment of any adverse events also should be conducted at this time.
10. Educate the patient on the importance of taking prophylactic antibiotics prior to having any dental or surgical procedure in an effort to prevent the future development of another infection. Stress the potential complications as well as the morbidity and mortality that are associated with IE and that taking precautions can minimize or prevent them.

72 TUBERCULOSIS

Charles A. Peloquin and Rocsanna Namdar

LEARNING OBJECTIVES

UPON COMPLETION OF THE CHAPTER, THE READER WILL BE ABLE TO:

1. Compare the risk for active tuberculosis disease among patients based on their age, immune status, place of birth, and time since exposure to an active case.
2. Design, evaluate, and assess an appropriate therapeutic plan for an immunocompetent, immunocompromised, pregnant, and pediatric patient.
3. Assess the effectiveness of therapy in tuberculosis patients.
4. Cite the names of the tuberculosis drugs most likely to cause hepatotoxicity.
5. Select patients for whom therapeutic drug monitoring may be valuable.
6. Design, evaluate, and assess appropriate regimens for the treatment of latent tuberculosis infection (LTBI) in all patient populations.
7. Identify the necessary laboratory monitoring parameters for patients on antituberculosis medications.
8. Design a therapeutic plan for a patient with tuberculosis meningitis or tuberculosis osteomyelitis.

KEY CONCEPTS

❶ Tuberculosis (TB) is the most prevalent communicable infectious disease on earth and remains out of control in many developing nations. These nations require medical and financial assistance from developed nations in order to control the spread of tuberculosis globally.

❷ In the United States, tuberculosis disproportionately affects ethnic minorities as compared with whites, reflecting greater ongoing transmission in ethnic minority communities. Additional tuberculosis surveillance and preventive treatment are required within these communities.

❸ Coinfection with human immunodeficiency virus (HIV) and tuberculosis accelerates the progression of both diseases, thus requiring rapid diagnosis and treatment of both diseases.

❹ Mycobacteria are slow-growing organisms; in the laboratory, they require special stains, special growth media, and long periods of incubation to isolate and identify.

❺ Tuberculosis can produce atypical signs and symptoms in infants, the elderly, and immunocompromised hosts, and it can progress rapidly in these patients.

❻ Latent tuberculosis infection (LTBI) can lead to reactivation disease years after the primary infection occurred.

❼ The patient suspected of having active tuberculosis disease must be isolated until the diagnosis is confirmed and he or she is no longer contagious. Often, isolation takes place in specialized "negative pressure" hospital rooms to prevent the spread of tuberculosis.

❽ Isoniazid and rifampin are the two most important tuberculosis drugs; organisms resistant to both these drugs [multidrug-resistant tuberculosis (MDR-TB)] are much more difficult to treat.

❾ Never add a single drug to a failing regimen!

❿ Directly observed treatment (DOT) should be used whenever possible to reduce treatment failures and the selection of drug-resistant isolates.

Worldwide, tuberculosis (TB) kills about 2 million people each year, more than any other infectious organism. TB is caused by *Mycobacterium tuberculosis*, it presents either as latent TB infection (LTBI) or as progressive active disease.[1] The latter typically causes progressive destruction of the lungs, leading

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

to death in most patients who do not receive treatment. Currently, one-third of the world's population is infected, and drug resistance is increasing in many areas.[1]

EPIDEMIOLOGY

❶ *Roughly one of every three people on earth is infected by M. tuberculosis.*[1–3] *The distribution is very uneven, with the highest incidences found in southern Asia and sub-Saharan Africa. In the United States, about 13 million people have LTBI, evidenced by a positive skin test [purified protein derivative (PPD)] but no signs or symptoms of disease.* Such patients have roughly a 1 in 10 chance of active disease during their lives, with the greatest risk in the first 2 years after infection. Active disease occurs in over 14,000 Americans each year, resulting in about 1500 deaths.[4] *[For detailed data analysis, visit the Centers for Disease Control and Prevention (CDC) Web site at* www.*cdc.gov/nchstp/tb.]*

Risk Factors for Infection

Location and Place of Birth

California, Florida, Illinois, New York, and Texas accounted for over 50% of all TB cases in 2002, reflecting the high immigration rates into these states.[4] TB is most prevalent in large urban areas, exacerbated by crowding in poor immigrant neighborhoods, where more than half of all United States cases now are found.[3,4] Mexico, the Philippines, Vietnam, India, China, Haiti, and South Korea account for the largest numbers of these immigrants.[4] Those in close contact with patients with active pulmonary TB are most likely to become infected.[2,3] These include family members, coworkers, or coresidents in places such as prisons, shelters, and nursing homes.

Race, Ethnicity, Age, and Gender

❷ *In the United States, the incidence of TB is more concentrated in non-white individuals. In 2002, non-Hispanic blacks accounted for 30% of all TB cases, followed by Hispanics at 27%.*[5] *Asians and Pacific Islanders accounted for 22%, whereas non-Hispanic whites accounted for only 20% of the new TB cases.*[5] TB is most common among people 25 to 44 years of age (35% of all cases), followed by those 45 to 64 years of age (28%) and 65+ years of age (21%).

Coinfection with Human Immunodeficiency Virus (HIV)

HIV is the most important risk factor for active TB because the immune deficit prevents patients from containing the initial infection.[2,3,5,6] ❸ *Roughly 10% of United States TB patients are coinfected with HIV, and roughly 20% of TB patients ages 25 to 44 years are coinfected with HIV.*[4,5] Consistent with HIV in general, HIV-associated TB is most common among 25- to 44-year-olds. Substance abuse and other risk factors are shared among some TB and HIV-infected individuals, promoting the spread of both diseases.[2,7,8]

Patient Encounter, Part 1

HPI

AF is a 56-year-old man who presents to the medical clinic complaining of a 1-month history of a persistent cough that has become productive over the past 2 weeks. He also complains of malaise, fever, night sweats, and a 6-kg weight loss over the past 2 months.

PMH

- *Non-insulin-dependent diabetes mellitus (NIDDM)—well controlled*
- *Hypertension (HTN) × 5 years—well controlled*

FH

- *Mother and father died in an MVA 10 years ago.*
- *One brother, age 54, is HIV+ and lives with the patient.*
- *One sister, age 50, is alive and has had breast cancer.*

SH

Single, one daughter. He works as an undercover agent and just returned from an operation in Cambodia. He denies smoking or intravenous drug use. He had a 20-year history of alcohol abuse but has been sober for 10 years.

Meds

- *Lisinopril 20 mg daily*
- *Amlodipine 5 mg daily*
- *Metformin 500 mg twice daily*

Patient reports that he tries to be compliant with his therapies and takes them regularly except when he is unable to get his refills; over the past 2 months, he has gone 3 to 4 days without medication.

Allergies: NKDA

- What information is suggestive of tuberculosis?
- What factors place this patient at increased risk for acquiring tuberculosis?

Risk Factors for Disease

Once infected with *M. tuberculosis*, a person's lifetime risk of active TB is about 10%, with about half this risk evident during the first 2 years after infection.[2,3,6] Young children, the elderly, and immunocompromised patients have greater risks. HIV-infected patients with *M. tuberculosis* infection are roughly 100 times more likely to develop active TB than normal hosts owing to the lack of normal cellular immunity.[3,9]

ETIOLOGY

❹ *Microscopic examination ("smear") detects about 8 to 10 × 10^6 organisms/L of specimen using the older AFB (acid-fast bacillus) stain, with the newer auramine-rhodamine fluorescent*

technique being perhaps one-third more sensitive. A smear-negative patient still can grow M. tuberculosis *on culture, which is more sensitive than either staining technique. Unfortunately, culture is much slower than staining due to the doubling time of the bacilli of about 20 hours.* Further, microscopic examination cannot determine which of over 90 mycobacterial species is present. The usual practice is to assume the worst (TB) until confirmed by genetic probe or positive culture.

Culture and Susceptibility Testing

Susceptibility testing is essential for directing proper treatment. The most common agar method, known as the *proportion method,* takes many weeks to produce results. The Bactec and newer MIGIT systems use liquid media and detect live mycobacteria in about 2 weeks.[1,10,11] Rapid-identification tests include nucleic acid probes and DNA fingerprinting using restriction fragment length polymorphism (RFLP) analysis, and polymerase chain reaction (PCR).[1,6,10,12–14] These tests differentiate among mycobacterial species but currently cannot provide susceptibility data. Investigational tests looking for specific mutations associated with drug resistance may facilitate rapid drug therapy decisions in the future.

Transmission

M. tuberculosis is transmitted from person to person by coughing or sneezing.[2,6,15] This produces small particles known as *droplet nuclei* that float in the air for long periods of time. Each droplet contains one to three organisms. It is estimated that 30% of individuals with prolonged contact with an infectious TB patient become infected.

PATHOPHYSIOLOGY

Primary Infection

Primary infection usually results from inhaling droplet nuclei that contain *M. tuberculosis*.[2,6,17] The progression to clinical disease depends on three factors: (1) the number of *M. tuberculosis* organisms inhaled (infecting dose), (2) the virulence of these organisms, and (3) the host's cell-mediated immune response.[2,4,6,12,15,16] If pulmonary macrophages inhibit or kill the bacilli, the infection is aborted.[15] If not, *M. tuberculosis* eventually spreads throughout the body through the bloodstream.[2,6,15] *M. tuberculosis* most commonly infects the posterior apical region of the lungs, where conditions are most favorable for its survival.

T lymphocytes become activated over the course of 3 to 4 weeks, producing interferon-γ (IFN-γ) and other cytokines. These stimulate microbicidal macrophages to surround the tuberculous foci and form granulomas to prevent further extension.[15] At this point, the infection is largely under control, and bacillary replication falls off dramatically. Any remaining mycobacteria are believed to reside primarily within granulomas or within macrophages that have avoided detection and lysis. Over 1 to 3 months, tissue hypersensitivity occurs, resulting in a positive tuberculin skin test.[2,6,17] ❺ ***Progressive primary disease*** *occurs in roughly 5% of patients, especially children, the elderly, and immunocompromised patients.*[18,19] *This presents as a progressive pneumonia and frequently spreads, leading to meningitis and other severe forms of TB, even before their skin tests become positive.*[18]

Reactivation Disease

❻ *About 10% of infected patients develop reactivation TB, with half occurring in the first 2 years after infection.*[2,6,12] Upper lobe pulmonary disease is the most common (85% of cases).[2] **Caseating granulomas** result from the vigorous immune response, and liquefaction leads to local spread. Eventually, a pulmonary cavity results, and this provides a portal to the outside that allows for person-to-person spread. Bacterial counts in the cavities can be as high 10^{11} per liter of cavitary fluid (10^{8} per milliliter).[2,15] Prior to the chemotherapy era, pulmonary TB usually was associated with hypoxia, respiratory acidosis, and eventually death.

Extrapulmonary and Miliary Tuberculosis

Caseating granulomas, regardless of location, can undergo liquefaction, spread tubercle bacilli and cause symptoms.[2,6] Because of muted or altered symptoms, the diagnosis of TB is difficult and often delayed in immunocompromised hosts.[2,3,6] HIV-infected patients may present with only extrapulmonary TB, which is very uncommon in HIV-negative persons. A widely disseminated form of the disease called *miliary TB* can occur, particularly in children and immunocompromised hosts, and it can be rapidly fatal.[17] Immediate treatment is required.

Influence of HIV Infection on Pathogenesis

HIV infection is the most important risk factor for active TB.[2,6,17] As CD4+ lymphocytes multiply in response to the mycobacterial infection, HIV multiplies within these cells and selectively destroys them, gradually eliminating the TB-fighting lymphocytes.[17] HIV-infected patients infected with TB are at a substantially higher risk of early mortality compared with HIV-negative TB patients.[20,21] Because of the large pill burden, overlapping toxicities, and paradoxical worsening of the TB when TB and HIV treatments are initiated simultaneously, most clinicians elect to begin TB treatment first.[12,22] A reasonable time to begin HIV treatment is after 2 months of TB treatment, although individual circumstances often dictate the exact timing.

CLINICAL PRESENTATION

Fever, night sweats, weight loss, fatigue, and a productive cough are the classic symptoms of TB.[1,2,6,16] Onset may be gradual, and the diagnosis is easily missed if the symptoms are muted, such as in the elderly.[2,6,16] Progressive pulmonary disease leads to cavitation visible on x-ray. Physical examination

is non-specific but may be consistent with pneumonia. Dullness to chest percussion, rales, and increased vocal **fremitus** may be observed on examination. Laboratory data often are uninformative, but a modest increase in the white blood cell (WBC) count with a lymphocyte predominance can be seen.

Atypical presentations are common in patients coinfected with HIV.[1,2,6,16,23] HIV-positive patients often have negative skin tests and fail to produce **cavitary lesions,** and fever may be absent. Symptoms for these patients range from classic pulmonary to muted and non-specific. Extrapulmonary TB typically presents as a slowly progressive decline in organ function, and lymphadenopathy is relatively common.[2,6,16,17] Abnormal behavior, headaches, or convulsions suggest tuberculous meningitis, although other acute central nervous system (CNS) infections must be exlcuded.[6,16]

The Elderly

❺ *Many clinical findings are muted in the elderly or absent altogether, so there can be considerable diagnostic uncertainty. Absent may be positive skin tests, fevers, night sweats, sputum production, or hemoptysis, making TB hard to distinguish from other bacterial or viral infections or chronic lung diseases.*[2,16,24,25] In contrast, mental status changes are twice as common in the elderly, and CNS disease must be considered when TB is entertained. Mortality is six times higher in the elderly in part owing to delays in diagnosis.[2,16,24] Ethnic distributions of disease are different in the elderly and include more white patients because these patients often were infected decades ago, when TB was more prevalent in the United States.

Children

❺ *Because very young children have immature cellular immunity, TB can be particularly dangerous in this population. TB in children may present as a typical bacterial pneumonia, called progressive primary TB, and often involves the lower and middle lobes.*[16–19] Dissemination to the lymph nodes, gastrointestinal (GI) and genitourinary tracts, bone marrow, and meninges is fairly common. For these reasons, **bacille Calmette-Guérin (BCG)** vaccinations are administered in countries where TB remains very common. BCG appears to stimulate the children's immune systems just enough to ward off the most serious forms of the disease. However, BCG does not block infection, and these same children often experience reactivation TB as young adults. Because cavitary lung lesions are uncommon, children do not spread TB readily. From the public health perspective, pediatric TB is the clearest indication of recent spread of TB.

DIAGNOSIS

Skin Testing

TB skin testing with the 5-TU strength of brand **purified protein derivative (PPD),** also known as the *Mantoux test*, is the preferred method for skin testing.[2,16,20] The product is injected into the skin (not subcutaneously) with a fine (27-gauge) needle and produces a small, raised, blanched wheal to be read by an experienced professional in 48 to 72 hours. Criteria for interpretation are listed in Table 72–1.[1,2,6,16,20] The Centers for Disease Control and Prevention (CDC) does not recommend the routine use of

TABLE 72–1. Criteria for Tuberculin Positivity, by Risk Group

Reaction greater than or equal to 5 mm of Induration	Reaction greater than or equal to 10 mm of Induration	Reaction greater than or equal to 15 mm of Induration
Human immunodeficiency virus (HIV)–positive persons	Recent immigrants (i.e., within the last 5 years) from high-prevalence countries	Persons with no risk factors for TB
Recent contacts of tuberculosis (TB) case patients	Injection drug users	
Fibrotic changes on chest radiograph consistent with prior TB	Residents and employees[b] of the following high-risk congregate settings: prisons and jails, nursing homes and other long-term facilities for the elderly, hospitals and other health care facilities, residential facilities for patients with acquired immunodeficiency syndrome (AIDS), and homeless shelters	
Patients with organ transplants and other immunosuppressed patients (receiving the equivalent of greater than or equal to 15 mg/day of prednisone for 1 month or more)[a]	Mycobacteriology laboratory personnel Persons with the following clinical conditions that place them at high risk: silicosis, diabetes mellitus, chronic renal failure, some hematologic disorders (e.g., leukemias and lymphomas), other specific malignancies (e.g., carcinoma of the head or neck and lung), weight loss of greater than or equal to 10% of ideal body weight, gastrectomy, and jejunoileal bypass	
	Children younger than 4 years of age or infants, children, and adolescents exposed to adults at high risk	

[a]Risk of TB in patients treated with corticosteroids increases with higher dose and longer duration.
[b]For persons who are otherwise at low risk and are tested at the start of employment, a reaction of greater than or equal to 15 mm of induration is considered positive.

CXR

Profound bilateral upper lobe infiltrates with cavitation on left; small left pneumothorax

Clinical Course

The patient was admitted and placed on respiratory isolation. Three separate sputum Gram stain specimens were reported to contain 3+ AFB. A PPD tuberculin skin test was placed. Sputum samples were sent for AFB, fungi, and bacterial cultures and sensitivities. After 48 hours, the PPD skin test was read as a 12-mm area of induration.

Assessment

1. Active pulmonary tuberculosis
2. Pneumothorax
3. Hypertension
4. Non-insulin-dependent diabetes mellitus

- Which signs, symptoms, and other findings are consistent with active TB infection?

anergy panels.[20,26] The "booster effect" occurs in patients who do not respond to an initial skin test but show a positive reaction if retested about a week later.[16,26]

Additional Tests

Morning sputum collections have the highest yield of organisms.[2,10,16] Daily sputum collections over three consecutive days improve the yield of positive results. Sputum induction with aerosolized hypertonic saline may produce a diagnostic sample in patients unable to produce sputum. Bronchoscopy or aspiration of gastric fluid via a nasogastric tube may be attempted in selected patients, the latter being used more often in children.[16] For patients with suspected extrapulmonary TB, samples of draining fluid, biopsies of the infected site, or both may be attempted. Blood cultures are positive occasionally, especially in acquired immune deficiency syndrome (AIDS) patients who have low CD4 counts.[16,23,27]

TREATMENT

General Approaches to Treatment

Monotherapy can be used only for infected patients who do not have active TB [**latent TB infection** (LTBI), as shown by a positive skin test in the absence of signs or symptoms of disease]. Once active disease is present, a minimum of two drugs and typically *three or four drugs* must be used simultaneously from the outset of treatment.[2,6,12,28] For most patients, the shortest duration of treatment is 6 months, and 2 to 3 years of treatment may be necessary for advanced cases of multidrug-resistant TB (MDR-TB).[2,6,12,28] **Directly observed therapy** (DOT) by a health care worker is a cost-effective way to ensure completion of treatment.[2,6,12,28–30]

Nonpharmacologic Therapy

❼ *Steps should be taken to (1) prevent the spread of TB (respiratory isolation), (2) find where TB has already spread (contact investigation), and (3) return the patient to a state of normal weight and well-being.* The older term for TB is *consumption* because wasting was a primary symptom of disease progression in the prechemotherapy era and remains descriptive today. Items 1 and 2 are performed by public health departments. Clinicians involved in the treatment of TB should verify that the local health department has been notified of all new cases of TB. Surgery may be needed to remove destroyed lung tissue, space-occupying infected lesions (tuberculomas), and certain extrapulmonary lesions.[2,12,28]

Pharmacologic Therapy

Treating Latent Infection (LTBI)

Isoniazid is used for treating LTBI.[2,6,12,28] Typically, isoniazid 300 mg daily (5–10 mg/kg of body weight) is given alone for 9 months. Lower doses usually are less effective.[2,31] The treatment of LTBI reduces a person's lifetime risk of active TB from about 10% to about 1%[20] (Table 72–2). Rifampin 600 mg

TABLE 72–2. Recommended Drug Regimens for Treatment of Latent Tuberculosis Infection (LTBI) in Adults[32]

Drug	Interval and Duration	Comments	Rating[a] HIV−	Evidence HIV+
Isoniazid	Daily for 9 months[c,d]	In human immunodeficiency virus (HIV)–infected patients, isoniazid may be administered concurrently with nucleoside reverse transcriptase inhibitors (NRTIs), protease inhibitors, or non-nucleoside reverse transcriptase inhibitors (NNRTIs).	A (II)	A (II)
	Twice weekly for 9 months[c,d]	Directly observed therapy (DOT) must be used with twice-weekly dosing.	B (II)	B (II)
Isoniazid	Daily for 6 months[d]	Not indicated for HIV-infected persons, those with fibrotic lesions on chest radiographs, or children.	B (I)	C (I)
	Twice weekly for 6 months[d]	DOT must be used with twice-weekly dosing.	B (II)	C (I)
Rifampin	Daily for 4 months	For persons who are contacts of patients with isoniazid-resistant rifampin susceptible TB. In HIV-infected patients, protease inhibitors or NNRTIs generally should not be administered concurrently with rifampin; rifabutin can be used as an alternative for patients treated with indinavir, nelfinavir, amprenivir, ritonavir, or efavirenz, and possibly with nevirapine or soft-gel saquinavir[e]	B (II)	B (III)

[a]*Strength of recommendation:* A = preferred; B = acceptable alternative; C = offer when A and B cannot be given.
[b]*Quality of evidence:* I = randomized clinical trial data; II = data from clinical trials that are not randomized or were conducted in other populations; III = expert opinion.
[c]Recommended regimen for children younger than 18 years of age.
[d]Recommended regimens for pregnant women. Some experts would use rifampin and pyrazinamide for 2 months as an alternative regimen in HIV-infected pregnant women, although pyrazinamide should be avoided during the first trimester.
[e]Rifabutin should not be used with hard-gel saquinavir or delavirdine. When used with other protease inhibitorsor NNRTIs, dose adjustment of rifabutin may be required.
With permission.

daily for 4 months can be used when isoniazid resistance is suspected or when the patient cannot tolerate isoniazid.[2,19,32,33] Rifabutin 300 mg daily might be substituted for rifampin in patients at high risk of drug interactions. The combination of pyrazinamide and rifampin is no longer recommended because of unacceptable rates of hepatotoxicity.[34] When resistance to isoniazid and rifampin is suspected in the isolate causing infection, there is no regimen proven to be effective.[2,28]

Treating Active Disease

In the United States, all patients diagnosed with TB can receive treatment free of charge through the local health department, and this is encouraged because local health departments generally have the greatest expertise. Treating active TB disease requires combination chemotherapy. Generally, *four drugs* are given at the onset of treatment. ❽ *Isoniazid and rifampin should be used together for most cases because they are the best drugs for preventing drug resistance.*[2,6,28,35,36] Drug susceptibility testing should be done on the initial isolate for all patients with active TB and should be used to guide the selection of drugs over the course of treatment.[2,6,12,28] Susceptibility testing may be repeated in cases where the patient remains culture-positive 8 weeks or more into therapy.

❽ *The standard TB treatment regimen is isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months, followed by isoniazid and rifampin for 4 months, for a total of 6 months of treatment.*[2,12,28] *A total of 9 months of isoniazid and rifampin treatment is recommended for patients at greater risk of failure and relapse, including those with cavitation on initial chest radiograph or positive cultures at the completion of the initial 2-month phase of treatment, as well as for patients treated initially without pyrazinamide. Treatment should be continued for at least 6 months from the time that patients convert to smear- and culture-negative.*[2,6,12,28] Some authors recommend therapeutic drug monitoring for such patients because one of the proven reasons for treatment failure is malabsorption of orally administered drugs.[2,28,36,37] Table 72–3 shows the recommended treatment regimens for tuberculosis. When isoniazid and rifampin cannot be used, treatment durations become 2 years or more, regardless of immune status.[2,12,28,36] When intermittent therapy is used, DOT is essential. Doses missed during an intermittent TB regimen decrease the efficacy of the regimen and increase the relapse rate. Further, outcomes appear to be worse for immunocompromised patients when intermittent treatment, especially twice-weekly treatment, is used. Therefore, HIV-positive TB patients should receive TB drugs at least three times weekly. When the patients' **sputum smears** convert to negative, the risk of them infecting others is greatly reduced, but it is not zero.[2,15,28] Such patients can be removed from respiratory isolation, but they must be careful not to cough on others and should meet only in well-ventilated places.

Adjustments to the regimen should be made once the susceptibility data are available.[2,12,28] Drug resistance should be expected in patients who have been treated previously for TB. Two or more drugs with in vitro activity against the patient's isolate that were not used before should be added to the regimen as needed.[2,12,28] TB specialists should be consulted regarding cases of drug-resistant TB or in any setting where there is uncertainty regarding appropriate treatment.[2,12,28] ❾ *It is critical to avoid monotherapy, and it is critical to avoid adding a single drug to a failing regimen.*[2,12,28]

Special Populations

Patients with CNS tuberculosis usually are treated for longer periods (9–12 months instead of 6 months) because the consequences of undertreatment are severe.[2,12,28] TB of the bone typically is treated for 9 months, occasionally with surgical débridement.[2,12,28] Drug selection is the same as for pulmonary disease. Extrapulmonary TB of the soft tissues can be treated with conventional regimens.[2,12,28] TB in children may be treated with regimens similar to those used in adults, although some physicians extend treatment to 9 months.[2,12,16,18,28,32,38] Pediatric doses of isoniazid and rifampin on a milligram per kilogram basis are higher than those used in adults[28] (Table 72–4).

Pregnant women receive the usual treatment of isoniazid, rifampin, and ethambutol for 9 months.[2,28,32,36,38] Pyrazinamide has not been studied in large numbers of pregnant women, but anecdotal data suggest that it may be safe.[28] B vitamins should be provided. Streptomycin, other aminoglycosides, capreomycin, and ethionamide generally are avoided because they have been associated with toxic effects on the fetus.[28,39] *Para*-Aminosalicylic acid and cycloserine are used sparingly.[39] Quinolones generally are avoided in pregnancy because of concern about adverse effects on cartilage development.[28,39] Although most antituberculosis drugs are excreted in breast milk, the amount of drug received by the infant through nursing is insufficient to cause toxicity. Quinolones should be avoided in nursing mothers, if possible, for the same reason as above.

Human Immunodeficiency Virus

Patients with AIDS and other immunocompromised hosts may be managed with chemotherapeutic regimens similar to those used in immunocompetent individuals, although treatment is

Patient Encounter, Part 3: Creating a Care Plan

Based on the information provided, what are the goals of therapy for this patient? Select and recommend a therapeutic plan for treatment of this patient's TB infection. What drugs, dose, schedule, and duration of therapy are best for this patient? How should any contacts infected by this patient be evaluated and treated? Select and recommend a therapeutic plan. What drugs, dose, and schedule of therapy are best for his close contacts?

TABLE 72–3. Drug Regimens for Culture-Positive Pulmonary Tuberculosis Caused by Drug-Susceptible Organisms[32]

		Initial Phase			Continuation Phase	
Regimen	**Drugs**	**Interval and Doses[c] (*Minimal Duration*)**	**Regimen**	**Drugs**	**Interval and Doses[c,d] (*Minimal Duration*)**	**Range of Total Doses (*Minimal Duration*)**
1	INH RIF PZA EMB	Seven days per week for 56 doses (8 weeks) *or* 5 days/week for 40 doses (8 weeks)[e]	1a	INH/RIF	Seven days per week for 126 doses (18 weeks) *or* 5 days/week for 90 doses (18 weeks)[e]	182–130 (26 weeks)
			1b	INH/RIF	Twice weekly for 36 doses (18 weeks)	92–76 (26 weeks)[f]
			1c[g]	INH/RPT	Once weekly for 18 doses (18 weeks)	74–58 (26 weeks)
2	INH RIF PZA EMB	Seven days per week for 14 doses (2 weeks)[e], *then* twice weekly for 12 doses (6 weeks) *or* 5 days/week for 10 doses (2 weeks), *then* twice weekly for 12 doses (6 weeks)	2a	INH/RIF	Twice weekly for 36 doses (18 weeks)	62–58 (26 weeks)[f]
			2b[g]	INH/RPT	Once weekly for 18 doses (18 weeks)	44–40 (26 weeks)
3	INH RIF PZA EMB	Three times weekly for 24 doses (8 weeks)	3a	INH/RIF	Three times weekly for 54 doses (18 weeks)	78 (26 weeks)
4	INH RIF EMB	Seven days per week for 56 doses (8 weeks) *or* 5 days/week for 40 doses (8 weeks)[e]	4a	INH/RIF	Seven days per week for 217 doses (31 weeks) *or* 5 days/week for 155 doses (31weeks)[e]	273–195 (39 weeks)
			4b	INH/RIF	Twice weekly for 62 doses (31 weeks)	118–102 (39 weeks)

[a]*Definitions of evidence ratings*: A = preferred; B = acceptable alternative; C = offer when A and B cannot be given; E = should never be given.
[b]*Definitions of evidence ratings*: I = randomized clinical trial; II = data from clinical trials that were not randomized or were conducted in other populations; III = expert opinion.
[c]When DOT is used, drugs may be given 5 days/week and the necessary number of doses adjusted accordingly. Although there are no studies that compare five with seven daily doses, extensive experience indicates this would be an effective practice.
[d]Patients with cavitation on initial chest radiograph and positive cultures at completion of 2 months of therapy should receive a 7-month [31-week; either 217 doses (daily) or 62 doses (twice weekly)] continuation phase.
[e]Five-day-a-week administration is always given by DOT. Rating for 5 day/week regimens is A(III).
[f]Not recommended for HIV-infected patients with CD4+ cell counts less than 100 cells/mL.
[g]Options 1c and 2b should be used only in HIV-negative patients who have negative sputum smears at the time of completion of 2 months of therapy and who do not have cavitation on the initial chest radiograph. For patients started on this regimen and found to have a positive culture from the 2-month specimen, treatment should be extended an extra 3 months.
EMB, ethambutol; INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; RPT, rifapentine.
With permission.

often extended to 9 months[2,12,28] (Table 72–3). The precise duration to recommend remains a matter of debate. Highly intermittent regimens (twice or once weekly) are not recommended for HIV-positive TB patients.[28] Prognosis has been particularly poor for HIV-infected patients infected with MDR-TB. Some patients with AIDS malabsorb their oral medications, and drug interactions are common.[2,28,36,37] It is advisable that such patients are managed by TB-HIV experts because the challenges are many.

Renal Failure

Because they are hepatically cleared, isoniazid and rifampin do not require dose modification in renal failure.[31,36,39] Pyrazinamide and ethambutol typically are reduced to three times weekly to avoid accumulation of the parent drug (ethambutol) or metabolites (pyrazinamide).[28,31] Renally cleared TB drugs include the aminoglycosides (e.g., amikacin, kanamycin, and streptomycin), capreomycin, ethambutol, cycloserine, and levofloxacin.[28,31,33,39] Dosing intervals need to be extended for

TABLE 72–4. Antituberculosis Drugs for Adults and Children[a32]

Drug	Daily Doses[b]	Adverse Effects	Monitoring
Isoniazid	Adults: 5 mg/kg (300 mg) Children: 10–15 mg/kg (300 mg)	Asymptomatic elevation of aminotransferases, clinical hepatitis, fatal hepatitis, peripheral neurotoxicity, CNS system effects, lupus-like syndrome, hypersensitivity, monoamine poisoning, diarrhea	LFT monthly in patients who have preexisting liver disease or who develop abnormal liver function that does not require discontinuation of drug Dosage adjustments may be necessary in patients receiving anticonvulsants or warfarin
Rifampin	Adults[c]: 10 mg/kg (600 mg) Children: 10–20 mg/kg (600 mg)	Cutaneous reactions, gastrointestinal reactions (nausea, anorexia, abdominal pain), flulike syndrome, hepatotoxicity, severe immunologic reactions, orange discoloration of bodily fluids (sputum, urine, sweat, tears), drug interactions owing to induction of hepatic microsomal enzymes	Rifampin causes many drug interactions. For a complete list of drug interactions and effects refer to CDC Web site: www.cdc.gov/nchstp/tb/tb
Rifabutin	Adults[c]: 5 mg/kg (300 mg) Children: Appropriate dosing unknown	Hematologic toxicity, uveitis, gastrointestinal symptoms, polyarthralgias, hepatotoxicity, pseudojaundice (skin discoloration with normal bilirubin), rash, flulike syndrome, orange discoloration of bodily fluids (sputum, urine, sweat, tears)	Drug interactions are less problematic than rifampin
Rifapentine	Adults: 10 mg/kg (continuation phase) (600 mg) Dosed weekly. Children: The drug is not approved for use in children	Similar to those associated with RIF	Drug interactions are being investigated and are likely similar to RIF
Pyrazinamide	Adults: Based on IBW: 40–55 kg: 1000 mg; 56–75 kg: 1500 mg; 76–90 kg: 2000 mg Children: 15–30 mg/kg	Hepatotoxicity, gastrointestinal symptoms (nausea, vomiting), non-gouty polyarthralgia, asymptomatic hyperuricemia, acute gouty arthritis, transient morbilliform rash, dermatitis	Serum uric acid can serve as a surrogate marker for compliance LFTs in patients with underlying liver disease
Ethambutol[d]	Adults: Based on IBW: 40–55 kg: 800 mg; 56–75 kg: 1200 mg; 76–90 kg: 1600 mg Children[c]: 15–20 mg/kg daily	Retrobulbar neuritis, peripheral neuritis, cutaneous reactions	Baseline visual acuity testing and testing of color discrimination Monthly testing of visual acuity and color discrimination in patients taking greater than 15–20 mg/kg, renal insufficiency, or receiving the drug for greater than 2 months
Cycloserine	Adults[e]: 10–15 mg/kg per day, usually 500–750 mg/day in two doses Children: 10–15 mg/kg per day	Central nervous system effects	Monthly assessments of neuropsychiatric status Serum concentration may be necessary until appropriate dose is established
Ethionamide	Adults[f]: 15–20 mg/kg per day, usually 500–750 mg/day in a single daily dose or two divided doses Children: 15–20 mg/kg per day	Gastrointestinal effects, hepatotoxicity, neurotoxicity, endocrine effects	Baseline LFTs Monthly LFTs if underlying liver disease is present TSH at baseline and monthly intervals

(*Continued*)

TABLE 72–4. Antituberculosis Drugs for Adults and Children[a32] (*Continued*)

Drug	Daily Doses[b]	Adverse Effects	Monitoring
Streptomycin	Adults: See footnote[g] Children: 20–40 mg/kg per day	Ototoxicity, neurotoxicity, nephrotoxicity	Baseline audiogram, vestibular testing, Romber testing and SCr Monthly assessments of renal function and auditory or vestibular symptoms
Amikacin/ kanamycin	Adults: See footnote[g] Children: 15–30 mg/kg per day intravenous or intramuscular as a single daily dose	Ototoxicity, nephrotoxicity	Baseline audiogram, vestibular testing, Romber testing and SCr Monthly assessments of renal function and auditory or vestibular symptoms
Capreomycin	Adults: See footnote[g] Children: 15–30 mg/kg per day as a single daily dose	Nephrotoxicity, ototoxicity	Baseline audiogram, vestibular testing, Romberg testing and SCr Monthly assessments of renal function and auditory or vestibular symptoms Baseline and monthly serum K^+ and Mg^{2+}
p-Aminosalicylic acid (PAS)	Adults: 8–12 g/day in two or three doses Children: 200–300 mg/kg per day in two to four divided doses	Hepatotoxicity, gastrointestinal distress, malabsorption syndrome, hypothyroidism, coagulopathy	Baseline LFTs and TSH TSH every 3 mos
Levofloxacin	Adults: 500–1000 mg daily Children: See footnote[h]	Gastrointestinal disturbance, neurologic effects, cutaneous reactions	No specific monitoring recommended
Moxifloxacin	Adults: 400 mg daily Children: See footnote[i]		
Gatifloxacin	Adults: 400 mg daily Children: See footnote[j]		

[a]For purposes of this document, adult dosing begins at age 15 years.
[b]Dose per weight is based on ideal body weight. Children weighing more than 40 kg should be dosed as adults.
[c]Dose may need to be adjusted when there is concomitant use of protease inhibitors or nonnucleoside reverse transcriptase inhibitors.
[d]The drug likely can be used safely in older children but should be used with caution in children younger than 5 years of age, in whom visual acuity cannot be monitored. In younger children, EMB at the dose of 15 mg/kg per day can be used if there is suspected or proven resistance to INH or RIF.
[e]It should be noted that although this is the dose recommended generally, most clinicians with experience using cycloserine indicate that it is unusual for patients to be able to tolerate this amount. Serum concentration measurements are often useful in determining the optimal dose for a given patient.
[f]The single daily dose can be given at bedtime or with the main meal.
[g]Dose: 15 mg/kg per day (1 g) and 10 mg/kg in persons older than 50 years of age (750 mg). Usual dose: 750–1000 mg administered intramuscularly or intravenously, given as a single dose 5–7 days/week, and reduced to two or three times per week after the first 2–4 months or after culture conversion, depending on the efficacy of the other drugs in the regimen.
[h]The long-term (more than several weeks) use of levofloxacin in children and adolescents has not be approved because of concerns about effects on bone and cartilage growth. However, most experts agree that the drug should be considered for children with tuberculosis caused by organisms resistant to both INH and RIF. The optimal dose is not known.
[i]The long-term (more than several weeks) use of moxifloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. The optimal dose is not known.
[j]The long-term (more than several weeks) use of gatifloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. The optimal dose is not known.
LFT, liver function test; SCr, serum creatinine; TSH, thyroid-stimulating hormone.
With permission.

these drugs. Serum concentration monitoring must be performed for cycloserine to avoid dose-related toxicities in renal failure patients.[33,36,37]

Hepatic Failure

Elevations of serum transaminase concentrations generally are not correlated with the residual capacity of the liver to metabolize drugs, so these markers cannot be used directly as guides for residual metabolic capacity. Hepatically cleared TB drugs include isoniazid, rifampin, pyrazinamide, ethionamide, and *p*-aminosalicylic acid.[39] Ciprofloxacin is about 50% cleared by the liver. Further, isoniazid, rifampin, pyrazinamide, and to a lesser degree ethionamide, *p*-aminosalicylic acid, and rarely ethambutol may cause hepatotoxicity.[28,36,39] These patients require close monitoring, and serum concentration monitoring may be the most accurate way to dose them.

The TB Drugs

The interested reader is referred to several other publications for more detailed information regarding these drugs.[2,11,28,34–37,39–42] A summary of daily doses, adverse effects, and monitoring

parameters of first- and second-line antituberculosis drugs is provided in Table 72–4.[28] Isoniazid and rifampin are considered the two key drugs for the treatment of active TB, followed by pyrazinamide, which has a special role in the first 2 months of treatment. Other drugs are used to suppress the emergence of drug resistance in conjunction with the first-line drugs or for preexisting drug-resistant TB. In general, the most important toxicity with first-line drugs is hepatotoxicity, whereas various organs may be affected by each of the second-line drugs. Recent research is placing emphasis on the potential role of quinolones such as levofloxacin and moxifloxacin in the treatment of TB. It is possible that future regimens may consider these agents part of the first-line drugs.

EVALUATION OF OUTCOMES

Effectiveness of TB therapy is determined by AFB smears and cultures. Sputum samples should be sent for AFB staining and microscopic examination (smears) every 1 to 2 weeks until two consecutive smears are negative. This provides early evidence of a response to treatment.[28] Once on maintenance therapy, **sputum cultures** can be performed monthly until two consecutive cultures are negative, which generally occurs over 2 to 3 months. If sputum cultures continue to be positive after 2 months, drug susceptibility testing should be repeated, and serum concentrations of the drugs should be checked.

⑩ *The most serious problem with TB therapy is patient nonadherence to the prescribed regimens.*[43,44] *Unfortunately, there is no reliable way to identify such patients a priori. The most effective way to achieve this end is with DOT.*[2,11,28] The use of DOT in non-compliant patients may be of benefit.[45] DOT also provides increased opportunities to observe the patient for any apparent toxicities, thus improving overall care.

Serum chemistries, including blood urea nitrogen (BUN), creatinine, aspartate transaminase (AST), and alanine transaminase (ALT), and a complete blood count with platelets should be performed at baseline and periodically thereafter depending on the presence of other factors that may increase the likelihood of toxicity (e.g., advanced age, alcohol abuse, and pregnancy).[2,28] Hepatotoxicity should be suspected in patients whose transaminases exceed five times the upper limit of normal or whose total bilirubin exceeds 51 µmol/L and in patients with symptoms such as nausea, vomiting, and jaundice. At this point, the offending agent(s) should be discontinued. Sequential reintroduction of the drugs with frequent testing of liver enzymes is often successful in identifying the offending agent; other agents may be continued[28] (Table 72–4).

Therapeutic Drug Monitoring

Therapeutic drug monitoring (TDM) or applied pharmacokinetics is the use of serum drug concentrations to optimize therapy.[28,36,37] Non-AIDS patients with drug-susceptible TB generally do well. TDM may be used if patients are failing appropriate DOT (no clinical improvement after 2 to 4 weeks or smear-positive after 4 to 6 weeks). On the other hand, patients with AIDS, diabetes, and various GI disorders often fail to absorb these drugs properly and are candidates for TDM. Also, patients with hepatic or renal disease should be monitored, given their potential for overdoses. In the treatment of MDR-TB, TDM may be particularly useful.[39,41] Finally, TDM of the TB and HIV drugs is perhaps the most logical way to untangle the complex drug interactions that take place. For a complete list of drug interactions visit the CDC Web site at www.cdc.gov/nchstp/tb/tb_hiv_drugs/toc.htm[46] In particular, interactions between the rifamycins (e.g., rifampin, rifapentine, and rifabutin) and the HIV protease inhibitors and nonnucleoside reverse transcriptase inhibitors are common and require dose and frequency modifications in many cases. Since these are constantly being updated, the preceding link is an excellent way to keep current.

Patient Encounter, Part 4: Creating a Care Plan

Based on the information provided, which clinical and laboratory parameters should be monitored in this patient to determine efficacy and avoid toxicity? Is this patient a candidate for therapeutic drug monitoring? Why or why not?

Patient Care and Monitoring

1. Rapidly identifiy a new TB case.
2. Assess the patient's risk factors and signs and symptoms to determine if the patient might be infected with TB.
3. Isolate the patient with active disease to prevent the spread of the disease.
4. Collect appropriate samples for smears and cultures.
5. Obtain a throrough medication history.
6. Select and recommend appropriate antituberculosis treatment. Consider HIV status, pregnancy, type of TB infection, renal function, liver function etc.
7. Ensure adherence to the treatment regimen by the patient.
8. Obtain AFB stains to evaluate the effectiveness of treatment.
9. Consider TDM if no clinical improvement.
10. Secondary goals are identification of the index case that infected the patient, identification of all persons infected by both the index case and the new case of TB, and the completion of appropriate treatments for those individuals.

ABBREVIATIONS

AIDS	Acquired immunodeficiency syndrome
ALT	Alanine transaminase
AST	Aspartate transaminase
CNS	Central nervous system
(HIV)	Human immunodeficiency virus
(HTN)	Hypertension
NIDDM	Non-insulin dependent diabetes mellitus
PCR	Polymerase chain reaction
RFLP	Restriction fragment length polymorphism
TB	Tuberculosis
WBC	White blood cell

73 Gastrointestinal Infections

Elizabeth D. Hermsen and Ziba Jalali

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Describe the epidemiology and clinical presentation of the various gastrointestinal infections.
2. Develop an individualized treatment plan given a patient with each of the gastrointestinal infections.
3. Understand the impact of resistance on the treatment of the various gastrointestinal infections.
4. Recognize the effect of immunosuppression on gastrointestinal infections.
5. Educate patients on appropriate prevention measures.
6. Describe the role of antimicrobial prophylaxis and/or vaccination for gastrointestinal infections.

Key Concepts

❶ Rehydration is the foundation of therapy for gastrointestinal infections.
❷ Blood in stool indicates the possibility of inflammatory mucosal disease of the colon. Enterohemorrhagic *Escherichia coli* (EHEC) is an important cause of bloody diarrhea in the United States.
❸ Travelers' diarrhea is most commonly caused by bacteria such as *Shigella, Salmonella, Campylobacter*, and *Escherichia coli*, although viruses are being recognized increasingly as a significant cause of travelers' diarrhea as well.
❹ Education of travelers about high-risk food items is the key to the prevention of travelers' diarrhea.
❺ Nosocomial *Clostridium difficile*–associated diarrhea (CDAD) is almost always associated with antimicrobial use; therefore, we should avoid unnecessary and inappropriate antibiotic therapy. Almost all antibiotics except aminoglycosides have been associated with CDAD.
❻ Viruses are the most common cause of diarrheal illness in the world. A live, oral vaccine is licensed and recommended for use in infants for the prevention of rotavirus infection.

One of the primary concerns related to gastrointestinal (GI) infection, regardless of the cause, is dehydration, which is the second leading cause of worldwide morbidity and mortality.[5] Worldwide, dehydration is especially problematic for children younger than age 5. However, the highest rate of death in the United States occurs among the elderly.[5] ❶ *Rehydration is the foundation of therapy for GI infections, and oral rehydration therapy (ORT) is usually preferred* (Table 73–1).

BACTERIAL INFECTIONS

Shigellosis

Epidemiology

Shigella causes bacillary **dysentery,** which refers to a diarrheal stool containing pus and blood. Worldwide, there are an estimated 165 million cases of shigellosis annually with 1 million associated deaths.[6] Shigellosis is a disease that mostly affects children 6 months to 10 years of age. In the United States, shigellosis is a serious problem in day-care centers and areas with crowded living conditions such as urban centers. Most cases of shigellosis are a result of person-to-person transmission. *Shigella* transmission from contaminated food and water, although less common, is associated with large outbreaks.

Pathogenesis

Shigella are nonmotile, gram-negative, non-lactose-fermenting rods and are members of the family Enterobacteriaceae. There

TABLE 73–1. Clinical Assessment of Degree of Dehydration in Children Based on Percentage of Body Weight Loss

Variable	Mild, 3–5%	Moderate, 6–9%	Severe, 10% or More
Blood pressure	Normal	Normal	Normal to reduced
Quality of pulses	Normal	Normal to slightly decreased	Moderately decreased
Heart rate	Normal	Increased	Increased (bradycardia in severe cases)
Skin turgor	Normal	Decreased	Decreased
Fontanelle	Normal	Sunken	Sunken
Mucous membranes	Slightly dry	Dry	Dry
Eyes	Normal	Sunken orbits/ decreased tears	Deeply sunken orbits/ decreased tears
Extremities	Warm, normal capillary refill	Delayed capillary refill	Cool, mottled
Mental status	Normal	Normal to listless	Normal to lethargic to comatose
Urine output	Slightly decreased	Less than 1 mL/kg per hour	Less than 1 mL/kg per hour
Thirst	Slightly increased	Moderately increased	Very thirsty
Fluid replacement	ORT 50 mL/kg over 2–4 hours	ORT 100 mL/kg over 2–4 hours	Lactated Ringers 40 mL/kg in 15–30 minutes, then 20–40 mL/kg if skin turgor, alertness, and pulse have not returned to normal *or* Lactated Ringers or normal saline 20 mL/kg, repeat if necessary, and then replace water and electrolyte deficits over 1–2 days, followed by ORT 100 mL/kg over 4 hours

From Martin S, Jung R. Gastrointestinal infections and enterotoxigenic poisonings. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005:2037.

are four species of *Shigella*: *S. dysenteriae* (serogroup A), *S. flexneri* (serogroup B), *S. boydii* (serogroup C), and *S. sonnei* (serogroup D). Infection with *Shigella* occurs after ingestion of as few as 10 to 100 organisms.[7] This low dose of organisms probably explains the person-to-person spread and the high secondary attack rate when an index case is introduced into a family.

Shigella strains invade intestinal epithelial cells with subsequent multiplication, inflammation, and destruction.[8] The organism infects the superficial layer of the gut, rarely penetrates beyond the mucosa, and seldom invades the bloodstream. However, bacteremia can occur in malnourished children and **immunocompromised** patients.

Clinical Presentation and Diagnosis

- Biphasic illness
  - Early—high fever, watery **diarrhea** without blood
  - Later—after approximately 48 hours, colitis develops with urgency, **tenesmus**, and dysentery.
    - Low-grade fever
    - More frequent small-volume stools ("fractional stools")
    - Abdominal cramping
- Major complications of shigellosis include
  - Proctitis or rectal prolapse (infants and young children)
  - Toxic megacolon (primarily in the setting of *S. dysenteriae* 1 infection)
  - Intestinal obstruction
  - Colonic perforation
  - Bacteremia (more common in children)
  - Metabolic disturbances
  - **Leukemoid reaction**
  - Neurologic disease
  - Reactive arthritis or Reiter's syndrome
  - **Hemolytic-uremic syndrome (HUS)**
- Microscopic examination of stool is extremely useful and reveals multiple polymorphonuclear leukocytes and red blood cells. Diagnosis is usually confirmed by stool culture.

Treatment and Monitoring

Although infection with *Shigella* generally is self-limited and responds to supportive care, antibiotic therapy is indicated because it shortens the duration of illness and shedding and consequently reduces the risk of transmission. Antibiotic resistance is a worldwide concern and growing problem for enteric bacterial pathogens. Currently, the treatment of choice is a fluoroquinolone when the antibiotic susceptibility of the organism is unknown[9] (Table 73–2). Cephalosporins or azithromycin can be used in the management of pediatric shigellosis.

TABLE 73–2. Antibacterial Therapy for Adults with Shigellosis

Agent	Dosage
Levofloxacin	500 mg daily × 3 days
Ciprofloxacin	500 mg twice daily × 3 days
Norfloxacin	400 mg twice daily × 3 days
Azithromycin	500 mg daily × 3 days
Rifaximin	200 mg three times daily × 3 days

DuPont H. Shigella species (bacillary dysentery). IN: Mandell GL, Bennett JE, and Dolin R, (eds.) Principles and Practice of Infectious Diseases, 6th ed. New York: Churchill Livingstone; 2004:2655.

Rifaximin is likely to be effective in the treatment of milder forms of shigellosis and has been shown to be effective at preventing infection owing to *S. flexneri*.[10] Antimotility agents are not recommended because they can worsen dysentery and may be related to the development of toxic megacolon. No vaccines are licensed currently for the prevention of shigellosis.

Salmonellosis

Epidemiology

Salmonella typhi and *Salmonella paratyphi*, which cause typhoid fever, have high host specificity for humans. In the United States, typhoid fever has become less prevalent and is associated primarily with international travel, especially to developing countries. Nontyphoidal *Salmonella* are important causes of reportable foodborne infection. There are an estimated 1.4 million cases of nontyphoid *Salmonella* illness annually in the United States.[11] The highest incidence is in those younger than 1 year of age and older than 65 years of age or in those with HIV/AIDS. Outbreaks of intestinal salmonellosis have been reported owing to unpasteurized orange juice, tomatoes, cantaloupe, alfalfa sprouts, and cilantro. Exotic pets, especially reptiles (e.g., snakes, turtles, and iguanas), are an increasing source of human salmonellosis, accounting for an estimated 3% to 5% of all cases.

Risk factors for salmonellosis include extremes of age, alteration of the endogenous bowel flora of the intestine (e.g., as a result of antimicrobial therapy or surgery), diabetes, malignancy, rheumatologic disorders, human immunodeficiency virus (HIV) infection, and therapeutic immunosuppression of all types.

Pathogenesis

Salmonella are motile, non-lactose-fermenting, gram-negative bacilli. In salmonellosis, the organisms penetrate the epithelial lining to the lamina propia with production of diffuse inflammation. The distal ileum and colon are sites of infection.

Treatment and Monitoring

Gastroenteritis

Salmonella gastroenteritis is usually self-limited, and antibiotics have no proven value. Patients respond well to ORT. Symptoms typically diminish in 3 to 7 days without sequelae. Antibiotic use may result in a higher rate of chronic carriage and relapse. Antimicrobial use should be limited to preemptive therapy among patients at higher risk for extraintestinal spread or invasive disease (Table 73–3). Antimotility agents should not be used.

Enteric Fever

The current drug of choice for typhoid fever is a fluoroquinolone, such as ciprofloxacin. The recommended dose of ciprofloxacin for uncomplicated typhoid is 500 mg orally twice daily for 5 to 7 days. Drug resistance is a recognized problem in the Indian subcontinent, Southeast Asia, Mexico, the Arabian Gulf, and Africa. All *S. typhi* isolates should be screened for nalidixic acid and fluoroquinolone resistance. If nalidixic acid resistance is present, the patient should be given higher doses of ciprofloxacin or ofloxacin (10 mg/kg twice

Clinical Presentation and Diagnosis

Gastroenteritis

- Onset 8 to 48 hours after ingestion of contaminated food.
- Fever, diarrhea, and cramping
- Stools are loose, of moderate volume, and without blood.
- Headache, myalgias, and other systemic symptoms can occur.
- Diagnosis relies on isolation of the organism from stool or ingested food.
- Certain underlying conditions (e.g., AIDS, inflammatory bowel disease, and prior gastric surgery) predispose the patient to more severe disease.

Enteric Fever

- Febrile illness 5 to 21 days after ingestion of contaminated food or water
- Chills, diaphoresis, headache, anorexia, cough, weakness, sore throat, dizziness, and muscle pains are frequently present before the onset of fever.
- Diarrhea is an early symptom and occurs only in 50% of cases. Intestinal hemorrhage or perforation, leukopenia, anemia, and subclinical disseminated intravascular coagulopathy may be seen.
- Culture of stool, blood, or bone marrow for *Salmonella* species is helpful.

Vascular Infection and Bacteremia

S. choleraesuis and *S. dublin* are the most common causative organisms. The risk of bacteremia is greater for infants, the elderly, and the immunocompromised.

Localized Infections

Localized infections occur in 5% to 10% of cases with *Salmonella* bacteremia. Sites for extraintestinal complications of salmonellosis include endocarditis, arteritis, central nervous system, lung, bone, joints, muscle/soft tissue, splenic, and genitourinary.

Chronic Carriers

The chronic carrier state, defined as positive stool or urine cultures for more than 12 months, develops in 1% to 4% of adults with typhoid fever. Persistence of the organism, in many cases, is due to billiary tract carriage, and the frequency of chronic carriage is higher in persons with biliary abnormalities.

Salmonella and HIV Infection

Salmonella is more likely to cause severe invasive infection in the HIV-infected population. Recurrent nontyphoidal *Salmonella* bacteremia is an AIDS-defining illness.

TABLE 73–3. Antimicrobial Indications for Nontyphoidal Salmonellosis

Less than or equal to 3 months, greater than or equal to 65 years of age
Fever and systemic toxicity
AIDS and other immunodeficiencies (including steroid use or organ transplantation)
Uremia or hemodialysis or renal transplant
Malignancy
Sickle cell anemia or hemoglobinopathy
Inflammatory bowel disease
Aortic aneurysm, prosthetic heart valve, vascular or orthopedic prosthesis

daily) for 10 to 14 days. A third-generation cephalosporin and azithromycin (1000 mg once on day 1 followed by 5 days of 500 mg daily) are alternative agents for *S. typhi* strains, with minimum inhibitory concentration (MIC) values for ciprofloxacin of 2 mcg/mL or greater.[12]

Patients with complicated typhoid fever (i.e., metastatic foci, ileal perforation, etc.) should receive parenteral therapy with ciprofloxacin 400 mg twice daily or ceftriaxone 2000 mg once daily. Antimicrobial therapy can be completed with an oral agent after initial control of the symptoms of typhoid fever. In persons with AIDS and a first episode of *Salmonella* bacteremia, a longer duration of antibiotic therapy (1–2 weeks of parenteral therapy followed by 4 weeks of oral fluoroquinolone) is recommended to prevent relapse of bacteremia.

Three typhoid vaccines are available currently for use in the United States: (1) an oral live-attenuated vaccine (Vivotif Berna-TM vaccine, Swiss Serum and Vaccine Institute), (2) a parenteral heat-phenol-inactivated vaccine (Typhoid Vaccine, Wyeth-Ayerst), and (3) a parenteral capsular polysaccharide vaccine (Typhim Vi, Pasteur Merieux). Immunization is recommended only for travelers going to endemic areas such as Latin America, Asia, and Africa; household contacts of a chronic carrier; and laboratory personnel who frequently work with *S. typhi*.[13]

Chronic Carriers

In patients with normal gallbladder function, effective agents for eradication of chronic carriage include amoxicillin (3 g divided three times a day in adults for 3 months), trimethoprim-sulfamethoxazole (one double-strength tablet twice a day for 3 months), and ciprofloxacin (750 mg twice daily for 4 weeks). In patients with anatomic abnormalities, such as biliary or kidney stones, surgery combined with antibiotic therapy is indicated.

Campylobacteriosis

Epidemiology

Campylobacter jejuni is the most commonly identified bacterial cause of diarrhea worldwide. The organism accounts for 2.1 to 2.4 million cases of illness in the United States each year. Risk factors for *Campylobacter* infection include consumption of chicken, sausage, red meat, and contaminated water; foreign travel; receipt of an antimicrobial agent; household exposure to chickens; and contact with pets (especially birds and cats). Between 25% and 50% of *C. jejuni* infections in the United States appear to be related to chicken exposure or consumption.

The age and sex distributions of *Campylobacter* infections are unique among bacterial enteric pathogens. In developed countries, there are two age peaks: younger than 1 year of age and 15 to 44 years of age. There is a mild male predominance among infected persons. The reason for this distinct age and sex distribution remains unknown. The epidemiology of *Campylobacter* infections is quite different in developing countries; *Campylobacter* diarrhea is primarily a pediatric disease in developing countries.

Pathogenesis

Campylobacter spp. are gram-negative bacilli that have a curved or spiral shape. *Campylobacter* are sensitive to stomach acidity; as a result, diseases or medications that buffer gastric acidity may increase the risk of infection. Data suggest that the infectious dose for *C. jejuni* is similar to that for *Salmonella* spp. After an incubation period, infection is established in the jejunum, ileum, colon, and rectum.

Clinical Presentation and Diagnosis

- Incubation period of 1 to 7 days
- Abdominal cramps, fever, and diarrhea
- Dysentery is seen in approximately 50% of cases.
- Diarrhea is either loose and watery or grossly bloody.
- Some patients present mainly with abdominal cramps and pain and minimal diarrhea.
- Fecal leukocytes and red blood cells (RBCs) are detected in the stools of 75% of infected individuals. Diagnosis of *Campylobacter* is established by stool culture.
- Extraintestinal *C. jejuni* infection, including septic arthritis, cholecystitis, pancreatitis, meningitis, endocarditis, osteomyelitis, and neonatal sepsis, can present in three different ways:
  - Transient bacteremia with acute *Campylobacter* enteritis in a normal host with benign course
  - Sustained bacteremia or deep focus of infection in a previously normal host that responds to antimicrobial therapy
  - Sustained bacteremia or deep infection in a compromised host
- The most important postinfectious complication of *C. jejuni* is Guillain-Barré syndrome (GBS). The risk of developing GBS is very small (less than one case of GBS per 1000 *C. jejuni*). GBS typically occurs 1 to 3 weeks after diarrhea.

Treatment and Monitoring

Hydration and electrolyte balance, often with ORT, are the cornerstone of treatment. The specific circumstances that antibiotics should be considered include high fevers, bloody stools, symptoms longer than 1 week, pregnancy, infection with HIV, and other immunocompromised hosts.

Until a few years ago, fluoroquinolones were the drug of choice for campylobacteriosis. However, a major problem among *Campylobacter* strains is growing resistance, occurring worldwide. Fluoroquinolone resistance in human isolates of *C. jejuni* in the United States occurs at a rate of 18%, and resistance levels in Barcelona and Thailand are over 80%. Fluoroquinolones should not be used unless susceptibility is confirmed.

Erythromycin is considered the optimal drug for treatment of *Campylobacter* infections. The rate of resistance of *Campylobacter* to erythromycin remains low. Other advantages of this drug include ease of administration, low cost, lack of major toxicity, and narrow spectrum of activity.[14] The recommended dosage for adults is 250 mg orally four times daily or 500 mg orally twice daily for 5 to 7 days. For very ill patients, treatment with gentamicin, imipenem, cefotaxime, or chloramphenicol is indicated, but susceptibility tests should be performed.

Enterohemorrhagic *Escherichia coli* (EHEC)

Epidemiology

EHEC are the pathogenic subgroup of Stx-producing *E. coli* (STEC). Acute hemorrhagic colitis has been associated mainly with the O157:H7 serotype. This serotype has been responsible for larger outbreaks of infection, has higher rates of complications, and appears to be more pathogenic than non-EHEC STEC strains. ❷ *The spectrum of disease associated with E. coli O157:H7 includes bloody diarrhea, which is seen in as many as 95% of patients, nonbloody diarrhea, hemolytic-uremic syndrome (HUS), and thrombotic thrombocytopenic purpura.*

Approximately 70,000 cases of EHEC illness occur each year in the United States. The highest incidence is in patients aged 5 to 9 years and 50 to 59 years. Outbreaks of diarrhea due to O157:H7 *E. coli* and other STECs have occurred from contaminated beef, classically hamburgers served at fast-food chains, raw milk and other dairy products, vegetables (e.g., alfalfa sprouts, coleslaw, and lettuce), and apple juice. The most important reservoir for *E. coli* O157:H7 is the gastrointestinal tract of cattle. Person-to-person transmission is also possible because of the low infectious dose. Swimming in infant pools or contaminated lakes or drinking municipal water also appears to be a risk factor. The incidence of diagnosed *E. coli* O157:H7 infections in the United States is greater among rural than urban populations, and *E coli* O157:H7 infections occur in summer and autumn.

Pathogenesis

The infectious dose of EHEC is very low, between 1 and 100 colony-forming units (CFUs).[15] The two major virulence factors for EHEC are the production two Shigalike cytotoxins (Stx I and II) and adhesion-causing attachment-effacement (A/E) lesions. These Stx cytotoxins are responsible for vascular damage and systemic effects such as HUS. Adhesion mediates initial attachment of EHEC to intestinal epithelial cells. Following attachment, these organisms produce A/E lesions on individual intestinal epithelial cells. A/E lesions infect the small or large intestine and cause diarrhea.

Clinical Presentation and Diagnosis

- Incubation period of 3 to 5 days
- Bloody stools
- Fever usually absent
- Leukocytosis
- Abdominal tenderness
- HUS in 2% to 10% of patients (especially children 1–5 years of age and the elderly in nursing homes). Develops on average 1 week after the onset of diarrhea.
- EHEC belonging to serotype 0157:H7 characteristically do not ferment sorbitol, whereas more than 70% of intestinal floral *E. coli* do. To properly screen EHEC strains in cases of diarrhea, stool should be placed on special sorbitol-MacConkey agar. Colonies of *E. coli* 0157:H7, which do not ferment the sorbitol, can be identified readily and confirmed by serotyping with specific antisera. In addition, stool should be tested directly for the presence of Stx I and II by enzyme immunoassay (EIA).

Treatment and Monitoring

The only current treatment of EHEC infection is supportive, including fluid and electrolyte replacement, often in the form of ORT. Most illnesses resolve in 5 to 7 days. Patients should be monitored for the development of HUS. Antibiotics are currently contraindicated because they can induce the expression and release of toxin. Antimotility agents should be avoided because they may delay clearance of the pathogen and toxin. This, in turn, may increase the risk of systemic complications.

Proper cooking of foods is essential. Supervision of hand washing by children in day-care centers and exclusion of symptomatic children may reduce person-to-person spread.

Cholera

Epidemiology

Cholera, the first reportable disease, is endemic in South Asia, particularly in the Ganges delta region.[2] The biotypes of *Vibrio cholerae* responsible for pandemics are serogroup O1 (El Tor) and serogroup O139.[16,17] Cholera can be transmitted by water or by food contaminated with contaminated water, particularly undercooked seafood. *V. cholerae* grows well in warm temperatures, causing marked seasonality in the incidence of cholera.[2]

People of blood type O are more susceptible to El Tor vibrios than people of other blood types.[18] Inoculum size affects the likelihood and severity of cholera infection. The infectious dose is lower in patients who are taking antacids owing to the neutralization of gastric acid.[19]

Pathogenesis

V. cholerae is a gram-negative bacillus. Vibrios pass through the stomach to colonize the upper small intestine. Vibrios have filamentous protein extensions that attach to receptors on the intestinal mucosa, and their motility assists with penetration of the mucus layer.[2] The cholera enterotoxin consists of two subunits, one of which (subunit A) is transported into the cells and causes an increase in cyclic AMP, which leads to a deluge of fluid into the small intestine.[20] This large volume of fluid results in the watery diarrhea that is characteristic of cholera. The stools are an electrolyte-rich isotonic fluid, the loss of which results in blood volume depletion followed by low blood pressure and shock.[2] Of note, the diarrheal fluid is highly infectious.

Treatment and Monitoring

The cornerstone of cholera treatment is fluid replacement. Without treatment, the case-fatality rate for severe cholera is approximately 50%. For cholera, rice-based ORT is better than glucose-based ORT because it reduces the number of stools.[21] Patients with significant disease should receive a short antibiotic course, 1 to 3 days, to shorten the duration of illness and decrease the number of stools. Doxycycline 300 mg once daily is the drug of choice. Other antibiotics shown to be effective include erythromycin, azithromycin, trimethoprim-sulfamethoxazole, and ciprofloxacin.[2] Antibiotic resistance has been documented in *V. cholerae* since 1977.[2] Antibiotic prophylaxis is not warranted.

The main prevention strategies include ensuring a safe water supply and safe food preparation, improving sanitation, and patient education. Several oral vaccines are in development, and two are available in countries outside the United States.[22–27] However, these vaccines do not provide protection against all cases of cholera because the immunity may be overcome by high inocula.[2]

Clinical Presentation and Diagnosis[2]

- Incubation period of 18 hours to 5 days
- Abrupt onset of watery diarrhea and vomiting
- Large volumes of rice-water stools
- Dehydration, may be severe. Patients suffering from severe dehydration owing to rapid fluid loss are at risk for death within several hours of disease onset.
- Severe muscle cramps in extremities owing to the electrolyte imbalance caused by the fluid loss. These cramps should resolve with treatment.
- Metabolic acidosis

Travelers' Diarrhea

Epidemiology

Travelers' diarrhea occurs commonly when visitors from developed countries travel to developing countries. Over 50 million people are at risk for travelers' diarrhea each year.[28] Travelers' diarrhea can occur following the consumption of food or water contaminated with bacteria, viruses, or parasites. ❸ *Bacteria such as Shigella, Salmonella, Campylobacter, and E. coli are responsible for 60% to 85% of the travelers' diarrhea cases.*[28] *Noroviruses are being recognized increasingly as a significant cause of travelers' diarrhea as well.*[29]

Risky foods include tap water; uncooked foods, including seafood, fruits, and vegetables; and foods that are stored inadequately, particularly buffet-style meals. Additionally, alcohol consumption of more than five drinks per day has been demonstrated to be a risk factor, especially in males.[30] Education about the types of foods to avoid during travel can be an effective method of prevention.

Pathogenesis

Refer to the specific microorganism sections of this chapter for pathogenesis information.

Treatment and Monitoring

The goal of treatment is to maintain hydration and functional status to prevent disruption of travel plans. For travelers with mild cases of diarrhea, ORT is often all that is needed. However, antibiotics are very effective at reducing the duration of illness. The use of trimethoprim-sulfamethoxazole has fallen out of favor because of the development of resistance in many regions. In general, fluoroquinolones, specifically levofloxacin (500 mg once daily) and ciprofloxacin (500 mg twice daily), are the drugs of choice for travelers' diarrhea. A 24-hour regimen can be used unless the traveler has a fever or bloody stools, in which case a 3-day regimen is necessary.[28] Alternatives to fluoroquinolones should be used in Asia, where resistance is high among *Campylobacter*. Azithromycin, as a single 1000-mg dose, represents an alternative to the fluoroquinolone class.[28] Additionally, the Food and Drug Administration (FDA) recently approved rifaximin for the treatment of travelers' diarrhea at a dose of 200 mg three times daily for 3 days. Rifaximin is not effective against *C. jejuni,* and efficacy has not been documented against *Salmonella* or *Shigella*.

Clinical Presentation and Diagnosis

- Frequent, loose stools
- Associated with nausea and vomiting
- Abdominal pain
- Fecal urgency
- Dysentery
- Signs and symptoms related to specific causative pathogen

Although antimotility agents are effective at shortening the duration of illness, they do not eradicate microorganisms and should not be used in moderate to severe cases with systemic symptoms unless in combination with an antibiotic. The combination of an antimotility agent and an antibiotic can reduce the duration of illness to a few hours.[28]

❹ *Education of travelers about high-risk food items is the key to the prevention of travelers' diarrhea.* Slogans such as "Peel it, boil it, cook it, or forget it" can help to remind travelers of the foods that may be contaminated. Prophylaxis of travelers' diarrhea with antibiotics is effective but should be restricted to individuals who have a repeated history of travelers' diarrhea; cannot afford to make travel alterations (e.g., business trip, competitors, or politicians); have a predisposing factor for travelers' diarrhea, such as achlorhydria, gastrectomy, or inflammatory bowel disease; or are immunosuppressed.[28] The use of antibiotics for prophylaxis is not widely recommended because of the selective pressure for the development of resistance, adverse effects, effect on the normal flora of the gastrointestinal tract, and cost. The fluoroquinolones are used when prophylaxis is necessary. However, rifaximin may represent an ideal option for prophylaxis of travelers' diarrhea, with virtually no systemic absorption and an excellent safety profile, although it is not approved by the FDA for this indication. Bismuth subsalicylate 525 mg one to four times daily is also effective for travelers' diarrhea prophylaxis. No effective vaccines exist for travelers' diarrhea.

Clostridium difficile–Associated Diarrhea (CDAD)

Epidemiology

C. difficile is the leading cause of nosocomial enteric infection. *C. difficile* toxins can be found in the stool of 15% to 25% of patients with antibiotic-associated diarrhea (AAD) and more than 95% of patients with pseudomembranous colitis.[31] More than 90% of health care–associated CDAD occurs after or during antimicrobial therapy. ❺ *Clindamycin, cephalosporins, and penicillins are the antibiotics most associated with CDAD, but almost all antimicrobial agents except aminoglycosides have been associated with CDAD.*[32] Recent studies have shown fluoroquinolones to be strongly associated with CDAD.[33,34] Other risk factors for CDAD include increasing age, severe underlying disease, nonsurgical GI procedures, presence of a nasogastric tube, receipt of antiulcer medications, stay on an intensive-care unit, long duration of hospital stay, long duration of antibiotic, and receiving multiple antibiotics.[35]

The incidence of community-associated *C. difficile* infection (defined as occurring in patients not hospitalized in the year prior to diagnosis) is increasing.[36] In addition to antibiotic use, community-associated *C. difficile* cases are associated with the use of gastric acid suppressive agents (e.g., proton pump inhibitors and H_2-receptor antagonists).

C. difficile is spread by the fecal-oral route, and patient-to-patient transmission has been documented.

Pathogenesis

C. difficile is a gram-positive, spore-forming anaerobe. The organism is ingested either as the vegetative form or spores, which can survive for long periods in the environment and

Clinical Presentation and Diagnosis

- Symptoms can start as early as the first day of antimicrobial therapy or several weeks after antibiotic therapy is completed.
- Asymptomatic carriage
- Diarrhea
  - Acute watery diarrhea with lower abdominal pain, low-grade fever, and mild or absent leukocytosis
  - Mild, with only three or four loose watery stools per day
  - *C. difficile* toxins are present in stool, but sigmoidoscopic examination is normal.
- Colitis
  - Profuse, watery diarrhea with 5 to 15 bowel movements per day, abdominal pain, abdominal distention, nausea, and anorexia
  - Left or right lower quadrant abdominal pain and cramps that are relieved by passage of diarrhea
  - Dehydration and low-grade fever
  - Sigmoidoscopic examination may reveal a nonspecific diffuse or patchy erythematous colitis without pseudomembranes.
- Pseudomembranous colitis: Same symptoms as colitis, but sigmoidoscopic examination reveals a characteristic membrane with adherent yellow or off-white plaques, usually in distal colon.
- Toxic megacolon: Suggested by acute dilatation of the colon to a diameter greater than 6 cm, associated systemic toxicity, and the absence of mechanical obstruction. It carries a high mortality rate.
- Fulminant colitis: Acute abdomen and systemic symptoms such as fever, tachycardia, dehydration, and hypotension. Some patients have marked leukocytosis (up to 40,000 white blood cells/mm^3). Diarrhea is usually prominent but may not occur in patients with paralytic ileus and toxic megacolon.
- Relapsing colitis
  - Risk factors include increased age, recent abdominal surgery, increased number of *C. difficile* diarrheal episodes, and leukocytosis.
  - 12% to 24% of patients develop a second episode of CDAD within 2 months of the initial diagnosis.
- In most instances, *C. difficile* toxin testing of a single stool specimen effectively establishes the diagnosis. Various ELISA kits are available to detect toxin A or toxin B or both. Those that detect both toxin A and B are preferred. Repeated testing can boost sensitivity.
- Leukocytosis, hypoalbuminemia, and fecal leukocytes are nonspecific but suggestive of *C. difficile* infection.
- In selected patients, sigmoidoscopy, colonoscopy, or abdominal computed tomographic (CT) scan can provide useful diagnostic information.

can transverse the acidic stomach. In the small intestine, spores germinate into the vegetative form. In the large intestine, CDAD can develop if the normal flora is disrupted by antibiotic therapy. Toxin production is essential for disease to occur. The main virulence factor for disease related to *C. difficile* is the production of toxins A and B. These toxins are responsible for inflammation, fluid and mucus secretion, and mucosal damage, which lead to diarrhea or colitis.

Treatment and Monitoring

Stopping the inciting antibiotic is the most important step in the initial treatment of CDAD.[37] If stopping antibiotic therapy is not effective or not practical, antimicrobial therapy directed specifically against *C. difficile* should be given for 10 days. Oral metronidazole (500 mg three times daily or 250 mg four times daily) and oral vancomycin (125 mg four times daily) have similar rates of efficacy, but metronidazole is considered the drug of choice for most cases because of cost and concerns regarding the emergence of vancomycin-resistant enterococcus (VRE).

Severe disease is defined as the presence of complications of colitis, such as sepsis, volume depletion, electrolyte imbalance, hypotension, paralytic ileus, and toxic megacolon. Patients with signs of severe disease should receive oral vancomycin as initial therapy. Surgical intervention may be indicated and lifesaving, particularly in cases complicated by toxic megacolon or colonic perforation.

In circumstances where oral therapy cannot be given, intravenous metronidazole (500 mg every 6–8 hours), vancomycin retention enemas (500 mg every 4–8 hours), or vancomycin via colonic catheter should be considered.[38] Antiperistaltic agents should not be given because the use of these agents is associated with the development of toxic megacolon.

Therapeutic response should be based on clinical signs and symptoms. A repeat toxin assay as a "test of cure" is not recommended because some patients may remain colonized with this organism following recovery. Treatment of asymptomatic colonized patients is not recommended as an infection-control measurement.

Relapse is suggested by the returning of symptoms 3 to 21 days after stopping metronidazole or vancomycin. Since antibiotic resistance is not a factor in relapse, most relapses usually respond to another course of either metronidazole or vancomycin.

Vigilant hand washing and isolation precautions are keys to controlling *C. difficile*.

PARASITIC INFECTIONS

Please refer to Chapter 75 for information regarding giardiasis.

Cryptosporidiosis

Epidemiology

Cryptosporidiosis has been recognized as a human disease since the 1970s, with increasing importance in the 1980s and 1990s because of its relationship with HIV/AIDS. *Cryptosporidium* accounts for 2.2% and 6.1% of diarrhea cases in immunocompetent people in developed and developing countries, respectively.[3] These percentages increase to 7% and 12% in children in developed and developing countries, respectively, and to 14% and 24% in immunocompromised persons in developed and developing countries, respectively.[3]

Infection is spread person to person, usually via the fecal-oral route; by animals, particularly cattle and sheep; and through the environment, especially water. People at increased risk of contracting cryptosporidiosis include household and family contacts and sexual partners of someone with the disease, health care workers, day-are workers, users of public swimming areas, and people traveling to regions of high endemicity.[3]

Pathogenesis

Cryptosporidium is an intracellular protozoan parasite that is capable of completing its entire life cycle within one host. Humans become infected on ingestion of the oocysts, and autoinfection and persistent infections are possible owing to repeated life cycles within the GI tract.[3] As few as 10 to 100 oocysts can cause infection.[3]

Treatment and Monitoring

There is no antimicrobial available that is effective at consistently eradicating *Cryptosporidium*, particularly in immunocompromised hosts. In general, immunocompetent persons

Clinical Presentation and Diagnosis[3,4]

General

- 7- to 10-day incubation period
- Profuse, watery diarrhea with mucus but not blood or leukocytes that lasts for approximately 2 weeks
- Nausea, vomiting, and abdominal cramps often accompany the diarrhea.
- Fever may be present.
- Simplest method of diagnosis is detection of oocysts by modified acid-fast staining of a stool specimen. Standard ova and parasite test does not include *Cryptosporidium*.

Immunocompetent

- May manifest as asymptomatic disease, acute diarrhea, or persistent diarrhea lasting for several weeks
- Usually self-limiting

Immunocompromised

- May manifest as asymptomatic disease; transient infection for less than 2 months; chronic diarrhea lasting at least 2 months, or fulminant infection, with at least 2 L of watery stool per day
- Asymptomatic disease more common in those with a CD4+ cell count greater than 200 cells/mm^3, and fulminant infection more common in those with a CD4+ cell count of less than 50 cells/mm^3

and those with asymptomatic infection do not require antimicrobial therapy. In patients with HIV/AIDS, the optimal therapy is restoration of immune function through the use of antiretroviral therapy (ART). In persons in whom antimicrobial therapy is deemed necessary or in HIV/AIDS patients in whom ART is ineffective, a combination of an antimicrobial and an antidiarrheal agent is recommended.[3]

Azithromycin and clarithromycin have shown some success for cryptosporidiosis, even in HIV-positive patients.[4] However, the most promising agent is nitazoxanide, which was approved recently by the FDA for the treatment of cryptosporidiosis in children. In randomized, placebo-controlled trials, nitazoxanide has demonstrated efficacy in cryptosporidiosis in immunocompetent persons, malnourished children, and HIV/AIDS patients with CD4+ cell counts above 50 cells/mm^3.[39] Limited evidence suggests that patients with CD4+ cell counts of less than 50 cells/mm^3 may benefit from higher doses, longer durations, or both.[39]

Prevention of cryptosporidiosis can prove difficult because the oocysts are resilient to many disinfectants and antiseptics, including ammonia, alcohol, and chlorine.[3] Therefore, most traditional water-treatment methods, including filtration, do not eradicate all oocysts, which is problematic in the face of the small infective dose of *Cryptosporidium*. Routine screening of drinking water should be considered for water-treatment plants, and severely immunocompromised individuals should be advised to avoid water in lakes and streams and contact with young animals.[3] For these persons, drinking water should be brought to a boil and cooled before ingestion.

VIRAL GASTROENTERITIS

❻ *Viruses are the most common cause of diarrheal illness in the world, resulting in about 450,000 and 160,000 hospitalizations for adults and children, respectively, and over 4000 deaths.*[40,41] A number of viruses may cause gastroenteritis, including rotaviruses, noroviruses, astroviruses, enteric adenoviruses, and coronoviruses (Table 73–4). This chapter will focus on rotaviruses.

Clinical Presentation and Diagnosis[1]

- Incubation period of 2 days
- 2- to 3-day **prodrome** of fever and vomiting
- Profuse diarrhea without blood or leukocytes (up to 10–20 stools per day)
- Severe dehydration
- Anorexia
- Fever may be present.
- Presentation in adults may vary from asymptomatic to nonspecific symptoms of headache, malaise, and chills to severe diarrhea, nausea, and vomiting.
- Diagnosis can be made by PCR of the stool.

Rotavirus

Epidemiology

Rotavirus causes between 600,000 and 875,000 deaths each year, with the highest rates in the very young and in developing countries.[1] Rotavirus is the leading cause of childhood **gastroenteritis** and death worldwide. Most infections occur in children between 6 months and 2 years old, typically during the winter season, but adults may be infected as well. Rotavirus causes over 2 million hospitalizations and 600,000 deaths per year in children younger than 5 years of age.[42] Person-to-person transmission occurs through the fecal-oral route.

Pathogenesis

The mechanism of diarrhea has not been clearly elucidated, but theories include a reduction in the absorptive surface along with impaired absorption owing to cellular damage, enterotoxigenic effects of a rotavirus protein, and stimulation of the enteric nervous system.[43]

Treatment and Monitoring

The cornerstone of rotavirus treatment is supportive care and rehydration with ORT or intravenous fluids if necessary. Antimotility and antisecretory agents should not be used

TABLE 73–4. Agents Responsible for Acute Viral Gastroenteritis and Diarrhea

Virus	Peak Age	Peak Time	Duration	Transmission	Symptoms
Rotavirus	6 mo–2 yr	Winter	3–8 days	Fecal-oral, water, food	Diarrhea, vomiting, fever, abdominal pain
Enteric adenovirus	less than 2 yr	Year-round	7–9 days	Fecal-oral	Diarrhea, respiratory symptoms, vomiting, fever
Astrovirus	less than 7 yr	Winter	1–4 days	Fecal-oral, water, shellfish	Vomiting, diarrhea, fever, abdominal pain
Noroviruses	greater than 5 yr	Variable	12–24 hours	fecal-oral, food, aerosol	Nausea, vomiting, diarrhea, abdominal cramps, headache, fever, chills, myalgia

Modified from Martin S, Jung R. Gastrointestinal infections and enterotoxigenic poisonings. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach.* 6th ed. New York: McGraw-Hill; 2005:2049.

Patient Care and Monitoring

1. Observe the patient for signs and symptoms of dehydration, and rehydrate as necessary (see Tables 73–1 and 73–2).
2. Monitor for increase in stool consistency and decrease in stool frequency.
3. If pharmacologic agents are used, monitor for any adverse effects.
4. Evaluate the patient for any complications or effects specific to the afflicting pathogen.

owing to their potential side effects in children and the self-limited nature of the disease. ❻ *A new live oral rotavirus vaccine was approved recently by the FDA for use in infants aged 6 weeks to 32 weeks and provides protection against rotavirus infection for at least 24 months.*[44] The CDC Advisory Committee on Immunization Practices recommends vaccination at 2, 4, and 6 months.

FOOD POISONING

Each year in the United States, approximately 76 million foodborne illnesses occur, leading to 325,000 hospitalizations and over 5000 deaths.[40] A number of bacterial and viral pathogens that have been discussed previously in this chapter (e.g., *Salmonella*, *Shigella*, *Campylobacter*, *E. coli*, and noroviruses) can cause food poisoning. Other bacteria that can cause foodborne illness include *Staphylococcus aureus*, *C. perfringens*, *C. botulinum*, and *Bacillus cereus* (Table 73–5). Food poisoning should be suspected if at least two individuals present with similar symptoms after the ingestion of a common food in the prior 72 hours.

Patient Encounter 1

A 70-year-old man presents to the emergency department because of diffuse abdominal pain and nonbloody diarrhea. One day earlier he had been discharged from the hospital, where he had received ceftriaxone and levofloxacin for 7 days for an upper respiratory infection. Soon after going home, he passed numerous liquid brown stools. A few hours later, the patient became disoriented, and an ambulance was called. His medical history is unremarkable. Laboratory values: White blood cell count 50,000 cells/mm^3, hematocrit 43%, sodium 125 mmol/L, potassium 5.6 mmol/L, CO_2 14 mmol/L, and metabolic acidosis. An abdominal radiograph series show no evidence of obstruction. The patient was admitted to the hospital.

What GI disease do you suspect based on this information? From your suspicion, what diagnostic tests and treatment would you recommend for this patient?

In the hospital, he receives fluids and metronidazole 500 mg every 8 hours intravenously. Stool was sent for *C. difficile* toxin assay, which came back positive. The patient continues to have abdominal pain but no bowel movement. On day 3 of hospitalization, his abdomen is distended with diffuse pain. His white blood cell count remains elevated. A CT scan of the abdomen showed colonic dilatation to greater than 6 cm. The patient became febrile and hypotensive, requiring multiple pharmacologic support for hypotension.

- What are this patient's risk factors for CDAD?
- What do these new findings suggest?
- How does this progression change your treatment recommendations?

TABLE 73–5. Food Poisonings

Organism	Onset (hour)	Associated Foods	Duration	Symptoms	Treatment
Staphylococcus aureus	1–6	Salad, pastries, ham, poultry	12 hour	Nausea, vomiting	Supportive
Bacillus cereus—emetic	0.5–6	Rice, noodles, pasta, pastries	24 hour	Vomiting	Supportive
Bacillus cereus—diarrheal	8–16	Meats, vegetables, soups, sauces, milk products	24 hour	Diarrhea, abdominal pain	Supportive
Clostridium perfringens (type A)	8–12	Meats, poultry	24 hour	Nausea, abdominal cramps, profuse, watery diarrhea	Supportive
Clostridium botulinum	18–24	Canned fruits, vegetables, meats, honey, salsa, relish	Weeks	Acute GI symptoms followed by symmetric, descending, flaccid paralysis; death is possible	Supportive (including mechanical ventilation); trivalent antitoxin

Patient Encounter 2

A 45-year-old Hispanic man with AIDS presents to the emergency department with fever, nausea, two episodes of vomiting, abdominal pain, and nonbloody diarrhea for 2 days. He reports that his diarrhea is improving, but he developed fever and chills a few hours before he came to the emergency room. Other history is noncontributory. His physical examination is positive for fever and diffuse abdominal pain. An abdominal ultrasound did not show any abnormal findings. Two sets of blood cultures were sent. He was admitted to the hospital.

1. What GI pathogen(s) do you suspect in this patient?
2. His blood cultures came back positive for nontyphoidal *Salmonella*.
3. What treatment do you recommend? Do any further tests need to be performed before you can decide on your treatment recommendation? Are there any special considerations owing to this patient's HIV infection?

OUTCOME EVALUATION

Patients with GI infections should be evaluated for resolution of GI symptoms, as well as any related systemic signs and symptoms. If antimicrobial therapy was used, completion of the course of therapy should be assessed. Documented clearance of the offending microorganism is not necessary.

ABBREVIATIONS

AAD: antibiotic-associated diarrhea

74 Intraabdominal Infections

Joseph T. DiPiro and Thomas R. Howdieshell

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Define and differentiate between primary and secondary intraabdominal infections.
2. Describe the microbiology typically seen with primary and secondary intraabdominal infections.
3. Describe the clinical presentation typically seen with primary and secondary intraabdominal infections.
4. Describe the role of culture and susceptibility information for diagnosis and treatment of intraabdominal infections.
5. Recommend the most appropriate drug and nondrug measures to treat intraabdominal infections.
6. Recommend an appropriate antimicrobial regimen for treatment of a primary and a secondary intrabdominal infection.
7. Describe the patient-assessment process during the treatment of intraabdominal infections.

Key Concepts

❶ Most intraabdominal infections are "secondary" infections that are caused by a defect in the gastrointestinal tract that must be treated by surgical drainage, resection, and/or repair.

❷ Primary peritonitis generally is caused by a single organism (*Staphylococcus aureus* in patients undergoing continuous ambulatory peritoneal dialysis (CAPD) and *Escherichia coli* in patients with cirrhosis).

❸ Secondary intraabdominal infections usually are caused by a mixture of enteric gram-negative bacilli and anaerobes. This mix of organisms enhances the pathogenic potential of the bacteria.

❹ For peritonitis, early and aggressive intravenous fluid resuscitation and electrolyte replacement therapy are essential. A common cause of early death is hypovolemic shock caused by inadequate intravascular volume expansion and tissue perfusion.

❺ Cultures of secondary intraabdominal infection sites generally are not useful for directing antimicrobial therapy. Treatment generally is initiated on a "presumptive" or empirical basis.

❻ Antimicrobial regimens for secondary intraabdominal infections should include coverage for enteric gram-negative bacilli and anaerobes. Antimicrobial agents that may be used for treatment of secondary intraabdominal infections include (1) a β-lactam–β-lactamase-inhibitor combination, (2) a carbapenem, and (3) a quinolone plus metronidazole or an aminoglycoside plus clindamycin (or metronidazole).

❼ The duration of antimicrobial treatment should be for a total of 5 to 7 days for most intraabdominal infections.

Intraabdominal infections are those contained within the peritoneal cavity or retroperitoneal space. The peritoneal cavity extends from the undersurface of the diaphragm to the floor of the pelvis and contains the stomach, small bowel, large bowel, liver, gallbladder, and spleen. The duodenum, pancreas, kidneys, adrenal glands, great vessels (aorta and vena cava), and most mesenteric vascular structures reside in the retroperitoneum. Intraabdominal infections may be generalized or localized. They may be contained within visceral structures, such as the liver, gallbladder, spleen, pancreas, kidney, or female reproductive organs. Two general types of intraabdominal infection are discussed throughout this chapter: peritonitis and abscess.

Peritonitis is defined as the acute inflammatory response of the peritoneal lining to microorganisms, chemicals, irradiation, or foreign-body injury. This chapter deals only with peritonitis of infectious origin.

Patient Encounter

A 67-year-old man presents to the emergency room in acute distress with abdominal pain, nausea, and vomiting. The patient was in a reasonably good state of health until yesterday evening when he had a sudden onset of excruciating abdominal pain. During the night, he had a few episodes of vomiting, and the pain did not diminish.

The patient is taking glyburide for non-insulin-dependent diabetes mellitus and has been treated in the past for peptic ulcer disease with ranitidine and omeprazole. He has a history of allergy to various types of pollen but reports no allergies to drugs. He reports moderate consumption of alcohol and smoking 2 packs of cigarettes per day.

- What other information would you like to have about this patient?

An **abscess** is a purulent collection of fluid separated from surrounding tissue by a wall consisting of inflammatory cells and adjacent organs. It usually contains necrotic debris, bacteria, and inflammatory cells. Peritonitis and abscess differ considerably in presentation and approach to treatment.

EPIDEMIOLOGY AND ETIOLOGY

Peritonitis may be classified as primary, secondary, or tertiary. Primary peritonitis, also called *spontaneous bacterial peritonitis,* is an infection of the peritoneal cavity without an evident source of bacteria from the abdomen.[1,2] In secondary peritonitis, a focal disease process is evident within the abdomen. Secondary peritonitis may involve perforation of the gastrointestinal (GI) tract (possibly because of ulceration, ischemia, or obstruction), postoperative peritonitis, or posttraumatic peritonitis (e.g., blunt or penetrating trauma). Tertiary peritonitis occurs in critically ill patients and is infection that persists or recurs at least 48 hours after apparently adequate management of primary or secondary peritonitis.

❶ *Primary peritonitis develops in up to 25% of patients with alcoholic cirrhosis.*[3] *Patients undergoing continuous ambulatory peritoneal dialysis (CAPD) average one episode of peritonitis every 2 years.*[4] *Secondary peritonitis may be caused by perforation of a peptic ulcer; traumatic perforation of the stomach, small or large bowel, uterus, or urinary bladder; appendicitis; pancreatitis; diverticulitis; bowel infarction; inflammatory bowel disease; cholecystitis; operative contamination of the peritoneum; or diseases of the female genital tract such as septic abortion, postoperative uterine infection, endometritis, or salpingitis. Appendicitis is one of the most common causes of intraabdominal infection. In 1998, 278,000 appendectomies were performed in the United States for suspected appendicitis.*[5]

Primary peritonitis in adults occurs most commonly in association with alcoholic cirrhosis, especially in its end stage, or with ascites caused by postnecrotic cirrhosis, chronic active hepatitis, acute viral hepatitis, congestive heart failure, malignancy, systemic lupus erythematosus, and nephrotic syndrome. It also may result from the use of a peritoneal catheter for dialysis with renal failure or central nervous system (CNS) ventriculoperitoneal shunting for hydrocephalus. Abscesses are the result of chronic inflammation and may occur without preceding generalized peritonitis. They may be located within the peritoneal cavity or in a visceral organ and may vary in size, taking a few weeks to years to form.

The causes of intraabdominal abscess overlap those of peritonitis and, in fact, may occur sequentially or simultaneously. Appendicitis is the most frequent cause of abscess.

PATHOPHYSIOLOGY

Intraabdominal infection results from bacterial entry into the peritoneal or retroperitoneal spaces or from bacterial collections within intraabdominal organs. In primary peritonitis, bacteria may enter the abdomen via the bloodstream or the lymphatic system by transmigration through the bowel wall, through an indwelling peritoneal dialysis catheter, or via the fallopian tubes in females. Hematogenous bacterial spread (through the bloodstream) occurs more frequently with tuberculosis peritonitis or peritonitis associated with cirrhotic ascites. When peritonitis results from peritoneal dialysis, skin-surface flora are introduced via the peritoneal catheter.[7] In secondary peritonitis, bacteria most often enter the peritoneum or retroperitoneum as a result of perforation of the GI or female genital tracts caused by diseases or traumatic injuries.

If bacteria that enter the abdomen are not handled by cellular and humoral defense mechanisms, bacterial dissemination occurs throughout the peritoneal cavity, resulting in peritonitis. This is more likely to occur in the presence of a foreign body, hematoma, necrotic tissue, large bacterial inoculum, continuing bacterial contamination, and contamination involving a mixture of synergistic organisms.

The fluid and protein shift into the abdomen (called *third-spacing*) may be so dramatic that circulating blood volume is decreased, which causes decreased cardiac output and hypovolemic shock. Accompanying fever, vomiting, or diarrhea may worsen the fluid imbalance. A reflex sympathetic response, manifested by sweating, tachycardia, and vasoconstriction, may be evident. With an inflamed peritoneum, bacteria and endotoxins are absorbed easily into the bloodstream (translocation), and this may result in septic shock. Other foreign substances present in the peritoneal cavity potentiate peritonitis, notably feces, dead tissues, barium, mucus, bile, and blood.

Many of the manifestations of intraabdominal infections, particularly peritonitis, result from cytokine activity. Inflammatory cytokines are produced by macrophages and neutrophils in

response to bacteria and bacterial products or to tissue injury resulting from the surgical incision.[8] These cytokines produce wide-ranging effects on the endothelium of organs, particularly the liver, lungs, kidneys, and heart. With uncontrolled activation of these mediators, sepsis may result.[9] Peritonitis may result in death because of the effects on major organ systems.

An abscess occurs if peritoneal contamination is localized but bacterial elimination is incomplete. The location of the abscess often is related to the site of primary disease. For example, abscesses resulting from appendicitis tend to appear in the right lower quadrant or the pelvis; those resulting from diverticulitis tend to appear in the left lower quadrant or pelvis. A mature abscess may have a fibrinous capsule that isolates bacteria and the liquid core from antimicrobials and immunologic defenses.

Microbiology of Intraabdominal Infection

❷ *Primary bacterial peritonitis is often caused by a single organism. In children, the pathogen is usually Streptococcus pneumoniae or a group A Streptococcus.*[4] *When peritonitis occurs in association with cirrhotic ascites, Escherichia coli is isolated most frequently. Other potential pathogens are Hemophilus pneumoniae, Klebsiella, Pseudomonas, anaerobes, and S. pneumoniae.*[10] *Occasionally, primary peritonitis may be caused by Mycobacterium tuberculosis. Peritonitis in patients undergoing peritoneal dialysis is caused most often by common skin organisms such as S. epidermidis, Staphylococcus aureus, streptococci, and diphtheroids.* Occasionally, aerobic gram-negative bacilli may cause infections, particularly in patients undergoing dialysis during hospitalization. Death from primary peritonitis caused by gram-negative bacteria occurs much more frequently than from gram-positive bacteria.[11]

❸ *Because of the diverse bacteria present in the GI tract, secondary intraabdominal infections are often polymicrobial.*[12] *The mean number of different bacterial species isolated from infected intraabdominal sites ranged from 2.9 to 3.7, including an average of 1.3 to 1.6 aerobes and 1.7 to 2.1 anaerobes.*[13,14]

Bacterial Synergism

A combination of aerobic and anaerobic organisms appears to increase the severity of infection. ❸ *Facultative bacteria (such as E. coli) may provide an environment conducive to the growth of anaerobic bacteria.*[12] *Although many bacteria isolated in mixed infections are nonpathogenic by themselves, their presence may be essential for the pathogenicity of the bacterial mixture.*[3] Facultative bacteria in mixed infections can:

- Promote an appropriate environment for anaerobic growth through oxygen consumption
- Produce nutrients necessary for anaerobes
- Produce extracellular enzymes that promote tissue invasion by anaerobes

Bacteria such as *E. coli* appear responsible for the early mortality from peritonitis, whereas anaerobic bacteria are major pathogens in abscesses, with *B. fragilis* predominating.[15] *Enterococcus* can be isolated from many intraabdominal infections in humans, but its role as a pathogen is not clear.[16]

CLINICAL PRESENTATION AND DIAGNOSIS

Intraabdominal infections have a wide spectrum of clinical features. Peritonitis usually is easily recognized, but intraabdominal abscess often may continue for long periods of time. Patients with primary and secondary peritonitis present quite differently.

TREATMENT

Desired Outcomes

The primary goals of treatment are correction of the intraabdominal disease processes or injuries that have caused infection and drainage of collections of purulent material (abscess). A secondary objective is to resolve the infection without major organ system complications (e.g., pulmonary, hepatic, cardiovascular, or renal failure) or adverse drug effects. Ideally, the patient should be discharged from the hospital with full function for self-care and routine daily activities.

Clinical Presentation of Primary Peritonitis

General
Patients may not be in acute distress, particularly with peritoneal dialysis.

Symptoms
Patient may complain of nausea, vomiting (sometimes with diarrhea), and abdominal tenderness.

Signs
- Temperature may be only mildly elevated or not elevated in patients undergoing peritoneal dialysis.
- Bowel sounds are hypoactive
- Cirrhotic patients may have worsening encephalopathy.
- There may be cloudy dialysate fluid with peritoneal dialysis.

Laboratory Tests
- The white blood cell (WBC) count may be only mildly elevated.
- Ascitic fluid usually contains greater than 300 leukocytes/mm^3, and bacteria may be evident on Gram stain of a centrifuged specimen.

Other Diagnostic Tests
Culture of peritoneal dialysate or ascitic fluid should be positive.

Clinical Presentation of Secondary Peritonitis

General
Patients may be in acute distress.

Symptoms
- Patients may complain of nausea, vomiting, and generalized abdominal pain.
- Patients may demonstrate abdominal guarding and a "boardlike abdomen."

Signs
- Tachypnea and tachycardia are present.
- Temperature is normal initially, then may increase to 100 to 102°F (37.7–38.8°C) within the first few hours, and may continue to rise for the next several hours.
- Hypotension and shock may develop if intravascular volume is not restored.
- Decreased urine output may develop owing to dehydration.
- Bowel sounds are faint initially and eventually cease.

Laboratory Tests
- The WBC count is high (15,000–20,000 WBCs/mm^3), with neutrophils predominating and an elevated percentage of immature neutrophils (bands).
- The hematocrit and blood urea nitrogen increase because of dehydration.
- Hyperventilation and vomiting result in early alkalosis, which changes to acidosis and lactic acidemia.

Other Diagnostic Tests
Abdominal radiographs may be useful because free air in the abdomen (indicating intestinal perforation) or distension of the small or large bowel is often evident.

Patient Encounter, Part 2: Physical Examination and Diagnostic Tests

PE
The patient is found responsive but in acute distress. He is lying on the examination table with knees drawn up to his chest. There is involuntary abdominal guarding with a rigid abdomen. There are no audible bowel sounds. He is alert and oriented × 3. Neurologic function is intact. Mucous membranes are dry. Stool is heme-negative.

VS: Temp 38.3°C, BP 105/70 mm Hg, P 132, wt 82 kg, (180 lbs) Ht 170 cm, RR 24/minute.

Labs
Hct 46% (0.46 volume fraction), Hgb 15.4 g/dL, WBC count 15,200/mm^3 (45% neutrophils, 20% bands)

Serum: Glucose 213 mg/dL (11.8 mmol/L), serum creatinine 1.9 mg/dL (168 µmol/L), BUN 42 g/dL, Na 138 mEq/L (138 mmol/L), K 3.7 mEq/L (3.7 mmol/L), Cl 101 mEq/L (101 mmol/L), CO_2 21 mEq/L (21 mmol/L), calcium 9.8 mg/dL (2.45 mmol/L), magnesium 2.0 mEq/L (0.822 mmol/L), total bilirubin 0.4 mg/dL (6.84 µmol/L), albumin 4.2 g/dL (42 g/L), lactic acid 3.2 mEq/L

KUB: An upright abdominal x-ray shows dilated loops of small bowel and free air under the diaphragm.

DPL (Diagnostic Peritoneal Lavage: Examination of Fluid in Peritoneal Cavity): No blood is found, but WBCs are evident.

- What is your assessment of the patient's condition?
- Develop a care plan for this patient for the first 7 days of his hospitalization. This plan should include the goals of therapy, specific drug recommendations, and monitoring parameters to evaluate outcome.

General Approach to Treatment

The treatment of intraabdominal infection most often requires the coordinated use of three major modalities: (1) prompt drainage, (2) support of vital functions, and (3) appropriate antimicrobial therapy to treat infection not eradicated by surgery. Antimicrobials are an important adjunct to drainage procedures in the treatment of secondary intraabdominal infections; however, the use of antimicrobial agents without surgical intervention usually is inadequate. For most cases of primary peritonitis, drainage procedures may not be required, and antimicrobial agents become the mainstay of therapy.

In the early phase of serious intraabdominal infections, attention should be given to preserving major organ system function. ❹ *With generalized peritonitis, large volumes of intravenous (IV) fluids are required to maintain intravascular volume, to improve cardiovascular function, and to ensure adequate tissue perfusion and oxygenation. Adequate urine output should be maintained to ensure appropriate fluid resuscitation and to preserve renal function. A common cause of early death is hypovolemic shock caused by inadequate intravascular volume expansion and tissue perfusion.*

An additional important component of therapy is nutrition. Intraabdominal infections often involve the GI tract directly or disrupt its function (paralytic ileus). The return of GI motility may take days, weeks, and occasionally, months. In the interim, enteral or parenteral nutrition as indicated facilitates improved immune function and wound healing to ensure recovery.

Nonpharmacologic Therapy

Drainage Procedures
Primary peritonitis is treated with antimicrobials and rarely requires drainage. Secondary peritonitis requires surgical removal of the inflamed or gangrenous tissue to prevent further bacterial contamination. If the surgical procedure is suboptimal, attempts are made to provide drainage of the infected or gangrenous structures.

The drainage of purulent material is the critical component of management of an intraabdominal abscess. This may be performed surgically or with percutaneous image-guided techniques.[17,18] Without adequate drainage of the abscess, antimicrobial therapy and fluid resuscitation can be expected to fail. The most valuable microbiologic information may be obtained at the time of percutaneous or operative abscess drainage.

Fluid Therapy

In patients with peritonitis, hypovolemia is often accompanied by acidosis, so large volumes of a solution such as lactated Ringers may be required initially to restore intravascular volume. Maintenance fluids should be instituted (after intravascular volume is restored) with 0.9% sodium chloride and potassium chloride (20 mEq/L) or 5% dextrose and 0.45% sodium chloride with potassium chloride (20 mEq/L). The administration rate should be based on estimated daily fluid loss through urine and nasogastric suction, including 0.5 to 1.0 L for insensible fluid loss. Potassium would not be included routinely if the patient is hyperkalemic or has renal insufficiency. Aggressive fluid therapy often must be continued in the postoperative period because fluid will continue to sequester in the peritoneal cavity, bowel wall, and lumen.

Pharmacologic Therapy

Antimicrobial Therapy

The goals of antimicrobial therapy are

- To control bacteremia and prevent the establishment of metastatic foci of infection
- To reduce suppurative complications after bacterial contamination
- To prevent local spread of existing infection

After suppuration has occurred (e.g., an abscess has formed), a cure by antibiotic therapy alone is difficult to achieve; antimicrobials may serve to improve the results with surgery.

❺ *An empirical antimicrobial regimen should be started as soon as the presence of intraabdominal infection is suspected and before identification of the infecting organisms is complete. Therapy must be initiated based on the likely pathogens, which vary depending on the site of intraabdominal infection and the underlying disease process. Cultures of secondary intraabdominal infection sites generally are not useful for directing antimicrobial therapy.* Table 74–1 lists the likely pathogens against which antimicrobial agents should be directed.

Antimicrobial Experience

Many studies have been conducted evaluating or comparing the effectiveness of antimicrobials for treatment of intraabdominal infections. Substantial differences in patient outcomes from treatment with a variety of agents generally have not been demonstrated.

Important findings from the last 20 years of clinical trials regarding selection of antimicrobials for intraabdominal infections are

- Antimicrobial regimens for secondary intraabdominal infections should cover a broad spectrum of aerobic and anaerobic bacteria from the GI tract.
- Single-agent regimens (such as antianaerobic cephalosporins, extended-spectrum penicillins with β-lactamase inhibitors, or carbapenems) are as effective as combinations of aminoglycosides or fluoroquinolones with antianaerobic agents. This is also true for antimicrobial treatment of acute bacterial contamination from penetrating abdominal trauma.[19,20]
- Clindamycin and metronidazole appear to be equivalent in efficacy when combined with agents effective against aerobic gram-negative bacilli (e.g., gentamicin or aztreonam).
- For most patients, antimicrobial treatment can be completed orally with amoxicillin-clavulanate or the combination of ciprofloxacin and metronidazole.
- Five to seven days of antimicrobial treatment are sufficient for most intraabdominal infections of mild to moderate severity.

TABLE 74–1. Likely Intraabdominal Pathogens

Type of Infection	Aerobes	Anaerobes
Primary Bacterial Peritonitis		
Children (spontaneous)	Pneumococci, group A *Streptococcus*	—
Cirrhosis	*E. coli, Klebsiella,* pneumococci (many others)	—
Peritoneal dialysis	*Staphylococcus, Streptococcus*	—
Secondary Bacterial Peritonitis		
Gastroduodenal	*Streptococcus, E. coli*	—
Biliary tract	*E. coli, Klebsiella,* enterococci	*Clostridium* or *Bacteroides* (infrequent)
Small or large bowel	*E. coli, Klebsiella* spp., *Proteus* spp.	*Bacteroides fragilis* and other *Bacteroides*; *Clostridium.*
Appendicitis	*E. coli, Pseudomonas*	*Bacteroides* spp.
Abscesses	*E. coli, Klebsiella,* enterococci	*B. fragilis* and other *Bacteroides, Clostridium,* anaerobic cocci
Liver	*E. coli, Klebsiella,* enterococci staphylococci, amoeba	*Bacteroides* (infrequent)
Spleen	*Staphylococcus, Streptococcus*	

From DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005:Table 112–5.

Intraabdominal infection presents in many different ways and with a wide spectrum of severity. The antibiotic regimen employed and duration of treatment depend on the specific clinical circumstances (i.e., the nature of the underlying disease process and the condition of the patient).

Recommendations

❻ *For most intraabdominal infections, the antimicrobial regimen should be effective against both aerobic and anaerobic bacteria.*[21] Although it is impossible to provide antimicrobial activity against every possible pathogen, agents with activity against enteric gram-negative bacilli, such as *E. coli* and *Klebsiella,* and anaerobes, such as *B. fragilis* and *Clostridia* spp., should be administered.

Table 74–2 presents the recommended agents for treatment of community-acquired and complicated intraabdominal infections from the Infectious Diseases Society of America and the Surgical Infection Society.[21–23] *These recommendations were formulated using an evidence-based approach.* Most community-acquired infections are "mild to moderate," whereas health care–associated infections tend to be more severe and difficult to treat. Table 74–3 presents guidelines for treatment and alternative regimens for specific situations. These are general guidelines; there are many factors that cannot be incorporated into such a table.

When used for intraabdominal infection, aminoglycosides should be combined with agents that are effective against the majority of *B. fragilis.* Clindamycin or metronidazole is the agent of first choice, but others, such as antianaerobic cephalosporins (e.g., cefoxitin, cefotetan, or ceftizoxime), piperacillin, mezlocillin, and combinations of extended-spectrum penicillins with β-lactamase inhibitors, would be suitable alternatives. Patients receiving multiple broad-spectrum antimicrobial agents who are immunocompromised should receive an oral antifungal agent (nystatin) for prevention of fungal overgrowth in the mouth and GI tract. The benefits of systemic antifungal prophylaxis (with fluconazole) have not been established for intraabdominal infection and should not be used routinely.

TABLE 74–2. Recommended Agents for the Treatment of Community-Acquired Complicated Intraabdominal Infections

Agents Recommended for Mild to Moderate Infections	Agents Recommended for High-Severity Infections
β-Lactam/β-Lactamase Inhibitor Combinations	
Ampicillin-sulbactam Ticarcillin-clavulanate	Piperacillin-tazobactam
Carbapenems	
Ertapenem	Imipenem/cilistatin Meropenem
Combination Regimens	
Cefazolin or cefuroxime plus metronidazole	Third- or fourth-generation cephalosporins (cefotaxime, ceftriaxone, ceftizoxime, ceftazidime, cefepime) plus metronidazole
Ciprofloxacin, levofloxacin moxifloxacin, or gatifloxacin, in combination with metronidazole	Ciprofloxacin, in Combinaion with metronidazole
	Aztreonam plus metronidazole

From DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: Table 112–6.[21–23]

In immunocompromised patients or patients with valvular heart disease or a prosthetic heart valve, there is justification to provide specific antimicrobial activity against enterococci. Ampicillin or other penicillins that are active against enterococci (e.g., penicillin, piperacillin, and mezlocillin) should be used in patients at high risk, patients with persistent or recurrent intraabdominal infection, or patients who are immunosuppressed, such as after organ transplantation. Ampicillin remains the drug of choice for this indication because it is most active in vitro against enterococci and is relatively inexpensive. Vancomycin is active against most enterococci; however, resistance is increasing, and this agent should be reserved for established infections when first-line therapies cannot be used.

Intraperitoneal (IP) administration of antibiotics is preferred over IV therapy in the treatment of peritonitis that occurs in patients undergoing continuous ambulatory peritoneal dialysis (CAPD). The International Society of Peritoneal Dialysis (ISPD) recently revised its guidelines for the diagnosis and pharmacotherapy of peritoneal dialysis (PD)–associated infections.[24] The guidelines provide dosing recommendations for intermittent and continuous therapy based on the modality of dialysis [CAPD or automated peritoneal dialysis (APD)] and the extent of the patient's residual renal function.

Antimicrobial agents effective against both gram-positive and gram-negative organisms should be used for initial IP empirical therapy for peritonitis in PD patients. The most important factors to take into consideration for initial antimicrobial selection are the dialysis center's and the patient's history of infecting organisms and their sensitivities. The use of cefazolin [loading dose (LD) 500 mg/L, maintenance dose (MD) 125 mg/L] plus ceftazidime (LD 500 mg/L, MD 125 mg/L) or cefepime (LD 500 mg/L, MD 125 mg/L) or an aminoglycoside (gentamicin-tobramycin LD 8 mg/L, MD 4 mg/L) is suitable for initial empirical therapy; if patients are allergic to cephalosporin antibiotics, vancomycin (LD 1000 mg/L, MD 25 mg/L) or an aminoglycoside should be substituted. Another option is monotherapy with imipenem-cilastin (LD 500 mg/L, MD 200 mg/L) or cefepime. Antimicrobial doses should be increased empirically by 25% in patients with residual renal function (more than 100 mL/day urine output).[24] Antimicrobial therapy should be continued for at least 1 week after the dialysate fluid is clear and for a total of at least 14 days. The reader is referred to these guidelines for additional information.[27]

After acute bacterial contamination, such as with abdominal trauma where GI contents spill into the peritoneum, combination antimicrobial regimens are not required. If the patient is seen soon after injury (within 2 hours) and surgical measures are instituted promptly, antianaerobic cephalosporins

TABLE 74–3. Guidelines for Initial Antimicrobial Agents for Intraabdominal Infections

	Primary Agents	Alternatives
Primary Bacterial Peritonitis		
Cirrhosis	Cefotaxime	1. Add clindamycin or metronidazole if anaerobes are suspected 2. Other third-generation cephalosporins, extended-spectrum penicillins, aztreonam, and imipenem as alternatives 3. Aminoglycoside with antipseudomonal penicillin
Peritoneal dialysis	Regimen based on organism isolated 1. Staphylococcus: penicillinase-resistant penicillin or first-generation cephalosporin 2. *Streptococcus:* penicillin G 3. Aerobic gram-negative bacilli: cefotaxime, ceftazidime, or aminoglycoside plus an antipseudomonal penicillin 4. *Pseudomonas aeruginosa:* aminoglycoside plus antipseudomonal penicillin or ceftazidime	1. Alternative for resistant staphylococci is vancomycin 2. Alternative for Streptococcus is a first-generation cephalosporin 3. Alternatives for gram-negative bacilli are other third-generation cephalosporins, aztreonam, and extended-spectrum penicillins with *β-lactamase inhibitors*
Secondary Bacterial Peritonitis		
Perforated peptic ulcer	First-generation cephalosporins	1. Antianaerobic cephalosporins[a] 2. Possibly add aminoglycoside if patient condition is poor 3. Aminoglycoside with clindamycin or metronidazole; add ampicillin if patient is immunocompromised or if biliary tract origin of infection
Other	Imipenem/cilistatin, meropenem, ertapenem, or extended-spectrum penicillins with β-lactamase inhibitor	1. Ciprofloxacin with metronidazole 2. Aztreonam with clindamycin or metronidazole 3. Antianaerobic cephalosporins.[a]
Abscess		
General	Imipenem/cilastatin, meropenem, ertapenem, or extended-spectrum penicillins with β-lactamase inhibitor	1. Aztreonam with clindamycin or metronidazole 2. Ciprofloxacin with metronidazole 3. Aminoglycoside with clindamycin or metronidazole;
Liver	As above but add a first-generation cephalosporin	Use metronidazole if amoebic liver abscess is suspected
Spleen	Aminoglycoside plus penicillinase-resistant penicillin	Alternatives for penicillinase-resistant penicillin are first-generation cephalosporins or vancomycin
Appendicitis		
Normal or inflamed	Antianaerobic cephalosporins[a] (discontinued immediately postoperation)	1. Ampicillin-sulbactam
Gangrenous or perforated	Imipenem/cilastatin, meropenem, ertapenem, antianaerobic cephalosporins or extended-spectrum penicillins with β-lactamase inhibitor	1. Aztreonam with clindamycin or metronidazole 2. Ciprofloxacin with metronidazole 3. Aminoglycoside with clindamycin or metronidazole
Acute Cholecystitis	First-generation cephalosporin	Aminoglycoside plus ampicillin if severe infection
Cholangitis	Aminoglycoside with ampicillin with or without clindamycin or metronidazole	Use vancomycin instead of ampicillin if patient is allergic to penicillin
Acute Contamination from Abdominal Trauma	Antianaerobic cephalosporins[a] or ampicillin-sulbactam	1. A carbapenem 2. Ciprofloxacin plus metronidazole
Pelvic Inflammatory Disease	Cefotetan or cefoxitin with doxycycline	1. Clindamycin with gentamicin 2. Ampicillin-sulbactam with doxycycline 3. Ciprofloxacin with doxycycline and metronidazole

[a]Cefoxitin, cefotetan, and ceftizoxime.
From DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005:Table 112–7.

(such as cefoxitin or cefotetan) or extended-spectrum penicillins are effective in preventing most infectious complications. Antimicrobials should be administered as soon as possible after injury.

For appendicitis, the antimicrobial regimen used should depend on the appearance of the appendix at the time of operation, which may be normal, inflamed, gangrenous, or perforated. Because the condition of the appendix is unknown preoperatively, it is advisable to begin antimicrobial agents before the appendectomy is performed. Reasonable regimens would be antianaerobic cephalosporins or, if the patient is seriously ill, a carbapenem or β-lactam–β-lactamase-inhibitor combination.

If, at operation, the appendix were normal or inflamed, postoperative antimicrobials would not be required. If the appendix is gangrenous or perforated, a treatment course of 5 to 7 days with the agents listed in Table 74–2 is appropriate.

❼ *Acute intraabdominal contamination, such as after a traumatic injury, may be treated with a very short course (24 hours) of antimicrobials.*[25] *For established infections (i.e., peritonitis or intraabdominal abscess), an antimicrobial course limited to 5 to 7 days is justified.* Under certain conditions, therapy for longer than 7 days would be justified, e.g., if the patient remains febrile or is in poor general condition, when relatively resistant bacteria are isolated, or when a focus of infection in the abdomen still may be present. For some abscesses, such as pyogenic liver abscess, antimicrobials may be required for a month or longer.

OUTCOME EVALUATION

Whether diagnosed with primary or secondary peritonitis, monitor the patient for relief of symptoms. Once antimicrobials are initiated and the other important therapies described earlier are used, most patients should show improvement within 2 to 3 days. Successful antimicrobial therapy with resolution of infection will result in decreased pain, manifested as resolution of abdominal guarding and decreased use of pain medications over time. The patient should not appear in distress, with the exception of recognized discomfort and pain from incisions, drains, and a nasogastric tube.

Monitor vital signs and WBC count with differential; each should normalize as the infection resolves. At 24 to 48 hours, aerobic bacterial culture results should be available. If a suspected pathogen is not sensitive to the antimicrobial agents being given, the regimen should be changed if the patient has not shown sufficient improvement. If the isolated pathogen is extremely sensitive to one antimicrobial and the patient is progressing well, concurrent antimicrobial therapy often may be discontinued.

With anaerobic culturing techniques and the slow growth of these organisms, anaerobes often are not identified until 4 to 7 days after culture, and sensitivity information is difficult to obtain. For this reason, anaerobic culture information generally is not helpful for selection of the antianaerobic component of the antimicrobial regimen. A report indicating that anaerobes were not isolated should not be the sole justification for discontinuing antianaerobic drugs because anaerobic bacteria that were present in the infectious process may not have been transported properly to the microbiology laboratory, or other problems may have led to bacterial death in vitro.

Once the temperature is normal for 48 to 72 hours and the patient is eating, consider changing the IV antibiotic to an oral regimen for the duration of antibiotic treatment. Monitor the serum creatinine level to evaluate for renal complications as well as potential drug toxicity, especially if an aminoglycoside is a component of the antibiotic regimen. Bowel sounds should return to normal. Evaluate the patient daily for development of rash or other drug-related adverse effects.

For patients with primary peritonitis, if peritoneal dialysate cultures were positive initially, repeat cultures should be negative. For patients with secondary peritonitis, monitor the amount of fluid draining if a drain was placed. The volume of drainage should lessen as the infection resolves. Repeat abdominal radiographs should return to normal.

If symptoms do not improve, the patient should be evaluated for persistent infection. There are many reasons for poor patient outcome with intraabdominal infection; improper antimicrobial selection is only one. The patient may be immunocompromised, which decreases the likelihood of successful outcome with any regimen. It is impossible for antimicrobials to compensate for a nonfunctioning immune system. There may be surgical reasons for poor patient outcome. Failure to identify all intraabdominal foci of infection or leaks from a GI anastomosis may cause continued intraabdominal infection. Even when intraabdominal infection is controlled, accompanying organ system failure, most often renal or respiratory, may lead to patient demise.

The outcome from intraabdominal infection is not determined solely by what transpires in the abdomen. Unsatisfactory outcomes in patients with intraabdominal infections may result from complications that arise in other organ systems. A complication commonly associated with mortality after intraabdominal infection is pneumonia.[26] A high APACHE (Acute Physiology And Chronic Health Evaluation) II score, a low serum albumin, and a high New York Heart Association cardiac function status were significantly and independently associated with increased mortality from intraabdominal infection.[27]

Reasons for antimicrobial failure may not always be apparent. Even when antimicrobial susceptibility tests indicate that an organism is susceptible in vitro to the antimicrobial agent, therapeutic failures may occur. Possibly there is poor penetration of the antimicrobial agent into the focus of infection, or bacterial resistance may develop after initiation of antimicrobial therapy. Also, it is possible that an antimicrobial regimen may encourage the development of infection by organisms not susceptible to the regimen being used. Superinfection in patients being treated for intraabdominal infection can be caused by *Candida;* however, enterococci or opportunistic gram-negative bacilli such as *Pseudomonas* and *Serratia* may be involved.

Treatment regimens for intraabdominal infection can be judged as successful if the patient recovers from the infection without recurrent peritonitis or intraabdominal abscess and without the need for additional antimicrobials. A regimen can be considered unsuccessful if a significant adverse drug reaction occurs, reoperation or percutaneous drainage is necessary, or patient improvement is delayed beyond 1 or 2 weeks.

Patient Care and Monitoring

1. A thorough patient medication history should be taken at the time of admission to document all recent medication use, including nonprescription medications and use of complementary or alternative medicines. Any drug allergies or intolerances also should be documented.
2. The initial antimicrobial regimen should conform to standard guidelines unless an appropriate justification for an alternative regimen is evident. With the first few doses of antimicrobial, assess the patient for hypersensitivity reactions or other acute intolerances.
3. Review the dosages of all medications to be sure that they are appropriate for age, weight, and major organ function. Verifiy that the drugs selected are not contraindicated in the patient with allergies or other intolerances.
4. Confirm that all necessary acute and chronic medications are continued postoperatively.
5. Monitor vital signs (i.e., temperature and heart rate) and laboratory assessments (i.e., WBC count) daily to assess resolution of infection and efficacy of pain medications. When possible, interview the patient to obtain additional information about pain control.
6. Evaluate fluid status to ensure that the patient is not hypovolemic. In a seriously ill patient, assess intravascular volume by monitoring blood pressure and heart rate, but do so more accurately by measuring central venous pressure or urinary output via a urinary bladder catheter. Urine output should equal or exceed 0.5 mL/kg of body weight per hour.
7. Review results of cultures obtained preoperatively or during the surgical procedure. Evaluate the appropriateness of antibiotic therapy based on susceptibility information. Although some investigators suggest that routine culturing of patients with community-acquired intraabdominal infections contributes little to their management,[28] other investigators suggest that antimicrobial therapy should be based on susceptibility of the bacteria collected from the operative site because this has been shown to correlate with clinical outcome.[29]
8. Assess serum creatinine and aminoglycoside serum concentrations if the patient is being treated with an aminoglycoside. Adjust aminoglycoside dose based on serum concentrations; target peak concentration with multiple doses per day = 6 mcg/mL (12.54 µmol/L).
9. On the fifth day of antimicrobial treatment, determine if parenteral antimicrobial agents can be switched to oral agents to complete therapy.
10. Assess nutritional needs and recommend appropriate supplementation. When the patient is tolerating an oral diet, determine if any parenteral medications can be switched to the oral route.
11. Monitor the patient for the development of potential complications of treatment such as delayed hypersensitivity reactions, antibiotic-induced diarrhea, pseudomembraneous colitis, or fungal superinfections (manifested as oral thrush).
12. Provide information to the patient concerning the medications administered in the hospital as well as any new medications prescribed for use at home. Advise the patient to contact his or her doctor or pharmacist if he or she experience any adverse effects from medications.

75 Parasitic Diseases

J.V. Anandan

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Identify the primary reasons why some parasitic diseases may be more prevalent in the United States population.
2. Describe the treatment algorithm for giardiasis and amebiasis.
3. List one effective therapy for nematodes and select the drugs of choice for strongyloidiasis and tapeworms.
4. List three major reasons why travelers are infected with malaria.
5. Describe the presenting signs and symptoms of malaria.
6. List some specific toxicities of mefloquine.
7. Identify the monitoring parameters for quinidine gluconate in severe malaria.
8. Define the major complications of falciparum malaria.
9. Discuss the cardiovascular complications of chronic South American trypanosomiasis.
10. Describe the steps to take to eradicate lice infestation and scabies.

Key Concepts

❶ For treatment of giardiasis (or as empirical treatment), metronidazole 250 mg three times daily for 7 days or tinidazole 2 g as a single dose is recommended.

❷ Diagnostic tests for amebiasis include stool for ova, antigen detection, or polymerase chain reaction (PCR) testing.

❸ The drug of choice for nematode infestations (hookworm, enterobiasis, and ascariasis) is mebendazole, while ivermectin is indicated for strongyloidiasis and praziquantel is indicated for tapeworms.

❹ The primary reasons why travelers are infected with malaria are failure to take chemotherapy, inappropriate chemotherapy, and delay in seeking medical care.

❺ Falciparum malaria must be considered a life-threatening medical emergency.

❻ Treatment of serious malarial infection requires admission to an acute care service, intravenous administration of quinidine gluconate, and symptomatic support.

❼ Complications of falciparum malaria include hypoglycemia, acute renal failure, pulmonary edema, seizure, and coma.

❽ The chronic presentation of American trypanosomiasis includes cardiovascular, gastrointestinal, and central nervous system manifestations.

❾ Lice infestation should be treated with 1% permethrin followed by treatment of immediate family members and sexual partners. Bedding and clothes should be sterilized by washing in the hot cycle of the washing machine.

❿ The diagnosis of scabies is made by obtaining skin scrapings and detecting the mite in a wet mount. Topical therapy is 5% permethrin.

Parasitic medicine is an ever changing field. The increased desire of large segments of the United States population to travel to Asia, Africa, and other parts of the world can expose them to parasitic infections that are endemic in those areas. The influx of refugees and new immigrant populations from Asia and other parts of the world have brought new parasitic infections to our shores. Migrant farm workers who work and live in substandard hygienic conditions, the large and growing Central and South American immigrant population, and the presence of immunosuppressed populations (e.g.,

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

those with the acquired immunodeficiency syndrome [AIDS] and transplant patients) represent other significant sources of parasitic infections in the United States. Clearly, there is a need for health professionals in the United States to be familiar with the pathophysiology and treatment of parasitic diseases.

Defined below are some terms that are frequently used when discussing parasitic diseases. *Symbiosis* is defined as "living together," when two species are dependent on each other for food and protection. The term *commensalism,* from the Latin translation of "eating at the same table," implies a mutual association in which both organisms may benefit, or at least one benefits but does no harm to the other. In contrast, *parasitism*, although resembling symbiosis in one aspect (i.e., it is also an intimate relationship between two species), does not represent a mutually beneficial association. One species (the host) does not benefit from the relationship, and in fact the relationship may be detrimental to its very survival. Parasites have made morphologic, biochemical, reproductive, and defensive adaptations over time. These adaptations have increased the ability of parasites to survive host defenses and have allowed them to utilize the host's biochemical systems to synthesize necessary cellular components. Beef and pork tapeworms (cestodes) possess highly developed reproductive systems which allow them to transfer easily to new hosts. Because of the lack of digestive systems cestodes are completely host-dependent for all nutrients. Cestodes (tapeworms) (*Taenia saginata* and *T. solium*) use specialized suckers which enable them to obtain blood and vital nutrients from their host. *Entamoeba histolytica*, the causative agent for amebiasis, once it has gained access to the human colon or large intestine is able to invade and utilize its specialized proteolytic enzyme to penetrate and erode the gastrointestinal mucosa. *E. histolytica* is also able to survive in adverse conditions when it leaves the host by walling itself off and forming **cysts**; this protects the parasite from environmental conditions until it is ready to infect the next host.

Although acquired immunity to some parasitic diseases may lower the level of infection, absolute immunity as seen in bacterial and viral infections is seldom seen in parasitic diseases. Since parasitic infections produce a wide variety of antigens because of the many life cycle phases, it is more difficult to identify a constant antigenic protein against which specific antibodies are protective. However, malaria remains a likely candidate for a vaccine and there are ongoing studies to develop one.

Space constraints do not allow detailed discussions of the world of parasites, and clinicians and students are directed to some excellent resources for further details on parasites and parasitic diseases.[1,2] Discussion in this chapter will include those parasitic diseases that are more likely to be seen in the United States and will include gastrointestinal parasites (primarily giardiasis and amebiasis), protozoan infections (malaria and South American trypanosomiasis), some common helminthic diseases (specifically those caused by nematodes and cestodes), and ectoparasites (lice and scabies).

GIARDIASIS

Epidemiology and Etiology

Giardia lamblia (also known as *G. intestinalis* or *G. duodenalis*), an enteric protozoan, is the most common intestinal parasite responsible for diarrheal syndromes throughout the world. Giardia is the most frequently identified intestinal parasites in the United States, with a prevalence rate of 5% to 15% in some areas. *G. lamblia* has been identified as the first enteric pathogen seen in children in developing countries, with prevalence rates between 15% and 30%.

There are two stages in the life cycle of *G. lamblia*: the **trophozoite** and the cyst. *G. lamblia* is found in the small intestine, the gallbladder, and in biliary drainage. The distribution of giardiasis is worldwide with children being more susceptible than adults.

Pathology

Giardiasis is caused by ingestion of *G. lamblia* cysts in fecally contaminated water or food.[2] The protozoan excysts in the low gastric pH to release the trophozoite. Colonization and multiplication of the trophozoite lead to mucosal invasion, localized edema, and flattening of the villi, resulting in malabsorption states in the host. Achlorhydria, hypogammaglobulinemia, or deficiency in secretory immunoglobulin A (IgA) predispose to giardiasis. Individuals with human immunodeficiency virus (HIV) infection and AIDS may have higher carriage rates than the general population. Some patients may develop lactose intolerance after chronic giardiasis.

Patient Encounter

MK is a 15-year old high school student who had traveled to Mexico as part of a school group to practice his Spanish language skills. While in Mexico, he was careful in not drinking any local water and only consumed warm or heated food and soda. He is seen in the travel clinic with complaints of some "explosive" crampy diarrhea and has had constipation alternating with diarrhea for the last 2 weeks. MK indicates that his stools have been foul-smelling.

- Are his symptoms characteristic of giardiasis?
- How would you differentiate giardiasis from possible *Escherichia coli*–induced diarrhea?

Clinical Presentation and Diagnosis

Clinical Presentation of Giardiasis

Acute Onset
- Diarrhea, cramp-like abdominal pain, bloating, and flatulence
- Malaise, anorexia, nausea, and belching

Chronic Symptoms
- Diarrhea: Foul-smelling, copious, light-colored and fatty stools
- Weight loss, steatorrhea, and vitamin B_{12} and fat-soluble vitamin deficiencies

Diagnosis
- Diagnosis is made by examination of fresh stool or a preserved specimen during acute diarrheal phase
- Fresh stool may show trophozoites while preserved specimens yield cysts. (*Note*: stool for ova may show the presence of other parasites [e.g., *Cryptosporidium parvum*, *E. histolytica*, or *E. hartmanni*]; multiple stool samples may be needed.)
- Even though stool examination for ova and parasites has remained the major means of diagnosis, other diagnostic tests include enzyme-linked immunosorbent assay (ELISA), which is considered to be between 85% to 98% sensitive and almost 100% specific (ProSpec T, Giardia Microplate Assay, Remel, Lenexa, KS).

Pharmacologic Therapy

❶ *All symptomatic adults and children over the age of 8 years should be treated with metronidazole 250 mg three times daily for 7 days, or tinidazole 2 g as a single dose, or nitazoxanide 500 mg twice daily for 3 days.*[3] *The pediatric dose of metronidazole is 15 mg/kg per day three times daily for 7 days. Alternative drugs include furazolidone 100 mg four times daily or paromomycin 25 to 30 mg/kg per day in divided doses daily for 7 days. Paromomycin may be used in pregnancy instead of metronidazole. Pediatric patients can also be treated with suspensions of either furazolidone 8 mg/kg per day in four divided doses for 7 days, or nitazoxanide (Alina) 100 to 200 mg every 12 hours for 3 days.*

Quinacrine 100 mg three times in adults or 5 mg/kg per day in pediatric patients for 5 to 7 days, is available from a specialized pharmacy (e.g., Ponorama Compounding Pharmacy).[3]

Outcome Evaluation

Patients with symptomatic giardiasis and positive stool samples or positive ELISA tests should be treated with metronidazole for 7 days. Patients who fail initial therapy with metronidazole should receive a second course of therapy. Pregnant patients can receive paromomycin 25 to 30 mg/kg per day in divided doses for 7 days. Giardiasis can be prevented by good hygiene and by using caution in food and drink consumption.

Patient Care and Monitoring

- Metronidazole produces cure rates between 85% and 95%.
- Diarrhea will cease within a few days, although in some patients it may take 1 to 2 weeks.
- Cyst excretion will cease within days.
- Intestinal dysfunction (manifested as increased transit time) and radiologic changes primarily due to chronic infection may take months to resolve.
- Patients who fail therapy with metronidazole should receive a second course with either metronidazole or an alternative agent; nitazoxanide has been shown to be effective in resistant giardiasis.

AMEBIASIS

Epidemiology and Etiology

Amebiasis remains one of the most important parasitic diseases because of its worldwide distribution and serious gastrointestinal manifestations. The major causative agent in amebiasis is *Entamoeba histolytica*, which invades the colon and must be differentiated from *E. dispar*, which is associated with an asymptomatic carrier state and is considered nonpathogenic.[4] Invasive amebiasis is almost exclusively the result of ingesting *E. histolytica* cysts found in fecally-contaminated food or water. Approximately 50 million cases of invasive disease result each year worldwide, leading to an excess of 100,000 deaths. In the general population, the highest incidence is found in institutionalized mentally retarded patients, sexually active homosexuals, AIDS patients, the Native American population, and new immigrants from endemic areas (e.g., Mexico, South and Southeast Asia, West and South Africa, and portions of Central and South America).

Pathology

E. histolytica invades mucosal cells of colonic epithelium, producing the classic flask-shaped ulcer in the submucosa. The trophozoite toxin has a cytocidal effect on cells. If the trophozoite gets into the portal circulation, it will be carried to the liver, where it produces abscess and periportal fibrosis. Liver abscesses are more common in men than women and are rarely seen in children. Amebic ulcerations can affect the perineum and genitalia, and abscesses may occur in the lung and brain.

Erosion of liver abscesses can result in peritonitis. Liver abscesses that are located in the right lobe can spread to the lungs and pleura. Pericardial infection, although rare, may be associated with extension of the amebic abscesses from the liver.

Clinical Presentation and Diagnosis

Clinical Presentation of Amebiasis

Review of the patient's history should include: recent travel, type of foods ingested (e.g., salads or unpeeled fruit), the nature of water and fluid consumed, and description of any symptoms of friends or relatives who ate the same food.

Intestinal Disease

- Vague abdominal discomfort
- Symptoms may range from malaise to severe abdominal cramps, flatulence, and nonbloody or bloody diarrhea (heme-positive in 100% of cases) with mucus
- May have low-grade fever, but this may be absent in many patients
- Eosinophilia is usually absent, although mild leukocytosis is not unusual

Note: Fecal screening may show other intestinal parasites, including *Cryptosporidium* spp., *Balantidium coli*, *Dientamoeba fragilis*, *Isospora belli*, *G. lamblia*, or *Blastocystis hominis*.

Amebic Liver Abscess

- May present with high fever with significant leukocytosis with left shift, anemia, elevated alanine aminotransferase, and dull abdominal pain on palpation
- Physical findings: Right upper quadrant pain, hepatomegaly, and liver tenderness, with referred pain to the left or right shoulder (*Note:* Erosion of liver abscesses may present as peritonitis)

❷ Diagnosis

- *Intestinal amebiasis is diagnosed by demonstrating* E. histolytica *cysts or trophozoites (may contain ingested erythrocytes) in fresh stool or from a specimen obtained by sigmoidoscopy.*
- *Microscopy may not differentiate between the pathogenic E. histolytica and the nonpathogenic E. dispar or E. moshkovskii in stools.*
- *Sensitive techniques are available to detect E. histolytica in stool: antigen detection, antibody test (ELISA) and PCR.*
- **Endoscopy** with scrapings or biopsy and stained slides (**iron hematoxylin** or trichrome) may provide more definitive diagnosis of amebiasis.
- Diagnosis for liver abscess includes serology and liver scans (using isotopes by **ultrasound** or **computed tomography**) or **magnetic resonance imaging**; however, none of these are specific for liver abscess. In rare instances, needle aspiration of hepatic abscess may be attempted using ultrasound guidance.

Patient Encounter

WR is a 37-year-old native of India and a permanent resident in the United States who has recently returned from a trip to Calcutta, India where he was visiting a relative. He presents in the emergency department with complaints of a 3-week history of sharp, crampy, and postprandial abdominal pain. The pain is more intense over the right lower quadrant, and associated with watery nonbloody diarrhea and **tenesmus**.

- What specific findings in this patient suggest that he may have giardiasis or amebiasis?
- What other information do you need to confirm a diagnosis of amebiasis?
- What is the major complication of amebiasis?

Pharmacologic Therapy

Metronidazole (Flagyl), dehydroemetine, and chloroquine (Aralen) are tissue-acting agents, and iodoquinol (Yodoxin), diloxanide furoate (Furamide), and paromomycin (Humatin) are luminal amebicides. A systemic or tissue-acting agent may be so well absorbed that the amounts of the drug remaining in the bowel may be insufficient to have luminal or local effects. A luminally-active agent, on the other hand, may not attain effective enough levels in the tissue to be efficacious. Asymptomatic cyst passers (identified by stool examinations, and who may develop invasive disease) and patients with mild intestinal amebiasis should receive a luminal agent: paromomycin 25 to 30 mg/kg per day three times daily for 7 days, or iodoquinol 650 mg three times daily for 20 days, or diloxanide furoate 500 mg three times daily for 10 days. These regimens have cure rates of between 84% and 96%. Diloxanide furoate is available from Ponorama Compounding Pharmacy (6744 Balboa Blvd., Lake Balboa, CA 91406; [800] 247-9767).[3]

The pediatric dose of paromomycin is the same as that used in adults, whereas the pediatric dose of iodoquinol is 30 to 40 mg/kg (maximum: 2 g) per day in three doses for 20 days, and the pediatric dose of diloxanide furoate is 20 mg/kg per day in three doses for 10 days. Paromomycin is the preferred agent in pregnant patients.[3]

Patients with severe intestinal disease or liver abscess should receive metronidazole 750 mg three times daily for 10 days, followed by the luminal agents indicated above. The pediatric dose of metronidazole is 50 mg/kg per day in divided doses, which should be followed by a luminal agent. An alternative regimen of metronidazole is 2.4 g/day for 2 days in combination with the luminal agent. Tinidazole (Tindamax, recently introduced on the United States market) administered in a dose of 2 g daily for 3 days (pediatric dose: 60 mg/kg for 5 days) is an alternative to metronidazole. If there is no prompt response to metronidazole or aspiration of the abscess, an antibiotic regimen should be added. Patients who cannot tolerate oral doses of metronidazole should receive an equivalent dose intravenously.

Patient Care and Monitoring

1. Follow-up in patients with amebiasis should include repeat stools (one to three), colonoscopy (in colitis) or computed tomography (CT, in liver abscess) between days 5 and 7, at the end of the course of therapy, and a month after the end of therapy.
2. Most patients with either intestinal amebiasis or colitis will respond in 3 to 5 days with amelioration of symptoms.
3. Those with liver abscess may take up to 7 days before there will be decreases in pain and fever. In liver abscess, patients not responding by the fifth day may require aspiration of the abscesses or exploratory laparotomy.
4. Serial liver scans have demonstrated that healing of liver abscesses take from 4 to 8 months following adequate therapy.

Preventive Measures

- Travelers and tourists visiting endemic areas should avoid local tap water, ice, salads, and unpeeled fruits. Boiled water is safe.
- Water can be disinfected by the use of iodine 2% (5 drops/L) or chlorine 6% (laundry bleach: 4 drops/L) or use of a commercial water purifier, such as Portable Aqua tablets (Wisconsin Pharmaceutical).

Outcome Evaluation

Follow-up in patients with amebiasis should include repeat stool examinations, serology, colonoscopy (in colitis) or CT on day 7, at the end of therapy, and a month after the end of therapy. Serial liver scans have demonstrated healing of liver abscesses over 4 to 8 months after adequate therapy.

HELMINTHIC DISEASES

Helminthic infections include three groups of organisms: roundworms or nematodes, flukes (trematodes), and tapeworms (cestodes). Because of space constraints, only brief descriptions of some of the helminthic infections most commonly seen in North America and their treatments will be provided here. Although helminthic infections may not produce clinical manifestations, they can cause significant pathology. One factor that determines the pathogenicity of helminthic infections is their population density; a high-density population ("worm burden") results in predictable disease presentation. In the United States, these infections are reported most frequently in recent immigrants from Southeast Asia, the Caribbean, Mexico, and Central America.[5,6] Populations at risk include institutionalized patients (both young and elderly), preschool children in day care centers, residents of Native American reservations, and homosexuals. Certain conditions and drugs (anesthesia and corticosteroids) can cause atypical localization of worms. Immunocompromised hosts can be overwhelmed by some helminthic infections, such as *Strongyloides stercoralis*.

Nematodes

Hookworm Disease

Hookworm infection is caused by *Ancylostoma duodenale* or *Necator americanus*. *N. americanus* is found in the southeastern United States. Infective larvae enter the host in contaminated food or water or penetrate the skin and migrate to the small intestine. The adult worm attaches to gastrointestinal mucosa and causes injury by lytic destruction of the tissue. Over a period of time, the adult worm can cause anemia and hypoproteinemia in the host.

Treatment

❸ *The drug of choice is mebendazole (Vermox), which is also active against ascariasis, enterobiasis, trichuriasis, and hookworm.*[3] The adult and pediatric (age greater than 2 years) oral dose of mebendazole for hookworm is 100 mg twice daily for 3 days. An alternative agent that can be used in both pediatric and adult patients is albendazole (Zentel), 400 mg as a single dose. Diagnosis is by detection of eggs or larvae in stool. Stool examination for eggs and the larvae should be repeated in 2 weeks and the patient retreated if necessary.

Ascariasis

The causative agent in ascariasis is the giant roundworm *Ascaris lumbricoides,* which is found worldwide and is responsible about 4 million infections in the United States (it primarily affects residents of the Appalachian mountain range and the Gulf Coast states). Migration of the worm into the lungs usually produces pneumonitis, fever, cough, eosinophilia, and pulmonary infiltrates. *Ascaris* infection can also cause abdominal discomfort, intestinal obstruction, and appendicitis. Diagnosis is made by detection of the characteristic eggs in the stool or passed worms.

Treatment

In both adults and pediatric patients older than 2 years of age, mebendazole 100 mg twice daily for 3 days is the treatment to use. An alternative agent is pyrantel pamoate (Antiminth). The stool should be checked within 2 weeks and the patient retreated when warranted.

Enterobiasis

Enterobiasis, or pinworm infection, is caused by *Enterobius vermicularis*. It is the most widely distributed helminthic infection in the world. There are approximately 42 million cases in the United States, primarily affecting children. The most common manifestation of the infection is cutaneous irritation

in the perianal region, resulting from the migrating female or the presence of eggs. The intense pruritus may lead to dermatitis and secondary bacterial infections. Diagnosis is made by the use of a perianal swab and cellophane tape sampling, which will aid in egg identification.

Treatment

The three agents that are administered for enterobiasis include pyrantel pamoate, mebendazole, and albendazole. The dose of pyrantel pamoate is 11 mg/kg (maximum: 1 g) as a single dose that can be repeated in 2 weeks. The dose of mebendazole for both adults and children older than 2 years of age is 100 mg as a single dose. This may be repeated in 2 weeks. Following treatment, to eradicate the eggs all bedding and underclothing should be sterilized by steaming or washing in the hot cycle of the washing machine.

Strongyloidiasis

Strongyloidiasis is caused by *Strongyloides stercoralis*, which has a worldwide distribution and is predominantly prevalent in South America (Brazil and Columbia) and in Southeast Asia. Strongyloidiasis is primarily seen among institutionalized populations (those in mental hospitals and children's hospitals) and immunocompromised individuals (those with HIV infection, AIDS, and patients with hematologic malignancies). The worm is usually found in the upper intestine where the eggs are deposited and hatch to form the rhabditiform larvae. The rhabditiform larva (male and female) migrate to the bowel where they may be excreted in the feces. If excreted in the feces, the larva can evolve into either one of two forms after **copulation**: a free-living noninfectious rhabditiform larvae, or an infectious filariform larvae. The filariform larva can penetrate host skin and migrate to the lungs and produce progeny, a process called autoinfection. This can result in hyperinfection (i.e., an increased number of larva in the intestine, lungs, and other internal organs), especially in an immunocompromised host.

Patients with acute infection may develop a localized pruritic rash, but heavy infestations can produce eosinophilia (10 % to 15%), diarrhea, abdominal pain, and intestinal obstruction. Administration of corticosteroids or other immunosuppressive drugs to an infected individual can result in hyperinfections and disseminated strongyloidiasis. Diagnosis of strongyloidiasis is made by identification of the rhabditiform larva in stool, sputum, or duodenal fluid, or from small bowel biopsy specimens or via antigen testing (ELISA essay). Multiple stool and other samples may need to be checked, both for diagnosis and to ensure eradication of the larva in patients after treatment.

Treatment

❸ *The drug of choice for strongyloidiasis is oral ivermectin 200 mcg/kg per day for 2 days, while albendazole 400 mg twice daily is given for 7 days as an alternative.*[3] With hyperinfection or disseminated strongyloidiasis, immunosuppressive drugs should be discontinued and treatment should be initiated with ivermectin 200 mcg/kg per day until all symptoms are resolved. Patients should be tested periodically to ensure the elimination of the larva. Individuals from an endemic area who are candidates for organ transplantation should be screened for *S. stercoralis*.

CESTODIASIS

Cestodiasis (tapeworm infection) is caused by species of the phylum Platyhelminthes (flatworms), and include among others the pork tapeworm (*Taenia solium*) and the beef tapeworm (*T. saginata*). The tapeworm attaches itself to the mucosal wall of the upper jejunum by the scolex (mouth parts), and by two to four cup-shaped suckers and a structure called a rostellum, which may have hooks in some species. Since the parasite lacks a digestive system it obtains all nutrients directly from the host. The scolex, proglottids (segments), and eggs are specific for each species and used for identification of tapeworms. Tapeworm infections are caused by ingestion of poorly cooked meat which contains the larva or cysticerci. Cysticerci, when released from the contaminated meat by host digestive juices, mature in the host jejunum. Cystericercosis is a systemic disease caused by the larva of *T. solium* (oncosphere or hexacanth), and is usually acquired by ingestion of eggs in contaminated food or by autoinfection. The larvae can penetrate the bowel and migrate through the bloodstream to infect different organs including the central nervous system (neurocysticercosis). Diagnosis of both *T. saginata* and *T. solium* is accomplished by recovery of the gravid proglottids and the scolex in the stool.

Treatment

❸ *Tapeworm infections (*T. saginata *and* T. solium*) are treated with praziquantel 5 to 10 mg/kg as a single dose (use the same dose for adults and pediatric patients).*[3] The treatment for cysticercosis and neurocysticercosis may include surgery, anticonvulsants (neurocysticercosis can cause seizures), and anthelmintic therapy. The anthelmintic therapy of choice is albendazole 400 mg twice daily for 8 to 30 days. The pediatric dose of albendazole is 15 mg/kg (maximum: 800 mg) in two divided doses for 8 to 30 days. The doses for both adults and pediatric subjects can be repeated if necessary. Praziquantel is an alternative therapy.[3]

Outcome Evaluation

Morbidity and disease due to helminthic infections is related to the intensity of infection. The major adverse effects of helminthic infections are malnutrition, fatigue, and diminished

work capacity. Unlike other helminthic infections, strongyloidiasis can cause autoinfection, and in the presence of immunosuppression, it can cause central nervous system and disseminated infections which have high mortality.

The most serious complication of cysticercosis is neurocysticercosis that can cause strokes and seizures. Treatment of neurocysticercosis with anthelmintic treatment remains controversial.

MALARIA

Malaria is one of the most devastating parasitic diseases, affecting a population in excess of 500 million and causing between 700,000 and 2.7 million deaths a year worldwide.[7,8] It is reported that in the year 2000, approximately 27 million United States travelers visited countries where malaria is endemic. In 2002, the Centers for Disease Control and Prevention (CDC) indicated that there were 1,337 cases of malaria, of which 849 were in United States civilians, 33 in United States military personnel, and the rest in foreign civilians. There were eight fatalities, all due to *Plasmodium falciparum*. ❹ *The primary reasons for morbidity and death in malaria are failure to take recommended chemoprophylaxis, inappropriate chemoprophylaxis, delay in seeking medical care or in initiating therapy promptly, and misdiagnosis*. Evaluation of a patient should include specific travel history, details of chemoprophylaxis, and physical findings (e.g., splenomegaly).

Malaria is transmitted by the bites of the *Anopheles* mosquitoes which introduce into the bloodstream one of four species of sporozoites of the plasmodia (*Plasmodium falciparum*, *P. ovale*, *P. vivax* or *P. malariae*). Initial symptoms of malaria are nonspecific and may resemble influenza and include: chills, headache, fatigue, muscle pain, rigors, and nausea. The onset of the symptoms is between 1 to 3 weeks following exposure. Fever may appear 2 to 3 days after initial symptoms and may follow a pattern and occur every 2 or 3 days (*P. vivax, P. ovale* and *P. malariae*). Fever with *P. falciparum* can be erratic and may not follow specific patterns. It is not unusual for patients to have concomitant infections with *P. vivax* and *P. falciparum*. Falciparum malaria must always be regarded as a life-threatening medical emergency.

Epidemiology and Etiology

The distribution of the various species of malaria is not well defined but *P. vivax* is reported to be prevalent in the Indian subcontinent, Central America, North Africa, and the Middle East, whereas *P. falciparum* is predominantly in Africa (including sub-Saharan Africa), both East and West Africa, Haiti, the Dominican Republic, the Amazon region of South America, Southeast Asia, and New Guinea. Most *P. ovale* infections occur in Africa, while the distribution of *P. malariae* is worldwide.[7] Most infections in the United States are reported in American travelers, recent immigrants, or immigrants who have visited friends and family in an endemic area.[8] Placental transmission and blood transfusions are also sources of malaria.

Patient Encounter, Part 1

TW is a 27-year-old male who had returned from Bamako, Mali in West Africa after visiting his college classmate who was in the Peace Corps. While there, he accompanied his friend on a river trip to visit a number of villages. He indicates that he took steps to minimize mosquito bites and had slept under a mosquito net. He was well since returning from Africa until the previous day, when he had a temperature as high 39°C (102°F), with anorexia, headache, chills, sweats, myalgias, and abdominal pain. He took a few doses of ibuprofen but his fever came back after a few hours and he now presents in the emergency department with chills, high fever (greater than 39.8°C) (greater than 104°F) , headache, abdominal pain, nausea, stiffness of the neck, and back pain.

- Are the symptoms in this patient consistent with malaria?
- What places this patient at risk for malaria?
- What additional information do you need to develop a therapeutic plan for this patient?

Within minutes after the bite of the *Anopheles* mosquito, the sporozoites invade hepatocytes in the liver and begin an asexual phase called schizonts (exoerythrocytic stage or schizogony). The patient may be asymptomatic during this period. After a lapse of between 5 and 15 days (depending on the species), schizonts rupture to release daughter cells (merozoites) into the blood, which then invade erythrocytes. In erythrocytes the merozoites undergo a number of sequential forms: a ring form, trophozoite, schizont, and merozoite, which then invade new erythrocytes. This asexual phase is about 48 hours for *P. falciparum*, *P. vivax,* and *P. ovale,* and 72 hours for *P. malariae*. Subsequently, the merozoites develop into gametocytes and undergo a sexual phase (sporogony) in the *Anopheles* mosquito. In the mosquito, the gametocytes undergo a number of stages: zygote, ookinete, and oocyst, and finally transform into sporozoites in the salivary glands where it is again able to infect the next host. Unlike *P. falciparum* and *P. malariae,* which only remain in the liver for about 3 weeks before invading erythrocytes, *P. ovale* and *P. vivax* can remain in the liver for extended periods in a latent stage (as hypnozoites); this can result in the recurrence of the infection after weeks or months. Primaquine therapy is necessary to eradicate this stage of the infection.

Pathology

The clinical presentation of malaria can be quite variable. Normally, the appearance of a prodrome with headache, abdominal pain, fatigue, fever, and chills, which coincides

with the erythrocytic phase of malaria occurs frequently between 10 and 21 days after being exposed. This phase causes extensive hemolysis, which results in anemia and splenomegaly. The most serious complications are caused by *P. falciparum* infections. Infants and children under the age of 5 years and nonimmune pregnant women are at high risk for severe complications with falciparum infections. The complications associated with falciparum malaria are related to two unique features of *P. falciparum*: (1) its ability to produce high parasitism (up to 80%) of red cells of all ages, and (2) the propensity to be sequestered in postcapillary venules of critical organs such as brain, liver, heart, lungs, and kidneys.[7] It has been postulated that tissue hypoxia from anemia, together with *P. falciparum*–parasitized red blood cell adherence to endothelial cells in capillaries, contribute to severe ischemia and metabolic derangements. *P. malariae* is implicated in immune-mediated **glomerulonephritis** and nephrotic syndrome.

Clinical Presentation and Diagnosis

Clinical Presentation of Malaria

Initial Presentation

Include a careful travel history of patient and physical findings (e.g., splenomegaly) and details of antimalarial chemoprophylaxis, when obtainable.

Erythrocytic Phase

1. Prodrome: Headache, anorexia, malaise, fatigue, and myalgia
2. Nonspecific complaints include: abdominal pain, diarrhea, chest pain, and arthralgia
3. Paroxysm: High fever, chills, and rigor
4. Cold phase: Severe pallor, cyanosis of the lips and nail beds
5. Hot phase: Fever between 40.5°C (104.9°F) and 41°C (105.8°F) (seen more frequently with *P. falciparum*)
6. Sweating phase: Follows the hot phase by 2 to 6 hours
7. When fever resolves, it is followed by marked fatigue and drowsiness, warm dry skin, tachycardia, cough, headache, nausea, vomiting, abdominal pain, diarrhea and delirium, anemia, and splenomegaly

❺ *P. falciparum malaria is a life-threatening emergency. Complications include hypoglycemia, acute renal failure, pulmonary edema, severe anemia (high parasitism), thrombocytopenia, heart failure, cerebral congestion, seizures, coma, and adult respiratory distress syndrome.*

Diagnostic Procedures for Malaria

1. To ensure a positive diagnosis, blood smears (both thick and thin films) should be obtained every 12 to 24 hours for 3 consecutive days.
2. The presence of parasites in the blood 3 to 5 days after initiation of therapy suggests resistance to the drug regimen.

Patient Encounter, Part 2

HPI

TW presents with fever, nausea, headache, myalgias, chills, and body aches including back pain. When questioned about his travels, he indicates that he had not taken any antimalarial prophylaxis.

PMH

Healthy 27-year-old male

FH

Father died of stroke at age 87 years; mother, who is 82 years old, has rheumatoid arthritis and lives with an unmarried daughter

SH

Systems analyst, works for local school district; occasionally drinks wine with meals

Meds

Ibuprofen 200 mg

ROS

In addition to the complaints noted above, he complains of severe nausea and fatigue

PE

Gen: Patient is lucid but slightly agitated and febrile
VS: Blood pressure 105/70 mm Hg; pulse 120 bpm, respiratory rate 32/minute, temperature 40.1°C (104.1°F)
Skin: Warm and dry to touch
HEENT: Slightly icteric sclerae and dry oral mucosa
ABD: Soft with diffuse tenderness with hepatomegaly and splenomegaly
Rest of the systems were WNL

Labs

Sodium 131mEq/L (131 mmol/L)
Hemoglobin 10.2 g/dL (6.3 mmol/L)
Potassium 4.9 mEq/L (4.9 mmol/L)
Hematocrit 31% (0.31)
Chloride 96 mEq/L (96 mmol/L)
White blood cells $14.8 \times 10^3/mm^3$ ($14.8 \times 10^9/L$)
Blood urea nitrogen 28 mg/dL (9.99 mmol/L)
Total bilirubin 1.8 mg/dL (30.8 mcg mol/L)
Serum creatinine 1.4 mg/dL (123.8 mcg mol/L)
Platelets $110 \times 10^3/mm^3$ ($110 \times 10^9/L$)
Glucose 77 mg/dL (4.27 mmol/L)
Aspartate aminotransferase 87 U/L (1.45 mcg kat/L)
Albumin 3.2 g/dL (32 g/L)
Alanine aminotransferase 94 U/L (1.57 mcg kat/L)
Blood smear (Giemsa stain): *P. falciparum*

- In view of the above information, what is your assessment of this patient?
- Identify your treatment goals and monitoring parameters.

Recent innovations for detecting malaria include DNA or RNA probes by polymerase chain reaction (PCR). These, however, are not widely available for clinical use. A rapid dipstick test (ParaSight F, Becton-Dickinson, Cockeyville, MD) reportedly has a sensitivity of 88% and a specificity of 97%, which is comparable to microscopy. However, ParaSight F can give false-positive results with rheumatoid factor; thus microscopy remains the optimal test.

Treatment

The primary goal in the management of malaria is the rapid identification of the *Plasmodium* species by blood smears (both thick and thin smears repeated every 12 hours for 3 days). Antimalarial therapy should be initiated promptly to eradicate the infection within 48 to 72 hours and avoid complications such as hypoglycemia, pulmonary edema, and renal failure.

Pharmacologic Therapy

The chemoprophylaxis regimen for malaria is outlined in Table 75–1.[3]

Chemotherapy for Malarial Infection

In an uncomplicated attack of malaria (for all plasmodia except chloroquine-resistant *P. falciparum and P. vivax*), the recommended regimen is chloroquine 600 mg (base) initially, followed by 300 mg (base) 6 hours later, and then 300 mg (base) daily for 2 days.[3] ❻ *In severe illness or falciparum malaria, patients should be admitted to an acute care unit and quinidine gluconate 10 mg salt/kg*

TABLE 75–1. Chemoprophylaxis for Malaria

Plasmodia-Sensitive	Drug	Dose	Pediatric Dose	Comments
Chloroquine-sensitive	Chloroquine phosphate (oral)[a]	300 mg (base) once weekly beginning 1 week prior to departure and continued for 4 weeks after leaving endemic area	5 mg (base)/kg of body weight once weekly (maximum 300 mg)	Hydroxychloroquine sulfate 310 (base) or 400 mg salt once a week may be used instead of chloroquine; regimen will be similar to chloroquine
When leaving an area endemic for *P. vivax* or *P. ovale*	Primaquine (oral)	30 mg base (52.6 mg salt) daily for 14 days after departure, in addition to the above	0.6 mg/kg base (1 mg/kg salt) daily for 14 days after departure	*Contraindicated* in those with G6PD deficiency and in pregnancy and lactation
Chloroquine-resistant *P. falciparum*	Atovaquone-proguanil (oral)	250 mg atovaquone and 100 mg proguanil (1 tablet) once daily	62.5 mg atovaquone and 25 mg proguanil once daily 11–20 kg: 1 tablet 21–30 kg: 2 tablets 31–40 kg: 3 tablets Greater than or equal to 40 kg: 1 adult tablet daily	Begin 1–2 days before departure and continue for 1 week after leaving high-risk area Recommended also for primary prophylaxis in mefloquine-resistant *P. falciparum*
	Alternatives Doxycycline (oral)	100 mg daily	Greater than or equal to 8 years of age 2 mg/kg (maximum 100 mg)	Effective for mefloquine-resistant *P. falciparum* Start 1–2 days before departure, continue through stay in endemic area, and continue regimen for 4 weeks after returning
	Mefloquine (oral)	228 mg (base) (250 mg salt) weekly	Less than or equal to 15 kg: 4.6 mg/kg base (5 mg/kg salt) once weekly 15–19 kg: ¼ tablet 20–30 kg: ½ tablet 31–45 kg: ¾ tablet Greater than or equal to 45 kg: 1 tablet	Start 1–2 wk before departure and continue for 4 wk after leaving endemic area; may start 3–4 wk earlier to assess tolerance *Contraindications*: History of seizure, psychiatric disorders (including depression and anxiety), or arrhythmias
	Primaquine (oral)	30 mg base (1 mg/kg salt for adult) daily	0.6 mg/kg base (1 mg/kg salt up to adult dose)	Alternative or second-line regimen; see above for contraindications

[a]Pediatric dose can be calculated and tablet pulverized and placed in gelatin capsules. Parents can be instructed to suspend dose in food, simple syrup, or drink.

For further information, see Eyers JE. Sources of information in tropical medicine. In: Cook GC, Zumla A, eds. Manson's Tropical Diseases. 21st ed. London: Saunders; 2003:1807–1816.

G6PD, glucose-6-phosphate dehydrogenase deficiency.

as a loading dose (maximum 600 mg) in 250 mL normal saline should be administered intravenously slowly over 1 to 2 hours. This should be followed by continuous infusion of 0.02 mg/kg per minute of quinidine for at least 24 hours until oral therapy can be started. In patients who have received either quinine or mefloquine, the loading dose of quinidine should be omitted. Oral quinine salt (650 mg every 8 hours) plus doxycycline 100 mg twice daily should follow the intravenous dose of quinidine to complete 7 days of therapy. The pediatric dose of intravenous quinidine gluconate is the same as the dose for adults. The pediatric dose of oral quinine is 25 mg/kg per day in three divided doses, while the dose of doxycycline (children greater than 8 years old) is 4 mg/kg in two divided doses for 7 days. An alternative to doxycycline is clindamycin 900 mg (20 mg/kg per day) three times daily for 3 days. The pediatric dose of clindamycin is the same as in adults.

In *P. falciparum, P. vivax, P. ovale* or *P. malariae* (chloroquine-resistant) infections, a dose of 750 mg mefloquine followed by 500 mg 12 hours later is recommended. The pediatric dose of mefloquine is 15 mg/kg (less than 45 kg) followed by 10 mg/kg 8 to 12 hours later. Mefloquine is associated with sinus bradycardia, confusion, hallucinations, and psychosis and should be avoided in patients with a history of cardiovascular problems or depression. Intravenous quinidine gluconate followed by quinine plus doxycycline or clindamycin should be administered for severe illness as indicated above. The intravenous quinidine regimen requires close monitoring of the electrocardiogram (QT-segment) and other vital signs (hypotension and hypoglycemia). An alternative oral treatment for *P. falciparum* infections in adults, especially those with history of seizures, psychiatric disorders, or cardiovascular problems, is the combination of atovaquone 250 mg and proguanil 100 mg (Malarone) (2 tablets twice daily for 3 days).[3,8] The pediatric dose of Malarone: less than 5 kg :not indicated; 9 to 10 kg:3 pediatric tablets/day × 3 days; 11 to 20 kg: one adult tablet/day × 3 days; 21 to 30 kg: 2 adult tablets/day × 3 days; 31 to 40 kg:3 adult tablets/day × 3 days; greater than 40 kg: 2 adults tablets twice daily × 3 days. ❼ *Since falciparum malaria is associated with serious complications, including pulmonary edema, hypoglycemia, jaundice, renal failure, confusion, delirium, seizures, coma, and death, careful monitoring of fluid status and hemodynamic parameters is mandatory.*

Patient Encounter, Part 3

Following treatment of falciparum malaria, TW has remained well for 2 months. However, 2 days ago, he started developing fever and chills, nausea, and abdominal pain. When seen in the emergency department he has a fever of 38.4°C and complains of severe headache. Examinations of a thick and thin blood smear of the patient's blood identified *P. vivax* infection. TW received a course of chloroquine and primaquine. In a follow-up 2 weeks later, a repeat blood smear was negative for parasites and the patient was asymptomatic.

Exchange transfusion that may be required in patients with *P. falciparum* malaria in whom parasitemia may be between 5% and 15% remains a questionable modality. Either peritoneal or hemodialysis may be indicated in renal failure.

Outcome Evaluation

When advising potential travelers on prophylaxis for malaria, be aware of the incidence of chloroquine-resistant *P. falciparum* malaria and the countries where it is prevalent. In patients who have *P. vivax* or *P. ovale* malaria (note that some patients can have *P. falciparum* and one of these species), following the treatment of the acute phase of malaria and screening for glucose-6-phosphate dehydrogenase deficiency, patients should receive a regimen of primaquine for 14 days to ensure eradication of the hypnozoite stage of *P. vivax* or *P. ovale*. For detailed recommendations for prevention of malaria go to www.cdc.gov/travel/.

Patient Care and Monitoring

- Acute *P. falciparum* malaria resistant to chloroquine should be treated with intravenous quinidine via central venous catheter and fluid status and the electrocardiogram (ECG) should be monitored closely.
- The loading dose of quinidine should be omitted in those patients who have received quinine or mefloquine.
- Hypoglycemia that is associated with both *P. falciparum* and quinidine administration, should be checked every 4 to 6 hours and corrected with dextrose infusions (5% to 10%).
- Quinidine infusions should be slowed temporarily or stopped if the QT interval is greater than 0.6 second, the increase in the QRS complex is greater than 25%, or hypotension unresponsive to fluid challenge results.
- The suggested quinidine levels should be maintained at 3 to 7 mg/dL (9.2 to 21.6 mcg mol/L).
- Blood smears should be checked every 12 hours until parasitemia is less than 1%.
- Resolution of fever should take place between 36 and 48 hours after initiation of the intravenous quinidine therapy, and the blood should be clear of parasites in 5 days.
- When parenteral therapy is required for more than 48 hours or the patient's renal function deteriorates, the dose of quinidine should be lowered by half.

Advice to Travelers

All travelers to endemic areas should be advised to remain in well-screened areas, to wear clothes that cover most of the body, and sleep in mosquito nets. Travelers should adhere to malaria chemoprophylaxis regimens and carry the insect repellant DEET (N, N,-diethylmetatoluamide) or other insect sprays containing DEET for use in mosquito-infested areas.

AMERICAN TRYPANOSOMIASIS

Etiology

Two distinct forms of the genus *Trypanosoma* occur in humans. One is associated with African trypanosomiasis (sleeping sickness) and the other with American trypanosomiasis (Chagas' disease). *T. brucei gambiense* and *T. brucei rhodesiense* are the causative organisms for the East African and West African trypanosomiasis, respectively. *T. brucei rhodesiense* causes the acute disease and is the more virulent of the two species. Both East and West African trypanosomiasis are transmitted by various species of tsetse fly belonging to the genus *Glossina*. Further discussion of this subject will focus on American trypanosomiasis.

T. cruzi is the agent that causes American trypanosomiasis. American trypanosomiasis is transmitted by a number of species of reduviid bugs *(Triatoma infestans* and *Rhodrium prolixus)* that live in wall cracks of houses in rural areas of North, Central, and South America.[9] The reduviid bug is infected by sucking blood from animals (e.g., opossums, dogs, and cats) or humans infected with circulating trypomastigotes. American trypanosomiasis is endemic in all Latin American countries and can be transmitted congenitally, by blood transfusion, and by organ transplantation.

Clinical Presentation and Diagnosis

Clinical Presentation of Trypanosomiasis

Acute
- Unilateral orbital edema (Romana's sign)
- Granuloma (chagoma)
- Fever, hepatosplenomegaly, and lymphadenopathy

Chronic
- *Cardiac: cardiomyopathy and heart failure*
- *ECG: first-degree heart block, right bundle-branch block, and arrhythmias*
- *Gastrointestinal: enlargement of the esophagus and colon ("mega" syndrome)*
- *Central nervous system: meningoencephalitis, strokes, seizures, and focal paralysis*

Diagnosis

Positive history of exposure and use of serology: indirect hemagglutination test, ELISA (Chagas EIA, Abbott Labs, Abbott Park, IL), and complement fixation (CF) test. (*Note:* CF may produce false-positive reactions in those exposed to leishmaniasis, syphilis, and malaria. PCR may be more definitive for diagnosis.)

Patient Care and Monitoring

- It is essential to identify *T. cruzi*–infected patients by serology and to monitor the cardiovascular status of these patients by electrocardiogram periodically.
- Some patients will benefit from implantation of pacemakers.
- All transplant candidates from areas endemic for Chagas' disease need to be screened for T. cruzi. Immunosuppression in these patients can lead to overwhelming infections.

Pharmacologic Therapy

The drugs used for *T. cruzi* include nifurtimox (Lampit) and benznidazole (Rochagan). Oral nifurtimox is available from the CDC, while benznidazole is only available in Brazil. The adult dose of nifurtimox is 8 to 10 mg/kg per day in divided doses for 120 days. Since children seem to tolerate the dose better than adults, the pediatric dose of nifurtimox in children 1 to 10 years old is 15 to 20 mg/kg per day, and the dose for children 11 to 16 years old is 12.5 to 15 mg/kg per day in divided doses. Symptomatic treatment for heart failure associated with Chagas' disease should be initiated. The gastrointestinal complications may require surgical revisions and reconstruction.

Outcome Evaluation

Treatment of the acute phase of the disease (i.e., fever, malaise, edema of the face, and hepatosplenomegaly) is nifurtimox. The congestive heart failure associated with cardiomyopathy of Chagas' disease is treated the same way as cardiomyopathy from other causes.

ECTOPARASITES

A parasite that lives outside the body of the host is called an ectoparasite. Approximately 6 to 12 million subjects become infested with pediculosis (lice infestation) yearly in the United States. Pediculosis is usually associated with poor hygiene, and infections are passed from person to person through social and sexual contact.

Lice

The two species that belong to this group include *Pediculus humanus capitis* (head louse) and *P. humanus corporis* (body louse). The eggs (or nits) remain firmly attached to the hair, and in about 10 days the lice hatch to form nymphs, which mature in 2 weeks. The lice become attached to the base of the hair follicle and feed on the blood of the host.[10] Pubic or crab lice are found on the hairs around the genitals, but may occur

in other parts of the body (e.g., eyelashes or axillae). Hypersensitivity to the secretions from lice can produce macular swellings and lead to secondary bacterial infections.

Treatment

❾ *The agent of choice for all three infections (body, head, and crab lice) is 1% permethrin (Nix).* Permethrin has both pediculicidal and ovicidal activity against *P. humanus capitis*. The cure rate is reported to be between 90% and 97%. A cream rinse of permethrin 1% (Nix-Crème Rinse) is also available. Individuals with a history of hypersensitivity to ragweed or chrysanthemum may react to permethrin and should avoid this preparation. An alternative agent is oral ivermectin 100 mcg/kg for 3 days (days 1, 2, and 10). Permethrin can cause itching, burning, stinging, and tingling with application. Permethrin 1% should be applied to the dry scalp after shampooing and be left on the scalp for 10 minutes. The application may need to be repeated. Because of the reports of resistance to permethrin, an alternative agent is 0.5% malathion (Ovide), which has to be left on the scalp for 90 minutes, has also been found to be effective. For the relief of pruritus, calamine lotion with 0.1% menthol or an equivalent agent may be used. ❾ *All individuals, including immediate family members and sexual partners of the primary host, should be treated. All bedding and clothes should be sterilized as previously indicated for enterobiasis.*

Scabies

Scabies is caused by the itch mite *Sarcoptes scabiei hominis*, which affects both humans and animals. Infection usually affects the interdigital and popliteal folds, axillary folds, the umbilicus, and the scrotum. The infection causes severe itching and excoriations in the interdigital web spaces, buttocks, groin, and scalp.[10] ❿ *Diagnosis is made by identifying the mite from skin scrapings on a wet mount.*

Treatment

❿ *The agent of choice for scabies is permerthrin 5% (Elimite) cream.* Alternative agents in subjects who cannot use permethrin are crotamiton 10% (Eurax) and oral ivermectin (Stromectal) 200 mcg/kg as a single dose. To initiate the treatment with permerthrin, the skin should be scrubbed in a warm soapy bath to remove the scabs. The permerthrin lotion should then be applied to the whole body, avoiding the face, mucous membranes, and eyes, and left on for 8 to 14 hours. A single application eradicates 97% of scabies. All close contacts should be treated appropriately. The pruritus associated with scabies may persist for 2 to 4 weeks because of the remnants of mite parts in the skin.

Outcome Evaluation

Infections due to arthropods can be controlled by preventing their access to the host. Improving living conditions and avoiding sharing common personal items like hats and hair brushes may minimize these infections due to arthropods. Permerthrin (1% to 5%) is an effective agent for all these infections.

ABBREVIATIONS

AIDS:	Acquired immunodeficiency syndrome
CDC:	Centers for Disease Control and Prevention
CF:	complement fixation
CT:	computed tomography
DEET:	N, N,-diethylmetatoluamide
ECG:	electrocardiogram
ELISA:	enzyme-linked immunosorbent assay
HIV:	human immunodeficiency virus

76 Urinary Tract Infection

Brian A. Potoski

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Identify the diagnostic criteria for significant bacteriuria.
2. Describe the organism responsible for the majority of uncomplicated urinary tract infections.
3. Explain the three identified routes for bacteria to gain entry into the urinary tract.
4. Describe the signs and symptoms of urinary tract infections (UTIs) and how they differ in upper versus lower urinary tract disease.
5. Explain the laboratory tests that help in diagnosing patients with urinary tract infection.
6. Recommend an appropriate drug, dose, and duration for uncomplicated and complicated urinary tract infections.

Key Concepts

❶ Urinary tract infections are thought of as complicated and uncomplicated. Generally this refers to presence or absence, respectively, of functional or structural abnormalities within the urinary tract.

❷ The majority (85%) of **uncomplicated UTIs** are caused by *Escherichia coli*. The remaining 15% are caused by *Klebsiella* spp., *Staphylococcus saprophyticus*, *Enterococcus* spp., *Proteus* spp., and other organisms.

❸ Symptoms of lower UTIs include **dysuria**, urgency, frequency, **nocturia**, and suprapubic heaviness.

❹ Symptoms of upper UTIs include fever, nausea, vomiting, and often severe **flank pain**.

❺ The goals of antimicrobial treatment in UTIs are to eradicate the offending organism and prevent recurrence of infection.

❻ Uncomplicated UTIs may be managed with 3-day or even 1-day regimens, while complicated UTIs should be treated for at least 7 days, and sometimes up to 2 weeks.

Urinary tract infections (UTIs) are comprised of a diverse array of diseases. UTIs occur frequently, and are responsible for approximately 8 million patient visits annually.[1] In simplest of terms, a UTI is bacteria in the urinary tract seen either by wet prep or identified via bacterial culture, that does not represent contamination.

Bacteriuria, or bacteria in the urine, does not always represent infection. For this reason a number of quantitative diagnostic criteria have been created to identify the amount of bacteria in the urine that most likely represents true infection (hence the term "significant bacteriuria"). These are shown in Table 76–1. Furthermore, UTIs are classified as lower tract or upper tract disease. Patients will present differently with upper versus lower tract disease, and upper tract disease is thought of as a much more severe infection, as patients are more likely to be admitted to the hospital with upper urinary tract disease than lower tract disease. An example of lower tract infection is **cystitis.** Cystitis refers to the syndrome associated with a UTI involving dysuria, frequency, urgency, and occasional suprapubic tenderness. An example of upper urinary tract disease is pyelonephritis. Pyelonephritis is an inflammation of the kidney usually due to infection. Frequently, patients with uncomplicated UTI are treated as outpatients, while those patients with complicated UTIs are treated as inpatients.

EPIDEMIOLOGY AND ETIOLOGY

It is known that the prevalence of UTIs varies by age and gender. UTIs may occur at any age, even in the very young. Premature infants, for example, have a higher rate than full-term infants, and neonatal boys are five to eight times more likely to have

Patient Encounter, Part 1

A 28-year-old female presents to her primary care physician's office with complaints of painful urination and frequent need to urinate which began 2 days ago. She denies vomiting, fever, nausea, or flank pain. Upon questioning she does admit that she is sexually active with only one partner and uses spermicidal jelly.

- What symptoms are suggestive of UTI?
- Does she have risk factors for UTI?
- What additional information do you need to know before creating a treatment plan for this patient?

UTIs than neonatal girls. In young children 1 to 5 years of age, **significant bacteriuria** occurs more in girls than boys, 4.5% compared to 0.5%, respectively.[2] Once adulthood is reached, bacteriuria increases in young, non-pregnant women (range, 1% to 3%), yet remains very low in men (up to 0.1%).[3] Symptomatic UTI affects 30% of women between the 20 and 40 years of age, which represents a prevalence that is 30 times greater than men of the same age group. With each year in adulthood, an equal number of bacteriuric women clear their bacteriuria, as do those who go on to develop a UTI. It is believed that upwards of 40% to 50% of the female population will experience a symptomatic UTI at sometime during their life.[4]

The etiology of UTIs has remained relatively unchanged over the past several decades. The frequency of causative organisms changes depending on whether the setting is a complicated or uncomplicated UTI. ❶ *There is a lack of consensus regarding the definition of what makes a UTI complicated, but in general a* ***complicated UTI*** *refers to a structural or functional abnormality of the urinary tract.* Patients with complicated UTIs are typically given longer treatment durations than those patients with uncomplicated infections. Those with complicated UTIs by definition are also prone to more frequent infections. It is important to note that an upper UTI does not necessarily imply complicated UTI, nor does lower UTI imply uncomplicated UTI.

❷ *Over 95% of uncomplicated UTIs are the result of a single causative organism. In 85% of the cases, this organism is* Escherichia coli.[5,6] *A variety of other organisms may cause uncomplicated UTIs, but represent the minority of pathogens. Other organisms may include gram-positives such as* Staphylococcus saprophyticus *and* Enterococcus *spp., and gram-negatives such as* Pseudomonas aeruginosa, Klebsiella pneumoniae, Proteus *spp., and* Enterobacter *spp*. The chances of isolating these organisms are higher in patients that have recurrent UTIs, particularly those patients whose UTI is complicated. It is also more common for organisms other than *E. coli* to cause UTIs in the hospitalized population.[7]

TABLE 76–1. Diagnostic Criteria for Significant Bacteriuria

Greater than or equal to 10^2 CFU coliforms/mL or greater than or equal to 10^5 CFU non-coliforms/mL in a symptomatic female
Greater than or equal to 10^3 CFU bacteria/mL in a symptomatic male
Greater than or equal to 10^5 CFU bacteria/mL in asymptomatic individuals on two consecutive specimens
Any growth of bacteria on suprapubic catheterization in a symptomatic patient
Greater than or equal to 10^2 CFU bacteria/mL in a catheterized patient

CFU, colony-forming unit.

PATHOPHYSIOLOGY

Routes of Infection

There are three potential ways for bacteria to enter into the urinary tract and cause infection. These routes or pathways include the ascending, hematogenous, and lymphatic pathways.

Ascending Pathway

The ascending pathway occurs when bacteria colonizing the urethra subsequently travel upwards, or ascend, the urethra to the bladder and cause cystitis (Fig. 76–1). The ascending route may help to explain why urinary tract infections occur more commonly in women than in men. Women have a shorter urethra than men, and colonization of the female urethra is likely due to its proximity to the perirectal area. It is also known that the use of spermicidal agents increases the colonization of the vagina with uropathogens.[8] Additionally, massage of the urethra in women as well as sexual intercourse may lead to bacteria gaining entrance into the bladder.[9,10] Once in the bladder, bacteria are not limited to causing cystitis. These bacteria may continue to ascend the urinary tract via the ureters and cause more complicated infections, such as pyelonephritis.

Hematogenous Pathway

The hematogenous route occurs through the seeding of the urinary tract with pathogens carried by the blood supply. These pathogens represent an infection at some other primary site in the body. *Staphylococcus aureus* bacteremia, for example, can cause renal abscesses via the hematogenous route, and pyelonephritis can be experimentally produced by intravenous injection of *Salmonella*, *Mycobacterium tuberculosis*, or even yeast (*Candida* spp.) into rabbits.[11] However, experimentally creating this pathway has not been successful with all organisms. Experimental hematogenous seeding of the kidneys could not be created with the intravenous injection of large innocula of *E. coli* or *P. aeruginosa* in a mouse model.[12]

Lymphatic Pathway

The lymphatic system, also known as the secondary circulatory system, connects the bladder to the kidney and may represent a way for bacteria to be transported and subsequently cause

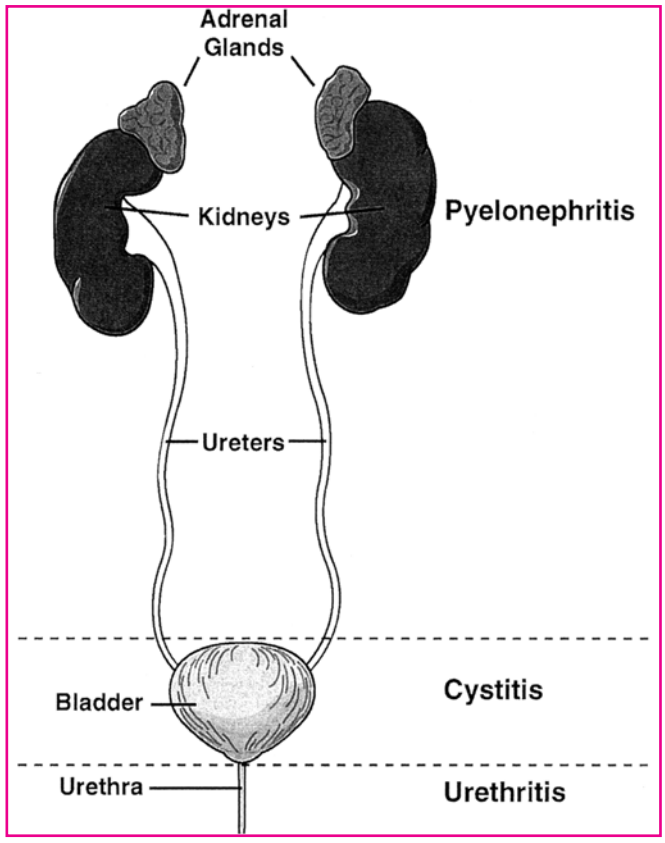

FIGURE 76–1. Anatomy and associated infections of the urinary tract. (From Sprandel KA, Lesch CA, Rodvold KA. Lower urinary tract infection. In: Schwinghammer TL, (ed.) *Pharmacotherapy Casebook: A Patient-Focused Approach*. 6th ed. New York: McGraw-Hill; 2005: 319, with permission.)

infection. Although this pathway is classically included as a route of infection, there is a lack of data showing the lymphatic pathway as a significant mechanism for development of infection. As a result this pathway is not believed to be a significant host mechanism.

Host Defense Mechanisms

Urine, although not an antimicrobial itself, does possess characteristics that are less than ideal for bacterial growth. Some of these characteristics include low pH, significant urea concentration, and high osmolality. Also, specifically in men, it is known that prostatic fluid secretions inhibit bacterial growth.[13] When they enter the bladder, bacteria stimulate an urge to urinate. This is yet another host defense mechanism targeted at preventing a bladder infection.

There are several other host factors present that should be mentioned that inhibit what are known as bacterial virulence factors. In general, these virulence factors are mechanisms that bacteria utilize to cause infection and/or ensure their survival. The first is glycosaminoglycan, a compound produced by the body that coats the epithelial cells of the bladder. This compound essentially separates the bladder from the urine by forming a protective layer against bacterial adhesion.[14] A second compound known as Tamm-Horsfall protein is secreted into the urine, and prevents *E. coli* from binding to receptors present on the surface of the bladder. Other factors implicated in contributing to host defense mechanisms include immunoglobulins, specifically IgA, and lactobacilli, bacteria that are part of the normal vaginal flora.[13,15]

Risk Factors

Several risk factors are known to exist in men and women. The common risk factors for UTI in women include sexual intercourse, lack of voiding after intercourse, use of a diaphragm, use of spermicidal jellies, diabetes, and pregnancy. In men, the risks are different, and are primarily centered on lack of circumcision, and at an older age include prostatic hyperplasia. Common risk factors for both men and women include urologic instrumentation, renal transplantation, neurogenic bladder, and urinary tract obstruction.[26]

CLINICAL PRESENTATION AND DIAGNOSIS

Clinical Presentation of Urinary Tract Infection

General

- Most women present with hematuria; however, this is not a presentation restricted only to UTIs.
- The elderly frequently will not present with common signs and symptoms of UTI, but may present with altered mental status.
- More than 95% of UTIs are caused by a single organism.
- Patients may present with **urosepsis.**

Signs and Symptoms of Lower UTI

❸ *Dysuria, suprapubic heaviness, gross hematuria, urinary frequency,* and nocturia

Signs and Symptoms of Upper UTI

❹ *Flank pain, fever, nausea, vomiting,* and *malaise*

Laboratory Tests

Urinalysis should show:

- **Pyuria** typically greater than 10 white blood cells/mm^3 urine
- Bacteriuria
- Nitrites present
- Leukocyte esterase present

Other Diagnostic Tests

- Bacterial quantitative culture, usually greater than 10^5 organisms/mL
- Upper UTI: presence of costovertebral tenderness

Patient Encounter, Part 2: The Medical History, Physical Exam, and Diagnostic Tests

PMH
None

FH
Father living with hypertension (controlled) and chronic obstructive pulmonary disease; mother living with hypertension (controlled)

SH
Works as a pharmacist at a local independent pharmacy

Allergies: Sulfa (patient states she breaks out in a rash that in some areas is "red and raised" and "red and flat")

Meds
None (occasional ibuprofen for headaches)

ROS
(+) dysuria, urinary frequency; (–) fever, nausea, vomiting, flank pain

PE
VS: Blood pressure 128/68 mm Hg, pulse 67 beats per minute, respiratory rate 16/minute, afebrile
CV: RRR, normal S1, S2; normal findings
Abd: Soft, non-tender, non-distended; (+) bowel sounds, no hepatosplenomegaly, heme (–) stool

Labs
Within normal limits

- Identify your treatment goals for the patient.
- What pharmacologic alternatives are available for the patient?

TREATMENT

Desired Outcomes

❺ *The goals of treatment are to eradicate the invading organism; to prevent or treat consequences of infection; and to prevent, if possible, recurrence of infection.* Therapy is directed at microbiologic eradication of the offending organism through antibiotics.

Pharmacologic Therapy

Antimicrobial therapy is the cornerstone of treatment in UTIs. This therapy should ideally be well tolerated, narrow in antimicrobial spectrum, lend itself to patient compliance (taken as infrequently as possible), have adequate concentrations at the site of the infection, and have good oral bioavailability. Table 76–2 reviews antibiotics frequently used to treat UTIs with comments on their use, and Table 76–3 reviews frequency, duration, and doses of those antibiotics.

Uncomplicated Cystitis

Uncomplicated cystitis represents the most common of UTIs. These are frequently managed in the outpatient setting, and occur in women of childbearing age. ❷ E. coli *is the most frequent (85%) of causal organisms in this setting, but in a minority of cases may be caused by* S. saprophyticus, K. pneumoniae, P. mirabilis, Enterococcus *spp., and a small percentage of others.*[16] As such, treatment in the outpatient setting is frequently relegated to a urinalysis and **empiric** therapy without a urine culture.[17] Patients are subsequently followed-up for resolution of signs and symptoms. ❻ *One significant benefit of treatment in the setting of uncomplicated cystitis is that treatment duration can be less than 7 days, and often may be 3 days or even 1 day.*

Although treatment duration of 1 day is advantageous because it strictly limits adverse events and drug interactions, and increases compliance, practitioners should know that 3-day courses of fluoroquinolones and trimethoprim-sulfamethoxazole are superior to single-doses in terms of cure rates in uncomplicated UTIs.[5,18] In the acute uncomplicated UTI, it is reasonable to pursue a 1-day course of therapy. Which agent to choose empirically partly hinges on known resistance rates in the geographic region, particularly *E. coli* resistance to trimethoprim-sulfamethoxazole.[19] Although no consensus has been reached on what percentage of *E. coli* isolates is resistant to trimethoprim-sulfamethoxazole should preclude its use, a model has recently been created that suggests that this threshold should be between 19% and 21% in the empiric setting.[20]

Acute Pyelonephritis

In contrast to patients that present with lower tract UTIs, those that present with pyelonephritis will have high-grade fever [greater than 38.3°C (100.9°F)] and severe flank pain. Select patients with pyelonephritis may be treated in the outpatient setting; however, patients whose infection is severe enough to cause vomiting, decreased food intake, and dehydration should be treated in an inpatient hospitalized setting. These patients will receive intravenous antibiotics at first before being switched to oral therapy.

Patients with pyelonephritis are traditionally given 14 days of therapy; however, there are limited data showing success in treating acute uncomplicated pyelonephritis for 7 to 10 days. More studies need to be conducted on treating for these shorter durations.[21] Gram stain and culture are important in ensuring appropriate antimicrobial coverage is selected. As stated above, a stratification exists for managing patients with acute pyelonephritis. Women who present with mild cases of pyelonephritis (defined as low-grade fever and a normal to slightly elevated peripheral white blood cell count, without nausea or vomiting) may be treated as outpatients.[21] Those women who exhibit more severe signs and symptoms will need to be admitted to an acute care setting for appropriate treatment. The same holds true for antibiotic selection in these patients. Those who are treated in an outpatient setting can be treated with trimethoprimsulfamethoxazole, fluoroquinolones, or even β-lactam/β-lactamase inhibitors, such as

TABLE 76–2. Commonly Used Antimicrobial Agents for the Treatment of Urinary Tract Infections

Agent	Comments
Oral Therapy	
Sulfonamides	These agents have been replaced by TMP-SMX.
Trimethoprim-sulfamethoxazole (TMP-SMX)	This combination is highly effective against most aerobic enteric bacteria except *P. aeruginosa*. High urinary tract tissue levels and urine levels are achieved, which may be important in complicated infection treatment. Also effective as prophylaxis for recurrent infections. Well tolerated, low cost. Patients with sulfa allergies may preclude its use.
Penicillins	
Ampicillin, amoxicillin, amoxicillin-clavulanic acid	Ampicillin is the standard penicillin that has broad-spectrum activity, and is the drug of choice for enterococci sensitive to penicillin. Amoxicillin is frequently used as well. Increasing *E. coli* resistance has limited amoxicillin use in acute cystitis. Amoxicillin-clavulanate is empirically preferred due to resistance.
Cephalosporins	
Cephalexin, cephradine, cefaclor, cefadroxil, cefuroxime, cefixime, cefzil, cefpodoxime	There are no major advantages of these agents over others in the treatment of UTIs, and they are more expensive. They may be useful in cases of resistance to amoxicillin and trimethoprim-sulfamethoxazole. These agents are not active against enterococci.
Tetracyclines	
Tetracycline, doxycycline minocycline	These agents have been effective for initial episodes of UTI; however, resistance develops rapidly, and their use is limited. Avoid in pregnancy.
Fluoroquinolones	
Ciprofloxacin, norfloxacin, levofloxacin	The newer quinolones have a greater spectrum of activity. These agents are effective for pyelonephritis. Avoid in pregnancy and children. Moxifloxacin is not listed due to lack of indication and efficacy data.
Nitrofurantoin	This agent is effective in treatment and prophylaxis in patients with recurrent UTIs. Contraindicated in patients with low creatinine clearances due to potential for neuropathy.
Azithromycin	Commonly used for sexually transmitted diseases (i.e., chlamydial infections) rather than UTIs.
Methenamine hippurate, methenamine mandalate	These agents are reserved for prophylactic therapy or suppressive use between episodes of infection.
Fosfomycin	Single-dose therapy for uncomplicated infections.
Parenteral Therapy	
Aminoglycosides	
Gentamicin, tobramycin, amikacin, netilmicin	Gentamicin and tobramycin are equally effective. Tobramycin has slightly better MICs to *Pseudomonas*. Amikacin generally is reserved for multi–drug resistant bacteria. Typically used as a short course of therapy followed by a switch to an oral agent.
Penicillins	
Ampicillin, ampicillin-sulbactam, ticarcillin-clavulanate, piperacillin, piperacillin-tazobactam	These agents are generally effective for susceptible bacteria. The extended-spectrum penicillins are more active against *P. aeruginosa* and enterococci and are preferred over cephalosporins. They are very useful in renally impaired patients or when an aminoglycoside is to be avoided.
Cephalosporins	
First-, second-, third-, and fourth-generation	Second- and third-generation cephalosporins have a broad spectrum of activity against gram-negative bacteria, but are not active against enterococci. Only ceftazidime and cefepime have activity against *P. aeruginosa*. They are useful for nosocomial infections and urosepsis due to susceptible pathogens.
Carbapenems	
Imipenem-cilastatin, meropenem, ertapenem	These agents have broad-spectrum activity, including gram-positive, gram-negative, and anaerobic bacteria. Imipenem and meropenem are active against *P. aeruginosa* and enterococci, but ertapenem is not. All may be associated with *Candida* superinfections. Rarely used for UTIs.
Fluoroquinolones	
Ciprofloxacin, levofloxacin	These agents have broad-spectrum activity against both gram-negative and gram-positive bacteria. They provide high urine and tissue concentrations and are actively secreted in reduced renal function. Switch to oral when possible due to excellent bioavailability.
Monobactam	
Aztreonam	Only active against gram-negative bacteria, including *P. aeruginosa*. Generally useful for nosocomial infections when aminoglycosides are to be avoided and in penicillin-susceptible patients.

MIC, minimum inhibitory concentration.

TABLE 76–3. Overview of Outpatient Antimicrobial Therapy for Lower Tract UTIs and Acute Pyelonephritis

Indications	Antibiotic	Dose	Frequency	Duration
Lower Tract Infections				
Uncomplicated	Trimethoprim-sulfamethoxazole	2 DS[a] tablets	Single dose	1 day
		or 1 DS[a] tablet	Twice a day	3 days
	Ciprofloxacin	250 mg	Twice a day	3 days
	Norfloxacin	400 mg	Twice a day	3 days
	Levofloxacin	250 mg	Once a day	3 days
	Amoxicillin	6 × 500 mg	Single dose	1 day
		500 mg	Twice a day	3 days
	Amoxicillin-clavulanate	500 mg	Every 8 hours	3 days
	Trimethoprim	100 mg	Twice a day	3 days
	Nitrofurantoin macrocrystals	50 or 100 mg	Every 6 hours	7 days
	Nitrofurantoin monohydrate	100 mg	Every 12 hours	7 days
	Fosfomycin	3 g	Single dose	1 day
Complicated	Trimethoprim-sulfamethoxazole	1 DS tablet	Twice a day	7–10 days
	Trimethorpim	100 mg		7–10 days
	Norfloxacin	400 mg		7–10 days
	Ciprofloxacin	250–500 mg	Twice a day	7–10 days
	Gatifloxacin	400 mg	Once a day	7–10 days
	Lomefloxacin	400 mg	Once a day	7–10 days
	Levofloxacin	250 mg	Once a day	10 days
	Amoxicillin-clavulanate	500 mg	Every 8 hours	7–10 days
	Nitrofurantoin macrocrystals	50 or 100 mg	Every 6 hours	6 months
Recurrent infections	Trimethoprim	100 mg	Once a day	6 months
	Trimethoprim-sulfamethoxazole	$^1/_2$ SS[b] tablet	Once a day	6 months
Acute pyelonephritis[c]	Trimethoprim- sulfamethoxazole	1 DS[a] tablet	Once a day	6 months
	Ciprofloxacin	500 mg	Twice a day	7 days
	Gatifloxacin	400 mg	Twice a day	14 days
	Norfloxacin	400 mg	Once a day	14 days
	Levofloxacin	250 mg	Twice a day	14 days
	Lomefloxacin	400 mg	Once a day	14 days
	Enoxacin	400 mg	Once a day	14 days
	Amoxicillin-clavulanate	500 mg	Twice a day	14 days
			Every 8 hours	14 days

[a]DS = double strength (160 mg trimethoprim/800 mg sulfamethoxazole).
[b]SS = single strength (80 mg trimethoprim/400 mg sulfamethoxazole).
[c]Doses listed for acute pyelonephritis are for oral regimens.

amoxicillin-clavulanate. In those patients that are admitted to the hospital, antibiotic therapy is usually broader in nature, especially in patients suspected of having bacteremia or urosepsis. These patients will typically receive intravenous therapy such as a fluoroquinolone, or a β-lactam plus an aminoglycoside.

Patient Encounter, Part 3: Creating a Care Plan

Based on the information presented, create a care plan for this patient's UTI. Your plan should include: (1) a statement of the drug-related needs and/or problems, (2) the goals of therapy, (3) a patient-specific detailed therapeutic plan including risk factor modification, and (4) a plan for follow-up to determine whether the goals have been achieved and adverse effects avoided.

Special Populations

Pregnant Women

Changes to the urinary tract in pregnant women predispose them to an increased incidence of bacteriuria, and subsequent urinary tract infections that may follow. These changes are not limited to amino acid and other nutrient concentrations in the urine, but extend to physiologic changes such as reduced bladder tone and dilation of the renal pelvis and ureters.[22,23]

It is known that an association exists between maternal UTI during pregnancy and fetal death, mental retardation, and developmental delay.[24] Because of this known association, and because up to 7% of pregnant women have an **asymptomatic bacteriuria** that may progress to pyelonephritis, screening is necessary. In patients with significant bacteriuria, whether symptomatic or asymptomatic, treatment is recommended to avoid the complications discussed above. In the majority

TABLE 76–4. Monitoring Parameters for Select Antibiotics Used in the Treatment of UTIs

Drug Class or Drug	What to Monitor	Frequency	Endpoint
Aminoglycosides	SCr	Every 24 hours	Prevention of nephrotoxicity manifested by a rise in SCr
	Aminoglycoside serum concentrations	At least once weekly; more frequently if evidence of changing renal function	Trough serum concentrations less than 2 mg/L (less than 3.42 mmol/L) to prevent nephrotoxicity (less than 8 mg/L or 13.68 mmol/L for amikacin)[a]
Nitrofurantoin	SCr	Only if renal function changing or unstable	Nitrofurantoin metabolites may accumulate in renal insufficiency and lead to neuropathy; avoid in CrCl less than 40 mL/minute

[a]Streptomycin concentrations are different than those listed here; because streptomycin is not used to treat UTIs, monitoring for this agent is not included.
CrCl, creatinine clearance; SCr, serum creatinine.

of patients, a sulfonamide (not in the third trimester due to concerns for hyperbilirubinemia), amoxicillin, amoxicillin-clavulanate, cephalexin, or nitrofurantoin are effective treatment options. Tetracyclines and fluoroquinolones should be avoided due to risk of teratogenicity and ability to inhibit cartilage and bone development, respectively. Follow-up usually consists of a urine culture 1 to 2 weeks after completion of therapy, and afterwards monthly until birth.

Catheterized Patients

An indwelling catheter is commonly used in various health care settings, and is associated with UTIs. Bacteria may be introduced into the bladder via the catheter in several ways. These include direct infection introduction during catheterization (via colonization and subsequently traveling the length of the catheter through bacterial motility or capillary action). UTIs as a result of an indwelling catheter are common and occur at a rate of 5% per day of catheter presence.[25]

The approach in the setting of a patient with bacteriuria and an indwelling urinary catheter follows two paths. The first, in asymptomatic patients with catheterization, is to hold antibiotics and remove the catheter if possible. The second as in the above-described patient who subsequently becomes symptomatic, antibiotics should then commence with removal of the catheter if possible. In both of the above situations, if discontinuation of the catheter is not possible, the patient should be re-catheterized with a new urinary catheter if the previous catheter is greater than 2 weeks old.

UTIs in Men

Although UTIs in men are not always complicated by definition, due to the relative infrequency of UTIs in men compared to women, an abnormality (structural or functional) should be suspected and therefore treated as a probable complicated infection until proven otherwise. For this reason, men should not be treated with a single dose or short course of therapy if diagnosed with a UTI. Typically these patients will receive 2 weeks of therapy, and in situations of failure may be treated up to 6 weeks, particularly if a prostatic source of infection is suspected. Prostatic enlargement, as previously mentioned, is a risk factor in men, and the prevalence of **benign prostatic hyperplasia** in the elderly population may predispose this population to UTIs.

OUTCOME EVALUATION

Outcome Parameters and Associated Goals

- Monitor the patient for resolution of symptoms (Table 76–4) Goal: 48 to 72 hours to resolution
- If possible, follow-up on susceptibilities of the infecting organism (urine culture)
- Repeat culture is necessary only if symptoms do not acutely abate or reinfection or recurrence occurs

Patient Care and Monitoring

1. Assess the patient's symptoms to determine response to the antimicrobial regimen you have chosen.
2. Review any microbiologic data:
   - Based on culture and Gram stain (if available), is your empiric selection reasonable?
   - Based on culture and susceptibility data (if available), are there any changes that need to be made from your initial empiric antimicrobial selection (i.e., resistance to the regimen initially selected)?
3. Determine if the patient would benefit from prophylactic therapy (recurrent UTIs secondary to, for example, chronic urinary catheterization due to paraplegia).
4. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and potential drug interactions.
5. Stress the importance of complying with the prescribed antimicrobial regimen, and to follow-up with the health care provider if signs and symptoms recur.

ABBREVIATIONS

CFU: colony-forming units
CrCl: Creatinine clearance
SCr: Serum creatinine
UTI: Urinary tract infection

Marlon Honeywell and Michael Thompson

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Analyze the behavioral considerations and assess the importance of contraception with regard to the contributing factors.
2. Apply the "expedited partner treatment" method when recommending treatment.
3. Identify the patient populations that are epidemiologically affected.
4. Identify causative organisms.
5. Devise a list of the clinical signs and symptoms corresponding to each disease state and classify patients based on recommended criteria.
6. Select appropriate diagnostic procedures.
7. Identify treatment regimens and recommend therapy when appropriate.
8. Design a patient care plan based on the monitoring parameters.

Key Concepts

❶ In order to yield positive results in terms of counseling a patient, intimate, friendly and knowledgeable clinician contact is vital. Additionally, patients, especially adolescents, should be counseled on the importance of using condoms properly.

❷ Generally, when treating a sexually transmitted infection (STI), the index patient should be provided with a sufficient quantity of medication for the partner to be treated, increasing the probability that the initial infection will be cured in both patients.

❸ When diagnosing and treating gonorrhea, assume co-infection with *Chlamydia trachomatis*; treatment recommendations should cover both organisms.

❹ Parenteral penicillin is the drug of choice for all stages of syphilis.

❺ The 5-nitroimidazoles are the standard therapy for trichomoniasis.

❻ Due to the variable appearance of genital warts, treatment may be based on the size, site, and morphology of the lesions. Additionally, switching to alternate therapy is appropriate if there has been no response after three treatment cycles.

❼ Therapy for genital herpes is generally based on patient compliance, host immunity, pregnancy, and observed symptoms.

❽ Bacterial vaginosis may be diagnosed according to the Amsel or Nugent criteria.

❾ With any suspicion of pelvic inflammatory disease, broad-spectrum coverage should be instituted immediately.

❿ Due to the low specificity of culture and clinical diagnosis, the multiplex polymerase chain reaction has been employed successfully in diagnosing *Haemophilus ducreyi*.

Though we have made many advances in medicine, age-old problems of infectious disease still plague us.[1] Even with the discovery of newly improved antibiotics, very few sexually transmitted infections (STIs) have been completely eliminated. Many have re-emerged secondary to modern social trends of promiscuity, and some as a result of the human immunodeficiency virus (HIV) epidemic, socioeconomic concerns, and the global lack of intimate preventive education. Educating the public has been shown to decrease the probability of infection in some individuals; however, this tactic alone may not be sufficient. *Globally, production of positive results, especially in younger patients and adolescents, may also require intimate, friendly, and knowledgeable clinician contact* ❶.

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

BEHAVIORAL CONSIDERATIONS

The correlation between risky sexual behavior and STIs is well documented.[2] Inconsistent and incorrect condom use has attributed to a rise in new STIs. *Assuming that patients, especially adolescents, consistently use and understand how to use condoms can be detrimental and may contribute to nonpharmacologic mismanagement.*[3] ❶ In addition to the increasing number of adolescents engaging in unsafe sexual practices is a high incidence of men who have sex with men (MSM). Studies demonstrate that many MSM do not disclose their HIV status. This "don't ask, don't tell" theory has been linked to an upsurge in newly diagnosed HIV infections and STIs among previously non-infected people.[4]

GENERAL APPROACH

Optimally, both sex partners should be treated simultaneously for a STI; however, this is difficult to accomplish. *Clinics and health departments often proactively attempt dual treatment by providing a prescription for the partner to the* ***index patient****, a practice commonly known as expedited partner treatment* ❷.

GONORRHEA

Gonorrhea is a curable STI caused by the gram-negative diplococcus *Neisseria gonorrhoeae*. Proper therapeutic management with antimicrobial agents is essential to eradicate this infection and prevent the development of associated sequelae.

Epidemiology

In the United States, the highest rate of gonococcal infection is seen in both sexes within the 15- to 24-year-old age groups; more cases are reported in men. It is estimated that approximately 600,000 new cases occur annually in the United States.[5] A variety of factors is associated with an increased risk for this disease, including ethnicity, low socioeconomic status, and illicit drug use. The risk of a cervical infection after a single episode of vaginal intercourse is approximately 50% and increases with multiple exposure. Furthermore, rates of reinfection are significantly higher among minorities.

Pathophysiology

Attachment to mucosal epithelium, mediated in part by pili and opa, is followed by penetration of *N. gonorrhoeae* through epithelial cells to the submucosal tissue within 24 to 48 hours. A vigorous response by neutrophils begins with sloughing of the epithelium, development of submucosal microabscesses, and exudation of pus. Stained smears usually reveal large numbers of gonococci within a few neutrophils, whereas most cells contain no organisms.[6]

Patient Encounter, Part 1

LK is a 24-year-old African-American male who visits a clinic complaining of profuse urethral discharge for the past several days. He also complains of rectal itching that has been occurring since yesterday. The patient admits to having sexual intercourse, without protection, 10 days prior with a female he met at a party.

- What information is suggestive of gonorrhea?
- What potential risk factors for STIs are present?
- What information is needed prior to developing a treatment plan?

Diagnosis

Several laboratory tests are available to aid in the diagnosis of gonorrhea and include gram-stained smears, culture, or the DNA hybridization probe.

Patient Encounter, Part 2

PMH
Currently receiving no medications
Diagnosed and treated for syphilis 3 years ago
Allergic to penicillins (anaphylactic reaction 5 years ago)

FH
Noncontributory

SH
Smokes 2 packs per day; drinks alcohol (beer) daily
Admits to having unprotected sex frequently

ROS
c/o severe lower back pain, (+) for pain in testicles, (+) urethral discharge, (+) rectal itching and discharge

PE
VS: Blood pressure 140/72 mm Hg, pulse 77 bpm, temperature 37°C (98.6°F)
Exam: WNL except notable exudates oozing from urethral opening after urination

Labs
Urethral discharge swab revealed *N. gonorrhoeae*

- Given this additional information, what is your assessment of the patient's condition?
- Identify your treatment goals for the patient.
- What pharmacologic alternatives are available for patient?

Patient Encounter, Part 3

Unprotected sex is a major risk factor for contracting STIs and this patient's symptoms are consistent with gonorrhea, as purulent urethral discharge is suggestive of this infection. In addition, the incubation period is also evidence that the infection could be gonococcal. Infection with *C. trachomatis* is usually associated with a very watery discharge and this patient lacks the characteristic ulcerations commonly observed with other STIs such as syphilis and herpetic infection.

Rectal itching with anal discharge in a male patient is highly suggestive of homosexual activity. Heterosexual women may become infected rectally due to the spread of the infection into the anal area, but this typically does not occur in men. Prior to designing an adequate therapeutic regimen for this patient, a more detailed history reveals that he has experienced an anaphylactic reaction to penicillins in the past. This finding is significant because it may limit the ability to utilize a cephalosporin as the initial drug of choice since cross-allergic reactions may occur. If cephalosporin therapy is to be avoided, a fluoroquinolone may be beneficial. Levofloxacin 500 mg orally once daily for 7 days may be prescribed to treat *N. gonorrhoeae* and provide effective coverage for *C. trachomatis*.

Clinical Presentation of Gonorrhea[7,15]

General
- Purulent discharge

Signs
- Painful or swollen testicles
- Tubal scarring

Symptoms
Men:
- May be asymptomatic, though acute urethritis is the predominant manifestation
- Urethral discharge and dysuria, usually without urinary frequency or urgency
- When compared with nongonococcal urethritis, the discharge in gonococcal urethritis is generally more profuse and purulent
- Pain during urination

Women:
- Cervicitis, urethritis, increased vaginal discharge, dysuria and intermenstrual bleeding
- Pain during urination
- Abdominal pain

Treatment

Desired Outcome
The desired outcome is complete eradication of *N. gonorrhoeae.*

PharmacologicTherapy[7]
Patients infected with gonorrhea often are co-infected with Chlamydia trachomatis *and should receive therapy to eradicate both organisms concurrently.* ❸ Though fluoroquinolones and broad-spectrum cephalosporins have been effective in the treatment of gonorrhea, recent evidence suggests that resistant strains of *N. gonorrhoeae* have emerged. In far eastern countries, as many as 50% of gonococcal strains exhibit decreased susceptibility to fluoroquinolones. Therefore, monitoring for fluoroquinolone resistance is now essential to ensure proper treatment and to ascertain the maximum time that this class may be employed as a treatment option.

Treatment of gonorrhea may vary according to clinical presentation and is indicated as follows:

Recommended Regimens (All Regimens Are Given for One Dose Only)
- Ceftriaxone 125 mg intramuscularly
- Ciprofloxacin 500 mg orally
- Cefixime 400 mg orally

Coverage for Co-Infection with Chlamydia trachomatis
- Azithromycin 1 g orally as a single dose

or

- Doxycycline 100 mg orally twice daily for 7 days

Treatment of Gonorrhea in Special Situations
Uncomplicated infections of the cervix, urethra, and rectum can be treated with one of the following regimens in adults:

Recommendations During Pregnancy
- Ceftriaxone 125 mg intramuscularly as a single dose plus therapy recommended for co-infection with *Chlamydia*
- Spectinomycin 2 g intramuscularly as a single dose plus therapy recommended for co-infection with *Chlamydia*
- Doxycycline and fluoroquinolones are contraindicated

Recommendations for Disseminated Gonococcal Infection
- Ceftriaxone 1 g intramuscularly or intravenously every 24 hours for 24 to 48 hours

After improvement begins, therapy is then switched to *one* of the following 7-day oral regimens:

- Cefixime 400 mg orally twice daily
- Ciprofloxacin 500 mg orally twice daily

Uncomplicated Infections of the Cervix, Urethra, and Rectum in Children (less than 45 kg)
- Ceftriaxone 125 mg intramuscularly as a single dose
- Spectinomycin 40 mg/kg intramuscularly as a single dose

- Ceftriaxone 50 mg/kg intramuscularly or intravenously once daily for 7 days in children with bacteremia or arthritis

Gonococcal Conjunctivitis

- Ceftriaxone 1 g intramuscularly once for adults
- Ceftriaxone 25 to 50 mg/kg intravenously or intramuscularly as a single dose for ophthalmia neonatorum or infants born to mothers with gonococcal infection as prophylaxis

Patient Care and Monitoring

Monitoring is generally not required.

CHLAMYDIA

Epidemiology

Infection with *C. trachomatis* has increased dramatically in recent years. Presently, this bacterium is the most common cause of nongonococcal urethritis, accounting for as many as 50% of cases. More than half of men infected with *C. trachomatis* exhibit symptoms, whereas, approximately 70% to 80% of women are asymptomatic.

Pathophysiology

C. trachomatis possesses characteristics resembling both bacteria and viruses. Its major membrane is comparable to that of gram-negative bacteria, although it lacks a peptidoglycan cell wall and requires cellular components from the host for replication. Chlamydia transmission risk is thought to be less than that of gonorrhea.

Diagnosis

Tests used to diagnose *C. trachomatis* include culture, the enzyme immunoassay, the DNA hybridization probe, or the direct fluorescent monoclonal antibody test. Given the fact that most women are asymptomatic, an annual screening or physical is necessary, as early detection may reduce rates of transmission.

Clinical Presentation of Chlamydia[8]

General
- Asymptomatic

Signs
- Beefy red cervix which bleeds easily (women)

Symptoms
- When present, the urethral discharge is watery and less purulent than that seen with acute gonococcal urethritis. Complications resulting from lack of treatment or inadequate treatment include: epididymitis (in males), and pelvic inflammatory disease including associated complications in women.

Other Diagnostic Tests
- Culture is usually positive for both chlamydia and gonorrhea.

Treatment[8]

Uncomplicated urethral, endocervical, or rectal infection in adults:
Recommended:
- Azithromycin 1 g orally for one dose only

or
- Doxycycline 100 mg orally twice daily for 7 days

Urogenital infections during pregnancy:
Recommended:
- Erythromycin base 500 mg orally four times daily for 7 days

or
- Amoxicillin 500 mg orally three times daily for 7 days

Patient Care and Monitoring

Monitoring is generally not required.

SYPHILIS

Syphilis, caused by the spirochete *Treponema pallidum*, can have numerous and complex manifestations. Clinician familiarity, stage-specific diagnosis, and effective treatment are vital. Missed or inappropriately treated syphilis may result in cardiovascular complications, neurologic disease, or congenital syphilis.

Epidemiology

Since the 1940s, the incidence of syphilis declined drastically following the introduction of penicillin, but rose when HIV arrived from obscurity in the 1980s. From 1990 to 2000, the rate declined again by approximately 90%. Unfortunately, recent data confirm a new spike in diagnosed cases among MSM. The 2003 morbidity and mortality report reflects a 62% increase among men and a 53% decrease in women. The disparity among men and women has been observed across racial and ethnic groups and is highest in the South and among non-Hispanic Blacks.[9]

Pathophysiology

T. pallidum rapidly penetrates intact mucous membranes or microscopic dermal abrasions, and within a few hours, enters the lymphatics and blood to produce systemic illness. During the secondary stage, examinations commonly demonstrate abnormal findings in the cerebrospinal fluid (CSF). As the infection progresses, the parenchyma of the brain and spinal cord may subsequently be damaged.

Stages[10]

- *Primary syphilis:* Usually manifests as a solitary, painless chancre. Primary syphilis develops at the site of infection

approximately 3 weeks after exposure to *T. pallidum*; the chancre is highly infectious.

- *Secondary syphilis:* Without appropriate treatment, primary syphilis will advance to secondary syphilis, a stage usually apparent from its clinical symptomatology. Symptoms include fatigue, diffuse rash, fever, lymphadenopathy, and genital or perineal condyloma latum. Also, the skin is most often affected and a rash may present as macular, macropapular, or pustular lesions, or involve skin surfaces including the palms of the hands and soles of the feet.
- *Latent syphilis:*
  1. *Early latent:* Involves the first year after infection and may be established in patients who have seroconverted in the past year, who have had symptoms of primary or secondary syphilis in the past year, or who have had sex with a partner with primary, secondary, or latent syphilis in the past year.
  2. *Late latent:* Patients should be considered to have late latent syphilis if the aforementioned criteria (early latent) are not met. In both stages, patients are usually asymptomatic and the lesions noted in the primary and secondary phase usually resolve; however, individuals are still seropositive for *T. pallidum*.
  3. *Tertiary syphilis:* Develops years after the initial infection and may involve any organ in the body.

Congenital Syphilis

Congenital syphilis is a condition in which the fetus is infected with *T. pallidum* as a result of the hematogenous spread from an infected mother, although transmission may also occur from direct contact with the infectious genitalia of the mother. Since the primary stage of syphilis is characterized by spirochetemia, infectious rates of the fetus are nearly 100% if the mother has primary syphilis.[11]

Diagnosis

Diagnostic procedures include dark-field microscopy[12], nontreponemal exams[10] (i.e., the Venereal Disease Laboratory and the rapid plasma reagin test), and treponemal exams (i.e., enzyme immunoassay, the *T. pallidum* hemagglutination test, the fluorescent treponemal antibody test, and the enzyme-linked immunosorbent assay).

Treatment

Desired Outcome

After confirming the diagnosis of syphilis, the desired outcome is a four-fold decrease in quantitative non-treponemal titers over a 6-month period and within 12 to 24 months after treatment of latent or late syphilis. An algorithm for the treatment of syphilis is shown in Fig. 77–1.

With regard to neurosyphilis, a reduction in neurologic manifestations is desired, which may include seizures, paresis, hyperreflexia, visual disturbances, hearing loss, neuropathy, or loss of bowel and bladder function. In late neurosyphilis, vascular lesions (meningovascular neurosyphilis) may also be observed; thus, a reduction in the number of observed lesions is warranted. A diminution in CSF white blood cell (WBC) count (less than $10 \times 10^3/\mu L$ [$10 \times 10^9/L$]) or protein levels (0.05 g/dL [0.5 g/L]) is also preferred.

Pharmacologic Treatment

Parenterally administered penicillin is recommended for all stages of syphilis. ❹ Alternative agents may be used in allergic individuals and include doxycycline, minocycline, tetracycline, or erythromycin base or stearate. Some patients may not respond favorably to alternative modalities. Therefore, in patients who must be administered penicillin (i.e., patients who are pregnant or have central nervous system [CNS] involvement) or are allergic, **desensitization** must be performed before the drug is initiated.

Additionally, some patients may experience fever, chills, tachycardia, and tachypnea, a condition commonly known as the Jarisch-Herxheimer reaction. Postulated to occur secondary to spirochete lysis and proinflammatory cytokine cascades, this reaction may transpire as early as 2 hours after penicillin administration and usually resolves within 24 hours. Treatment is supportive and may include antipyretic and anti-inflammatory agents, as well as fluid resuscitation and bed rest.

Pertinent information related to benzathine penicillin G is found in Table 77–1.

Primary Syphilis

- ***Drug of choice:*** Benzathine penicillin, 2.4 million units intramuscularly as a single dose.
- ***Alternatives:*** Oral doxycycline 100 mg twice daily for 2 weeks or tetracycline 500 mg by mouth four times daily for 2 weeks. Limited literature also supports the use of ceftriaxone 1 g intramuscularly or intravenously once daily for 10 days or oral azithromycin as a single 2-g dose.[13]

Secondary and Early Latent Syphilis

Treatment modalities administered in primary syphilis are also effective in secondary syphilis and latent syphilis (less than 1 year duration).

Tertiary Syphilis

- *Drug of choice:* Benzathine penicillin 2.4 million units administered intramuscularly once weekly for 3 weeks.
- *Alternatives:* In non-pregnant patients with a penicillin allergy, alternative regimens include doxycycline 100 mg orally two times daily for 4 weeks or tetracycline 500 mg orally four times daily for 4 weeks.

Gummatous and Cardiovascular Syphilis

As long as no evidence of CNS involvement exists, antibiotic therapy for **gummatous** and cardiovascular syphilis is identical to that for tertiary syphilis.

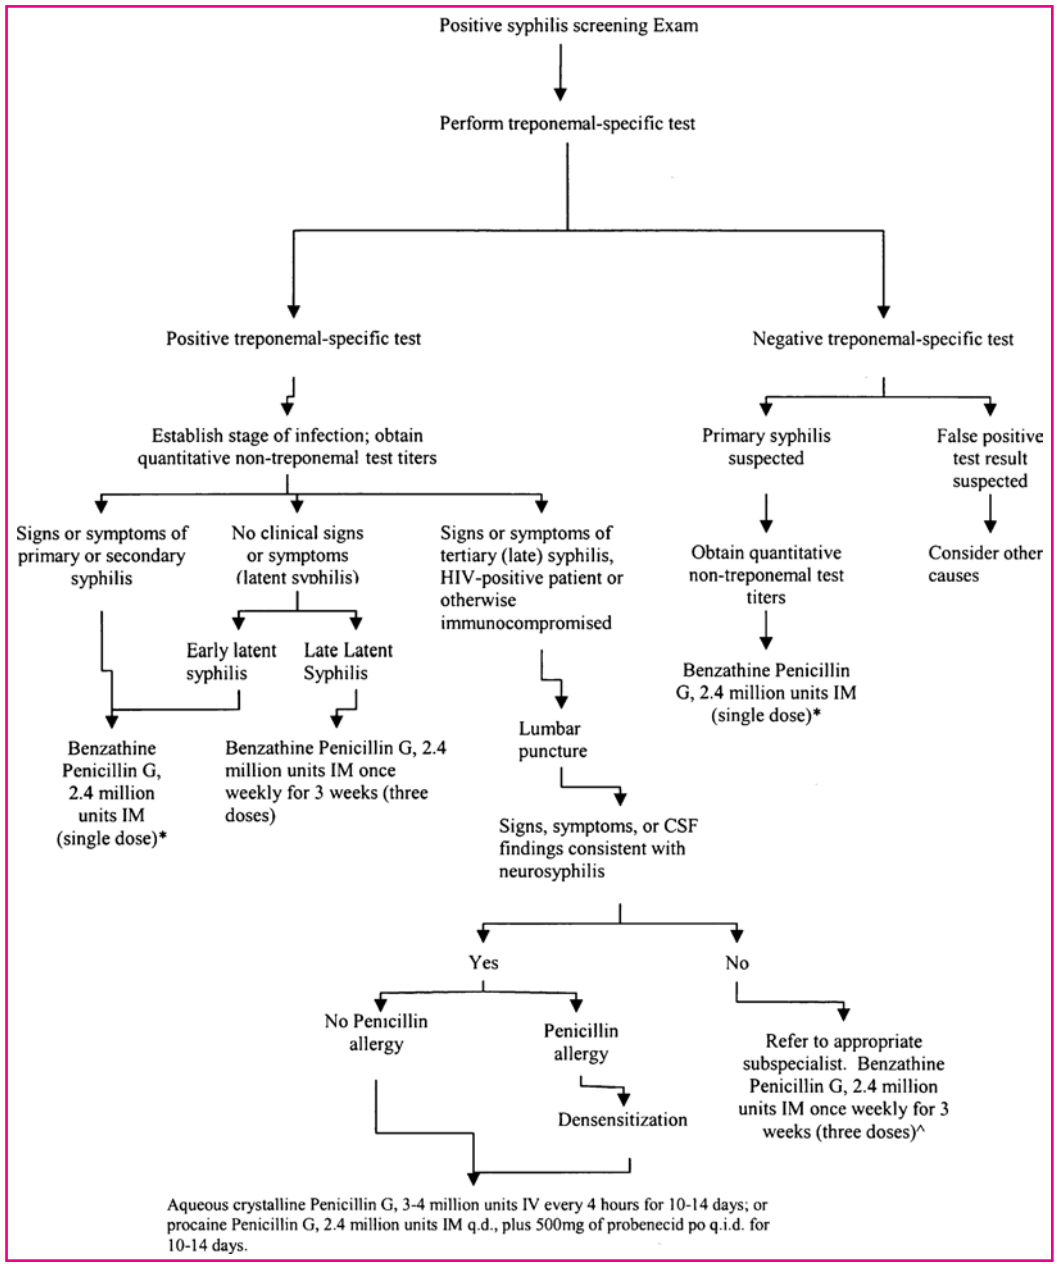

FIGURE 77–1. Treatment of syphilis.
*Alternative treatments for non-pregnant penicillin-allergic patients: doxycycline 100 mg orally twice daily for 2 weeks, or tetracycline 500 mg four times daily for 2 weeks; limited data support ceftriaxone 1 g once daily IM or IV for 8 to 10 days; or azithromycin, 2 g orally (single dose).
^Alternative treatments for non-pregnant penicillin-allergic patients: doxycycline, 100 mg orally twice daily for 4 weeks, or tetracycline 500 mg orally four times daily for 4 weeks.
CSF, cerebrospinal fluid; IM, intramuscularly.
Brown D, Frank J. Diagnosis and Management of Syphilis. American Family Physician. 2003;68(2):283–290.

Neurosyphilis

As an effective treatment for neurosyphilis, the Centers for Disease Control and Prevention (CDC) endorses two regimens of penicillin. Alternatively, ceftriaxone may also be prescribed.[13]

The regimens are as follows:

Drugs of choice:

- Aqueous penicillin G: 3 to 4 million units administered intravenously every 4 hours for 10 to 14 days
- Procaine penicillin G: 2.4 million units administered intramuscularly once daily, plus probenecid 500 mg orally four times daily for 10 to 14 days.

Congenital Syphilis

Maternal Syphilis After screening the mother, guidelines recommend that treatment decisions be based on:

- Diagnosing syphilis in the mother
- Confirming the adequacy of maternal treatment

TABLE 77–1. Benzathine and Procaine Penicillin G Informational Chart[a]

Categories	Benzathine Penicillin G	Procaine Penicillin G
Mode of action	Interferes with bacterial cell wall synthesis during active multiplication, causing cell wall death and resultant bactericidal activity	Inhibits bacterial cell wall synthesis by binding to one or more of the penicillin-binding proteins, which in turn inhibit the final transpeptidation step of peptidoglycan synthesis in bacterial cell walls; bacteria usually lyse from ongoing autolytic enzyme activity
Pharmacodynamics	Duration: 1–4 weeks Absorption IM: slow Time to peak serum levels: 12–24 hours	Duration: 15–24 hours; Absorption IM: slow; Distribution: Poor blood–brain barrier penetration, enters breast milk; Metabolism: ≅30% hepatic inactivation; Protein binding: 65%; Time to peak serum levels: 1–4 hours; Excretion: Urine (60–90% as unchanged drug); Clearance: Renal
Adverse reactions	CNS: Convulsions, confusion, drowsiness, myoclonus, fever; Dermatologic: Rash; Metabolic: Electrolyte imbalance; Hematologic: Positive Coombs test, hemolytic anemia; Local: Pain, thrombophlebitis; Renal: Acute interstitial nephritis; Miscellaneous: Anaphylaxis, hypersensitivity, Jarisch-Herxheimer reaction	CNS: Seizures, confusion, drowsiness, myoclonus, CNS stimulation; Cardiovascular: Myocardial depression, vasodilation, conduction disturbances Hematologic: Positive Coombs test, hemolytic anemia, neutropenia; Local: Thrombophlebitis, sterile abscess at injection site; Renal: Interstitial nephritis; Miscellaneous: Pseudoanaphylactic reactions, hypersensitivity, Jarisch-Herxheimer reaction, serum sickness
Monitoring parameters	Observe for anaphylaxis during first dose	Periodic renal and hematologic function tests with prolonged therapy; fever, mental status, WBC count
Test interactions	Positive Coombs (direct) test, false-positive urinary and/or serum proteins, false-positive or false-negative urinary glucose using Clinitest	Positive Coombs (direct) test, false-positive urinary and/or serum proteins
Pregnancy category	B	B
Lactation	Enters breast milk	Enters breast milk
Stability	Refrigerate	Refrigerate
Nursing Implications	Monitor: CBC, urinalysis, renal function tests	Periodically evaluate renal and hematologic systems during prolonged therapy; do not inject into gluteal muscle in children less than 2 years of age
Availability	BiCillin® L-A: 600,000 U/mL (1, 2, 4 ml); Permapen® Isoject: 600,000 U/mL (2 mL)	Injection, suspension: 600,000 U/mL (1, 2 mL)
Combination	Bicillin® C-R: (1, 2, 4 mL) Bicillin® C-R 900/300: (2 mL)	Same

CBC, complete blood cell count; CNS, central nervous system; IM, intramuscular; WBC, white blood cell count.
Lacy C, Armstrong L, Goldman M, Lance L. Lexi-Comp's Drug Information Handbook, 12th edition. 2004:1128–1132.

- Ascertaining clinical, laboratory, or radiographic evidence of syphilis in the infant
- Comparing maternal non-treponemal titers (at delivery) with the infant's non-treponemal titers.

In treatment of maternal syphilis, recommend the following regimens:

- *Drug of choice:* Benzathine penicillin G 2.4 million units or 7.2 million units intramuscularly over 3 weeks if the duration of syphilis has been at least a year
- *Alternatives:* Procaine penicillin 0.6 to 0.9 million units intramuscularly for 10 to 14 days, or ceftriaxone 1 g daily intramuscularly or intravenously for 8 to 10 days.

In women that experience uterine cramping, pelvic pain, or fever, administer acetaminophen to combat these symptoms. Additionally, make certain that the patient is well hydrated and has the opportunity to rest.

Congenital Syphilis[14]

- *Asymptomatic neonates:* 50,000 U/kg of benzathine penicillin G in a single intramuscular dose

- *Symptomatic neonates:* 50,000 U/kg of aqueous crystalline penicillin G every 12 hours intramuscularly for the first 7 days of life, then every 8 hours for 3 days, or procaine penicillin G 50,000 IU/kg intramuscularly as a single dose daily for 10 days

Patient Care and Monitoring

The CDC has provided patient care monitoring guidelines for syphilis (Fig. 77–2).[10]

Primary and Secondary Syphilis

- After 6 and 12 months of treatment, re-examine the patient and recommend a follow-up non-treponemal titer. If the patient is asymptomatic, yet has a four-fold increase in non-treponemal titer or persistent or recurrent symptoms are observed, order an HIV test and a lumbar puncture; if the patient is HIV-positive, suggest an infectious disease consult.
- In patients who are both negative for HIV and the lumbar puncture, administer benzathine penicillin G 2.4 million units intramuscularly once weekly for 3 additional weeks. Perform a patient follow-up in 6 months including a clinical examination and another non-treponemal titer. In HIV-negative patients with lumbar puncture findings compatible with neurosyphilis, treat the patient accordingly for neurosyphilis.
- Six months after the original diagnosis, institute a standard clinical follow-up exam in patients who show no symptomatology and a four-fold decrease in non-treponemal titers. By testing and observing the patient for signs of remission, you

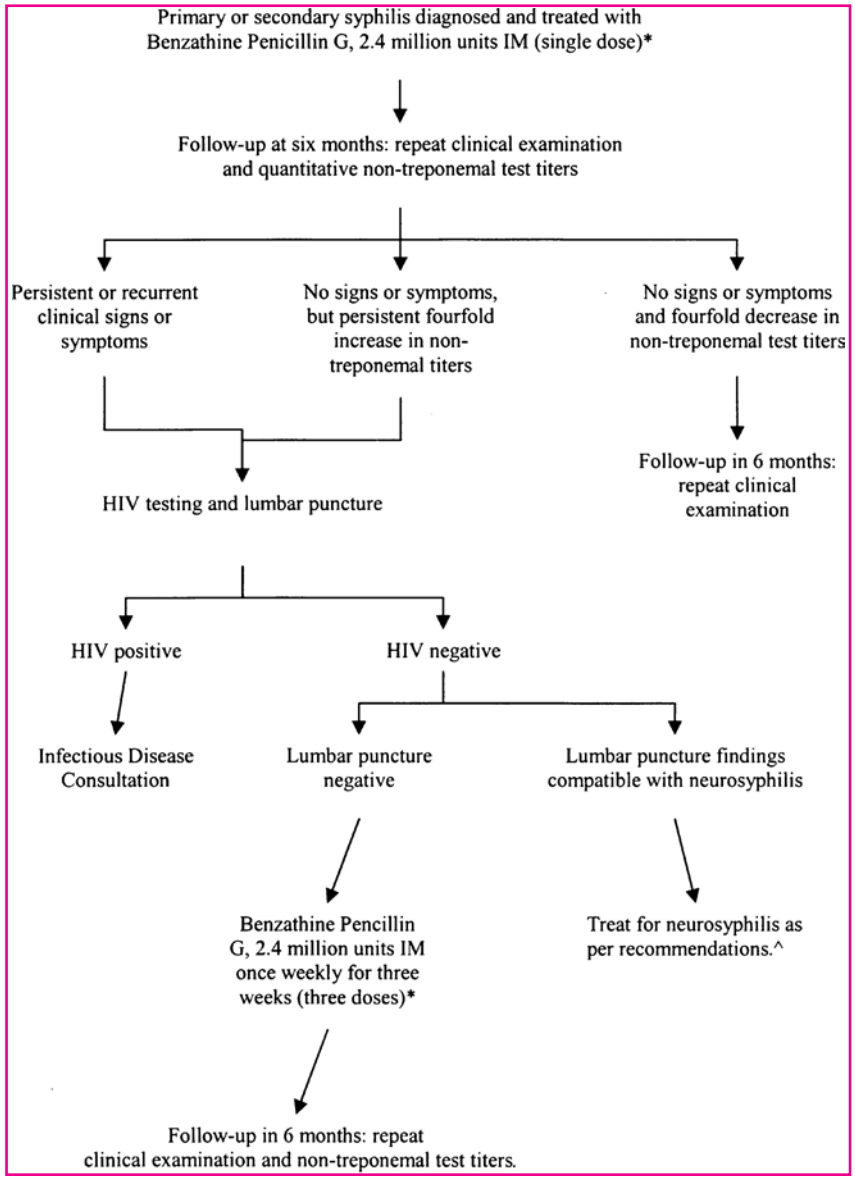

FIGURE 77–2. Patient care monitoring for syphilis.
*See text for alternative treatment recommendations for non-pregnant penicillin-allergic patients.
^See text for treatment recommendations for neurosyphilis.
HIV, human immunodeficiency virus; IM, intramuscularly.
Brown D, Frank J. Diagnosis and Management of Syphilis. American Family Physician. 2003;68(2):283–290.

may be able to initiate proper treatment or recommend a consult in a timely fashion, thereby decreasing the propensity of the patient's condition to advance to a higher stage.

Early and Late Latent Syphilis

- Order non-treponemal titers 6, 12, and 24 months after instituting treatment for early or late latent syphilis.
- Strongly consider neurosyphilis in individuals who show a four-fold increase in titers, patients who have an initially high titer (1:32 or greater) that fails to decline at least four-fold, HIV-positive patients, and those who develop symptoms consistent with neurosyphilis.

Neurosyphilis

- Follow-up is dependent on the CSF findings. If **pleocytosis** is present, re-examine the CSF every 6 months until the WBC count normalizes. Consider recommending a second course of treatment if the CSF white count does not decline after 6 months or completely normalize after 2 years.[15] Failure to normalize may require retreatment; most treatment failures occur in immunocompromised patients.

Congenital Syphilis

- Observe the patient for changes in clinical features; hepatomegaly, jaundice, and bone changes will usually resolve in 3 months.
- Monitor elevated serologic markers (non-treponemal exams) for reduction. Given effective treatment, clinical features will usually disappear after 6 months. On this basis, evaluate seropositive infants periodically for at least 6 months.[14]

TRICHOMONIASIS

Trichomoniasis is caused by the protozoan *Trichomonas vaginalis* and is far more prevalent than *C. trachomatis* or *N. gonorrhoeae*. In the United States, it is estimated that 5 million new cases appear annually, compared with 3 million chlamydial and 650,000 gonococcal cases annually.[16]

Pathophysiology

T. vaginalis may be isolated from the vagina, urethra, and Bartholin or Skene glands. After attachment to the host cells, it ignites an inflammatory response exhibited as a discharge containing elevated levels of polymorphonuclear leukocytes. The protozoal pathogen causes direct damage to the epithelium, leading to microulcerations.

Diagnosis

Diagnosis is usually performed with a wet mount or Papanicolaou smear.

Clinical Presentation of Trichomoniasis[16]

General
- Asymptomatic

Signs
- Strawberry cervix (women)
- Colpitis macularis (women)
- Prostatitis or epididymitis (men)

Symptoms
- Vaginal/vulvar erythema
- Excessive yellow-green discharge
- Vulvar itching
- Vaginal odor
- Urethral discharge or irritation
- Dysuria
- Vaginal pH greater than 4.5

Treatment

Desired Outcome

The desired outcome is the complete eradication of *T. vaginalis* in both partners and elimination of the signs and symptoms observed.

Pharmacologic

The 5-nitroimidazoles have been the standard therapy for trichomoniasis for over 40 years. ❺ Drugs included in this class are metronidazole, tinidazole, ornidazole, and secnidazole; metronidazole and tinidazole are the only drugs in this class available in the United States.

Metronidazole

Metronidazole may be administered orally as a single 2-g dose or 500 mg twice daily for 7 days.[17] Pregnant women should be prescribed the single dose of metronidazole. Cure rates are greater than 90% when metronidazole is administered as either a single 2-g dose or a 7-day regimen. Possible adverse effects include an unpleasant metallic taste, reversible neutropenia, urticaria, rash, flushing, dry mouth, darkened urine, and a disulfiram-like reaction.

Tinidazole

Tinidazole, a second-generation nitroimidazole with protozoal and anaerobic activity, has been available outside the United States for over 30 years.[18] Recently, the Food and Drug Administration (FDA) approved it for use in the United States. As a single 2-g dose, tinidazole has an efficacy equivalent to a 2-g dose of metronidazole. Tindazole also has a longer half-life than metronidazole, 14 and 7 hours respectively, and penetrates into male reproductive tissue better than metronidazole.

Various studies demonstrate the successful use of tinidazole for metronidazole-resistant trichomoniasis.[19] Possible side effects include a metallic taste, dizziness, loss of coordination, seizures, severe diarrhea, darkened urine, nausea, vomiting, and a swollen or discolored tongue.

Patient Care and Monitoring

Monitoring for *T. vaginalis* is generally not required.

GENITAL WARTS

Genital warts, caused by the human papillomavirus (HPV), are regularly encountered in primary care. Responsible for various visible, **keratotic,** and non-keratotic manifestations, HPV has nearly 120 noted strains, some of which have been linked to squamous cell carcinoma.[20]

Epidemiology

Affecting over 20 million Americans, HPV is one of the most common STIs in the United States, with an estimated prevalence of approximately 15%. Furthermore, among adolescent and college-aged women, HPV may be the most common STI.[15] The frequency of cervicovaginal HPV infection among sexually active women has been observed at 43%, with the greatest incidence noticed in men with three or more sex partners and women whose most recent regular sexual partner had two or more lifetime partners.

Pathophysiology

HPV replicates in terminally differentiated squamous cells in the intermediate layers of the genital mucosa. Hence, these effects of the viral early region genes on DNA synthesis are critical for viral survival. Genital warts are the clinical manifestation of active viral replication and virion production at the infection site.

Diagnosis

- Diagnosis is generally made from the clinical presentation and may be classified into several categories: classic condyloma acuminata, which are pointed or cauliform; keratotic warts with a thick, horny surface resembling common skin warts; and flat warts, frequently observed on the surface.
- Tissue **biopsy** or viral typing is only indicated if diagnosis is uncertain and is not recommended for patients with routine or typical lesions.
- Since HPV has been recently discovered to be highly associated with cervical cancer and since there are more than 20 different cancer-associated HPV types, patients who are diagnosed with HPV should be tested for cervical cancer.

Clinical Presentation of Genital Warts[21]

General
- Appear as rough, thick cauliflower-like lesions

Signs
- Black dots within warts
- Disrupted surface

Symptoms
- Anogenital pruritus
- Burning
- Vaginal discharge or bleeding
- Although rare, **dyspareunia** may occur with vulvovaginal condyloma

Treatment

Desired Outcome

Removal of visible warts and reduction of infectivity are the goals of treatment. According to the Department of Vaccines and Other Biologicals, a vaccine may be available in the near future to aid in reducing the spread of the disease.[22]

Pharmacologic

Currently, the choice of therapy is based on the size, site, and morphology of lesions, as well as patient preference, treatment costs, convenience, adverse effects, and patient experience. Assuming that the diagnosis is correct, switching to alternate therapy is appropriate if there has been no response observed after three treatment cycles. ❻ A comparison of adverse effects related to treatment options may be found in Table 77–2.

TABLE 77–2. Comparison of Adverse Effects Seen with Treatments for Genital Warts

Treatment	Adverse Effects
Podofilox	Burning at site of application, pain, inflammation
Imiquimod	Erythema, irritation, ulceration, pain, burning, edema, pigmentary changes
Podophyllin resin	Local irritation, erythema, burning, soreness at application site; possibly oncogenic
Bichloroacetic and trichloroacetic acid	Local irritation and pain, minimal systemic effects
Cryotherapy	Pain or blisters at application site
Surgical excision	Pain, bleeding, scarring; possible burning or allergic reaction to local anesthetic
Vaporization	Pain, bleeding, scarring; risk of HPV spreading via smoke plumes
Intralesional interferon	Burning, itching, irritation at injection site, systemic myalgia, headache, fever, chills, leukopenia, elevated liver enzymes, and thrombocytopenia

HPV, human papillomavirus.

[20]Kodner C, Nasraty S. Management of Genital Warts. American Family Physician. 2004;70(12):2335–2342, 2345–2346.
[41]McEvoy G eds. AHFS Drug Information. ASHP. Bethesda, MD. 2005.

Patient-Applied Treatment

Podofilox

- Available as a 0.5% gel or solution containing purified extract of the most active compound of podophyllin
- Arrests the formation of the mitotic spindle, prevents cell division, and may also induce damage in blood vessels within the warts
- The surface area treated must not exceed 10 cm^2, and a maximum of 0.5 mL should be used on a daily basis
- Treatment regimen:

Apply twice daily for three consecutive days followed by four consecutive days without treatment. This cycle may be repeated until there are no visible warts or for a maximum of 4 weeks.

- Side effects are generally local and may include erythema, swelling, and erosions.
- Podofilox is not recommended for use in the vagina, anus, or during pregnancy.

Imiquimod

- A cell-mediated immune response modifier, available as a topical 5% cream in single-dose application packets
- Two recommended dosage regimens:
  1. Apply at bedtime for 3 days, rest for 4 days.
  2. Apply every other day for three applications.
  3. Weekly cycles may be repeated for up to 16 weeks.
- Mild to moderate erythema has been noted with imiquimod use; however, this generally suggests that the drug is reaching a therapeutic range and may be clearing the lesion.[23]

Physician-Applied Treatments

Podophyllin Resin[21,24]

- A 10% to 25% solution of podophyllin resin has been the standard in-office treatment for genital warts.
- It is neurotoxic and due to its systemic absorption; a small amount (no more than 0.5 mL) should be applied.
- Affected area will likely become erythematous and painful within 48 hours of application.
- Treatment regimen:

Topical podophyllin is applied once weekly and the area should be allowed to dry. Immediately following treatment, the dried drug should be removed using alcohol or soap and water. Contraindicated in pregnant patients.

Bichloroacetic and Trichloroacetic Acid

- Excellent when used to treate a few, small, moist lesions.
- May be applied to both keratinized epithelial and mucosal surfaces.
- Available in 80% to 90% concentrations and is not systemically absorbed.
- May be used in pregnancy.
- A noted reaction to these medications is transient burning, and contact with surrounding epithelium may prove to be painful, producing significant local erythema and swelling. To avoid these effects, place petroleum jelly around the external lesion, including unaffected skin, and carefully apply the agent with a small applicator.

Other Treatments[21]

Other treatments may include fluorouracil/epinephrine/bovine collagen gel, an intralesional injection that has been proven effective in clinical trials for refractory patients, or an intralesional injection of interferon.

Ablative Therapy

Several ablative options have been employed in the treatment of genital warts and include cryotherapy, surgical removal, and vaporization.

Special Therapeutic Issues[21,22]

- *Large warts*: Treat warts greater than 10 mm in diameter with surgical excision. Use imiquimod for three to four treatment cycles to reduce the number of warts and improve surgical outcomes. Fifty percent reduction in wart size after four treatment cycles warrants continued use of imiquimod until warts clear or eight cycles have been completed; less than 50% reduction warrants surgical excision or other ablative therapy.
- *Subclinical warts*: Subclinical warts may be identified through colonoscopy, biopsy, acetic acid application, or laboratory serology. However, early treatment has not been linked to a favorable effect during the course of therapy in the index patient or the partner with regard to reduction of the transmission rate.
- *Pregnancy*: Agents contraindicated in pregnancy include podofilox, fluorouracil, and podophyllin. Imiquimod is not approved for use in pregnancy, although it has been considered after signed consent has been obtained. Bichloroacetic and trichloroacetic acid have been used without problems. Ablative therapy is also a viable option.

Patient Care and Monitoring

Monitor patients every 3 to 6 months for a reduction in lesions or disease remission. Monitoring parameters include patient compliance, disease remission, and benign or cancerous tumors.

GENITAL HERPES

Genital herpes, caused by herpes simplex virus (HSV) types 1 and 2, is a common STI for which there is no cure. Once latency is established, neither competent host immunity nor therapeutic agents can eradicate the virus. Currently, there is

no vaccine available for HSV, and it seems that the development of one is unlikely in the near future.

Epidemiology

Despite a decline in the number of bacterial STIs, HSV-2 in adults has increased from approximately 20% to 32%.[25] Prevalence of HSV-2 infection has grown by approximately 30% since the late 1970s, and currently it is believed that over 500,000 new cases of HSV-2 occur annually.

Pathophysiology

Since HSV is only found in humans, infection may only be transmitted from infectious secretions onto mucosal surfaces (i.e., cervix or urethra) or abraded skin. It has also been noted that the virus may survive for a limited amount of time on environmental surfaces.

Diagnosis

Laboratory confirmation is vital to effective treatment of HSV, especially in individuals in whom a clinical diagnosis cannot be obtained. There are several methods by which a definitive diagnosis may be acquired, and these include virologic typing, serologic diagnosis, rapid point-of-care antigen detection, enzyme-linked immunosorbent assay (ELISA), immunoblot, and DNA polymerase chain reaction.[27]

Treatment

Desired Outcome

The desired outcome is to curtail the number of episodic prodromes and to minimize any side effects experienced due to the antivirals.

Clinical Presentation of Genital Herpes[26]

General
- Asymptomatic

Classic Sign
- A cluster of painful vesicles on an erythematous base

Symptoms
- Itching
- Burning
- Tingling
- Groin lump
- Dysuria
- Dyspareunia
- Increased urinary frequency

Other Symptoms
- Ulcerative lesions, fissures, cervicitis

Pharmacologic

Treatment is based on several factors including likelihood of patient compliance, whether it is the first or a recurrent episode, host immunity, and pregnancy. ❼ However, patient response has been linked to the time it takes to initiate treatment after symptom onset.

First Episode

The first episode is a systemic illness associated with the vesicular lesions, may last up to 21 days, usually has an uncomplicated course of infection, and in severe cases may require hospitalization. Several agents have been found to be effective during this period (Table 77–3).[28,29] At the cited dosages, these agents have had excellent outcomes with regard to lesion healing time, viral shedding, and loss of pain. Common adverse effects are nausea, headache, and diarrhea.

Episodic Therapy

In a patient with a previous diagnosis of genital herpes, the appearance of new vesicular lesions is synonymous with HSV reactivation. For most patients, genital herpes recurrence is self-limiting and short-lived, lasting approximately 6 to 7 days.

Suppressive Therapy

Suppressive therapy is effective for controlling all symptoms related to the disease and may impact troublesome complications of infection. Before beginning suppressive therapy, discuss patient expectations. Encourage patients to record any breakthrough episodes, as this may require treatment re-evaluation and adjustment.

Preventive Therapy

Valacyclovir 500 mg orally once daily has been implicated to prevent the sexual transmission of HSV to an uninfected partner. In addition to pharmacologic therapy, counsel patients regarding safe sex practices.

Immunocompromised Patients

Foscarnet, cidofovir, and trifuridine have been administered in acyclovir-resistant patients.[30] These agents are usually reserved for use after other agents have failed because of their associated toxicities.

Pregnancy

Women who are pregnant may transmit the virus to the neonate during delivery. There are two management strategies: cesarean section and antiviral therapy. A few studies indicate that acyclovir 200 mg 4 times daily can be effective.

Neonates

Herpes simplex virus infections should be considered in all neonates who present with nonspecific symptoms such as

TABLE 77–3. Comparison of Antivirals used for Herpes Simplex Infection

Agent	Dose	Side Effects
First Episode		
Acyclovir	*200 mg PO q4hour × 7–10 days* 400 mg PO 3 times daily × 7–10 days[a] 200 mg PO q12hour × 7–10 days[e]	Headache, confusion, nausea, vomiting, thrombocytopenia, renal insufficiency, rash, pruritus, fever, arthralgias, myalgia, thrombotic thrombocytopenic purpura, hallucinations, somnolence, depression
Valacyclovir	*1 g PO 2 times daily × 7–10 days* 1 g PO daily × 7–10 days[d] **or** 500 mg PO daily × 7–10 days[d]	Refer to acyclovir
Famciclovir	250 mg PO 3 times daily × 7–10 days	Refer to acyclovir
Episodic		
Acyclovir	*200 mg PO q4hour × 5 days* **or** 400 mg PO q8hour × 5 days **or** 800 mg PO 2 times daily × 5 days	Refer to acyclovir
Valacyclovir	*500 mg PO 2 times daily × 5 days* 500 mg PO once daily × 5 days[d]	Refer to acyclovir
Famciclovir[c]	*125 mg PO 2 times daily × 5 days* 125 mg PO once daily × 5 days[d]	Refer to acyclovir
Suppressive		
Acyclovir	*400 mg PO 2 times daily up to 1 year* **or** 200 mg PO 3–5 × daily up to 1 year	Refer to acyclovir
Valacyclovir[b]	250 mg PO 2 times daily up to 1 year **or** 500 mg PO once daily up to 1 year **or** 1 g PO once daily up to 1 year	Refer to acyclovir
Famciclovir	*250 mg PO 2 times daily up to 1 year*	Refer to acyclovir
Reserved Agents		
Foscarnet	40 mg/kg IV q8–12hours × 2–3 wk or until clinical resolution is attained	Renal insufficiency, metabolic disturbances, hypophosphatemia
Cidofovir	0.3%, 1%, and 3% topical agent used on a compassionate basis for acyclovir-resistant herpes lesions (3–7 days)	Application site reactions, lesion recrudescence
Trifluridine	1% topical agent used for acyclovir-resistant herpes infections for 7–14 days	Transient burning or stinging, palpebral edema, superficial punctuate, keratopathy, changes in intraocular pressure

[a]The Centers for Disease Control and Prevention states that this dosage may be useful for immunocompromised patients.
[b]Dose is based on the number of symptomatic recurrences.
[c]If administered at the same frequency, there is no evidence that 250 mg or 500 mg will provide greater benefit than 125 mg.
[d]Dose for administration in renal impairment (CrCl 30 mL/minute or less).
[e]Dose for administration in renal impairment (CrCl 10 mL/minute or less).
Italicized data indicate recommended dosages.
CrCl, creatinine clearance; IV, intravenously; PO, orally.
McEvoy G eds. AHFS Drug Information. ASHP. Bethesda, MD. 2005.

fever, poor feeding, lethargy, or seizures in the first month of life. Infants suspected to have or who are diagnosed with an HSV infection should be treated parenterally. Acyclovir 60 mg/kg per day in three divided doses intravenously for 14 days for disease limited to skin, eyes, and mucous membranes, and 21 days for central nervous system or disseminated disease is suggested.

Patient Care and Monitoring

Re-evaluation of the patient's condition and therapy adjustment are key elements in effective monitoring. Parameters may include:

- The patient's psychosocial and psychosexual status
- Frequent reassessment of recurrent episodes and therapy adjustment

- Ordering tests for malignancy
- Yearly testing of HIV status
- Side effects of drugs.

BACTERIAL VAGINOSIS

Bacterial vaginosis (BV) is a very common infection and a recurrent cause of abnormal discharge in women of childbearing age. BV is categorized by an overgrowth of anaerobic organisms such as *Gardenella vaginalis*, *Prevotella* species, *Mycoplasma hominis*, and *Mobiluncus* species, leading to the replacement of lactobacillus and an increase in vaginal pH from 4.5 to 7.0.[31]

Epidemiology

BV has been found in 12% to 25% of women in routine clinic populations, 10% to 26% of women in obstetrics clinics, and 32% to 64% of women in clinics for STIs. BV infection usually results from sexual activity, although some cases have been reported in women who are not sexually active.

Pathophysiology

A complex and intricate balance of microorganisms maintains the normal vaginal flora (i.e., lactobacilli, corynebacteria, and yeast). The normal postmenarchal and premenopausal vaginal pH is 3.8 to 4.2. At this pH, growth of pathogenic organisms is usually inhibited; however, disturbance of the normal vaginal pH can alter the vaginal flora, leading to overgrowth of pathogens.

Diagnosis

BV is diagnosed according to the Amsel criteria. In order for diagnosis to be confirmed, three of the four criteria must be present ❽:

1. Thin, white, homogenous discharge
2. Clue cells on microscopy
3. pH of vaginal fluid greater than 4.5
4. Release of a fishy odor upon the addition of an alkali (10% potassium hydroxide) to a vaginal sample

Alternatively, a Gram stain vaginal smear may be used to diagnose BV using the Nugent criteria. ❾ This relies on estimating the proportions of bacteria morphotypes to provide a score between 0 and 10. A score of less than 4 is normal, 4 to 6 is intermediate, and greater than 6 is consistent with BV.

Isolation of *G. vaginalis* may not be diagnostic because it can be cultured from the vagina in some normal women, although a high concentration may be indicative of infection.

Clinical Presentation of Bacterial Vaginosis[32]

General
- Offensive fishy-smelling vaginal discharge

Signs
- Thin, white, homogenous discharge, coating the walls of the vagina

Symptoms
- Many women are asymptomatic; usually not associated with soreness, itching, or irritation

Treatment

Desired Outcome

Reduction in the number of causative bacteria, cessation of vaginal discharge, and decrease in vaginal pH are the desired outcomes.

Pharmacologic[33]

Recommended regimens include:

- Metronidazole 400 to 500 mg orally twice daily for 5 to 7 days
- Metronidazole 2 g orally in one dose

Alternative regimens include:

- Intravaginal metronidazole 0.75% gel once daily for 5 days
- Intravaginal clindamycin 2% cream once daily for 7 days
- Clindamycin 300 mg orally twice daily for 7 days

Pregnancy

- It is unclear whether treating pregnant women for BV is beneficial. If treatment is initiated, the drugs of choice are oral or intravaginal metronidazole or oral clindamycin.

Patient Care and Monitoring

A test to determine if the patient has been cured is generally not recommended. However, in patients with recurrent BV, a follow-up after the course of therapy may be warranted. If treatment has been prescribed during pregnancy to reduce preterm birth, perform a repeat exam in 1 month and advise further treatment for recurrent BV.

PELVIC INFLAMMATORY DISEASE

Pelvic inflammatory disease (PID) usually affects young, sexually active, reproductive-age women. In the majority of cases, the pathogens responsible are *C. trachomatis* and *N. gonorrhoeae,*

although anaerobes have also been implicated in the pathogenesis.[34] PID has been correlated with ectopic pregnancy, infertility, tubo-ovarian abscess, and chronic pelvic pain.

Pathophysiology

It has been postulated that *Chlamydia* may produce a heat shock protein that causes tissue damage through a delayed hypersensitivity reaction. *C. trachomatis* may also possess DNA evidence of toxin-like genes that code for high-molecular-weight proteins with structures similar to *Clostridium difficile* cytotoxins, enabling inhibition of immune activation. This may explain the observation of a chronic *C. trachomatis* infection in subclinical PID.

Diagnosis[34,35]

Minimum criteria

- Uterine tenderness
- Cervical motion tenderness
- No other cause of the aforementioned criteria

Additional criteria

- Oral temperature greater than 101°F
- Abnormal cervical or vaginal discharge
- White blood cell presence on saline microscopy of vaginal secretions
- Elevated erythrocyte sedimentation rate
- Elevated C-reactive protein

Treatment

Desired Outcome

The removal of causative bacteria and reduction of any related sequelae are the desired goals of treatment.

Clinical Presentation of Pelvic Inflammatory Disease[35]

General
- Signs and symptoms may vary from mild to severe

Signs
- Vague

Symptoms
- Lower abdominal or pelvic pain
- Malodorous vaginal discharge
- Abnormal uterine bleeding
- Dyspareunia
- Dysuria
- Nausea and/or vomiting
- Fever

TABLE 77–4. Treatment Regimens for Pelvic Inflammatory Disease

Parenteral
Clindamycin 900 mg IV every 8 hours and gentamicin, loading dose IV or IM (2 mg/kg) followed by maintenance dose (1.5 mg/kg) every 8 hours (a single daily dose may be used)
Levofloxacin 500 mg IV every 24 hours with or without metronidazole 500 mg IV every 8 hours
Ampicillin-sulbactam, 3 g IV every 6 hours and doxycycline 100 mg PO or IV every 12 hours
Oral
Levofloxacin 500 mg PO daily for 14 days with or without metronidazole 500 mg PO twice daily for 14 days
Ceftriaxone 250 mg IM single dose and probenecid 1 g single dose, plus doxycycline 100 mg PO twice daily for 14 days with or without metronidazole, 500 mg PO twice daily for 14 days
Third-generation cephalosporin plus doxycycline 100 mg PO twice daily for 14 days with or without metronidazole 500 mg PO twice daily for 14 days

IM, intramuscularly; IV, intravenously; PO, orally.
Epperly A, Viera A. Pelvic Inflammatory Disease. Clin Fam Pract. 2005;7:67–78.

Pharmacologic

Providing broad-spectrum coverage for N. gonorrhoeae, C. trachomatis, Streptococcus *spp., and gram-negative facultative bacteria should be the main goal of pharmacologic therapy.* ❾ CDC-approved treatment regimens are shown in Table 77–4.[34,36] Optimal management of PID should be individualized based on clinical setting and patient characteristics. For some patients, hospitalizations, intravenous antibiotics, and surgical treatment of complications may be needed. Though outpatient management remains contentious, many feel that outpatient management should be limited to: those who remain afebrile, have WBC counts less than 11,000 mm^3, have minimal evidence of peritonitis, have active bowel sounds, and can tolerate oral nourishment. Nonetheless, outpatient therapy with a parenteral cephalosporin followed by doxycycline and metronidazole is recommended.

Patient Care and Monitoring

The goals of monitoring patients with PID are related to reducing long-term complications. To this end, the primary approach should be prevention and education of at-risk women. Secondary prevention may include screening by conducting a pelvic exam during a routine check-up.

CHANCROID

Haemophilus ducreyi, a gram-negative bacterium, has been isolated as the causative organism of chancroid, a genital ulcerative disease usually accompanied by inguinal lymphadenitis and bubo formation. Chancroid may possibly spread to other anatomic sites, a clinical feature first discovered by Ducrey in 1889.[37]

Epidemiology

In 2003, more than 50,000 patients were diagnosed with chancroid in the United States. The majority of cases were diagnosed in the South Atlantic region, which included Delaware, North and South Carolina, Georgia, and Florida.[38]

Pathophysiology

Transmission commences through direct contact with the skin, presumably through minor abrasions. The ulcer may be quite deep, and more than half of patients have multiple ulcers.

Diagnosis

The multiplex polymerase chain reaction has been used successfully in diagnosis, demonstrating approximately 75% specificity in studies employing genital ulcer swabs. ⑩ It offers an acceptable sensitivity in the detection of the three most common organisms involved in the etiology of genital ulcer disease: HSV, *T. pallidum*, and *H. ducreyi*.[37,39] Additionally, several amplification techniques have been created in hopes of improving the sensitivity of laboratory diagnosis.

Treatment

Management of the syndrome has been the accepted approach of the World Health Organization (WHO) in lieu of the limitations seen with most diagnostic procedures. The prevailing thought is that patients should be treated during the first visit with a combination of antibiotics to cover for probable etiologic organisms.[39]

Clinical Presentation of Chancroid[37]

General
- The ulcer edge is commonly ragged and poorly defined.

Signs
- Four to seven days after infection, a tender, erythematous papule usually develops and subsequently progresses to the pustular stage.[37] The pustules often rupture after 2 to 3 days.
- Lesions typically occur on the prepuce and frenulum in men and on the vulva, cervix, and perianal area in women. Some extragenital cases have been noted on the inner thighs, breasts, and fingers, though rarely seen in practice.

Symptoms
- Painful and tender lesions
- Painful shallow ulcers with granulomatous bases and purulent exudates.

TABLE 77–5. Recommended Treatment Regimens for Chancroid from the World Health Organization (WHO), and the Centers for Disease Control and Prevention (CDC)

Antimicrobial	Regimen	Recommending Body
Erythromycin	500 mg PO 3 times daily for 7 days **or** 500 mg PO 4 times daily for 7 days	WHO, CDC
Azithromycin	1 g PO as a single dose	CDC
Ceftriaxone	250 mg IM as a single dose	WHO, CDC
Ciprofloxacin	500 mg PO as a single dose **or** 500 mg PO 2 times daily for 3 days	WHO, CDC
Spectinomycin	2 g IM as a single dose	WHO

IM, intramuscularly; PO, orally.
Lewis D. Diagnostic Tests for Chancroid. Sex Transm Infect. 2000 Apr; 76(2):137–141.

Desired Outcome

The desired outcome is to effectively treat the ulceration and reduce the potential for spread of the disease by instigating overall syndromic management.

Pharmacologic

The WHO and CDC recommended treatment regimens are shown in Table 77–5.[37] There has been some debate about a suitable dosage of ciprofloxacin in the treatment of chancroid. Though the CDC recommends 500 mg orally three times daily, the WHO supports a single 500-mg oral dose. Ciprofloxacin has demonstrated an acceptable cure rate for a single dose (92%) when compared to erythromycin (91%).

Patient Care and Monitoring

Follow-up should include patient education, counseling, and repeated inspections of the ulceration to ensure healing.

PREVENTION STRATEGIES

Though previous literature suggests several prevention strategies, a combination of efforts may be more advisable. Alteration in sexual behavior should undoubtedly be the first counseling concern, as promiscuous sexual activity has been shown to augment the probability of infection.

Abstinence is the best course of action, especially in patients with herpes during lesional episodes. However, compliance in some may be minimal, in which case, appropriate condom use should always be recommended. To alleviate any possible misconceptions about condom application, either demonstrate how to apply a condom or ask the patient to demonstrate. During the demonstration, explicitly educate the patient with regard to application, storage, and the use of lubricants.[43]

CONCLUSION

STIs encompass a number of diseases that seem to be increasing with regard to newly documented infections. With proper education, effective drug therapy, and patient monitoring, clinicians may be able to drastically diminish the number of new infections and the overall disease burden.

78 OSTEOMYELITIS

Melinda M. Neuhauser and Susan L. Pendland

LEARNING OBJECTIVES

UPON COMPLETION OF THE CHAPTER, THE READER WILL BE ABLE TO:

1. Discuss the pathophysiology of osteomyelitis.
2. List common risk factors for osteomyelitis.
3. Compare and contrast the classic signs and symptoms of acute and chronic osteomyelitis.
4. Evaluate microbiology culture data and other laboratory tests utilized for the diagnosis and treatment of bone infections.
5. List the most common pathogens isolated in acute and chronic osteomyelitis.
6. Develop a treatment plan for osteomyelitis.
7. Recommend parameters to monitor antimicrobial therapy for efficacy and toxicity.
8. Educate patients regarding disease state and drug therapy.

KEY CONCEPTS

❶ Osteomyelitis, an infection of the bone, can be an acute or chronic process.
❷ Osteomyelitis is most often classified by route of infection and duration of disease.
❸ *Staphylococcus aureus* is the predominant pathogen seen in all types of osteomyelitis. However, the spectrum of potential causative pathogens varies with patient-specific risk factors and route of infection.
❹ Typical signs and symptoms of osteomyelitis include local pain and tenderness over the affected bone, as well as inflammation, erythema, edema, and decreased range of motion. Patients with acute hematogenous osteomyelitis may also present with fever, chills, and malaise.
❺ The gold standard for diagnosis is a bone biopsy with isolation of microorganism(s) from culture and the presence of inflammatory cells and osteonecrosis on histologic exam. However, more commonly, the diagnosis of osteomyelitis is based on clinical findings coupled with results from imaging studies and laboratory tests such as white blood cell (WBC) count, erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP).
❻ The treatment goals for acute and chronic osteomyelitis are to eradicate the infection and prevent recurrence. Higher cure rates are seen with acute compared to chronic osteomyelitis. Therefore, in chronic osteomyelitis, a common treatment goal for many patients is to prevent complications such as amputation.
❼ Treatment of osteomyelitis is dependent on the extent of bone necrosis. For acute osteomyelitis with minimal bone destruction, an extended course of antimicrobial therapy should effectively treat the infection; however, in chronic osteomyelitis surgical intervention is also typically required.
❽ Empiric antimicrobial therapy should target likely causative pathogen(s) based on patient-specific risk factors and route of infection. However, therapy should be modified based on culture and sensitivity data.
❾ The total duration of antimicrobial therapy is typically 4 to 6 weeks. Therapy is often administered intravenously for 1 or 2 weeks and then switched to the oral route.
❿ Patients should be monitored for clinical response, development of adverse drug reactions, and potential drug-drug interactions.

❶ *Osteomyelitis is an infection of the bone that is associated with high morbidity and increased health care costs. The inflammatory response associated with acute osteomyelitis can lead to bone necrosis and subsequently chronic infections.* Bacterial pathogens, particularly *Staphylococcus aureus*, are the most common microorganisms implicated in these infections. Diagnosis and treatment are often difficult due to the heterogeneous

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

nature of osteomyelitis. Medical management is the mainstay of treatment for acute infections; however, surgical intervention is necessary for chronic cases that involve bone necrosis. Outcomes may vary based on patient-specific risk factors, duration of disease, and site of infection.

EPIDEMIOLOGY AND ETIOLOGY

❷ *There are multiple classification schemes for osteomyelitis.*[1] *Due to the heterogeneity of bone infections, no single classification system has been universally accepted.*[1,2] *Two of the most common classification schemes are based on* route of infection *and* duration of disease.[1–5] In the classification scheme developed by Waldvogel and colleagues,[5] the route of infection is categorized as either hematogenous or contiguous (Fig. 78–1). Osteomyelitis secondary to a contiguous focus was further subdivided into infections with or without vascular insufficiency.

Historically, osteomyelitis has been classified as acute or chronic based on duration of disease (Fig. 78–2).[2,4] However, there are no established definitions for acute and chronic infections.[2–4] Acute infection has been defined as first episode or recent onset of symptoms (less than 1 week).[2,3] Chronic osteomyelitis is generally defined as relapse of the disease or symptoms persisting beyond 4 weeks.[2,3] Others describe chronic osteomyelitis as the presence of necrotic bone.[3]

An alternative classification, the Cierny-Mader staging system, is based on anatomic site and physiologic status of the patient.[1] This classification scheme was developed for chronic osteomyelitis involving long bones and has limited application for small bones and digits. The detailed stratification has the greatest utility in clinical trials since it would permit comparison of treatment regimens in patients with diverse comorbidities and infection sites.

The epidemiology of osteomyelitis has been changing over the past several decades.[6] The incidence of acute hematogenous osteomyelitis, which is most often seen in children, has been declining.[6,7] In contrast, the frequency of contiguous osteomyelitis has been increasing. This trend may be related to the rising rates of diabetes and peripheral vascular disease (PVD), as well as the increased presence of prosthetic implants and surgical interventions.[3,6,8]

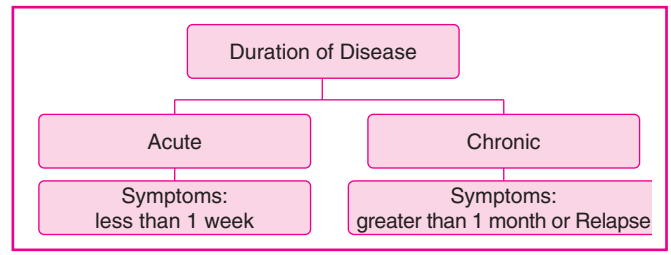

FIGURE 78–2. Classification by duration of disease.

PATHOPHYSIOLOGY

Healthy bone tissue is normally resistant to infection but may become susceptible under certain conditions.[9] Bone can become infected: (1) via the presence of bacteria in the bloodstream, (2) by direct inoculation from trauma or surgery, and (3) by spread from an adjacent site (e.g., soft-tissue infection).[9] The latter is particularly problematic in patients with foreign body implants (e.g., hip replacement) and chronic skin ulcers.[3,9,10] Microorganisms adhere to the bone and elicit an inflammatory response.[3] The subsequent release of leukocytes and cytokines leads to changes in vascular permeability (edema) and decreased oxygen tension (ischemia). In some cases, these processes can lead to bone necrosis.[2] Pieces of dead bone may become separated forming sequestra.[2,3] These areas typically cannot be penetrated by antimicrobials and phagocytic cells and thus require surgical intervention to eradicate the bacterial nidus (Fig. 78–3).[3]

Both microbial and host factors are important determinants in the development of osteomyelitis.[2,3,9] *Staphylococcus* species possess bacterial adhesions, which promote their attachment to tissues and foreign devices. ❸ *As such,* S. aureus

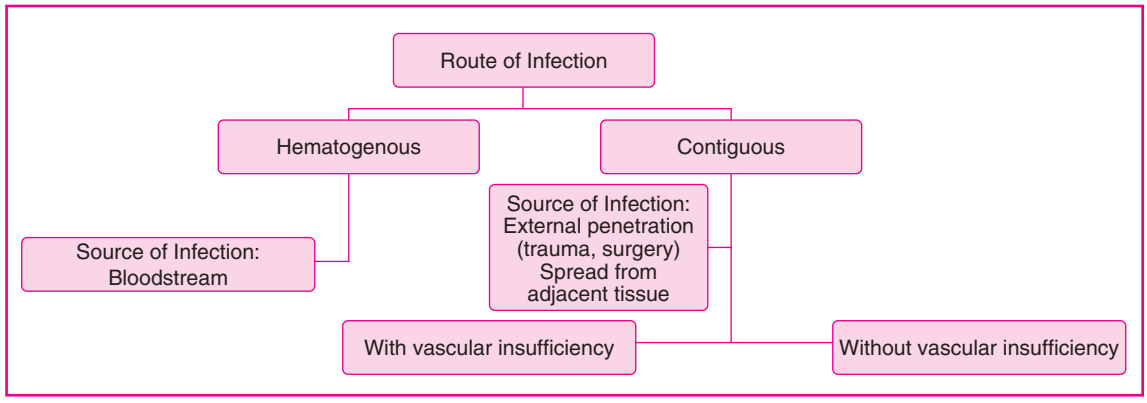

FIGURE 78–1. Classification by route of infection.

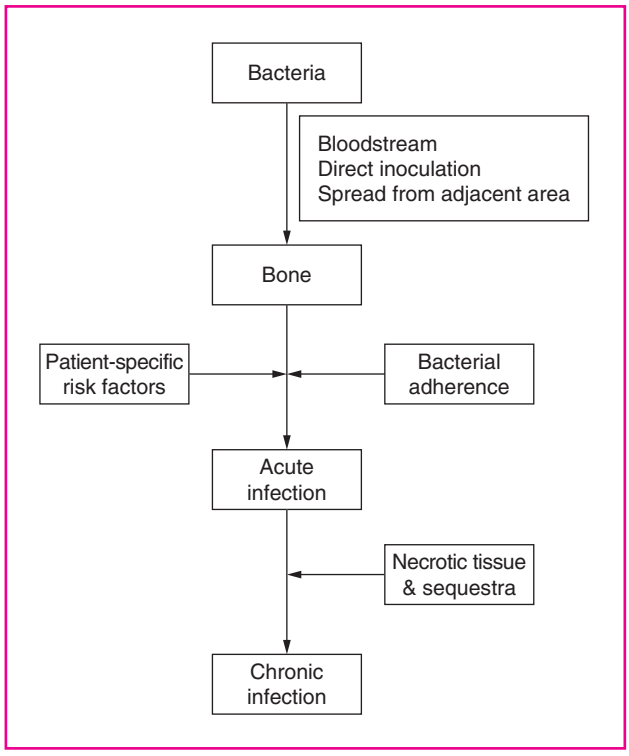

FIGURE 78–3. Pathogenesis of osteomyelitis.

Acute Hematogenous Osteomyelitis

- Single pathogen most often isolated
- *S. aureus* is the predominant pathogen
- Other pathogens based on risk factors:
  Neonates: *E. coli* or group B streptococci
  Elderly: *E. coli* [secondary to urinary tract infections (UTIs)]

is the predominant pathogen seen in all types of osteomyelitis.[11] *Host factors such as age, comorbidities, and presence of foreign devices can influence the spectrum of infection (i.e., bone and pathogen involvement)* (Table 78–1).[4,9] For example, patients with diabetes and PVD have poor wound healing and often present with non-healing skin ulcers. These wounds are typically colonized with a mixture of aerobic and anaerobic microorganisms, which can lead to polymicrobial osteomyelitis. Therefore, if a wound is deep or extensive, these patients should be evaluated for underlying osteomyelitis.[10] Other special populations that have a varied pathogen spectrum include intravenous drug abusers (IVDA) (*P. aeruginosa* and methicillin-resistant *S. aureus* [MRSA]), sickle cell patients

TABLE 78–1. Empiric Antimicrobial Therapy for Osteomyelitis[2,4,7,12,13,17]

Classification	Age of Onset	Infection Site	Risk Factors	Typical Pathogens	Antimicrobial Therapy
Hematogenous	Neonates	Long bones (femur, tibia)		*Staphylococcus aureus,*[a] *E. coli,* group B streptococci	Nafcillin[b] and cefotaxime
	Prepubertal children	Long bones (femur, tibia)		*S. aureus*[a]	Nafcillin[b] or cefazolin
	Elderly	Vertebra	UTI	*S. aureus,*[a] *E. coli*	Nafcillin[b] and cefotaxime/ ceftriaxone
Contiguous					
With Vascular Insufficiency	Adult (greater 50 years)	Feet, fingers	Diabetes, PVD, peripheral neuropathy	*S. aureus* (MRSA), Enterobacteriaceae, *P. aeruginosa, Enterococcus* spp., anaerobes	Several therapeutic options: Vancomycin **PLUS** (1) piperacillin/tazobactam (2) imipenem/cilastatin or meropenem (3) cefepime or ceftazidime and clindamycin or metronidazole (4) ciprofloxacin or levofloxacin and clindamycin or metronidazole
Without Vascular Insufficiency	Adult (greater 50 years)		Postoperative (e.g., hip fractures), soft-tissue infections	*S. aureus*[a]	Nafcillin[b] or cefazolin

[a]If the patient has risk factors for MRSA present, vancomycin should be substituted for nafcillin. MRSA risk factors may include: previous antimicrobial therapy, prolonged hospitalization, hemodialysis, presence of an indwelling catheter, intravenous drug abuse.
[b]Oxacillin can be substituted for nafcillin.
MRSA, methicillin-resistant *S. aureus;* PVD, peripheral vascular disease; UTI, urinary tract infection.

Contiguous Focus Osteomyelitis with Vascular Insufficiency

- Multiple pathogens often isolated
- Mixture of aerobic and anaerobic organisms:
  S. aureus, Enterococcus spp.
  Enterobacteriaceae, *P. aeruginosa*
  Anaerobes

(*Salmonella*), and individuals with prosthetic implants (coagulase-negative staphylococci).[3]

CLINICAL PRESENTATION AND DIAGNOSIS

The clinical presentation of osteomyelitis may vary depending on route and duration of infection, as well as patient-specific factors such as infection site, age, and comorbidities. ❹ *In hematogenous osteomyelitis, the patient typically experiences systemic and localized signs and symptoms.*[3,4,7,12,13] *In comparison, patients with chronic infection typically present with only localized signs and symptoms.*[4,6] A cardinal sign of chronic osteomyelitis is the formation of sinus tracts with purulent drainage.[2,3,6]

Common signs and symptoms of osteomyelitis include:
- Systemic: Fever, chills, malaise
- Localized: Pain or tenderness, edema, erythema, inflammation, decreased range of motion of infected area

❺ *The diagnosis of osteomyelitis is based on clinical findings, laboratory tests, and imaging studies.*[2,3] A thorough history and physical examination are especially important for diagnosis in patients with limited or atypical symptoms. *The gold standard for diagnosis is a bone biopsy with isolation of microorganism(s) from culture and the presence of inflammatory cells and osteonecrosis on histological exam.*[4,10] *Due to the invasive nature of this procedure, imaging studies and laboratory tests are generally used in making diagnoses.*

Contiguous Focus Osteomyelitis without Vascular Insufficiency

- Single or multiple pathogens isolated
- *S. aureus* is predominant pathogen
- Other pathogens based on source of infection:
  For example: Mandibular osteomyelitis (mixture of aerobic and anaerobic oral flora)

Patient Encounter, Part 1

A 62-year-old male with history of diabetes and PVD comes to the emergency department complaining of a "painful sore" on his left lower leg. After questioning him, you determine that the wound has been present for months and has not responded to oral antibiotic therapy. On physical examination, a large, deep wound with purulent drainage is seen.

- What information is suggestive of osteomyelitis?
- What risk factors, if any, does he have for osteomyelitis?

Non-specific inflammatory markers for infection include:[2,3,6,12]
- WBC, **ESR**, and **CRP** may be elevated or within normal limits.
- An elevated WBC is mostly seen in patients with acute osteomyelitis.
- CRP rises faster than ESR during early stages of infection.
- CRP returns to normal levels more quickly than ESR.

Imaging studies include:[2,3,4,6,8,10]
- Plain film radiographs
  -Most commonly used for initial screening
  -Bone destruction is not apparent for 10 to 21 days following infection
- **Magnetic resonance imaging (MRI)**
  -Most accurate for diagnosing bone infection
  -Can detect early infection
  -More expensive than radiograph
- Others
  -**Nuclear medicine scans:** useful for early detection
  -**Computed tomography (CT) scan:** useful for monitoring clinical improvement

Microbiologic evaluation:[2,3,6,10,12]
- Isolation of causative pathogen is essential for targeted antimicrobial therapy
- Bone biopsy can provide definitive diagnosis:
  Samples should be submitted for culture and histology
  Rarely performed due to invasive nature
- Blood cultures may be positive in patients with hematogenous osteomyelitis
- Superficial swabs should have limited role in directing therapy
  -May represent colonization rather than infecting organism(s)

Patient Encounter, Part 2

The medical resident suspected osteomyelitis and ordered plain film radiographs. He also swabbed the open wound and sent the swab to the microbiology laboratory for culture and sensitivity. The following result was reported:

Radiograph: lytic changes consistent with bone destruction

- How would you classify the infection in this patient?
- How should the results of the wound swab culture be utilized to target the patient's antimicrobial therapy?

TREATMENT

Desired Outcomes

❻ *The treatment goals for osteomyelitis are to eradicate the infection and prevent recurrence. Cure rates of greater than 85% have been reported for acute hematogenous osteomyelitis.*[7,13] *In contrast, chronic osteomyelitis is associated with higher failure rates largely due to the presence of necrotic bone.*[9] These patients typically require surgical intervention to remove the necrotic bone and tissue, and if applicable, to replace infected hardware.[3,14] Comorbidities such as vascular insufficiency can further contribute to the poor outcomes seen with chronic osteomyelitis. Due to the high failure rates, treatment in this patient population may require prolonged therapy with the primary goal of preventing amputation of infected areas.[3,6,10,15]

General Approach To Treatment

❼ *Antimicrobial therapy alone is the mainstay of treatment for acute osteomyelitis.*[7,12] *In comparison, treatment for chronic osteomyelitis typically requires a combination of antimicrobial therapy and surgical intervention.*[3,6,14,15] If the patient is not a candidate for surgical intervention, prolonged antimicrobial therapy is generally necessary.[6,10,16]

Pharmacologic Therapy

❽ *Empiric antimicrobial therapy should target likely causative pathogen(s) based on patient-specific risk factors and route of infection* (Table 78–1).[2] *Empiric antimicrobial coverage against* S. aureus *should be considered for all classifications of osteomyelitis. Specific recommendations may vary based on factors such as patient allergies, potential for harboring a resistant organism, institution formulary, and cost considerations.*

❽ *Antimicrobial therapy should be modified based on culture and sensitivity data of appropriately collected specimens (Table 78–2).*[2,17,18] ❾ *Typically, treatment is initiated with intravenous antimicrobials to ensure that therapeutic drug concentrations will be achieved in the bone.*[16] *Intravenous therapy can be administered in the inpatient or outpatient setting.*[15,19] *Following 1 to 2 weeks of intravenous therapy, a switch to oral antibiotics may be considered in patients with good adherence and outpatient follow-up.*[12,15,20,21] Oral agents should possess such characteristics as high bioavailability, good bone penetration, and long half-life (i.e., extended dosing interval).[16,20] Antimicrobials commonly used as oral therapy for osteomyelitis include fluoroquinolones, clindamycin, linezolid, and trimethoprim-sulfamethoxazole (TMP-SMX).[6,13,17,18,20,21] Additionally, oral rifampin may be

Patient Encounter, Part 3: The Medical History, Physical Exam, and Diagnostic Tests

PMH
Diabetes mellitus, PVD, hypertension

SH
Tobacco smoker (2 packs per day for the past 30 years), social drinker ("3 cans of beer per day"), non-employed with medical disability

Meds
Aspirin 81 mg orally once daily
Atorvastatin 40 mg orally once daily
Clopidogrel 75 mg orally once daily
Lisinopril 10 mg orally once daily
Insulin glargine 20 units every day at bedtime
Insulin lispro 7 units before breakfast and lunch; insulin lispro 9 units before dinner

PE
Gen: His general appearance is that of an obese male with tenderness and pain in the region of the non-healing skin ulcer
Skin: Large, deep ulcer with purulent drainage on his left lower leg
VS: Blood pressure 145/87 mm Hg, pulse 80 beats per minute, respiratory rate 18/minute, temperature 36.0°C (96.8°F), Ht 5'6" (165 cm), Wt 93 kg (205 lb)

Labs
WBC 13,000 cells/mm^3 (13 × 10^9 cells/L), blood urea nitrogen (BUN)/serum creatinine (Scr) 19/1.3 mg/dL (6.8/99.2 mmol/L), fasting blood glucose 156 mg/dL (8.7 mmol/L), ESR 80 mm/hour, CRP 2.1 mg/dL (0.02g/L)
Culture from wound swab: *Enterococcus*, coagulase-negative staphylococci, and *P. aeruginosa*
Culture from bone biopsy during débridement: MRSA and *Bacteroides fragilis*

- Against which organisms should the antimicrobial therapy be targeted?
- Based on the information presented, create a care plan for this patient's osteomyelitis. Your plan should include: (1) goals of therapy, (2) patient-specific detailed therapeutic plan, (3) nonpharmacologic interventions, and (4) follow-up plan to determine if outcomes have been achieved.

TABLE 78–2. Pathogen-Targeted Antimicrobial Therapy and Dosing Recommendations in Pediatrics and Adults[2,4,6,8,13,17,18]

Microorganism	Recommended Therapy	Alternatives
S. aureus		
MSSA	Antistaphylococcal penicillin: Nafcillin[a]/oxacillin Adult: 2 g IV every 4–6 hours Pediatric[b]: 100–200 mg/kg per day IV in divided doses every 4–6 hours First-generation cephalosporin: Cefazolin[c] Adult: 1–2 g IV every 8 hours Pediatric[b]: 50–100 mg/kg per day IV in divided doses every 6–8 hours	β-Lactam allergy: Vancomycin Linezolid
MRSA	Vancomycin[c]: Adult: 10–15 mg/kg per dose IV every 8–12 hours Pediatric[b]: 40 mg/kg per day IV in divided doses every 6 hours Linezolid: Adult: 600 mg IV/oral every 12 hours Pediatric[b]: 10 mg/kg per dose IV/oral every 8 hours	
Enterococcus spp.		
Ampicillin-sensitive	Ampicillin[c]: Adult: 2 g IV every 4–6 hours Pediatric[b]: 100–200 mg/kg per day IV in divided doses every 4–6 hours	β-Lactam allergy: Vancomycin
Ampicillin-resistant Vancomycin-resistant	Vancomycin Linezolid	
***Streptococcus* spp.**	Penicillin G[c]: Adult: 2–4 million units IV every 4–6 hours Pediatric[b]: 250,000–400,000 units/kg per day IV in divided doses every 4–6 hours	β-Lactam allergy: Vancomycin
Enterobacteriaceae	Third- or fourth-generation cephalosporin: Ceftriaxone[a] Adult: 1–2 g IV every 24 hours Pediatric[b]: 50–75 mg/kg per dose IV every 24 hours Cefotaxime[a,c]: Adult: 1–2 g IV every 8 hours Pediatric[b]: 50–200 mg/kg per day IV in divided doses every 8 hours Ceftazidime[c]: Adult: 1–2 g IV every 8 hours Pediatric[b]: 100–150 mg/kg per day IV in divided doses every 8 hours Cefepime[c]: Adult: 2 g IV every 8–12 hours Pediatric[b]: 50 mg/kg per dose IV every 8–12 hours Piperacillin/tazobactam[c]: Adult: 3.375 g IV every 4–6 hours **OR** 4.5 g IV every 6–8 hours Fluoroquinolones[e]: Ciprofloxacin[c] Adult: 400 mg IV every 12 hours; 500–750 mg oral twice daily Levofloxacin[c]: Adult: 500–750 mg IV/oral once daily Moxifloxacin[d]: Adult: 400 mg IV/oral once daily	Carbapenems: Imipenem/cilastatin[c] Adult: 500 mg IV every 6–8 hours Pediatric[b]: 60–100 mg/kg per day in divided doses every 6 hours Meropenem[c]: Adult: 1 g IV every 8 hours Pediatric[b]: 60–120 mg/kg per day in divided doses every 8 hours Ertapenem[c]: Adult: 1 g IV every 24 hours
P. aeruginosa	Antipseudomonal cephalosporin: Ceftazidime Cefepime Antipseudomonal fluoroquinolone[e]: Ciprofloxacin Levofloxacin	Piperacillin/tazobactam Carbapenems (only imipenem/cilastatin or meropenem)
Anaerobes	Clindamycin[d]: Adult: 600–900 mg IV every 8 hours 300–450 mg oral every 6–8 hours Pediatric[b]: 25–40 mg/kg per day IV in divided doses every 6–8 hours 10–30 mg/kg per day orally in divided doses every 6–8 hours Metronidazole[c,d]: Adult: 500 mg IV/oral every 8 hours Pediatric[b]: 30 mg/kg per day IV/oral in divided doses every 6–8 hours	

[a]Dosage adjustment necessary in patients with concomitant renal and hepatic dysfunction.
[b]Refer to specialized pediatric reference for maximum pediatric dose and neonatal recommendations and dosing.
[c]Dosage adjustment necessary in renal dysfunction.
[d]Dosage adjustment necessary in severe hepatic dysfunction.
[e]Fluoroquinolones: Not approved by the United States Food and Drug Administration for use in children except for anthrax (ciprofloxacin).
MRSA, methicillin-resistant *S. aureus;* MSSA, methicillin-sensitive *S. aureus*.

TABLE 78–3. Selective Toxicities and Drug Interactions Associated with Antimicrobials[6,12,17,18]

Antimicrobial	Adverse Events	Drug-Drug Interactions
β-Lactams Clindamycin	Hypersensitivity (rash, anaphylaxis) Nausea/vomiting (oral) Diarrhea (oral)	
Fluoroquinolones	Photosensitivity CNS disturbances (e.g., dizziness, confusion) particularly in the elderly QTc prolongation Use in children is generally avoided (assess individual patient risk versus benefit); studies conducted in immature dogs revealed signs of arthropathy	Separate administration from aluminum- or magnesium-containing antacids, calcium, iron, and carafate Ciprofloxacin is a moderate inhibitor of CYP1A2 Significant drug interactions may be seen with theophylline and methylxanthines
Linezolid	Myelosuppression: monitor CBC once weekly if more than 2 weeks of therapy Peripheral and/or optic neuropathy has been reported with long-term therapy	Mild MAO inhibitor; evaluate for potential drug-drug or drug-food interactions
Metronidazole	Nausea/vomiting Metallic taste	Refrain from using alcoholic beverages: potential for disulfiram-like reaction Substrate for CYP2C9 and inhibitor of CYP2C9, 3A3/4 and 3A5-7; potential interactions may include warfarin (enhanced prothrombin time) and lithium (increased concentrations)
Rifampin	Hepatic abnormalities: monitor LFTs Reddish-orange discoloration of secretions (e.g., urine, sweat, tears)	Potent inducer of CYP-mediated metabolism; evaluate for drug-drug interactions
TMP-SMX	Nausea/vomiting Myelosuppression: monitor CBC Hepatic abnormalities: monitor LFTs Rash including severe reactions such as Stevens-Johnson syndrome	Inhibitor of CYP2C9; evaluate for potential drug-drug interactions such as warfarin
Vancomycin	Infusion related toxicity (phlebitis, red man syndrome) Potential for additive renal toxicity if being coadministered with a nephrotoxic agent (e.g., aminoglycoside): monitor renal function (BUN/SCr) weekly in stable patients Consider vancomycin troughs to ensure therapeutic concentrations	

BUN, blood urea nitrogen; CBC, complete blood cell count; CNS, central nervous system; CYP, cytochrome P-450 isoenzyme; LFT, liver function test; MAO, monoamine oxidase; QTc, Q-T interval corrected for heart rate; SCr, serum creatinine; TMP-SMX, trimethoprim-sulfamethoxazole.

Patient Encounter, Part 4

The patient received 4 weeks of intravenous antimicrobial therapy following débridement. Due to clinical improvement, the physician contacts you for a recommendation for an oral antibiotic to complete a total of 6 weeks of therapy.

- What antimicrobial therapy would you recommend for this patient?
- Evaluate the patient's medication profile for drug-drug interactions.
- Counsel the patient regarding this drug therapy.

used in combination with another antibiotic in the treatment of chronic osteomyelitis, particularly in patients with foreign devices.[15,17,20]

❾ *The duration of treatment is typically 4 to 6 weeks for acute osteomyelitis.*[15] *Chronic osteomyelitis also requires 4 to 6 weeks of therapy; however, the total length of therapy should be counted after the date of the last major surgical intervention.*[8,15] Longer courses may be necessary for certain populations such as patients with vascular insufficiency.[3,6,10,16]

In addition to medical and surgical management, non-pharmacologic interventions that reduce risk factors for developing osteomyelitis should be communicated to the patient. Examples include smoking cessation, weight-control, exercise, and good nutrition.[2] Additionally, a diabetic patient

should be counseled regarding the necessity of controlled blood glucose, routine care and self-examination of lower extremities, and aggressive wound care.[10]

Outcome Evaluation

Therapeutic success is measured by the extent to which the care plan (1) resolves signs and symptoms, (2) eradicates the microorganism(s), (3) prevents relapses, and (4) prevents complications such as amputation. Patients should be evaluated for resolution of clinical signs and symptoms and normalization of laboratory tests (WBC, CRP, and ESR). Improvement in clinical manifestations should be seen within 48 to 72 hours of initiation of intravenous antimicrobial therapy.[10] A reduction in CRP should be seen within 1 week of therapy and should be monitored weekly throughout therapy for a continued downward trend. ESR can also be monitored weekly although normalization will be slower than for CRP. If poor response is noted, the following should be evaluated: (1) patient compliance, (2) significant drug-drug or drug-food interactions, (3) appropriate dosage to achieve therapeutic concentrations, (4) development of antimicrobial resistance, (5) need for additional imaging studies, and (6) diagnostic re-evaluation.[10] Due to high rates of relapse, patients should have medical follow-up for at least 1 year following resolution of symptoms.[10]

⑩ Patient Care and Monitoring

1. Assess the patient's symptoms and laboratory test results to determine if patient-directed therapy is appropriate.
2. Obtain a thorough history of prescription, non-prescription, and natural drug product use.
3. Educate the patient on lifestyle modifications that will reduce the risk of recurrent infections.
4. Develop a plan to assess the effectiveness of antimicrobial therapy.
5. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions (Table 78–3).
6. Stress the importance of adherence to the therapeutic regimen.
7. Provide patient education with regard to disease state and drug therapy. Explain the following:
   - Causes of osteomyelitis
   - Complications associated with osteomyelitis
   - The drug, dose, duration, and route of administration of the patient's antimicrobial regimen
   - Optimal medication administration time for the patient's lifestyle and other concurrent medications
   - Available options for missed dose(s)
   - Adverse effects that may occur
   - Provide patient education monographs for antibiotic(s)

79 Sepsis and Septic Shock

S. Scott Sutton

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Compare and contrast the definitions used for sepsis.
2. Identify the pathogens that cause sepsis.
3. Discuss the pathophysiology of sepsis as it relates to endotoxin, peptidoglycan, and pro- and anti-inflammatory mediators.
4. Identify patient symptoms as early or late sepsis and evaluate diagnostic and laboratory tests for patient treatment and monitoring.
5. Assess complications of sepsis and discuss their impact on patient outcomes.
6. Design desired treatment outcomes for septic patients.
7. Formulate a treatment and monitoring plan (pharmacologic and nonpharmacologic) for septic patients.
8. Evaluate patient response and devise alternative treatment regimens for non-responding septic patients.

Key Concepts

❶ Sepsis represents a continuum of physiologic stages that is defined by categories that describe the sepsis process.

❷ Gram-positive and gram-negative bacteria, fungal species, anaerobes, and viruses cause sepsis.

❸ Inflammation is the key factor in the development of sepsis. Patients with severe infections, trauma, debilitating conditions, or an immunocompromised status may experience an imbalance between inflammatory mediators that progresses to sepsis.

❹ The cumulative burden of sepsis complications is the leading factor of mortality. The risk of death increases 20% with failure of each additional organ. Severe sepsis averages two failed organs, with a mortality rate of 40%.

❺ Treatment is aimed at early goal-directed resuscitation; reducing or eliminating organ failures; treating and eliminating the source of infection; avoiding adverse reactions of treatment; and providing cost-effective therapy.

❻ Appropriate empiric anti-infective therapy decreases 28-day mortality. Appropriate therapy administered within 1 hour of the recognition of sepsis decreases complications and mortality.

❼ Drotrecogin alfa may be utilized for patients at a high risk of mortality, and is not utilized for patients at a low risk of mortality (as defined by APACHE II scores).

Sepsis is a continuum of physiologic stages characterized by infection, systemic inflammation, and hypoperfusion with widespread tissue injury.[1] ❶ The American College of Chest Physicians and the Society of Critical Care Medicine developed definitions to utilize for sepsis (Table 79–1).[2] ❶ They provide physiologic parameters categorizing patients as having: bacteremia, infection, systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis, septic shock, or multiple-organ-dysfunction syndrome (MODS).[2] Standardized definitions have been developed for infections in critically ill patients.[3]

EPIDEMIOLOGY AND ETIOLOGY

Sepsis is the leading cause of morbidity and mortality for critically ill patients, and the tenth leading cause of death overall.[1,4] Sepsis causes 660,000 to 750,000 cases annually, a four-fold increase from 1979.[1,4,5] Care of septic patients costs $17 billion in the United States annually ($22,000 to $50,000 per patient).[4,6]

❶ **TABLE 79–1. Definitions Related to Sepsis[2]**

Bacteremia (fungemia): Presence of viable bacteria or fungi in the bloodstream.
Infection: Inflammatory response to invasion of normally sterile host tissue by microorganisms.
Systemic Inflammatory Response Syndrome (SIRS): A systemic inflammatory response to a variety of clinical insults which can be infectious, but can have a noninfectious etiology. The response is manifested by two or more of the following conditions: temperature greater than 38°C (100.4°F) or less than 36°C (96.8°F); pulse greater than 90 beats/minute; respiratory rate greater than 20 breaths/minute or $PaCO_2$ less than 32 torr; WBC greater than 12,000 cells/mm^3, less than 4,000 cells/mm^3, or greater than 10% immature (band) forms.
Sepsis: The systemic inflammatory response syndrome and documented infection (culture or Gram stain of blood, sputum, urine, or normally sterile body fluid positive for pathogenic microorganisms
Severe sepsis: Sepsis associated with organ dysfunction, hypoperfusion, or hypotension (systolic blood pressure less than 90 mm Hg). Hypoperfusion and perfusion abnormalities may include, but are not limited to, lactic acidosis, oliguria, or acute alteration in mental status.
Septic shock: Sepsis with hypotension, despite fluid resuscitation, along with the presence of perfusion abnormalities. Patients who are on inotropic or vasopressor agents may not be hypotensive at the time perfusion abnormalities are measured.
Multiple-Organ Dysfunction Syndrome (MODS): Presence of altered organ function requiring intervention to maintain homeostasis.

$PaCO_2$, partial pressure of carbon dioxide; WBC, white blood cell count.

Risk factors for sepsis include: age, cancer, immunodeficiency, chronic organ failure, genetic factors (male, and nonwhite ethnic origin in North America), bacteremic patients, and polymorphisms in genes that regulate immunity.[4,7–10] Pulmonary, gastrointestinal, genitourinary, and bloodstream infections account for the majority of sepsis cases.[4,7,8]

❷ Gram-positive and gram-negative bacteria, fungal species, anaerobes, and viruses cause sepsis (Table 79–2). Gram-positive infections account for 30% to 50% of sepsis and septic shock cases.[4,7,8] The percentages of gram-negative, polymicrobial, and viral sepsis cases are 25%, 25%, and 4%, respectively.[4,7-8,11] Multi–drug resistant bacteria are responsible for approximately 25% of sepsis cases, are difficult to treat, and increase mortality.[7,8] The rate of fungal infections increased 200% from 1979 to 2000.[4] ❷ *Candida albicans* is the most common fungal species; however, non-albicans species (*C. glabrata*, *C. krusei*, and *C. tropicalis*) have increased from 24% to 46%.[4,11–12] Other fungi identified as causes of sepsis include *Cryptococcus*, *Coccidioides*, *Fusarium*, and *Aspergillus*.

PATHOPHYSIOLOGY

The development of sepsis is complex and multifactorial. The normal host response to infection is designed to localize and control bacterial invasion and initiate repair of injured tissue through **phagocytic** cells and inflammatory mediators.[1] Sepsis results when the inflammatory response becomes systemic and extends to normal tissue distant from the initial tissue site.

❷ **TABLE 79–2. Pathogens in Sepsis[4–7]**

Organism	Frequency (%)
Gram-positive bacteria	30–50
Methicillin-susceptible *Staphylococcus aureus*	14–24
Methicillin-resistant *S. aureus*	5–11
Other *Staphylococcus* species	1–3
Streptococcus pneumoniae	9–12
Other *Streptococcus* species	6–11
Enterococcus species	3–13
Anaerobes	1–2
Other gram-positive bacteria	1–5
Gram-negative bacteria	25–30
Escherichia coli	9–27
Pseudomonas aeruginosa	8–15
Klebsiella pneumoniae	2–7
Enterobacter species	6–16
Haemophilus influenzae	2–10
Anaerobes	3–7
Other gram-negative bacteria	3–12
Fungi	
Candida albicans	1–3
Other *Candida* species	1–2
Parasites	1–3
Viruses	2–4

Pro- and Anti-Inflammatory Mediators

❸ The key factor in the development of sepsis is inflammation. Inflammation is intended to be a local and contained response to infection or injury. Infection or injury is controlled through pro- and anti-inflammatory mediators. Proinflammatory mediators facilitate clearance of the injuring stimulus, promote resolution of injury, and are involved in processing of damaged tissue.[1,13–16] In order to control the intensity and duration of the inflammatory response, anti-inflammatory mediators are released that act to regulate proinflammatory mediators.[15–16] ❸ The balance between pro- and anti-inflammatory mediators localizes infection/injury of host tissue.[13–16] However, systemic responses ensue when equilibrium in the inflammatory process is lost.

The inflammatory process in sepsis is linked to the coagulation system. Pro-inflammatory mediators may be procoagulant and antifibrinolytic, whereas anti-inflammatory mediators may be fibrinolytic. A key factor in the inflammation of sepsis is activated protein C, which enhances fibrinolysis and inhibits inflammation. Protein C levels are decreased in septic patients.

CLINICAL PRESENTATION AND DIAGNOSIS

The clinical presentation of sepsis varies and the rate of development of clinical manifestations may differ from patient to

Clinical Presentation of Sepsis

The signs and symptoms of septic patients are referred to as early and late sepsis.

Signs and Symptoms

The initial clinical signs and symptoms represent early sepsis, and they include: fever, chills, and change in mental status. Other signs and symptoms include:

- **Tachycardia**
- **Tachypnea**
- Nausea and vomiting
- Hyperglycemia
- Myalgias
- Lethargy and malaise
- **Proteinuria**
- **Leukocytosis**
- **Hypoxia**
- **Hyperbilirubinemia**

Septic patients may have an elevated, low, or normal temperature. The absence of fever is common in neonates and elderly patients. Hypothermia is associated with a poor prognosis. Hyperventilation may occur before fever and chills and may lead to respiratory alkalosis. Disorientation and confusion may develop early in septic patients, particularly in the elderly and patients with preexisting neurologic impairment. Disorientation and confusion may be related to the infection or due to sepsis signs and symptoms (e.g., hypoxia).

Late sepsis represents a slow process that develops over several hours of hemodynamic instability. Signs and symptoms of late sepsis include:

- **Lactic acidosis**
- **Oliguria**
- **Leukopenia**
- **Thrombocytopenia**
- Myocardial depression
- Pulmonary edema
- Hypotension
- Hypoglycemia
- Gastrointestinal hemorrhage

Oliguria often follows hypotension because of decreased perfusion. Metabolic acidosis ensues because of diminished clearance by the kidneys and liver of lactic acid.

patient. Certain disease states or bacterial organisms may cause progression to late sepsis more rapidly; examples include patients with immunosuppression, meningococcemia, and *Pseudomonas aeruginosa* infections.

Physical Examination Results in Sepsis

HEENT: Scleral icterus, dry mucous membranes, pinpoint pupils, dilated and fixed pupils, nystagmus

Neck: Jugular venous distention, carotid bruits

Lungs: Crackles (rales), consolidation, egophony, absent breath sounds

CV: Irregular rhythm, S_3 gallop, murmurs

Abd: Tense, distended, tender, rebound, guarding, hepatosplenomegaly

Rectal: Decreased tone, bright red blood

Exts: Swollen calf, disparity of blood pressure between upper extremities

Neurologic: Agitation, confusion, delirium, obtundation, coma

Skin: Cold, clammy, or warm; hyperemic skin; rashes

Physical Examination

The physical examination should be performed rapidly and efficiently, with efforts directed toward uncovering the most likely cause of sepsis. The patient may or may not provide any medical history; therefore historical data may be obtained from medical records and/or family. The patient's medical condition, recent illnesses, infections, or activities may provide valuable information about the cause of sepsis.

Diagnostic and Laboratory Tests

Microbiologic cultures should be obtained before anti-infective therapy is initiated. However, cultures take 6 to 48 hours and may be negative (no growth of bacterial organisms). Negative cultures do not rule out infection.

Two sets of blood cultures should be obtained, because two sets of cultures are required to rule out contamination. At least one should be drawn percutaneously and one drawn through each vascular access device, unless the device was recently (less than 48 hours) inserted.

Cultures to obtain if clinical situation dictates:

- Urine culture and urinalysis, respiratory secretions, cerebrospinal fluid, wounds

Laboratory tests to evaluate infection or complications of sepsis:

- Complete blood count with differential
- Coagulation parameters

Patient Encounter, Part 1

A 67-year-old man with a history of chronic obstructive pulmonary disease presents to the emergency department with high fevers, shaking chills, severe chest pain, and shortness of breath. His family members state that he has been confused all day. He started having a severe cough 2 days ago, with excessive sputum production. He received doxycycline 100 mg twice daily for an upper respiratory tract infection 7 days ago.

- What information is suggestive of infection and/or sepsis?
- Does this patient have factors that could lead to the development of sepsis?
- What information do we need in order to confirm or diagnose sepsis in this patient?

- Basic metabolic panel
- Serum lactate concentration
- Arterial blood gas

Biomarkers of sepsis have been controversial. The routine use of endotoxin, procalcitonin, or other markers is not routinely recommend. Concentrations of procalcitonin in serum are usually increased in sepsis, but fail to differentiate between infection and inflammation. However, procalcitonin has a high negative predictive value and could allow for the discontinuation of antibiotics.

Complications of Sepsis

❹ Recognition and treatment of sepsis complications is essential for improving outcomes. The cumulative burden of sepsis complications is the leading factor of mortality. The risk of death increases 20% with failure of each additional organ. Severe sepsis averages two failed organs, with a mortality rate of 40%. The most common complications are: disseminated intravascular coagulation, acute respiratory distress syndrome, acute renal failure, and hemodynamic compromise.

Disseminated Intravascular Coagulation

❹ Disseminated intravascular coagulation (DIC) complicates 25% to 50% of septic patients, and is an independent predictor of mortality.[17] DIC is a syndrome characterized by coagulation and activation and production of pro-inflammatory **cytokines**, culminating in intravascular fibrin formation and deposition in the microvasculature. Bleeding results from consumption and exhaustion of coagulation proteins and platelets, because of continued activation of the coagulation system.[17] DIC may produce acute renal failure, hemorrhagic necrosis of the gastrointestinal mucosa, liver failure, acute pancreatitis, ARDS, and pulmonary failure.[17]

Acute Respiratory Distress Syndrome

❹ Acute respiratory distress syndrome (ARDS) is an acute and persistent lung inflammatory process with increased vascular permeability leading to severe hypoxia. ARDS can affect 20% of septic shock patients.[18–19] Lung deterioration is a multi-phase process that begins after infection, injury, or exacerbation of the medical condition. The patient appears stable; however, the chest radiograph reveals parenchymal infiltrates. At this time the patient has pulmonary edema and may be hyperventilating.[18–19] During the next phase the patient develops respiratory insufficiency and pulmonary edema can be seen on chest radiographs. Severe hypoxia may ensue, leading to mechanical ventilation.

Acute Renal Failure

❹ Acute renal failure (ARF) occurs in 19% of septic patients, 25% of severe septic patients, and 51% of septic shock patients.[20] Sepsis and acute renal failure have a 70% mortality, compared to 45% among patients with ARF alone.[20] ARF leads to fluid in the extravascular space, including the lungs, followed by impairment in gas exchange and severe hypoxemia. The hypoxemia will exacerbate ischemia and organ damage. Renal replacement therapy with the use of continuous venovenous hemofiltration and intermittent hemodialysis can be used to facilitate volume and electrolytes.[20]

Hemodynamic Compromise

❹ Arterial vasodilatation is the hallmark of hemodynamic effects related to sepsis. High cardiac output and low systemic vascular resistance characterize arterial vasodilation. Tumor necrosis factor-α (TNF-α) and endotoxin directly depress cardiovascular function. Persistent hypotension offsets the delivery of oxygen to tissues (D_{O_2}) and oxygen consumption by tissues (V_{O_2}).[21] Certain tissues may receive adequate oxygen during sepsis; however, in other tissues oxygen demands may not be met because of decreased perfusion. This perfusion defect is accentuated by increased precapillary atrioventricular shunt. If perfusion decreases, oxygen extraction increases, and the atrioventricular oxygen gradient widens. Cellular D_{O_2} is decreased, but V_{O_2} remains unchanged. If perfusion decreases significantly, reserve D_{O_2} will be exceeded, and tissue ischemia results. Tissue ischemia leads to organ failure. Therefore, increasing oxygen delivery or decreasing oxygen consumption in a hypermetabolic patient should optimize systemic D_{O_2} relative to V_{O_2}.[21]

TREATMENT AND OUTCOME EVALUATION

Desired Outcomes

❺ The primary treatment goal of sepsis is to prevent morbidity and mortality. Treatment is aimed at early goal-directed resuscitation; reducing or eliminating organ failures; treating and eliminating the source of infection; avoiding adverse reactions of treatment; and providing cost-effective therapy.[22–28]

General Approach to Treatment

The speed and appropriateness of therapy administered in the initial hours after sepsis develops influences outcome, as is the case for acute myocardial infarction and cerebrovascular accidents.[22]

Pertinent issues in the management of septic patients are (Fig. 79–1):[24]

1. Early goal-directed resuscitation of septic patients during the first 6 hours after recognition.
2. Early administration of broad-spectrum anti-infective therapy.
3. Activated protein C in patients with severe sepsis and high risk of death (Acute Physiology, Age, and Chronic Health Evaluation II [APACHE II] score greater than 25).
4. Hydrocortisone for septic shock patients refractory to resuscitation and vasopressors, with adrenal insufficiency.
5. Glycemic control via infusion of insulin and glucose to maintain a glucose level between 80 and 110 mg/dL (4.4 and 6.1 mmol/L).
6. Adjunctive therapies: nutrition, deep vein thrombosis prophylaxis, stress ulcer prophylaxis, and sedation for mechanically ventilated patients.

Pharmacologic Therapy

Treatment for sepsis focuses on infection, inflammation, hypoperfusion, and widespread tissue injury. Septic patients may require

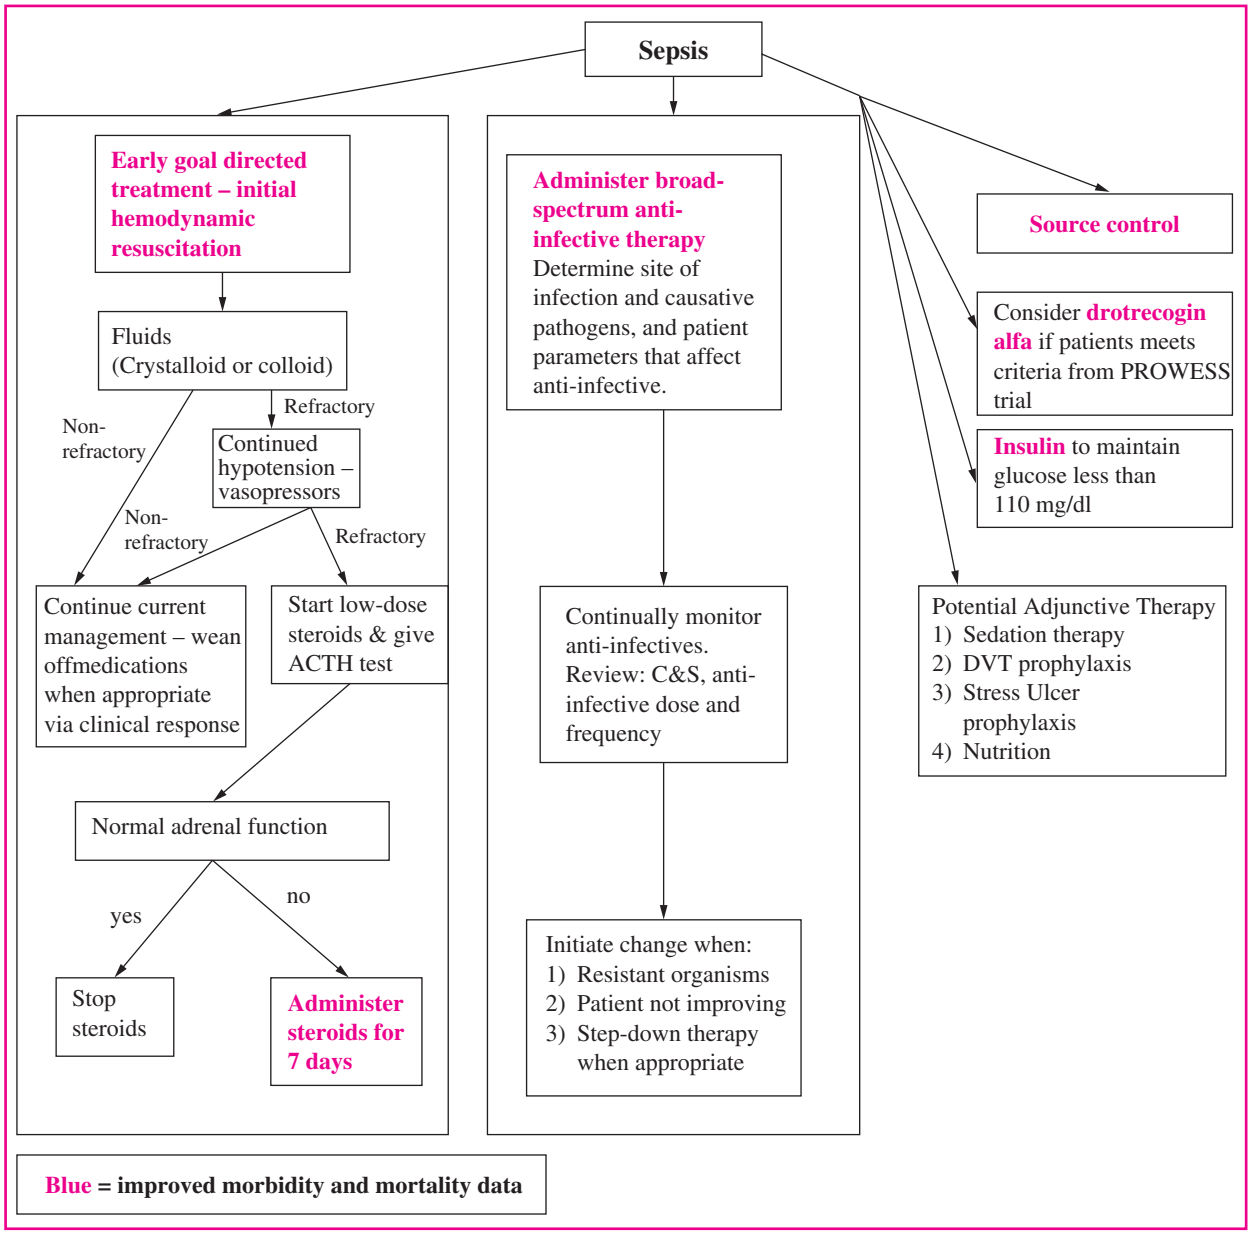

FIGURE 79–1. Therapeutic approach to sepsis. C&S, culture and sensitivity.

Patient Encounter, Part 2: The Medical History, Physical Exam, and Diagnostic Tests

PMH
Chronic obstructive pulmonary disease
Hypertension
Diabetes mellitus
Chronic renal insufficiency (baseline serum creatinine 1.6 mg/dL [141.44 µmol/L])

FH
Father had stroke at age 59; mother has history of hypertension and diabetes mellitus

SH
Construction worker; smoker with 35 pack-year history

Meds
No known drug allergies
Albuterol/ipratropium inhaler 2 puffs every 6 hours
Glipizide 10 mg once daily
Hydrochlorothiazide 25 mg once daily
Lisinopril 20 mg once daily

ROS
Unable to obtain; patient has become more confused

PE
VS: Blood pressure 87/53 mm Hg, pulse 97 bpm, respiratory rate 34/minute, temperature 39.3°C (102.7°F)
Lungs: decreased breath sounds

Labs
Serum creatinine 2.7 mg/dL (238.68 µmol/L); glucose 298 mg/dL (16.54 mmol/L); white blood cells: leukocytosis with left shift
Cultures: Blood, urine, and respiratory cultures pending
Radiology: Chest x-ray shows infiltrates in left lower lobe

- According to the patient's parameters what does he have (i.e., systemic inflammatory response syndrome, sepsis, or septic shock)?
- Identify treatment goals (nonpharmacologic and pharmacologic).

multiple simultaneous treatment regimens to achieve desired outcomes of decreased morbidity and mortality.

Initial Resuscitation

❺ Early goal-directed resuscitation decreases 28-day mortality in septic patients. The treatment goals of sepsis-induced hypoperfusion (hypotension or lactic acidosis) during the first 6 hours include:[24,27–29]

- Central venous pressure: 8 to 12 mm Hg (12 to 5 mm Hg for intubated patients)
- Mean arterial pressure greater than or equal to 65 mm Hg
- Urine output greater than or equal to 0.5 mL/kg per hour
- Central venous or mixed venous oxygen saturation greater than or equal to 70%

❺ Crystalloid or colloid fluids are used for resuscitation and clinical studies comparing the fluids found them to be equivalent.[29] Crystalloids require more fluids, which may lead to more edema (utilize caution in patients at risk for fluid overload, e.g., congestive heart failure and ARDS); however, colloids are significantly more expensive. Most patients require aggressive fluid resuscitation during the first 24 hours because of persistent venodilation and capillary leak.[24]

Monitoring parameters and alternative treatment for resuscitation:[24,27–29]

- An elevated serum lactate concentration may be an early marker for tissue hypoperfusion.
- Administer a fluid challenge to hypovolemic patients (hypotension or lactic acidosis): crystalloids 500 to 1,000 mL; colloids 300 to 500 mL. Administer over 30 minutes and repeat based on response (increase in blood pressure and urine output).
- Patients may require maintenance fluid therapy.

Anti-Infective Therapy

❻ Appropriate empiric anti-infective therapy decreases 28-day mortality compared to inappropriate empiric therapy (24% versus 39%).[22–23,30] ❻ Additionally, appropriate therapy administered within 1 hour of sepsis recognition also decreases complications and mortality.[22–23,30] Empiric anti-infective therapy should include one, two, or three drugs, depending on the site of infection and causative pathogens (Table 79–3). Anti-infective clinical trials in sepsis and septic shock patients are scarce and have not demonstrated differences among agents; therefore, factors that determine selection are:

- Site of infection
- Causative pathogens
- Community- or nosocomial-acquired infection
- Immune status of patient
- Antibiotic susceptibility and resistance profile for the institution
- Patient history (underlying disease, previous cultures or infections, and drug intolerance)
- Adverse reactions
- Cost

❻ Anti-infective regimens should be broad-spectrum since there is little margin for error in critically ill patients.

Monitoring and treatment strategies to maximize efficacy and minimize toxicity for anti-infectives:

- Administer broad-spectrum anti-infectives for initial therapy.
- Administer antibiotics that concentrate at the site of infection.
- Monitor patient parameters to ensure adequate dosing.

- Abnormal renal and hepatic function will increase drug concentration and predispose the patient to toxicity.
- Septic patients may have altered volume of distribution due to initial resuscitation.
- Re-evaluate the initial regimen in 48 to 72 hours by reviewing microbiologic and clinical data.
- Initiate step-down therapy based on microbiologic cultures to: prevent resistance and reduce toxicity and cost.
- Monotherapy is equivalent to combination therapy once a causative pathogen has been identified. Empiric therapy should include combination regimens to ensure coverage of causative organisms.

Selection of Antimicrobial Agents

Urinary Tract Infections

Septic patients with a community-acquired urinary tract infection should be treated with a third-generation cephalosporin or a fluoroquinolone. ❷ The causative pathogen is commonly a enteric gram-negative bacilli (i.e., *Escherichia coli*). ❷ Nosocomially-acquired urinary tract infections are often related to catheters and are caused by fermenting and nonfermenting (*Pseudomonas*) gram-negatives, and *enterococci* (see Table 79–3). β-Lactam/β-lactamase inhibitors (i.e., piperacillin-tazobactam), an antipseudomonal cephalosporin (i.e., cefepime or ceftazidime), or a carbapenem, plus an aminoglycoside are recommended treatment options (see Table 79–3).[31]

Clinical Parameters for Aminoglycosides

Tobramycin is more active against *Pseudomonas aeruginosa* than gentamicin, whereas gentamicin is more active against *Serratia* species. Amikacin is the most potent aminoglycoside against the Enterobacteriaceae; however, it should be reserved for bacterial organisms resistant to gentamicin and tobramycin. Select an aminoglycoside based on:

- Local sensitivity patterns
- Patient parameters (infection and microbiologic culture history)
- Cost

Aminoglycosides may be administered by traditional methods (1.5 to 2 mg/kg every 8 hours) or by an extended dosing interval method (4 to 7 mg/kg every 24 hours). The extended dosing method maximizes the pharmacodynamic properties of aminoglycosides (concentration-dependent killing and post-antibiotic effect) and reduces the incidence of nephrotoxicity. Extended dosing interval aminoglycosides have prolonged drug-free periods, during which the saturable uptake of aminoglycosides into the proximal renal tubular cells can be completed. Extended dosing interval aminoglycosides should not be used in pediatric patients, burn victims, pregnant patients, patients with preexisting or progressive renal insufficiency, or for synergy with gram-positive organisms.[32]

TABLE 79–3. Empirical Intravenous Antimicrobial Regimens in Sepsis[31,33–35,38–40]

Infection (Site or Type)	Community-Acquired	Hospital-Acquired
Urinary tract	Third-generation cephalosporin (ceftriaxone) **OR** Fluoroquinolone (levofloxacin or ciprofloxacin)	Antipseudomonal penicillin **OR** Antipseudomonal cephalosporin **OR** Antipseudomonal carbapenem plus aminoglycoside
Community-acquired pneumonia	Third-generation cephalosporin **plus** a macrolide or doxycycline	
Health care–associated, ventilator-asociated, or nosocomial pneumonia (Early onset; no risk factors for MDR pathogens)		Third-generation cephalosporin **OR** Fluoroquinolone **OR** Ampicillin-sulbactam **OR** Ertapenem
Health care–associated, ventilator-associated, or nosocomial pneumonia (Late onset and/or MDR pathogen risk factors)		Antipseudomonal penicillin **OR** Antipseudomonal cephalosporin **OR** Antipseudomonal carbapenem **plus** Aminoglycoside **OR** Antipseudomonal fluoroquinolone **plus** Vancomycin or linezolid
Intra-abdominal	Ampicillin-sulbactam **OR** Fluoroquinolone + metronidazole	Piperacillin-tazobactam **OR** Imipenem or meropenem **OR** Cefepime **plus** metronidazole **OR** Ciprofloxacin or levofloxacin **plus** metronidazole
Skin and soft tissue	Nafcillin or cefazolin	Ceftriaxone +/– vancomycin
Catheter-related		Vancomycin
Unknown source of infection		Antipseudomonal penicillin **OR** Antipseudomonal cephalosporin **OR** Antipseudomonal carbapenem **plus** Aminoglycoside **plus** Vancomycin

MDR, multi–drug resistant.

Community-Acquired Pneumonia

Septic patients with community-acquired pneumonia (CAP) are treated with a third-generation cephalosporin plus a macrolide or doxycycline, or a respiratory fluoroquinolone (see Table 79–3).[33] ❷ The causative organisms for CAP are *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and atypical organisms (*Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Legionella pneumophila*). *S. pneumoniae* accounts for 60% of the deaths associated with CAP, and is resistant to penicillin and macrolides (multi–drug resistant *S. pneumoniae*; MDRSP) 30% to 40% of the time.[33–34] Controversy exists relating to the clinical significance of this resistance for non-meningitis infections. Respiratory fluoroquinolones are indicated for MDRSP; however, clinical data have not shown them to be superior to cephalosporins plus a macrolide or doxycycline. The Centers for Disease Control and Prevention recommends reserving fluoroquinolones as last-line options in order to maintain their broad-spectrum antibacterial activity.[34]

Hospital-, Ventilator-, and Health Care–Associated Pneumonia

Treatment for septic patients with hospital-acquired, ventilator-acquired, and health care–associated pneumonia is dependent on risk factors for multi–drug resistant (MDR) organisms (Fig. 79–2). Recommended treatment for patients with no MDR risk factors are: third-generation cephalosporins, fluoroquinolones, ampicillin-sulbactam, or ertapenem (see Table 79–3).[35] Recommended treatment for patients with MDR risk factors are: β-lactam/β-lactamase inhibitors (piperacillin-tazobactam), antipseudomonal cephalosporin, or carbapenem, plus an aminoglycoside, plus vancomycin or linezolid (see Table 79–3).[35] If an aminoglycoside is undesirable, a antipseudomonal fluoroquinolone may be utilized with a β-lactam/β-lactamase inhibitor.

❷ Clinical Dilemma about Methicillin-Resistant *Staphylococcus aureus*

Methicillin-resistant *Staphylococcus aureus* (MRSA) is a common hospital-acquired pathogen and is also increasing in the community. MRSA has presented a problem in the past because it required treatment with vancomycin. Community-acquired MRSA presents a major therapeutic challenge. MRSA can cause pneumonia, cellulitis, and other infections. Clinicians should be aware of the rate of hospital and community MRSA in your geographic area. New treatment options are available for MRSA. They include linezolid, tigecycline, and daptomycin. Prospective clinical trials have not demonstrated benefits of these agents over vancomycin.[36–37]

Patient Encounter, Part 3

Treatment and Outcome Evaluation

The patient has continued hypotension despite previous intervention. Continued hypoxia has led to mechanical ventilation. The patient's serum creatinine has risen to 6.8 mg/dL. Blood cultures reveal gram-positive cocci and lactose-negative oxidase-positive gram-negative rods.

- Design a therapeutic regimen for this patient. Include all necessary medications.

Skin and Soft Tissue Infections

❷ Community-acquired skin and soft tissue infections are caused by *Streptococcus pyogenes* and *Staphylococcus aureus.* Treatment with nafcillin or cefazolin is recommended (see Table 79–3).[38] Soft tissue infections caused by *Streptococcus pyogenes* can lead to streptococcal toxic shock syndrome. Although penicillins and cephalosporins are efficacious, experimental models show clindamycin to be more effective than penicillin.[31] ❷ Hospital-acquired skin and soft tissue infections are caused by *Streptococcus pyogenes, Staphylococcus aureus,* and enteric gram-negatives. Recommended treatment is a third-generation cephalosporin, ampicillin-sulbactam, or ertapenem, plus vancomycin (see Table 79–3).[38]

Intra-Abdominal Infections

❷ Intra-abdominal infections are polymicrobial, including enteric aerobes and anaerobes. Patients with community-acquired infections of mild to moderate severity should be administered antibiotics with activity against enteric gram-negative bacilli, gram-negative anaerobes, and gram-positive cocci. Recommended treatment for mild to moderate community-acquired intra-abdominal infections are: ampicillin-sulbactam; cephalosporins plus metronidazole; fluoroquinolones plus metronidazole; and ertapenem (see Table 79–3).[39] Patients with nosocomial-acquired or high severity intra-abdominal infections or immunosuppression should receive empiric treatment with broad-spectrum antibiotics. Broad-spectrum antibiotics such as antipseudomonal β-lactam/β-lactamase inhibitors, carbapenems, antipseudomonal cephalosporins plus metronidazole, or antipseudomonal fluoroquinolones plus metronidazole are recommended (see Table 79–3).[39]

Antifungal Therapy

Septic patients not responding to conventional antibiotics should be evaluated for fungal infections. ❷ *Candida albicans* is the most common fungal species; however, the prevalence of non-albicans species is increasing. Amphotericin B is utilized in septic patients with fungal or suspected fungal infections

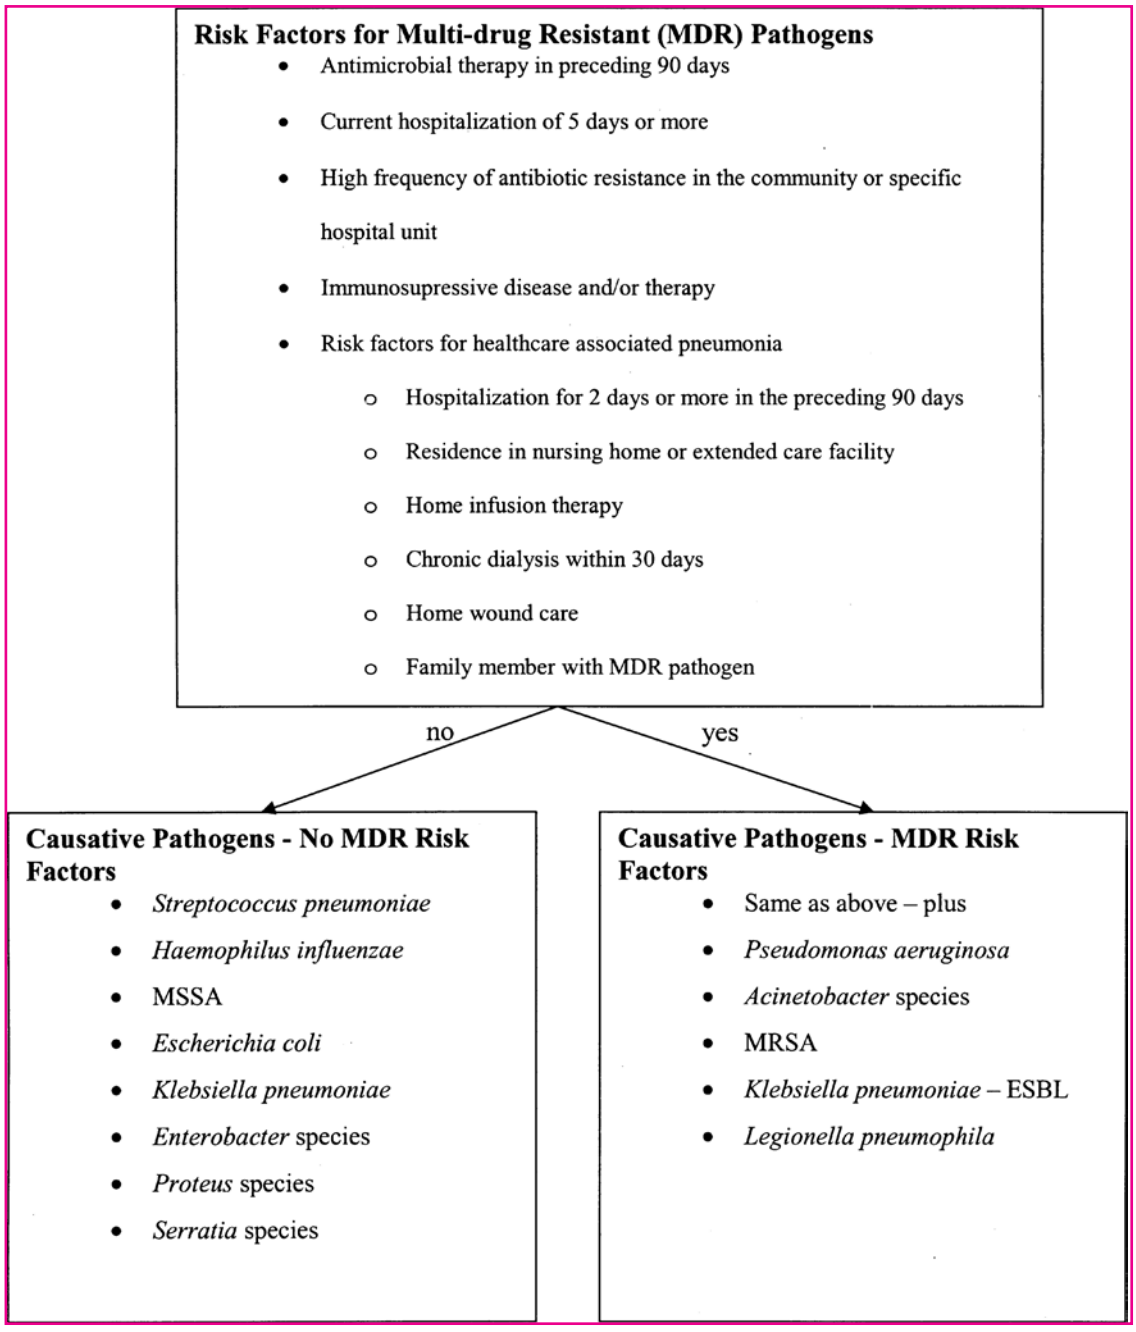

FIGURE 79–2. Risk factors for multi–drug resistant pathogens and causative pathogens for hospital-acquired, ventilator-acquired, and health care–associated pneumonia.[35] ESBL, extended spectrum β-lactamase; MDR, multi–drug resistant; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-sensitive *Staphylococcus aureus*.

because of greater activity against non-albicans *Candida* compared to fluconazole.[40] However, amphotericin B has a significantly higher rate of adverse reactions. Lipid formulations of amphotericin B are available that are less nephrotoxic and have decreased infusion-associated side effects. Efficacy among the amphotericin products is equivalent, but the lipid formulations are significantly more expensive. Lipid products are recommended for patients intolerant of conventional amphotericin. Other alternatives for treatment of fungal infections include voriconazole and echinocandins (caspofungin). Data are lacking that demonstrate clinical superiority between agents.

Duration of Therapy

Average duration of anti-infective therapy for septic patients is 7 to 10 days. However, the durations vary depending on the site of infection and response to therapy. Step-down therapy from intravenous to oral anti-infectives is recommended for:

- Hemodynamically stable patients
- Patients afebrile for 48 to 72 hours
- Patients with normalized white blood cell count
- Patients able to take oral medications

Clinical Controversy

Enterococcus species are normal inhabitants of the gastrointestinal tract, but should empiric treatment of intra-abdominal infections have activity against *Enterococcus* species? Empiric treatment that covered *Enterococcus* species in intra-abdominal infections was equivalent to empiric treatment that lacked enterococcal coverage. Routine coverage for *Enterococcus* is not necessary for patients with community-acquired intra-abdominal infections. However, in patients with nosocomial or high-severity infections, enterococcal coverage may be warranted.[39]

Vasopressors and Inotropic Therapy

When fluid resuscitation does not provide adequate arterial pressure and organ perfusion, vasopressors and/or intropic agents should be initiated. Vasopressors are recommended in patients with a systolic blood pressure less than 90 mm Hg or mean arterial pressure (MAP) lower than 60 to 65 mm Hg, after failed treatment with crystalloids.[24,27–28] Vasopressors and inotropes are effective in treating life-threatening hypotension and improving cardiac index, but complications such as tachycardia and myocardial ischemia require slow titration of the adrenergic agents to restore MAP without impairing stroke volume. Vasopressor therapy may also be required transiently to sustain life and maintain perfusion in the face of life-threatening hypotension, even when fluid resuscitation is in progress and hypovolemia has not yet been corrected. Agents commonly considered for vasopressor or inotropic support include dopamine, dobutamine, norepinephrine, phenylephrine, and epinephrine. Norepinephrine or dopamine are first-line vasopressors to correct hypotension in septic shock.[24,27–28]

Norepinephrine is a potent α-adrenergic agent with less pronounced β-adrenergic activity. Doses of 0.01 to 3 mcg/kg per minute can reliably increase blood pressure with small changes in heart rate or cardiac index. Norepinephrine is a more potent agent than dopamine in refractory septic shock.[24,27–28]

Dopamine is a α- and β-adrenergic agent with dopaminergic activity. Low doses of dopamine (1 to 5 mcg/kg per minute) maintain renal perfusion, higher doses (greater than 5 mcg/kg per minute) exhibit α- and β-adrenergic activity and are frequently utilized to support blood pressure and to improve cardiac function. Low doses of dopamine should not be used for renal protection as part of the treatment of severe sepsis.[24,27–28]

Dobutamine is a β-adrenergic inotropic agent that can be utilized for improvement of cardiac output and oxygen delivery. Doses of 2 to 20 mcg/kg per minute increase cardiac index; however, heart rate increases significantly. Dobutamine should be considered in septic patients with adequate filling pressure and blood pressure, but low cardiac index. If used in hypotensive patients, dobutamine should be combined with vasopressor therapy.[24,27–28]

Phenylephrine is a fast-acting, short-duration α_1 agonist. Phenylephrine has primarily vascular effects, and does not impair cardiac or renal function. Phenylephrine is useful when tachycardia limits the use of other vasopressors.[24,27–28]

Epinephrine is a nonspecific α- and β-adrenergic agonist. Epinephrine can increase cardiac index and produce significant peripheral vasoconstriction. However, it can also increase lactate levels and impair blood flow to the splanchnic system. Because of these undesirable effects, epinephrine should be reserved for patients who fail to respond to traditional therapies.[24,27–28]

Vasopressin levels are increased during hypotension to maintain blood pressure by vasoconstriction. However, there is a vasopressin deficiency in septic shock. Low doses of vasopressin increase MAP, leading to the discontinuation of vasopressors. However, routine use of vasopressin is not recommended because of lack of evidence of efficacy. Vasopressin is a direct vasoconstrictor without inotropic or chronotropic effects and may result in decreased cardiac output and hepatosplanchnic flow. Vasopressin use may be considered in patients with refractory shock despite adequate fluid resuscitation and high-dose vasopressors.[24,27–28]

Recombinant Human Activated Protein C

❼ Recombinant human activated protein C (drotrecogin alfa) is recommended for patients at a high risk of death (APACHE II score greater than or equal to 25, multiple organ failure, septic shock, or ARDS) and no absolute contraindications related to bleeding.[41] Drotrecogin alfa has antithrombotic, anti-inflammatory, and profibrinolytic properties. The Recombinant Human Activated Protein C Worldwide Evaluation in Severe Sepsis (PROWESS) trial evaluated the effects of a 96-hour continuous infusion of drotrecogin alfa. Drotrecogin alfa decreased 28-day mortality compared to placebo (30.8% versus 24.7%). A higher incidence of serious bleeding occurred during the 28-day period in the drotrecogin alfa group (3.5%) than in the placebo group (2.0%). An analysis of secondary endpoints suggested that the incidence of multiple organ dysfunction was lower in patients treated with drotrecogin alfa, and that therapy was associated with more rapid recovery of cardiac and pulmonary function. A second study of patients with severe sepsis (ENHANCE trial) noted that 28-day all cause mortality for patients treated with drotrecogin alfa was similar to that observed in PROWESS. ENHANCE also found that patients treated within the first 24 hours of their first sepsis-induced organ dysfunction had significantly lower mortality than those treated after 24 hours (22.9% to 27.4%). Cost-effectiveness models have found that for septic patients with a APACHE II score greater than or equal to 25, the cost per year of life saved with drotrecogin alfa is $24,000 to $27,000, suggesting that this is a cost-effective therapy in patients with severe sepsis and septic shock. The effect of drotrecogin alfa on long-term

survival was evaluated in a retrospective analysis of patients in PROWESS. The mortality benefit of drotrecogin alfa persisted up to hospital discharge; however, there were no mortality differences between drotrecogin alfa and placebo thereafter.[42]

❼ Drotrecogin alfa is not recommended for severe sepsis patients at low risk for death. The Drotrecogin Alfa (Activated) for Adults with Severe Sepsis and a Low Risk of Death (ADDRESS) trial evaluated the effects of a 96-hour continuous infusion of drotrecogin alfa. There were no statistically significant differences between drotrecogin alfa and placebo in 28-day mortality (18.5% versus 17.0%).[43] The rate of serious bleeding was higher for drotrecogin alfa during the 96-hour infusion and the 28-day study period.

Steroids

Stress-induced adrenal insufficiency complicates 9% to 24% of septic patients and is associated with increased mortality. Adrenal-insufficient patients are identified by a adrenocorticotropic hormone (ACTH) stimulation test. Patients are given 250 mcg ACTH and a cortisol level is checked within 30 to 60 minutes. Responders are defined as a greater than 9-mcg/dL increase in cortisol and non-responders as a less than 9-mcg/dL increase in cortisol. Septic shock patients refractory to resuscitation and vasopressors, and with adrenal insufficiency (non-responders to the ACTH test) should be administered intravenous hydrocortisone 200 to 300 mg per day in three divided doses for 7 days.[24,44]

Sedation and Neuromuscular Blockade

Patients with progressive hypoxia leading to ARDS require mechanical ventilation. Critically ill patients may require sedation when high ventilator settings are used or when patients fight the ventilator. Mechanically ventilated patients should receive sedation by a protocol that includes a daily interruption or lightening of a sedative infusion until the patient is awake.[24] The utilization of sedation protocols decreases the duration of mechanical ventilation, length of hospitalization, and tracheostomy rates.

Paralysis usually is reserved for cases in whom sedation alone does not improve the effectiveness of mechanical ventilation. Neuromuscular blockers may lead to prolonged skeletal muscle weakness and should be avoided if possible. Patients requiring neuromuscular blockade are to be monitored and intermittent boluses should be utilized.

Patient Encounter, Part 4

During medical rounds, you are asked to discuss clinical trials.

- What antibiotics are found to be superior in septic patients?
- What are the results of the PROWESS and ADDRESS trials?
- Is this patient a candidate for drotrecogin alfa?

Glucose Control

Glycemic control improves survival in postoperative surgical patients and is recommended in septic patients. Following initial stabilization of septic patients, maintain blood glucose levels between 80 and 110 mg/dL (4.4 and 6.1 mmol/L).[24,45] Septic patients with high glucose levels should receive insulin and glucose with frequent blood glucose monitoring (every hour initially, then every 2 to 4 hours once glucose levels have stabilized).

Adjunctive Therapies

Enteral nutrition is recommended in septic patients to meet the increased energy and protein requirements. Protein requirements are increased to 1.5 to 2.5 g/kg per day. Nonprotein caloric requirements range from 25 to 40 kcal/kg per day.[24]

Deep vein thrombosis prophylaxis is recommended for septic patients. Low-dose unfractionated heparin or low-molecular-weight heparin may be utilized. Graduated compression stockings or an intermittent compression device is recommended for patients with a contraindication to heparin products (thrombocytopenia, severe coagulopathy, active bleeding, or recent intracerebral hemorrhage).[24]

Stress ulcer prophylaxis is recommended in septic patients. Patients at greatest risk for stress ulcers are: coagulopathic, mechanically ventilated, and hypotensive. Histamine-receptor antagonists are more efficacious than sucralfate, and proton pump inhibitors have not been compared to histamine-receptor antagonists. However, they do demonstrate equivalence in the ability to increase gastric pH.[24]

Nonpharmacologic Therapy

❺ Evaluate septic patients for the presence of a localized infection amenable to source control measures. Common source control measures include:[24–26]

- Drainage and débridement
- Device removal
- Prevention

❺ Implementation of source control methods should be instituted as soon as possible following initial fluid resuscitation. The selection of optimal source control methods must weigh benefits and risks of the intervention. Source control measures may cause complications (bleeding, fistulas, and organ injury), therefore the method with the least risk should be employed.[24]

Prognosis

Short-term mortality from sepsis has decreased in recent years. There are various factors that influence outcome. Gram-negative bacteria are more likely to produce septic

Patient Care and Monitoring

1. Evaluate patient parameters and classify as infection, SIRS, sepsis, severe sepsis, septic shock, or MODS.
2. Review available diagnostic and laboratory data.
3. Evaluate early goal-directed resuscitation therapy. Understand what parameters define efficacy and failure of initial therapy. Recommend alternative resuscitation therapy if the patient does not respond to initial fluid challenge.
4. Evaluate the source of infection and make recommendations to remove potential source(s).
5. Analyze anti-infective therapy (dose, frequency, and duration) and revise as necessary based on clinical response and culture and sensitivity reports. Prepare an appropriate step-down therapy for the patient.
6. Determine the risk of sepsis complications and construct recommendations for treatment and monitoring.
7. Formulate appropriate doses of medications involved in patient therapy and revise as needed. Patient parameters may change frequently, thus requiring different doses and/or medications. Examples include: antibiotic therapy, sedatives, insulin, fluids, or vasopressors.
8. Continually monitor patient parameters to ensure optimal therapy to maximize outcomes.

shock than gram-positive bacteria (50% versus 25%) and have a higher mortality than other pathogens. This may be related to the severity of the underlying condition. Patients with rapidly fatal conditions, such as leukemia, aplastic anemia, and burn patients have a worse prognosis than patients with nonfatal underlying conditions, such as diabetes mellitus or chronic renal insufficiency. Other factors that worsen the prognosis of septic patients are: advanced age, malnutrition, resistant bacteria, utilization of medical devices, and immunosuppression. Data for long-term mortality are lacking (it is estimated that the mortality for sepsis survivors within the first year is 20%).[5] Patients may have prolonged physical disability related to muscle weakness and post-traumatic stress.

CONCLUSION

Sepsis is a leading cause of morbidity and mortality and has a significant financial impact in our health care system. Treatment for sepsis should begin as soon as sepsis is recognized and key therapeutic priorities are:

- Provide supportive measures that counter physiologic abnormalities such as hypoxemia, hypotension, and impaired tissue oxygenation.
- Focus efforts on distinguishing sepsis from systemic inflammatory response syndrome, since identification and treatment of an infection should be initiated as soon as possible (with antibiotics or surgical drainage).

Septic patients must be monitored closely in order to assess their response to therapy. A combination of clinical and laboratory tests should be evaluated daily and decompensating patients should be rapidly and thoroughly re-evaluated.

ABBREVIATIONS

ACTH:	adrenocorticotropic hormone
APACHE II:	Acute Physiology, Age, and Chronic Health Evaluation II
ARDS:	acute respiratory distress syndrome
ARF:	acute renal failure
CAP:	community-acquired pneumonia
DIC:	disseminated intravascular coagulation
Do_2:	delivery of oxygen to tissues
ESBL:	extended spectrum β-lactamase
MAP:	mean arterial pressure
MDR:	multi–drug resistant
MDRSP:	multi–drug resistant *Streptococcus pneumoniae*
MODS:	multiple-organ-dysfunction syndrome
MRSA:	methicillin-resistant *Staphylococcus aureus*
MSSA:	methicillin-sensitive *Staphylococcus aureus*

80 Superficial Fungal Infections

Lauren S. Schlesselman

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Explain the underlying pathophysiology of vulvovaginal candidiasis, oropharyngeal candidiasis, esophageal candidiasis, and fungal skin infections.
2. Identify symptoms of vulvovaginal candidiasis, oropharyngeal candidiasis, esophageal candidiasis, and fungal skin infections.
3. Identify the desired therapeutic outcomes for patients with uncomplicated and complicated vulvovaginal candidiasis, oropharyngeal candidiasis, esophageal candidiasis, and fungal skin infections.
4. Recommend appropriate lifestyle modifications and pharmacotherapy interventions for patients with vulvovaginal candidiasis, oropharyngeal candidiasis, esophageal candidiasis, and fungal skin infections.
5. Recognize when long-term suppressive therapy is indicated for a patient with vulvovaginal candidiasis.
6. Recognize when topical versus oral treatment is indicated for a patient with oropharyngeal candidiasis, esophageal candidiasis, and fungal skin infections.
7. Educate patients about the disease state, appropriate lifestyle modifications, and medication therapy required for effective treatment of vulvovaginal candidiasis, oropharyngeal candidiasis, esophageal candidiasis, and fungal skin infections.

Key Concepts

❶ The predominant pathogen associated with vulvovaginal candidiasis is *Candida albicans*, although a small percentage of cases are caused by *Candida glabrata, Candida tropicalis, Candida krusei,* and *Candida parapsilosis.*

❷ A variety of factors may increase the risk of developing symptomatic vulvovaginal candidiasis, including antibiotic use, diabetes, and immunosuppression. No risk factors are consistently associated with all cases of vulvovaginal candidiasis.

❸ Asymptomatic vaginal colonization of *Candida albicans* is not diagnostic of vulvovaginal candidiasis since 10% to 20% of women are asymptomatic carriers of *Candida* species. Asymptomatic vaginal colonization does not require treatment.

❹ Selection of antifungal agents to treat uncomplicated vulvovaginal candidiasis is influenced by patient preference, including route of administration, duration of therapy, cost, risk of adverse effects, and potential for medication interactions.

❺ Recurrent vulvovaginal candidiasis, defined as four or more infections per year, requires long-term suppressive therapy for 6 months.

❻ The occurrence of oropharyngeal and esophageal candidiasis is an indicator of immune suppression, often developing in infants, the elderly, and the immunocompromised.

❼ Topical agents are first-line therapy for oropharyngeal candidiasis, although oral agents may be used for severe or unresponsive cases.

❽ Representing a severe form of extension of oropharyngeal candidiasis, esophageal candidiasis requires oral antifungal therapy.

❾ Since dermatophyte hyphae seldom penetrate into the living layers of the skin, instead remaining in the stratum corneum, most infections can be treated with topical antifungals. Infections

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

covering large areas of the body or infections involving nails or hair may require oral therapy.

⑩ Onychomycosis, fungal infections involving the nails, requires oral antifungal therapy. Topical agents do not adequately penetrate the nail.

VULVOVAGINAL CANDIDIASIS

Vulvovaginal candidiasis (VVC), whether symptomatic or asymptomatic, refers to infections in women whose vaginal cultures are positive for *Candida* species.

Epidemiology and Etiology

Vulvovaginal candidiasis, also known as moniliasis, is a common form of vaginitis, accounting for 20% to 25% of vaginitis cases. Although VVC is uncommon prior to **menarche**, nearly 50% of women will experience one or more episodes by the age of 25 years.[1] A survey of women in the United States found that 6.5% of women over the age of 18 years reported experiencing at least one episode of vaginitis during the previous 2 months.[2]

According to the treatment guidelines of the Centers for Disease Control and Prevention (CDC),[3] VVC can be classified as uncomplicated or complicated. Uncomplicated infections are typically infrequent and cause mild to moderate symptoms. Complicated infections, including recurrent or severe infections, may be caused by azole-resistant fungal organisms. Immunocompromise, including immunosuppression, uncontrolled diabetes, pregnancy, or debilitation, is a risk factor for developing recurrent infection. Recurrent VVC, defined as four or more infections per year, occurs in less than 5% of women.[4] Recurrent infection is distinguishable from a persistent infection by the presence of a symptom-free interval between infections.

Pathophysiology

❶ *Candida albicans* is the primary pathogen responsible for vulvovaginal candidiasis, accounting for more than 90% of cases.[5] A small percentage of cases are caused by non-albicans species including *Candida glabrata, Candida tropicalis, Candida krusei,* and *Candida parapsilosis*. In patients with recurrent vaginitis, the causative *Candida* is twice as likely to be non-albicans.[6] Some research suggests that the incidence of non-albicans VVC is increasing, possibly due to overuse of over-the-counter vaginal antifungal products, short-course treatments, and long-term suppressive therapy with antifungals.[7]

Risk Factors

❷ *Although no risk factors are consistently associated with conversion to symptomatic infection, a variety of factors may*

Patient Encounter, Part 1

A 28-year-old woman with a history of diabetes presents to your clinic complaining of what she calls "itching in my private areas." After questioning her, you determine that she has vaginal burning and itching, accompanied by a curd-like discharge. On examination, she has erythema of the labia and a non-odorous discharge.

- What information is suggestive of VVC?
- What additional information do you need to know before creating a treatment plan for this patient?

Clinical Presentation and Diagnosis of Vulvovaginal Candidiasis

Patients with vulvovaginal candidiasis may present with vulvar and/or vaginal symptoms. Symptoms often develop the week before menses and resolve with the onset of menses.
Symptoms include:

- Itching
- Soreness
- Burning
- Irritation
- External dysuria
- **Dyspareunia**

Signs include:

- Non-odorous discharge (may vary from watery to curd-like)
- Erythema and edema of the labia and vulva
- Fissures
- Pustulopapular lesions
- Normal cervix

Diagnostic Testing

- Microscopic investigation for the presence of **blastospores** or **pseudohyphae**; saline wet mount has a sensitivity of 40% to 50%, while a potassium hydroxide (KOH) preparation has a sensitivity of 50% to 70%.[7] ❸ *Asymptomatic vaginal colonization of* Candida albicans *is not diagnostic of VVC since 10% to 20% of women are asymptomatic carriers of* Candida *species. Asymptomatic vaginal colonization does not require treatment; therefore the presence alone of* Candida *should not determine care.*
- Vaginal pH less than or equal to 4.5; pH should remain normal in cases of fungal infection, while an elevated pH suggests bacterial infection.
- *Candida* cultures should be obtained only if signs and microscopy are inconclusive or in cases of recurrent VVC.

TABLE 80–1. Possible Risk Factors Associated with Vulvovaginal Candidiasis (VVC)

Risk Factor	Proposed Mechanism
Broad-spectrum antibiotic use	Altered vaginal flora allowing overgrowth of *Candida* organisms; risk increases with duration of antibiotic use
Systemic corticosteroid or immunosuppressant use	Reduced vaginal protection by immunoglobulins
Sexual activity	A small percentage of male partners have penile or oral colonization of identical strains; VVC is often associated with the onset of sexual activity
Tight-fitting and non-absorbent clothing	Promotes warm, moist environment for fungus growth
Elevated estrogen levels, hormonal contraceptives, and pregnancy	Estrogen enhances *Candida* adherence to vaginal epithelial cells and yeast-mycelial transformation; this is supported by the fact that infection rates are lower before menarche and after menopause (except in women taking hormone replacement therapy), while rates are higher during pregnancy
Vaginal pH	Changes in glycogen and lactic acid levels
Gastrointestinal reservoir of *Candida* organisms	Transfer of organism from rectum to vagina; irritation of the vulvovaginal area during sexual intercourse may enhance invasion of organisms
Diabetes	Enhanced binding of *Candida* to epithelial cells due to hyperglycemia; asymptomatic colonization is more common in patients with diabetes; elevated sugar levels may cause conversion to symptomatic infection

increase the risk of developing symptomatic VVC in certain women (Table 80–1).

Treatment

The goals of treatment of VVC are:

- Relief of symptoms
- Eradication of infection
- Re-establishment of normal vaginal flora
- Prevention of recurrent infections in complicated infections

Nonpharmacologic Treatments

In combination with pharmacologic treatment, the practitioner should recommend basic nonpharmacologic approaches to treatment and prevention of VVC:

- Keep the genital area clean and dry
- Avoid prolonged use of hot tubs
- Avoid constrictive clothing
- Wear underwear made of breathable materials, such as cotton
- To reduce vulvar irritation, avoid soaps and perfumes in the genital area
- Although study results are conflicting, the daily consumption of active *Lactobacillus acidophilus* may reduce recurrence. One study found that the daily ingestion of 8 ounces of yogurt produced a threefold reduction in the incidence of infection,[8] while other studies found no difference in infection rates in women who ingested yogurt.[9,10]

Pharmacologic Treatment of Uncomplicated VVC

Most cases of uncomplicated VVC will resolve with a single course of antifungal therapy. Treatment with an oral or vaginal antifungal agent, either prescription or nonprescription, is appropriate for most uncomplicated cases. Nonprescription azole antifungal products are available as 1-night, 3-night, and 7-night regimens in a variety of formulations, including cream, suppository, and vaginal tablets (Table 80–2).

To avoid inappropriate use of over-the-counter (OTC) products, the practitioner should only recommend them to women who have previously been diagnosed with VVC. Estimates of how

TABLE 80–2. Treatment Options for Uncomplicated VVC

1-Day Therapies
Butoconazole 2% sustained-release cream, 5 g intravaginally as a single application
Fluconazole 150 mg, one tablet orally as a single dose
Tioconazole 6.5% ointment, 5 g intravaginally as a single application

3-Day Therapies
Butoconazole 2% cream, 5 g intravaginally for 3 nights
Clotrimazole 100-mg vaginal tablet, two tablets for 3 nights
Miconazole 200-mg vaginal suppository, one suppository for 3 nights
Terconazole 0.8% cream, 5 g intravaginally for 3 nights
Terconazole 80-mg vaginal suppository, one suppository for 3 nights

7 to 14-Day Therapies
Clotrimazole 1% cream, 5 g intravaginally for 7–14 nights
Clotrimazole 100-mg vaginal tablet, one tablet for 7 nights
Miconazole 2% cream, 5 g intravaginally for 7 nights
Miconazole 100-mg vaginal suppository, one suppository for 7 nights
Nystatin 100,000-unit vaginal tablet, one tablet for 14 nights
Terconazole 0.4% cream, 5 g intravaginally for 7 nights

accurately women self-diagnose VVC are difficult to assess. One study found that only one-third of women accurately diagnosed an episode of vaginitis.[11] Women with a previous clinically based diagnosis of VVC are no more accurate at self-diagnosing than women without prior clinical diagnosis.[11]

❹ *Due to the numerous treatment options available, a variety of factors can influence product selection, with patient preference playing a significant role.* To improve adherence with therapy, the practitioner should discuss with the patient what options are available and what her preferences are.

Route of Administration

Adherence rates are greater with oral treatment than with vaginal therapy. This may be due to the ease of administration, short duration, and flexibility on time of administration. Vaginal creams provide rapid relief of itching and burning. The need to clean the vaginal applicator for reuse is unappealing for some women. Many OTC vaginal products are now packaged with sufficient disposable applicators to prevent the need for reuse with subsequent doses.

Duration of Therapy

Available regimens range from 1 to 7 days. Cure rates are similar among different durations of therapy.[12]

Cost

Most OTC products cost $10 to $20 per course of therapy. The cost of prescription products can vary based on if and what type of insurance coverage the patient has.

Risk of Adverse Effects

Systemic adverse effects associated with vaginal azoles are less frequent than with oral products. Local discomfort such as burning may occur with the first application. Fifteen percent of patients experience gastrointestinal side effects with orally administered antifungal agents.[13] Oral ketoconazole is associated with hepatic toxicity at a rate of 1 in 15,000.[14]

Risk of Medication Interactions

Oral azoles are associated with significant interactions, particularly due to cytochrome P-450 isoenzymes. Medications that interact with azoles include warfarin, phenytoin, theophylline, rifampin, cyclosporine, and zidovudine. For patients receiving only a few doses, these interactions do not pose a significant risk. These interactions may pose a risk for patients receiving long-term suppressive therapy for recurrent infections.

Inability to resolve an infection may indicate a mixed infection, infection due to a non-albicans strain, or an infection that is not fungal. Difficulty treating VVC can also be indicative of serious underlying conditions, such as diabetes or human immunodeficiency virus (HIV) infection. For these reasons, if infection does not resolve easily with a single course of antifungal therapy or if symptoms return within 2 months, practitioners should check cultures and further evaluate the patient's health status or refer the patient to a physician.

Treatment of Recurrent VVC

The goal of treating recurrent VVC is control of the infection, rather than cure. First, any acute episodes are treated, followed by maintenance therapy. For the treatment of acute episodes, intravaginal or oral azoles can be utilized. Although acute episodes of recurrent VVC will respond to azole therapy, some patients may require prolonged therapy in order to achieve remission. To achieve remission, a second dose of oral fluconazole 150 mg repeated 3 days after the first dose or 14 days of topical azole therapy can be used. The practitioner should consider that non-albicans infections are more common in recurrent VVC; therefore fluconazole and itraconazole resistance may make these agents less effective.

❺ *After achieving remission, recurrent VVC requires long-term suppressive therapy for 6 months* (Table 80–3). To improve adherence to long-term suppressive therapy, oral therapy, typically with fluconazole, is preferred. Studies have shown that fluconazole 150 mg weekly for 6 months will prevent recurrence of infection in 90% of women.[15] Cessation of suppressive therapy is associated with resurgence of symptomatic infection in 50% of women.[16]

Treatment of Non-Albicans Infections

Response rates are lower for non-albicans infections. Although an optimal regimen is unknown, use of intravaginal azole therapy for 7 to 14 days is recommended. Terconazole may prove more effective than other azoles in the treatment of non-albicans infections since *C. glabrata* and *C. tropicalis* are more susceptible to terconazole.[17] For second-line therapy, boric acid 600 mg in a gelatin capsule administered vaginally twice daily for 2 weeks followed by once daily during menstruation is effective.[18] Local irritation often limits the use of boric acid. Topical 4% flucytosine is also effective but use should be limited due to the potential for resistance.

VVC during Pregnancy

During pregnancy, VVC may prove difficult to treat due to elevated estrogen levels, accompanied by concern about harm to the fetus. Response rates are lower and recurrences are frequent during pregnancy. Vaginal antifungals remain the preferred treatment during pregnancy, although therapy should continue for 1 to 2 weeks to ensure effectiveness.[16] Most topical

TABLE 80–3. Treatment Options for Maintenance Therapy

Daily
Boric acid 600 mg in gelatin capsule vaginally daily during menses (5 days)
Itraconazole 100 mg orally once daily
Ketoconazole 100 mg orally once daily
Weekly
Clotrimazole 500 mg vaginal suppository once weekly
Fluconazole 100 or 150 mg orally once weekly
Terconazole 0.8% cream 5 g vaginally once weekly
Monthly
Fluconazole 150 mg orally once monthly
Itraconazole 400 mg orally once monthly

Patient Care and Monitoring

1. Assess the patient's symptoms to determine if self-treatment with OTC antifungal therapy is appropriate or whether the patient should be evaluated by a practitioner or physician. OTC preparations should only be recommended for patients who have previously been diagnosed with VVC. Patients who experience more than four episodes per year should be referred to a physician for culturing and initiation of maintenance therapy.
2. Review any available diagnostic data, including cultures and KOH preps.
3. Obtain a thorough history of prescription, nonprescription, and natural drug product use. Is the patient taking any medications, such as steroids or immunosuppressants, that may contribute to VVC? Is the patient taking any medications that may interfere with treatment?
4. If the patient has had VVC previously, determine what treatments were helpful to the patient in the past.
5. Educate the patient on lifestyle modifications that may prevent recurrence, including decreased consumption of sucrose and refined carbohydrates, increased consumption of yogurt containing live cultures, and wearing cotton underwear.
6. Develop a plan to assess effectiveness of antifungal therapy.
7. Determine if long-term suppressive therapy is necessary.
8. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.
9. Stress the importance of adherence with the antifungal regimen, including lifestyle modifications.
10. Provide patient education pertaining to vulvovaginal candidiasis and antifungal therapy.
    - Causes of vulvovaginal candidiasis
    - How to administer vaginal antifungal creams
    - Vaginal antifungal creams' and suppositories' adverse effects on latex condoms and diaphragms
    - Potential adverse effects that may occur with antifungal therapy
    - Medications which may interact with antifungal therapy
    - Warning signs to report to a physician (recurrent or difficult-to-cure infections, infections with malodorous discharge)

antifungals are classified as risk category C, while clotrimazole is classified as risk category B. The primary reason for the risk category C classification is the lack of studies, rather than increased risk. Fluconazole is also classified as risk category C. Despite oral fluconazole's classification, studies have not demonstrated an increased risk to the fetus when the pregnant mother was exposed to fluconazole,[19,20] although case studies have reported congenital limb deformities.[21]

Outcome Evaluation

Patients should notice relief of itching and discomfort within 1 to 2 days. The volume of discharge should also begin to decrease within a few days. The entire course of therapy should be continued even if symptoms have resolved. If the condition does not resolve or worsens, the patient should be referred to a physician for aggressive therapy. If the condition recurs within 4 weeks or more than four times per year, the patient should be further evaluated or referred to a physician for evaluation of possible non-*Candida* infections, resistant organism, or other complicating factors, along with assessment of need for long-term suppressive therapy.

OROPHARYNGEAL AND ESOPHAGEAL CANDIDIASIS

Oropharyngeal candidiasis (OPC) is a common fungal infection, usually associated with immune suppression. If left untreated, it will progress to more serious oral disease. Esophageal candidiasis, representing a serious progression of oropharyngeal candidiasis, is associated with increased morbidity.

Epidemiology and Etiology

❻ *The occurrence of oropharyngeal and esophageal candidiasis is an indicator of immune suppression, often developing in infants, the elderly, and the immunocompromised.* One-third to one-half of geriatric inpatients develop oropharyngeal candidiasis. Denture stomatitis is present in 24% to 60% of denture wearers,[22] more commonly in women than men. Oral candidiasis is the most commonly reported adverse drug event reported by patients receiving inhaled corticosteroids.[23] Recent studies have reported the prevalence of esophageal candidiasis as 37% among patients treated with inhaled corticosteroids.[24] The incidence is highest among patients receiving high doses of corticosteroids or those with diabetes.

The prevalence of HIV infection plays a significant role in the incidence of oropharyngeal and esophageal candidiasis. In the 1980s, the incidence of oropharyngeal candidiasis increased fivefold, in association with the spread of HIV infections.[25] Although HIV infection remains a risk factor for candidiasis, the introduction of highly active antiretroviral therapy precipitated a decline in the incidence of both infections by 50% to 60%.[26]

Oropharyngeal candidiasis remains the most common opportunistic infection in patients with HIV. Eighty to ninety percent of HIV-positive patients develop oropharyngeal candidiasis.[27] For 70% of these patients, it is the first manifestation of HIV infection.[28] The incidence of oropharyngeal infection increases with decreasing CD4 lymphocyte counts, with an incidence of 60% in patients with a CD4 count less than 200 cells/mm^3.

Although esophageal candidiasis represents the first manifestation of HIV infection in less than 10% of cases, it is the second most common acquired immunodeficiency syndrome (AIDS)-defining disease.[29] As with oropharyngeal candidiasis, the incidence of esophageal candidiasis increases with decreasing CD4 counts.

Pathophysiology

Candida albicans accounts for 80% of cases of OPC and esophageal candidiasis. Over the last 20 years, an increasing incidence of *C. albicans* resistance has been accompanied by an increased incidence of non-albicans species infections, including *Candida glabrata, Candida tropicalis, Candida krusei*, and *Candida parapsilosis*. In patients with cancer, non-albicans *Candida* species account for almost half of all cases.[29]

Risk Factors

Risk factors for OPC can be found in Table 80–4.

Clinical Presentation and Diagnosis

Oropharyngeal Candidiasis

Oropharyngeal candidiasis is often a presumptive diagnosis based on signs and symptoms, along with the resolution of them after treatment with antifungal agents.

Symptoms

- Sore, painful mouth and tongue
- Burning tongue
- **Dysphagia**
- Metallic taste

Signs

Signs vary depending on the type of oropharyngeal candidiasis.

- Diffuse erythema on the surface of buccal mucosa, throat, tongue, and gums
- White patches on tongue, gums, or buccal mucosa; removal of patches reveals erythematous and bloody tissue; ability to remove patches distinguishes OPC from oral hairy leukoplakia
- Angular cheilitis presents with small cracking lesions, erythema, and soreness at the corners of the mouth; associated with vitamin and iron deficiency
- Denture stomatitis presents with flat, red lesions on mucosa beneath dentures; signs of chronic erythema and edema on mucosa
- Hyperplastic OPC presents with discrete, transparent raised lesions on the inner mucosa of the cheek; typically found in men who smoke
- Pseudomembranous OPC presents with yellow-white plaques that may be small and discrete or confluent; most common form found in HIV patients

Diagnostic Testing

Diagnosis is primarily based on identification of characteristic lesions. Although rarely necessary, diagnostic testing is possible if a definitive diagnosis is required.

- Cytology, although presence of *Candida* is not diagnostic since colonization is common
- Culture to identify species of yeast or presence of resistance
- Biopsy

Esophageal Candidiasis

Symptoms

- Fever
- Odynophagia
- Dysphagia
- Retrosternal pain

Signs

- Fever
- **Hyperemic** or edematous white plaques
- Ulceration of esophagus
- Increased mucosal friability
- Narrowing of lumen

Diagnostic Testing

Unlike OPC, diagnosis of esophageal candidiasis is not based solely on clinical presentation, instead requiring endoscopic visualization of lesions and culture confirmation. Due to the invasive nature of these procedures, most practitioners opt to treat the infection presumptively, reserving endoscopic evaluation for patients who fail therapy.

- Cytology and culture to identify species of yeast or presence of resistance
- Barium esophagogram
- Endoscopy revealing whitish plaques with progression to superficial ulceration of the esophageal mucosa
- Mucosal biopsy

Treatment

Along with selecting an effective treatment, selection of an appropriate antifungal agent requires consideration of location and severity of infection, medication adherence, potential drug

Patient Encounter

A 35-year-old woman presents to your clinic complaining of "burning and soreness in my mouth" along with a metallic taste and "this funny white stuff." On initial examination, she has white patches on her tongue, gums, and buccal mucosa. These patches are easily removed, revealing erythematous tissue underneath.

This is the woman's first visit to your clinic, therefore no medical history is available in her chart.

- What additional information do you need to know before creating a treatment plan for this patient?
- What underlying medical conditions might make her susceptible to fungal infections?
- How is the treatment care plan altered if the patient has a history of frequent and severe OPC? if the patient is HIV-positive? If the patient is neutropenic?

TABLE 80–4. Risk Factors for Oropharyngeal and Esophageal Candidiasis

Factor	Proposed Mechanism
Extremes of age	Immature immunity in infants and reduced immunity in the elderly
Impaired mucosal integrity	Breaks in the protective barrier allows fungal invasion; often due to radiation, surgery, or mucositis
Dentures	Adherence of fungus to dentures, along with reduced salivary flow under dentures; ill-fitting dentures may impair mucosal integrity
Xerostomia	Reduced cleansing and defense factors of saliva
Use of antibiotics	Altered flora of mucosa allowing fungal overgrowth
Use of steroids	Suppression of immunity
Use of immunosuppressants	Suppression of immunity
HIV infection	Decreased CD4 T lymphocytes
Diabetes mellitus	Elevated glucose levels and defense factors in saliva
Nutritional deficiencies	Altered defense mechanisms, impaired mucosal integrity, or enhanced pathogenic potential of fungus

interactions, concomitant medical conditions, and presence of sucrose or dextrose. Topical agents require frequent dosing and prolonged contact time with oral mucosa. Rough surfaces of tablets and troches may irritate sensitive mucosa. Patients with **xerostomia** may have inadequate saliva to dissolve troches. Topical agents containing sucrose or dextrose may increase the risk of caries or cause elevated blood sugar in patients with diabetes. Along with being expensive, oral azoles exhibit an increased risk of toxicity and drug interactions due to cytochrome P-450.

Since oropharyngeal and esophageal candidiasis are signs of immunocompromise, the immune status of the patient should be considered in the therapeutic care plan. For HIV-infected patients, this should also include an evaluation of the patient's antiretroviral therapy since fungal infections may represent deterioration in immune status.

❼ *For low-risk patients, topical agents are first-line therapy for oropharyngeal candidiasis, although systemic agents may be used for severe or unresponsive cases.* For patients with severe OPC, oral fluconazole remains the agent of choice. Oral fluconazole administered for 2 weeks exhibits a mycological cure rate of 48% and a **clinical cure** rate of 84% in HIV patients.[30] Response occurs within 5 days in patients receiving 100 to 200 mg daily.[16] Doses as low as 50 mg are effective, but clinical response is slow and potentially leads to resistance. Two weeks of oral itraconazole solution is as effective as fluconazole but is less well tolerated. Due to variable absorption, risk of toxicity, and potential for drug interactions, ketoconazole and itraconazole capsules are considered second-line alternatives to fluconazole.

For non–HIV-infected patients who have suppressed immune systems, the practitioner must consider the patient's risk of dissemination. Patients with cell-mediated immune deficiency but near-normal granulocyte function, such as patients with diabetes, solid organ transplant, or solid tumors, are at low risk for dissemination. The risk of dissemination is higher for patients who develop neutropenia, including patients with leukemia or bone marrow transplant. These patients should be treated aggressively to prevent invasive fungal infection.

For the treatment of OPC in HIV-infected individuals, initial episodes can be adequately controlled with topical agents, such as clotrimazole troches, so long as symptoms are not severe and no esophageal involvement is suspected.[26] Topical nystatin is the least effective agent, especially in severely immunocompromised patients.[31] Topical clotrimazole appears to be the most effective topical antifungal, exhibiting clinical responses equivalent to oral fluconazole and itraconazole solution, but **mycological cure** rates are lower and relapse rates higher with clotrimazole.[29]

❽ *Representing a severe extension of oropharyngeal candidiasis, esophageal candidiasis requires systemic antifungal therapy.* The significant morbidity associated with esophageal candidiasis warrants aggressive treatment. The diagnosis of esophageal candidiasis requires endoscopic evaluation, but rather than employing invasive procedures, patients can be treated with an appropriate course of antifungal based on clinical presentation. If patients do not respond, endoscopy should be considered.

Two to three weeks of fluconazole or itraconazole solution are highly effective and demonstrate similar clinical response rates.[32] Doses of 100 to 200 mg are effective in immunocompetent patients but doses up to 400 mg are recommended for immunocompromised patients. Due to variable absorption, ketoconazole and itraconazole capsules should be considered second-line therapy. In severe cases, oral azoles may prove ineffective, warranting the use of amphotericin B for 10 days. Although echinocandins and voriconazole are effective in treatment of esophageal candidiasis, experience remains limited.

Patient Care and Monitoring

1. Assess the patient's symptoms to determine if symptoms are consistent with oropharyngeal or esophageal candidiasis. All patients with suspected oropharyngeal or esophageal candidiasis should be referred to a practitioner or physician since no antifungal products appropriate for oral use are available without a prescription.
2. Review any available diagnostic data, including cultures.
3. Obtain a thorough history of prescription, nonprescription, and natural drug product use. Is the patient taking any medications that may contribute to candidiasis? Is the patient taking any medications that may interfere with treatment?
4. If the patient has had oropharyngeal or esophageal candidiasis previously, determine what treatments were helpful to the patient in the past.
5. If the patient has had oropharyngeal or esophageal candidiasis previously, determine if the patient has risk factors for recurrent infection.
6. Develop a plan to assess effectiveness of antifungal therapy.
7. Determine if long-term suppressive therapy is necessary.
8. Evaluate the patient for the presence of adverse drug reactions, drug allergies, or drug interactions.
9. Stress the importance of adherence with the antifungal regimen.
10. Provide patient education pertaining to oropharyngeal or esophageal candidiasis and antifungal therapy.
    - Causes of oropharyngeal or esophageal candidiasis
    - Risk factors for developing candidiasis
    - How to administer topical antifungal agents, including cleaning the oral cavity prior to administration, administering after meals, how to dissolve troches, and how to swish suspensions
    - Importance of completing the course of therapy
    - Potential adverse effects that may occur with antifungal therapy
    - Medications that may interact with antifungal therapy
    - Warning signs to report to a physician (recurrent or difficult-to-cure infections, or worsening symptoms)

Fluconazole-Resistant Infections

Twenty percent of HIV-infected patients develop fluconazole-resistant *Candida albicans* isolates after repeated exposure to fluconazole.[33] To treat fluconazole-resistant oropharyngeal candidiasis, daily itraconazole for 2 to 4 weeks may be used. Oral itraconazole solution exhibits a mycological cure rate of 88% and a clinical cure rate of 97% in immunocompromised patients.[34] Fluconazole-resistant esophageal candidiasis should be treated with intravenous amphotericin B or caspofungin.

Recurrent Infections

If immunocompromised patients experience frequent or severe recurrences, particularly of esophageal candidiasis, chronic maintenance therapy with fluconazole 100 to 200 mg daily should be considered. In patients with infrequent or mild cases, secondary prophylaxis is not recommended. The rationale for not giving prophylaxis includes availability of effective treatments for acute episodes, risk of developing resistant organisms, potential for drug interactions, and the cost of therapy.

Outcome Evaluation

- Patients should notice symptomatic relief within 2 to 3 days of initiating therapy. Complete resolution typically occurs within 7 to 10 days. The entire course of therapy should be continued even if symptoms have resolved. If the condition does not resolve or worsens, the patient should be referred to a specialist for aggressive therapy.
- Short courses of oral azoles are associated with gastrointestinal upset, while courses lasting longer than 7 to 10 days are associated with increased risk of hepatotoxicity. In patients receiving prolonged therapy lasting more than 3 weeks, periodic monitoring of liver function tests should be considered.
- Immunocompetent patients generally do not require reassessment after treatment. Patients with neutropenia exhibit an increased risk of dissemination of infection, and therefore should be monitored for signs of systemic fungal infection. Due to an increased risk of recurrence, HIV-positive patients should routinely be evaluated for recurrence at each visit.

MYCOTIC INFECTIONS OF THE SKIN, HAIR, AND NAILS

Tinea infections are superficial fungal infections in which the pathogen remains within the keratinous layers of the skin or nails. Typically these infections are named for the affected body part, such as tinea pedis (feet), tinea cruris (groin), and tinea corporis (body). Tinea infections are commonly referred to as ringworm due to the characteristic circular lesions. In actuality, tinea lesions can vary from rings to scales and single or multiple lesions.

Epidemiology and Etiology

Tinea infections are second only to acne in frequency of reported skin disease.[35] The common tinea infections are tinea pedis, tinea corporis, and tinea cruris. Tinea pedis, the most prevalent cutaneous fungal infection, afflicts more than 25 million people annually in the United States.

Pathophysiology

Fungal skin infections are primarily caused by **dermatophytes** such as *Trichophyton, Microsporum,* and *Epidermophyton*. *Trichophyton rubrum* accounts for more than 75% of all cases in the United States.[36] To a lesser extent, *Candida* and other fungal species cause skin infections. With tinea infections, the causative dermatophyte typically invades the stratum corneum without penetration into the living tissues, leading to a localized infection.

Risk Factors

- Prolonged exposure to sweaty clothing
- Excessive skin folds
- Sedentary lifestyle
- Warm, humid climate
- Use of public pools
- Skin trauma
- Poor nutrition
- Diabetes mellitus
- Immunocompromise
- Impaired circulation

Nonpharmacologic Therapy

- Since fungi thrive in warm, moist environments, the practitioner should encourage patients to wear loose-fitting clothing and socks, preferably garments made of cotton or other fabrics that wick moisture away from the body. Avoid clothing made with synthetic fibers or wool.
- Clean the infected area daily with soap and water.
- The infected area should be dried completely prior to dressing, paying particular attention to skin folds.
- To prevent spread, towels, clothing, and footwear should not be shared with other persons.
- Wear protective footwear in public showers and pool areas.

Clinical Presentation and Diagnosis

Symptoms and Signs (Table 80–5)

Diagnostic Testing

- KOH prep
- Wood's ultraviolet lamp
- Microscopic examination
- Fungal cultures
- Periodic acid-Schiff (PAS) staining of nail

Treatment of Skin and Hair Infections

The goals of treatment include:

- Providing symptomatic relief
- Resolution of infection
- Preventing spread of infection

Pharmacologic Therapy

❾ *Since dermatophyte hyphae seldom penetrate into the living layers of the skin, instead remaining in the stratum corneum, most infections can be treated with topical antifungals. Infections covering large areas of the body or infections involving nails or hair may require systemic therapy.* Patients with chronic infections or infections that do not respond to topical therapy are also candidates for systemic therapy.

Treatment is typically initiated based on symptoms, rather than on microscopic evaluation. Since several species can cause tinea infections, the choice of antifungal agent is not always clear. For infections accompanied by inflammation, combination therapy with a topical steroid can be considered.

The selection of vehicle is based on the type of lesion and location of the infection. Solutions are recommended for hairy areas and oozing lesions, while creams are better for moderately scaling and non-oozing lesions. For hyperkeratotic lesions, ointments can be considered. The selected formulation should be applied to the affected area after it is cleaned and dried. The medication should be rubbed into the infected area for improved penetration. Since most patients do not rub in sprays and powders, penetration of the epidermis is minimal, making them less effective than other formulations. Sprays and powders should be considered as adjuvant therapy with a cream or lotion or as prophylactic therapy to prevent recurrence.

Tinea pedis requires treatment one to two times daily for 4 weeks, while tinea corporis and tinea cruris require treatment one to two times daily for 2 weeks. Due to the severity of infection and inflammation, tinea capitis does not adequately respond to topical agents. Oral agents for 6 to 8 weeks are recommended for eradication of tinea capitis. Griseofulvin has long been considered the treatment of choice due to its ability to achieve high levels within the stratum corneum. Itraconazole has also demonstrated effectiveness. Due to its lipophilicity, itraconazole achieves high levels in the skin. These levels are maintained for 4 weeks after medication is discontinued. Some practitioners recommend adjunct therapy with the oral agent to decrease dissemination, including ketoconazole or selenium sulfide shampoos. Treatment of any infection should continue at least 1 week after resolution of symptoms.

Treatment of Onychomycosis

Onychomycosis is a chronic infection that rarely remits spontaneously. Adequate treatment is essential to prevent spread to other sites, secondary bacterial infections, cellulitis, or gangrene. ❿ *Due to the chronic nature and impenetrability of nails, topical agents have low efficacy rates for treating onychomycosis.* Oral agents that can penetrate the nail matrix and nail base, such as itraconazole and terbinafine, are more effective than ciclopirox lacquer. Itraconazole and terbinafine demonstrate mycological cure rates of 62%[37] and 76%,[38] respectively, while ciclopirox has a cure rate of 29% to 36%.[39]

Itraconazole can be administered continuously (200 mg daily) or as pulse therapy (200 mg twice daily for 1 week per

TABLE 80–5. Signs and Symptoms of Superficial Fungal Infections

Infection	Symptoms and Signs
Tinea pedis	• Involves plantar surface and interdigital spaces of foot • Interdigital infections produce itching; presents as fissures, scaling, or macerated skin; can occur between any toes but most often between fourth and fifth toes; may cause foul smell due to superinfection with *Pseudomonas* or diphtheroids • Hyperkeratotic infections present with slivery white scales on a thickened, red base; usually covers entire foot; occasionally may also affect hand • Vesiculobullous tinea pedis presents as pustules or vesicles on soles of feet; associated with maceration, itching, and thickening of sole; may cause lymphangitis and cellulitis; most common during summer months • Ulcerative tinea pedis presents as macerated, denuded, and weeping ulcers on soles; may produce extreme pain and erosion of interdigital spaces; typically complicated by opportunistic gram-negative infections • Risk factors include occlusive footwear and foot trauma
Tinea manuum	• Infection of the interdigital and palmar surfaces • Presents as white scales in palmar folds; may also develop scales on remainder of palm; may present as singular plaque • More commonly affecting only one hand • Presents with hyperkeratotic skin
Tinea cruris	• Presents with follicular papules and pustules on the medial thigh and inguinal folds • Ringed lesions may extend from inguinal fold over adjacent inner thigh • Lesions usually spare the penis and scrotum, in contrast to candidiasis • Frequency increases during summer • Primarily develops in young men • Risk factors include tight-fitting clothing • Commonly referred to as jock itch
Tinea corporis	• Presents with circular, scaly patch with enlarged border • Lesions may have red papules or plaque in center that clears, leaving hypopigmentation or hyperpigmentation • Itching may be present • Commonly referred to as ringworm of the body
Tinea versicolor	• Characterized by skin depigmentation but can present as hyperpigmentation, particularly in dark-skinned patients • Typically occurs in areas with sebaceous glands, including neck, trunk, and arms • Depigmentation may persist for years • Primarily develops in young and middle-aged adults • Risk factors include application of oil, greasy skin, high ambient temperature, high relative humidity, tight-fitting clothing, immunodeficiency, malnutrition, hereditary predisposition
Tinea barbae	• Infection of beard area
Tinea capitis	• Infection of the head and scalp • May be asymptomatic initially, then progress to inflammatory alopecia • "Black dot" alopecia may develop due to breakage of hair at the root • May form kerions (nodular swellings) • Scaling or favus may develop on scalp • Cervical lymphadenopathy is common • Primarily found in infants, children, and young adolescents, often in African-American and Hispanic populations • Can be spread from person to person or animal to person
Onychomycosis (tinea unguium)	• Infection of nail plate and bed • Nail becomes opaque, thick, rough, yellow, and friable; nail may separate from bed • Toenails affected more frequently than fingernails • Prevalence increases with advanced age

month). Terbinafine is administered 250 mg per day as continuous therapy. Whether administered continuously or as pulse therapy, oral treatment for toenail infections should continue for at least 3 months, while treatment for fingernail infections should continue for at least 2 months. Treatment with itraconazole or terbinafine for prolonged periods requires laboratory monitoring of liver function tests before initiation of therapy and at monthly intervals. Griseofulvin is also effective for the treatment of onychomycosis, but therapy must be continued for 4 months for fingernail infections or 6 months for toenail infections. For patients with liver disease or who are unable to use oral agents, ciclopirox nail lacquer remains a reasonable alternative, although it requires 48 weeks of therapy.

Outcome Evaluation

For infections of the skin, patients should notice relief of symptoms, including pruritus, scales, and inflammation, within 1 to 2 weeks. Therapy should be continued at least 1 week after complete resolution of symptoms. If the condition worsens or does not resolve within 4 weeks, the patient should be treated with oral therapy.

For onychomycosis, relief of symptoms is slow. The infected nail will need months to grow out. The practitioner should advise the patient not to become frustrated by the slow resolution. Despite the slow progress, the antifungal agent is curing the infection. The practitioner should also advise the patient that even after the infection is cured, the nail may not look "normal."

Patient Care and Monitoring

1. Assess the patient's symptoms to determine if self-treatment with OTC antifungal therapy is appropriate or whether the patient should be evaluated by a practitioner. Exclusions for self-treatment include infection of nails or hair, unsuccessful initial treatment, worsening condition, signs of secondary bacterial or systemic infection, or chronic medical conditions such as diabetes, immunosuppression, or impaired circulation.
2. Review any available diagnostic data, including cultures and KOH preps.
3. Obtain a thorough history of prescription, nonprescription, and natural drug product use.
4. If the patient has had a mycotic infection previously, determine what treatments were helpful to the patient in the past.
5. Educate the patient on lifestyle modifications that will prevent recurrence, including keeping the area dry, wearing shower shoes, washing clothing in hot water, use of drying powders, and wearing loose-fitting clothing.
6. Develop a plan to assess effectiveness of antifungal therapy.
7. Determine if long-term prophylactic therapy is necessary to prevent recurrence.
8. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.
9. Stress the importance of adherence with the antifungal regimen.
10. Provide the patient education pertaining to mycotic infections and antifungal therapy.
    - Causes of mycotic infections of the skin, hair, or nails
    - Different types of OTC antifungal products, such as creams, sprays, and powders
    - How to apply various OTC antifungal products
    - How long therapy should be continued
    - How to avoid spread of infection
    - How to avoid recurrent infection
    - Potential adverse effects that may occur with antifungal therapy
    - Dietary modifications that are necessary with oral agents
    - Medications that may interact with antifungal therapy, particularly with oral agents used for nail infections
    - Warning signs to report to a physician (recurrent or difficult-to-cure infections, infections with malodorous discharge or bleeding)

81 Invasive Fungal Infections

Russell E. Lewis and P. David Rogers

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Differentiate epidemiologic differences and host risk factors for acquisition of primary and opportunistic invasive fungal pathogens.
2. Recommend appropriate empiric or targeted antifungal therapy for the treatment of invasive fungal infections.
3. Describe the components of a monitoring plan to assess effectiveness and adverse effects of pharmacotherapy for invasive fungal infections.
4. Evaluate the role of antifungal prophylaxis in the prevention of opportunistic fungal pathogens.

Key Concepts

❶ The most common route of infection for endemic fungi is via the respiratory tract, where conidia aerosolized from contaminated soil are inhaled into the lung.

❷ The diagnosis of endemic fungal infections is often prompted by a patient history of prolonged (subacute) infectious symptoms, travel or residence in an endemic area, and/or participation in activities that result in exposures to soil contaminated by endemic fungi.

❸ The approach to antifungal therapy in patients with endemic fungal infections is determined by the severity of clinical presentation, the patient's underlying immunosuppression, and potential toxicities and drug interactions associated with antifungal treatment.

❹ Secondary prophylaxis or suppressive therapy is recommended for endemic mycoses in immunocompromised patients, especially in hosts with pronounced defects in T-cell–mediated immunity (i.e., AIDS).

❺ Commensal or environmental fungi that are typically harmless can become invasive mycoses when the host immune defenses are impaired. Host immune suppression and risk for opportunistic mycoses can be broadly classified into three categories: (1) quantitative or qualitative deficits in neutrophil function, (2) deficits in cell-mediated immunity, and (3) disruption of mechanical/and or microbiologic barriers.

❻ Familiarity with the epidemiology and frequency of non-albicans *Candida* species in the institution or ICU is essential before selecting empiric antifungal therapy for invasive candidiasis.

❼ Colonization at multiple distinct body sites or with high density of *Candida* species, however, often precedes invasive infection. Preemptive antifungal therapy may be indicated in colonized high-risk populations such as neutropenic fever, transplant recipients, or following major abdominal surgery.

❽ Laboratory identification of *Candida* in clinical samples must be performed to the species level whenever possible, as *Candida* species differ considerably in their susceptibility to antifungal agents.

❾ If a patient is non-neutropenic and has never received prior azole therapy, fluconazole 800 mg/day is an appropriate first-line therapy for invasive candidiasis until identification of the *Candida* isolate. Amphotericin B deoxycholate 0.7 mg/kg per day or caspofungin 70 mg on day 1, then 50 mg/day, voriconazole, or a lipid amphotericin B formulation are recommended as empiric therapy in patients with neutropenic fever.

❿ Direct visualization of *C. neoformans* in the CSF by India ink staining is the most rapid method for diagnosing cryptococcal meningitis.

⓫ Clinical trials performed by the National Institute of Allergy and Infectious Diseases (NIAID) Mycoses Study Group showed that 2 weeks of induction antifungal therapy with combination amphotericin B (0.7 mg/kg per day) plus

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

flucytosine (100 mg/kg per day) for cryptococcal meningitis, followed by consolidation therapy with fluconazole (400 mg daily) for 8 weeks was as effective as 4 weeks of combination therapy, and had fewer toxicities.

⑫ Nodular or halo-like lesions detected by high-resolution computed tomography (HRCT) scans are often the first indication of invasive pulmonary aspergillosis.

⑬ Immunocompromised patients on fluconazole with progressive sinus or pulmonary disease by radiography should be evaluated for possible mold infection.

⑭ Many experts now consider voriconazole as the initial drug of choice for invasive aspergillosis in patients without significant contraindications (e.g., drug interactions or preexisting liver dysfunction) to azole therapy.

⑮ Zygomycetes are generally resistant to voriconazole and echinocandins and their presence should be suspected in any patient with progressive mold infection while receiving voriconazole and/or echinocandin therapy.

Invasive fungal infection or **invasive mycoses** are general terms for diseases caused by invasion of living tissue by fungi. Unlike superficial mycoses (Chapter 80), invasive mycoses invade internal organs, can disseminate throughout the body, and are associated with high rates of morbidity and mortality, particularly in the immunocompromised host. Invasive fungal infections are broadly categorized as either primary or opportunistic invasive mycoses. Primary invasive fungal infections are caused by fungal spores or **conidia** in the soil that, when disturbed, can become aerosolized and inhaled leading to infection, even in an immunocompetent patient. Because these fungi are often endemic to certain soil types and hence geographically restricted, primary invasive fungal pathogens are also known as **endemic fungi**. In the United States, three species (*Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis*) account for the majority of these infections (Table 81–1). In contrast, opportunistic fungal infections occur only in the setting of compromised host immune defenses and are caused by a wider spectrum of less virulent fungal species that are generally incapable of causing infection in healthy patients (see Table 81–1). Hence, the spectrum, severity, and outcome of opportunistic fungal infections are heavily influenced by the degree, type, and severity of host immunosuppression. As a general rule, opportunistic fungal infections are difficult to diagnose, uniformly fatal if not treated early and aggressively, and associated with high rates of morbidity and mortality.

TABLE 81–1. Invasive Mycoses

Primary (Endemic) Invasive Fungi
Histoplasma capsulatum[a]
Coccidioides immitis[a]
Blastomyces dermatitidis[a]
Opportunistic Invasive Fungi
Yeast
Candida species (*C. albicans, C. glabrata, C. parapsilosis, C. tropicalis, C. krusei* and others)
Cryptococcus neoformans[a]
Trichosporon spp. and others

Patient Encounter, Part 1

A 39-year-old male with chronic steroid-dependent asthma who recently relocated to Phoenix, Arizona presents with a 4-week history of increasing fever, dry cough, and pain upon deep inspiration. He also reports arthralgias and night sweats over the last 3 weeks. A chest radiograph reveals a small area of consolidation in the left lower lobe and some hilar adenopathy. Otherwise, all other routine tests and cultures appear negative.

- What are this patient's risk factors for developing an endemic fungal infection?
- What is the most likely endemic fungal pathogen based on this patient's history?
- What additional information is needed to select antifungal therapy?

ENDEMIC MYCOSES

Epidemiology

Endemic mycoses are true primary fungal pathogens capable of causing infection in otherwise healthy individuals. In immunocompromised patients, endemic fungal infections often present with a more fulminant course (in the case of primary infections) or reactivate to cause life-threatening infection. Because initial symptoms of an endemic fungal infection are often non-specific and overlap with other slowly-progressing infections (e.g., tuberculosis and infective endocarditis), a careful patient history concerning travel and activities associated with potential exposure to soil contaminated with endemic fungi is essential for the diagnosis and early treatment of infection.

Two of the most common endemic fungal infections (histoplasmosis and North American blastomycosis) are found in

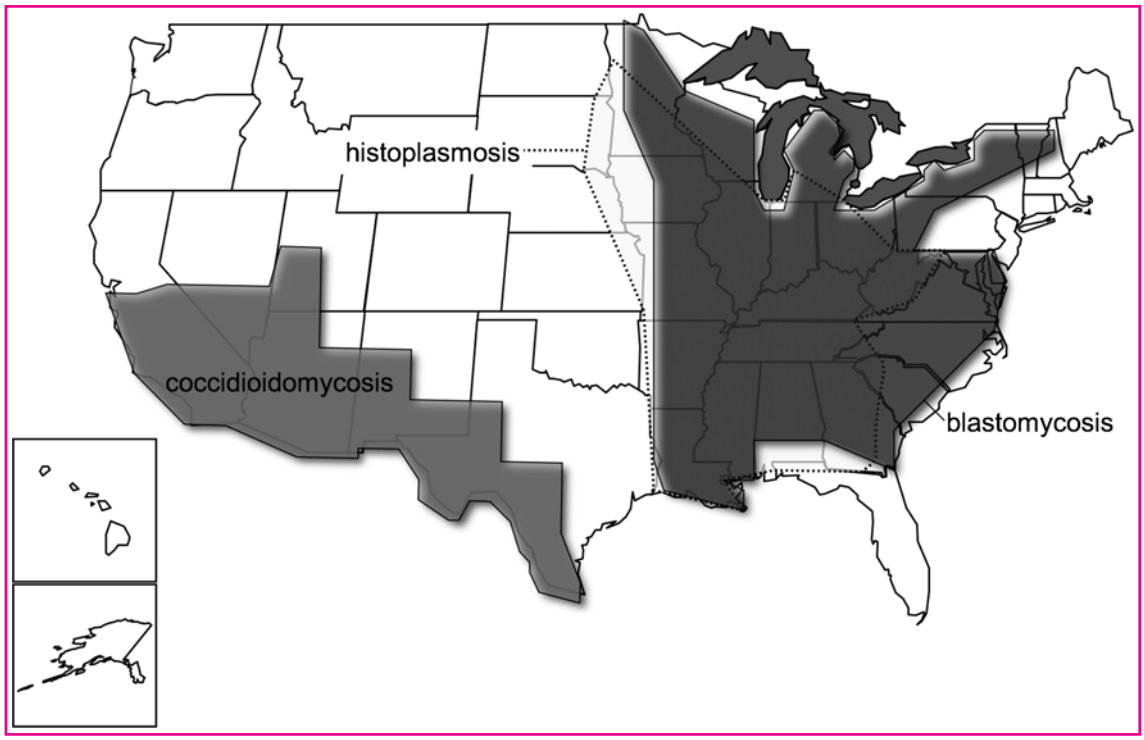

FIGURE 81–1. Geographic localization of primary (endemic) fungi in the United States.

overlapping regions in the eastern and central river basins of the United States (Fig. 81–1).[1] *Histoplasma capsulatum* var. *capsulatum*, the causative fungus of histoplasmosis, grows heavily in soil contaminated with bird or bat excreta, which serve to enhance sporulation of the fungus.[2] Activities in endemic regions that are classically associated with high exposures to *Histoplasma capsulatum* include cave exploration (spelunking), working in or demolishing chicken coops, demolition of older buildings, woodcutting in forests with large bird roosts, or spreading avian excreta as fertilizer. For blastomycosis, decaying organic matter, warm humid conditions, and close proximity to water or frequent rainfall seems to support growth of this fungus.[3] Occupational or recreational activities that disturb soil heavily contaminated with *Blastomyces dermatitidis* are the most common risk factor for development of blastomycosis. Coccidioidomycosis differs from histoplasmosis and blastomycosis, as the fungus is associated with arid to semi-arid climates, hot summers, low altitude, alkaline soil, and sparse flora. Hence the fungus is found in the southwestern regions of the United States stretching from western Texas to southern California (see Fig. 81–1).[4] Epidemics of coccidioidomycosis have been reported in California following dust storms and earthquakes, as well as cycles of intense drought and rain which favor the growth cycle of the fungus and enhance dispersion of its specialized spore forms called arthroconidia.

Pathophysiology

Endemic fungi share several key biologic and ecological characteristics that contribute to their pathogenicity in humans. All endemic fungi exhibit temperature-dependent dimorphism, meaning they can propagate as either a **yeast** (single cells that reproduce by budding into daughter cells) or **molds** (multi-cellular filamentous fungi that reproduce through production of conidia or spores). At environmental temperatures (25° to 30°C) *H. capsulatum*, *B. dermatitidis*, and *C. immitis* grow in the mold form producing 2- to 10-μm round to oval-shaped (*Histoplasma* and *Blastomyces*) or barrel-shaped (*Coccidioides*) conidia that are dispersed throughout the environment and in air currents. At physiologic temperatures, the conidia germinate into yeast (*Histoplasma* and *Blastomyces*) or in specialized cell forms called spherules (*Coccidioides*) that are resistant to killing by resident alveolar macrophages and neutrophils in the lung. Control of infection is mediated by the development of antigen-specific T-lymphocyte response to enhance macrophage fungicidal activity, and lymphocyte/macrophage-mediated formation of a granuloma to contain the fungus.[5] Not surprisingly, patients with T-cell–mediated immune deficiency (e.g., acquired immunodeficiency syndrome [AIDS] patients and transplant recipients) or suppressed cellular immunity due to drug therapy (e.g., chemotherapy, high-dose corticosteroids, or tumor necrosis-α blockers) are especially prone to severe infections.

❶ The most common route of infection for endemic fungi is the respiratory tract, where conidia aerosolized from contaminated soil are inhaled into the lung. Once in the lung, conidia are phagocytosed but not destroyed by resident macrophages and neutrophils in the alveoli and bronchioles. Within 2 to 3 days, conidia germinate into **facultative** yeast resistant to phagocytosis and killing by macrophages

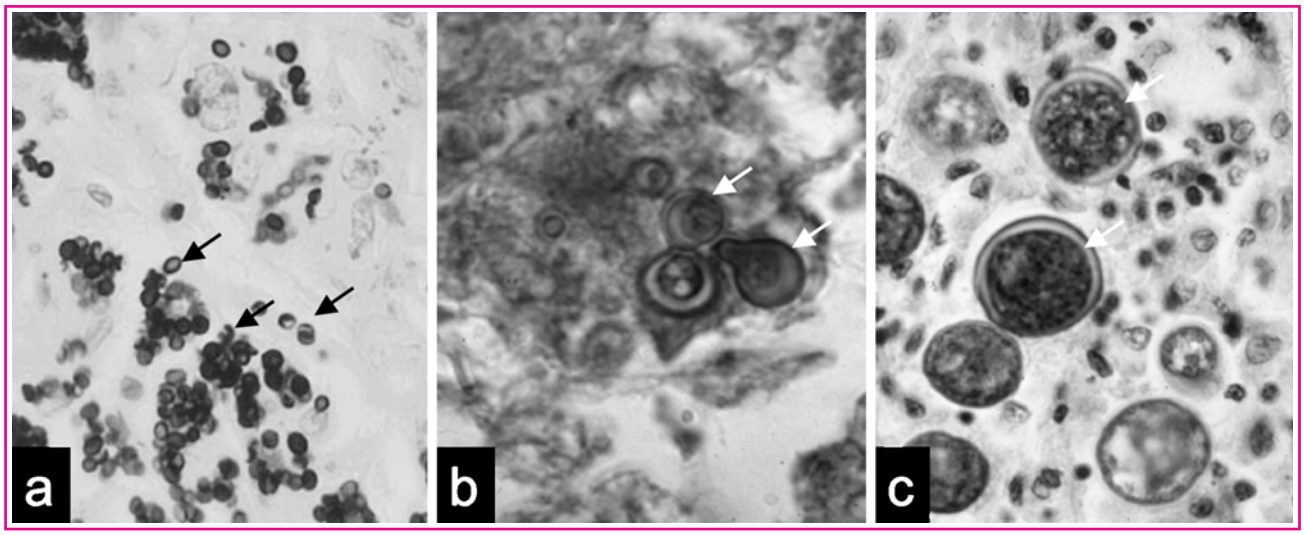

FIGURE 81–2. Histopathology of endemic mycoses in tissue. *a.* Histoplasmosis (yeast). *b.* Blastomycoses (broad-based budding yeast). *c.* Coccidioidomycoses (spherules with endospores).

and neutrophils (Fig. 81–2a and 2b). For *C. immitis* germination of the arthroconidia results in the formation of a sac-like structure called a spherule filled with endospores (Fig. 81–2c). Spherules then rupture to release large numbers of endospores, which are the propagating form of the infection. Control of infection in the lungs is typically accomplished through formation of **granulomas**. However, in patients exposed to an overwhelming inoculum, or lower inocula in the setting of suppressed T-cell–mediated immunity, dissemination outside the lung to the skin and oral mucosa (especially blastomycoses), adrenal glands, bone, spleen, thyroid, gastrointestinal tract, heart, and central nervous system is possible and uniformly fatal if left untreated.

Clinical Presentation and Diagnosis

Histoplasmosis and coccidioidomycosis are frequently asymptomatic infections in a majority of immunocompetent patients or present as a self-limiting, influenza-like illness 1 to 3 weeks after inhalation of conidia. The clinical presentation of blastomycosis varies ranging from asymptomatic infection, to acute or chronic pneumonia that develops 30 to 40 days after exposure, to full-blown disseminated disease. Symptomatic endemic fungal infections generally present as persistent and sometimes progressive pneumonia accompanied by fever, chills, cough, arthralgias, night sweats, and weight loss that is indistinguishable from other chronic infections such as pulmonary tuberculosis. ❷ Therefore, diagnosis of endemic fungal infection is often prompted by a patient history of a prolonged infectious symptoms, travel or residence in an endemic area, and/or participation in activities that result in exposures to soil contaminated by endemic fungi. Chest radiographs often reveal either diffuse or nodular infiltrates in the lung, accompanied by enlargement of the hilar and/or mediastinal lymph nodes. Fulminant pneumonia may be seen with high inoculum exposures, resulting in diffuse lung infiltrates that proceed to acute respiratory distress syndrome (ARDS) and respiratory failure. Rheumatologic symptoms such as severe arthritis, pericarditis, and erythema nodosum may be seen in 10% to 30% of patients with endemic fungi.[2,6] Dissemination outside the lung is common in patients with suppressed cellular immunity and frequently produces signs of progressing infection. Ulcerative oral and cutaneous lesions may also arise with any endemic fungal infections. Verrucose skin lesions on sun-exposed areas on the face, however, are particularly suggestive of progressing blastomycosis and are frequently mistaken for cutaneous malignancy.[6] Dissemination of the fungi to bone may result in anemia or thrombocytopenia. Hepatomegaly, splenomegaly, and adrenal insufficiency are also common with dissemination of the endemic fungi to these internal organs. Seizures, meningeal signs, and hydrocephalus are common findings with dissemination to the central nervous system and portends an especially poor prognosis in the setting of disseminated coccidioidomycosis.

Definitive diagnosis of an endemic fungal infection requires growth of the fungus from body fluids or tissue, or evidence of cellular or tissue invasion in clinical samples by histopathologic staining. However, cultures may only be positive in the setting of high inoculum exposures or disseminated disease.[7] Serologic testing has been shown to be helpful in the diagnosis and management of patients with histoplasmosis or coccidioidomycosis, but has lacked sufficient sensitivity for diagnoses of *B. dermatitidis*.[6] In general, a four-fold rise in antibody titers of *Histoplasma* or *Coccidioides*, or any titer greater than 1:16 suggests active infection. However, many clinicians still consider titers as low as 1:8 as evidence of active disease because undetectable

titers may be present in one-third of all active infections.[4] More recently, enzyme-linked immunosorbent assays (ELISAs) have been developed for detection of *Histoplasma* antigen in serum and urine, and a new radioimmunoassay directed against surface proteins of *B. dermatitidis* has shown promising sensitivity.[8] Serial serologic monitoring and antigen testing can also provide a means for assessing response to antifungal therapy and early detection of relapse in patients with histoplasmosis or coccidioidomycosis.

TREATMENT

General Approach

❸ The approach to antifungal therapy in patients with endemic fungal infections is determined by the severity of clinical presentation, the patient's underlying immunosuppression, and potential toxicities and drug interactions associated with antifungal treatment. Immunocompetent patients with mild disease following exposure to *H. capsulatum* or *C. immitis* often experience a benign course of infection and rarely require antifungal therapy. Typically these patients are followed in the outpatient setting with serial antigen testing to confirm resolving infection. Patients without clinical improvement in the first 6 weeks are typically treated with oral itraconazole or fluconazole for 6 to 12 weeks (Table 81–2).[4] Other newer azoles such as voriconazole and posaconazole appear to have good activity against endemic fungi; however, there are currently insufficient data to recommend their routine first-line use. Patients with prolonged, progressive symptoms longer than 2 weeks or titers greater than 1:8 of histoplasmosis or coccidioidomycosis antigen are candidates for immediate antifungal therapy.[1,4] Any patient with underlying immunosuppression

TABLE 81–2. Therapeutic Approach to Endemic Fungal Infections

Mycosis	Recommended Treatment Regimens	Comments
Histoplasmosis		
Mild to moderate	Observation or itraconazole 200 mg PO daily for 6–12 weeks **OR** Itraconazole 200 mg PO daily for 6–12 weeks or IV 200 mg q12hour for 1 day, then 200 mg q24hour (non-CNS disease only), **OR** Fluconazole 12 mg/kg/day PO for 6–12 weeks	Itraconazole is less effective for CNS infections Fluconazole is less effective but better tolerated than itraconazole Lipid formulation may be more effective than conventional formulations, especially for CNS disease. Once the patient is clinically stable, may be transitioned to itraconazole or fluconazole Corticosteroid therapy should be considered in hypoxic patients with acute pulmonary infection
Severe including CNS disease or immunocompromised host	Amphotericin B (AM-B) 0.7 mg/kg per day IV or liposomal AM-B 3–5 mg/kg per day for 12 weeks or until clinically stable	
Blastomycosis		
Mild to moderate	Itraconazole 200 mg PO daily × 6 months **OR** Fluconazole 6–12 mg/kg/day PO	Relapses are common in immuno-compromised host Suppressive therapy with itraconazole 200 mg/day PO or fluconazole 800 mg/day PO is recommended
Severe including CNS disease or immunocompromised host	AM-B 0.7 mg/kg per day IV until patient is clinically stable, then Itraconazole (non-CNS) or fluconazole 800 mg PO daily for 6 months	
Coccidioidomycosis		
Mild to moderate	Observation or itraconazole 200 mg PO twice daily for 6–8 months **OR** Fluconazole 6–12 mg/kg/day PO daily	Itraconazole demonstrated trend towards superiority over fluconazole in a randomized controlled trial for progressive, non-meningeal coccidioidomycosis; however, fluconazole is better tolerated than itraconazole
Diffuse pneumonia or disseminated infection	AM-B 1–1.5 mg/kg per day with dose and frequency decreased as improvement occurs **OR** Lipid AM-B formulations	Fluconazole 800–1000 mg/day is sometimes recommended after initial AM-B therapy for meningitis

CNS, central nervous system; IV, intravenous; PO, oral.

Patient Encounter, Part 2

Selecting Antifungal Therapy

The patient's serum titer for coccidioidomycosis returns as greater than 1:32. Based on the information presented, select an appropriate treatment plan for the patient's coccidioidomycosis.

- Does the patient require antifungal treatment at this time?
- If the patient is considered to have moderately severe disease, what are the recommended treatment options?

should also receive immediate antifungal therapy. The following signs and symptoms are considered to be indicators of severe disease that requires hospitalization and initial treatment with systemic amphotericin B therapy (see Table 81–2).[1,4]

- Hypoxia indicated by a partial pressure of oxygen less than 80 mm Hg
- Hypotension (systolic blood pressure less than 90 mm Hg)
- Impaired mental status
- Anemia (hemoglobin less than 10 g/dL (100 g/L or 6.2 mmol/L)
- Leukopenia (less than 1,000/cm^3)
- Elevated hepatic transaminases (greater than 5 times upper limit of normal) or bilirubin (greater than 2.5 upper limit of normal)
- Coagulopathy
- More than 10% loss in body weight
- Evidence of dissemination including cutaneous manifestations
- Meningitis

The clinical presentation of blastomycosis covers a wide spectrum ranging from asymptomatic infections, to flu-like illness resembling other upper respiratory tract illnesses, to infections resembling bacterial pneumonia with acute onset, high fever, lobar infiltrates and cough, to subacute or chronic respiratory illness with complex symptoms resembling tuberculosis or lung cancer, or fulminant lung infections with high fever, diffuse infiltrates, and an ARDS-like presentation.[6] As mentioned previously, the skin is the most common site of dissemination, typically involving sunlight exposed body areas (i.e., nose, face, and arms) and mucous membranes. The treatment of blastomycoses, therefore, is heavily dependent on the severity of clinical manifestations. Generally, patients with mild disease can be managed as outpatients with oral itraconazole or fluconazole.[6] Patients with evidence of severe pulmonary disease or dissemination require initial treatment as inpatients with amphotericin B–based regimens until they are clinically stable, whereupon they can complete a 6- to 12-month treatment course as outpatients with oral itraconazole or fluconazole.

Patient Monitoring and Side Effects

Response to antifungal therapy may be slow in patients with a prolonged history of infection or severe manifestations. However, gradual improvements in symptoms and reduction in fever are indicators of response to antifungal therapy. For histoplasmosis and coccidioidomycosis, decreasing antigen titers are also indicative of response to antifungal therapy.[1]

Antifungals used for the treatment of endemic mycoses can be associated with a number of clinically-significant drug interactions and toxicities, especially with the prolonged treatment courses that are often required in the management of endemic mycoses. Itraconazole is available as a capsule formulation and as a liquid. The liquid formulation of itraconazole has several advantages over the capsule: it has a better oral bioavailability and does not require the low gastric pH that is required for dissolution and absorption of the capsule. However, the oral solution is somewhat dilute, has an unpalatable aftertaste (an issue when taking months of therapy), and has a much higher rate of gastrointestinal side effects. Therefore the capsule formulation is often preferred provided patients are not on acid-suppression therapy (i.e., proton pump inhibitors, histamine antagonists, or antacids).

Drug interactions are a particularly important concern in patients taking long-term azole therapy, especially with itraconazole. Itraconazole is a substrate and inhibitor of the cytochrome P-450 (CYP)3A4 enzyme and P-glycoprotein. Co-administration of itraconazole with inducers of this enzyme system (e.g., rifampin, phenytoin, and phenobarbital) can dramatically increase the clearance of itraconazole (and to a lesser extent fluconazole), resulting in ineffective plasma and tissue concentrations of the drug.[9–11] In general, co-administration of itraconazole with these inducers should be avoided. In some cases, plasma trough levels can be drawn once the patient reaches steady state (greater than 7 days of therapy). Concentrations less than 0.25 mcg/mL should be considered evidence of insufficient itraconazole exposure.[12] As a potent inhibitor of CYP3A4, itraconazole can dramatically decrease the clearance of a number of important medications metabolized through this enzyme, leading to potentially dangerous drug interactions. Patients receiving anticoagulation therapy with warfarin, immunosuppressive therapy with cyclosporine or tacrolimus, those taking midazolam, HMG-CoA reductase inhibitors (statins), rifabutin, chemotherapy agents (e.g., vinca alkaloids, busulfan, and cyclophosphamide), and digoxin will require dosage adjustment and careful monitoring while receiving itraconazole therapy.[13] Although fluconazole is not as potent an inhibitor of CYP3A4 as itraconazole, drug interactions can still be severe, especially at higher fluconazole dosages (i.e., 800 mg/day).[13]

All azole antifungals carry the potential for rash, photosensitivity, and hepatotoxicity. In general, hepatotoxicity is mild and reversible, presenting as asymptomatic increases in liver transaminases. However, fulminant hepatic failure has been reported with itraconazole. Therefore, serial monitoring of liver function

is recommended in all patients on long-term azole therapy. Long-term therapy with itraconazole has also been associated with reversible adrenal suppression and cardiomyopathy. These adverse effects can be prevented or managed with close monitoring and follow-up of patients on long-term therapy.

Amphotericin B is the mainstay of treatment of patients with severe endemic fungal infections. The conventional deoxycholate formulation of the drug can be associated with substantial infusion-related adverse effects (e.g., chills, fever, nausea, rigors, and in rare cases hypotension, flushing, respiratory difficulty, and arrhythmias). Pre-medication with low doses of hydrocortisone, acetaminophen, nonsteroidal anti-inflammatory agents, and meperidine is common to reduce acute infusion-related reactions. Venous irritation associated with the drug can also lead to thrombophlebitis, hence central venous catheters are the preferred route of administration in patients receiving more than a week of therapy.

The most severe adverse effect associated with amphotericin B therapy is nephrotoxicity, which occurs through the drug's renal vascular effects (constriction of afferent arterioles in the kidney tubule) and direct toxicity to the renal tubules. Generally, nephrotoxicity with amphotericin B is reversible provided the drug is stopped. However, treatment interruptions can be problematic in patients with severe infections. Precipitous decreases in glomerular filtration occasionally are seen with the initiation of amphotericin B therapy, and can be minimized by ensuring that patients remain well hydrated during therapy, and using normal saline infusions before and after amphotericin B to counter decreases in renal perfusion pressure, a practice known as sodium loading. Tubular toxicity can be delayed by avoiding the use of other drugs with known tubular toxicity such as aminoglycosides, cyclosporine, cisplatin, or foscarnet. Generally, tubular toxicity manifests in patients with severe wasting of potassium and magnesium in the urine. Therefore, patient electrolytes must be carefully monitored and potassium and magnesium supplementation is often required. Hypokalemia and hypomagnesemia frequently precede decreases in glomerular filtration (increased serum creatinine), especially in patients who are adequately hydrated.[14] Continued tubular damage, however, eventually results in decreases in renal blood flow and glomerular filtration through tubuloglomerular feedback mechanisms that further constrict the afferent arteriole.

In the last decade, amphotericin B has been reformulated into three different lipid-based formulations (Abelcet, Ambisome, and Amphotec) that have reduced rates of nephrotoxicity compared to the conventional deoxycholate formulation (Fungizone). Two of the formulations (Abelcet and Ambisome) have also shown to varying degrees reductions in the rates of infusion-related reactions. Although these lipid formulations are generally considered to be as effective as conventional amphotericin B deoxycholate, they are not dosed equivalently to the standard formulation. Unlike conventional amphotericin B, which is administered at dosages ranging from 0.6 to 1.5 mg/kg per day, lipid formulation doses are three- to five-fold higher on a milligram-per-milligram basis, ranging from 3 to 5 mg/kg per day. Only one prospective study has directly compared the efficacy of a lipid amphotericin formulation to the conventional formulation.[15] In a small study of AIDS patients with moderate to severe histoplasmosis, liposomal amphotericin B (Ambisome) was more effective than amphotericin B, with response rates of 84% and 64%, respectively. Ambisome may also be the preferred agent in patients with central nervous system (CNS) infections, due to its high penetration into the brain compared to other lipid amphotericin B formulations.[16]

Prophylaxis

Primary prophylaxis is generally not recommended for endemic fungi, but may be considered for patients who are severely immunocompromised and living in endemic areas with high case rates (greater than 5 cases per 100 patient-years). ❹ Secondary prophylaxis or suppressive therapy is recommended for endemic mycoses in immunocompromised patients, especially in hosts with pronounced defects in T-cell immunity (i.e., AIDS patients).[4,6,17] Itraconazole 200 mg/day or fluconazole 200 to 400 mg/day are the most common prophylactic regimens used for endemic fungi. In patients with prior CNS disease, fluconazole is the preferred drug due to the limited penetration of itraconazole into the CNS.

OPPORTUNISTIC MYCOSES

❺ Commensal or environmental fungi that are typically harmless can become invasive mycoses when the host immune defenses are impaired. Host immune suppression and risk for opportunistic mycoses can be broadly classified into three categories:

- Quantitative or qualitative deficits in neutrophil function
- Deficits in cell-mediated immunity
- Disruption of mechanical/and or microbiologic barriers

Quantitative defects in neutrophils (neutropenia) resulting from neoplastic diseases, cytotoxic chemotherapy, marrow transplantation, or aplastic anemia are among the most common risk factors for opportunistic mycoses. Qualitative defects may be seen in certain disease states (e.g., advanced diabetes mellitus and chronic granulomatous disease) or with high-dose corticosteroid therapy. Deficits in T-cell–mediated immunity secondary to AIDS, high-dose corticosteroid therapy, cyclosporine or other anti-rejection drugs, chemotherapy, transplantation, bone marrow failure, and various other disorders have become increasingly common with the prolonged survival of transplant patients on chronic immunosuppressive therapy. Immune deficits arising from disruption of the integument or gastrointestinal/genitourinary barriers can also predispose patients to fungal infections. The most common types of mechanical/barrier immunosuppression are surgery,

use of central venous and urinary catheters, hyperalimentation, and mucositis secondary to cytotoxic chemotherapy. Broad spectrum antibacterial therapy can also predispose patients to fungal infections through disruption of the microbiologic flora in the gut, which allows overgrowth of opportunistic fungal pathogens such as *Candida*. Successful management of opportunistic fungal pathogens, therefore, requires the reversal or reduction of underlying deficits in the host immune system.

The most common opportunistic fungal pathogen is *Candida* species, which are commensal colonizers of the gastrointestinal tract and the genitourinary tract of women. *Candida* infections can arise in any of the three types of immune deficits listed above, but are most common in patients with disruptions in mechanical and/or microbiologic barriers. *Cryptococcus*, on the other hand, is seen predominantly in patients with cell-mediated immune deficits (AIDS and/or high-dose corticosteroid therapy). Opportunistic molds such as *Aspergillus* are acquired primarily through inhalation of spores in the environment and cause invasive infection most commonly in patients with either prolonged neutropenia or severe defects in cell-mediated immunity. Additional risk factors such as environmental exposures, prior antifungal therapy, and metabolic disorders can predispose patients to specific types of opportunistic molds including *Fusarium* or Zygomycetes.

All of the opportunistic mycoses are difficult to diagnose and often must be treated empirically before diagnosis is proven. Deciding when to initiate antifungal therapy and what opportunistic pathogens to cover is a decision governed largely by the *cumulative* immune deficits of the host. For example, a post-surgical patient with persistent fever on broad-spectrum antimicrobials who has a central venous catheter may only require empiric therapy for suspected *Candida* infections, because the deficits in host defenses (surgery, catheters, and antimicrobial therapy) are largely restricted to disruption of mechanical and/or microbiologic barriers. However, if the patient had a history of prolonged high-dose corticosteroid use (e.g., greater than 600 mg prednisone equivalent in the previous month), deficits in cell mediated immunity in combination with barrier disruption need to be considered, possibly warranting empiric coverage of opportunistic molds along with *Candida* species.

Patient Encounter, Part 1

A 43-year-old male in the surgical ICU after exploratory laparotomy following a motor vehicle accident develops fever that is unresponsive to broad-spectrum antibacterial therapy (piperacillin-tazobactam 3.75 g every 6 hours, gentamicin 120 mg every 8 hours, and vancomycin 1 g every 12 hours). The patient has a central venous catheter and a Foley catheter. Blood cultures are negative at the time, but the patient has yeast growing in the sputum and urine. Laboratory studies reveal a white blood cell count of 11,300 cells/mm^3 (11.3 × 10^9/L).

- What are this patient's risk factors for developing an invasive fungal infection?
- What current evidence suggests that this patient has an invasive fungal infection?
- If antifungal therapy is empirically started in this patient, which species need to be treated?

INVASIVE CANDIDIASIS

Epidemiology

Candida species are the most common opportunistic fungal pathogens encountered in hospitals, ranking as the third to fourth most common cause of nosocomial bloodstream infections in United States Hospitals.[18] The incidence of nosocomial candidiasis has increased steadily since the early 1980s, with the widespread use of central venous catheters, broad-spectrum antimicrobials, and other advancements in the supportive care of critically-ill patients. In the 1980s, *C. albicans* accounted for over 80% of all bloodstream yeast isolates cultured from patients. By the late 1990s, this relative frequency of *C. albicans* had decreased to 50% in national surveys of bloodstream infections without a corresponding decrease in infections caused by non-albicans species. Because of the inherent resistance (e.g., *C. krusei*) or diminished susceptibility (e.g., *C. glabrata*) of many of the non-albicans species, the introduction of fluconazole in the early 1990s is often cited as the key element driving the shift in the microbiology of invasive candidiasis. However, it is likely that other institution-specific factors (e.g., increasing use of central venous catheters and increasing intensity of cytotoxic/mucotoxic chemotherapy) have contributed equally to this trend. ❻ It is important to be familiar with the relative epidemiology and frequency of non-albicans *Candida* species in the institution or intensive care unit (ICU) before selecting empiric antifungal therapy for invasive candidiasis.

Pathogenesis and Clinical Presentation

Invasive candidiasis is not a single syndrome, but rather a spectrum of infections that differ in terms of clinical presentation and course depending on host immune deficits. All forms of invasive candidiasis, however, are potentially severe, with high (30% to 60%) rates of crude morbidity and mortality. The most common form of invasive candidiasis is seen in non-neutropenic patients with disruption of mechanical/microbiologic barriers giving rise to a bloodstream infection (fungemia) from, or seeding to, a central venous catheter. Catheter-related candidemia carries a good prognosis if appropriate antifungal therapy is instituted early with catheter removal.[19] Fungemia can be of high density, however, leading

to distal sites of infection and increased morbidity. Therefore the infection must be taken seriously, especially in patients with poor performance status (i.e., a high Acute Physiology, Age, and Chronic Health Evaluation II score) in the ICU.

Patients with acute disseminated candidiasis share many similar features as patients with catheter-related candidemia, except infection generally arises from the gut following mucotoxic chemotherapy and the patients are often profoundly ill. Hematogenous spread to non-contiguous organs is common in patients with acute disseminated candidiasis and outcome is heavily dependent upon recovery from neutropenia. Fluconazole prophylaxis has markedly decreased the incidence of acute disseminated candidiasis among high-risk patient groups such as bone marrow transplant and acute leukemia patients. However, breakthrough infections with fluconazole-resistant *C. glabrata* and *C. krusei* are still a concern.

Some forms of invasive candidiasis are dominated by deep organ infection and may never be detected by blood cultures. Chronic disseminated candidiasis or hepatosplenic candidiasis is a unique form of candidemia seen after recovery from neutropenia. Candidemia during the period of neutropenia may be initially localized to the portal circulation with dissemination to contiguous organs. After recovery of neutrophils, an inflammatory response is seen against areas of focal infection in the liver and spleen. This inflammatory response produces abdominal pain that is associated with increases in alkaline phosphatase levels and hepatocellular enzymes. Diagnosis is typically confirmed by patient history (recent neutropenia), and multiple areas of lucency in the liver and spleen on computed tomography (CT).

Focal invasive candidiasis has been reported for virtually every organ, even following apparently uncomplicated catheter-related fungemia. The most common sites of infection are the kidney, eye, and bone. *Candida* in the urine can be an indication of renal candidiasis; however, it must be distinguished from more benign colonization of the urinary tract, especially in catheterized patients. All patients with candidemia should undergo an eye exam to rule out *Candida* endophthlamitis, which can be sight-threatening if not recognized early.

Laboratory diagnosis of invasive candidiasis is established by detection of the yeast in blood cultures or another sterile site (Fig. 81–3a). Growth of *Candida* from urine, sputum, or respiratory secretions (including bronchoalveolar lavage) is not considered to be evidence of invasive infection, as these areas frequently become colonized with *Candida* species in patients receiving broad-spectrum antibiotics. Colonization at multiple distinct body sites or with high density of *Candida* species, however, may precede invasive infection. Therefore preemptive antifungal therapy may be indicated in colonized high-risk populations such as those with neutropenic fever, transplant recipients, or following major abdominal surgery.[20] Although

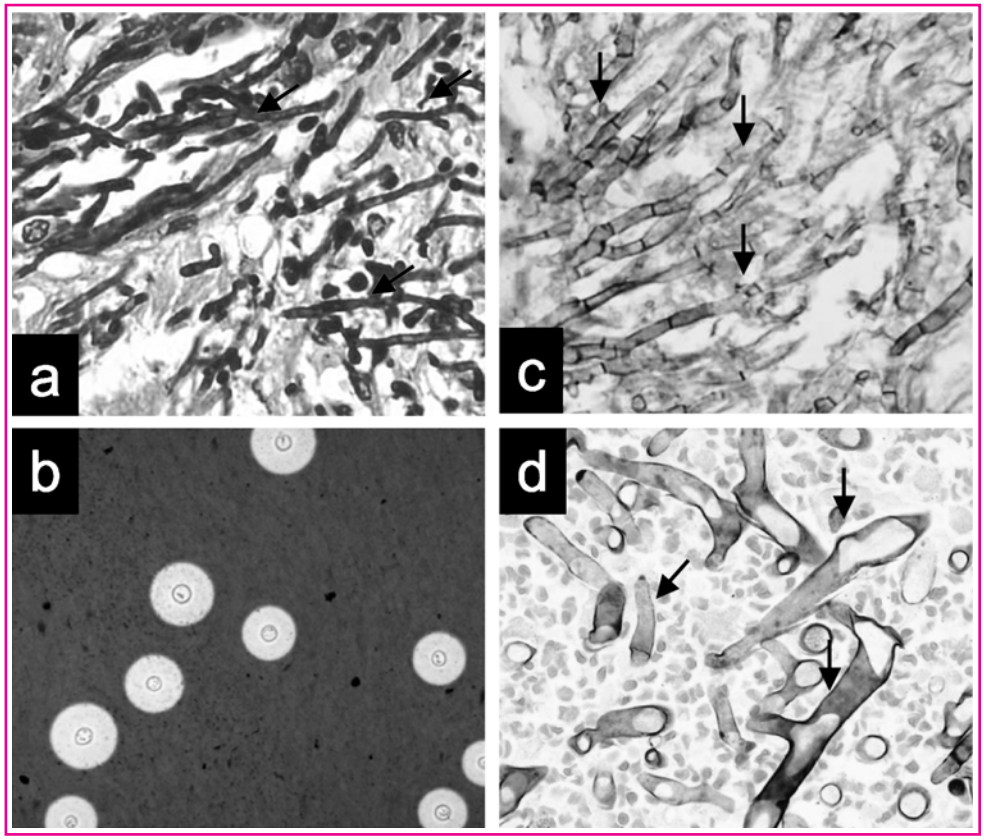

FIGURE 81–3. Opportunistic mycoses in clinical samples. *a.* Candidiasis (tissue). *b.* Cryptococcosis (India ink stain of CSF). *c.* Aspergillosis (tissue). *d.* Zygomycosis (tissue).

Candida are not particularly fastidious organisms, the sensitivity of blood cultures is relatively poor (less than 60%) and a negative culture does not rule out infection.[20] The poor sensitivity of blood cultures for detecting invasive disease has led to the study of novel serodiagnostic tests to detect antibodies, fungal metabolites, fungal cell wall antigens, or nucleic acids of *Candida* species. Of the four approaches, antigen testing based on the detection of β-glucan polymers in the cell wall of *Candida* have appeared most promising; however, none of these diagnostic tests have achieved routine clinical use.

❽ Laboratory identification of *Candida* in clinical samples must be performed to the species level whenever possible, as *Candida* species differ considerably in their susceptibility to antifungal agents.[20] Rapid discrimination of *C. albicans* from most common non-albicans *Candida* species can be accomplished by the germ-tube test, which presumptively identifies *C. albicans* by the early formation (less than 4 hours) of a hyphae-like structure when the yeast in incubated in serum at 98.6°F (37°C). Definitive species identification, however, may require an additional 48 to 72 hours after the organism is isolated on agar. *C. albicans* remains the most common cause of invasive candidiasis, is the most virulent of *Candida* species, but is the most susceptible to commonly used antifungals including fluconazole. Like *C. albicans*, *C. tropicalis* is a relatively virulent species and has tropism for causing deep tissue infections, such as myositis. *C. tropicalis* is generally sensitive to antifungals including fluconazole. *C. parapsilosis* is a less virulent species seen frequently in neonates and in adults with central venous catheters. Although *C. parapsilosis* is not as invasive, many isolates form thick biofilms that make the organism difficult to eradicate from prosthetic materials. *C. parapsilosis* is generally susceptible to most antifungals including fluconazole.[21] However, higher dosages of echinocandins (e.g., 70 to 100 mg/day of caspofungin) have been suggested due to the decreased potency of the echinocandin class against this species. *C. krusei* is a less-common species associated with breakthrough infections in heavily immunocompromised patients and should always be considered resistant to fluconazole. Interestingly, most fluconazole-resistant isolates of *C. krusei* retain susceptibility to itraconazole and voriconazole, based on laboratory analysis.[22]

C. glabrata has become a common cause of both de novo candidemia in heavily immunocompromised hosts and breakthrough infection in patients on fluconazole prophylaxis. Although *C. glabrata* is less virulent than other *Candida* species, infections with this organism are typically seen in patients with poor performance status, therefore mortality remains high. The marginal susceptibility of *C. glabrata* to fluconazole dictates that other agents such as amphotericin B or the echinocandins be considered as first-line therapy until susceptibility to fluconazole can be documented. The effectiveness of voriconazole or posaconazole for fully fluconazole-resistant *C. glabrata fungemia* is not well-established, although cross-resistance has been documented in laboratory studies.[23]

Treatment

At the time of writing, three antifungals (amphotericin B, fluconazole, and caspofungin) have been studied in prospective, randomized comparative clinical trials for the treatment of invasive candidiasis.[24–26] Two other echinocandins (micafungin and anidulafungin) are nearing completion of prospective candidemia studies and are anticipated to have similar efficacy to caspofungin, and voriconazole was recently compared to amphotericin B in patients with candidemia.[27] Although other antifungal agents that can be administered intravenously (lipid amphotericin B formulations and itraconazole) are possibly as effective as amphotericin B, fluconazole, and caspofungin for invasive candidiasis, evidence supporting their use is derived principally from open-label observational studies, and empiric therapy trials of febrile neutropenia. As a result, their first-line use is not prominently recommended in evidence-based guidelines for proven infection.[20] No prospective randomized, controlled clinical trials have been published comparing antifungal therapies for proven acute disseminated candidiasis in neutropenic patients, chronic disseminated candidiasis, or other forms of deep-organ candidiasis.

A majority of patients are treated empirically for invasive candidiasis before conclusive evidence of infection is available to direct therapy. Empiric therapy for invasive candidiasis should be considered in any patient with persistent, unexplained fever and host deficits that predispose patients to candidemia, including broad-spectrum antibacterial therapy, presence of a central venous catheter, patients with severe organ dysfunction or on dialysis, patients with neutropenia or qualitative deficiencies in host immunity (e.g., due to high-dose corticosteroid therapy), or colonization with *Candida* at one or more body sites. ❾ If a patient is non-neutropenic and has never received prior azole therapy, fluconazole 800 mg/day is an appropriate first-line therapy for invasive candidiasis until speciation of the *Candida* isolate is confirmed (Table 81–3). Amphotericin B deoxycholate 0.7 mg/kg per day or caspofungin 70 mg on day 1, then 50 mg/day; voriconazole; or a lipid amphotericin B formulation are recommended as empiric therapy in patients with neutropenic fever. Other newer echinocandins (micafungin and anidulafungin) are effective alternatives to caspofungin. If the neutropenia is of shorter duration and the patient is at lower risk for mold infections (e.g., solid tumor patients with less than 2 weeks of neutropenia), higher-dose fluconazole (i.e., 800 mg/day or 12 mg/kg) could be considered. Lipid amphotericin B formulations, an echinocandin, or voriconazole are often the preferred agents in higher-risk patients with neutropenic fever to expand coverage against molds.[28,20] If the yeast is identified as *C. glabrata*, published treatment guidelines recommend the use of either caspofungin or possibly amphotericin B deoxycholate. Voriconazole is not recommended until further clinical data support its use for *C. glabrata*, as laboratory studies have suggested potential cross-resistance with fluconazole-resistant isolates of this species. High-dose fluconazole can also be considered for *C. glabrata*

TABLE 81–3. Therapeutic Approach to Opportunistic Fungal Infections

Mycoses	Recommended Treatment Regimens	Comments
Candidiasis		
Catheter-related and acute hematogenous	Amphotericin B 0.7 mg/kg per day IV **OR** Fluconazole 6–12 mg/kg/day IV q24hour **OR** Caspofungin[a] 70 mg IV on day 1, then 50 mg q24hour **OR** Amphotericin B + fluconazole *Second line:* Lipid amphotericin B formulation 3–5 mg/kg per day[b] **OR** Amphotericin B 0.5–7 mg/kg per day + flucytosine 100 mg/kg per day PO divided q6hour **OR** Voriconazole 6 mg/kg q12hour for 1 day, then 3 mg/kg q12hour **OR** Itraconazole 200 mg q12hour for 2 days, then 200 mg IV q24hour	Treat for 14 days after the last positive blood culture and resolution of signs and symptoms catheter should be removed whenever possible Patients can be switched to oral fluconazole when clinically stable if isolate is susceptible Caspofungin and amphotericin B are preferred agents for fluconazole-resistant species Voriconazole appears to be effective against fluconazole-resistant *C. krusei* Echinocandins likely equivalent
Empirical therapy in neutropenic patient	Fluconazole 6–12 mg/kg/day (low risk) **OR** Amphotericin B 0.7 mg/kg per day IV **OR** Itraconazole 200 mg q12hour for 2 days, then 200 mg IV q24hour **OR** Liposomal amphotericin B 3 mg/kg q24hour	Antifungals with coverage of *Aspergillus* should be used in higher-risk patients or prolonged neutropenia (i.e., longer than 2 weeks)
Urinary candidiasis	Fluconazole 200 mg IV or PO for 7–14 days **OR** Amphotericin B 0.3 mg/kg per day IV for 1–7 days	Asymptomatic candiduria does not required therapy However, treatment is recommended in neutropenic, low-birth-weight infants, and patients undergoing urologic manipulations or those with renal allografts Amphotericin B bladder irrigation no longer recommended
Cryptococcosis		
Pulmonary-isolated Severe pulmonary and meningitis	Fluconazole 6 mg/kg/day IV or PO for 6–12 mo *Induction:* Amphotericin B 0.7–1 mg/kg per day + flucytosine 100 mg/kg per day PO divided q6hour for 2 weeks *Consolidation:* Fluconazole 6–12 mg/kg/day for 10 weeks *Second line:* Fluconazole + flucytosine for 2 weeks then fluconazole for 10 weeks **OR** Amphotericin + fluconazole for 2 weeks then fluconazole for 10 weeks **OR** Liposomal amphotericin B 5 mg/kg per day × 2 weeks then fluconazole for 10 weeks	Regimens reported to produce faster sterilization of CSF compared to amphotericin B deoxycholate alone during the first 2 weeks: Amphotericin B + 5-flucytosine Amphotericin B + Fluconazole Liposomal amphotericin B Echinocandins have no activity against cryptococci
Aspergillosis	Voriconazole 6mg/kg q12hour for 1 day, then 4 mg/kg q12hour **OR** Lipid formulations of amphotericin B **OR** Caspofungin 70 mg IV for 1 dose, then 50 mg IV q12hour **OR** Posaconazole 200 mg PO qid × 14 days, then 200 mg PO bid **OR** Combination therapy	Voriconazole can be administered as oral therapy in patients taking oral medications Voriconazole can cause reversible visual disturbances and occasionally hallucinations Because of the high-dosages and prolonged treatment courses, lipid formulations are preferred for amphotericin B–based therapy

TABLE 81–3. Therapeutic Approach to Opportunistic Fungal Infections (*Continued*)

Mycoses	Recommended Treatment Regimens	Comments
		Preclinical studies suggest mold-active azoles plus echinocandins have enhanced activity against *Aspergillus* *A. terreus* should be considered resistant to amphotericin B Activity of amphotericin B and voriconazole is decreased versus *Aspergillus* species; higher doses or combination therapy may be indicated in more refractory cases
Fusariosis	Lipid formulations of amphotericin B **OR** Voriconazole 6 mg/kg q12hour for 1 day, then 4 mg/kg q12hour **OR** Posaconazole 200 mg PO qid for 14 days, then 200 mg PO q12hour **OR** Combination therapy	
Zygomycoses	High-dose lipid amphotericin B (e.g., 7.5–10 mg/kg per day) **OR** Posaconazole 200 mg PO qid for 14 days, then 200 mg PO q12hour **OR** Combination therapy	Prompt diagnosis and surgical débridement are essential for successful outcome; high dosages of lipid amphotericin B are required; posaconazole is the only azole with activity against zygomycoses

[a]Or equivalent echinocandin (micafungin 100–150 mg/day, anidulafungin 200 mg day 1, then 100 mg/day)
[b]Ambisome 3–5 mg/kg per day; Abelcet 5 mg/kg per day; Amphotec 4 mg/kg per day.
CSF, cerebrospinal fluid; IV, intravenous; PO, oral.

infections if the isolate is documented to be susceptible or susceptible-dose-dependent to fluconazole.[20] *C. krusei* infections can be treated with an echinocandin, amphotericin B or voriconazole. Patients who respond to therapy, are medically stable, not neutropenic, and are taking oral medications can be transitioned to oral fluconazole provided isolate susceptibility is documented by minimum inhibitory concentration testing. For uncomplicated catheter-related candidemia (no evidence of organ involvement), therapy should be continued for at least 2 weeks from the last positive blood culture.[20] In neutropenic patients, therapy should be continued until resolution of neutropenia.[20] All central venous catheters should be removed to decrease the duration of fungemia and risk of recurrent infections.[20]

Treatment recommendations for other forms of invasive candidiasis are based primarily on anecdotal evidence and expert opinion. Deep organ candidiasis requires prolonged therapy to achieve a cure; therefore importance is placed on the use of convenient and non-toxic long-term treatment regimens. Fluconazole (400 mg/day or 6 mg/kg per day) is the preferred regimen in clinically stable patients. Amphotericin B, lipid amphotericin B formulations, and possibly caspofungin can be considered for refractory cases or clinically unstable patients. Infections of the eye, bone, pancreas, or gallbladder are typically treated with either amphotericin B or fluconazole; however, there are few data to support the use of echinocandins. Urinary candidiasis is an ill-defined group of syndromes that can range from benign colonization (candiduria) to invasive disease of the renal parenchyma. Asymptomatic non-neutropenic patients with candiduria do not require antifungal therapy, as no study has demonstrated the value of transiently clearing *Candida* from the urine. Patients should

Patient Encounter, Part 2

Selecting Antifungal Therapy

The patient is started on fluconazole 400 mg/day, but 3 days later has persistent fever and develops hypotension and decreased urine output. Blood cultures reveal a germ tube–negative yeast growing in the blood. Laboratory studies revealed a white blood cell count of 12,300/mm^3 (12×10^9/L), aspartate aminotransferase 68 IU/L (1.13 μKat/L), alanine aminotransferase 75 IU/L (1.25 μKat/L), alkaline phosphatase 168 IU/L (2.8 μKat/L), and normal bilirubin. Serum creatinine is 1.8 mg/dL (159 μmol/L).

- What factors suggest empiric antifungal therapy should be changed in this patient?
- What are the most likely fungal species growing from the blood?
- What other procedures should be recommended in this patient to improve response to antifungal therapy?

receive 7 to 14 days of antifungal therapy for urinary candidiasis if they are: (1) symptomatic, (2) have clinical or laboratory evidence of infection, (3) are neutropenic, (4) are low-birth-weight infants, (5) will undergo urologic manipulations, or (6) have renal allografts. Removal of urinary tract instruments, including Foley catheters and stents, is recommended whenever possible. The preferred therapy is fluconazole 200 mg daily, although intravenous amphotericin B deoxycholate 0.3 to 1 mg/kg per day is also effective. Other antifungal agents do not achieve appreciable concentrations in the urine and therefore should not be considered for urinary candidiasis. Irrigation with amphotericin B is not effective for infections above the bladder and should not be used in higher-risk patients with the possible exception of as a diagnostic tool for confirming a localized infection of the bladder.

Mucocutaneous candidiasis is generally not life-threatening nor invasive and can be treated with topical azoles (clotrimazole troches), oral azoles (fluconazole, ketoconazole, or itraconazole), or oral polyenes (such as nystatin or oral amphotericin B). Orally administered and absorbed azoles (ketoconazole, fluconazole, or itraconazole solution), amphotericin B suspension, intravenous caspofungin, or intravenous amphotericin B are recommended for refractory or recurrent infections.[20]

Although more invasive, esophageal candidiasis does not typically evolve into a life-threatening infection. However, topical therapy is ineffective. Azoles (fluconazole, itraconazole solution, or voriconazole), echinocandins, or intravenous amphotericin B (in cases of unresponsive infections) are effective treatment options. Parenteral therapy should be used in patients who are unable to take oral medications.[20]

Patient Monitoring and Side Effects

Response to antifungal therapy in invasive candidiasis is often more rapid than for endemic fungal infections. Resolution of fever and sterilization of blood cultures are indications of response to antifungal therapy. Toxicity associated with antifungal therapy is similar in these patients as described earlier with the caveat that some toxicities may be more pronounced in critically-ill patients with invasive candidiasis. Nephrotoxicity and electrolyte disturbances, with amphotericin B in particular, are problematic and may not be avoidable even with lipid amphotericin B formulations. Fluconazole and echinocandins are generally safer options, and are generally well tolerated. Decisions to use one class of agents over the other is principally driven by concerns of non-*albicans* species, patient tolerability, or history of prior fluconazole exposure (risk factor for non-*albicans* species.).

Prophylaxis

Fluconazole (400 mg/day) has been extensively studied as a prophylactic regimen to prevent invasive candidiasis in patients with prolonged (greater than 2 weeks) neutropenia.[29–32] Placebo-controlled, prospective randomized trials performed in the 1990s demonstrated that fluconazole was effective in reducing the frequency, morbidity, and in some trials mortality, due to invasive candidiasis when administered until marrow recovery. However, the major limitation with fluconazole is its lack of mold coverage needed for high-risk patients with persistent neutropenia. More recent studies have examined the use of itraconazole or the echinocandin micafungin as prophylaxis in hematopoietic cell transplant recipients until engraftment to provide protection against both *Candida* and *Aspergillus* species.[33,34] Although both agents were effective, neither therapy was ideal because of either poor tolerability (itraconazole) or lack of an oral formulation (micafungin). Posaconazole has also shown promise as a prophylactic agent for both yeast and molds in high-risk cancer patients.

Antifungal prophylaxis in the non-neutropenic, non-cancer population is focused on the prevention of invasive candidiasis, and should be similarly targeted towards certain high-risk transplant populations (e.g., liver, pancreatic, or small-bowel transplantation) or ICU patients (i.e., neonatal intensive care) with rates of invasive candidiasis exceeding 10% despite aggressive infection-control procedures. Fluconazole prophylaxis (400 mg/day) has been shown to reduce the rate of *Candida* peritonitis in patients with refractory gastrointestinal perforation, and trended towards decreased rates of invasive candidiasis in select adult patients admitted to a surgical ICU for more than 3 days.[35] Fluconazole has also been shown to be effective in reducing the rate of invasive candidiasis in neonates.[36] It is hoped that ongoing studies will define the risks versus benefits of routine antifungal prophylaxis in the general ICU setting.

CRYPTOCOCCOSIS

Epidemiology

Cryptococcus neoformans is an encapsulated yeast that can infect apparently normal hosts, but is more frequently associated with severe infections in immunocompromised patients. *C. neoformans* is divided into two varieties based on serotype: *C. neoformans* var. *neoformans* (Serotypes a and d) and *C. neoformans* var. *gatti* (serotypes b and c). *C. neoformans* var. *gatti* is found predominantly in tropical and sub-tropical climates associated with eucalyptus trees, whereas *C. neoformans* var. *neoformans* is found worldwide and is associated with pigeon droppings and other avian excreta. Before the AIDS pandemic, cryptococcosis was a relatively uncommon disease, but became a leading cause of meningitis among HIV-infected patients. Although the incidence of this infection has declined somewhat with the widespread use of highly active antiretroviral therapy (HAART), *C. neoformans* remains an important pathogen in immunocompromised patients, including cancer

patients who often present with the pulmonary form of the infection.

Pathogenesis and Clinical Presentation

C. neoformans is acquired primarily through inhalation of the desiccated yeast particles found in the environment. Inhaled cells reach distal alveolar spaces where they gradually rehydrate and form their characteristic polysaccharide capsules that enable resistance to phagocytosis. Defects in cellular immunity allow reconstitution of the protective capsule and multiplication of yeast in the lungs. Although alveolar macrophages phagocytose the yeast, containment and killing requires a coordinated response between innate and adaptive humoral (complement and anticryptococcal antibodies) and T-cell–mediated host responses.[5] Deficiencies in cell-mediated immunity allow the yeast to survive as a facultative intracellular pathogen in macrophages as they migrate from the lung to draining lymph nodes, leading to dissemination via the bloodstream to the meninges.

Unlike most opportunistic fungi, true virulence factors have been identified for *C. neoformans*. The capsules, as well as the soluble polysaccharides released from the yeast cells during infection, impair phagocytosis and binding of anticryptococcal antibodies. Primary cryptococcal infection begins in the lung, presenting as a mildly symptomatic or asymptomatic infection that resolves spontaneously or results in an encapsulated, usually non-calcified lung nodule. It is not uncommon for these isolated nodules to be detected on chest x-rays during routine work-up. Diagnosis of primary cryptococcosis is only made if the nodule is aspirated or removed because of concerns of primary lung cancer.

In the immunocompromised host, infection of the lung may present with more diffuse, bilateral, interstitial disease that mimics the presentation of *Pneumocystis jiroveci (carinii)* pneumonia (PCP). Dissemination to other organs, particularly the CNS, eye, and possibly the skin, is more likely to occur in patients with severe deficits in cell-mediated immunity. Fever, cough, dyspnea, and pleural pain are common at presentation with accompanying hypoxemia that can rapidly evolve to acute respiratory failure. Because of the overlapping features of diffuse pulmonary cryptococcosis with other opportunistic pathogens, early diagnosis requires bronchoalveolar lavage or transbronchial biopsy, which can effectively diagnose 80% to 100% of cases.[37] The clinical course of diffuse cryptococcal pneumonia can be as severe as PCP, with mortality rates approaching 100% in untreated patients by 48 hours.

C. neoformans is strongly neurotropic and readily disseminates from the lung to the CNS, specifically the leptomeninges, and occasionally the parenchyma of the brain. The clinical characteristics of cryptococcal meningitis differ somewhat, however, between patients with and without underlying AIDS. In patients without AIDS, disease presentation is more insidious and symptoms such as dizziness, irritability, decreased comprehension, and unstable gait may present many weeks to months before the diagnosis is made.[37] Patients with AIDS generally present much later in the course of disease with severe meningoencephalitis.[37] The most common signs and symptoms on presentation are fever, headache, meningismus, photophobia, mental status changes, and seizures. Computed tomography or more sensitive magnetic resonance imaging may reveal cerebral edema, multiple areas of enhanced nodules, or a single mass lesion (cryptococcoma). Examination of the cerebrospinal fluid often reveals increased opening pressure upon lumbar puncture, but glucose, protein, and leukocyte levels can be normal.[37]

Laboratory Diagnosis

Clinical diagnosis is confirmed by cultures from the blood, CSF, or other clinically relevant fluids or tissue. ⑩ Direct visualization of *C. neoformans* in the CSF by India ink staining is the most rapid method for diagnosing cryptococcal meningitis.[37] Detection of cryptococcal antigen in either serum or CSF has greater than 95% sensitivity and specificity in the diagnosis of true invasive cryptococcal infection and appears to correlate with fungal burden.[37] A positive serum antigen test of greater than 1:4 strongly suggests cryptococcal infection, and greater than or equal to 1:8 is indicative of active disease. Antigen titers in serum are positive in 99% of patients with cryptococcal meningitis, and typically exceed titers of 1:2,048 in patients with AIDS.[37] However, the time course of cryptococcal antigen elimination is unknown and a positive test result can persist for many years. Changes in the CSF cryptococcal antigen titers have limited value in the monitoring of drug therapy for cryptococcal meningitis, although it is expected that a decrease should be seen after 2 or more weeks of antifungal therapy.[37]

Treatment

Cryptococcal meningitis is fatal if left untreated. Because pneumonia frequently precedes dissemination of disease and subsequent meningitis, all patients with culture-, histopathology-, or serology-proven disease should receive antifungal therapy. In patients with isolated pulmonary cryptococcosis, fluconazole is generally considered to be the therapy of choice (see Table 81–2).[37] Alternatively, itraconazole or combination therapy (fluconazole plus flucytosine) has also been used with some success in patients.

Disseminated or CNS cryptococcosis requires a more aggressive treatment approach, particularly in the immunocompromised host. Pretreatment predictors of poor outcome with antifungal therapy include:

- Progressive underlying disease or immunodysfunction
- Abnormal mental status at the time of presentation
- Increased opening pressure on lumbar puncture (greater than 260 mm H_2O)
- High fungal burden as reflected by a CSF antigen titer [in AIDS patients] of greater than 1:2048

Prospective randomized trials completed prior to the recognition of AIDS demonstrated high response rates (approximately 80%) with the combined use of amphotericin B and flucytosine for 4 to 6 weeks. Although sterilization of the CSF could be achieved in most patients within 2 weeks with this regimen, a substantial number of patients (30% to 40%) developed dose-limiting toxicities and relapse was seen in roughly 50% of patients. Therefore a new treatment approach was devised that consisted of distinct treatment phases to minimize toxicity and reduce the risk of relapse. ⓫ Clinical trials performed by the National Institute of Allergy and Infectious Diseases (NIAID) Mycoses Study Group after the recognition of AIDS showed that 2 weeks of induction antifungal therapy with combination amphotericin B (0.7 mg/kg per day) plus flucytosine (100 mg/kg per day) for cryptococcal meningitis, followed by consolidation therapy with fluconazole (400 mg daily) for 8 weeks was as effective as 4 weeks of combination therapy, with fewer toxicities (see Table 81–2). More recent studies have suggested fluconazole plus amphotericin may be an acceptable option in patients who cannot tolerate therapy with flucytosine (see Table 81–2).

Prophylaxis

Fluconazole (200 mg per day) is recommended as maintenance therapy for life in patients with persistent underlying immune dysfunction to prevent recurrent cryptococcal meningitis. With the introduction of HAART, the United States Public Health Service guidelines have recently changed secondary prophylaxis recommendations for cryptococcosis based on data that demonstrated it is safe to discontinue maintenance therapy in AIDS patients who have had a sustained immunologic response on effective antiretroviral therapy.[38] Occasionally, initiation of HAART can result in the reactivation of a sub-clinical, immunologic manifestation of cryptococcal infection (or other opportunistic infections). Manifestations of this so-called *immune reconstitution syndrome* may include exacerbations of meningitis or necrotizing pneumonia. Antifungal therapy plus a nonsteroidal anti-inflammatory agent or prednisone have been used successfully in patients with cryptococcal-associated immune reconstitution syndrome. However, the optimal management of this recently defined clinical entity remains unknown.

INVASIVE ASPERGILLOSIS

Epidemiology

Invasive molds, particularly *Aspergillus,* have become an increasingly important complication of cancer therapy and organ transplantation. Patients with acute leukemia and recipients of allogeneic hematopoietic cell transplants are at especially high risk for invasive aspergillosis due to prolonged neutropenia and deficiencies in cell-mediated immunity associated with graft-versus-host disease and its treatment. More than 180 species within the genus *Aspergillus* have been described, but only four species are commonly associated with invasive infection: *Aspergillus fumigatus*, *Aspergillus flavus*, *Aspergillus terreus*, and *Aspergillus niger.* Of these four species, *A. fumigatus* accounts for the majority of human pulmonary fungal infections. However, identification of *Aspergillus* mold in culture to the species level is still essential, because the incidence of amphotericin B–resistant *Aspergillus terreus* and *Aspergillus flavus* have increased over the last 5 years among high-risk patients. Early and accurate diagnosis of invasive aspergillosis (IA) remains the most important barrier to the effective management of this infection, which is associated with crude mortality rates ranging from 60% to 100%.[39]

Pathogenesis and Clinical Presentation

The pathogenesis of IA is defined largely by the underlying immune dysfunction of the host. The most common route of acquisition for *Aspergillus* is through the respiratory tract. Conidia dispersed in air currents are continuously inhaled through the sinuses and mouth and penetrate down to distal alveolar spaces (see Fig. 81–3c). Most conidia are rapidly phagocytosed and removed by resident macrophages in the upper and lower respiratory tract.[5] However, macrophage function may be suppressed following transplantation, cytotoxic chemotherapy, or in patients who have received high-dose corticosteroid therapy. Conidia that escaped phagocytosis begin to germinate into hyphal forms that are too large for ingestion by macrophages. Hyphal forms of *Aspergillus* then invade blood vessels or contiguous tissues or bone (in sinuses) resulting in hemorrhage and/or infarction, and coagulative necrosis. Once in the bloodstream, viable hyphal fragments can break off and disseminate to distal organs including the brain. Control of the infection at this stage requires development of an adaptive Th-1 type response to enhance the fungicidal activity of professional effector cells (i.e., neutrophils) against hyphal elements.[5] Patients with dysregulated, suppressed T-cell–mediated immunity, or prolonged neutropenia are unable to control the infection and are at high risk for dissemination of the infection. Without antifungal therapy, invasive aspergillosis is uniformly fatal.

Signs and symptoms of invasive aspergillosis are predictably muted in the immunocompromised host. Fever is common but non-specific for infection and may be accompanied by pleuritic chest pain, cough, hemoptysis, and/or friction rub.[40] Neurologic signs including seizures, hemiparesis, and stupor may be present in patients with dissemination to the brain. Cutaneous plaques or papules characterized by a central necrotic ulcer or eschar occur in up to 10% of patients with disseminated disease; however, concomitant blood cultures are often negative. Chest radiographs cannot detect early forms of disease and may remain negative in up to 10% of patients within 1 week of death.[41] ⓬ Nodular lesions detected

Patient Encounter, Part 1

Invasive Mold Infection

A 40-year-old female with acute myelogenous leukemia at day 115 post matched-allogeneic donor hematopoietic stem cell transplantation presents to the clinic with increasing complaints of nausea, stomach cramping, and rash on the hands spreading up her arms. She also complains of pain upon deep inspiration. By laboratory examination, she is noted to have an alanine aminotransferase of 85 IU/L (1.42 μKat/L), aspartate aminotransferase 75 IU/L (1.25 μKat/L) and total bilirubin of 2.1 mg/dL (36 μmol/L). Her current medications include tacrolimus 5 mg twice daily (most recent level: 8 ng/mL), levofloxacin 500 mg daily, fluconazole 200 mg/day, valacyclovir 500 mg twice daily, metoprolol 25 mg twice daily, and benzonatate (tessalon) pearls. She is admitted to the hospital for suspected graft-versus-host disease exacerbation. Computed tomography scan of the chest revels three to four dense pleural base nodules in both lung fields. The primary service wishes to start voriconazole.

- What are the patient's risk factors for developing an invasive mold infection?
- Is voriconazole an acceptable option in this patient? Are there any drug interaction concerns?

by high-resolution computed tomography (HRCT) scans are often the first indication of invasive pulmonary aspergillosis along with fever, and reveal small wedge-shaped or nodular lesions, typically surrounded by intermediate attenuation called the "halo sign."[41–43] These early lesions on CT scans represent hemorrhage and edema surrounding an infarcted blood vessel. Despite "effective" antifungal therapy, lesions on CT scan may continue to increase in size in neutropenic patients until neutrophils recover, at which time they begin to cavitate, forming the "air-crescent sign" on chest radiographs, indicative of resolving infection. ⓭ Immunocompromised patients on fluconazole with progressive sinus or pulmonary disease by radiography should be evaluated for possible mold infection.[40,43,44]

Laboratory Diagnosis

Like other invasive mycoses, definitive diagnosis of aspergillosis requires histopathologic evidence of hyphal invasion in tissue (Fig. 81–4). However, procedures needed to establish a definitive diagnosis by sampling of suspicious lesions (e.g., fine-needle aspiration or thoracoscopic lung biopsy) are not feasible in a large proportion of patients with underlying thrombocytopenia secondary to hematologic malignancies or chemotherapy. Even if hyphae are observed in tissue, histopathology alone cannot

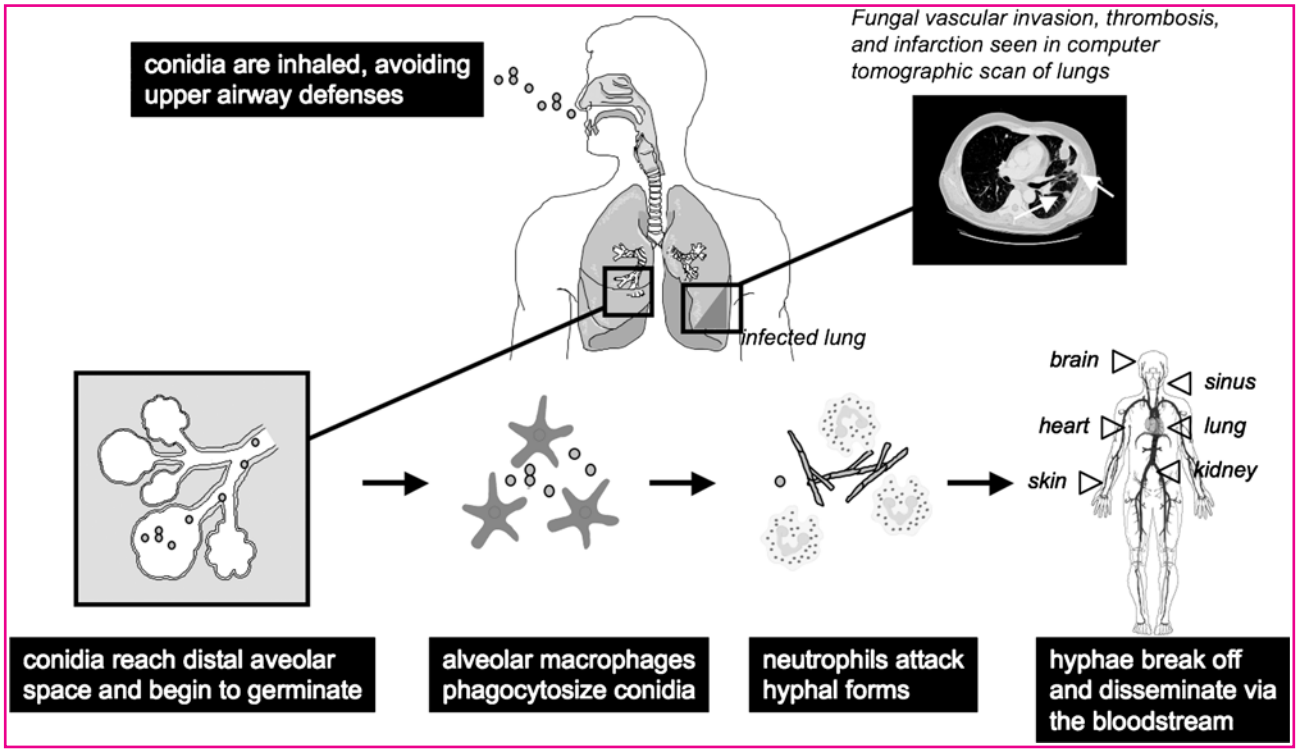

FIGURE 81–4. Pathogenesis of invasive aspergillosis.

distinguish *Aspergillus* from other angioinvasive septate molds such as *Fusarium*, which have different patterns of antifungal susceptibility.[40] Therefore, respiratory and/or wound cultures (if cutaneous or sinus/hard palate lesions are present) are important factors in the modification of empiric antifungal therapy.

Respiratory cultures including sputum, bronchial washings, or bronchoalveolar lavage have a low sensitivity for diagnosis of invasive aspergillosis but a high positive predictive value in immunocompromised patients.[45] Therefore, a negative bronchoalveolar lavage culture does not rule out invasive pulmonary aspergillosis, but a positive culture in a high-risk patient (e.g., allogeneic hematopoietic cell transplant patients) indicates pulmonary aspergillosis in at least 60% of such patients. Blood cultures have little diagnostic value for invasive aspergillosis, but may reflect true disease with *A. terreus.* Patients with limited lung involvement or on prophylactic or empiric antifungal therapy may continue to be culture-negative for *Aspergillus* species despite the appearance of progressing disease. Therefore, clinical specialists should never consider negative cultures as an indication for stopping antifungal therapy in patients with suspected or proven aspergillosis.

Considerable effort has been focused in the last decade to develop non–culture based laboratory methods (antigen detection, polymerase chain reaction [PCR], and metabolite detection) for the diagnosis of invasive aspergillosis. The hope is that these surrogate tests could detect early evidence of *Aspergillus* infection before significant target organ damage eventually detected by CT scans occurs. Recently, the Food and Drug Administration has approved an ELISA-based assay for the detection of a polysaccharide component of the *Aspergillus* cell wall called galactomannan. Although several large prospective studies have found that the sensitivity and specificity of the assay exceeded 90% in neutropenic patients with hematologic malignancies, the median time span between galactomannan detection and clinical signs and symptoms of IA averages less than 6 days.[46,41] Other factors such as patient immune status (neutropenia versus graft-versus-host disease), antifungal therapy, and diet may affect the interpretation of the galactomannan test.[47,48] For example, false-positive results have been reported in pediatric patients, patients receiving piperacillin-tazobactam for neutropenic fever, and following the ingestion of certain cereals, pastas, nutritional supplements, or soy sauce.[48] Hence, there are numerous opportunities for false-positive tests. Although some animal studies and clinical data suggest that rising galactomannan levels are a harbinger of breakthrough infection, there are still limited data supporting the use of this test to guide and monitor antifungal therapy. At this time it appears that the galactomannan test (and other non–culture based strategies) will be serve as complementary methods to confirm results from microbiologic, histopathologic, and radiographic investigations directed towards diagnosing invasive aspergillosis.

Treatment

To date, only two comparative randomized controlled clinical trials have evaluated antifungal therapies for the treatment of invasive aspergillosis and only one study was sufficiently powered to measure differences in response to antifungal therapy.[49] In that study, unblinded investigators compared patients initially randomized to the newer triazole, voriconazole, to patients initially treated with amphotericin B deoxycholate.[49] The study design was unique in that it allowed a change from the randomized drug to any other licensed antifungal therapy, without requiring that the patient be classified as a treatment failure on randomized therapy. Nearly 80% of patients randomized to receive amphotericin B deoxycholate were switched to other licensed antifungal therapies (mean duration 10 days) versus 36% of patients in the voriconazole arm (mean duration 77 days). The poor tolerability of amphotericin B deoxycholate was not surprising given the relatively higher dosages (1 mg/kg per day intravenously) and prolonged treatment courses required in the treatment of invasive aspergillosis. At the end of the study (12 weeks), a higher proportion of patients in the voriconazole arm remained alive (70.8%) compared to amphotericin B deoxycholate–treated patients (57.9%). ⓮ On the basis of these results, many experts now consider voriconazole as the initial drug of choice for invasive aspergillosis in patients without significant contraindications (e.g., drug interactions or preexisting liver dysfunction) to azole therapy (see Table 81–2). Voriconazole also appears to have some efficacy in CNS aspergillosis, a form of invasive aspergillosis with historical mortality rates approaching 100%. Itraconazole has activity against *Aspergillus* and is frequently used as prophylaxis, but is not considered a particularly effective treatment option for invasive disease.[50,51]

Lipid formulations of amphotericin B, caspofungin, or other echinocandins, and the investigational triazole posaconazole, can be considered as possible alternatives to voriconazole therapy and may be preferred agents in patients with breakthrough infection on azole antifungals (including itraconazole or fluconazole). Several recent open-label case series have suggested that combination therapy, with an echinocandin and mold-active traizole such as voriconazole, may be more effective than voriconazole alone for invasive aspergillosis that has failed amphotericin B–based therapy.[52,53] Once antifungal therapy has begun, the duration and intensity of antifungal therapy is directed by host-specific factors including clinical response, underlying immunosuppression, tolerability, and plans for future chemotherapy/immunosuppression. In the heavily immunocompromised patient, complete eradication of the fungus is unlikely and suppressive therapy may be required until well after recovery of cellular immune function. Reactivation from residual infracts or devitalized tissue in the sinus or lung harboring aspergillosis is a concern if the patient will receive further immunosuppressive therapy. Therefore, surgical débridement of the sinus or excision of large lung lesions is often pursued. Relapsing or breakthrough *Aspergillus*

Patient Encounter, Part 2

Voriconazole is started in the patient along with 1 mg/kg per day of methylprednisolone to control the graft-versus-host disease. Her tacrolimus dose was also decreased by 70% with the addition of voriconazole and a recent tacrolimus blood level of 10 ng/mL. Unfortunately, the patient remains febrile with worsening respiratory pain. A repeat CT scan of the lung demonstrates new nodules, and pleural effusion in the right lung.

- What are the possible reasons this patient appears to be progressing on voriconazole therapy?
- What other molds may be implicated as a cause of infection that may not respond to voriconazole in this patient?
- What treatment options can be considered in this patient?

infections respond less favorably to antifungal therapy than de novo IA and may require more aggressive measures (combination therapy, immunotherapy, or surgery) to stabilize the infection.

Prophylaxis

Although recently published guidelines for preventing opportunistic infections in hematopoietic cell transplant recipients do not provide concrete recommendations for antifungal prophylaxis against *Aspergillus*, prophylaxis should be considered in certain high-risk subgroups with rates of invasive aspergillosis exceeding 10%. These groups include: (1) patients with prolonged pre-engraftment periods (e.g., cord-blood transplant recipients), (2) patients with a history of invasive aspergillosis prior to transplantation, (3) patients receiving transplants with a high risk of graft-versus-host disease (e.g., haploidentical allogeneic transplant) or infection (e.g., T-cell–depleted transplant), any patient with graft-versus-host disease on high-dose corticosteroid therapy (greater than 1 mg/kg prednisone equivalent) with or without anti-thymocyte globulin or tumor necrosis factor blockade (i.e., infliximab), and (4) any patient transplanted with active cytomegalovirus disease, which is associated with an increased risk of subsequent mold infections due to the immunosuppressive effect of the virus.

Patient Monitoring and Side Effects

Response to antifungal therapy in invasive molds is slow and difficult to judge by clinical signs alone. Resolution of fever, and eventual clearing of CT scans (in the case of lung infections) are indications of response to antifungal therapy. Toxicity associated with antifungal therapy is similar in these patients as in those described earlier. Patients often require prolonged therapy, particularly if they remain immunosuppressed. In many cases, antifungal therapy may be continued indefinitely until complete resolution of underlying immunosuppression.

OTHER MOLDS

Although *Aspergillus* is the most common mold infection in immunocompromised patients, virtually any mold can cause invasive infection in the right immunocompromised host. However, studies describing the epidemiology, management, and outcome of these less-common opportunistic molds are available only from case reports or case series. For this reason, current treatment guidelines for fungal infections do not address the management of these less-common mycoses. Yet, as survival has improved in patients with *Candida* and *Aspergillus* infections, less common opportunistic molds, particularly the agents of zygomycosis and fusariosis are becoming important causes of breakthrough infections on antifungal prophylaxis and therapy. Therefore, the epidemiology, clinical presentation, and treatment of these infections will be briefly reviewed.

Fusariosis

Fusarium species are the second to third most common pathogenic mold among immunocompromised patients, particularly those with hematologic malignancies. Risk factors for disseminated fusariosis are similar to those of invasive aspergillosis and include neutropenia, lymphopenia, graft-versus-host disease, and high-dose corticosteroid therapy. Although the clinical presentation of fusariosis is often indistinguishable from that of invasive aspergillosis, skin lesions and fungemia are significantly more common with *Fusarium* infections.[54] Skin lesions typically precede fungemia, which can be detected by blood culture in up to 40% of patients. Histopathology reveals acute-branching septate hyphae similar to those found in aspergillosis. Invasive fusariosis carries a mortality rate of up to 80% depending on the underlying host immune status. Patients with persistent neutropenia are at especially high risk for poor outcome. Anecdotal success has been reported with the use of high-dose (greater than 7.5 mg/kg per day) lipid amphotericin B, voriconazole, and posaconazole.[54] Transfusions of granulocytes stimulated with cytokines have also been attempted in patients with persistent neutropenia to control refractory infections.

ZYGOMYCOSIS

Zygomycosis is an uncommon infection caused by the fungi of the order Mucorales, class Zygomycetes, with the most commonly representative organisms being *Mucor, Rhizopus,*

Absidia, Cunninghamella, and *Rhizomucor*.[55] Zygomycosis is classically associated with progressive invasive rhinocerebral infections in patients with diabetes mellitus and/or diabetic ketoacidosis that extends to the periorbital region and face and invades the brain.[56] However, invasive zygomycosis is increasingly encountered in cancer patients, particularly transplant or leukemic patients who have received high doses of steroids, or patients with prolonged, profound neutropenia. Unlike the classic rhinocerebral form of invasive zygomycosis seen in diabetic patients, pulmonary infections appear to be more common in the cancer population. ⓯ Zygomycetes are generally resistant to voriconazole and echinocandins and their presence should be suspected in any patient with progressive mold infection while receiving voriconazole and/or echinocandin therapy.[56,57] Because of the rapid progression of disease, early diagnosis and aggressive therapy are essential for favorable outcome. Lipid amphotericin B, radical surgical débridement, cytokine-stimulated granulocyte transfusions, and even hyperbaric oxygen therapy have been reported to reduce the morbidity and high mortality of this devastating infection. Posaconazole is the only triazole antifungal with activity against Zygomycetes and has been reported to be effective against sinopulmonary forms of infection.[57]

CONCLUSION

Modern medical practices and advances in transplantation and cancer therapy have elevated primary and opportunistic mycoses to relatively common causes of infectious disease–related morbidity and mortality in humans. Although invasive mycoses are often more difficult to diagnose and treat compared to common bacterial pathogens, the continued introduction of effective and better-tolerated treatment alternatives to amphotericin B–based therapy has allowed greater flexibility and more treatment options for these challenging infections. The development of early, accurate, and effective non–culture based diagnostic tests remains the key obstacle to improving pharmacotherapeutic trial designs and outcomes of invasive mycoses in immunocompromised patients.

82 Antimicrobial Prophylaxis in Surgery

Jeremy A. Schafer and John C. Rotschafer

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Discuss the epidemiology and impact of surgical wound infections on patient outcomes and health care costs.
2. Name and differentiate the four different types of surgical procedures.
3. Recognize at least three risk factors for post-operative wound infections.
4. Identify likely pathogens associated with different surgical operations.
5. Compare and contrast antimicrobials used for surgical prophylaxis and identify potential advantages and disadvantages for each antibiotic.
6. Discuss the importance of timing, duration, and redosing in relation to antimicrobial prophylaxis in surgery.
7. Discuss the possible impact of antibiotic-impregnated bone cement and how this affects the use of antimicrobial prophylaxis in surgery.
8. Be able to recommend appropriate prophylactic antimicrobial(s) given a surgical operation.
9. Discuss the importance of β-lactam allergy screening and how this could impact resistance and health care costs.
10. Identify non-antimicrobial methods that can reduce the risk of post-operative infection.

Key Concepts

❶ Surgical site infections (SSIs) are a significant cause of morbidity and mortality.
❷ The distinction between prophylaxis and treatment influences the choice of antimicrobial and duration of therapy.
❸ Surgical operations are classified as clean, clean-contaminated, contaminated, or dirty.
❹ Choosing the appropriate prophylactic antimicrobial relies on anticipating which organisms are likely to be encountered during the operation.
❺ A thorough drug allergy history should be taken to discern true allergy (anaphylaxis) from adverse event (stomach upset).
❻ Further study is needed before antibiotic-impregnated bone cements can be recommended as an alternative to preoperative prophylaxis with traditional antimicrobials.
❼ Correct timing of antibiotic administration is imperative to preventing SSI.
❽ The goal of antimicrobial dosing for surgical prophylaxis is to maintain antibiotic concentrations above the minimum inhibitory concentration (MIC) of suspected organisms for the duration of the operation.
❾ Studies have not shown benefit for additional doses of antibiotic and the duration of antimicrobial prophylaxis should not exceed 24 hours.
❿ According to Centers for Disease Control criteria, SSI may appear up to 30 days after an operation and up to 1 year if a prosthesis is implanted.

❶ ***Surgical site infections*** *(SSIs) are a significant cause of morbidity and mortality*. Approximately 2% to 5% of patients undergoing clean **extra-abdominal** operations and 20% undergoing **intra-abdominal** operations will develop an SSI.[1] SSIs have become the second most common cause of nosocomial infection and these data are likely underestimated.[1] More than 70% of surgical procedures are now performed on an outpatient basis, leaving significant potential for underreporting.[2]

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

SSIs negatively affect patient outcomes and increase health care costs. Patients who develop SSIs are five times more likely to be readmitted to the hospital and have twice the mortality of patients who do not develop an SSI.[1] A patient infected with an SSI is also 60% more likely to be admitted to an intensive care unit.[1] Clinical studies have shown that SSIs increase lengths of hospital stay and costs.[1,3,4] The type of SSI can also affect outcome. Deep SSIs, involving organs or spaces, result in longer durations of hospital stay and higher costs compared to SSIs that are limited to the incision.[5]

SSIs are defined and reported according to Centers for Disease Control and Prevention (CDC) criteria.[5] SSIs are classified as either incisional or organ/space. Incisional SSIs are further divided into superficial incisional SSI (skin or subcutaneous tissue) and deep incisional SSI (deeper soft tissues of the incision). Organ/space SSIs involve any anatomic site other than the incised areas. For example, a patient who develops meningitis after removal of a brain tumor could be classified as having an organ/space SSI. An infection is considered an SSI if any of the above criteria is met and the infection occurs within 30 days of the operation. If a prosthetic is implanted, the timeline extends out to 1 year.

EPIDEMIOLOGY AND ETIOLOGY

Numerous **risk factors** for SSI have been identified in the literature.[5–7] These factors can be divided into two categories: patient and operative characteristics. Patient risk factors for SSI include: age, comorbid disease states (especially chronic lung disease and diabetes), malnutrition, immunosuppression, nicotine or steroid use, and colonization of the nares with *Staphylococcus aureus*. Many patients developing post-operative wound infections bring the organism with them into the hospital. Modifying risk factors may decrease the threat of SSI. Studies have shown that the use of intranasal mupirocin can decrease the incidence of SSI due to methicillin-sensitive *Staphylococcus aureus* (MSSA) or methicillin-resistant *Staphylococcus aureus* (MRSA).[8–10] Malnutrition can be corrected using enteral or parenteral feedings. Additional non-antimicrobial strategies to reduce SSI will be discussed later.

Operative characteristics are based on the actions of both the patient and the operating staff. Shaving of the surgical site prior to operating can produce microscopic lacerations and increase the chance of SSI.[5] Maintaining aseptic technique and proper sterilization of medical equipment is effective in preventing SSI. Surgical staff should wash hands thoroughly. Post-operative bacterial inoculums of clean surgeries are generally small. However, subsequent patient contact with contaminated areas (nares or rectum) and then the surgical site can lead to SSI. Finally, the appropriate use of **antimicrobial prophylaxis** can have a significant impact on decreasing SSIs.

PATHOPHYSIOLOGY

Prophylaxis versus Treatment

Properly identifying the state of an infection is important when using antimicrobial prophylaxis in surgery. Antibiotic prophylaxis begins with the premise that no infection exists but that during surgery there can be a low level inoculum of bacteria introduced into the body. However, if sufficient antibiotic concentrations are present, the situation can be controlled without infection developing. This is the case when surgery is done under controlled conditions, there are no major breaks in technique or spillage of gastrointestinal (GI) contents, and perforation or damage to the surgical site is absent. An example would be an elective hysterectomy done with optimal surgical technique.

If an infection is already present, or presumed to be present, then antimicrobial use is for treatment, not prophylaxis, and the goal is to eliminate the infection. This is the case when there is spillage of GI contents, gross damage or perforation is already present, or the tissue being operated on is actively infected (pus is present and cultures are positive). An example would be a patient undergoing surgery for a ruptured appendix with diffuse peritonitis.

❷ *The distinction between prophylaxis and treatment influences the choice of antimicrobial and duration of therapy.* Appropriate antimicrobial selection, dosing, and duration of therapy differ significantly between these two situations. A regimen for antimicrobial prophylaxis ideally involves one agent and lasts less than 24 hours. Treatment regimens can involve multiple antimicrobials with durations lasting weeks to months depending on desired antimicrobial coverage and the surgical site.

Types of Surgical Operations

❸ *Surgical operations are classified as clean, clean-contaminated, contaminated, or dirty.* Antimicrobial prophylaxis is appropriate for clean, clean-contaminated, and contaminated operations. Dirty operations take place in situations of existing infection and antimicrobials are used for treatment, not prophylaxis (Table 82–1).

Microbiology

❹ *Choosing the appropriate prophylactic antimicrobial relies on anticipating which organisms will be encountered during the operation.* SSIs associated with extra-abdominal operations are the result of skin flora organisms in nearly all cases. These organisms include gram-positive cocci, with *S. aureus* and *S. epidermidis* being among the most frequently isolated SSI pathogens according to the National Nosocomial Infections Surveillance System (NNIS)[5] (Table 82–2). *Streptococcus* spp. and other gram-positive aerobes may also be implicated.

TABLE 82–1. National Red Cross Wound Classification, Risk of Surgical Site Infection (SSI), and Antibiotic Indication[6,24]

Classification	Description	SSI Risk	Antibiotic Prophylaxis
Clean	No acute inflammation or transection of GI, oropharyngeal, GU, biliary, or respiratory tracts; elective case, no technique break	Low	Indicated
Clean-contaminated	Controlled opening of aforementioned tracts with minimal spillage or minor technique break; clean procedures performed emergently or with major technique breaks	Medium	Indicated
Contaminated	Acute, non-purulent inflammation present; major spillage or technique break during clean-contaminated procedures	High	Indicated
Dirty	Obvious preexisting infection present (abscess, pus, or necrotic tissue present)	—	Not indicated; antibiotics used for treatment

GI, gastrointestinal; GU, genitourinary.

Intra-abdominal operations involve a diverse flora with the potential for polymicrobial SSIs. *Escherichia coli* make up a large portion of bowel flora and are frequently isolated as pathogens according to the NNIS.[5] Other enteric gram-negative bacteria, as well as anaerobes (especially *Bacteroides* spp.), may be encountered during intra-abdominal operations.

Candida albicans is being implicated as the cause of a growing number of SSIs. According to the NNIS, from 1991 to 1995, the incidence of fungal SSIs rose from 0.1 to 0.3 per 1000 discharges.[5] Increased use of broad spectrum antibiotics and rising prevalence of immunocompromised and human immunodeficiency virus–infected individuals are factors in fungal SSIs. Despite this increase, antifungal prophylaxis for surgery is not currently recommended.

TABLE 82–2. Major Pathogens in Surgical Wound Infections

Pathogen	Percent of Infections[a]
Staphylococcus aureus	20
Coagulase-negative staphylococci	14
Enterococci	12
Escherichia coli	8
Pseudomonas aeruginosa	8
Enterobacter spp.	7
Proteus mirabilis	3
Klebsiella pneumoniae	3
Other *Streptococcus* spp.	3
Candida albicans	3
Group D streptococci	2
Other gram-positive aerobes	2
Bacteroides fragilis	2

[a]Data reported by the NNIS from 1990 to 1996, adapted from National Academy of the Sciences National Research Council. Postoperative wound infections: The influence of ultraviolet irradiation of the operating room and of various other factors. Ann Surg 1984; 160:32–135.
(From Kanji S, Devlin JW. Antimicrobial prophylaxis in surgery. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 2219, with permission.)

Choosing an Antibiotic

An antimicrobial used in surgical prophylaxis should meet certain criteria. Selecting an antibiotic with a spectrum that covers expected pathogens is crucial. The antibiotic should be inexpensive, available in a parenteral formulation, and easy to use. Adverse event potential should be minimal. Choosing an agent with a longer half-life reduces the likely need to redose unless the surgical procedure is prolonged.

Operations can be separated into two basic categories: extra-abdominal and intra-abdominal. SSIs resulting from extra-abdominal operations are frequently caused by gram-positive aerobes. Thus, an antimicrobial with strong gram-positive coverage is useful. Cefazolin benefits from a benign adverse-event profile, simple dosing, and low cost. These aspects have made cefazolin the mainstay for surgical prophylaxis of extra-abdominal procedures. For patients with a **χ-lactam allergy,** clindamycin or vancomycin can be used as an alternative.

Intra-abdominal operations necessitate broad-spectrum coverage of gram-negative organisms and anaerobes. Anti-anaerobic cephalosporins, cefoxitin and cefotetan, are useful but suffer from limited availability. Fluoroquinolones or aminoglycosides, paired with clindamycin or metronidazole, should provide adequate coverage for intra-abdominal operations.

The Hospital Infection Control Practices Advisory Committee allows for the use of vancomycin for surgical prophylaxis when MRSA rates at an institution are "high."[1] Unfortunately, a "high" rate of MRSA has not been standardized, but with most hospitals reporting MRSA rates greater than 50%, the definition is irrelevant. The increasing prevalence of community-acquired methicillin-resistant *Staphylococcus aureus* in patients admitted to the hospital is a concern, although this pathogen is often sensitive to clindamycin. Vancomycin use may not translate into a lower incidence of SSI. Finkelstein and associates found that the incidence of SSI between patients on cefazolin or vancomycin did not differ despite a high MRSA rate at the study institution. However,

patients who received cefazolin were more likely to develop an SSI due to MRSA.[11]

Newer antimicrobials have not demonstrated superiority in the prevention of SSI and should be reserved for treatment only. Carbapenems, antipseudomonal penicillins, and third- or fourth-generation cephalosporins are not appropriate antibiotics for surgical prophylaxis. Overuse of these antibiotics may contribute to collateral damage and the development of bacterial resistance.

Beta-Lactam Allergy

Penicillin allergy is one of the most common reported drug allergies. Concerns over cross-reactivity may limit the use of β-lactams for surgical prophylaxis. ❺ *A thorough drug allergy history should be taken to discern true allergy (e.g., anaphylaxis) from adverse event (e.g., stomach upset).* Allergy testing may be helpful in confirming a patient's penicillin allergy and could spare vancomycin. Cross-sensitivity between penicillin allergy and cephalosporins is low. Pichichero and colleagues stated that the increased risk of cephalosporin allergy in patients with a history of penicillin allergy may be as low as 0.4% when taking first-generation cephalosporins and nearly zero for second- and third-generation agents.[12] Apter and co-workers also found the risk of cross-reactivity to be very low.[13] However, in the case of severe penicillin allergy (anaphylaxis), cephalosporins should be avoided.

Alternative Methods to Decrease SSI

Several non-antimicrobial methods have been studied for reducing the risk of SSI.[14] Kurz and associates found that providing supplemental warming to patients (36.6°C or 98°F) during the intraoperative period reduced infection rates compared to control patients (34.7°C or 94.5°F).[15] Van den Berghe and co-workers studied the impact of intensive glucose control [80 to 110 mg/dL (4.44 to 6.1 mmol/L)] versus conventional control [glucose less than 210 mg/dL (less than 11.7 mmol/L)] and found an advantage for intensive glucose control in reducing infections in critically ill patients.[16] Finally, Greif and colleagues found that patients randomized to 80% inspired oxygen had lower SSI rates compared to patients on 30% oxygen after colorectal resection.[17] Despite these findings, there are insufficient data to make definitive recommendations on the use of these therapies.

Antibiotic-impregnated bone cement is being used as an adjunct or alternative to traditional antimicrobial prophylaxis. A study by Chiu and associates found cefuroxime-impregnated cement lowered the risk of deep infection after primary total knee arthoplasty.[18] Other studies have been inconclusive regarding superiority of antibiotic-impregnated bone cement versus conventional therapies.[19] Confounding this issue is the lack of standards regarding antibiotic-impregnated cements. An array of drugs, from aminoglycosides to macrolides, are used in the preparations. Some cements are produced commercially whereas others are made in the operating room. The long-term durability of impregnated cements is also unknown, as the addition of antibiotics may reduce the tensile strength of bone cement. ❻ *Further study is needed before antibiotic-impregnated bone cements can be recommended as an alternative to preoperative prophylaxis with traditional antimicrobials.*

Principles of Antimicrobial Prophylaxis

Route of Administration

Intravenous antibiotic administration is the most common delivery method for surgical prophylaxis. Intravenous administration ensures complete bioavailability while minimizing the impact of patient-specific variables. Oral administration is also used in some bowel operations. Non-absorbable compounds like erythromycin base and neomycin are given up to 24 hours prior to surgery to cleanse the bowel. Note that oral agents are used adjunctively and do not replace IV agents.

Timing of First Dose

❼ *Correct timing of antibiotic administration is imperative to preventing SSI.* The National Surgical Infection Prevention Project recommends infusing antimicrobials for surgical prophylaxis within 60 minutes of the first incision. Exceptions to this rule are fluoroquinolones and vancomycin, which can be infused 120 minutes prior to avoid infusion-related reactions.[1] No consensus has been reached on whether the infusion should be complete prior to the first incision. However, if a proximal tourniquet is used, antibiotic administration should be complete prior to inflation.

Studies have found that administration of the antimicrobial should begin as close to the first incision as possible. This is important for antibiotics with short half-lives so that therapeutic concentrations are maintained during the operation and reduce the need for redosing. Beginning the infusion after the first incision is of little value in preventing SSI. Stone and associates found that administration of the antimicrobial after the first incision had SSI rates similar to patients who did not receive prophylaxis.[20]

Dosing and Redosing

❽ *The goal of antimicrobial dosing for surgical prophylaxis is to maintain antibiotic concentrations above the MIC of suspected organisms for the duration of the operation.* Dosing recommendations can vary between institutions and guidelines. Clinical judgment should be exercised regarding dose modifications for renal function, age, and especially weight. Obese patients often require higher doses than do non-obese patients.[1] Forse and associates showed that morbidly obese patients (body mass index greater than 40) who received 2 g of cefazolin had a lower incidence of SSI compared to patients receiving 1 g.[21]

Guidelines suggest that if an operation exceeds two half-lives of the selected antimicrobial, then another dose should be administered.[1] Repeat dosing has been shown to lower rates of SSI. For example, cefazolin has a half-life of about 2 hours, thus

another dose should be given if the operation exceeds 4 hours. The clinician should have extra doses of antibiotic ready in case an operation lasts longer than planned.

Duration

The National Surgical Infection Prevention Project and published evidence suggest that the continuation of antimicrobial prophylaxis beyond wound closure is unnecessary.[1] ❾ *Studies have not shown benefit for additional doses of antibiotic and the duration of antimicrobial prophylaxis should not exceed 24 hours.* Longer durations of antibiotic prophylaxis are advocated by some guidelines and will be discussed later.

TREATMENT

Antimicrobial Prophylaxis in Specific Surgical Procedures

Gynecologic and Obstetric

Enteric gram-negative bacilli, anaerobes, group B streptococci, and enterococci are all possible pathogens that may be encountered in gynecologic or obstetric surgeries. For patients undergoing hysterectomy, cefoxitin or cefotetan are appropriate therapies (Table 82–3). Unfortunately, the availability of these drugs is an issue. Cefazolin or ampicillin/sulbactam may be used. In the case of β-lactam allergy, the following regimens are appropriate: clindamycin combined with gentamicin, aztreonam, or ciprofloxacin; metronidazole combined with gentamicin or ciprofloxacin, or clindamycin monotherapy. Metronidazole monotherapy is also indicated but has been shown to be less effective than other regimens.[1]

Cesarean sections are stratified into low- and high-risk groups. Patients who undergo emergency operations or have cesarean sections after the rupture of membranes and/or onset of labor are considered high risk. Prophylactic antimicrobials are most beneficial for high-risk patients but are used in both groups. Antimicrobial regimens similar to those for hysterectomy are appropriate. Antimicrobials should not be administered until after the first incision and the umbilical cord has been clamped. This practice prevents potentially harmful antibiotic concentrations from reaching the newborn.

TABLE 82–3. Recommended Regimens for Antimicrobial Prophylaxis of Specific Surgical Procedures[a]

Type of Operation	Recommended Prophylaxis Regimen	Alternative Regimen
Vascular	Cefazolin 1–2 g IV or cefuroxime 1.5 g IV	Clindamycin 600–900 mg IV or vancomycin 1 g IV
Neurosurgery	Cefazolin 1–2 g IV	Vancomycin 1 g IV
Head and neck	Cefazolin 1–2 g IV	Clindamycin 600–900 mg IV
Urologic	Cefazolin 1–2 g IV	Ciprofloxacin 400 mg IV
Cesarean section	Cefazolin 1–2 g IV, ampicillin/sulbactam 3 g IV	See hysterectomy
Hysterectomy	Cefazolin 1–2 g IV or cefoxitin 1–2 g IV Ampicillin/sulbactam 3 g IV	Antianaerobic agent (metronidazole 0.5–1 g IV or clindamycin 600–900 mg IV) combined with gentamicin 1.5 mg/kg IV, aztreonam 1–2 g IV, or ciprofloxacin 400 mg IV
Gastroduodenal (high-risk only: obstruction, acid suppression, morbid obesity, hemorrhage, malignancy)	Cefazolin 1–2 g IV	Ciprofloxacin 400 mg IV
Biliary tract (high-risk only: age greater than 70, acute cholecystitis, obstructive jaundice, duct stones, non-functioning gallbladder)	Cefazolin 1–2 g IV or cefoxitin 1–2 g IV	Ciprofloxacin 400 mg IV
Colorectal	[b]Oral: neomycin 1 g plus erythromycin base 1 g (give 19, 18, and 9 hours prior to procedure) IV: cefoxitin 1–2 g	Cefazolin 1–2 g IV plus metronidazole 0.5–1 g IV or hysterectomy regimens
Appendectomy	Cefoxitin 1–2 g IV	Metronidazole 0.5–1 g IV plus gentamicin 1.5 mg/kg IV
Orthopedic	Cefazolin 1–2 g IV	Vancomycin 1 g IV or clindamycin 600–900 mg IV
Cardiothoracic	Cefazolin 1–2 g IV or cefuroxime 1.5 g IV	Vancomycin 1 g IV or clindamycin 600–900 mg IV
Dental prophylaxis	Amoxicillin 2 g PO 1 hour prior to procedure	Clindamycin 600 mg PO 1 hour prior to procedure

IV, intravenous; PO, oral.
[a]Dosing recommendations are based on common clinical doses; dosing for individual patients and institutions may vary.
[b]Oral regimens should be used in conjunction with IV prophylaxis.
Adapted from references 1, 14, 24.

Patient Encounter 1, Part 1

AD is a 60-year-old woman with a history of poorly controlled diabetes mellitus and MSSA nasal colonization. She weighs 54 kg and is 156 cm tall. She presents today for a hysterectomy. She has no allergies to any medications. The surgeon approaches you for recommendations on prophylactic antibiotic use.

PE

VS: Blood pressure 128/76 mm Hg, pulse 76 beats per minute, respiratory rate 15/minute, temperature 36.4ºC (97.5°F)

Labs

White blood cell count: 5000 cells/mm^3, serum creatinine 80 µmol/L (0.9 mg/dL), glucose 5.3 mmol/L (100 mg/dL)

- What drug would you choose for this operation and why?
- What organisms are likely to be encountered in this operation?
- The surgeon asks about using metronidazole as a solo agent; what is your opinion on this?
- The surgeon agrees with your decision and wants to begin infusing the antibiotic 1 hour *after* the first incision. Comment on this.
- What other interventions besides antibiotic use could prove useful in lowering AD's risk of SSI?

Orthopedic Surgery

Orthopedic surgery is generally a clean operation done under controlled conditions. Likely pathogens include gram-positive cocci, mostly staphylococci. In the case of total joint (knee and hip) arthroplasty, cefazolin is the antimicrobial of choice. Patients with a β-lactam allergy should receive either clindamycin or vancomycin. Antimicrobial prophylaxis should not exceed 24 hours and does not need to be continued until all drains and catheters have been removed. Antibiotic-impregnated bone cement can be useful in lowering infection rates in orthopedic surgery but has not been approved for prophylaxis.

Cardiothoracic and Vascular Surgery

Cefazolin or cefuroxime are appropriate for prophylaxis in cardiothoracic and vascular surgeries. In the case of β-lactam allergy, vancomycin or clindamycin are advised. Debate exists on the duration of antimicrobial prophylaxis. The National Surgical Infection Prevention Project cites data that extending prophylaxis beyond 24 hours does not decrease SSI rates and may increase bacterial resistance.[1] American Society of Health-System Pharmacists guidelines from 1999 allow for the continuation of prophylaxis for up to 72 hours.[22] Duration of therapy should be based on patient factors and risk of development of an SSI. SSIs are rare after cardiothoracic operations, but the potentially devastating consequences lead some clinicians to support longer periods of prophylaxis.

Patient Encounter 2

GL is a 56-year-old male who presents to the emergency department with crushing chest pain described as a "10/10" and shortness of breath. He weighs 82 kg (180 lbs) and is 175 cm tall. An electrocardiogram reveals an elevated ST segment and lab data is significant for elevated troponins. GL is diagnosed with acute myocardial infarction. After GL is stabilized, the decision is made to place multiple stents. The surgeon consults with you on recommendations for antibiotic prophylaxis. Significant history for GL: allergy to amoxicillin (anaphylaxis), smokes 2 packs of cigarettes per day, and he lives with his wife and two children.

PE

VS: Blood pressure 162/95 mm Hg, pulse 120 beats per minute, respiratory rate 28/minute, temperature 35.8ºC (96.4°F)

Labs

serum creatinine 80 µmol/L (0.9 mg/dL), troponins 1.67 µmol/L (0.8 µg/L)

- The surgeon wants to use vancomycin for this case; what is your opinion on this?
- The surgeon decides to use vancomycin at a dose of 1 gram over 30 minutes. During the infusion, GL experiences a rash and a call is made for an epinephrine pen. What is happening to GL and how would you alter the therapy?
- What is the risk of overuse of vancomycin in hospitals and what pathogens are becoming problematic?
- Forty-eight hours after the end of GL's surgery he is still on vancomycin. The surgeon argues that prophylaxis should be continued for 72 hours and cites guidelines. What guidelines are the surgeon citing and what is your opinion on this decision?

Colorectal Surgery

Antimicrobial prophylaxis for colorectal operations must cover a broad range of gram-positive, gram-negative, and anaerobic organisms. Strategies include oral antimicrobial bowel preparations, parenteral antimicrobials, or both. Oral prophylaxis combinations of neomycin and erythromycin or neomycin and metronidazole are common. Oral antimicrobials should be administered at 19, 18, and 9 hours prior to surgery. A delay in surgery may require a redose, depending on the length of postponement. For parenteral prophylaxis, cefoxitin or cefotetan is appropriate. Cefazolin combined with metronidazole or ampicillin/sulbactam is an effective alternative if antianaerobic cephalosporins are not available. For patients with β-lactam allergies, use clindamycin combined with gentamicin, aztreonam, or ciprofloxacin; metronidazole combined with gentamicin or ciprofloxacin is also appropriate.

Appendectomy is one of the most common intra-abdominal operations. Antimicrobial prophylaxis used for appendectomy is similar to that used for colorectal regimens. In the case

of ruptured appendix, antimicrobials are used for treatment, not prophylaxis.

Dental Procedures

The goal of antimicrobial prophylaxis in dental procedures is to prevent endocarditis. According to American Heart Association guidelines, at-risk individuals should receive 2 g of amoxicillin 1 hour prior to the procedure.[23] Patients with a β-lactam allergy may receive clindamycin 600 mg 1 hour prior to the procedure. Interested readers should refer to the American Heart Association guidelines for a complete discussion on risk stratification and recommendations.

OUTCOME EVALUATION

The clinician should consistently follow-up post-operative patients and screen for any sign of SSI. ⑩ *According to CDC criteria, SSI may appear up to 30 days after an operation and up to 1 year if a prosthesis is implanted.*[5] This period often extends beyond hospitalization so patients should be educated on warning signs of SSI and be encouraged to contact a clinician immediately if necessary. The presence of fever or leukocytosis in the immediate post-operative period does not constitute SSI and should resolve with proper patient care. Distal infections, such as pneumonia, are not considered SSIs even if these infections occur in the 30-day period. The appearance of the surgical site should be checked regularly and any changes documented (e.g., erythema, drainage, or pus). The presence of pus or other signs suggestive of SSI must be treated accordingly. Any wound requiring incision and drainage is considered an SSI regardless of appearance. Prompt cultures should be collected and appropriate antimicrobial therapy initiated to reduce any chance of morbidity and mortality.

Patient Encounter 1, Part 2

AD has been admitted to the ward after completion of her hysterectomy. A physical examination is performed and laboratory data are collected in the immediate post-operative period. AD complains of tenderness around the incision site but no erythema is noted.

PE

VS: Blood pressure 132/80 mm Hg, pulse 82 beats per minute, respiratory rate 20/minute, temperature 37.8ºC (100.0°F)

Labs

White blood cell count 11,000 cells/mm^3, serum creatinine 88.4 μmol/L (1 mg/dL), glucose 5.55 mmol/L (100 mg/dL)

- Based on the available data, does AD have an SSI?
- What interventions may increase AD's comfort?
- How should AD be screened for SSI?
- How long should AD be followed in order to identify a possible SSI?

Patient Care and Monitoring

- Conduct a thorough medication history including prescription and non-prescription medications as well as herbals and vitamins.
- Verify the patient's allergy history and the type of reaction experienced. Attempt to discern between true allergy and adverse event. β-Lactam–allergic patients may receive clindamycin, vancomycin, or other antimicrobials. Cross-reactivity between penicillin allergy and cephalosporins is low but cephalosporins should be avoided in patients with a history of anaphylaxis to penicillins.
- Document the type of operation the patient is undergoing. Verify the surgical procedure with the patient.
- Prophylactic antimicrobials should be started within an hour of the first incision to optimize patient outcomes. Exceptions to this include vancomycin and fluoroquinolones.
- The patient should be monitored for signs of an allergic reaction during the operation. These include rash, hives, difficulty breathing, or substantial drops in blood pressure.
- Major breaks in surgical technique may cause the classification of the operation to change and require adjustments in antimicrobial prophylaxis.
- The patient should be monitored for signs and symptoms of infection post-operatively. These could include pus, erythema, and fever. If signs consistent with SSI appear, cultures should be taken and additional antimicrobial therapy should be considered.
- Patients being discharged should be counseled on recognizing signs and symptoms of SSI. An SSI can appear up to 30 days after an operation is completed.

83 Vaccines and Toxoids

Marianne Billeter

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Define vaccination and immunization.
2. Classify each of the routine vaccines as an inactivated, polysaccharide, conjugate, toxoid, or subunit vaccine.
3. Describe the effect of each routine vaccine on preventing infection.
4. Recommend an immunization schedule for a child, including immunocompromised children.
5. Recommend an immunization schedule for an adult based on comorbid conditions and lifestyle issues.
6. Evaluate an adverse reaction and its probable association with a vaccine.

Key Concepts

❶ Vaccines provide active immunity against viral and bacterial pathogens.
❷ Polysaccharide vaccines are poorly immunogenic in children younger than 2 years of age.
❸ Combination vaccines decrease the number of injections and increase the likelihood of completing the immunization schedule.
❹ Health care professionals should report vaccine-adverse events.
❺ Live virus vaccines should not be given to an immunocompromised host.
❻ Vaccines are cost-effective in preventing disease.

The development and widespread use of vaccines is one of the greatest public health achievements of the twentieth century. Other than safe drinking water, no other modality has had a greater impact on reducing mortality from infectious diseases. The first accounts of deliberate inoculation to prevent disease date back as far as the tenth century. However it wasn't until 1798 that Edward Jenner published his work on inoculation of natural cowpox as a means to prevent infection with smallpox. This was the first scientific attempt to prevent infection by inoculation. Since 1900, vaccines have been developed against more than 20 diseases, with half of these recommended for routine use. The widespread use of vaccines has resulted in the eradication of smallpox worldwide and wild-type poliovirus from the Western hemisphere. There have also been dramatic declines in the incidence of diphtheria, pertussis, tetanus, measles, mumps, rubella, and *Haemophilus influenzae* type b.

❶ *Vaccines provide active immunity against a variety of viral and bacterial infections.* Most vaccines are designed to prevent acute infections that can be rapidly controlled and cleared by the immune system. Successful immunization involves activation of antigen-presenting cells with processing of the antigen by lysosomal or cytoplasmic pathways. T and B lymphocytes will be activated to replicate and differentiate to form large pools of memory cells for protection against subsequent exposure to the antigen.[1]

Vaccines against viral infections may be **attenuated** live viruses or inactivated viral particles. Attenuation may be accomplished by several methods to decrease the viruses' virulence while retaining their **immunogenicity**. Bacterial vaccines utilize antigenic particles of the outer membrane to elicit an immune response. ❷ *Outer membrane polysaccharides are poorly immunogenic in children less than 2 years of age* unless conjugated with a carrier protein. Also, bacterial toxins may undergo chemical treatment to render them non-toxic to form **toxoids** against infectious agents.

Patient Encounter 1

A 1-year-old child is brought to the pediatrician's office for a routine 1-year checkup. The child is healthy and meeting all growth and developmental targets. The child has received all vaccinations to date. The pediatrician discusses with the mother the need for more vaccinations during this visit.

- Which vaccine should the child receive during this visit?
- Is there a way to minimize the number of shots the child receives?
- What risks are involved with vaccinating this child?

COMMON TERMINOLOGY

Often the terms vaccination and immunization are used interchangeably even though they are very distinct concepts. Vaccination refers to the act of administering a vaccine, while immunization refers to the development of immunity to a pathogen. The delivery of a vaccine does not imply that the individual mounted an adequate immune response to the vaccine to elicit protection. However, immunization implies that the act of vaccination resulted in the development of protective immunity.

Herd immunity refers to high levels of immunization in one population resulting in protection of another unvaccinated population. For example, concentrated vaccination of children with the 7-valent pneumococcal conjugate vaccine resulted in decreased invasive *Streptococcus pneumoniae* infection not only in the vaccinated children, but also in elderly persons within the same community.

Cocoon immunization is a strategy used to immunize all persons surrounding another high-risk individual. This strategy is used to protect individuals who are not able to be vaccinated themselves, such as vaccinating parents, siblings, and grandparents of a new infant who is too young to be vaccinated.

THE ROUTINE VACCINES

Diphtheria, Tetanus, and Pertussis Vaccines

Diphtheria Toxoid

Diphtheria is a bacterial respiratory infection characterized by membranous pharyngitis. The membrane may cover the pharynx, tonsillar areas, soft palate, and uvula. Diphtheria may also cause anal, cutaneous, vaginal, and conjunctival infections. The impact of diphtheria is not from the causative bacteria, *Corynebacterium diphtheriae*, but rather from complications attributed to its exotoxin, such as **myocarditis** and peripheral **neuritis**. In the late 1800s, death due to diphtheria ranged from 46 to 196 cases per 100,000 annually. Mortality from diphtheria dropped in the 1900s mostly due to the availability of diphtheria antitoxin, which elicited passive immunity. Diphtheria is rarely reported in the United States since the introduction of vaccination with diphtheria toxoid; however, diphtheria continues to be a major problem in developing countries.

In the early 1900s, a balanced mixture of diphtheria toxin and antitoxin was found to produce active immunity in both animals and humans. This preparation gained widespread acceptance and protected approximately 85% of recipients. Several years later, diphtheria toxoid was developed by treating the toxin with small amounts of formalin. This process caused the toxin to lose its toxic properties while maintaining its immunogenic properties. In the mid-1920s, the addition of an alum precipitate enhanced the immunogenic properties of the toxoid.

In the 1940s, diphtheria toxoid was combined with tetanus toxoid and whole cell pertussis vaccines, and later with the acellular pertussis vaccine. The diphtheria toxoid, tetanus toxoid, and acellular pertussis vaccine are part of the routine childhood immunization schedule. Diphtheria toxoid is also combined with tetanus toxoid and is commonly used as a booster vaccine. The pediatric product (DT) has a higher amount of diphtheria toxoid than does the adult product (Td). Diphtheria toxoid is not available as an individual vaccine.

Recent outbreaks of diphtheria have demonstrated that immunity wanes in adulthood. Approximately 50% of all adults no longer have immunity to diphtheria. Regular boosters with tetanus and diphtheria toxoids every 10 years will provide adequate recall immunity to diphtheria provided the adult was previously immunized.[2]

Tetanus Toxoid

The tetanus vaccine differs from others in that it does not protect against a contagious disease such as diphtheria, but rather against an environmental pathogen. *Clostridium tetani* is widely found in the environment, especially in dirt and soils. Additionally, animals and humans may harbor and excrete the organism. *C. tetani* produces two neurotoxins, tetanospasmin and tetanolysin, which are responsible for producing the painful muscular contractions associated with tetanus. Tetanus continues to be a major problem in the developing world, causing approximately 1 million deaths each year. Approximately 40% of the cases are neonatal tetanus most likely associated with the use of non-sterile instruments or poultices on the umbilical cord. Tetanus is rarely seen in developed countries.

Immunity to tetanus decreases with increasing age, therefore a regular booster every 10 years with tetanus toxoid is recommended. The preferred agent to use in adults is tetanus and diphtheria toxoid (Td) in order to give a booster for diphtheria. Tetanus immunization status should be assessed in the management of wounds in individuals seeking medical care. A tetanus booster should be administered if a tetanus-containing

vaccine has not been given in the preceding 5 years for moderate and severe wounds or contaminated wounds. If the wound is minor and uncontaminated, then a tetanus booster is needed if the previous tetanus vaccination was more than 10 years ago.

Pertussis

Pertussis is a highly contagious respiratory tract infection caused by the bacteria *Bordetella pertussis*. Pertussis is characterized by a protracted severe cough with or without posttussive vomiting, whoop, difficulty breathing, difficulty sleeping, and rib fractures. It is often referred to as "whooping cough" or the 100-day cough. In the pre-vaccine era, pertussis accounted for more than 250,000 cases of severe illness and 10,000 deaths per year in the United States. Pertussis has always been thought of as a pediatric disease since most cases occurred in preschool-aged children with relatively no cases seen in adolescents and adults. The first pertussis vaccine was introduced in the 1940s and within 30 years resulted in a 99% reduction in disease. However, during the past two decades there has been a steady increase in reported cases of pertussis among adolescents and adults, indicating a waning immunity after primary immunization.[4]

The first pertussis whole cell vaccine was a mixture of killed organisms that was associated with frequent local and systemic reactions. In the late 1980s, an acellular pertussis vaccine was introduced that contains purified pertussis components that are immunogenic but associated with fewer adverse reactions. Acellular pertussis vaccine is available in combination with tetanus and diphtheria toxoids. Pertussis is not available as a separate vaccine component. In the spring of 2005, the Food and Drug Administration (FDA) approved tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccines for use in adolescents and adults.

Use of Diphtheria, Tetanus, and Acellular Pertussis Vaccine

Diphtheria and tetanus toxoids and acellular pertussis (Dtap) vaccine should be administered in a five-shot series to all children beginning at 2 months of age (Table 83–1). The shots are given at 2, 4, 6, and 15 to 18 months, and 4 to 6 years. Complete immunity to diphtheria and tetanus is achieved after the third vaccination.

Tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine (Tdap) is recommended as a single booster for the following groups in place of a tetanus booster.

- Adolescents 11 to 18 years of age: An interval of 5 years, with a minimum of 2 years, between the last tetanus-containing vaccine is recommended to minimize local and systemic adverse events; however, shorter intervals may be used.
- Adults 19 to 64 years of age: Tdap should replace the next routine tetanus booster. Intervals as short as 2 years between Tdap and Td may be used.
- Tetanus prophylaxis in wound management: Adolescents and adults 11 to 64 years of age, who have completed a primary series and require a tetanus-containing product should receive Tdap instead of Td if they have not already received Tdap.
- Prevention of pertussis in infants less than 12 months of age: Adults who have close contact with infants less than 12 months of age, especially parents, grandparents, and child care providers, should receive a single dose of Tdap. An interval of at least 2 years since the last tetanus-containing vaccine was given is suggested, but shorter intervals may be used. Ideally, Tdap should be given 1 month prior to contact with the infant.
- Postpartum women: Women should receive a single booster of Tdap in the immediate postpartum period if Tdap has not been previously received.

Haemophilus influenzae Type b Vaccine

Haemophilus influenzae is a bacterial respiratory pathogen that causes a wide spectrum of disease ranging from colonization of the airways to bacterial meningitis. It causes considerable morbidity and mortality, especially in children less than 5 years of age. *H. influenzae* is either encapsulated or unencapsulated. The encapsulated strains can be further differentiated into six antigenically distinct serotypes, a through f. *H. influenzae* type b was primarily found in cerebrospinal fluid and blood of children with meningitis, while the unencapsulated strains were found in the upper respiratory tract of adults. Before the introduction of the vaccine, *H. influenzae* was responsible for 20,000 to 25,000 cases of invasive disease annually and was the most common cause of bacterial meningitis. Since the introduction of the vaccine, invasive disease due to *H. influenzae* type b has been nearly eliminated.

The first *H. influenzae* type b vaccine was an aqueous solution of capsular polysaccharide, polyribosylribitol phosphate. As with all polysaccharide vaccines, it showed poor immunogenicity in children less than 2 years of age. This vaccine is no longer used.

The current *H. influenzae* type b vaccine is a protein conjugate that utilizes a carrier-hapten for antigen presentation. The polysaccharide is conjugated to an immunogenic protein carrier, which is recognized by T cells and macrophages that stimulates T-dependent immunity. The conjugated vaccine elicits an immune response characterized by T-helper cell activation. The T-dependent antigens induce an enhanced immune response in younger children. Within 10 years of its introduction, the *H. influenzae* type b vaccine use has resulted in widespread herd immunity.

H. influenzae type b conjugate vaccine is a recommended routine childhood vaccine given at 2, 4, 6, and 12 to 15 months of age. Adolescents and adults with functional or anatomic asplenia should also receive a booster dose of *H. influenzae* type b vaccine. The currently available vaccines are labeled for pediatric use, but can be used in adults when vaccination is indicated. There are several *H. influenzae* type b vaccines on

TABLE 83–1. Vaccine Dosing

Vaccine	Common Abbreviation	Dose	Route	Cautions
Diphtheria and tetanus toxoid	DT	0.5 mL	Intramuscular	
Diphtheria, tetanus, acellular pertussis	Dtap	0.5 mL	Intramuscular	• Systemic neurologic reaction from previous vaccine • Brachial neuritis • Cried for 3 hours non-stop after previous dose • Temperature greater than 40.5°C (105°F)
Haemophilus influenzae type b	HIB	0.5 mL	Intramuscular	
Hepatitis A	HAV	C: 0.5 mL A: 1 mL	Intramuscular	
Hepatitis B	HBV	C: 0.5 mL A: 1 mL	Intramuscular	• Allergic reaction to yeast (baking yeast)
Inactivated influenza	TIV	0.5 mL	Intramuscular	• Severe egg allergy • History of Guillain-Barré syndrome
Live attenuated influenza	LAIV	0.5 mL	Intranasal	• Severe egg allergy • Asthma • Chronic health problems • Immunocompromised host • Pregnant women • History of Guillain-Barré syndrome
Measles, mumps, rubella	MMR	0.5 mL	Subcutaneous	• Allergic reaction to gelatin or neomycin • Pregnant women • Immunocompromised host • Recently received a blood transfusion • Severe egg allergy
Meningococcal polysaccharide	MPSV4	0.5 mL	Subcutaneous	• History of Guillain-Barré syndrome
Meningococcal conjugate	MCV4	0.5 mL	Intramuscular	• History of Guillain-Barré syndrome
Pneumococcal 7-valent conjugate	PCV7	0.5 mL	Intramuscular	
Pneumococcal polysaccharide	PPV23	0.5 mL	Intramuscular route preferred; subcutaneous	• Children less than 2 years of age
Poliovirus, inactivated	IPV	0.5 mL	Intramuscular, subcutaneous	• Allergic reaction to neomycin, streptomycin, polymyxin B
Rotavirus vaccine		2 mL	Oral	• Immunocompromised host
Tetanus and diphtheria toxoid	Td	0.5 mL	Intramuscular	
Tetanus, reduced diphtheria, acellular pertussis	Tdap	0.5 mL	Intramuscular	• History of Guillain-Barré syndrome • Systemic neurologic reaction from previous vaccine
Varicella	VAR	0.5 mL	Subcutaneous	• Allergic reaction to gelatin or neomycin • Pregnant women • Immunocompromised host • Recently received a blood transfusion • Hematopoietic stem cell transplant

C, children; A, adult.

the market that differ in the size of the polysaccharide and type of carrier protein; however, the immune response to *H. influenzae* type b is similar among the different vaccines. The different brands are interchangeable without affecting the primary immune response or booster response.

H. influenzae type b and influenza vaccines have the potential for confusion and medication errors because of the similarity of the names. Care should be taken when ordering, dispensing, and administering these vaccines.

Hepatitis A Vaccine

Hepatitis A virus continues to be a frequent cause of illness despite the availability of a highly effective vaccine. Hepatitis A typically has an abrupt onset of symptoms including fever, malaise, nausea, abdominal discomfort, and jaundice. Frequently children less than 6 years of age are asymptomatic while adults typically have symptomatic disease. Symptoms may persist for 2 months or longer. There is wide geographic variation in the incidence of hepatitis A infection, with the number of cases ranging from 50 to more than 700 cases per 100,000 persons annually. The economic burden of hepatitis A is estimated to be greater than $300 million annually in combined direct and indirect costs. Widespread use of the vaccine offers the opportunity to substantially decrease the disease burden caused by hepatitis A infection.[5]

Hepatitis A vaccine was licensed in the United States in 1995. It is an inactivated whole virus vaccine that is administered in a

two-dose series. More than 94% of children, adolescents, and adults will have protective antibodies 1 month after receiving the first dose and 100% following the second dose.[5] Recommended use of the hepatitis A vaccine utilizes an incremental implementation schedule beginning with high-risk populations or those at increased risk for serious complications from the disease. Currently hepatitis A vaccine is recommended for all children following the first birthday, with the second dose administered 6 months later. Adults who are at high risk for hepatitis A should receive two doses at least 6 months apart. High-risk adults include persons with clotting disorders or chronic liver disease, men who have sex with men, illicit drug users, international travelers going to areas with high to intermediate endemicity of hepatitis A, or any other person who wishes to become immune.

Hepatitis B Vaccine

Hepatitis B virus is a blood-borne or sexually transmitted virus. Most acute infections occur in adults, while chronic infections usually occur in individuals infected as infants or children. However, about 10% of adults who contract hepatitis B virus will fail to clear their infection and develop chronic hepatitis B infection. Individuals with chronic hepatitis B infection are at risk for cirrhosis or hepatocellular carcinoma. Vaccination with hepatitis B vaccine is the most effective way to prevent hepatitis B infection.[6]

Hepatitis B vaccine is manufactured using recombinant DNA technology to express hepatitis B surface antigen (HBsAg) in yeast. This is further purified with biochemical separation techniques to produce the vaccine. The vaccines are formulated to contain 10 to 40 mcg of HBsAg protein/mL. Hepatitis B vaccine is available as a single component or in combination vaccines.

Hepatitis B vaccine is recommended for routine use in children. The first dose should be given within 12 hours of birth. The second and third doses are given at 2 months and 6 months after the first dose if using the single component vaccine, or at 2, 4, and 6 months if using combination vaccines. If the infant weighs less than 2000 g at birth, the birth dose is not counted in the three-dose series. Infants less than 2000 g do not produce an adequate immune response to the birth dose of hepatitis B vaccine. Adolescents should receive the three-dose series if not previously vaccinated.[6]

Adults at high risk for hepatitis B because of occupation or lifestyle should receive the hepatitis B vaccine series. The typical series has the second and third doses given 1 month and 6 months after the first dose. Accelerated schedules may also be used. Frequently, individuals do not follow through with the complete three-dose series and questions arise about restarting the series. Hepatitis B vaccine produces an amnesic response; therefore the series may be continued at any time in order to complete the three doses.

Following vaccination with hepatitis B vaccine, hepatitis B virus serologic markers will remain negative with the exception of anti-HBs (antibody to hepatitis B surface antigen), which will be positive indicating immunity. Persons with anti-HBs concentration greater than 10 mIU/mL after vaccination will have complete protection against acute and chronic infection.[6] It is unclear if a booster dose of hepatitis B vaccine should be administered when anti-HBs concentrations fall below 10 mIU/mL, since a good memory response will occur following exposure to hepatitis B virus.

Influenza Vaccine

Influenza is a contagious viral respiratory infection that usually occurs during the winter months in the Northern Hemisphere and all year round in the Southern Hemisphere. All age groups are affected by influenza; however, children have the highest rate of infection. Serious illness and death due to influenza usually occurs in extremes of age, those over 65 years or under 2 years. Influenza is responsible for approximately 36,000 deaths annually in the United States.[7]

Influenza A and B viruses are responsible for causing human disease. Influenza A is further categorized into subgroups by its surface antigens, hemagglutinin and neuraminidase (e.g., influenza A H1N1 virus). Influenza B virus is not sub-typed. Both influenza A and B undergo frequent antigenic drift, creating new influenza variants. Immunity to the surface antigens decreases the likelihood of infection. Unfortunately, antibody to one influenza subgroup does not give complete protection against other influenza sub-types. Therefore, annual influenza vaccination is recommended during October and November and continuing until the vaccine supply is exhausted.

The best way to protect against influenza is through vaccination. The influenza vaccine is composed of two influenza A sub-types and one influenza B sub-type. The viral sub-types contained in the vaccine usually changes each year. The exact composition is selected by a panel of experts and announced by the Centers for Disease Control and Prevention (CDC) in March or April each year. The vaccine becomes available for use in late August and September. Two types of influenza vaccine are licensed for use in the United States; both vaccines contain the same viral subunits. The influenza viruses for both vaccine preparations are grown in eggs. Therefore, the vaccines are contraindicated in individuals with severe allergy to eggs.

The trivalent inactivated influenza vaccine can be administered to all age groups and risk populations. It is recommended that the vaccine be administered yearly to children older than 6 months of age at risk for complications from influenza, such as those with asthma, cardiac disease, sickle cell disease, human immunodeficiency virus (HIV) infection, diabetes, and other conditions that compromise respiratory function. Healthy children 6 to 23 months of age should be vaccinated because of the increased risk for influenza-related

hospitalizations. Other groups of healthy children may also be vaccinated since this is a significant population for transmission to older adults. It is postulated that vaccination of young children may produce herd immunity and elicit protection in older adults who may not produce a fully protective immune response to the vaccine. If the child is less than 8 years old and is receiving influenza vaccine for the first time, two doses separated by 4 to 6 weeks should be given.

Influenza vaccine should be given yearly to all adults 50 years of age or older. Younger adults with chronic disorders of the cardiovascular or pulmonary systems, chronic metabolic diseases, renal dysfunction, immunosuppression, or disorders that compromise respiratory function should also be vaccinated. Women who will be pregnant during the winter months should be vaccinated against influenza.

Healthy individuals 5 to 49 years of age can receive the live attenuated influenza vaccine instead of the inactivated vaccine. There are limited data on transmission of the vaccine strain following intranasal vaccination; however, **secondary transmission** does not appear to be a concern.

Measles, Mumps, and Rubella Vaccine

Measles

Measles, also known as rubeola, is characterized by a rash that is often complicated by diarrhea, middle ear infection, or pneumonia. Encephalitis occurs in 1 of every 1000 reported cases. Individuals who recover from encephalitis usually have permanent brain damage. Death occurs in 1 to 2 of every 1000 reported measles cases.[8]

Prior to measles vaccine availability the number of cases of measles approached the birth rate of approximately 3 to 4 million annually. The first measles vaccine was licensed in 1963. Since that time there has been a 99% reduction in reported measles cases. Currently, there is a goal to eliminate measles transmission in the United States through aggressive immunization programs.

There have been several types of measles vaccines used since its introduction. There have been inactive and live attenuated vaccines using different strains of the virus. The current vaccine uses a live attenuated preparation of the Enders-Edmonston virus strain. Following vaccination with measles-containing vaccine, a mild non-communicable infection develops. Approximately 95% of individuals will develop antibodies following a single dose if administered after 12 months of age. More than 99% of individuals who receive two inoculations will develop long-term, probably lifelong, immunity to measles.[8]

Mumps

Mumps is usually thought of as a disease of children, but it has also gained notoriety as a prominent illness affecting military units. Mumps produces a typical acute parotitis, but may also cause nonspecific respiratory symptoms. In post-pubertal males, mumps may also cause orchitis in 38% of those infected, which may result in infertility.[8]

Since the introduction of the mumps vaccine in 1967 there has been a 99% reduction in reported cases. The mumps vaccine is a live virus preparation of the Jeryl-Lynn strain. It produces a sub-clinical, non-communicable infection following vaccination. Single doses of mumps vaccine will elicit immunity in 75% to 95% of individuals. Vaccine-induced immunity lasts for more than 30 years.

Rubella

German measles, also known as rubella, is a mild exanthematous illness in children and young adults; however, rubella infection in pregnant women can cause a variety of congenital malformations in the infant. Congenital rubella syndrome occurs in approximately 25% of infants whose mother acquires rubella during the first trimester. Congenital rubella syndrome is characterized by congenital cataracts, heart disease, deafness, thrombocytopenia, mental retardation, and numerous other abnormalities.[8]

The first rubella vaccine was licensed in 1969. Initial vaccination campaigns were targeting young children, since this age group had the highest rate of rubella infection. This strategy significantly decreased rubella cases in children, but did not have the desired effect on infection in adolescents and adults or on congenital rubella syndrome. Adolescents, especially young girls, were then targeted for vaccination. This has resulted in a significant reduction in the number of cases of congenital rubella syndrome.

The live rubella vaccine available in the United States contains the RA 27/3 strain of the virus. Following a single dose of rubella vaccine after the first birthday, more than 90% of individuals will develop long-term immunity. Rarely has congenital rubella syndrome been reported in infants born to mothers with adequate rubella immunization.

Use of Measles, Mumps, and Rubella Vaccine

Measles, mumps, and rubella vaccines are available as single component vaccines or as combinations. Most authorities recommend use of the measles, mumps, and rubella combination vaccine and discourage use of the single- or double-component vaccines. Two doses of the measles, mumps, and rubella vaccine are recommended for all individuals born after 1957. The first dose should be administered soon after the first birthday and the second prior to entering school. For high-risk adolescents and adults who do not have adequate immunity, two doses of the vaccine should be separated by a minimum of 28 days.[8]

Measles, mumps, and rubella vaccine is a live virus vaccine that should be used with caution in immunosuppressed children, such as those with cancer receiving chemotherapy, solid organ or bone marrow transplantation, or receiving other immunosuppressive drugs, such as steroids in a dose

Patient Encounter 2

An 18-year-old male is having a routine physical before leaving for college. He will be a freshman and is looking forward to dormitory life. The health care provider recommends some vaccinations be given at this visit.

- Which vaccines should be administered?
- What is the risk of not receiving the vaccines?

equivalent to prednisone 1 mg/kg per day or higher or 20 mg per day for 2 weeks or longer. If possible, vaccines should be given prior to becoming immunosuppressed. Otherwise, it may be prudent to defer the vaccine until after the immunosuppression resolves.

Meningococcal Vaccines

Neisseria meningitidis is a significant cause of meningitis and severe sepsis. Meningococcus causes an estimated 2500 cases of invasive disease each year in the United States. Invasive meningococcal disease is associated with an estimated 15% mortality rate. Morbidity in survivors is substantial, with approximately 20% having loss of limb or neurologic sequelae. The highest rates of meningococcal disease are among young children; however, rates have been increasing in adolescents and young adults. Thirteen meningococcal serogroups have been identified; however, five serogroups, A, B, C, Y, and W-135, are responsible for epidemic and endemic disease worldwide. Despite the availability of highly active antibacterial agents against *N. meningitidis,* there has been little impact on decreasing the morbidity and mortality due to invasive meningococcal disease.[9]

A meningococcal polysaccharide vaccine containing serogroups A, C, Y, and W-135 has been available in the United States for a number of years. Meningococcal polysaccharide vaccine is similar to other polysaccharide vaccines, in that it is poorly immunogenic in infants and children less than 2 years of age, and does not produce lasting immunity. Meningococcal polysaccharide vaccine produces a T-cell–independent response and fails to induce a memory response. Repeated vaccination results in hyporesponsiveness to serogroups A and C; the clinical implication of this finding is unknown.

In January 2005, a new meningococcal polysaccharide diphtheria toxoid conjugate vaccine was approved by the FDA. This vaccine also contains meningococcal serogroups A, C, Y, and W-135. Polysaccharide-protein conjugate vaccines are known to produce improved immunogenicity and memory responses. Meningococcal conjugate vaccine has shown similar immunologic response for all four serogroups when compared to meningococcal polysaccharide vaccine. However, this vaccine does not offer protection against diphtheria.

Meningococcal conjugate vaccine is recommended for routine vaccination of young adolescents 11 to 12 years of age. This may be done at the routine preadolescent health care visit. Routine meningococcal vaccination is also recommended for persons at increased risk for meningococcal disease, such as college freshman living in dormitories, microbiologists who are routinely exposed to isolates of *N. meningitidis*, military recruits, persons who travel to or reside in countries in which *N. meningitidis* is hyperendemic or epidemic, persons who have terminal complement component deficiencies, and persons who have anatomic or functional asplenia. Meningococcal conjugate vaccine is preferred for persons 11 to 55 years of age. Meningococcal polysaccharide vaccine should be used in persons 2 to 10 years of age and those greater than 55 years of age. Routine revaccination is not recommended at this time.[9]

Pneumococcal Vaccines

Streptococcus pneumoniae is the most common bacterial cause of community-acquired respiratory tract infections. *S. pneumoniae* causes approximately 3000 cases of meningitis, 50,000 cases of bacteremia, 500,000 cases of pneumonia, and over 1 million cases of otitis media each year. The increasing prevalence of drug-resistant *S. pneumoniae* has highlighted the need to prevent infection through vaccination. Both licensed pneumococcal vaccines are highly effective in preventing disease from the common *S. pneumoniae* serotypes that cause human disease.

The 23-valent pneumococcal polysaccharide vaccine contains 23 serotypes that are responsible for causing more than 80% of invasive *S. pneumoniae* infections in adults. The vaccine includes those serotypes that are associated with drug resistance. Use of the vaccine will not prevent the development of antibiotic-resistant *S. pneumoniae*, but is likely to prevent infection from drug-resistant strains. The 23-valent pneumococcal polysaccharide vaccine has demonstrated good immunogenicity in adults, but an individual will not develop immunity to all 23 serotypes following vaccination.[10]

The 23-valent pneumococcal polysaccharide vaccine is recommended for use in all adults 65 years of age or older and adults less than 65 years who have medical comorbidities that increase the risk for serious complications from *S. pneumoniae* infection, such as chronic pulmonary disorders, cardiovascular disease, diabetes mellitus, chronic liver disease, chronic renal failure, functional or anatomic asplenia, and immunosuppressive disorders. Alaskan natives and certain Native American populations are also at increased risk. Children over the age of 2 years may be vaccinated with the 23-valent pneumococcal polysaccharide vaccine if they are at increased risk for invasive *S. pneumoniae* infections, such as children with sickle cell anemia or those receiving cochlear implants.

Revaccination with the 23-valent pneumococcal polysaccharide vaccine is recommended for adults over the age of 65 years if the first dose was administered when they were less than 65 years

of age and at least 5 years have passed. Revaccination results in a blunted immune response and increased local adverse reactions, therefore routine revaccination is not recommended.[10] Adults vaccinated at age 65 or greater do not require revaccination.

The 7-valent pneumococcal conjugate vaccine was licensed in February 2000 for use in children. It induces good immunogenicity in children under the age of 2 years. It is now part of the routine childhood immunization schedule beginning at 2 months of age. It is given at 2, 4, 6, and 12 to 18 months of age. The 7-valent pneumococcal conjugate vaccine has been shown to decrease the carriage rate of *S. pneumoniae* and the incidence of invasive disease in vaccinated populations. Widespread use of the 7-valent pneumococcal conjugate vaccine has also shown herd immunity and decreased the incidence of invasive *S. pneumoniae* disease among unvaccinated adults over 20 years of age.[10]

Poliovirus Vaccine

Poliomyelitis is a highly contagious disease that is often asymptomatic; however, approximately 1 in every 100 to 1000 cases will develop a rapidly progressive paralytic disease. Polio is caused by poliovirus which has three serotypes; type 1 is most frequently associated with paralytic disease. Poliovirus replicates in the oropharynx and intestinal tract and is excreted in oral secretions and feces, which can infect others. As a result, more than 90% of unvaccinated individuals will become infected with poliovirus following household exposure to wild-type poliovirus. Since the introduction of the first poliovirus vaccine, there has been a significant reduction in the number of polio cases. Today, polio caused by wild-type poliovirus has been eradicated from the Western Hemisphere with the goal of eradicating it from the world.[11]

The first inactivated poliovirus vaccine was introduced in the 1950s in an injectable formulation, and replaced in the 1960s by a live oral poliovirus vaccine. The oral poliovirus vaccine not only elicits systemic immunogenicity but also a localized immune response in the intestinal tract. Unfortunately, the oral poliovirus vaccine has the risk of vaccine-associated paralytic poliomyelitis occurring in approximately 1 case of every 2.4 million doses distributed. The risk with the first dose of oral poliovirus vaccine is 1 case in 750,000 doses.[11]

The last reported case of indigenous wild-type poliovirus in the United States was in 1979; subsequent cases were all vaccine-associated. In 1997, a transition period to the inactivated poliovirus vaccine was begun to reduce the risk of vaccine-associated paralytic poliomyelitis. By January 2000, the oral vaccine was no longer recommended for routine use. Currently, the inactivated poliovirus vaccine is recommended for routine use in the United States. The oral poliovirus vaccine is still widely used in some countries where poliovirus eradication has been more difficult.

The enhanced potency inactivated poliovirus vaccine contains all three serotypes. After two doses, more than 90% of those vaccinated will have immunity to the three serotypes and 99% after three doses. Inactivated poliovirus vaccine is recommended to be given at 2, 4, 6 to 18 months, and 4 to 6 years of age.

Rotavirus Vaccine

Rotavirus is the most common cause of diarrhea worldwide. Most children will become infected by the age of 5 years. In the United States, rotavirus is responsible for approximately 50,000 hospitalizations for severe diarrhea and dehydration, and 20 to 40 deaths annually. Most hospitalizations occur in children less than 3 years of age.

The first rotavirus vaccine was a tetravalent rhesus rotavirus strain. It was licensed in the United States in 1998 and subsequently withdrawn from the market due to an association with **intussusception**. A pentavalent human-bovine reassortant rotavirus vaccine was approved by the FDA in February 2006. The exact mechanism by which the vaccine produces an immune response is unknown; however, this live virus vaccine replicates in the small intestines and induces immunity.

The rotavirus vaccine is a three-dose series that is orally administered. The first dose is given to infants between 6 and 12 weeks of age with subsequent doses administered 4 to 10 weeks apart.

Varicella Vaccine

Varicella zoster virus causes two distinct diseases, chickenpox (varicella) and herpes zoster, also known as shingles. Chickenpox is one of the most common childhood diseases. It has always been thought to be a benign disease causing few serious complications in children. The rate of chickenpox prior to the vaccine becoming available was thought to approximate the birth rate with 3 to 4 million cases annually resulting in 11,000 hospitalizations and 100 deaths. Adults who develop chickenpox have a 25% greater risk for developing serious complications from varicella compared to children. Chickenpox is highly contagious and has a secondary household transmission rate of 87%.

Later in life, approximately 15% of the population will develop herpes zoster. Herpes zoster is the reactivation of latent varicella zoster virus in the sensory ganglia. Approximately 20% of persons with herpes zoster will develop post-herpetic **neuralgia**, which is a painful debilitating condition that can persist for months after resolution of the herpes zoster rash.

The varicella vaccine is relatively new and has only been recommended for use since 1996, therefore its true impact on chickenpox and herpes zoster is not yet known. Its continued use will undoubtedly change the epidemiology of these diseases.

The varicella vaccine is made up of an attenuated Oka strain of varicella zoster virus. This is a live attenuated vaccine. Attenuation was achieved by performing serial passages through human embryonic lung cells, embryonic guinea pig cells, and human diploid cells.

Children less than 12 years of age will have a 97% seroconversion rate following a single vaccination. Adolescents and adults more than 13 years old will only have 78% seroconversion after a single inoculation, but will have 99% conversion after the second vaccination administered 4 to 8 weeks after the first. Antibody titers appear to persist for at least 20 years following immunization. Despite excellent seroconversion rates, breakthrough chickenpox is reported at a rate of 1 case per 10,000 doses distributed. Most cases occurred within the first year following vaccination, and were due to wild-type varicella zoster virus. The majority of breakthrough cases were mild and of short duration.[12]

Secondary transmission to household contacts is always a concern with administration of a live vaccine. There are a few cases of possible secondary transmission of varicella following vaccination. Of the cases that varicella typing was done, 62% were wild-type virus, indicating exposure to an unvaccinated person. There are less than 10 confirmed cases of secondary transmission of the Oka vaccine strain following vaccination. A mild rash occurring in less than 5% of persons has been reported following vaccination. The varicella virus may be shed from the rash. Rashes due to the Oka vaccine strain typically occur more than 20 days following vaccination.[12]

Varicella vaccine should be administered after 12 months of age and a second dose at 4 years of age. Adolescents and adults without evidence of immunity to varicella zoster should receive two doses of varicella vaccine given 4 to 8 weeks apart. Varicella vaccine is available as a single-component vaccine or in combination with measles, mumps, and rubella vaccine.

COMBINATION VACCINES

The childhood immunization schedule is complex and requires a large number of injections. In small infants the large number of injections can be intolerable to the infant, parent, and health care provider. Limiting the number of injections at each visit can lead to missed vaccinations and increased expense for return visits. ❸ *Use of combination vaccines decreases the number of injections and increases the likelihood that the immunization schedule would be completed.*

Many factors have to be considered when developing combination vaccines. First the selected components need to be given on a similar schedule and all components should already be licensed in the United States. The excipients contained in the individual vaccines may interfere with another component when combined, altering a component's immunogenicity. Finally, the immunogenicity of the combination must be similar (within 10%) to the immune response when the components are administered separately. This has been problematic with combinations containing *Haemophilus influenza* type b vaccine, for which the immune response has been significantly blunted in some combinations.[13]

There are several combination vaccines available in the United States. One of the most popular pediatric combinations is Pediarix® a combination of diphtheria and tetanus toxoids, acellular pertussis, inactivated poliovirus, and hepatitis B vaccines. ComVax® is a combination of *Haemophilus influenzae* type b and hepatitis B vaccines. The most recent combination is ProQuad® which contains measles, mumps, rubella, and varicella vaccines. The only combination available for adults is Twinrix® which has hepatitis A and hepatitis B vaccines.

VACCINE ADMINISTRATION SCHEDULES

Most vaccines are administered in two- to four-shot series in order to elicit the best protection. Childhood and adult immunization schedules are revised frequently and published annually by the CDC Advisory Committee on Immunization Practices. Current immunization schedules can be found at www.cdc.gov/nip/. The childhood schedule is published in January and the adult schedule in October of each year. Recommendations will be published throughout the year in the Morbidity and Mortality Weekly Report (MMWR) as new vaccines are licensed or new information necessitates a change in previous recommendations.

VACCINE SAFETY

Vaccination is one of the most powerful tools used to prevent disease. As with all drugs, most vaccines have been reported to cause adverse reactions. The reactions are either acute, such as local reactions, or are related to risk of developing another disease. Health care professionals are to give vaccine information sheets to individuals or caregivers prior to vaccination; these provide information about the risks and benefits of each vaccine.

Vaccine safety is monitored by the FDA and CDC through a passive reporting system that allows anyone, health professionals or lay public, to report any event. ❹ *Health care professionals are bound by federal regulation to report certain adverse events* (Table 83–2). Additionally, any serious, life-threatening or unusual reactions should also be reported. The Vaccine Adverse Event Reporting System (VAERS) can be found at http://vaers.hhs.gov.

The VAERS database is continually monitored to determine if the prevalence of reactions is changing and to identify previously unreported reactions to a particular vaccine. One of the limitations of the VAERS data is that it does not contain denominator data. Therefore it is not possible to calculate a true rate of reaction occurrence: the number of cases of reaction per dose of vaccine administered. Rates are usually calculated using the number of doses distributed from the manufacture as the denominator. This makes the assumption that each dose distributed is administered.

TABLE 83–2. Vaccine Reportable Events

Vaccine/Toxoid	Event	Interval from Vaccination
Tetanus in any combination; (DTaP, DTP, DTP-Hib, DT, Tdap, Td, or TT)	Anaphylaxis or anaphylactic shock	7 days
	Brachial neuritis	28 days
	Systemic allergic reaction	7 days
	Systemic neurologic reaction	
Pertussis in any combination; (DTaP, DTP, DTP-Hib, or Tdap)	Anaphylaxis or anaphylactic shock	7 days
	Encephalopathy or encephalitis	7 days
	Progressive neurologic disorders, such as infantile spasms or uncontrolled epilepsy	7 days
Measles, mumps, and rubella in any combination; (MMR, MR, M, or R)	Anaphylaxis or anaphylactic shock	7 days
	Encephalopathy or encephalitis	15 days
Rubella in any combination; (MMR, MR, or R)	Chronic arthritis	42 days
Measles in any combination; (MMR, MR, or M)	Thrombocytopenic purpura	7–30 days
	Vaccine strain measles in immunodeficient recipient	6 months
Oral polio (OPV)	Paralytic polio	30 days to 6 months
	Vaccine strain polio infection	30 days to 6 months
Inactivated polio (IPV)	Anaphylaxis or anaphylactic shock	7 days
	Systemic allergic reaction	7 days
Hepatitis B	Anaphylaxis or anaphylactic shock	7 days
	Systemic allergic reaction	7 days
Haemophilus influenzae type b (conjugate)	Anaphylaxis or anaphylactic shock	7 days
	Systemic allergic reaction	7 days
Varicella (chickenpox)	Anaphylaxis or anaphylactic shock	7 days
	Systemic allergic reaction	7 days
Rotavirus	Intussusception	30 days
Pneumococcal conjugate	Anaphylaxis or anaphylactic shock	7 days
	Systemic allergic reaction	7 days

Local Reactions

Pain at the injection site is one of the most commonly reported adverse effects of vaccination. The reaction is usually mild with complaints of pain and tenderness at the injection site that may or may not be accompanied by erythema. Local reactions tend to be more frequent with repeated doses or booster doses of vaccine. The frequency and degree of the reactions appear to be related to the amount of preformed antibodies and rapid immunologic responses reflective of priming from previous doses. More serious Arthus reactions are infrequently reported. Arthus reactions are classified as type III hypersensitivity reactions, and are characterized by a massive local response involving the entire thigh or deltoid. Arthus reactions are also related to preformed antibody complexes that induce an inflammatory lesion.[14]

Tetanus-containing vaccines are well known for causing localized reactions; however, all vaccines can cause local reactions.

Fever

Fever is the most frequently reported adverse effect in children and adolescents. Fever associated with vaccination is defined as a temperature of greater than or equal to 38°C (100.4°F) measured at any site using a validated device. Fever is caused by a complex reaction induced by the production of cytokines that affect the hypothalamic neurons. This results in raising the hypothalamic set point. Temperature elevations above 40°C (104°F) can result in cellular and multi-organ dysfunction. Excessive temperature elevations rarely result from fever alone, but are usually coupled with other thermoregulatory dysfunction.[15]

The whole cell pertussis vaccine has been highly associated with temperature elevations; however, the prevalence has significantly decreased since the introduction of the acellular pertussis vaccine. Live virus vaccines are also associated with fever.

Guillain-Barré Syndrome

Guillain-Barré syndrome is a transient neurologic disorder involving inflammatory demyelination of the peripheral nerves. The syndrome is characterized by progressive symmetric weakness of the legs and arms with loss of reflexes. Occasionally sensory abnormalities and paralysis of respiratory muscles will occur.[16]

The etiology of Guillain-Barré syndrome is unknown, but increasing evidence suggests it is probably a humoral and

cellular autoimmune disease induced by infection with a variety of microorganisms. The background rate of Guillain-Barré syndrome is one to two cases per 100,000 persons annually. Guillain-Barré syndrome has been associated with several vaccines. An influenza vaccine used in the mid-1970s (swine flu vaccine) increased the incidence of Guillain-Barré syndrome by a factor of eight.[16] Warnings about Guillain-Barré syndrome continue to be given with annual influenza vaccinations. The hepatitis B vaccine derived from pooled plasma was also associated with Guillain-Barré syndrome; however, Guillain-Barré has not been reported with use of the currently available hepatitis B vaccines produced through recombinant DNA technology. Most recently, Guillain-Barré syndrome has been reported to occur with the meningococcal conjugate vaccine.

Other Safety Concerns

A clear cause-and-effect relationship between vaccine administration and chronic diseases, such as diabetes mellitus, multiple sclerosis, and chronic arthritis, has never been scientifically proven.

Thimerosal is a preservative used in vaccines that has been purported to cause autism in children. The assumption is that thimerosal, also known as ethyl mercury, causes similar effects as methyl mercury, which has neurotoxic and nephrotoxic effects at high doses. Several epidemiologic studies have not shown a higher rate of autism among children receiving thimerosal-containing vaccines when compared to the normal background rate of autism. Additionally, the mercury exposure with vaccination is much lower than through many other environmental exposures. Despite the lack of evidence of thimerosal causing neurologic disorders, vaccine manufacturers are producing vaccines that are thimerosal-free or only contain trace amounts of thimerosal.[14]

Patient Encounter 3

A 7-year-old child with acute leukemia is 1 year post–bone marrow transplantation. The child's clinical course has been uneventful since transplantation and everything is going as expected. The physician discusses with the child's parents the continued need for protection against infections and suggests that the child should receive some vaccinations.

- When should the child begin receiving vaccinations?
- Which vaccines should be administered and on what schedule?
- Should any vaccines be avoided?
- Which vaccines should household contacts receive?

SPECIAL POPULATIONS

Immunocompromised Host

The number of immunocompromised persons is continually increasing as advances are made in medicine. The life expectancy for persons with cancer, HIV infection, and solid organ or bone marrow transplantation is increasing. Vaccination provides one tool to prevent infection in the immunocompromised host; however, the individual's immunosuppressed state will alter the response to vaccine. In general all vaccinations should be updated prior to the person becoming immunosuppressed, if possible. ❺ *Once a person becomes significantly immunosuppressed, live virus vaccines should be avoided.*

Adults with HIV infection should be vaccinated with the 23-valent pneumococcal polysaccharide and hepatitis B vaccines as early in the course of the disease as possible. Inactivated influenza vaccine should be given yearly. Children should continue to receive vaccinations on the standard childhood immunization schedule. The individual may experience a transient elevation in HIV viral load following vaccination.[17]

Following hematopoietic stem cell transplantation the patient will need virtually all routine vaccines to be administered again; however, the patient will not be able to mount an adequate response for 6 to 12 months post-transplant. Diphtheria, tetanus, acellular pertussis, *Haemophilus influenzae* type b, hepatitis B, pneumococcal, and inactivated poliovirus should be given at 12, 14, and 24 months post–hematopoietic stem cell transplantation. Inactivated influenza vaccine should be given yearly, starting 6 months after transplant. Measles, mumps and rubella can be given 2 years after transplant and varicella vaccine is contraindicated.[16]

Solid organ transplant recipients have a blunted immune response to vaccines because the immunosuppressive regimens used to prevent organ rejection inhibit both T- and B-cell proliferation. Many of these patients will also have secondary hypogammaglobulinemia post-transplantation. Prior to transplant, children should complete primary immunization schedules if possible; accelerated schedules may be used. Adults should have all vaccinations updated prior to transplantation.[16]

Household contacts of immunocompromised persons should have all routine vaccines as scheduled, including yearly influenza vaccination. Children in the household may receive live virus vaccines without special precautions; however, if a rash develops following varicella vaccination, contact should be avoided with the immunocompromised host until the rash resolves.

Pregnancy

Immunization during pregnancy is done to ensure that the infant has sufficient antibodies during the period he or she is

most vulnerable to disease. Maternal antibodies are actively transported to the fetus throughout the pregnancy. However, in the last 4 to 6 weeks of gestation the active transport of immunoglobulins substantially increases. Vaccines administered during pregnancy should produce high antibody concentrations following a single vaccination and are administered in the second and third trimester, but no later than 2 weeks prior to delivery. Maternal vaccination has not shown any harmful effects to the developing fetus. However, live virus vaccines are avoided due to theoretical concerns of the virus being transported across the placenta and infecting the fetus. It is recommended that pregnant women be up to date on tetanus vaccine and receive the influenza vaccine if the second and third trimester will occur during the winter months.[18]

Health Care Workers

Most health care workers are at risk for exposure to many diseases in the normal course of their work. Additionally, health care workers may transmit vaccine-preventable diseases to their patients. At the time of employment and on a regular basis, health care workers should be screened for immunity to measles, rubella, and varicella; if found to be non-immune, the measles, mumps, and rubella, and varicella vaccines should be administered. The hepatitis B series should be given if not already completed. Tetanus should be updated and given every 10 years. Health care personnel in hospitals and ambulatory settings with direct patient contact should receive Tdap if not already received; an interval as short as 2 years from the last tetanus-containing vaccine should be used. Priority for receiving Tdap should be given to personnel with direct contact with infants less than 12 months of age.

All health care personnel should be strongly encouraged to receive the influenza vaccine yearly in order to prevent transmission of influenza within the health care facility and to decrease employee absenteeism for influenza-related reasons. The vaccine should be made available to employees at the workplace, free of charge. Employees should be asked to sign a declination if refusing to receive the influenza vaccine. Additionally, health care facilities should report the number of health care personnel receiving influenza vaccine as a patient safety measure.[19]

OUTCOME MEASURES

❻ *Vaccines are a cost-effective means for disease prevention.* It is estimated that for every dollar spent on routine childhood vaccines there will be a savings of $0.90 to $24.00 in direct medical expense. The rates of vaccination for children are well over 90%. This has been attributed to the requirements for proof of vaccination by states for enrollment into day care centers and school. Additionally, children (less than or equal to 18 years of age) may receive routine vaccinations free of charge through state health departments or other assistance programs, such as the national Vaccines for Children program. Many states have developed universal immunization databases to document pediatric and adult vaccination status. This eliminates the problems of lost immunization records if a child changes health care providers.

The vaccination rate in adults is much lower than that in children. Only 50% to 60% of adults who meet criteria have received pneumococcal or influenza vaccination. Comprehensive initiatives need to be implemented to increase the adult vaccination rate. Some proven concepts are providing reminders to patients that vaccines are due and implementation of standing orders for vaccines. This latter concept allows nurses and pharmacists to screen patients to see if pneumococcal, influenza, or other vaccines are needed and to vaccinate without a physician's order.

The Centers for Medicare and Medicaid Services has incorporated pneumococcal and influenza immunization rates into some of their quality standards. Patients admitted to a hospital for community-acquired pneumonia should be screened for, offered, and vaccinated with pneumococcal and influenza vaccines prior to discharge if not previously administered. In physicians' office practice, all persons over 65 years of age who have been hospitalized in the past year should be screened for, offered, and vaccinated with pneumococcal and influenza vaccines if not previously administered. Both of these standards will affect payment if the standard is not met. The Joint Commission on Accreditation of Healthcare Organizations has also incorporated these standards into their accreditation reviews of health care facilities.

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Explain the routes of transmission for HIV, and its natural disease progression.
2. Identify typical and atypical signs and symptoms of acute and chronic HIV infection.
3. Identify the desired therapeutic outcomes for patients with HIV infection.
4. Recommend appropriate first-line pharmacotherapy interventions for patients with HIV infection.
5. Recommend appropriate second-line pharmacotherapy interventions for patients with HIV infection.
6. Describe the components of a monitoring plan to assess effectiveness and adverse effects of pharmacotherapy for HIV infection.
7. Educate patients about the disease state, appropriate lifestyle modifications, and drug therapy required for effective treatment.

Key Concepts

❶ The treatment goals for HIV infection are to maximally and durably suppress HIV replication, avoid the development of drug resistance, restore and preserve immune function, prevent opportunistic infections, and minimize adverse effects.

❷ HIV RNA plasma concentrations and CD4+ T-cell counts are used to assess risk of progression to AIDS (or risk for opportunistic infection) and to monitor efficacy and durability of treatment.

❸ Effective and complete treatment of HIV infection involves a multidisciplinary approach, which includes pharmacists, clinicians, social workers, and others. Treatment of HIV infection always requires combination prescription antiretroviral therapy, and may include prescription treatment or prophylaxis for opportunistic infections, and prescription or nonprescription treatment for adverse effects.

❹ Treatment with two nucleoside reverse transcriptase inhibitors (NRTIs) *and* either a nonnucleoside reverse transcriptase inhibitor (NNRTI) or a protease inhibitor (PI) is the mainstay of treatment for HIV infection.

❺ All patients with HIV infection relapse if medication is withdrawn. Therefore, long-term maintenance treatment is required.

❻ Eventually, HIV becomes resistant to current medication therapy. To prolong this time to resistance, strict adherence to the drug regimen is critical.

❼ The majority of antiretroviral medications are metabolized by the cytochrome P-450 enzyme system (CYP). Therefore, it is important to review patient medication profiles for drugs that may interact with antiretroviral drugs.

❽ Most antiretroviral medications cause acute and chronic adverse effects. Patients should be closely monitored for these toxicities.

The acquired immune deficiency syndrome (AIDS) was first recognized in 1981, and described in a cohort of young homosexual men with significant immune deficiency. Since then, human immunodeficiency virus type 1 (HIV-1) has been clearly identified as the major cause of AIDS.[1] HIV-2 is much less prevalent than HIV-1, but also causes AIDS. HIV primarily targets CD4+ lymphocytes, which are critical to proper immune system function. If left untreated, patients experience a prolonged asymptomatic period followed by rapid, progressive immunodeficiency. Therefore, most complications experienced by patients with AIDS involve opportunistic infections and cancers.

HIV is primarily transmitted by sexual contact, by contact with blood or blood products, and from mother to child during gestation, delivery, or breast-feeding. The prevalence and incidence of HIV is rising globally, and to date there are no treatments which eradicate HIV from the body. Combinations of potent antiretroviral agents (called highly active antiretroviral therapy, or HAART) can suppress HIV replication to undetectable levels, delay the onset of AIDS, and prolong survival. However, there are a number of drug-induced long-term toxicities that challenge effective patient management. This chapter will address HIV treatment options and challenges, and give practical suggestions for patient management.

EPIDEMIOLOGY

Since the first cases of AIDS were identified in 1981, over 25 million people have died as a result of HIV infection. This makes AIDS one of the most destructive epidemics in recorded history. The epidemic remains extremely dynamic, and no country in the world remains unaffected. It is estimated that HIV currently infects approximately 40 million people worldwide. Approximately 65% of these cases are in sub-Saharan Africa, with a prevalence of approximately 7%. East Asia, Central Asia, and Eastern Europe are also seeing rapidly rising infection rates.

Five million people were newly infected with HIV in 2005 alone. Most of these infections were acquired through heterosexual transmission. As of December 2005, women accounted for 46% of all people living with HIV worldwide; in sub-Saharan Africa, women account for 57%. Persons aged 15 to 24 years accounted for nearly one-half of new HIV infections worldwide.

At the end of 2003, an estimated 1,039,000 to 1,185,000 persons were living with HIV/AIDS in the United States, with 24% to 27% undiagnosed and unaware of their HIV infection (who may be unknowingly transmitting the virus to others). Of the total number of HIV-infected patients, approximately 4% (42,514) were diagnosed with AIDS in 2004, and 2% (18,017) died with AIDS. The cumulative estimated number of diagnoses of AIDS through 2004 was 944,305, one-half of whom (529,113) had died.

Compared with their distribution in the overall population, African-American and Hispanic populations are disproportionately affected by HIV/AIDS, representing 50% and 18% of cases, respectively. HIV/AIDS is among the top three causes of death for African-American men aged 25 to 54 years, is among the top four causes of death for African-American women aged 20 to 54 years, and is the number one cause of death for African-American women aged 25 to 34 years. From 2000 through 2004, HIV/AIDS rates for African-American males were eight times those for white males and three times those for Hispanic males. HIV/AIDS rates for African-American females were 23 times the rates for white females and 5 times the rates for Hispanic females.

ETIOLOGY AND PATHOGENESIS

HIV-1 is a retrovirus and member of the genus *Lentivirus*. These viruses have a characteristically prolonged latency period. There are two molecularly and serologically distinct but related types of HIV: HIV-1 and HIV-2. HIV-2 is a less common cause of the epidemic and is found primarily in West Africa. HIV-1 is categorized by phylogenetic lineages into three groups (M [main], N [new], and O [outlier]). HIV-1 group M can be further categorized into nine subtypes: A through D, F through H, and J and K. HIV-1 sub-type B is primarily responsible for the North American and Western European epidemic.

Evidence suggests that HIV in humans is the result of cross-species transmission from primates infected with simian immunodeficiency virus (SIV). HIV-2 is closely related to the SIV found in sooty mangabeys in West Africa, and HIV-1 is similar to the SIV found in chimpanzees. The earliest known human HIV infection was in central Africa in 1959. Cultural practices such as the preparation and eating of bushmeat, or keeping primates as pets, may have allowed the virus to transmit from animal to human. The rapid spread of the virus throughout the world can be primarily attributed to high mobility due to modern transportation, sexual promiscuity, and drug abuse.

HIV infection occurs through three primary modes of transmission: sexual, parenteral, and perinatal. The most common method for transmission is receptive anal and vaginal intercourse, with the probability of transmission up to 3% per sexual contact for the former, and up to 0.2% per sexual contact for the latter. The probability of transmission increases when the index partner has a high level of viral replication (which occurs at the very beginning of infection or late in disease), or when the uninfected partner has ulcerative disease, compromised mucosal surfaces, or (in the case of men) has not been circumcised.

Parenteral transmission of HIV primarily occurs through injection drug use by sharing contaminated needles or injection-related supplies. As a result of a comprehensive North American screening program, less than 1% of all cases of HIV infection occurs as a result of transfusions of contaminated blood or blood products, or infected transplant organs. Health care workers have a 0.3% estimated risk of acquiring HIV infection through percutaneous needlestick injury.

Perinatal infection (also known as vertical transmission or mother-to-child transmission [MTCT]) can occur during gestation, at or near delivery, and during breast-feeding. The risk of MTCT up to and including delivery is approximately 25%, while the risk of transmission during breast-feeding is approximately 15% to 20% within the first 6 months of life. Since a high rate of HIV replication in the blood is a significant risk factor for transmission of HIV, it is important to treat women for their HIV infection during pregnancy. After delivery, mothers are strongly recommended not to breast-feed if safe alternatives are available.

It is important to understand the life cycle of the virus in order to understand how antiretroviral drugs are combined for optimal therapy (Fig. 84–1). Once HIV enters the body, an outer glycoprotein called gp120 binds to CD4 receptors found on the surface of dendritic cells, T lymphocytes, monocytes, and macrophages. This allows further binding to other chemokine receptors on the cell surface called CCR5 and CXCR4. Most newly infected patients have viruses that preferentially use CCR5 to enter the cell, and most patients with advanced disease have viruses that preferentially use CXCR4 to enter the cell. This becomes important in understanding the place in therapy for some of the new drugs in development.

After the virus has attached to CD4 and chemokine receptors, another viral glycoprotein (gp41) assists with viral fusion to the cell and internalization of the viral contents. The viral contents include single-stranded RNA, an RNA-dependent DNA polymerase (also known as reverse transcriptase), and other enzymes. Using the single-stranded viral RNA as a template, reverse transcriptase synthesizes a complementary strand of DNA. The single-stranded viral RNA is removed from the newly formed DNA strand by ribonuclease H, and reverse transcriptase completes the synthesis of double-stranded DNA. The viral reverse transcriptase enzyme is highly error-prone, and many mutations occur in the conversion of RNA to DNA. This inefficient reverse transcription activity is responsible for HIV's ability to rapidly mutate and develop drug resistance.

A chronic infection is established when the double-stranded DNA migrates to the host cell nucleus and is integrated into the host cell chromosome by an HIV enzyme called integrase. Once the cell becomes activated by antigens or cytokines, HIV replication starts: host DNA polymerase transcribes viral DNA into messenger RNA, and messenger RNA is translated into viral proteins. These proteins assemble beneath the bilayer of the host cell, a nucleocapsid forms containing these proteins, and the virus buds from the cell. After budding, the virus matures when an HIV protease enzyme cleaves large polypeptides into smaller functional proteins. Without this process, the virus is unable to infect other cells.

During the early stages of infection, approximately 10 billion viruses can be produced each day. Most of the cells containing these viruses will be lysed as a result of budding virions, killed by cytotoxic T-lymphocytes, or undergo apoptosis. However, virus will be protected within some cells, which can stay dormant for years. The initial immune response against

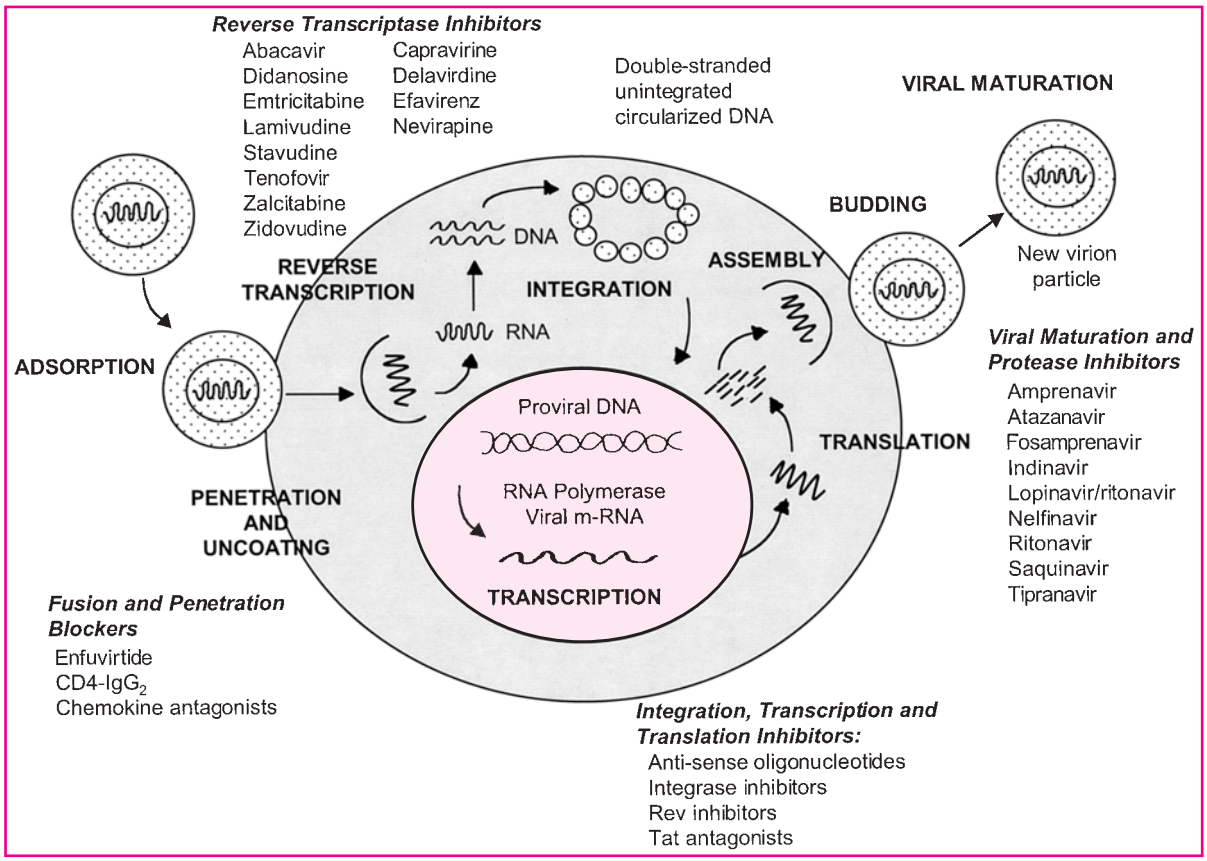

FIGURE 84–1. Life cycle of HIV and targets for antiretroviral drugs. (From Fletcher CV, Kakuda TN. Human immunodeficiency virus infection. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 2258, with permission.)

HIV is relatively effective, but it is unable to completely clear the infection, and the patient enters a latent, asymptomatic or mildly symptomatic stage lasting 5 to 15 years. During this time, a high rate of viral replication can be seen in the lymph nodes. Eventually immune deficiency occurs when the body is no longer able to replenish helper T cells at a rate equal to that at which HIV is destroying them.

❶ *Currently, the goal of therapy is to maximally and durably suppress HIV replication in order to restore and preserve immune system function and minimize morbidity and mortality*. Since HIV replication has been found in all areas of the body, it is important to use potent drug therapy that can achieve adequate concentrations in all tissues, including protected sites such as the brain and genital tract.

CLINICAL PRESENTATION AND DIAGNOSIS

HIV diagnosis is made either by a positive **HIV enzyme-linked immunosorbent assay (ELISA)** or rapid test (these tests may be positive as soon as 3 to 6 weeks after infection) and then confirmed by a positive confirmatory test, usually the HIV Western blot (Table 84–1).

Patients who are acutely infected with HIV may be asymptomatic or present with signs and symptoms associated with any viral infection, such as fever, myalgias, lymphadenopathy, pharyngitis, or rash. Taken together, these are the "acute retroviral syndrome." Providers should consider the possibility of HIV infection in any patients with these findings and inquire about recent high-risk sexual encounters or other modes of exposure. Risk factors for HIV/AIDS infection include: men who have sex with men; history of or current intravenous drug use (needle or equipment sharing); unprotected sexual intercourse with high-risk individuals; the presence of other sexually transmitted infections (e.g., *Chlamydia trachomatis* or *Neisseria gonorrhoeae*); persons with coagulation/hemophilia disorders; and previous blood product recipients. If patients are not identified during acute infection, they may later present with various nonspecific symptoms such as myalgias, fatigue, weight loss, thrush, or symptoms associated with opportunistic infections.

The diagnosis of HIV infection is made either by a baseline serologic screening test such as the ELISA or a rapid test. If reactive, then a confirmatory test is performed. The **Western blot (WB)** is the gold standard confirmatory test and is commonly used. The WB is considered reactive if two of the three major

Clinical Presentation of HIV

Patients with acute HIV infection may display symptoms described as "acute retroviral syndrome." Patients with chronic HIV infection may present with these same nonspecific symptoms and/or opportunistic infections.

Acute Retroviral Syndrome

The majority of patients may present with fever, lymphadenopathy, pharyngitis, and/or rash. Other symptoms include:

- Myalgia or arthralgia
- Diarrhea
- Headache
- Nausea and vomiting
- Hepatosplenomegaly
- Weight loss
- Thrush
- Neurologic symptoms (meningoencephalitis, aseptic meningitis, peripheral neuropathy, facial palsy, or cognitive impairment or psychosis)

Opportunistic Infections

Depending on the severity of immunosuppression (the CD4+ T lymphocyte count), patients may present with the following opportunistic infections (grouped by CD4+ count):

Any CD4+ count

- *Mycobacterium tuberculosis* disease
- Bacterial pneumonia (commonly *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Pseudomonas aeruginosa*, and *Staphylococcus aureus*)
- Herpes simplex virus disease
- Varicella zoster virus disease
- Bacterial enteric disease (most commonly *Salmonella*, *Campylobacter*, and *Shigella*)
- Syphilis
- Bartonellosis

Less than 250 cells/microliter

- Coccidioidomycosis
- *Pneumocystis jiroveci* (formerly *carinii*) pneumonia (PCP)
- Oropharyngeal and esophageal candidiasis
- Kaposi's sarcoma or human herpesvirus-8 disease

Less than 150 cells/microliter

- Disseminated histoplasmosis

Less than 100 cells/microliter

- Cryptosporidiosis
- Microsporidiosis

Less than 50 cells/microliter

- Disseminated *Mycobacterium avium* complex disease
- Cytomegalovirus disease
- Cryptococcosis, aspergillosis, and *Toxoplasma gondii* encephalitis

TABLE 84–1. Available HIV Tests

Test	Minimum Time to Detection after Exposure	Sample(s) Tested	Comments
Initial Screening Tests			
Enzyme-linked immunosorbent assay (ELISA)	3–6 weeks	Plasma	If nonreactive, no further testing is required, unless acute infection suspected
HIV RNA assay	Up to 14 days	Plasma	Obtain if recent high-risk exposure; if initially negative, repeat at months 1, 3, and 6
Rapid tests (currently FDA-approved products)	Detects HIV antibodies within minutes of sample application		
OraQuick ADVANCE	3–6 weeks	Whole blood, plasma, or oral fluid	Detects HIV-1 and HIV-2
Reveal Rapid HIV-1 Antibody Test	3–6 weeks	Plasma or serum	Detects HIV-1
Uni-Gold Recombigen HIV Test	3–6 weeks	Whole blood, plasma, or serum	Detects HIV-1
Confirmatory Tests			
Western blot (WB)	3–6 weeks	Plasma	Gold standard confirmatory test
Indirect immunofluorescence assay (IFA)	3–6 weeks	Plasma	Simple to perform, but requires expertise to interpret results

FDA, Food and Drug Administration; HIV, human immunodeficiency virus.

bands (p24, gp41, and/or gp120/160) change color. The test is nonreactive if no viral bands are visible. If the test is indeterminate (one band visible), patients are retested in 2 to 3 months. This is most likely if a recent (i.e., less than 3 to 6 weeks) infection has occurred, and HIV antibodies have not yet been fully formed. In this case, a plasma HIV RNA concentration (reverse transcriptase polymerase chain reaction [RT-PCR]) should be evaluated. Patients with acute infection will generally have HIV RNA concentrations greater than 10^6/μL. ❷ HIV severity is determined by following: (1) the CD4+ lymphocyte count (CD4 count) and percentage and (2) HIV RNA (viral load). The CD4 percentage is followed because the absolute count may fluctuate and does not necessarily indicate a change in the patient's condition.

TREATMENT

❶ *The goals of treatment are to maximally and durably suppress viral replication, avoid the development of drug resistance, restore and preserve immune function, prevent opportunistic infections, and minimize drug adverse effects*. Elimination of HIV is not possible with currently available therapies. ❷ Instead, maximal suppression of viral replication (defined as HIV RNA concentrations undetectable by the most sensitive assay available) is desired. After the initiation of antiretroviral therapy, a rapid decline to undetectable HIV RNA in 16 to 24 weeks has been shown to be a predictor of improved clinical outcomes.[2]

❷ *Degree of immune function preservation also correlates with decreased viral replication, and is measured by CD4+ T-cell counts. CD4 measures are the best predictor of progression to AIDS, and help decide when to initiate treatment*. At CD4+ T-cell counts of 200 cells/mm^3 and lower, patients require drug prophylaxis for opportunistic infections. Table 84–2 details the monitoring endpoints of HIV treatment for HIV RNA and CD4+ T-cell counts.

Four classes of drugs are available to treat HIV infection: **nucleoside (NRTI)/nucleotide (NtRI) reverse transcriptase inhibitor, protease inhibitor (PI), nonnucleoside reverse transcriptase inhibitor (NNRTI),** and fusion inhibitor. ❸ *Currently, combination antiretroviral drug therapy with three or more drugs is the standard of care*, which increases the durability of viral suppression and decreases the potential for the development of resistance. ❹ *Two nucleoside (nucleotide) reverse transcriptase inhibitors and either a nonnucleoside reverse transcriptase inhibitor or a protease inhibitor are the mainstay regimens of combination therapy*. In the late 1980s, when only zidovudine was available, achieving and maintaining viral suppression for more

TABLE 84–2. Monitoring Endpoints for CD4+ T-Cell Counts and HIV RNA

CD4+ T-Cell Counts			HIV RNA Concentration		
When to Monitor	**Why**	**Goal**	**When to Monitor**	**Why**	**Goal**
Initial diagnosis	Assess need for ART	Start therapy in appropriate patients	Initial diagnosis	Establish baseline and assess need for ART	Start therapy in appropriate patients
	Assess need for OI chemoprophylaxis	Start therapy when less than 200 cells/mm^3	2–8 weeks after starting or changing ART	Early assessment of regimen efficacy	Decrease of at least 1.0 $\log_{10}$ copies/mL
Every 3–6 months	Receiving ART: monitor success of treatment	Average increase of 100–150 cells/mm^3 per year	3–4 months after starting ART	Assess virologic efficacy of regimen	Undetectable
	Not receiving ART: assess need to begin therapy	Start therapy in appropriate patients	Every 3–4 months	Receiving ART: assess durability of RNA suppression with current regimen	Steadily decreasing and/or consistently low
	Assess need for OI chemoprophylaxis	Start therapy when less than 200 cells/mm^3		Not receiving ART: monitor changes in RNA	Start therapy in appropriate patients
Clinical event	Assess need for ART	Start therapy in appropriate patients	Clinical event or decrease in CD4+ T-cell count	Receiving ART: assess if event is due to virologic failure	Change regimen if needed (drugs or doses)
	Assess need for OI chemoprophylaxis	Start therapy when less than 200 cells/mm^3		Not receiving ART: assess need to begin therapy	Start therapy in appropriate patients

ART, antiretroviral therapy; HIV, human immunodeficiency virus; OI, opportunistic infection. (Adapted from the DHHS Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents, April 7, 2005.)

than 4 months was rarely possible. As more agents became available in the mid-1990s (most notably the protease inhibitors), HIV RNA was suppressed to undetectable concentrations and maintained there for long periods of time. Currently recommended combination regimens decrease HIV RNA to less than 50 copies/mL in 50% to 80% of patients in clinical trials. Therefore monotherapy, or the use of two NRTIs alone, are no longer treatment options at any time during HIV infection. Figure 84–1 details the mechanisms of action of the drug classes within the life cycle of HIV.

Nonpharmacologic Interventions

❻ *Patient adherence is a key component in treatment success.* Drug therapy is required for a lifetime, as the virus begins to replicate at high levels when medications are stopped. Early HIV combination therapy was exceedingly complicated for patients, with multiple daily doses, varying food restrictions, and large pill burdens. Advances in delivery and formulations now make possible once- or twice-daily dosing with fewer than six pills per day. Recently, a combination of tenofovir + emtricitabine + efavirenz was approved as a one pill, once per day regimen (Atripla™). The use of low-dose ritonavir to enhance the concentrations of other protease inhibitors (known as pharmacokinetic enhancement or "boosting") allows for significantly fewer doses and lower pill burdens. These advances, however, do not replace the need for patient counseling by a trained pharmacist and a multidisciplinary approach to promoting adherence.

Counsel all patients initially and repeatedly on ways to prevent viral transmission. Preventing the spread of resistant virus is particularly important. Patients receiving antiretroviral therapy can still transmit virus to sexual partners, and to those with whom they share needles or other drug equipment. Where both partners are HIV-positive, safe sex and needle practices reduce the risk of superinfection with differing strains of HIV and the transmission of other sexually transmitted diseases. General guidelines for preventing viral transmission include using condoms with a water-based lubricant for vaginal or anal intercourse, using condoms without lubricant or dental dams for oral sex, and not sharing equipment used to prepare, inject, or inhale drugs.

❸ *Nutrition and dietary counseling should also be included in the care of the HIV patient, as poor nutrition leads to poorer outcomes and complicates treatment.* Antiretroviral therapy itself introduces a host of nutritional issues, including drug-food interactions, gastrointestinal adverse effects that may affect appetite and limit dietary intake, lipid abnormalities, and fat redistribution. The American Dietetics Association currently recommends assessing HIV-infected patients for their level of nutritional risk and involving a registered dietician as part of the clinical team for optimal nutrition care.[3]

Pharmacologic Therapy for Antiretroviral-Naïve Patients

Two major panels of experts publish guidelines for the treatment of HIV-infected individuals. Although the recommendations are quite similar, slight differences do exist between the Department of Health and Human Services (DHHS) Guidelines[2] and the International AIDS Society-USA (IAS-USA) Panel Recommendations.[4] The DHHS Guidelines are updated every 6 months and current and archived versions are available online at www.aidsinfo.nih.gov. The IAS-USA Guidelines were last updated in 2006, and in 2004 prior to that revision. Due to the intense research and constant modifications to therapeutic approaches in the treatment of HIV, the majority of the treatment algorithms and recommendations presented herein follow the most up-to-date information found in the DHHS recommendations.

❷ *The decision of when to begin antiretroviral therapy is complex. Recommendations are based on the CD4+ T-cell count (which predicts disease-free survival) with consideration given to HIV RNA* (Table 84–3). Other factors to consider include the patient's willingness to begin therapy and maintain medication adherence, and the risk versus benefit of treating an asymptomatic patient. Once the decision is made to initiate treatment, the regimen is selected based on patient-specific factors. ❹ *All recommended regimens contain either an NNRTI or a PI in combination with two NRTIs (or NtRI)*. The preferred regimens are:

1. Efavirenz *and* (zidovudine or tenofovir) *and* (lamivudine *or* emtricitabine)
2. Lopinavir/ritonavir *or* atazanavir/ritonavir *or* fosamprenavir/ritonavir *and* (zidovudine) *or* tenofovir *and* (lamivudine *or* emtricitabine)

The decision to choose a NNRTI-based or PI-based regimen as initial therapy is based on many patient- and clinician-specific factors. NNRTI-based regimens have low pill burdens and may have decreased incidences of long-term adverse effects (e.g., dyslipidemia) in comparison to some PI-based regimens. However, this class also has a low threshold for drug resistance (the K103N mutation causes high level cross-class resistance), and patient adherence is a critical consideration. In pregnant women, or women with the potential to become pregnant, a PI-based regimen is preferred due to the potential teratogenicity of efavirenz (pregnancy category D). If a patient is at risk for having contracted a resistant virus (i.e., from someone currently on antiretroviral therapy) genotyping of the virus may assist in selecting the most appropriate drug regimen.

In patients who cannot tolerate the above preferred first-line therapies, or have a compelling reason to choose a different agent, the following first-line therapies are recommended. These regimens tend to be more complex and have higher pill burdens, but may be necessary in order to treat a specific patient:

1. Efavirenz *and* (didanosine *or* abacavir *or* stavudine) *and* (lamivudine *or* emtricitabine)
2. Nevirapine in place of efavirenz in selected populations (due to a more frequent incidence of hepatotoxicity, nevirapine should only be used in patients with low to moderate CD4+ T-cell counts: less than or equal to 250 cells/mm^3 for females, less than or equal to 400 cells/mm^3 for males)
3. Atazanavir *or* fosamprenavir *or* nelfinavir *or* saquinavir/ritonavir, *and* zidovudine *or* stavudine *or* tenofovir *or* abacavir *or* didanosine, *and* lamivudine *or* emtricitabine
4. Lopinavir/ritonavir, *and* abacavir *or* stavudine *or* tenofovir *or* didanosine, *and* lamivudine *or* emtricitabine

Triple NRTI therapy is recommended *only* when a first-line or alternative first-line therapy with either an NNRTI-based or PI-based regimen cannot be used. Abacavir plus zidovudine plus lamivudine is the only regimen approved by the DHHS. The following triple nucleoside therapy combinations have shown poor or limited efficacy, and should be avoided: abacavir plus tenofovir plus lamivudine (or emtricitabine), and didanosine plus tenofovir plus lamivudine (or emtricitabine).

Therapies *not recommended* for initial treatment due to poor potency or significant toxicity include delavirdine, nevirapine in patients with moderate to high CD4+ T-cell counts, indinavir or saquinavir used without ritonavir ("unboosted"), ritonavir used without another protease inhibitor, and tenofovir plus didanosine with an NNRTI.

Drugs that should *not be combined* due to overlapping toxicities include: amprenavir oral solution plus ritonavir oral solution, atazanavir plus indinavir (due to enhanced hyperbilirubinemia), and any combination of didanosine, stavudine, and zalcitabine. Emtricitabine and lamivudine should not be combined because of their similar chemical structures, and antagonism can result when lamivudine is combined with zalcitabine, or stavudine is combined with zidovudine.

TABLE 84–3. Summary of Recommendations for Initiating Antiretroviral Therapy

CD4+ T-Cell Count	Qualifier	Recommendation
Any	AIDS-defining illness	Begin treatment
	Severe HIV infection	
Less than 200 cells/mm^3	Asymptomatic	Begin treatment
201–350 cells/mm^3	Asymptomatic	Offer treatment
Greater than 350 cells/mm^3	HIV RNA greater than 100,000 copies/mL	May offer or defer treatment
	HIV RNA less than 100,000 copies/mL	Defer treatment

AIDS, acquired immune deficiency syndrome; HIV, human immunodeficiency virus. (Adapted from the DHHS Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents, April 7, 2005.)

Pharmacologic Therapy for Antiretroviral-Experienced Patients

❻ *Ongoing viral replication, whether at low levels in the face of adequate drug concentrations or at higher levels due to inconsistent systemic concentrations (or low concentrations in sanctuary sites; e.g., male and female genital fluids, cerebrospinal fluid, or lymph nodes), will eventually lead to resistance to the prescribed medications.* There is no consensus on the optimal time to change therapy based on virologic or immunologic failure (Table 84–4). ❷ Virologic failure is defined as HIV RNA greater than 400 copies/mL after 24 weeks, greater than 50 copies/mL after 48 weeks, or a repeated HIV RNA greater than 400 copies/mL after prior suppression to less than 400 copies/mL.[2] Some clinicians may change therapy with any repeated, detectable viremia (HIV RNA greater than 50 to 400 copies/mL), while others will set arbitrary thresholds of 1,000 to 1,500 copies/mL. Immunologic failure is defined as having an increase of less than 25 to 50 cells/mm^3 in CD4+ T lymphocyte count above baseline after 1 year of therapy, or a decline in CD4+ cell count below baseline while taking antiretroviral therapy.

Treatment considerations for antiretroviral-experienced patients are much more complex than for patients who are naïve to therapy. Prior to changing therapy, the reasons for treatment failure should be identified. A comprehensive review of the patient's severity of disease, antiretroviral treatment history, adherence to therapy, intolerance or toxicity, concomitant drug therapies, co-morbidities, and results of current and past HIV resistance testing should be performed. If patients fail therapy due to poor adherence, the underlying reasons must be determined and addressed prior to initiation of new therapy. Reasons for poor adherence include: problems with medication access, active substance abuse, depression and/or denial of the disease, and a lack of education on the importance of 100% adherence to therapy. Medication intolerance or toxicity can be remedied with therapy for the adverse event, exchanging the drug causing the toxicity with another in the same class, or changing the entire regimen. Pharmacokinetics or systemic drug exposure can be optimized by ensuring maximal drug absorption (taking the drug with or without food can alter exposure by up to 30%), and avoiding interactions with concomitant prescription or over-the-counter medications and dietary supplements or natural products (e.g., antacids, St. John's wort, and garlic). When causes for treatment failure are identified, appropriate strategies for therapy can be determined.

TABLE 84–4. Treatment Options Following Virologic Failure with the Initial Regimen

Initial Regimen	Recommended Change
2 NRTIs + NNRTI	• 2 NRTIs (based on resistance testing) + PI (with or without low-dose ritonavir)
2 NRTIs + PI (with or without low-dose ritonavir)	• 2 NRTIs (based on resistance testing) + NNRTI
3 NRTIs	• 2 NRTIs (based on resistance testing) + NNRTI **or** PI (with or without low-dose ritonavir) • NNRTI + PI (with or without low-dose ritonavir) • NRTI (based on resistance testing) + NNRTI + PI (with or without low-dose ritonavir)

NRTI, nucleoside reverse transcriptase inhibitor; NNRTI, nonnucleoside reverse transcriptase inhibitor; PI, protease inhibitor.
(Adapted from the DHHS Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents, April 7, 2005.)

Drug interactions between antiretrovirals and between antiretrovirals and concomitant medications should be evaluated for each patient to avoid under- and/or overexposure of either therapy. ❼ *NNRTIs and PIs are metabolized by CYP450 enzymes and are inducers and/or inhibitors of this enzyme system.* In addition, some of the antiretrovirals are substrates, inhibitors, and/or inducers of transporters such as P-glycoprotein, and therefore may lead to drug interactions. Information provided in Table 84–5 describes the drug interaction potential of each antiretroviral. Due to the ever-changing drug interactions with this class of medications, the regularly updated DHHS Guidelines for the Use of Antiretroviral Agents in HIV-1–Infected Adults and Adolescents are a recommended source of specific drug interactions.[2]

The goals of therapy differ for antiretroviral-experienced patients that have limited drug exposure (i.e., developing resistance to their first antiretroviral regimen) versus those with extensive exposure (i.e., developing resistance to their third or fourth antiretroviral regimen). It is reasonable to expect maximal viral suppression in those with limited drug exposure. However, this may not be feasible for patients with prior exposure to multiple medications. ❶ *In antiretroviral-experienced patients, a reasonable goal is to simply preserve immune function and prevent clinical progression.*

Several issues need to be considered in choosing a salvage regimen for HIV infection. Knowing prior medication exposure can assist in identifying which drugs to avoid. However, direct HIV resistance testing can better identify the resistance and susceptibility patterns of the major viral strains. Since HIV may be susceptible to certain components of the failing antiretroviral regimen, these drugs can be recycled into future regimens. Resistance testing should be used when initiating therapy in patients with acute HIV infection, in patients with virologic failure on a current ARV regimen, or with suboptimal suppression after initiation of ARV therapy. For resistance testing to be useful, the patient should have a plasma HIV RNA of at least 1,000 copies/mL, and should be currently taking their antiretroviral medications (or be within 4 weeks of discontinuing antiretroviral therapy). The former is because this concentration will yield reliable amplification of the virus, and the latter is because the dominant viral species reverts to wild-type within 4 to 6 weeks after medications are stopped.

TABLE 84–5. Summary of Currently Available Antiretroviral Agents

Drug Name Generic/(Abbreviation)/ Trade Name	Dosage Forms	Commonly Prescribed Doses	Dose Adjustments	Food Restrictions	Significant Adverse Events	Drug Interaction Potential
Nucleoside (tide) Reverse Transcriptase Inhibitors						
Abacavir (ABC) Ziagen®	300-mg tab; 20 mg/mL oral solution	150 mg bid or 300 mg qday qday	None	None Alcohol ↑ ABC conc. by 41%	Potentially fatal hypersensitivity reaction (rash, fever, malaise, nausea, vomiting, shortness of breath, sore throat, loss of appetite)	Alcohol dehydrogenase and glucuronyl transferase, 82% renal excretion of metabolites
Didanosine (ddI) Videx EC® Generic didanosine EC (same dosing as Videx EC®)	125-, 200-, 250-, 400-mg cap	Greater than 60 kg: 400 mg qday Less than 60 kg: 250 mg qday	**CrCl (mL/minute)** / **Greater than 60 kg** / **Less than 60 kg** 30–59 / 200 mg / 125 mg 10–29 / 125 mg / 100 mg Less than 10 / 125 mg / 75 mg	Take 30 minutes prior or 2 hours after meal (conc. ↓55% with food)	Pancreatitis; peripheral neuropathy; nausea; diarrhea	Renal excretion
Emtricitabine (FTC) Emtriva™	200-mg cap; 1 mg/mL oral solution	200 mg qday; 240 mg (24 mL) oral solution qday	**CrCl (mL/minute)** / **capsule** / **solution** 30–49 / 200 mg q48hours / 120 mg q24hours 15–29 / 200 mg q72hours / 80 mg q24hours Less than 15/HD / 200 mg q96hours / 60 mg q24hours (dose after dialysis on dialysis days)	None	Minimal	Renal excretion
Lamivudine (3TC) Epivir®	150-mg and 300-mg tabs or 10 mg/mL oral solution	150 mg bid or 300 mg qday	**CrCl (mL/minute)** / **Dose** 30–49 / 150 mg qday 15–29 / 150 mg × 1, then 100 mg qday 5–14 / 150 mg × 1, then 50 mg qday Less than 5/HD / 50 mg × 1, then 25 mg qday (dose after dialysis on dialysis days)	None	Minimal	Renal excretion
Stavudine (d4T) Zerit®	15-, 20-, 30-, 40-mg caps or 1 mg/mL for oral solution	Greater than 60 kg: 40 mg bid Less than 60 kg: 30 mg bid	**CrCl (ml/minute)** / **Dose greater than 60 kg** / **less than 60 kg** 26–50 / 20 mg q12hours / 15 mg q12hours 10–25/HD / 20 mg q24hours / 15 mg q24hours (dose after dialysis on dialysis days)	None	Peripheral neuropathy; lipodystrophy; rapidly progressive ascending neuro-muscular weakness (rare); pancreatitis; lactic acidosis with hepatic steatosis (higher incidence with d4T than with other NRTIs); hyperlipidemia	Renal excretion
Tenofovir disoproxil fumarate (TDF) Viread®	300 mg tab	300 mg qday	**CrCl (mL/minute)** / **Dose** 30–49 / 300 mg q48hours 10–29 / 300 mg twice weekly ESRD/HD / 200 mg q7days (dose after dialysis on dialysis days)	None	Asthenia, headache, diarrhea, nausea, vomiting, and flatulence; renal insufficiency	Renal excretion

TABLE 84–5. Summary of Currently Available Antiretroviral Agents *(Continued)*

Drug Name Generic/(Abbreviation)/ Trade Name	Dosage Forms	Commonly Prescribed Doses	Dose Adjustments	Food Restrictions	Significant Adverse Events	Drug Interaction Potential
Zalcitabine (ddC) Hivid® (anticipated discontinuation of distribution in 2006)	0.375-, 0.75-mg tab	0.75 mg tid	**CrCl (mL/minute)** **Dose** 10–40 0.75 mg bid less than 10 0.75 mg qday No data on hemodialysis	None	Peripheral neuropathy; stomatitis, lactic acidosis with hepatic steatosis (rare but potentially life-threatening toxicity with use of NRTIs); pancreatitis	Renal excretion
Zidovudine (AZT, ZDV) Retrovir®	100-mg caps, 300-mg tabs, 10 mg/mL intravenous solution, 10 mg/mL oral solution	300 mg bid	100 mg tid in severe renal impairment or HD	None	Bone marrow suppression: macrocytic anemia or neutropenia; gastrointestinal intolerance, headache, insomnia, asthenia	Glucuronyl transferase and renal
Zidovudine + lamivudine (AZT/3TC) Combivir®	AZT 300 mg + 3TC 150 mg tab	1 tablet bid	Do not use with CrCl less than 50 mL/minute	None	See adverse events for AZT and 3TC	See AZT and 3TC
Abacavir + lamivudine + zidovudine (ABC/3TC/ AZT) Trizivir®	ABC 300 mg + 3TC 150 mg + AZT 300 mg tab	1 tablet bid	Do not use with CrCl less than 50 mL/minute	None	See adverse events for AZT, 3TC, and ABC	See AZT, 3TC, and ABC
Abacavir + lamivudine (ABC/3TC) Epzicom®	ABC 600 mg + 3TC 300 mg tab	1 tablet bid	Do not use with CrCl less than 50 mL/minute	None	See adverse events for ABC and 3TC	See ABC and 3TC
Tenofovir + emtricitabine (TDF/FTC) Truvada™	TDF 300 mg + FTC 200 mg tab	1 tablet bid	**CrCl (mL/minute)** **Dose** 30–49 1 tablet q48hours Less than 30 Not recommended	None	See adverse events fo TDF and FTC	See TDF and FTC
Nonnucleoside Reverse Transcriptase Inhibitors						
Delavirdine (DLV) Rescriptor®	100-, 200-mg tabs	400 mg tid (100 mg tabs can be dispersed in greater than or equal to 3 oz of water to produce slurry); 200 mg tabs should be administered whole; separate dosing from buffered DDI or antacids by 1 hour	Use with caution in patients with hepatic impairment	None	Rash; increased LFTs, headaches	Metabolized by cytochrome P-450 (CYP); CYP3A inhibitor; 51% excreted in urine (less than 5% unchanged); 44% in feces

Efavirenz (EFV) Sustiva®	50-, 100-, 200-mg caps or 600-mg tabs	600 mg qday at or before bedtime	Use with caution in patients with hepatic impairment	Take on an empty stomach (high-fat/calorie meals ↑ C_{max} of caps 39% and C_{max} of tabs 79%	Rash; central nervous system symptoms (insomnia, irritability, lethargy, dizziness, vivid dreams) usually resolve in 2 weeks; increased LFTs; false-positive cannabinoid test; teratogenic in monkeys	Metabolized by CYP2B6 and CYP3A (3A mixed inducer/inhibitor); 14–34% excreted in urine (glucuronidated metabolites, less than 1% unchanged); 16–61% in feces
Nevirapine (NVP) Viramune®	200-mg tabs or 50 mg/5 mL oral suspension	200 mg qday for 14 days; then 200 mg bid	Use with caution in patients with hepatic impairment	No food restrictions	Rash including Stevens-Johnson syndrome; symptomatic hepatitis, including fatal hepatic necrosis	Metabolized by CYP2B6 and CYP3A (3A inducer); 80% excreted in urine (glucuronidated metabolites; less than 5% unchanged); 10% in feces
Tenofovir + Emtricitabine + Efavirenz (TDF/FTC/EFV) Atripla™	TDF 300 mg + FTC 200 mg + EFV 600 mg	1 tablet once daily	Do not use in patients with CrCl less than 50 ml/minute	High-fat/high caloric meals increase peak plasma concentrations of EFV capsules by 39% and EFV tablets by 79%; take on an empty stomach	See adverse events of TDF, FTC, and EFV	See TDF, FTC, and EFV
Protease Inhibitors						
Amprenavir (APV) Agenerase®	5 mg/mL oral solution	1,400 mg bid (Note: APV and RTV oral solution should not be co-administered due to competition of the metabolic pathway of the two vehicles)	Oral solution not recommended in patients with renal oral hepatic failure	Avoid high fat meal (AUC? ↓ 21%); can be taken with or without food	GI intolerance, nausea, vomiting, diarrhea; rash; oral paresthesias; hyperlipidemia; LFT elevation; hyperglycemia; fat maldistribution; possible increased bleeding episodes in patients with hemophilia (Note: oral solution contains propylene glycol; contraindicated in pregnant women, children less than 4 years old, patients with hepatic or renal failure, and patients treated with disulfiram or metronidazole)	CYP3A4 inhibitor, inducer, and substrate
Atazanavir (ATV) Reyataz™	100-, 150-, 200-mg caps	400 mg qday *If taken with efavirenz or tenofovir use the following:* ATV 300 mg qday + RTV 100 mg qday	**Child-Pugh Class** / **Dose** 7–9 / 300 mg qday Greater than 9 / Not recommended	Take with food (AUC ↑ 30%); pH-sensitive dissolution—avoid antacids or proton pump inhibitors; separate histamine blockers by taking 10 hours before ATV and if dosed twice daily, second dose 2 hours after ATV	Indirect hyperbilirubinemia; prolonged PR interval (asymptomatic first-degree AV block); use with caution in patients with underlying conduction defects or on concomitant medications that can cause PR prolongation; hyperglycemia; fat maldistribution; increased bleeding episodes in patients with hemophilia	CYP3A4 inhibitor and substrate; UGT1A1 inhibitor

(Continued)

TABLE 84–5. Summary of Currently Available Antiretroviral Agents (*Continued*)

Drug Name Generic/(Abbreviation)/ Trade Name	Dosage Forms	Commonly Prescribed Doses[a]	Dose Adjustments	Food Restrictions	Significant Adverse Events	Drug Interaction Potential[b]
Darunavir (DRV) Prezista™	300 mg tablet	DRV 600 mg + RTV 100 mg twice daily	Use with caution in patients with hepatic impairment	Should be given with food	Skin rash (has a sulfonamide moiety, Stevens Johnson & erythema multiforum have been reported); diarrhea, nausea; headache; hyperlipidemia; transaminase elevation; hyperglycemia; fat maldistribution; possible increased bleeding episodes in patients with hemophilia	CYP3A4 inhibitor and substrate
Fosamprenavir (fAPV) Lexiva™	700-mg tabs	*ARV-naïve pts:* fAPV 1,400 mg bid or fAPV 700 mg + RTV 100 mg bid *PI-experienced pts:* fAPV 700 mg + RTV 100 mg bid *Co-administration w/EFV:* fAPV 700 mg + RTV 100 mg bid or fAPV 1400 mg + RTV 300 mg qday	**Child-Pugh Class** **Dose** 5–8 700 mg bid 9–12 Not recommended Ritonavir should not be used in patients with hepatic impairment	None	Skin rash; diarrhea, nausea and vomiting; headache; hyperlipidemia; LFT elevation; hyperglycemia; fat maldistribution; increased bleeding episodes in patients with hemophilia	CYP3A4 inhibitor, inducer, and substrate
Indinavir (IDV) Crixivan®	200-, 333-, 400-mg caps	800 mg q8hours; IDV 800 mg + RTV 100 bid; IDV 800 mg + RTV 200 mg bid	Mild to moderate hepatic insufficiency due to cirrhosis: 600 mg q8hours	*For unboosted IDV:* Take 1 hour before or 2 hours after heavy meals, or concomitantly with low-fat meal No restrictions when used with RTV	Nephrolithiasis; GI intolerance, nausea; indirect hyperbilirubinemia; hyperlipidemia; headache, asthenia, blurred vision, dizziness, rash, metallic taste, thrombocytopenia, alopecia, hemolytic anemia; hyperglycemia; fat maldistribution; increased bleeding episodes in patients with hemophilia	CYP3A4 inhibitor (less than RTV)
Lopinavir + ritonavir (LPV/r) Kaletra®	LPV 200 mg + RTV 50 mg tablet, LPV 400 mg + RTV 100 mg/5 mL oral solution (contains 42% alcohol)	2 tablets or 5 mL bid 4 tablets qday *With EFV or NVP:* 3 tablets or 6.7 mL bid	Use with caution in patients with hepatic impairment	Take with food (AUC ↑ 48–80%)	Nausea, vomiting, diarrhea; asthenia; hyperlipidemia; LFT elevation; hyperglycemia; fat maldistribution; increased bleeding episodes in hemophiliacs	CYP3A4 inhibitor and susbstrate

Nelfinavir (NFV) Viracept®	250- 625-mg tabs, 50 mg/g oral powder	1,250 mg bid or 750 mg tid	Use with caution in patients with hepatic impairment	Take with meal or snack	Diarrhea; hyperlipidemia; hyperglycemia; fat maldistribution; increased bleeding in hemophiliacs; LFT elevation	CYP3A4 inhibitor and substrate
Ritonavir (RTV) Norvir®	100-mg caps, 600 mg/7.5 mL solution	600 mg bid (when ritonavir is used as sole PI); 100–200 mg/dose when used as pharmacokinetic enhancer	No dosage adjustment in mild hepatic impairment No data for moderate to severe impairment; use with caution	Take with food to improve tolerability	GI intolerance, nausea, diarrhea; paresthesias; hyperlipidemia; hepatitis; asthenia; taste perversion; hyperglycemia; fat maldistribution; increased bleeding in hemophiliacs	CYP3A4 greater than 2D6; potent (3A4 inhibitor)
Saquinavir tablets and hard gel capsules (SQV) Invirase®	200-mg capsules, 500-mg tablets	Unboosted SQV not recommended *With RTV:* (RTV 100 mg + SQV 1,000 mg) two times/day	Use with caution in patients with hepatic impairment	Take within 2 hours of a meal when taken with RTV	Nausea, diarrhea; headache; LFT elevation; hyperlipidemia; hyperglycemia; fat maldistribution; increased bleeding in hemophiliacs	CYP3A4 inhibitor and substrte
Tipranavir (TPV) Aptivus®	250-mg capsules	500 mg twice daily with RTV 200 mg twice daily	Contraindicated in patients with moderate to severe hepatic insufficiency	Take with food	Hepatotoxicity; skin rash; hyperlipidemia; hyperglycemia; fat maldistribution; possible increased bleeding in hemophiliacs	TPV/RTV mixed CYP inhibitor/ inducer; TPV is CYP3A4 substrate
Fusion Inhibitors						
Enfuvirtide (T20) Fuzeon™	Injectable, in lyophilized powder Each single-use vial contains 108 mg of enfuvirtide to be reconstituted with 1.1 mL of sterile water for injection for delivery of approximately 90 mg/1 mL	90 mg (1 mL) subcutaneously two times/day	No dosage recommendation	N/A	Local injection site reaction (pain, erythema, induration, nodules and cysts, pruritus, eachymosis) in most patients; increased rate of bacterial pneumonia; less than 1% hypersensitivity reaction (rash, fever, nausea, vomiting, chills, rigors, hypotension, or elevated serum transaminases); do not rechallenge	Catabolism to amino acids, with subsequent recycling in the body pool

AUC, area under the time-concentration curve; ARV, antiretroviral; AV, atrioventricular; C_{max}, maximum concentration; CrCl, creatinine clearance; ESRD, end-stage renal disease; GI, gastrointestinal; HD, hemodialysis; LFT, liver function test; NRTI, nucleoside reverse transcriptase inhibitor; UGT, uridine diphosphate-glucuronsyltransferase.
(Adapted from the DHHS Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents, October 12, 2006.)

Two types of HIV resistance testing are available, genotyping and phenotyping. Genotyping involves detecting mutations by genetically sequencing the virus, while phenotyping determines the ability of the virus to replicate in the presence of varying ARV concentrations. Genotyping is more rapid and less costly than phenotyping, but results in a list of mutations that may be more difficult to interpret than phenotyping. A report known as the *virtual phenotype* may also be reported when genotypes are ordered.[5–12] This compares the patient's viral sequence to a database of matched genotypes and drug susceptibilities. Since the predictability of *virtual phenotypes* are dependent on the robustness of the database from which they are derived, some clinicians believe their utility is limited. A number of web-based tools are available to assist with interpretation of resistance mutations (e.g., Stanford University's HIV Drug Resistance Database; http://hivdb.stanford.edu/index.html). However, expert interpretation of genotype and phenotype reports is recommended.

Certain guiding principles should be considered when treating ARV-experienced patients, and expert opinion is advised before selecting therapy. ❹ *As with ARV-naïve patients, three or more active drugs should be prescribed.*[8,13–15] Since considerable cross-resistance can occur between medications within an antiretroviral class, simply using drugs to which the patient has not been exposed may be insufficient. Complete cross-resistance occurs within the NNRTI class, whereas the NRTIs and PIs have variable overlapping resistance patterns. For this reason, HIV resistance assays are important tools for choosing subsequent effective therapies. The following factors are associated with superior virologic response: lower viral load at the time therapy is changed, using a new class of antiretroviral agent, and using ritonavir-enhanced PIs in patients previously exposed to PIs.[16,17]

Table 84–4 provides general treatment options based on previous drug use. If patients fail therapy with resistance to only one drug, one or two active agents may be substituted for this drug while retaining the remaining drugs in the regimen. If patients fail therapy with resistance to more than one drug, changing classes of antiretrovirals and/or adding new active drugs is warranted. Some patients may have partial response to ARV therapy, and continue to have detectable plasma HIV RNA. In this case, intensification of the current therapy with the addition of a new agent (such as tenofovir) or pharmacokinetic enhancement of a current PI-based regimen with the addition of ritonavir, may lead to complete response. New NRTIs should be selected from resistance testing. If this is not available, the assumption should be made that resistance has developed to all NRTIs used in the failing regimen. In general, HIV that is resistant solely to lamivudine and/or emtricitabine will be susceptible to other NRTIs. If HIV develops resistance solely to tenofovir, then it may have reduced susceptibility to didanosine, but should remain susceptible to zidovudine, stavudine, lamivudine, emtricitabine, and abacavir. Cross-resistance occurs between zidovudine and stavudine.

If a patient appears to fail an antiretroviral regimen without detectable HIV resistance, adherence should be investigated, and the adequacy of the plasma HIV RNA concentration in the resistance sample confirmed. Options include continuing the current regimen or starting a new regimen and repeating the resistance test 2 to 4 weeks after adherence is verified. An increasing number of patients have extensive HIV resistance, such that antiretroviral regimens cannot be designed to which the virus is fully susceptible. For these patients, continuing the current regimen may be beneficial because drug-resistant virus may have a compromised **replication capacity**. Other strategies may be considered for this type of patient, including pharmacokinetic enhancement with ritonavir, re-treatment with prior antiretroviral agents, treatment with multi-drug regimens (four or more antiretroviral drugs), and the use of new agents through expanded access programs or clinical trials.

Treatment Considerations in Special Populations

Acute HIV Infection Diagnosis of acute HIV infection is difficult, since many patients are asymptomatic, or have non-specific clinical symptoms similar to other common respiratory infections. If acute HIV infection is suspected, HIV antibody tests and a plasma HIV RNA concentration should be obtained. A clear diagnosis is made when an HIV antibody test is negative and the plasma HIV RNA concentration is high. There are limited outcomes data for treating acutely infected patients. Treatment of acute infection can decrease the severity of acute disease and decrease the viral set point; this may decrease progression rates and reduce the rate of viral transmission.[18–22] Limitations include an increased risk of chronic drug-induced toxicities and the development of viral resistance.

Adolescent Patients As a result of similar modes of HIV transmission, adolescents infected after puberty are treated with similar considerations as adults. In this population, dosing of antiretroviral drugs should not be based on age, but on the Tanner stage (which considers external primary and secondary sexual characteristics). Adolescents in early puberty should be dosed according to pediatric guidelines, while those in late puberty should be dosed as adults. During growth spurts, adolescents should be monitored closely for drug efficacy and toxicity, since rapid changes in weight can lead to altered drug concentrations. Adherence is of concern in this population due to denial of the disease, misinformation, distrust of health care professionals, low self-esteem, and lack of family and/or social support. Additionally, asymptomatic patients this age find it more difficult to adhere to therapy while feeling well.

Pediatric Patients There are unique considerations in the treatment of HIV-infected children. Specific treatment guidelines exist,[23] but a thorough review is outside the scope of this chapter. Most children acquire HIV infection through

perinatal transmission either in utero, intrapartum, or postpartum through breast-feeding, although antiretroviral interventions have dramatically reduced transmission rates.[2] Antiretroviral therapy is limited in pediatric patients, as some drugs have no dosing recommendations for this population, or are not available in a formulation that can be easily administered to children. Additionally, drug exposures can change dramatically during ontogeny due to altered drug-metabolizing enzyme and drug transporter activities.

Drugs of Abuse Treatment challenges in illicit drug users include comorbidities (such as hepatitis infection), limited access to care, inadequate adherence to therapy, side effects and toxicities, and the need for treatment of substance abuse which can lead to drug interactions. ❼ *Many drugs of abuse have the potential to interact with antiretroviral medications, and a number of case reports have documented drug overdose when combined with protease inhibitor therapy.*[24] In these populations, without addiction control, adherence is suboptimal and treatment failure is common.[2] Most protease inhibitors and nonnucleoside reverse transcriptase inhibitors decrease methadone concentrations up to 50%. As this can result in the development of withdrawal symptoms, patients should be closely monitored for 4 to 8 weeks after initiation of antiretroviral therapy. Withdrawal symptoms can be alleviated with a methadone dose increase of 5 to 10 mg. Although there are fewer data, buprenorphine concentrations may be similarly affected, and therefore this drug requires close monitoring.

Pregnancy and Women of Reproductive Potential The goals of antiretroviral therapy for women of reproductive age and pregnant women are the same as for other adult patients. Specific guidelines for HIV-infected pregnant women are available.[25] Recommended therapies in pregnancy include zidovudine, lamivudine, nelfinavir, lopinavir/ritonavir, and if the CD4+ count is less than 250 cells/mm^3, nevirapine. Drugs to be avoided include efavirenz (due to potential teratogenicity), the combination of didanosine and stavudine (due to a high incidence of lactic acidosis), nevirapine in patients with a CD4 count greater than 250 cells/mm^3 (due to an increased risk of hepatotoxicity), and the liquid formulation of amprenavir (due to high concentrations of propylene glycol). The goal of therapy is to reduce plasma HIV RNA below 1,000 copies/mL and prevent mother-to-child transmission of HIV. Limited data are available on antiretroviral pharmacokinetics in pregnancy, and standard doses of antiretroviral drugs are currently recommended with close HIV RNA and CD4 monitoring in the third trimester of pregnancy.

Women of reproductive potential prescribed efavirenz should be counseled on its potentially teratogenic effects and the importance of birth control. ❼ *Additionally, nevirapine, nelfinavir, ritonavir, lopinavir/ritonavir, and tipranavir/ritonavir have been shown to decrease the concentrations of estrogens and/or progestins in oral contraceptives, which could lead to failure.*[2] For patients prescribed these drugs, barrier forms of contraception are preferred to prevent pregnancy. DepoProvera may be a safe alternative, as it does not affect nelfinavir, efavirenz, or nevirapine concentrations; although the effect of antiretrovirals on medroxyprogesterone concentrations has not been examined, no evidence of ovulation has been seen in women on these combinations.[26]

Hepatitis B Co-Infection HIV-infected patients co-infected with hepatitis B virus (HBV) have higher concentrations of DNA and hepatitis B early antigen (HBeAg), and higher rates of HBV-associated liver disease. Therapy for HBV should be offered to patients who are HBeAg-positive, or have HBV DNA greater than 10^5 copies/mL and have either liver serologies (alanine aminotransferase) greater than 2 times the upper limit of normal or histologic evidence of moderate disease or fibrosis. Options include interferon alfa 2a or 2b and nucleoside/tide analogs. Nucleoside/tide analogs that treat HBV but not HIV are adefovir and entecavir. Nucleoside/tide analogs that treat HBV and HIV are lamivudine, emtricitabine, and tenofovir. These latter agents should be considered when treating HIV infection in HBV co-infected patients.

Hepatitis C Co-Infection Patients co-infected with hepatitis C virus (HCV) and HIV have a three-fold increase in rate of progression to cirrhosis compared to those with HCV alone. Therapy for HCV is considered in patients with detectable plasma HCV RNA and a liver biopsy showing bridging or portal fibrosis. Patients with HCV genotype 2 and 3 (and a CD4 count greater than 200 cells/mm^3) treated with pegylated interferon plus ribavirin have a better sustained viral response at 48 weeks (60% to 70%) compared to those with HCV genotype 1 (15% to 28%). Comprehensive treatment guidelines for HIV/HCV co-infected patients are available.[27] Important considerations addressed in these guidelines include avoiding the combination of ribavirin with didanosine (due to increased risk of pancreatitis and/or lactic acidosis), and ribavirin with zidovudine (due to increased risk of anemia). Growth factors may be needed to treat neutropenia from interferon and anemia from ribavirin. Antiretrovirals such as nevirapine, efavirenz, and tipranavir are hepatotoxic and in most cases should be avoided in HCV/HIV-infected patients.

OUTCOME EVALUATION

❶ *The success of antiretroviral therapy is measured by the degree to which the therapy (1) restores and preserves immunologic function, (2) maximally and durably suppresses HIV RNA, (3) improves quality of life, and (4) reduces HIV-related morbidity and mortality.* ❷ *The major outcome parameters are CD4+ lymphocyte absolute count and percentage, and plasma HIV RNA.* Adequate immunologic response in antiretroviral-naïve patients consists of an increase in CD4+ cell count that averages 100 to 150 cells/mm^3 per year (with a faster response in the first 3 months), and a 1 log decrease in HIV RNA by 2 to 8 weeks after starting

medications, followed by concentrations less than 50 copies/mL by 12 to 16 weeks (if HIV RNA less than 100,000/μL) or by 16 to 24 weeks (if HIV RNA greater than 100,000/μL). HIV RNA and CD4 count are monitored generally every 3 to 6 months. In highly treatment-experienced patients, adequate immunologic response may be a stable or slightly increasing CD4 T-cell count, and a stable HIV RNA to prevent clinical progression.

❺ *Currently, treatment of HIV infection is lifelong.* Treatment interruption may be necessary due to drug toxicity or illness that precludes administration of oral therapy. Occasionally, patients may experience treatment fatigue and can benefit from a temporary halt of their antiretroviral therapy. The duration of this "holiday" depends on the patient's HIV RNA and CD4+ count prior to initiation of their first antiretroviral regimen. Patients with higher CD4+ counts and lower viral loads prior to therapy maintain their immunologic status for longer periods of time compared to those who began therapy with more advanced disease. Ultimately, antiretroviral therapy will need to be reinstituted.

Each patient should have a plan to assess the effectiveness of antiretroviral therapy after initiation. At each clinic visit, patients should be evaluated for the presence of adverse drug reactions, drug allergies, medication adherence, and potential drug interactions. ❽ *Antiretrovirals have both class-associated and drug-specific adverse effects* (see Table 84–5). If the patient experiences any of the serious, life-threatening effects (Table 84–6), the offending agent should be discontinued promptly, and in most cases the patient cannot be rechallenged. Potential long-term complications that may reduce the quality of life are listed in Table 84–7. For drugs with a high likelihood of intolerability (such as nelfinavir-associated diarrhea), patients should be counseled to anticipate these effects and have concomitant prescriptions available for preemptive management (such as an antidiarrheal agent). Patients should have follow-up within the first week after initiating a new drug regimen. If the patient does not tolerate a medication despite all efforts to the contrary, consider changing the drug.

Patient Encounter, Part 1

A 46-year-old man with a history of hypertension and gastroesophageal reflux disease comes to your clinic complaining of increased fatigue, shortness of breath, and cough. He has noticed feeling tired more easily for the past 3 months, but the difficulty breathing and cough appeared 2 weeks ago. After questioning him further, he says has sex with men, but he has had the same sexual partner for the past 8 years. They do not use condoms. He also says that he smokes about 1 pack of cigarettes per day.

1. What information is suggestive of HIV/AIDS?
2. What risk factors are present for having HIV/AIDS?
3. What additional information do you need to know before creating a treatment plan for this patient?

Part 2

The Medical History, Physical Exam, and Diagnostic Tests

PMH

Hypertension for 5 years; it is often not well controlled because of poor patient adherence
Gastroesophageal reflux disease (GERD), currently controlled on histamine antagonists
History of hepatitis B

FH

Father died of myocardial infarction at the age of 68 years; mother is still alive with history of diabetes

SH

Works as a truck driver; reports distant history of intravenous drug use in his 20s; drinks alcohol occasionally

Meds

Hydrochlorothiazide 25 mg PO once daily
Famotidine 20 mg PO twice daily

ROS

(+) weight loss, decreased appetite, shortness of breath, and cough; (–) chest pain, nausea, vomiting, diarrhea

PE

VS: Blood pressure 144/84 mm Hg, pulse 100 bpm, respiratory rate 22/minute, temperature 38.3°C (100.9°F)
HEENT: Mild thrush on tongue
CV: RRR, normal S_1, S_2; no murmurs, rubs, gallops
Abd: Soft, nontender, nondistended; (+) bowel sounds, no hepatosplenomegaly
Rectal: Deferred

Labs

Sodium 135 mEq/L (135 mmol/L), potassium 3.6 mEq/L (3.6 mmol/L), chloride 100 mEq/L (100 mmol/L), bicarbonate 24 mEq/L (24 mmol/L), blood urea nitrogen 14 mg/dL (5 mmol/L), creatinine 1.0 mg/dL (88.4 μmol/L), WBC $5.2 \times 10^3/mm^3$, hemoglobin 11.5 g/dL, hematocrit 34.1%, platelets $151{,}000/mm^3$, neutrophils 58%, bands 9%, lymphocytes 32%, monocytes 1%, eosinophils 0%, basophils 0%, CD4 150 cells/mm^3
HIV ELISA: Pending
Chest x-ray: Diffuse interstitial infiltrates bilaterally

1. Given this additional information, what is your assessment of the patient's condition?
2. What other laboratory tests would you recommend?
3. Identify your treatment goals for the patient.
4. What nonpharmacologic and pharmacologic alternatives are available for the patient?

TABLE 84–6. Serious Adverse Effects and Management

Adverse Effects	Drug	Signs and Symptoms	Risk Factors	Prevention/Monitoring	Management
Hepatotoxicity	NVP	**Onset** Up to 18 weeks post initiation **Symptoms** Abrupt onset of flu-like symptoms, abdominal pain, jaundice, fever ± rash	1. Increased CD4 + count at initiation 2. Female 3. Elevated baseline AST/ALT 4. Any liver disease 5. High NVP conc	AST/ALT ⇒ every 2 weeks for first month, monthly for 3 months, then every 3 months	D/C antiretrovirals; D/C all hepatotoxic agents; rule out other causes; do not rechallenge with NVP
	Other NNRTIs, PIs, and NRTIs	**Onset** NNRTI—60% within first 12 weeks PI—weeks to months NRTI—months to years **Symptoms** NNRTI—asymptomatic to nonspecific symptoms, such as anorexia, weight loss, or fatigue PI—generally asymptomatic, some with anorexia, weight loss, jaundice NRTI—ZDV, ddI, d4T may cause hepatotoxicity associated with lactic acidosis; 3TC, FTC, or TDF may cause HBV flare when these drugs are withdrawn	1. HBV or HCV coinfection 2. Alcoholism 3. Concomitant hepatotoxic drugs	Monitor LFTs at least every 3–4 months	Rule out other causes; for symptomatic patients: D/C all antiretrovirals and other potential hepatotoxic agents; after symptoms and LFTs normalize, begin new antiretroviral regimen (without the potential offending agents); for asymptomatic patients: If ALT greater than 5–10x ULN, may consider D/C antiretrovirals or continue with close monitoring; after symptoms and LFTs normalize, begin new antiretroviral regimen (without the potential offending agents)
Lactic acidosis/ hepatic steatosis +/– pancreatitis	NRTIs (esp. d4T, ddI, ZDV)	**Onset** Months after initiation **Symptoms** Nonspecific gastrointestinal (nausea, anorexia, abdominal pain, vomiting, weight loss, fatigue) Laboratory values: ↑lactate, ↓ arterial pH, ↓serum bicarbonate, ↑AST/ALT, ↑PT, ↑T.bili, ↑amylase/lipase (with pancreatitis)	1. d4T + ddI 2. Female 3. Obesity 4. Pregnancy 5. ddI + hydroxyurea or ribavirin	None unless symptoms present ⇒ Consider lactate concentrations in patients with ↓ serum bicarbonate or ↑ anion gap	D/C all antiretrovirals; symptomatic support with fluids; some patients require IV bicarbonate, hemodialysis, parenteral nutrition, or mechanical ventilation; once syndrome resolves, consider using NRTIs with ↓ mitochondrial toxicity (ABC, TDF, 3TC, or FTC); monitor lactate after restarting NRTIs; some clinicians use NRTI-sparing regimens.
Stevens-Johnson syndrome/toxic epidermal necrosis	NVP greater than EFV, DLV; Also, APV, f-APV, ABC, ZDV, ddI, IDV LPV/r, ATV	**Onset** First days to weeks after therapy start **Symptoms** Skin eruption with mucosal ulcerations; fever, tachycardia, malaise, myalgia, arthralgia	NVP—female, black, Asian, Hispanic	Use 2-week lead in ⇒ 200 mg qday, then 200 mg bid Avoid corticosteroid use during dose escalation—may ↑rash incidence	D/C all antiretrovirals as well as any other possible cause; aggressive symptom support; do not rechallenge patient with offending agent; if caused by NVP, avoid NNRTI class, if possible

(Continued)

TABLE 84–6. Serious Adverse Effects and Management *(Continued)*

Adverse Effects	Drug	Signs and Symptoms	Risk Factors	Prevention/Monitoring	Management
Hypersensitivity reaction (HSR)	ABC	**Onset** Median = 9 days; 90% within first 6 weeks **Symptoms** Acute onset of symptoms (most frequent to least): high fever, diffuse skin rash, malaise, nausea, headache, myalgia, chills, diarrhea, vomiting, abdominal pain, dyspnea, arthralgia, respiratory symptoms	1. HLA-B*5701, HLA-DR7, HLA-DQ3 2. Antiretroviral-naïve patients 3. Higher incidence with 600 mg qday compared to bid dosing	Educate patients about signs and symptoms of HSR and the need of prompt report	D/C ABC and other antiretrovirals; rule out other causes of symptoms, most signs and symptoms resolve 48 hours after ABC/DC; do not rechallenge with ABC after suspected HSR
Bleeding episodes	PIs	**Onset** Few weeks **Symptoms** ↑Spontaneous bleeding tendency (in joints, muscles, soft tissues, and hematuria)	PI use in hemophiliac patients TPV and anticoagulants (risk of intracranial hemorrhage)	Consider using a NNRTI-based regimen	May require increased use of factor VIII products
Bone marrow suppression	ZDV	**Onset** Few weeks to months **Symptoms** Fatigue, risk of ↑ bacterial infections due to neutropenia; anemia, neutropenia	1. Advanced HIV 2. High dose ZDV 3. Preexisting anemia or neutropenia 4. Concomitant use of bone marrow suppressants	Avoid in patients with high risk for bone marrow suppression; avoid other suppressing agents; monitor CBC with differential at least every 3 months	Switch to another NRTI; D/C concomitant bone marrow suppressant, if possible; for anemia: Identify and treat other causes; consider erythropoietin treatment or blood transfusion, if indicated; for neutropenia: Identify and treat other causes; consider filgrastim treatment, if indicated
Nephrolithiasis/ urolithiasis/ crystalluria	IDV	**Onset** Any time after initiation of therapy, especially if ↓ fluid intake **Symptoms** Flank pain and/or abdominal pain, dysuria, frequency; pyuria, hematuria, crystallauria; rarely, ↑serum creatinine and acute renal failure	1. History of nephrolithiasis 2. Patients unable to maintain adequate fluid intake 3. High peak IDV concentration 4. ↑Duration of exposure	Drink at least 1.5–2 L of non-caffeinated fluid per day; ↑fluid intake at first sign of darkened urine; monitor urinalysis and serum creatinine every 3–6 months	Increased hydration; pain control; may consider switching to alternative agent; stent placement may be required
Nephrotoxicity	IDV potentially TDF	**Onset** IDV—months after therapy TDF—weeks to months after therapy **Symptoms** IDV—asymptomatic; rarely develop end-stage renal disease TDF—asymptomatic to symptoms of nephrogenic diabetes insipidus, Fanconi syndrome	1. History of renal disease 2. Concomitant use of nephrotoxic drugs	Avoid use of other nephrotoxic drugs; adequate hydration if on IDV; monitor creatinine, urinalysis, serum potassium and phosphorus in patients at risk	D/C offending agent, generally reversible; supportive care; electrolyte replacement as indicated

Pancreatitis	ddI; ddI + d4T; DDI + hydroxyurea (HU) or ribavirin (RBV); 3TC in children	**Onset** Usually weeks to months **Symptoms** Post-prandial abdominal pain, nausea, vomiting; ↑serum amylase and lipase	1. High intracellular and/or serum ddI concentrations 2. History of pancreatitis 3. Alcoholism 4. Hypertriglyceridemia 5. Concomitant use of ddI with d4T, HU, or RBV 6. Use of ddI + TDF without ddI dose reduction	ddI should not be used in patients with history of pancreatitis; avoid concomitant use of ddI with d4T, HU, or RBV; ↓ddI dose when used with TDF	D/C offending agents; symptomatic management of pancreatits—bowel rest, IV hydration, pain control, gradual resumption of oral intake
Skin rash	NVP greater than EFV, DLV APV, f-APV, TPV, ABC, ATV	**Onset** Within first few days to weeks after therapy initiation **Symptoms** Mild to moderate rash; diffuse maculopapular rash with or without pruritus; severe rash; see section on Stevens-Johnson syndrome (SJS)	NVP—see NVP SJS; APV, f-APV, TPV—sulfonamide derivative, potential for cross-reactivity with other sulfa drugs; EFV—↑ incidence in children	NVP—see SJS; advise patient to report first sign of rash; recommend avoiding other NNRTIs in patients with severe rash to one NNRTI	Mild to moderate rash: symptomatic treatment with antihistamine and continuation of offending agent; D/C offending drug if rash worsens to severe (blisters, fever, mucous membrane involvement, conjunctivitis, edema, or arthralgias) or if systemic symptoms are present

3TC, lamivudine; ABC, abacavir; APV, amprenavir; AST, aspartate aminotransferase; ALT, alanine aminotransferase; ATV, atazanavir; CBC, complete blood cell count; D/C, discontinue; ddI, didanosine; d4T, stavudine; EFV, efavirenz; FTC, emtricitabine; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; IDV, indinavir; IV, intravenous; LFT, liver function tests; LPV/r, lopinavir + ritonavir; NNRTI, nonnucleoside reverse transcriptase inhibitor; NRTI, nucleoside reverse transcriptase inhibitor; NVP, nevirapine; PI, protease inhibitor; PT, prothrombin time; T.bili, total bilirubin; TDF, tenofovir disoproxil fumarate; TPV, tipranavir; ULN, upper limit of normal; ZDV, zidovudine.

TABLE 84–7. Other Adverse Effects and Management

Adverse Effects	Drug	Signs and Symptoms	Risk Factors	Prevention/Monitoring	Management
Potential Long-term Complications					
Cardiovascular	Potentially all PIs	Onset: months to years after therapy initiation	Other risk factors for CVD	Consider non-PI based regimen; lifestyle modification counseling	Early diagnosis, prevention, and pharmacologic therapy for hyperlipidemia, HTN, insulin-resistance/diabetes mellitus; assess cardiac risk factors; switch to NNRTI- or ATV-based regimen; avoid d4T
Hyperlipidemia	All PIs (except ATV); d4T; EFV (to a lesser extent)	Onset: weeks to months after therapy initiation; symptoms: All PIs except ATV—↑LDL and total cholesterol (TC), ↓HDL; LPV/r and RTV—disproportionate ↑TG, d4T—↑TG; may also ↑LDL and TC; EFV or NVP—↑HDL, slight ↑TG	Underlying hyperlipidemia PI TPV/r greater than LPV/r and RTV greater than NFV and APV greater than IDV and SQV greater than ATV; NNRTI: less than PIs; NRTI: d4T greater than ZDV and TDF	Use non-PI non-d4T–based regimens; use ATV-based regimen; monitor fasting lipid profile at baseline, 3–6 months after new regimen, then at least annually	Lifestyle modification; switch to antiretrovirals with fewer lipid effects; total cholesterol greater than 200 mg/dL, ↑LDL, TG 200–500 mg/dL ⇒ pravastatin or atorvastatin; TG greater than 500 mg/dL ⇒ gemfibrozil or micronized fenofibrate
Insulin resistance/ Diabetes mellitus	All PIs	Onset: weeks to months after therapy initiation; symptoms: polyuria, polydipsia, polyphagia, fatigue, weakness; exacerbation of hyperglycemia in patients with underlying diabetes	Underlying hyperglycemia, family history of diabetes mellitus 1. Diabetes 2. Prior steroid use 3. Advanced age 4. Alcohol use 5. Hyperlipidemia	Use PI-sparing regimens; monitor fasting blood glucose 1–3 months after starting new regimen, then at least every 3–6 months Risk reduction: for asymptomatic cases with less than 15% bony head involvement, monitor with MRI every 3–6 months × 1 y, then every 6 months × 1 y, then annually	Diet and exercise; consider switching to an NNRTI-based regimen; if need for pharmacologic therapy, consider metformin, sulfonylurea, "glitazones," or insulin, where indicated Conservative: reduce weight-bearing activity on affected joint; reduce risk factors; analgesics as needed; Surgical: core decompression +/– bone grafting (early disease); total joint arthroplasty (severe disease)
Osteonecrosis	All PIs	Onset: insidious; symptoms: mild to moderate periarticular pain; 85% of cases involve one or both femoral heads			
Quality of Life Complications					
Central nervous system effects	EFV	Onset: first few doses; symptoms: one or more of the following: drowsiness, insomnia, abnormal dreams, dizziness, impaired concentration, depression, hallucination; exacerbation of psychiatric disorders; psychosis; suicidal ideation	1. Preexisting or unstable psychiatric illness 2. Use of other drugs with CNS effects	Take no earlier than 2–3 hours before bedtime; take on an empty stomach; counsel patients to avoid operating machinery during first 2–4 weeks of therapy	Symptoms usually diminish or resolve after 2–4 weeks; may consider discontinuing therapy if symptoms persist and significantly impair daily function or exacerbate psychiatric illness

Fat maldistribution	PIs, d4T	Onset: gradually, months after therapy initiation; symptoms: lipoatrophy-peripheral fat loss (facial thinning, thinning of extremities and buttocks); lipohypertrophy—increase in abdominal girth, breast size, and dorsocervical fat pad (buffalo hump)	Lipoatrophy—low baseline body mass index	DEXA scan	Switching to other agents may slow or stop progression, but may not reverse effects; injectable poly-L-lactic acid for facial lipoatrophy
Gastrointestinal intolerance	All PIs, ZDV, ddI	Onset: first few doses; symptoms: nausea, vomiting, abdominal pain; diarrhea commonly seen with NFV, LPV/r, and ddI-buffered formulations	All patients	Taking with food may reduce symptoms (not for ddI or unboosted IDV); may preemptively need ntiemetics or antidiarrheals	May spontaneously resolve or become tolerable with time; nausea and vomiting: consider antiemetic prior to dosing; switch to less emetogenic agent; diarrhea: consider antimotility agents, calcium tablets, bulk-forming agents, and/or pancreatic enzymes
Injection site reactions	Enfuvirtide	Onset: first new doses; symptoms: pain, pruritus, erythema, ecchymosis, warmth, nodules, rarely injection site infection	All patients	Educate regarding use of sterile technique, solution at room temperature, rotation of injection sites, avoidance of sites with little subcutaneous fat or existing reactions	Massaging the area vigorously before and after injection may reduce pain; wear loose clothing around injection site areas; take warm shower or bath prior to injection; Rarely, warm compact or analgesics may be necessary
Peripheral neuropathy	ddI, d4T, ddC	Onset: weeks to months after therapy initiation; symptoms: begins with numbness and paresthesias of toes and feet; may progress to painful neuropathy; upper extremities less frequently involved; may be irreversible despite drug discontinuation	1. Preexisting peripheral neuropathy 2. Combined use of these NRTIs or other drugs which may cause neuropathy 3. Advanced HIV 4. High dose of offending drugs	Avoid using these agents in patients at risk, if possible; avoid combined use of these agents; ask patient at each encounter	Consider D/C offending agent prior to onset of disabling pain; pharmacologic treatment (variable effectiveness): gabapentin, tricyclic antidepressants, lamotrigine, oxcarbamazepine, topiramate, tramadol, narcotic analgesics, capsaicin cream, topical lidocaine

APV, amprenavir; ATV, atazanavir; CNS, central nervous system; CVD, cardiovascular disease; D/C, discontinue; ddC, zalcitabine; ddI, didanosine; DEXA, dual-energy x-ray absorptiometry; d4T, stavudine; EFV, efavirenz; HDL, high-density lipoprotein; HIV, human immunodeficiency virus; HTN, hypertension; IDV, indinavir; LDL, low-density lipoprotein; LPV/r, lopinavir + ritonavir; MRI, magnetic resonance imaging; NNRTI, nonnucleoside reverse transcriptase inhibitor; NRTI, nucleoside reverse transcriptase inhibitor; NVP, nevirapine; PI, protease inhibitor; RTV, ritonavir; SQV, saquinavir; TDF, tenofovir disoproxil fumarate; TG, triglyceride; TPV/r, tipranivir + ritonavir; ZDV, zidovudine.

Patient Encounter, Part 3

Creating a Care Plan

Based on the information presented, create a care plan for this patient's HIV/AIDS. Your plan should include: (a) a statement of the best drug combinations and reasons supporting each drug recommended, as well as any adverse effects or potential drug-related problems, (b) the goals of therapy, (c) a patient-specific, detailed therapeutic plan, and (d) a plan for follow-up to determine whether the goals have been achieved and adverse effects avoided.

Patient Encounter, Part 4

The Patient Returns

Your patient begins treatment with atazanavir 300 mg PO once daily, ritonavir 100 mg PO once daily, tenofovir 300 mg PO once daily, and lamivudine 300 mg PO once daily. He initially does well on this regimen, but after about 3 months, he has difficulty taking his medications at the same time every day due to his busy schedule. Because of his job, he relocated to Alabama, and has not been seen in your clinic for 2 years. He returns today to see you in clinic and complains of feeling tired, but otherwise no specific complaints.

1. What laboratory tests do you recommend?
2. What additional information do you need to know before creating a treatment plan for this patient?

Patient Care and Monitoring

Patient Assessment

1. Medication history
   - Get a thorough history of prescription, nonprescription, and natural drug product use. Determine what prior antiretroviral regimens, if any, were used in the past.
   - *Is the patient taking the appropriate dose of each medication? Are the doses adjusted for renal or hepatic failure? Are the doses adjusted for drug interactions with concomitant medications?*
   - Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.
   - Assess improvement in quality-of-life measures such as physical, psychological, and social functioning and well-being. *Is the patient experiencing any drug-induced adverse effects? What can you do to help manage these adverse effects?*
2. Review any available diagnostic data to determine status of his HIV/AIDS.
3. Determine if initiation of antiretroviral therapy is indicated. Evaluate the patient's ability to adhere to medications, daily routine, social support, and financial stability. *Is the patient taking any medications that may interfere with the individual components of potential regimens? Does the patient have medical insurance and prescription coverage?*
4. Develop a plan to assess the effectiveness and tolerability of antiretroviral therapy.

Patient Education

1. Educate the patient on HIV/AIDS disease and the importance of strict adherence to medication (the patient must ideally take his or her medications at the same time every day). Recommend a therapeutic regimen that is as easy as possible for the patient to take. Talk to the patient specifically about when and how the patient will be taking the medications. *What time do they eat meals? When do they wake up? What other medications are they taking at the same time?* Educate patients whether to take their medications with or without food.
2. Educate the patient on common adverse drug effects and a few of the key signs and symptoms of severe toxicity (i.e., jaundice and abacavir hypersensitivity reaction). Tell them to call their provider immediately if any of those symptoms occur. Make sure they have the correct telephone number for the clinic.

Patient Encounter Answer Key

Part 1

1. Presence of risk factors for HIV, symptoms of chronic disease and/or opportunistic infections
2. Sex with men, unprotected sex
3. Does this patient have an opportunistic infection that needs treating first? It is also important to know what other medications the patient is taking, drug allergies, and the patient's daily routine.

Part 2

1. This patient has the subjective symptoms of weight loss, decreased appetite, shortness of breath, and cough. Abnormal laboratory values include: elevated temperature, decreased hemoglobin and hematocrit, and decreased CD4 count. Chest x-ray shows diffuse interstitial infiltrates bilaterally. Physical exam reveals thrush. The assessment is possible AIDS with CD4 count of 150 cells/mm^3, thrush, a respiratory illness (possibly *Pneumocystis jiroveci* pneumonia), and anemia of chronic disease. He also has a history of hepatitis B, hypertension, and GERD (on famotidine), poor adherence to his antihypertensive medications, and likely has an irregular daily regimen due to his occupation as a truck driver.
2. For PCP: Oxygen saturation on room air, induced sputum or bronchoalveolar lavage for presence of *Pneumocystis jiroveci* organisms
   For HIV: HIV RNA, baseline HIV genotypic resistance test
   For HIV treatment: Hepatitis B tests (hepatitis B surface antibody and antigen, hepatitis B envelope antigen, and HBV DNA), liver function tests
3. a. Treat opportunistic infections such as thrush and PCP, if the diagnosis is made, prior to starting antiretroviral therapy. This is because treatment with antiretroviral therapy may cause immune reconstitution syndrome.
   b. Restore and preserve immunologic function
   c. Maximally and durably suppress HIV RNA
   d. Improve quality of life
   e. Reduce HIV-related morbidity and mortality
4. Nonpharmacologic: Prevention of viral transmission (use protective barrier for oral and sexual intercourse; do not share needles or other equipment used in preparing, injecting, or inhaling drugs), adequate nutritional intake
   Pharmacologic: For treatment-naïve patients, two regimens are preferred, either:
   Efavirenz *and* (zidovudine or tenofovir) *and* (lamivudine *or* emtricitabine)
   or
   Lopinavir/ritonavir *or* atazanavir/ritonavir *and* (zidovudine *or* fosamprenavir/ritonavir *or* tenofovir) *and* (lamivudine *or* emtricitabine).

Part 3

a. Any preferred regimen may be okay for this patient; however, due to the patient's lifestyle as a truck driver, the potential side effects of the drugs, and the patient's history of hepatitis B, the combination of efavirenz, tenofovir, and emtricitabine may be the best choice for him. This regimen is taken once daily. Use of efavirenz avoids the high likelihood of gastrointestinal adverse effects of lopinavir/ritonavir such as nausea and diarrhea, which would be inconvenient for him if he is driving long distances. Tenofovir has activity against both hepatitis B and HIV, so would be a good choice in him. Emtricitabine and lamivudine are similar NRTIs with similar resistance profiles. Both also have activity against hepatitis B and HIV. Because tenofovir was recommended, a combination tablet of tenofovir emtricitabine and efavirenz is available, decreasing his pill burden. Zidovudine may not be the best choice, as it may worsen his anemia.

b. Goals of therapy:
   1. Restore and preserve immunologic function
   2. Maximally and durably suppress HIV RNA
   3. Improve quality of life
   4. Reduce HIV-related morbidity and mortality

c. Talk to the patient and based on his sleep/wake schedule, food intake, and other daily routines, find specific times for him to take his medications, both HIV and non-HIV. Counsel the patient about the importance of adherence and the potential side effects of the drugs. Efavirenz (rash; central nervous system symptoms including insomnia, irritability, lethargy, dizziness, and/or vivid dreams which usually resolve in 2 weeks; increased LFTs; false-positive cannabinoid test, if the patient uses marijuana), tenofovir (asthenia, headache, diarrhea, nausea, vomiting, flatulence, and renal insufficiency), and emtricitabine (minimal).

d. Call the patient in the first week after starting medications to evaluate development of any side effects or problems in adherence. In 2 to 8 weeks after starting medications, the patient should have a follow-up visit and/or blood drawn for CD4+ lymphocyte absolute count and percentage and plasma HIV RNA. Adequate immunologic response in antiretroviral-naïve patients consists of an increase in CD4+ cell count that averages 100 to 150 cells/mm^3 per year (with a faster response in the first 3 months), and a 1 log decrease in HIV RNA by 2 to 8 weeks after starting medications, followed by concentrations less than 50 copies/mL by 12 to 16 weeks (if HIV RNA less than 100,000/μL) or by 16 to 24 weeks (if HIV RNA greater than 100,000/μL). HIV RNA and CD4 count are monitored generally every 3 to 6 months.

Part 4

1. The patient may be failing his current regimen due to nonadherence or a drug interaction with famotidine. Check HIV RNA and CD4 count to evaluate HIV treatment efficacy and complete blood count with differential, chemistry profile, and liver function tests for routine follow-up.
2. If the patient is failing his current antiretroviral regimen, ask if the patient is currently taking his medications. If he is, then obtain a resistance test to help determine the cause for failure. Question him further about his previous regimen regarding tolerability and adherence, other concomitant medications, new disease states, and drug allergies.

ABBREVIATIONS

3TC: lamivudine
ABC: abacavir
AIDS: acquired immune deficiency syndrome
ALT: alanine aminotransferase
APV: amprenavir
ARV: antiretroviral
AST: aspartate aminotransferase
ATV: atazanavir
CBC: complete blood cell count
CNS: central nervous system
CVD: cardiovascular disease
CYP: cytochrome P-450 isoenzyme
D/C: discontinue
ddC: zalcitabine
ddI: didanosine
DEXA: dual-energy x-ray absorptiometry
DHHS: Department of Health and Human Services
DRV: darunavir
d4T: stavudine
ELISA: enzyme-linked immunosorbent assay
EFV: efavirenz
FDA: Food and Drug Administration
FTC: emtricitabine
GERD: gastroesophageal reflux disease
HAART: highly active antiretroviral therapy
HBeAg: hepatitis B early antigen
HBV: hepatitis B virus
HCV: hepatitis C virus
HDL: high-density lipoprotein
HIV: human immunodeficiency virus infection
HTN: hypertension
IAS-USA: International AIDS Society-USA
IDV: indinavir
IFA: indirect immunofluorescence assay
IV: intravenous
LDL: low-density lipoprotein
LFT: liver function tests
LPV/r: lopinavir + ritonavir
MRI: magnetic resonance imaging
MTCT: mother-to-child transmission
NNRTI: nonnucleoside reverse transcriptase inhibitor
NRTI: nucleoside reverse transcriptase inhibitor
NtRI: nucleotide reverse transcriptase inhibitor
NVP: nevirapine
PCP: *Pneumocystis jiroveci* (formerly *carinii*) pneumonia
PI: protease inhibitor
PT: prothrombin time
RT-PCR: reverse transcriptase polymerase chain reaction
RTV: ritonavir
SIV: simian immunodeficiency virus
SQV: saquinavir
T.bili: total bilirubin
TDF: tenofovir disoproxil fumarate
TG: triglyceride
TPV: tipranavir
TPV/r: tipranivir + ritonavir
ULN: upper limit of normal
WB: Western blot
ZDV: zidovudine

85 Cancer Chemotherapy and Treatment

Dianne Brundage

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Describe the etiology of cancer.
2. Define the TNM system of cancer staging.
3. Classify each drug used in the treatment of cancer, and compare and contrast the mechanisms of action, uses, and side effects.
4. Outline actions for all health care providers to prevent medication errors with cancer treatments.
5. Describe the role of the health care practitioner in the care of cancer patients.

Key Concepts

❶ The word cancer covers a diverse array of tumors types that affect a significant number of Americans and are a significant cause of mortality.
❷ Numerous cellular changes occur in the genetic material of the cancer cell so that programmed cell death, or **apoptosis,** does not occur. Proliferation of cancer cells goes unregulated.
❸ Many tumors are staged according to the tumor, nodes, metastases (TNM) system. Metastases are cancer cells that have spread to sites distant from the primary tumor site and have started to grow. The most frequently occurring sites of metastasis of solid tumors are the brain, bone, liver, and lungs.
❹ Each category of chemotherapy drugs has similar side effects. Anthracyclines cause cardiac toxicity, which is related to the cumulative dose. Tubulin interactive agents are associated with neuropathy and ileus. Alkylating agents are associated with secondary malignancies.
❺ Because of the severe toxicities associated with many of the chemotherapy agents, safety precautions must be in place to prevent chemotherapy errors, accidental chemotherapy exposures, and overdosages.
❻ Clinicians should play a role in chemotherapy safety, patient education, and monitoring patient response to therapy. For example, cumulative doses of anthracyclines should be monitored along with signs and symptoms of heart failure. Clinicians also should monitor concurrent medications along with chemotherapy for drug interactions.

❶ *The word cancer covers a diverse array of tumors types that affect a significant number of Americans and are a significant cause of mortality.* The term *cancer* actually refers to more than 100 diseases. What is common to all cancers is the cancerous cell has uncontrolled growth so that it invades tissues and spreads to other parts of the body, called *metastasis*. In 2005, it is projected that over 1.3 million Americans will be diagnosed with cancer, whereas more than 560,000 Americans will die from the cancer.[1] Figure 85–1 reveals cancers by gender, new cases, and deaths.

A cancer patient may encounter many different health care professionals: phlebotomists, pathologists, surgeons, medical and radiation oncologists, physician assistants, pharmacists, nurses, counselors, dieticians, social workers, and chaplains all may be involved with a single patient. Each one plays an important role in care of the cancer patient. The pharmacist's role may include education of patients and family members, education of staff about new agents and safety issues, preparation of therapies, resolution of reimbursement issues, development of order sets, and participation in clinical trials. Each patient should have access to an interdisciplinary team to assist him or her during treatment.

Cancer treatments have exploded technologically in the last couple of decades. The fields of radiation therapy, surgery, and pharmaceuticals have had numerous developments, so patients are receiving not only less toxic treatments but also treatments that have improved outcomes over those of 15 years ago. Supportive-care therapies have improved, so patients may be at

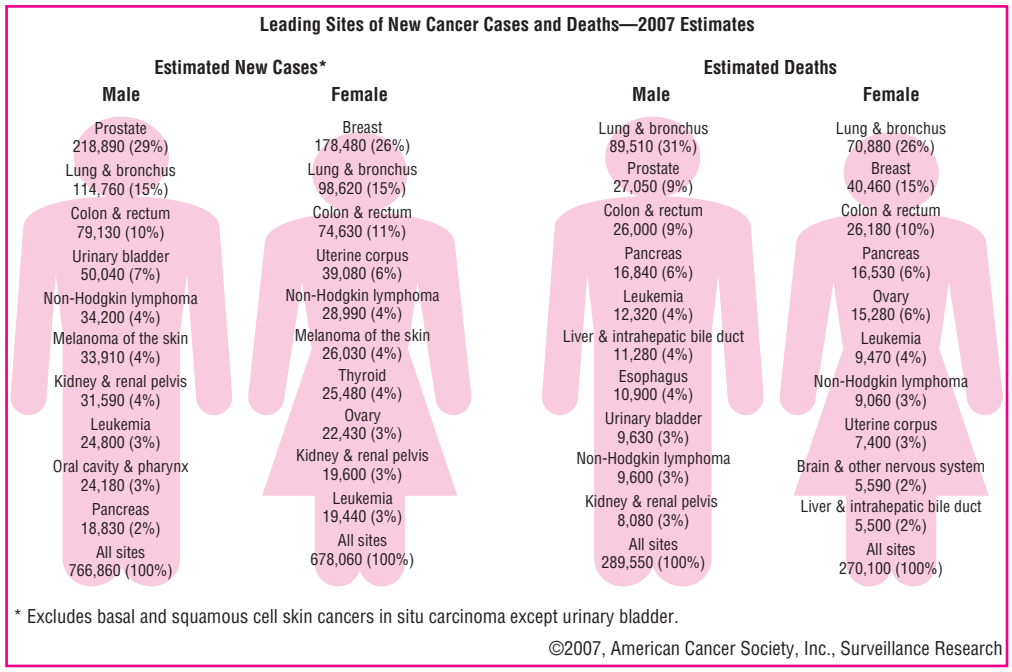

FIGURE 85–1. Cancer incidences (*left*) and deaths (*right*) in the United States for males and females estimate for 2007. (Reproduced from American Cancer Society. Cancer facts and figures—2007. Atlanta: American Cancer Society; 2007.)

less risk for toxicity and have a better **quality of life** than patients 10 to 15 years ago. In the early 1990s, most patients received chemotherapy while hospitalized because of side effects. Today, most patients receive chemotherapy in the clinic and/or are taking oral agents at home.

EPIDEMIOLOGY AND ETIOLOGY

Carcinogenesis

The exact cause of cancer remains unknown and probably is very diverse given the vast array of diseases called cancer. What is common to all cancer cells is that the usual cell cycle of proliferation and death no longer exists. Carcinogenesis may occur in the following steps: initiation, promotion, transformation, and progression. Initiation occurs when a carcinogenic substance encounters a normal cell to produce genetic damage, or a mutated cell. Environmental or other factors that favor the growth of the mutated cell refer to promotion. Transformation occurs when the mutated cell becomes malignant, and progression refers to the state where cell proliferation takes over, and the tumor spreads or develops metastases.

Carcinogenic agents include chemicals in the environment, such as aniline and benzene, which are associated with the development of bladder cancer and leukemia, respectively. Environmental factors, such as excessive sun exposure, also may result in cancer. Viruses, including the human papilloma virus and hepatitis B, may be associated with the development of cancer. Some of the chemotherapy agents cause secondary cancers after therapy has been completed. Numerous factors may contribute to the development of cancer.

Cancer Genetics

Since the human genome has been sequenced, and with the great improvements in genetic technology, there is an ever-increasing body of knowledge regarding the genetic changes of cancer. Currently, there are two major classes of genes involved in cancer: oncogenes and tumor-suppressor genes. Protooncogenes are normal genes that, through some genetic alteration caused by carcinogens, change into oncogenes. The oncogene produces abnormal or excessive gene product that disrupts normal cell growth and proliferation.[2] Table 85–1 provides examples of oncogenes.

Tumor-suppressor genes inhibit inappropriate cellular growth and proliferation by gene loss or mutation. The *p53* gene is one of the most common tumor-suppressor genes, and mutations of *p53* may occur in up to 50% of all malignancies. This gene stops the cell cycle to enable "repairs" of the cell. If *p53* is inactivated, then the cell allows the mutations to occur. While mutations of the *p53* gene are found in many tumors, it is also associated with drug resistance of cancer cells. DNA repair genes fix errors in DNA that occur because of environmental factors or errors in replication and sometimes are referred to as *tumor-suppressor genes*.

❷ *Numerous cellular changes occur in the genetic material of the cancer cell so that programmed cell death, or* ***apoptosis,*** *does not occur. Proliferation of cancer cells goes unregulated.* If mutations persist and cells aren't repaired or suppressed, cancer may develop. **Apoptosis,** or programmed cell death, may prevent the mutated cell from becoming cancerous. Loss of *p53* and overexpression of *bcl-2* are two examples of changes within the cell that occur to result in enhanced cell survival. *Cellular senescence* refers to cell death that occurs after a preset

TABLE 85–1. Examples of Oncogenes and Tumor-Suppressor Genes

Gene	Function	Associated Human Cancer
Oncogenes		
Genes for growth factors or their receptors		
EGFR or *ERB-B1*	Codes for epidermal growth factor (EGFR) receptor	Glioblastoma, breast cancer, squamous carcinoma
HER-2/neu or *ERB-B2*	Codes for a growth factor receptor	Breast, salivary gland, prostate, bladder and ovarian cancers
RET	Codes for a growth factor receptor	Thyroid cancer
Genes for cytoplasmic relays in stimulatory signaling pathways		
K-RAS		Lung, ovarian, colon, pancreatic binding cancers
N-RAS	Code for guanine nucleotide-proteins with GTPase activity	Neuroblastoma, acute leukemia
Genes for transcription factors that activate growth-promoting genes		
c-MYC		Leukemia and breast, colon, gastric, and lung cancers
N-MYC		Neuroblastoma, small cell lung cancer, and glioblastoma
Genes for cytoplasmic kinases		
BCR-ABL	Codes for a nonreceptor tyrosine kinase	Chronic myelogenous leukemia
Genes for other molecules		
BCL-2	Codes for a protein that blocks apoptosis	Indolent B-cell lymphomas
BCL-1 or *PRAD1*	Codes for cyclin D1, a cell cycle clock stimulator	Breast, head and neck cancers
MDM2	Protein antagonist of p53 tumor suppressor protein	Sarcomas
Tumor suppressor genes		
Genes for proteins in the cytoplasm		
APC	Step in a signaling pathway	Colon and gastric cancer
NF-1	Codes for a protein that inhibits the stimulatory Ras protein	Neurofibroma, leukemia, and pheochromocytoma
NF-2	Codes for a protein that inhibits the stimulatory Ras protein	Meningioma, ependymoma, and schwannoma
Genes for proteins in the nucleus		
MTS1	Codes for p16 protein, a cyclin-dependent kinase inhibitor	Involved in a wide range of cancers
RB1	Codes for the pRB protein, a master brake of the cell cycle	Retinoblastoma, osteosarcoma, and bladder, small cell lung, prostate and breast cancers
p53	Codes for the p53 protein, which can halt cell division and induce apoptosis	Involved in a wide range of cancers
Genes for protein whose cellular location is unclear		
BRCA1	DNA repair, transcriptional regulation	Breast and ovarian cancers
BRCA2	DNA repair	Breast cancer
VHL	Regulator of protein stability	Renal cell cancer
MSH2, MLH1, PMS1, PMS2, MSH6	DNA mismatch repair enzymes	Hereditary nonpolyposis colorectal cancer

From DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: Table 124–2.

number of cell doublings. Telomeres are DNA segments at the ends of chromosomes that shorten with each replication to the point where senescence is triggered.

Principles of Tumor Growth

It takes about 10^9 cancer cells to be clinically detectable by palpation. Figure 85–2 demonstrates the classic Gompertzian kinetics tumor-growth cycle. From the diagram, one can see that malignant cell growth occurs many times before a mass may be palpated. The number of malignant cells may plummet drastically because of surgery or in decreasing steps by each administration of chemotherapy. One dosing round, or cycle, of chemotherapy does not eliminate all malignant cells, and therefore, repeated cycles of chemotherapy are administered to eliminate tumor cell burden.

Metastases

A **metastasis** is a growth of the same cancer found at some distance from the primary tumor site.[3] The metastasis may be large, or it may be just a few cells that may be detected through polymerase chain reaction (PCR); however, the presence of metastasis at staging usually is associated with a poorer prognosis than the patient with no known metastatic disease. As the technology to find malignant cells evolves, the dilemma exists on how to treat patients based on current guidelines that were not based on cellular detection technology.

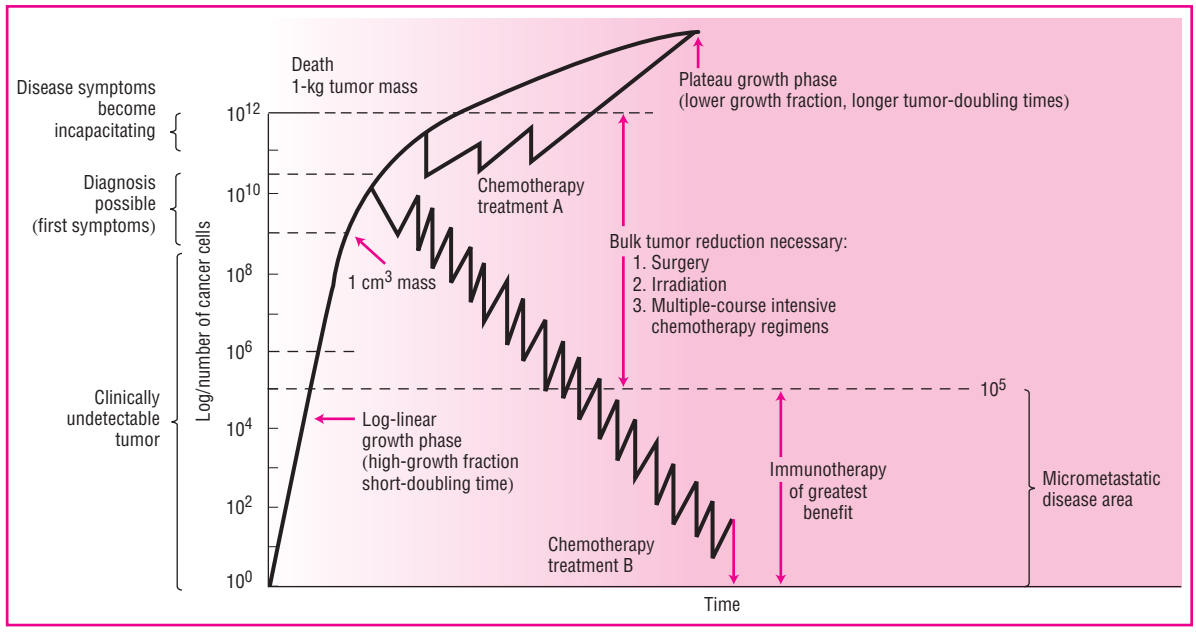

FIGURE 85–2. The Gompertzian growth curve demonstrating symptoms and treatments versus tumor volume. (From Buick RN. Cellular basis of chemotherapy. In: Dorr RT, Von Hoff DD, (eds.) Cancer Chemotherapy Handbook. 2nd ed. New York: Elsevier; 1994: 3–14.)

Cancers spread usually by two pathways: hematogenous (through the bloodstream) or through the lymphatics (drainage through adjacent lymph nodes). The malignant cells that split from the primary tumor find a suitable environment for growth. It is believed that malignant cells secrete mediators that stimulate the formation of blood vessels for growth and oxygen, the process of angiogenesis.

The usual metastatic sites for solid tumors are the brain, the bone, the lung, and the liver. It is important to realize and educate patients that breast cancer cells may metastasize to the brain, so the individual doesn't have brain and breast cancer but breast cancer metastases to the brain.

PATHOPHYSIOLOGY

Tumor Characteristics

Tumors are either benign or malignant.[4] Benign tumors often are encapsulated, localized, and indolent; they seldom metastasize; and they recur rarely once removed. Histologically, the cells resemble the cells from which they developed. Malignant tumors are invasive and spread to other locations, even if the primary tumor is removed. The cells no longer perform their usual functions, and their cellular architecture changes. *Anaplasia* is defined as the loss of structure and function.

Tumor Origin

Tumors may arise from epithelial, connective (i.e., muscle, bone, and cartilage), lymphoid, and nerve tissue. The suffix–*oma* is added to the name of the cell type if the tumor cells are benign. A *lipoma* is a benign growth that resembles fat tissue.

Precancerous cells have cellular changes that are abnormal but not yet malignant and may be described as *hyperplastic* or *dysplastic*. Hyperplasia occurs when a stimulus is introduced and reverses when the stimulus is removed. Dysplasia is an abnormal change in the size, shape, or organization of cells or tissues.

Malignant cells are divided into categories based on the cells of origin. Carcinomas arise from epithelial cells, whereas sarcomas arise from muscle or connective tissue. Adenocarcinomas arise from glandular tissue. *Carcinoma in situ* refers to cells limited to epithelial origin that have not yet invaded the basement membrane.

TREATMENT

Desired Outcome

While at the time of surgery the surgeon may be able to remove all macroscopic disease, microscopic cells may be present near the surgical site or may have traveled to other parts of the body. Thus, for chemotherapy-sensitive diseases, systemic therapies may be administered after surgery to destroy these microscopic malignant cells; this is called *adjuvant therapy*. The goals of **adjuvant** therapy are to decrease recurrence of the cancer and to prolong survival. Chemotherapy may be given prior to surgical resection of the tumor; this is referred to as *neoadjuvant therapy*. Chemotherapy given prior to surgery should decrease the tumor

Clinical Presentation and Diagnosis

Signs and Symptoms

The seven warning signs of cancer are:

- Change in bowel or bladder habits
- A sore that does not heal
- Unusual bleeding or discharge
- Thickening or lump in breast or elsewhere
- Indigestion or difficulty in swallowing
- Obvious change in wart or mole
- Nagging cough or hoarseness

The eight warning signs of cancer in children are:

- Continued, unexplained weight loss
- Headaches with vomiting in the morning
- Increased swelling or persistent pain in bones or joints
- Lump or mass in abdomen, neck, or elsewhere
- Development of a whitish appearance in the pupil of the eye
- Recurrent fevers not caused by infections
- Excessive bruising or bleeding
- Noticeable paleness or prolonged tiredness

Diagnostic Procedures

- Laboratory tests: Complete blood count, lactate dehydrogenase (LDH), renal function, and liver function tests
- Radiologic scans: x-rays, computed tomographic (CT) scans, magnetic resonance imaging (MRI), positron-emission tomography (PET)
- Biopsy of tissue or bone marrow with pathologic evaluation
- Cytogenetics
- Tumor markers
- Staging [determination of the primary tumor size, extent of lymph node involvement, and the presence or absence of metastases, or sometimes referred to the TNM system (Table 85–2)]. ❸ *Many tumors are staged according to the TNM system. Metastases are cancer cells that have spread to sites distant from the primary tumor site and have started to grow. The most frequently occurring sites of metastasis are the brain, bone, liver, and lungs.*
  From: DiPiro JT, Talbert RL, Yee GC, et al., (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: Tables 124–5, 124–6.

burden to be removed (which may result in a shorter surgical procedure) and make the surgery easier to perform because the tumor has shrunk away from vital organs or vessels.

Chemotherapy may be given to cure cancers that are curable, or it may be given to help control the symptoms of an incurable cancer, which is referred to as *palliative therapy*.

Response

The response to chemotherapy may be referred to as *complete response, partial response, stable disease*, or *disease progression*. A *cure* in oncology implies that the cancer is completely gone, and the patient will have the same life expectancy as a patient without cancer. A *complete response* (CR) refers to complete disappearance of all cancer for 1 month after treatment. A *partial response* (PR) is defined as a 50% decrease in tumor diameter along with no new disease for 1 month. The term *overall objective response rate* refers to the combination of PR and CR. *Stable disease* refers to tumor that has not grown and has shrunk by less than 25% of the diameter. *Disease progression* refers to tumor that has spread or the primary tumor has increased in size by 25%. Some cancers, such as leukemia, cannot be measured by size, so biopsy of the bone marrow provides a cellular indication of absence or presence of disease.

Cancer chemotherapy and the treatment of cancers are analogous to anti-infectives and the treatment of infections. Cancer cells may be *sensitive* to certain chemotherapy agents, but then with repeated exposure, the cells become *resistant* to treatment. The resistant cells then grow and multiply. While tumors may be tested for chemotherapy sensitivity, this area is still developing. Today, tumor sensitivity can demonstrate tumor resistance so that needless exposure to an inadequate therapy and its toxicity can be avoided.

Tumor cells may become resistant when genetic changes occur during cell proliferation. Resistant cancer cells with the *mdr-1* gene may possess a membrane-associated protein, p-glycoprotein, that facilitates efflux of chemotherapy agents out of the cells. Numerous attempts at blocking this efflux pump have been unsuccessful.

Nonpharmacologic Therapy

The four primary treatment modalities of cancer are surgery, radiation, chemotherapy, and biologic therapy. Surgery is useful to gain tissue for diagnosis of cancer and for treatment, especially those cancers with limited disease. Radiation plays a key role not only in the treatment and possible cure of cancer but also in palliative therapy. Together, surgery and radiation therapy may provide local control of symptoms of the disease. However, when cancer is widespread, surgery may play little or no role, whereas radiation therapy localized to specific areas may palliate symptoms.

Pharmacologic Therapy

Chemotherapy of cancer started in the early 1940s when nitrogen mustard was administered to patients with lymphoma. Since then, numerous agents have been developed for the treatment of different cancers.

Dosing of Chemotherapy

Many chemotherapy agents have significant organ toxicities that preclude using larger and larger doses to treat the cancer. The doses of chemotherapy must be spaced out to allow the patient to recover from the toxicity of the chemotherapy; each

TABLE 85–2. TNM Staging Classification System for Colorectal Cancer

Primary tumor (T)	
T_x	Primary tumor cannot be assessed
T_0	No evidence of primary tumor
T_{is}	Carcinoma in situ: intraepithelial or invasion of lamina propria
T_1	Tumor invades submucosa
T_2	Tumor invades muscularis propria
T_3	Tumor invades through the muscularis propria into the subserosa, or into nonperitonealized pericolic or perirectal tissues
T_4	Tumor perforates the visceral peritoneum, and/or directly invades other organs or structures
Regional lymph nodes (N)	
N_x	Regional lymph nodes cannot be assessed
N_0	No regional lymph node metastasis
N_1	Metastasis in one to three pericolic or perirectal lymph nodes
N_2	Metastasis in four or more pericolic or perirectal lymph nodes
Distant metastasis (M)	
M_x	Presence of distant metastasis cannot be assessed
M_0	No distant metastasis

period of chemotherapy dosing is referred to as a *cycle*. Each cycle of chemotherapy may have the same dosages, or the dosages may be modified based on toxicity, or a chemotherapy regimen may alternate from one set of drugs given during the first, third, and fifth cycles to another set of different drugs given during the second, fourth, and sixth cycles. *Dose density* of chemotherapy refers to shortening of the period between doses of chemotherapy. This can accomplish two things: First, the tumor has less time between doses of chemotherapy to grow, and second, patients receive chemotherapy over a shorter period of time and hopefully can get back to a normal life sooner. Usually dose-dense chemotherapy regimens require colony-stimulating factors to be administered to shorten the time period of neutropenia. The chemotherapy regimens that are dose-dense tend to be adjuvant regimens, where the tumor burden is not measurable, and the cancer outcome is a cure. When a chemotherapy regimen is used as palliative therapy (to control symptoms), the dosages of chemotherapy should be decreased based on toxicity, or the interval between dosages should be lengthened to maintain quality of life.

Patient and tumor biology also affect how cancer therapy is dosed. Patients with a uridine diphosphate–glucuronosyltransferease 1A1 enzyme deficiency can have life-threatening diarrhea and complications from irinotecan. The patient may have a blood test prior to therapy to determine if there is a genetic problem prior to receiving irinotecan. In the case of the some of the monoclonal antibodies, flow cytometry results will reveal whether the tumor has the receptor where the drug will bind and exert the pharmacologic effect.

Another consideration of chemotherapy administration is the patient. Factors that affect chemotherapy selection and dosing are age, concurrent disease states, and performance status. Performance status can be assessed through either the Eastern Cooperative Oncology Group Scale or the Karnofsky Scale (Table 85–3). The patient is evaluated on whether he or she is active to bedridden most of the day; performance status is a very important prognostic factor for many types of cancer. If a patient has kidney dysfunction, and the chemotherapy is eliminated primarily by the kidney, dosing adjustments will need to be made. If a patient has had a myocardial infarction recently, the clinician will weigh the risks of anthracycline therapy against the benefit of the treatment of the cancer.

Another important consideration for treatment of cancers is reimbursement by third-party payors for off-label use of chemotherapy agents because of the high expense. The American Association of Cancer Centers (www.accc-cancer.org) provides

TABLE 85–3. Performance Status Scales

Description: Karnofsky Scale	Karnofsky Scale (%)	Zubrod Scale (ECOG)	Description: ECOG Scale
No complaints; no evidence of disease	100	0	Fully active, able to carry on all predisease activity
Able to carry on normal activity; minor signs or symptoms of disease	90		
Normal activity with effort, some signs or symptoms of disease	80	1	Restricted in strenuous activity, but ambulatory and able to carry out work of a light or sedentary nature
Cares for self; unable to carry on normal activity or to do active work	70		
Requires occasional assistance but is able to care for most personal needs	60	2	Out of bed more than 50% of time; ambulatory and capable of self-care, but unable to carry out any work activities
Requires considerable assistance and frequent medical care	50		
Disabled; requires special care and assistance	40	3	In bed more than 50% of time; capable of only limited self-care
Severely disabled; hospitalization indicated, although death not imminent	30		
Very sick; hospitalization necessary; requires active supportive treatment	20	4	Bedridden; cannot carry out any self-care; completely disabled
Moribund; fatal processes progressing rapidly	10		
Dead	0		

ECOG, Eastern Cooperative Oncology Group.

a drug compendium quarterly to which clinicians may refer to verify coverage by Medicare based on ICD-9 codes. The drugs used according to Food and Drug Administration (FDA)–approved indications are almost always reimbursed. If sufficient literature exists, an insurer may pay for an off-label use.

Combination Chemotherapy

Again, the analogy to antibiotic therapy can be made when deciding on monotherapy versus combination therapy for the treatment of cancer. The underlying principles of using combination therapy are to use (1) agents with different pharmacologic actions, (2) drugs with different organ toxicities, (3) agents that are active against the tumor and ideally synergistic when used together, and (4) agents that do not result in significant drug interactions (although these can be studied carefully and the interactions addressed). When two or more agents are used together, the development of resistance may be slowed, but increased toxicity may result. ❹ *Each category of chemotherapy drugs has similar side effects. Anthracyclines cause cardiac toxicity, which is related to the cumulative dose. Tubulin interactive agents are associated with neuropathy and ileus. Alkylating agents are associated with secondary malignancies.*

Currently, anticancer agents are categorized by the mechanism of action. As depicted in Fig. 85–3, different agents work in different parts of the cell.

Antimetabolites

Fluorouracil

5-Fluorouracil, commonly referred to as 5-FU, is an analog of the pyrimidine uracil. It is metabolized by dihydropyrimidine dehydrogenase. 5-FU ultimately is metabolized to fluorodeoxyuridine monophosphate (FdUMP), which interferes with the function of thymidylate synthase, which is required for synthesis of thymidine. The triphosphate metabolite of 5-FU is incorporated into RNA to produce the second cytotoxic effect of 5-FU. It appears that inhibition of thymidylate synthesis occurs with the continuous infusion regimens, whereas the triphosphate form is associated with bolus administration. Patients with low activity of dihydropyrimidine dehydrogenase appear to be at risk for life-threatening toxicities.[5] Folates appear to increase the stability of the FdUMP thymidylate synthase inhibition, which enhances the activity of the drug in certain cancers. 5-FU has shown to be useful in the treatment of cancers of the colon, rectum, gastric, head and neck, and breast. 5-FU is metabolized extensively by the liver, whereas up to 15% of a dose may be found unchanged in the urine. The clearance of 5-FU ranges from 155 L/m^2 per hour (range 56–466 L/m^2 per hour) in women to 179 L/m^2 per hour (range 29–739 L/m^2 per hour) in men. Age does not appear to alter the pharmacokinetics of 5-FU. Fluorouracil has shown clinical activity in the treatment of colorectal, breast, esophageal, pancreas, stomach, anal, and

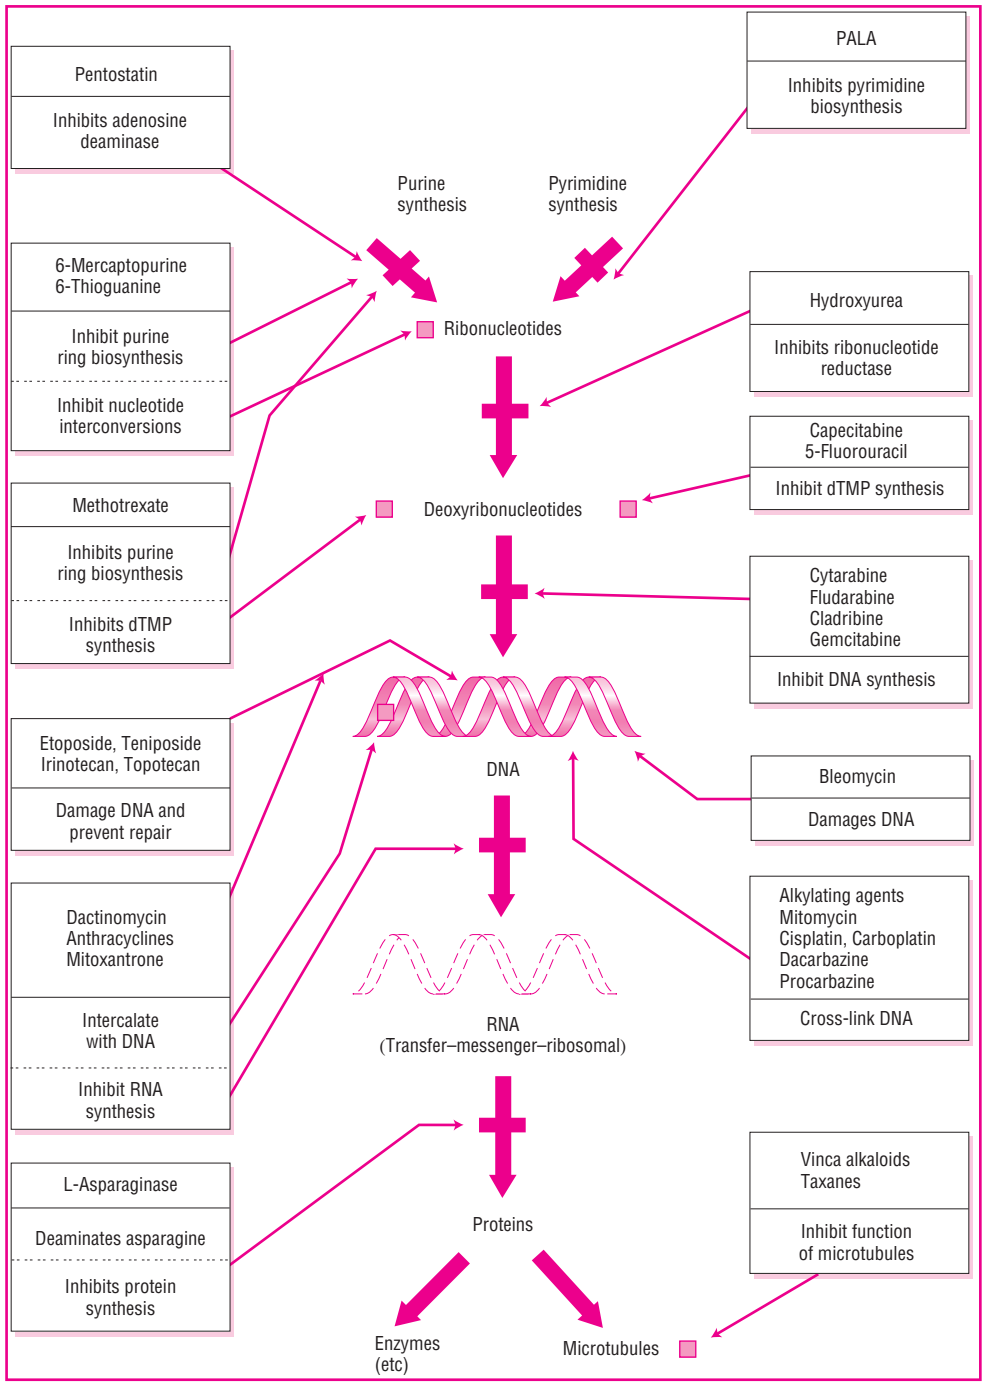

FIGURE 85–3. The mechanisms of action of antineoplastic agents. (From Chabner BA, Ryan DP, Paz-Ares L, et al. Antineoplastic agents. In: Hardman JG, Limbird LE, Gilman AG, (eds.) Goodman & Gilman's The Pharmacologic Basis of Therapeutics. 10th ed. New York: McGraw-Hill; 2001: 1381.)

head and neck cancers. Side effects of 5-FU include stomatitis, diarrhea, cardiac abnormalities, and rarely reported cerebellar toxicities. Esophagitis and gastric ulcerations also may occur. Some alopecia may occur, but hair regrowth may occur with subsequent doses. A recent study demonstrated that if the patient uses ice chips in the mouth for 30 minutes while receiving bolus 5-FU, **mucositis** may be decreased significantly. Neurotoxicity may consist of headaches, visual disturbances and cerebellar ataxia. Cardiac toxicity may consist of ST-segment elevation, which appears to be more common in patients with a prior history of coronary artery disease.

Capecitabine

Capecitabine is the prodrug of 5-FU and comes as oral tablets that are administered with food twice a day. Capecitabine has shown to be active in tumors of the colon, rectum, and breast. The toxicity profile of capecitabine is similar to that of 5-FU and includes diarrhea, mucositis, palmar-plantar erythrodysesthesia,

nausea, and **myelosuppression.** *Palmar-plantar erythrodyesthesia* refers to redness, itching, and blistering of the palms of the hands and soles of the feet. Patients should be educated to notify the prescriber when palmar-plantar erythrodyesthesia occurs. Significant increases in international normalization ratio (INR) and prothrombin time may occur within several days when capecitabine is started in patients who are on warfarin, and the INR should be monitored closely, or the patient may be switched to a low-molecular-weight heparin. Phenytoin levels may become elevated owing to possible CYP2C9 inhibition by capecitabine. Patients should be instructed to take capecitabine within 30 minutes of a meal.

Cytarabine

Cytarabine, often referred to as *Ara-C*, is an analog of cytosine and is phosphorylated intracellularly to the active triphosphate form, which inhibits DNA polymerase. The triphosphate form also may be incorporated into DNA to result in chain termination to prevent DNA elongation. The drug may be administered as a low-dose continuous infusion, high-dose intermittent infusion, and into the subdural space via intrathecal or intraventricular adminstration. There is also a liposomal formulation available for less frequent administration into the CNS. Cytarabine pharmacokinetics are best described by a two-compartment model, with an α half-life of 15 minutes and a β half-life of 2 hours. Cytarabine is eliminated by the kidney with a renal clearance of 90 mL/minute. Cytarabine has shown efficacy in the treatment of acute leukemias and some lymphomas. The toxicities of cytarabine include myelosuppression, cerebellar syndrome (i.e., nystagmus, dysarthria, and ataxia), and eye irritation with high doses that requires around-the-clock steroid eye drop administration. The risk of CNS toxicity is increased with the high-dose cytarabine regimen with renal dysfunction.

Gemcitabine

Gemcitabine is a deoxycytidine analog that is structurally related to cytarabine. Gemcitabine inhibits DNA polymerase activity and ribonucleotide reductase to result in DNA chain elongation. The pharmacokinetics of gemcitabine are best described by a two-compartment model, with a terminal half-life of 6 to 20 minutes. Approximately 5% of the dose is excreted unchanged by the kidney.[6] Gemcitabine has shown activity in cancers of the pancreas, breast, lung, ovary, and lung (non-small cell), along with some lymphomas. The toxicities include myelosuppression, flulike syndrome with fevers during the first 24 hours after administration, rash that appears 48 to 72 hours after administration, and hemolytic-uremic syndrome. While hemolytic-uremic syndrome is uncommon, it is a life-threatening side effect. Patients should be counseled about using acetaminophen to treat the fevers during the first 24 hours; however, fevers occurring 7 to 10 days after gemcitabine are likely to be febrile neutropenias and need prompt treatment with broad-spectrum antibiotics.

Azacitidine

Azacitidine, a cytidine analog, causes hypomethylation of DNA, which normalizes the function of genes that control cell differentiation to promote normal cell maturation. The suspension is administered as a subcutaneous injection daily for 7 days for the treatment of myelodysplastic syndrome, a preleukemia disease. The pharmacokinetics of azacitidine are best described by a two-compartment model, with a terminal half life of 3.4 to 6.2 hours, whereas peak concentrations are achieved 30 minutes after a subcutaneous injection.[7] Azacitidine has been shown to be clinically active in the treatment of myelodysplastic syndromes. The side effects include myelosuppression, renal tubular acidosis, renal dysfunction, and injection-site reactions.

Purines and Purine Antimetabolites

6-Mercaptopurine

6-Mercaptopurine (6-MP) is an oral purine analog that is converted to a ribonucleotide to inhibit purine synthesis. Mercaptopurine is converted into thiopurine nucleotides, which are catabolized by thiopurine *S*-methyltransferase (TPMT), which is subject to genetic polymorphisms and may cause severe myelosuppression. TPMT status may be assessed prior to therapy to reduce drug-induced morbidity and the costs of hospitalizations for neutropenic events. Mercaptopurine is poorly absorbed, with a time to peak concentration of 1 to 2 hours after an oral dose. The half-life is 21 minutes in pediatric patients and 47 minutes in adults. Mercaptopurine is used in the treatment of acute lymphocytic leukemia and chronic myelogenous leukemia. Significant side effects include myelosuppression, mild nausea, skin rash, and cholestasis. When allopurinol is used in combination with 6-MP, the dose of 6-MP must be reduced by 66% to 75% of the usual dose because allopurinol blocks the metabolism of 6-MP.

6-Thiogaunine

6-thioguanine (6-TG) is another oral purine analog that works similarly to 6-MP, and because of this, cross-resistance is observed. While little is known about the pharmacokinetics of thioguanine, it appears that absorption is incomplete and approximates 30% of the dose. Thioguanine may be used in the treatment of acute and chronic myelogneous leukemia. Side effects include myelosuppression, mild nausea, cholestasis, and rarely, veno-occlusive disease.

Fludarabine

Fludarabine is an analog of the purine adenine. It interferes with DNA polymerase to cause chain termination and inhibits transcription by its incorporation into RNA. Fludarabine is dephosphorylated rapidly and converted to 2-fluoro-Ara-AMP (2-FLAA), which enters the cells and is phosphorylated to 2-fluoro-Ara-ATP, which is cytotoxic. Fludarabine is converted rapidly to 2-FLAA. The pharmacokinetics of 2-FLAA

are best described by a two-compartment model, with an α half-life of 0.6 hours and a terminal half-life of 9.3 hours.[8] Fludarabine is used in the treatment of chronic lymphocytic leukemia, some lymphomas, and refractory acute myelogenous leukemia. This drug is given intravenously usually daily for 5 days every 4 weeks. Significant myelosuppression may occur, along with immunosuppression, so patients are susceptible to opportunistic infections. Mild nausea and vomiting and diarrhea have been observed. Rarely, interstitial pneumonitis has occurred.

Cladribine

Cladribine (2-chlorodeoxyadenosine, or 2-CDA) is a purine nucleoside that once it is in the triphosphate form is incorporated into DNA, which results in inhibition of DNA synthesis and chain termination. The pharmacokinetics of cladribine are best described by a two-compartment model, with an α half-life of 35 minutes and a terminal half-life of 6.7 hours.[9] It may be administered as a continuous 7-day intravenous infusion or as a 2-hour infusion daily for 5 days; both regimens deliver the same total dose of drug. Cladribine is used to treat hairy cell leukemia and, therefore, is myelosuppressive. Unfortunately, one of the other side effects of the drug is fever, so the clinician struggles with the dilemma of whether the fever is due to the drug or an infection. Rash occurs in approximately 50% of patients with hairy cell leukemia. Cladribine also may be used to treat chronic lymphocytic leukemia, refractory low-grade non-Hodgkin's lymphoma, and Waldenström's macroglobulinemia.

Antifolates

Folates carry one-carbon groups in transfer reactions required for purine and thymidylic acid synthesis. Dihydrofolate reductase is the enzyme responsible for supplying reduced folates intracellularly for thymidylate and purine synthesis.

Methotrexate

Methotrexate inhibits dihydrofolate reductase of both malignant and nonmalignant cells. When high doses of methotrexate are given, leucovorin, a reduced folate, is administered to bypass the methotrexate inhibition of dihydrofolate reductase of normal cells and is usually initiated 24 hours after methotrexate administration. For safety purposes, the term *folinic acid*, another term used for leucovorin, should not be used because of medication errors where folic acid was given instead. Methotrexate concentrations should be monitored to determine when to stop leucovorin administration. Generally, leucovorin administration may be stopped when methotrexate concentrations decrease to 5×10^{-8} M, although this may vary by the chemotherapy regimen. High dosages of methotrexate may cause methotrexate to crystallize out in the kidney, which may result in renal dysfunction and decreased methotrexate clearance. Intravenous hydration with sodium bicarbonate to maintain urinary pH greater than or equal to 7 helps to prevent methotrexate-induced renal dysfunction. The pharmacokinetics of methotrexate are best described by either a two- or three-compartment model. The α half-life is less than 1 hour, whereas the β half-life is 3 to 4 hours, and the γ half-life is 8 to 10 hours or longer with impaired kidney function. Approximately 60% to 100% of methotrexate is eliminated primarily as unchanged drug by the kidney. Since methotrexate is eliminated by tubular secretion, concomitant drugs that may inhibit or compete for tubular secretion should be avoided. Methotrexate doses must be adjusted for renal dysfunction. A recommended dosing adjustment is to divide the creatinine clearance of the patient by 70 mL/minute, which is the average creatinine clearance of patients who received methotrexate during clinical trials, and then to multiple this fraction by the dosage recommended for that disease state. Again, close monitoring of methotrexate concentrations in patients with renal impairment is advised. Methotrexate has shown activity in lymphoma, gastric, esophageal, bladder, and breast cancer and acute lymphocytic leukemia. Side effects of methotrexate include myelosuppression, nausea and vomiting, and mucositis. Methotrexate also may be administered via the intrathecal route at very low doses. Since methotrexate may be administered in doses as small as 12 mg intrathecally to 20 g intraveneously, it is crucial for the clinician to know the correct dose by the correct route in order to avoid substantial toxicity. Methotrexate also is administered as an intrathecal injection into the cerebrospinal fluid or directly into the ventricle via an Ommaya reservoir. The methotrexate used for intrathecal and intraventricular injection must be preservative-free. Drugs that may block the tubular secretion of methotrexate include probenecid, salicylates, penicillin G, and ketoprofen.

Pemetrexed

Pemetrexed inhibits at least three pathways in thymidine and purine synthesis. Pemetrexed is excreted primarly as unchanged drug by the kidney, with 70% to 90% of a dose recovered in 24 hours as unchanged drug in the urine. Patients with normal kidney function have a half-life of 3.5 hours.[10] Pemetrexed has shown activity in the treatment of mesothelioma and non–small cell lung cancer. Side effects include myelosuppression, rash, diarrhea, and nausea and vomiting. Patients should receive folic acid and cyanocobalamin to reduce bone marrow toxicity and diarrhea. Doses of folic acid of at least 400 mcg/day starting 5 days before treatment and continuing throughout therapy, as well as for 21 days after the last pemetrexed dose, have been used. Cyanocobalamin 1000 mcg intramuscularly is given the week prior to pemetrexed and then every three cycles thereafter. Dexamethasone 4 mg twice daily the day before, the day of, and the day after pemetrexed administration helps to decrease the incidence and severity of rash.

Tubulin Active Agents

The periwinkle, or vinca plant, served as a source for the drugs vincristine and vinblastine, which are commonly referred to as the *vinca alkaloids*. The vinca alkaloids inhibit the assembly

of microtubules, which interferes in the formation of the mitotic spindle. Care must be taken not to confuse the names and doses of vincristine and vinblastine.

Vincristine

Vincristine causes mitotic inhibition to arrest cells in metaphase. The pharmacokinetics of vincristine have been described by a three-compartment model, with an α half-life of 0.8 minutes, a β half-life of 7 minutes, and a γ half-life of 164 minutes.[11] Biliary excretion accounts for a significant portion of elimination of vincristine and its metabolites, so doses need to be adjusted for obstructive liver disease. Vincristine has been useful in the treatment of sarcomas, Wilms' tumor, many kinds of lymphoma, multiple myeloma, and acute lymphocytic leukemia. Vincristine is a **vesicant** that may cause significant neuropathy. Patients should be counseled regarding prevention of constipation and ileus caused by vincristine. Many clinicians cap intravenous vincristine doses at 2 mg to prevent severe neuropathic side effects. Several patients have died as a result of vincristine being administered intrathecally; it should only be administered intravenously, and appropriate labeling should be placed on all doses. Itraconazole has been reported to cause severe neurotoxicity when administered to patients receiving vincristine. Patients have been reported to experience paralytic ileus, neurogenic bladder, absence of deep reflexes, and severe paralysis of the lower extremeties within 10 days of starting itraconazole. Clinicians need to be aware of the potential interactions of the newer azoles with vincristine.

Vinblastine

Vinblastine is another vesicant vinca alkaloid that causes myelosuppression and less neurotoxicity than vincristine. The pharmacokinetics of vinblastine are best described by a three-compartment model, with an α half-life of 25 minutes, a β half-life of 53 minutes, and a terminal half-life of 19 to 25 hours.[12] Vinblastine has shown activity in the treatment of bladder, breast, and kidney cancer, as well as some lymphomas. The doses of vinblastine tend to be higher on a milligram per meter squared basis than vincristine. Nausea and vomiting are minimal with vinblastine. Other side effects include mild alopecia, rash, photosensitivity, and stomatitis.

Vinorelbine

The vesicant vinorelbine is structurally similar to vincristine and may cause many of the same side effects as vincristine. While this vesicant is administered intravenously over 6 to 10 minutes, patients should be counseled about neuropathy, ileus, and myelosuppression. The pharmacokinetics of vinorelbine are best described by a three-compartment model, with an α half-life of 2 to 6 minutes, a β half-life of 1.9 hours, and a γ half-life of 40 hours. Vinorelbine has shown efficacy in the treatment of breast cancer and non–small cell lung cancer. Additional side effects include myelosuppression, paresthesias, and mild nausea and vomiting.

Paclitaxel

Paclitaxel, a taxane, binds to tubulin to promote microtubule assembly and to prevent microtubule disassembly. The pharmacokinetics of paclitaxel can be described by a two-compartment model, with an α half-life of 30 to 45 minutes and a β half-life of 4 to 8 hours. Hepatic metabolism and biliary excretion account for the majority of paclitaxel's elimination. Paclitaxel has demonstrated activity in ovarian, breast, non–small cell lung, prostate, esophageal, gastric, and head and neck cancers. Considerable variability exists in paclitaxel dosing, from weekly 1-hour infusions to 24-hour infusions administered every 3 weeks. The diluent for paclitaxel, Cremophor EL, is composed of ethanol and castor oil. Infusions must be prepared and administered in non-PVC-containing bags and tubings, and solutions must be filtered. Patients receive dexamethasone, diphenhydramine, and an H_2 blocker to prevent hypersensitivity reactions from paclitaxel/Cremophor EL. Patients also may have asymptomatic bradycardia (i.e., heart rates around 45 beats per minute) during the infusion. Approximately 3 to 5 days after administration, patients may complain of myalgias and arthralgias that may last several days. Myelosuppression, flushing, neuropathy, ileus, and total-body alopecia are other common side effects. Since paclitaxel is a substrate for CYP 3A4, steady-state concentrations of paclitaxel were 30% lower in patients receiving phenytoin than in patients not receiving phenytoin. Paclitaxel clearance was decreased by 33% when it was administered following cisplatin, so paclitaxel is administered before cisplatin.

Recently, a nanoparticle albumin-bound paclitaxel product became available commercially for the treatment of metastatic breast cancer. This product does not have the serious allergic reactions encountered with paclitaxel in Cremophor EL, so premedication with H_1 and H_2 blockers and steroids is not necessary. The dose is infused over 30 minutes and does not require a special IV bag, tubing, or filter. The dosing of this product is different from that of the original paclitaxel, so practitioners need to be aware of which product is being prescribed. The pharmacokinetics of the albumin-bound paclitaxel display a higher clearance and larger volume of distribution than paclitaxel. The drug is eliminated primarily via fecal excretion.[13] The side effects of bone marrow suppression, neuropathy, ileus, arthralgias, and myalgias still occur.

Docetaxel

Docetaxel, another taxane, binds to tubulin to promote microtubule assembly. The pharmacokinetics of docetaxel are best described by a three-compartment model, with an α half-life of 0.08 hours, a β half-life of 1.6 to 1.8 hours, and a terminal half-life of 65 to 73 hours.[14] Docetaxel has activity in the treatment of breast, non–small cell lung, prostate, bladder, esophageal, stomach, ovary, and head and neck cancers. Dexamethasone, 8 mg twice daily for 3 days starting the day before treatment, is used to prevent the fluid retention syndrome associated with docetaxel and possible hypersensitivity reactions. The fluid

retention syndrome is characterized by edema and weight gain that is unresponsive to diuretic therapy and is associated with cumulative doses greater than 800 mg/m^2. Myelosuppression, alopecia, and neuropathy are other side effects associated with docetaxel treatment.

Estramustine

Estramustine, an oral drug, also inhibits microtubule assembly and has weak estrogenic activity at the estradiol hormone receptors of the cell. Approximately 75% of a dose of estramustine is absorbed.[15] The terminal half-life ranges between 20 to 24 hours, with nonrenal excretion as the major route of elimination. This drug is used primarily for the treatment of prostate cancer, but its use is limited by the side effects, which include nausea and vomiting, diarrhea, thromboembolic events, and gynecomastia.

Topoisomerase Inhibitors

Topoisomerase is responsible for relieving the pressure on the DNA structure during unwinding by producing strand breaks. Topoisomerase I produces single-strand breaks, whereas topoisomerase II produces double-strand breaks.

Etoposide

Etoposide causes multiple DNA double-strand breaks by inhibiting topoisomerase II. The pharmacokinetics of etoposide are described by a two-compartment model, with an α half-life of 0.5 to 1 hour and a β half-life of 3.4 to 8.3 hours. Approximately 30% of the dose is excreted unchanged by the kidney.[16] Etoposide has shown activity in the treatment of several types of lymphoma, testicular and lung cancer, retinoblastoma, and carcinoma of unknown primary. The intravenous preparation has limited stability, so final concentrations should be 0.4 mg/mL. Intravenous administration needs to be slow to prevent hypotension. Oral bioavailability is approximately 50%, so oral dosages are approximate two times those of intravenous doses; however, relatively low oral daily dosages are used for 1 to 2 weeks. Side effects include mucositis, myelosuppression, alopecia, phlebitis, hypersensitivity reactions, and secondary leukemias.

Teniposide

Teniposide, a topoisomerase II inhibitor, is administered as an infusion over 30 to 60 minutes to prevent hypotension. The pharmacokinetics are described by a three-compartment model, with an α half-life of 0.75 hours, a β half-life of 4 hours, and a terminal half-life of 20 hours. Considerable variability in clearance of teniposide in children has been reported.[17] Teniposide has shown activity in the treatment of acute lymphocytic leukemia, neuroblastoma, and non-Hodgkin's lymphoma. Side effects include myelosuppression, nausea, vomiting, mucositis, and venous irritation. Hypersensitivity reactions may be life-threatening.

Irinotecan

Irinotecan, a camptothecin analog, inhibits topoisomerase I to interfere with DNA synthesis through the active metabolite SN38, which is 100-fold more potent in vitro. The pharmacokinetics of irinotecan are best described by a three-compartment model, with an α half-life of 0.07 hours, a β half-life of 2.2 hours, and a terminal half-life of about 18 hours.[18] Irinotecan has shown activity in the treatment of cancers of the colon, rectum, cervix, and lung. Diarrhea owing to irinotecan may be life-threatening. Intravenous atropine should be used to treat diarrhea that occurs during the first 24 hours of administration. Loperamide 2 mg every 2 hours or 4 mg every 4 hours until diarrhea has stopped for 12 hours should be used for diarrhea occurring more than 24 hours after administration. Other side effects include myelosuppression, fatigue, and alopecia. Individuals homozygous for *UGT1A1*28* have an increased risk of febrile neutropenia and diarrhea and should be considered for an upfront dose reduction of one level; and heterozygotes should receive closer monitoring.

Topotecan

Topotecan inhibits topoisomerase I to cause single-strand breaks in DNA. The pharmacokinetics of topotecan can be described by a two-compartment model, with a terminal half-life of 80 to 180 minutes, with renal clearance accounting for approximately 70% of the clearance.[19] Topotecan has shown clinical activity in the treatment of ovarian and lung cancer, myelodysplastic syndromes, and acute myelogenous leukemia. The intravenous infusion may be daily for 5 days or once weekly. Side effects include myelosuppression, mucositis, and diarrhea.

Anthracyclines

All the anthracyclines contain a four-membered anthracene ring, a chromophore, with an attached sugar portion. Free radicals formed from the anthracyclines combine with oxygen to form superoxide, which can make hydrogen peroxide. Oxygen free-radical formation is a cause of cardiac damage and extravasation injury, which is common to these drugs. Daunorubicin, doxorubicin, epirubicin, and idarubucin cause cardiac toxicity, as manifested by a congestive heart failure/cardiomyopathy symptomotology, mucositis, myelosuppression, and tissue damage with extravasation.

Daunorubicin

Daunorubicin is an anthracycline that is sometimes referred to as an antitumor antibiotic. Daunorubicin inserts between base pairs of DNA to cause structural changes in DNA; however, the primary mechanism of cytotoxicity is the inhibition of topoisomerase II. The pharmacokinetics are best described by a two-compartment model, with a terminal half-life of about 20 hours. The predominant route of elimination of daunorubicin and hydroxylated metabolites is hepatobiliary

secretion. Daunorubicin has shown clinical activity in the treatment of acute lymphocytic leukemia, non-Hodgkin's lymphoma, neuroblastoma, and Ewing's and Kaposi's sarcoma. Myelosuppression is the major toxicity, along with alopecia, stomatitis, and mild to moderate nausea and vomiting, and it imparts a red to color to the urine so that patients need to be educated on side effects. Cardiac toxicity is manifested as congestive heart failure. The maximum cumulative dose in children older than 2 years of age is 300 mg/m^2, and the cumulative dose is 400 to 600 mg/m^2 in adults. Ventricular ejection fractions should be measured before therapy, and periodically if therapy is continued. Therapy should be halted if there is a 10% to 20% decrease from baseline in ejection fraction. Daunorubicin is a vesicant also.

Doxorubicin

The addition of a hydroxyl group to daunorubicin, resulted in the drug hydroxydaunorubicin (the H in CHOP therapy), or doxorubicin, which inhibits topoisomerase II. The pharmacokinetics of doxorubicin may be described by either a two- or three-compartment model, with a terminal half-life of 30 to 40 hours. Doxorubicin is metabolized extensively, and doxorubicinol, a major metabolite, is also a cardiotoxin. Biliary excretion accounts for about 40% of a dose; patients with cholestasis experience greater toxicity from standard doses. Doxorubicin has shown clinical activity in breast, esophageal, bladder, lung, ovarian, and head and neck cancers, along with lymphomas and multiple myeloma. This red drug causes a red-orange discoloration of the urine. Cumulative doses greater than 550 mg/m^2 are associated with cardiomyopathy. Doxorubicin is a vesicant and may cause significant pain when administered into the peritoneal cavity. Other side effects include myelosuppression, alopecia, mucositis, and nausea and vomiting.

Doxorubicin, Liposomal

Liposomal doxorubicin is an irritant, not a vesicant, and is dosed differently from doxorubicin, so clinicians need to be very careful when prescribing these two drugs. The pharmacokinetics of liposomal doxorubicin are best described by a two-compartment model, with a terminal half-life of 30 to 90 hours.[20] Liposomal doxorubicin has shown significant activity in the treatment of breast and ovarian cancer, along with multiple myeloma and Kaposi's sarcoma. Side effects include mucositis, myelosuppression, alopecia, and palmar-plantar erythrodysesthesia. The liposomal doxorubicin may be less cardiotoxic than doxorubicin.

Epirubicin

Epirubicin inhibits both DNA and RNA polymerases and thus inhibits nucleic acid synthesis and topoisomerase II enzymes. Epirubicin pharmacokinetics are best described by a three-compartment model, with an α half-life of 4 to 5 minutes, a β half-life of 2.4 hours, and a terminal half-life of 30 hours. Dosage alterations should be made in the presence of cholestasis because approximately 35% of a dose undergoes biliary excretion.[21] Epirubicin has shown clinical activity in the treatment of breast, esophageal, lung, ovary, and stomach cancers. Epirubicin also has been used in the treatment of lymphomas and soft tissue sarcomas. Cumulative doses of epirubicin greater than 900 mg/m^2 are associated with cardiomyopathy, so this drug may be less cardiotoxic on a milligram per milligram basis than doxorubicin. This topoisomerase II inhibitor may cause red-orange urine, myelosuppression, alopecia, and significant nausea and vomiting.

Idarubicin

Idarubicin inhibits both DNA and RNA polymerase, as well as topoisomerase II. The pharmacokinetics of idarubicin can best be described by a three-compartment model, with an α half-life of 13 minutes, a β half-life of 2.4 hours, and a terminal half-life of 16 hours.[22] Idarubicin is metabolized to an active metabolite, idarubicinol, which has a half-life of 41 to 69 hours. Idarubicin and idarubicinol are eliminated by the liver and through the bile. Idarubicin has shown clinical activity in the treatment of acute leukemias, chronic myelogenous leukemia, and myelodysplastic syndromes. Idarubicin causes cardiomyopathy at cumulative doses of greater than 150 mg/m^2 and produces cumulative cardiotoxic effects with other anthracyclines. Idarubicin is a vesicant and causes red-orange urine, mucositis, mild to moderate nausea and vomiting, and bone marrow suppression.

Mitoxantrone

This royal-blue-colored drug is an anthracenedione that inhibits DNA topoisomerase II. The pharmacokinetics of mitoxantrone may best be described by a three-compartment model, with an α half-life of 3 to 10 minutes, a β half life of 0.3 to 3 hours, and a median terminal half-life of 12 days. Biliary elimination appears to be the primary route of elimination, with less than 10% of the drug eliminated by the kidney.[23] Mitoxantrone has shown clinical activity in the treatment of acute leukemias, breast and prostate cancer, and non-Hodgkin's lymphomas. Myelosuppression, mucositis, nausea and vomiting, and cardiac toxicity are side effects of this drug. The total cumulative dose limit is 160 mg/m^2 for patients who have not received prior anthracycline or mediastinal radiation. Patients who have received prior doxorubicin or daunorubicin therapy should not receive a cumulative dose greater than 120 mg/m^2 of mitoxantrone. Patients should be counseled that their urine will turn a blue-green color.

Alkylating Agents

The alkylating drugs are the oldest category of chemotherapy agents. Globally, cytoxocity results from inhibition of DNA replication because interlinked strands do not separate.

Busulfan

Busulfan is an alkylating agent that forms DNA-DNA and DNA-protein cross-links to inhibit DNA replication. Oral busulfan is well absorbed, has a terminal half-life of 2 to 2.5 hours, and is eliminated primarily by metabolism. Busulfan has shown significant clinical activity in the treatment of acute myelogneous leukemia and chronic myelocytic leukemia. Side effects include bone marrow suppression, hyperpigmentation of skin creases, and rarely, pulmonary fibrosis. High doses used for bone marrow transplant preparatory regimens result in severe nausea and vomiting, tonic-clonic seizures, and sinusoidal obstruction syndrome (formerly known as *veno-occlusive disease*). Patients receiving high-dose busulfan should receive anticonvulsant prophylaxis.

Cyclophosphamide

Cyclophosphamide prevents cell division by cross-linking DNA strands. Cyclophophosphamide is activated to phosphoramide mustard and acrolein. Acrolein, which has no tumor activity, causes hemorrhagic cystitis of the bladder. The pharmacokinetics of cyclophosphamide are best described by a two-compartment model, with a terminal half-life that ranges from 4 to 10 hours. Approximately 15% of the dose is excreted unchanged by the kidney. Cyclophosphamide has shown clinical activity in numerous types of cancer, ranging from leukemias to lymphomas to breast and ovarian cancer. Whether the drug is administered orally or intravenously, patients need to be counseled on the importance of good hydration and frequent voiding to prevent hemorrhagic cystitis. Nausea and vomiting may occur 12 hours after administration, so patients need to have antiemetics available after the acute treatment period. Other side effects include myelosuppression, alopecia, SIADH (usually with doses greater than 50 mg/kg), secondary malignancies (e.g., bladder cancers and acute leukemias), and infertility issues.

Ifosfamide

Hemorrhagic cystitis is such a predominant side effect of the alkylator ifosfamide that mesna always must be given with ifosfamide, along with hydration. Dosing regimens of mesna range from an equal milligram dose to the ifosfamide mixed in the same intravenous bag to 20% of the dose prior to ifosfamide and 20% of the dose repeated at 4 and 8 hours after the dose. The pharmacokinetics of ifosfamide are best described by a one-compartment model, with a terminal half-life of 7 to 15 hours. Approximately 50% of a dose is excreted unchanged by the kidney. Ifosfamide has shown clinical activity in the treatment of acute lymphocytic leukemia, lymphomas, and breast, ovary, lung, and head and neck cancers. CNS side effects of confusion, delirium, and somnolence are associated with high doses infused quickly.

Carmustine

Carmustine, a nitrosurea, cross-links DNA strands to inhibit DNA replication. Carmustine, which is reconstituted with ethanol, crosses the blood-brain barrier when given intravenously. It also comes as a wafer formulation that may be implanted surgically for brain tumors. The pharmacokinetics are best described by a two-compartment model, with an α half-life of 6 minutes and a terminal half-life of 21 minutes.[24] Carmustine has shown clinical activity in the treatment of lymphoma, melanoma, and brain tumors. Side effects include myelosuppression, severe nausea and vomiting, and pulmonary fibrosis with long-term therapy.

Lomustine

Lomustine is an orally available nitrosurea alkylating agent. Lomustine is converted rapidly to the *cis*- and *trans*-4-hydroxy metabolites; the range of half-lives of these two metabolites is 2 to 4 hours.[25] Lomustine has shown clinical activity in the treatment of Hodgkin's lymphoma and melanoma. Side effects are similar to those of carmustine. Patients should receive only enough drug for one cycle at a time to prevent confusion and accidental overdose.

Dacarbazine

While the exact mechanism of action remains unclear, dacarbazine appears to inhibit DNA, RNA, and protein synthesis. Dacarbazine disappears rapidly from the plasma, with a terminal half-life of about 40 minutes. Dacarbazine has shown clinical benefit in the treatment of melanoma, Hodgkin's lymphoma, and soft tissue sarcomas. Side effects include myelosuppression, severe nausea and vomiting, and a flulike syndrome that starts about 7 days after treatment and lasts 1 to 3 weeks.

Temozolomide

Temozolomide is an orally active agent with the same mechanism of action as dacarbazine. It is well absorbed and crosses the blood-brain barrier. Temozolamide is converted enzymatically to the active metabolite 5-(3-methyltriazeno)-imidazole-4-carboxamide. Temozolamide has a terminal half-life of 1.8 hours, with a mean time to peak concentrations of 1.4 hours, and a small amount of the drug is excreted unchanged by the kidney.[26] The active metabolite has a terminal half-life of 1.5 hours and is metabolized primarily. Temozolamide may be used in the treatment of melanoma, refractory anaplastic astrocytoma, and glioblastoma multiforme. Nausea may be minimized by dosing the drug at bedtime. Since patients receiving temozolomide may have confusion secondary to their brain tumor, and because dosing can consist of multiple capsule sizes, care must be taken by all providers to simplify regimens to prevent chemotherapy overdose.

Procarbazine

While the exact mechanism of action of procarbazine is unknown, it does inhibit DNA, RNA, and protein synthesis. The pharmacokinetics have never been fully characterized, but it is known that the drug is metabolized extensively. Procarbazine is used most often in the treatment of lymphoma.

Myelosuppression is the major side effect. Nausea, vomiting, and a flulike syndrome occur initially with therapy. Patients must be counseled to avoid tyramine-rich foods because procarbazine is a monoamine oxidase inhibitor. Patients should be provided a list of foods and beverages to avoid to prevent a hypertensive crisis. A disulfiramlike reaction can occur with the ingestion of alcohol.

Thiotepa

Thiotepa is an alkylating agent that reacts with DNA phosphate groups to produce chromosomal cross-linkage. The pharmacokinetics of thiotepa are best described by a two-compartment model, with an α half-life of 6 to 24 minutes and a terminal half-life of 78 to 160 minutes. Thiotepa has shown clinical activity in the treatment of breast, bladder, and ovarian cancer, along with carcinomatous meningitis and malignant effusions, and usually is administered intravenously or as an intravesicular infusion. It also may be used intrathecally. Side effects include myelosuppression, nausea and vomiting, and venous irritation.

Heavy-Metal Compounds

Platinum drugs form reactive platinum complexes that bind to cells, so the pharmacokinetics of the individual drug may be of the platinum, both free and bound, rather than of the parent drug.

Cisplatin

Cisplatin forms inter- and intrastrand DNA cross-links to inhibit DNA synthesis. The pharmacokinetics are best described by a three-compartment model, with an α half-life of 20 minutes, a β half-life of 48 to 70 minutes, and a terminal half-life of 24 hours. Ninety percent of the drug is removed by the kidney by glomerular filtration and tubular secretion. Cisplatin has shown clinical activity in the treatment of numerous tumor types, from head and neck cancers to anal cancer, including many types of lymphoma and carcinoma of unknown primary. Cisplatin is highly emetogenic, even when low doses are given daily for 5 days, and causes delayed nausea and vomiting as well; patients require aggressive antiemetic regimens for both delayed and acute emesis. Significant nephrotoxicity and electrolyte abnormalities can occur if inadequate hydration occurs. Ototoxicity, which manifests as a high-frequency hearing loss, and a glove-and-stocking neuropathy may limit therapy.

Carboplatin

While carboplatin has the same mechanism of action as cisplatin, it has a much less toxic side-effect profile than cisplatin. The pharmacokinetics of carboplatin are best described by a two-compartment model, with an α half-life of 90 minutes and a terminal half-life of 180 minutes. Carboplatin is eliminated almost entirely by the kidney by glomerular filtration and tubular secretion. Many chemotherapy regimens dose carboplatin based on an area under the curve (*AUC*), which is referred to as the *Calvert equation*. According to the Calvert equation, the dose in milligrams = (CrCl + 25) $\times$ *AUC* desired.[27] Carboplatin has shown clinical activity in the treatment of ovarian, lung, breast, testicular, esophageal, and head and neck cancers, as well as lymphomas. Thrombocytopenia, nausea and vomiting, and hypersensitivity reactions are side effects.

Oxaliplatin

The pharmacokinetics of oxaliplatin are best described by a three-compartment model, with an α half-life of 0.28 hours, a β half-life of 16.3 hours, and a terminal half-life of 273 hours.[28] Oxaliplatin has shown clinical activity in the treatment of colorectal cancer. Oxaliplatin, while similar in action to cisplatin and carboplatin, causes a cold-induced neuropathy. Patients should be counseled to avoid cold beverages, to use gloves to remove items from the freezer, and to wear protective clothing in cold climates for the first week after treatment. A glove-and-stocking neuropathy also occur with long-term dosing. Hypersensitivity reactions and moderate nausea and vomiting are also side effects.

Miscellaneous Agents

Altretamine

Altretamine, formerly known as *hexamethylmelamine*, is similar in structure to alkylating agents but is known to have anticancer activity in cancer cells resistant to alkylating agents. Altretamine is well absorbed after oral administration and undergoes rapid and extensive demethylation in the liver. Peak plasma concentrations were observed 0.5 to 3 hours after administration. The terminal half-life is 4.7 to 10.2 hours.

Patient Encounter 1

AB is a 40-year-old white woman who went to urgent care because she hasn't been feeling well for a couple of days and has a fever. Her white blood cell (WBC) count results are greater than 100×10^9/L (100×10^3/μL) with greater than 85% blast cells, which is indicative of acute leukemia. AB is admitted directly to the hospital to start chemotherapy.

The oncologist prescribes the normal doses of idarubicin 12 mg/m^2 IV daily for 3 days and cytarabine 100 mg/m^2 per day by continuous infusion for 7 days to treat her acute myelogenous leukemia. Her baseline laboratory measurements are significant for an elevated WBC count, a creatinine concentration of 2.5 mg/dL (221 μmol/L), and a bilirubin level of 1.6 mg/dL (27 μmol/L).

- Should her chemotherapy dosages be adjusted? If so, how would you adjust the dosages?
- What should be monitored while she is receiving her chemotherapy?

Altretamine has shown activity in the treatment of ovarian and lung cancer. This orally administered drug has the dose-limiting side effects of anorexia, nausea, vomiting, diarrhea, and abdominal cramping. Other side effects include neuropathy, agitation, confusion, and depression.

Bleomycin

Bleomycin is a mixture of peptides with drug activity expressed in units, where 1 unit equals 1 mg. Bleomcyin causes DNA strand breakage. The pharmacokinetics of bleomycin are best described by a two-compartment model, where the α half-life is 10 to 20 minutes and a terminal elimination half-life of 2 to 3 hours, which can be prolonged to 21 hours in patients with renal impairment.[29] Bleomycin has shown clinical activity in the treatment of testicular cancer and malignant effusions, squamous cell carcinomas of the skin, and Kaposi's sarcoma. Hypersensitivity reactions and fever may occur, so premedication with acetaminophen may be required. The most serious side effect is the pulmonary toxicity that presents as a pneumonitis with a dry cough, dyspnea, rales, and infiltrates. Pulmonary function studies will show decreased carbon monoxide diffusing capacity and restrictive ventilatory changes. "Bleomycin lung" is associated with cumulative dosing greater than 400 units and occurs rarely with a total dose of 150 units. The pulmonary toxicity is potentiated by thoracic radiation and by hyperoxia. Additional side effects include fever with or without chills, mild to moderate alopecia, and nausea and vomiting. Bleomycin has been used to manage malignant effusions at doses of 15 to 60 units through installation into the affected area. The drainage tube of the effusion is clamped off for some period of time after administration of the bleomycin (time varies based on the location of the effusion), and then the amount of drainage is monitored to determine efficacy of the bleomycin treatment.

Hydroxyurea

Hydroxyurea is an oral drug that inhibits ribonucleotide reductase, which converts ribonucleotides into the deoxyribuoncleotides used in DNA synthesis and repair. The time to peak concentrations of hydroxyurea is 1 to 2 hours after oral administration. Approximately 50% is degraded by the liver to form urea and respiratory carbon dioxide. The remainder is excreted by the kidney. The half-life ranges from 3.5 to 4.5 hours. Hydroxyurea has shown clinical activity in the treatment of chronic myelocytic leukemia, polycythemia vera, and thrombocytosis. The major side effects are myelosuppression, nausea and vomiting, diarrhea, and constipation. Rash, mucositis, and renal tubular dysfunction occur rarely.

L-Asparaginase

L-Asparaginase is an enzyme that may be produced by *Escherichia coli*. Asparaginase hydrolyzes the reaction of asparagines to aspartic acid and ammonia to deplete lymphoid cells of asparagine, which inhibits protein synthesis. The pharmacokinetics of L-asparaginase are best described by a two-compartment model, with an initial half-life of 4 to 9 hours and a terminal half-life of 1.4 to 1.8 days. L-Asparaginase has shown clinical activity in the treatment of acute lymphocytic leukemia and childhood acute myeloid leukemia. Severe allergic reactions may occur when the interval between doses is 7 days or greater, so while a skin test may be negative, patients should be observed closely after asparaginase administration. Pancreatitis and fibrinogen depletion also may occur during therapy. Repletion of fibrinogen should be done to prevent disseminated intravascular coagulation and fatal bleeding. If the patient suffers an allergic reaction to L-asparaginase, pegaspargase, which is L-asparaginase modified through a linkage with polyethylene glycol, which extends the half-life and allows for lower doses and less frequent administration, may be given. Cost and limited availability are the reasons why pegaspargase is not used first.

Arsenic Trioxide

Arsenic trioxide, which was approved recently for the treatment of acute promyelocytic leukemia, induces the growth of cancer cells into mature, more normal cells, as well as induces programmed cell death, or apoptosis. The pharmacokinetics of arsenic trioxide are best described by a two-compartment model, with an α half-life of 0.89 hours and a β half-life of 12.1 hours. Less than 10% of a dose is excreted by the kidney.[30] Arsenic trioxide causes QT-interval prolongation, so daily electrocardiograms (ECGs) need to be done prior to each dose, and other drugs that may prolong the QT interval need to be avoided during therapy. Other side effects include dry skin with itching, nausea and vomiting, loss of appetite, and elevations of serum hepatic enzymes.

Mitomycin C

Mitomycin C is an alkylating agent that forms cross-links with DNA to inhibit DNA and RNA synthesis. The pharmacokinetics of mitomycin C are best described by a two-compartment model, with an α half-life of 8 minutes and a terminal half-life of 48 minutes.[31] Liver metabolism is the primary route of elimination. Mitomycin C has shown clinical activity in the treatment of anal, bladder, cervix, gallbladder, esophageal, and stomach cancer. Side effects consist of myelosuppression and mucositis, and it is a vesicant.

Tretinoin

Tretinoin, also referred to *ATRA*, which stands for all-trans-retinoic acid, is a retinoic acid that is not cytotoxic but promotes the maturation of early promyelocytic cells and is specific to the t(15;17) cytogenetic marker. The time to peak concentrations is 1 to 2 hours after an oral dose. The elimination half-life is 21 to 51 minutes.[32] These maroon-and-gold capsules are dosed at 45 mg/m^2 per day divided into two doses. The most significant side effect is the retinoic acid syndrome, which may occur anywhere from the first couple of days of therapy until the end of therapy and consists of symptoms of

fever, respiratory distress, and hypotension. Chest radiographs are consistent with a pneumonia-like process. The syndrome can be confused easily with pneumonia in a patient with possible neutropenia. The treatment for retinoic acid syndrome is dexamethasone 10 mg intravenously every 12 hours; the syndrome may resolve within 24 hours of the start of dexamethasone therapy. However, the use of steroids in a febrile neutropenic patient may further compromise the treatment of infection.

Thalidomide

Thalidomide was introduced into the market on October 1, 1957, as a sedative-hypnotic, and when it was taken by pregnant women, it resulted in severe limb deformities (phocomelia). Thalidomide is used for the treatment of leprosy but now is part of the treatment of multiple myeloma. While thalidomide is believed to be an angiogenesis inhibitor, the mechanism of action is still unknown. Possible mechanisms of action include free-radical oxidative damage to DNA, inhibiting tumor necrosis factor α production, altering the adhesion of cancer cells, and altering cytokines that affect the growth of cancer cells. The pharmacokinetics of thalidomide demonstrate a time to peak concentration of 2 to 3 hours and a terminal half-life of 4 to 7 hours.[30] Thalidomide has shown clinical activity in the treatment of multiple myeloma and is still being studied for the treatment of several other cancers. Because of thalidomide's potential to cause phocomelia, each patient must be counseled on the risks of thalidomide not only for the patient but also the patient's reproductive partner. Physicians must be registered to prescribe thalidomide. Pharmacists can fill prescriptions only where both the patient and the physician have completed surveys on a monthly basis.

Lenalidomide

Lenalidomide was approved recently for the indication of myelodysplastic syndrome where the 5q deletion is present. Since lenalidomide is an analog of thalidomide, all the same precautions must be taken to prevent phocomelia. The time to maximum lenalidomide concentrations occurs 0.5 to 4 hours after the dose. The terminal half-life ranges from 3 to 9 hours. Approximately 65% of lenalidomide is eliminated unchanged in the urine, with clearance exceeding the glomerular filtration rate. To date, no pharmacokinetic studies have been done in patients with renal dysfunction. Lenalidomide is used in the treatment of myelodysplastic syndrome and multiple myeloma. Other side effects are neutropenia, thrombocytopenia, deep vein thrombosis, and pulmonary embolus.

Immune Therapies

Interferons

The categories of α, β, and γ interferons exist; the α interferons are used in the treatment of cancer. Interferon enhances the immune system's attack on cancer cells, can decrease new blood vessel formation, and can augment expression of antigen on tumor cell surfaces. Interferon has an elimination half-life of 3.7 to 8.5 hours. Interferon is filtered through the glomeruli and then degraded during tubular reabsorption. Interferon has shown clinical activity in the treatment of melanoma, kidney cancer, Kaposi's sarcoma, and chronic myelocytic and lymphocytic leukemia. Unfortunately, interferon is not well tolerated by patients because it causes a flulike syndrome that consists of fevers and chills; depression, malaise, and fatigue are other side effects. Premedication with acetaminophen will help alleviate the flulike symptoms, which will decrease with chronic administration.

Aldesleukin

Aldesleukin, commonly referred to as *interleukin 2*, is a lymphokine that promotes B- and T-cell proliferation and triggers a cytokine cascade to attack the tumor. The pharmacokinetics are best described by a two-compartment model, with an α half-life of 13 minutes and a terminal half-life of 85 minutes. Aldesleukin is eliminated by both glomerular filatration and peritubular extraction in the kidney. Aldesleukin has shown clinical activity in the treatment of kidney cancer and melanoma. Side effects of interleukin 2 vary by dose and route. Intravenous high-dose interleukin 2 causes a drug-induced shock-like picture. Patients may develop hypotension despite aggressive intravenous hydration. Patients develop a red, itching skin; liver and kidney function tests change; fluid and electrolyte imbalances occur; and high fevers occur while receiving scheduled acetaminophen and nonsteroidal anti-inflammatory agents. Severe rigors and chills may require intravenous meperidine for symptom control. All the side effects reverse within 24 hours of stopping the drug. The toxicity profile is much less with subcutaneous administration. However, with subcutaneous administration, little nodules form at the injection site and may take months to resolve. Corticosteroids should not be administered to patients while receiving aldesleukin unless a life-threatening emergency should occur. Steroids will reverse all the symptoms and the antitumor effect, even with topical administration. The itching, red skin may be treated with topical creams and antihistamines.

Denileukin Diftitox

Denileukin diftitox is a combination of the active sections of interleukin 2 and diphtheria toxin. It binds to high-affinity interleukin 2 receptors on the cancer cell (and other cells), and the toxin portion of the molecule inhibits protein synthesis to result in cell death. The pharmacokinetics of denileukin diftitox are best described by a two-compartment model, with an α half-life of 2 to 5 minutes and a terminal half-life of 70 to 80 minutes. Denileukin diftitox is used for the treatment of persistent or recurrent cutaneous T-cell lymphoma whose cells express the CD25 receptor. Side effects include vascular leak syndrome, fevers/chills, hypersensitivity reactions, hypotension, anorexia, diarrhea, and nausea and vomiting.

TABLE 85–4. Syllable Source Indicators for Monoclonal Antibodies

U	Human
O	Mouse
A	Rat
E	hamster
I	primate
Xi	A cross between humanized and an animal source

Here, mab stands for monoclonal antibody. These letters appear before -mab. Programme on International Nonproprietary Names (INN) Division of Drug Management and Policies, World Health Organization, Geneva. 1997. Web address: whalibdoc.who.int/hg/1997/WHO_Pharm_S_NOM_1570.pdf

Monoclonal Antibodies

The cell surface contains antigens, which are referred to as *CD*, which stands for "cluster of differentiation." The antibodies are produced against a specific antigen. When administered, usually by an intravenous injection, the antibody binds to the antigen, which may trigger the immune system to result in cell death through complement-mediated cellular toxicity, or the antigen-antibody cell complex may be internalized to the cancer cell, which results in cell death. Monoclonal antibodies also may carry radioactivity, sometimes referred to as *hot antibodies*, and may be referred to as *radioimmunotherapy*, so the radioactivity is delivered to the cancer cell. Antibodies that contain no radioactivity are referred to as *cold antibodies*.

All monoclonal antibodies end in the suffix *-mab*. The syllable before *-mab* indicates the source of the monoclonal antibody (see Table 85–4). When administering an antibody for the first time, one should consider the source. The less humanized an antibody, the greater is the chance for the patient to have an allergic-type reaction to the antibody. The more humanized the antibody, the lower is the risk of a reaction. The severity of the reactions may range from fever and chills to life-threatening allergic reactions (which have resulted in death). Premedication with acetaminophen and diphenhydramine is common before the first dose of any antibody. If a severe reaction occurs, the infusion should be stopped and the patient treated with antihistamines, corticosteroids, or other supportive measures.

Alemtuzumab

Alemtuzumab is the antibody to the CD52 receptor present on B and T lymphocytes. The pharmacokinetics of alemtuzumab demonstrate a terminal half-life of 7 days. Alemtuzumab has shown clinical activity in the treatment of chronic lymphocytic leukemia. Severe and prolonged (6 months) immunosuppression may result, which necessitates prophylaxis with cotrimoxazole and antivirals to prevent opportunistic infections.

Bevacizumab

Bevacizumab is a humanized monoclonal antibody that binds to vascular endothelial growth factor, which prevents it from binding to its receptors, ultimately resulting in angiogenesis. The pharmacokinetics of bevacizumab demonstrate a terminal half-life of 21 days, with a volume of distribution consistent with limited extravascular distribution.[34] Bevacizumab has shown clinical activity in the treatment of colorectal, kidney, lung, breast, and head and neck cancer. Patients may develop hypertension requiring chronic medication during therapy. Impaired wound healing, thrombolembolic events, proteinuria, bleeding, and perforation are serious side effects.

Cetuximab

Cetuximab is a human/mouse antibody that binds to the epidermal growth factor receptor to block its stimulation. The pharmacokinetics of cetuximab demonstrate a volume of distribution that approximates the vascular space and a terminal half-life of 70 to 100 hours. Cetuximab has shown clinical activity in the treatment of colorectal cancer. An acnelike rash may appear on the face and upper torso 1 to 3 weeks after the start of therapy. Other side effects include hypersensitivity reactions, interstitial lung disease, fever, malaise, diarrhea, abdominal pain, and nausea and vomiting.

Gemtuzumab Ozogamicin

Gemtuzumab ozogamicin is a humanized antibody to the CD33 receptor present on about 80% of acute myelogenous leukemia cells. The antibody is linked to calicheamicin, a cellular toxin that is released intracellularly after the antigen-antibody complex is internalized. The pharmacokinetics of gemtuzumab ozogamicin show a terminal half-life of 67 to 78 hours of the antibody portion of the drug and a terminal half-life of about 45 hours of the calicheamicin.[35] Gemtuzumab ozogamicin has shown clinical activity in the treatment of acute myeloid leukemia. Severe rigors and chills, which may occur after the infusion is completed, respond to meperidine intravenously. Premedications should include acetaminophen, diphenhydramine, and methylprednisolone to prevent rigors and chills.

Ibrotumomab Tiuxetan

This "hot antibody" is linked to yttrium and binds to the CD20 receptor of B lymphocytes (see "Rituximab" below). Hematologic toxicity may occur several weeks after administration and may take weeks to resolve.

Rituximab

Rituximab is a monoclonal antibody to the CD20 receptor expressed on the surface of B lymphocytes; the presence of the antibody is determined during flow cytometry of the tumor cells. Cell death results from antibody-dependent cellular cytotoxicity. The pharmacokinetics of rituximab are best described by a two-compartment model, with a terminal half-life of 76 hours after the first infusion and a terminal half-life of 205 hours after the fourth dose.[36] Rituximab has shown clinical activity in the treatment of B-cell lymphomas that are CD20+. Side effects include hypersensitivity reactions, hypotension, fevers, chills, rash, headache, and mild nausea and vomiting.

Tositumomab

This "hot antibody" is linked to radioactive iodine and binds to the CD20 receptor present on B lymphocytes (see "Rituximab" above). Tositumomab has shown activity in non-Hodgkin's lymphoma. Hematologic toxicity occurs several weeks after administration and may persist for months. Since radioactive iodine may have adverse effects on the thyroid, all patients must receive thyroid-blocking agents.

Trastuzumab

Trastuzumab is the antibody directed against human epidermal receptor 2 (HER2), which is overexpressed by 25% to 30% of breast cancers and is associated with aggressive disease and decreased survival. Breast cancer tissue must be tested for the presence of HER2. The pharmacokinetics of trastuzumab are best described by a two-compartment model, with a terminal half-life of 19 to 28 days.[34] Severe congestive heart failure may occur with concurrent anthracycline administration. Cardiac toxicity may be seen when the drug is administered months after anthracycline administration, so patients must be counseled on the signs and symptoms of heart failure. Other side effects include hypersensitivity reactions, fever, diarrhea, infections, chills, cough, headache, rash, and insomnia.

Tyrosine Kinase Inhibitors

There are more than 100 different types of tyrosine kinases present in the body. Sometimes tyrosine kinase inhibitors are referred to as small-molecule inhibitors. Each of the following drugs was developed to block either several or a specific tyrosine kinase.

Imatinib

Imatinib was the first FDA-approved tyrosine kinase inhibitor. The drug was designed to block the breakpoint cluster region tyrosine kinase (BCR:ABL) produced by the Philadelphia chromosome associated with chronic myelogenous leukemia and acute lymphocytic leukemia. The pharmacokinetics of imatinib demonstrate a mean time to maximum concentration of 2 to 4 hours, with a terminal half-life of 15 hours.[37] Imatinib also has shown activity against gastrointestinal stroma tumors (GIST). Numerous drug interactions have been reported for imatinib. CYP450 3A4 inducers, such as rifampicin and St. John's wort, increase the clearance of imatinib.[39,40] Ketoconazole, a CYP450 3A4 inhibitor, has been shown to decrease imatinib clearance by almost 30%.[41] Imatinib also may increase the exposure of simvastatin, a CYP450 3A4 substrate.[42]

Erlotinib

Erlotinib, whose pharmacology is not entirely understood, is believed to inhibit the intracellular phosphorylation of the epidermal growth factor receptor. Erlotonib is about 60% absorbed after oral administration; food increases bioavailability to almost 100%. The time to peak concentrations is approximately 4 hours after a dose. The half-life of erlotinib is about 36 hours, and it is eliminated predominately by CYP450 3A4. Smoking increases the clearance of erlotinib by 24%, which may result in treatment failure.[43] Erlotinib is used in the treatment of non–small cell lung cancer and cancer of the pancreas. Side effects include interstitial lung disease, rash, diarrhea, anorexia, pruritus, conjunctivitis, and drug skin. Again, significant drug interactions have been documented with CYP450 3A4 inducers and inhibitors.

Sorafenib

Sorafenib is a multikinase inhibitor that inhibits both intracellular and extracellular kinases to decrease renal cell cancer proliferation. The half-life of sorafenib is 25 to 48 hours, with a bioavailability of 38% to 49% and a time to peak concentration of 3 hours. Sorafenib is metabolized primarily by the liver by CYP450 3A4. Sorafenib is used for the treatment of renal cell cancer. The primary side effects of sorafenib include rash, hand-foot skin reaction, diarrhea, pruritus, and elevations in serum lipase.

Sunitinib

Sunitinib blocks several tyrosine kinases, so it inhibits platelet-derived growth factor, vascular endothelial growth factor receptor, stem cell factor receptor, fms-like receptor growth factor, colony-stimulating growth factor receptor type 1, and glial-cell-line-derived neurotrophic factor receptor. The active metabolite of sunitinib blocks these same enzymes with similar potency. The pharmacokinetics of sunitinib demonstrate a time of peak concentration of about 5 hours, with a half-life of 41 to 86 hours.[44] It is indicated for the treatment of gastrointestinal stromal tumors (GISTs) after disease progression or intolerance to imatinib. It is also indicated for the treatment of advanced renal cell cancer. Significant side effects include left ventricular dysfunction, hemorrhage, asthenia, hypertension, nausea and vomiting, and diarrhea. Approximately one-third of patients may develop a yellow color of the skin, along with dryness and cracking of the skin. Also, hair may become depigmented with doses of 50 mg/day or more, and the depigmentation is reversible when therapy is stopped. Clinically significant drug interactions exist with drugs metabolized via the CYP450 3A4 system; ketoconazole has been shown to increase concentrations of sunitinib, whereas rifampin has been shown to decrease concentrations of sunitinib.

Hormonal Therapies

Hormonal therapies have shown activity in the treatment of cancers whose growth is affected by gonadal hormonal control. Hormonal treatments either block or decrease the production of endogenous hormones.

Antiandrogens: Bicalutamide, Flutamide, and Nilutamide

The antiandrogens block androgen receptors to inhibit the action of testosterone and dihydrotestosterone in prostate

cancer cells. Unfortunately, prostate cancer cells may become hormone refractory.

Flutamide is an androgen receptor antagonist that achieves peak concentrations approximately 2 to 4 hours after an oral dose. Flutamide is metabolized extensively, with a terminal half-life of about 8 hours. Bicalutamide achieves peak concentrations approximately 6 hours after the dose, with a terminal half-life of 6 to 10 days. Bicalutamide undergoes stereospecific metabolism, where the *S*-enantiomer is cleared more rapidly by the liver than the *R*-enantiomer. Nilutamide achieves peak serum concentrations between 1 to 4 hours after an oral dose and has a terminal half-life of 38 to 60 hours. Nilutamide is metabolized extensively, with less than 2% excreted as unchanged drug by the kidney. Side effects common to these agents are hot flashes, gynecomastia, and decreased libido. Flutamide tends to be associated with more diarrhea and requires three-times-daily administration, whereas bicalutamide is dosed once daily. Nilutamide may cause interstitial pneumonia and is associated with the visual disturbance of delayed adaptation to darkness.

Luteinizing Hormone–Releasing Hormone (LHRH) Agonists: Goserelin and Leuprolide

Initially, LHRH agonists increase levels of leutinizing hormone and follicle-stimulating hormone, but testosterone and estrogen levels are decreased because of continuous negative-feedback inhibition. Major side effects are testicular atrophy, decreased libido, gynecomastia, and hot flashes. Leuprolide is well absorbed, with a terminal half-life of 2.9 hours, whereas goserelin has a terminal half-life of 4.9 hours. Goserelin is injected as a pellet under the skin, so subcutaneous injection of lidocaine prior to administration helps to decrease the pain associated with goserelin administration. Numerous dosage forms are available for leuprolide with varying strengths and dosing intervals. Antiandrogens may be administered during initial therapy to decrease symptoms of tumor flare (e.g., bone pain and urinary tract obstruction).

Ketoconazole

While ketoconazole is an antifungal agent, it has been used for treatment of prostate cancer. In high doses of 400 mg three times daily, ketoconazole blocks the production of testosterone.

LHRH Antagonist: Abarelix

Abarelix is a gonadotropin-releasing hormone antagonist that is associated with life-threatening hypersensitivity reactions. Patients must be observed for 30 minutes after administration. The drug is limited to men who cannot risk tumor flare and refuse orchiectomy.

Aminoglutethimide

Aminoglutethimide blocks the conversion of androgens to estrogens and decreases the synthesis of glucocorticoids. Adrenocorticoid suppression may occur, so replacement therapy with hydrocortisone may be required. Other side effects include rash (which usually resolves in 5–8 days), lethargy, and anorexia.

Anastrozole

Anastrozole is a selective nonsteroidal aromatase inhibitor that lowers estrogen levels. The pharmacokinetics of anastrozole demonstrate good absorption, with hepatic metabolism the primary route of elimination and only 10% excreted unchanged by the kidney. The elimination half-life is approximately 50 hours. Anastrozole is used for the adjuvant treatment of postmenopausal women with hormone-positive breast cancer and in breast cancer patients who have had disease progression following tamoxifen. Side effects include hot flashes, arthralgias, osteoporosis/bone fractures, and thrombophlebitis.

Exemestane

Exemestane is an irreversible aromatase inactivator that binds to the aromatase enzyme to block the production of estrogen from androgens. Exemestane is absorbed rapidly after oral administration, with a terminal half-life of 24 hours. The drug is eliminated primarily by the liver and feces, with less than 1% of the dose excreted unchanged in the urine. Exemestane is indicated for the treatment of advanced breast cancer in postmenopausal women who have had disease progression following tamoxifen therapy. Side effects include hot flashes, fatigue, osteoporosis/bone fractures, and flulike symptoms.

Fulvestrant

Fulvestrant is an estrogen receptor antagonist that binds to the estrogen receptor and is given as a monthly intramuscular injection. Fulvestrant has a terminal half-life of 40 days and a large volume of distribution of 3 to 5 L/kg. Fulvestrant is metabolized primarily, with excretion primarily via feces. Fulvestrant is used for the treatment of hormone-receptor-positive metastatic breast cancer in postmenopausal women with disease progression following antiestrogen therapy. Side effects are hot flashes, abdominal pain, depression, and myalgias.

Letrozole

Letrozole is another selective aromatase that inhibits the conversion of androgens to estrogen. Maximum plasma concentrations occur 1 hour after oral dosing; concomitant food has not been shown to have an effect on the extent of absorption of letrazole. The terminal half-life is approximately 2 days. Letrozole is used in the treatment of postmenopausal women with hormone-receptor-positive or unknown advanced breast cancer. Side effects include bone pain, hot flushes, back pain, nausea, arthralgia, osteoporosis/bone fractures, and dyspnea.

Megestrol Acetate

Megestrol is a synthetic progestin with antiestrogen properties that is used for breast cancer and in higher doses for weight

gain. Side effects include fluid retention, hot flashes, vaginal bleeding and spotting, breast tenderness, and thrombosis.

Tamoxifen

Tamoxifen is an estrogen receptor antagonist. Most of a dose of tamoxifen is eliminated primarily by metabolism, with significant enterohepatic recirculation. The time to a peak concentration is 6 hours after an oral dose, and the terminal half-life is 7 days. Tamoxifen is used primarily for the treatment of postmenopausal hormone-receptor-positive breast cancer patients and the prevention of breast cancer in postmenopausal women. Side effects include hot flashes, fluid retention, mood swings, thrombosis, endometrial and uterine cancer, and corneal changes and cataracts. Since tamoxifen is a substrate of CYP450 3A4, decreased tamoxifen levels have occurred with use of St. John's wort, and decreased tamoxifen levels have observed with use of rifampin. Tamoxifen is also a substrate for CYP450 2D6, and recent evidence suggests that those who are *CYP2D6*4/*4* may have a poorer response and more toxicity with tamoxifen.

Toremifene

Toremifene is an estrogen receptor antagonist. The pharmacokinetics of toremifene are best described by a two-compartment model, with an α half-life of 4 hours and an elimination half-life of 5 days. Peak plasma concentrations are achieved approximately 3 hours after an oral dose. Toremifene is metabolized extensively, with metabolites found primarily in the feces. Toremifene is used for the treatment of metastatic breast cancer in postmenopausal women with estrogen-receptor-positive or unknown tumors. Toremifene causes hot flashes, vaginal bleeding, thromboembolism, and visual acuity changes.

Supportive Care

Many of the older chemotherapy treatments of cancer cause severe, even life-threatening toxicities. Toxicities range from nausea and vomiting, pain, myelosuppression, mucositis, decreased nutrition, and alopecia to secondary malignancies from the treatments themselves. This section will focus on the side-effect management of myelosuppression, mucositis, and secondary malignancies. While not a direct toxicity of chemotherapy, medication safety in oncology is of the utmost importance owing to the life-threatening side effects that can occur with inappropriate dosing.

Myelosuppression

Myelosuppression is one of the most common dose-limiting side effects of cancer drugs that cause myelosuppression. Myelosuppression may occur several days to several weeks after treatment and varies with the chemotherapy drugs used. WBCs, in particular, neutrophils, are the first cell line that is decreased because of their rapid proliferation and short life span of 6 to 12 hours. Platelets, with a life span of 9 to 11 days are the next cell line affected by myelosuppressive therapy. The last cell line to be affected by myelosuppressive therapy is red blood cells (RBCs), which have a life span of approximately 120 days. After the first dose of chemotherapy, subsequent doses may need to be held until WBC recovery so that the patient is not at an increased risk of infection. If WBC counts are persistently low owing to numerous myelosuppressive chemotherapy treatments, chemotherapy doses will need to be decreased to prevent febrile neutropenia for palliative chemotherapy regimens, or hematopoietic growth factors will need to be administered in order to deliver full doses of chemotherapy for cancers that are curable.

Neutropenia occurs when the percent of mature neutrophils plus the percent of bands (or immature neutrophils) times the WBC count is less than 500/mm^3 (0.5×10^9/L). The risk of infection increases as the extent of neutropenia becomes severe and the duration increases. The assessment of infection is different in the neutropenic cancer patient. First, WBC counts may be profoundly low, so no left shift is available to evaluate. Second, there is no pus without WBCs. Some bacterial pneumonias may not be readily apparent by chest x-ray. Third, if patients are receiving steroids as part of the cancer treatment, fever curves may be blunted or absent. When a patient does have a fever and is neutropenic, prompt initiation of anti-infectives is necessary.

The colony-stimulating factors sargramostim, filgrastim, and pegfilgrastim are growth factors that shorten the duration and decrease the magnitude of neutropenia by stimulating the production of neutrophils. These drugs usually are administered by subcutaneous injection starting at least 24 hours after the end of chemotherapy and are continued until a WBC count of 2000 to 10,000/mm^3 ($2–10 \times 10^9$/L) is obtained. Pegfilgrastim is the pegylated version of filgrastim that allows a single injection to replace 10 to 14 daily injections of filgrastim or sargramostim. The agents tend to be well tolerated, with the main side effect being bone pain that usually can be relieved with acetaminophen. These agents are relatively expensive, so evidence-based guidelines have been established by the American Society of Clinical Oncology and are updated every few years.[45] These drugs may be used for primary prevention where the incidence of febrile neutropenia with the chemotherapy is approximately 20% and no other equally effective and less myelosuppresive regimen is available or for secondary prevention where the patient already has experienced febrile neutropenia with the previous cycle of chemotherapy. The colony-stimulating growth factors also may be used to stimulate stem cell production, which later can be used for a bone marrow transplant. Colony-stimulating factors have been used in other diseases such as AIDS, congenital neutropenia, and aplastic anemia.

Thrombocytopenia is another dose-limiting side effect of chemotherapy. The primary treatment for thrombocytopenia is platelet transfusions. The risk of bleeding is significant when platelet counts are less than 10,000/mm^3 (10×10^9/L);

Patient Encounter 2

JP is receiving a highly myelosuppressive chemotherapy regimen for the next 3 days for his lymphoma. The chemotherapy orders specify ifosfamide, carboplatin, and etoposide. The goal of this cycle of chemotherapy is to put the cancer into remission so that his lymphoma can be cured with a bone marrow transplant.

- What drug is missing from his ifosfamide orders?
- What instructions should the patient receive about ifosfamide?
- Should JP receive a growth factor after chemotherapy?

the risk of fatal intracranial bleeding occurs when platelet counts are less than 1000 to 2000/mm^3 (1–2 × 10^9/L). Oprelvekin, sometimes referred to as *interleukin 11* (interleukin 11 should be avoided because medication errors have been made with dispensing interleukin 2 instead), is indicated for thrombocytopenia that has occurred after the first cycle of chemotherapy. Unfortunately, oprelvekin has the significant side effect of fluid retention and edema. It also is relatively expensive, and it comes as a powder that has short drug stability when reconstituted, which makes it difficult for home administration. If a patient has bleeding or severe thrombocytopenia, the preferred treatment is still platelet transfusion.

Anemia is a significant side effect of chemotherapy. Products available for the treatment of anemia of cancer include epoetin-α and darbepoietin. The starting dose of epoetin for oncology-associated anemia ranges from 150 units/kg subcutaneously three times weekly to 40,000 units subcutaneously once weekly. Darbepoietin is an analog of epoetin with a sialic acid content that increases the serum half-life to 33 to 50 hours, which allows weekly to every-3-week administration. Clinical practice guidelines for the use of erythropoietic agents are available from the American Society of Hematology/American Society of Clinical Oncology and the National Comprehensive Cancer Network.[46] Medicare also has reimbursement guidelines for these drugs; each state has similar, albeit somewhat different, criteria for reimbursement in the ambulatory clinic. Adverse effects of these agents are nausea, vomiting, fever, hypertension, and increased risk for thrombotic events.

Mucositis and Diarrhea

The rapidly proliferating cells of the GI tract make them susceptible to the effects of chemotherapy. Mucositis is the inflamed, ulcerated mucosa of the mouth, esophagus, and lower GI tract that may result in infection and pain with subsequent decreased fluid and nutritional intake. Methotrexate, 5-FU, etoposide, and doxorubicin are the chemotherapy agents most commonly associated with mucositis. Patients should be instructed on good oral mouth care and use saline rinses several times a day during therapy to prevent mucositis. Oral cryotherapy has demonstrated benefit when used for 30 minutes around the time of bolus 5-FU administration.[47] Nonsmokers benefited more from cryotherapy than did smokers.

The keratinocyte growth factor palifermin was approved by the FDA for the prevention of mucositis in patients receiving high-dose chemotherapy prior to hematopoietic stem cell transplantation. The usual dose is 60 mcg/kg per day as an intravenous bolus for 3 consecutive days before and 3 days after myelotoxic therapy; total number of doses is six. The median number of days with severe mucositis was 3 for the palifermin group versus 9 for the patients on placebo. There also were significant reductions in the incidence of very severe mucositis, opioid doses, and total parenteral nutrition utilization for the patients who received palifermin. Adverse reactions included rash, pruritus, erythema, and taste disorders.[48]

Once mucositis has occurred, supportive care palliates the symptoms of mucositis. During mucositis, patients need to maintain good oral hygiene (saline rinses). Analgesics, ranging from viscous lidocaine to parenteral morphine, may be used for pain control. The mouth needs to be observed for signs of infection from such organisms as herpes viruses and *Candida* species. Topical antifungal therapy, such as nystatin suspension or clotimazole troches, may be sufficient for milder forms of mucositis, whereas systemic azoles or other antifungals may be necessary for severe oral or esophageal fungal infections.[49]

Diarrhea may occur from effects of chemotherapy on the lower portion of the GI tract. Diarrhea can be severe and may need to be treated with intravenous fluids and electrolytes. Infectious causes, such as *C. difficile*, should be ruled out. Pharmacologic therapy of diarrhea can range from loperamide or cholestyramine to octreotide for severe cases of diarrhea that are refractory to usual treatments.

Extravasation

Another issue of chemotherapy safety is extravasation. Antineoplastic agents that cause severe tissue damage when they escape from the vasculature are called *vesicants*. Some examples of vesicants are the anthracyclines and the vinca alkaloids. The tissue damage may be severe, with tissue sloughing and loss of mobility, depending on the area of extravasation. Patients need to be educated to notify the nurse immediately if there is any pain on administration. If extravasation of a vesicant occurs, the injection should be stopped, and any fluid aspirated out of the injection site. If an antidote should be administered, such as with nitrogen mustard extravasation, the pharmacy should be notified immediately so that the sodium thiosulfate can be prepared and delivered quickly. Cold compresses should be applied (heat should be used for vincas) to the affected area. The area of extravasation should be recorded and inked and followed closely to detect early signs of infection and to treat pain. Obviously, prevention of extravasation is very important. Good intravenous access is key, which may include the placement of a central venous catheter, along with free-flowing intravenous fluids. During

administration of a vesicant, blood return should be checked to be sure that the drug is going into the vein. Central venous catheters can be placed for patients needing infusions of vesicants or for patients with small, friable veins to prevent extravasation.

Alopecia

Alopecia, or hair loss, may be very distressing psychologically to some patients. Alopecia varies by patient and by drug but is reversible after therapy stops. Hair loss may extend to areas other than the scalp. Hair loss usually starts about 2 weeks after chemotherapy, and some hair growth may be apparent before the next chemotherapy treatment. Hair may have a different texture when it does regrow. Patients should be encouraged to wear hats, scarfs, or wigs during this period.

Secondary Malignancies

Chemotherapy and radiation therapy treatments may cause cancers later in life; these are referred to as *secondary cancers*. The most common type of secondary cancer is myelodysplastic syndrome, or acute myeloid leukemia. The antineoplastic agents most commonly associated with secondary malignancies are alkylating agents, etoposide, teniposide, and anthracyclines. While the risk for secondary cancers is extremely low, it must outweigh the risk of survival produced by treatment of the primary malignancy. Since secondary malignancies may not occur for several years after treatment, patients with relatively short-term survival owing to the primary malignancy should consider the more immediate benefits of chemotherapy. Radiation therapy rarely may cause solid tumors as secondary cancers decades after treatment. The most common example of radiation therapy–induced secondary malignancy is breast cancer, which rarely occurs after mantle field radiation therapy for Hodgkin's disease.

Reproduction and Fertility

Females

Cancer patients are surviving longer, and issues of reproduction and fertility are becoming important. Radiation therapy can cause progressive and irreversible damage to the ovary that may result in loss of normal menses. Although women younger than 35 years of age may resume normal menses, the risk of infertility and premature menopause increases as the dosage of radiation increases. Radiation therapy also has an effect on the uterus that is associated with infertility, spontaneous pregnancy loss, and intrauterine growth retardation. However, as long as radiation is not done during pregnancy, the risk of teratogenicity is not increased.

The age of the patient duration of chemotherapy and the dose of chemotherapy are the factors affecting amenorrhea. Alkylating agents tend to have a more profound effect on menses and menopause than other chemotherapy agents. Preliminary evidence suggests that gonadotropin-releasing hormone agonists may create an artificial prepubescent state to protect ovarian function. In a small, retrospective study, no protective benefit was observed in patients receiving oral contraceptives. The risk of teratogenicity from chemotherapy occurs if the pregnancy starts following or during chemotherapy treatment. Limited data with limited follow-up suggest that there are no increases in congenital malformations or preterm labor rates in pregnancies following chemotherapy. A minimum period of 6 months is recommended between the time of last chemotherapy and pregnancy, but this is based on animal data. In vitro fertilization, freezing oocytes, and ovarian cyropreservation are options for females.

Treatment of cancer during pregnancy is a challenging situation. Based on limited information, perinatal problems do not appear at a higher rate as long as teratogens are avoided during pregnancy. Careful review of the literature of the chemotherapy drugs used in pregnancy, in conjunction with the weeks of gestation, will guide the clinician to the appropriate treatment. However, all the nonchemotherapy drugs that are used in the supportive care of the patient need to be reviewed for safety.

Males

Male infertility may result from cancer surgery, radiotherapy, hormonal imbalances, or damage of germinal stem cells. Testicular damage from radiotherapy depends on the treatment field, total dose, and fractionation schedule. Depending on the radiation, sperm counts may return to pretreatment levels in 10 to 24 months after therapy or may be permanent in 80% of men after total-body irradiation for transplant.

High dosages of alkylating agents can cause prolonged azoospermia in greater than 90% of men, whereas platinum drugs can cause it in up to 50% of men. Cyropreservation of semen before treatment starts should be discussed with males at risk for treatment-induced infertility.[52]

CHEMOTHERAPY SAFETY

One of the first Institute of Medicine reports starts out with a patient who died from an overdose of chemotherapy; the patient did not have an immediately life-threatening cancer, so her death was hastened by a medication error. Chemotherapy agents may cause harm to patients, health care workers, and the environment if not handled correctly. ❺ *Because of the severe toxicities associated with many of the chemotherapy agents, safety precautions must be in place to prevent chemotherapy errors, accidental chemotherapy exposures, and overdosages.* The Oncology Nursing Society and the American Society of Health-System Pharmacists have information to assist in the safe handling of chemotherapy agents.[51] National, state, and local regulations regarding the safe disposal of chemotherapy agents and the equipment used to administer them need to be followed to protect the environment.

Each organization should have chemotherapy safety checks built into the prescribing, preparation, and administration of chemotherapy.[50] Dosing based on patient-specific body information should be included on every order for chemotherapy, whether it is oral or parenteral. Many chemotherapy regimens

TABLE 85–5. Dosing Adjustment Guidelines for Chemotherapy for Renal Dysfunction

Drug	Dosing Adjustment
Bleomycin	Creatinine 1.5–2.0 mg/dL (133–177 µmol/L): decrease dose by 50% CrCl less than 20 mL/minute (0.19 mL/s × m^2): decrease dose by 60%
Cladribine	No dosing guidelines
Cytarabine	High dose (greater than 2 g/m^2): Creatinine 1.5–1.9 mg/dL (133–177 µmol/L) or increase of 0.5–1.2 mg/dL (44–106 µmol/L): Decrease dose to 1 g/m^2 Creatinine greater than 1.9 mg/dL (168 µmol/L) or an increase greater than 1.2 mg/dL (106 µmol/L): Decrease dose to 0.1 g/m^2 per day continuous infusion
Etoposide	CrCl 15–50 mL/minute (0.001–4.8 mL/s × m^2): decrease dose by 25%
Carboplatin	Dosing adjustment based on Calvert equation
Cisplatin	Proportional to lower creatinine clearance, where normal equal to 70 mL/minute (0.67 mL/s × m^2)
Methotrexate	Proportional to lowered creatinine clearance, where normal equal to 70 mL/minute (0.67 mL/s × m^2)
Melphalan	If BUN greater than 30 mg/dL (10.7 mmol/L) and creatinine greater than 1.5 mg/dL (132 µmol/L): decrease dose by 50%
Pemetrexed	Greater than or equal to 80 mL/minute (0.77 mL/s × m^2): 600 mg/m^2 40–79 mL/minute (0.38–0.76 mL/s × m^2): 500 mg/m^2
Topotecan	20–39 mL/minute (0.2–37 mL/s × m^2): decrease dose by 50% Less than 20 mL/minute (0.2 mL/s × m^2): not established

From DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy a Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: Table 124–10.

are acronyms; these should not be allowed in the prescribing of chemotherapy. Also, abbreviations for the names of chemotherapy agents should be avoided because one abbreviation may stand for two different drug entities. For drugs such as doxorubicin and liposomal doxorubicin, the names should be written out fully, and in this case, the addition of the brand name may help to prevent a mistake.

The measured height and weight, along with the body surface area, if applicable, should be readily available, along with the dosage in milligrams per meter squared or killigram, so that the dosage may be checked. If a chemotherapy regimen is a continuous infusion of 800 mg/m^2 per day for 4 days, an added safety feature would be to include the total dosage of 3200 mg in order to prevent any ambiguity. In cases where the clinician wants to decrease the dosage based on a laboratory value or side effect, it is recommended that the clinician include that information with the order so that everyone understands what the correct dosage is for that patient.

TABLE 85–6. Dosing Adjustment Guidelines for Chemotherapy for Hepatic Impairment

Drug	Dosing Adjustment
Doxorubicin	Bilirubin greater than 1.5 mg/dL (26 µmol/L), reduce dose by 50%
Daunorubicin	Bilirubin greater than 3.0 mg/dL (51 µmol/L), reduce dose by 75%
Vincristine Vinblastine	
Vinorelbine	Bilirubin greater than 2.0 mg/dL (34 µmol/L), reduce dose by 50% Bilirubin greater than 3.0 mg/dL (51 µmol/L), reduce dose by 75%
Gemcitabine	Bilirubin greater than 1.6 mg/dL (27 µmol/L), reduce dose by 20% Bilirubin greater than 7.5 mg/dL (128 µmol/L), should be avoided
Idarubicin	Bilirubin greater than 5 mg/dL (86 µmol/L): avoid use
Docetaxel	Contraindicated with bilirubin greater than 1.5 × ULN or greater than 1.5 × ULN or transaminases greater than 1.5 × ULN or alkaline phosphatases greater than 2.5 × ULN
Irinotecan	Contraindicated with bilirubin greater than 2 mg/dL (34 µmol/L) or transaminases greater than 3 × ULN (without liver metastases), greater than 5 × ULN (with liver metastases)
Paclitaxel	If transaminase levels less than 10 × ULN and bilirubin 1.5–2.4 mg/dL (26–41 µmol/L): reduce dose by 25% Bilirubin 2.5–7.5 mg/dL (43–128 µmol/L): reduce dose by 50% Bilirubin greater than 7.5 mg/dL (128 µmol/L): not recommended

ULN, upper limit of normal.

Patient Encounter 3

DQ is a 57-year-old man who came to the emergency room because of shortness of breath. A radiographic examination demonstrates a large mass pressing on the bifurcation of the main stem bronchus. A biopsy demonstrates an aggressive lymphoma; a five-drug chemotherapy regimen with both intravenous and intrathecal chemotherapy will start today.

- What steps should be taken to make sure that DQ gets the correct dosages of chemotherapy?

Chemotherapy dosages should be checked for route and dose to determine that the dosages prescribed are correct according to the regimen and do not exceed dosing guidelines. Appropriate laboratory values should be checked to verify that dosages are correct for any organ dysfunction present, and drug interactions should be scrutinized closely. Health care practitioners administering chemotherapy should check the dosage calculation for the body size, along with the five R's of administering medication (i.e., right patient, right medication, right dose, right route, at the right time). If there is any question about the safe dosage or safe administration of a chemotherapy agent, the chemotherapy should not be administered until the question is resolved.

CANCER PREVENTION

Since most cancers are not curable in advanced stages, cancer prevention is an important avenue of exploration. Both lifestyle modifications and chemoprevention agents ultimately may reduce the risk of developing cancer.

Tobacco

Tobacco smoking increases the risk of developing not only lung cancer but also many other types of cancer, including cancer of the bladder, mouth, pharynx, larynx, and esophagus. While the immediate benefit of smoking cessation is minimal for lung cancer, documented benefit has been observed 6 or more years after stopping.

Sun Exposure

Ultraviolet light and increased skin exposure may increase the risk of skin malignancies, especially in individuals who are fair-skinned. Practitioners can counsel patients to minimize skin exposure to the sun and to use to strong sun screens on exposed areas.

TREATMENT OUTCOMES

Once a pathologic diagnosis of cancer is made, the patient may be evaluated by a radiation oncologist, a surgical oncologist, and a medical oncologist. Options for treatment are presented that may include surgery, radiation, chemotherapy, or some combination of these modalities. The goals of treatment will vary by the cancer and the stage of disease. For example, the patient who has metastatic kidney cancer could be cured by high-dose aldesleukin or receive palliative therapy with sorafenib or sunitinib or may decline any therapy because of fears of significant toxicity that would decrease quality of life. In this case, if the patient's performance status is poor, such as an Eastern Cooperative Oncology Group (ECOG) performance status 3, then the patient would not be a candidate for aldesleukin therapy because of significant toxicity or even death from treatment for a patient who has a performance status of 3. The patient with the poor performance status will receive palliative therapy to control symptoms of the disease to improve the quality of life at the end of life. For the patient with a poor performance status and extensive metastatic disease, no treatment of the cancer may be appropriate, and the patient may be enrolled in a hospice program or provided comfort care.

Patient Care and Monitoring

❻ *Clinicians should play a role in chemotherapy safety, patient education, and monitoring patient response to therapy.*

Chemotherapy Administration

1. Evaluate the chemotherapy regimen to ensure the correct dose and route of administration.
2. Check patient laboratory values to ensure that the complete blood count (CBC) and organ function studies are normal prior to administering chemotherapy.
3. If a patient has renal or hepatic impairment or a poor metabolizer genotype, adjust chemotherapy doses if necessary.
4. Ensure appropriate antiemetic therapy for the degree of emetegenicity.
5. Assess the regimen to determine if primary prophylaxis with colony-stimulating factors is needed.
6. Assess the patient's concurrent medications for the possibility of drug interactions, and discontinue potentially interacting medications, if possible.
7. Employ safe handling and disposal methods.

Monitoring

1. *Efficacy:* Monitor CT scans or other imaging studies, and categorize patient with a complete response (CR), partial response (PR), stable disease (SD), or progressive disease.
2. *Toxicity:*
   - Monitor CBC and other lab tests.
   - Monitor patient for other known toxicities of the chemotherapy regimen, and decrease the dose or discontinue the regimen if necessary.

86 Breast Cancer

Kristine Hahn and Laura Boehnke Michaud

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. List factors associated with an increased risk of breast cancer in the United States.
2. Assess patients for signs and symptoms related to breast cancer in early and late stages of the disease.
3. List all modalities that are appropriate screening tools for breast cancer and determine how they should best be used in the public domain.
4. Discuss available options for breast cancer prevention.
5. Critique available prognostic variables for clinical utility.
6. Determine which patient populations may benefit from adjuvant systemic therapy for breast cancer.
7. Determine the treatment goals for early-stage, locally advanced, and metastatic breast cancer.
8. Determine appropriate indications for endocrine therapy, chemotherapy, and biologic therapy for patients with metastatic breast cancer.
9. Evaluate available chemotherapy options for patients with metastatic breast cancer based on pertinent patient and disease-state characteristics.
10. Discuss the role of trastuzumab in the management of early- and advanced-stage breast cancer.

Key Concepts

❶ Although controversial, the benefits of annual screening mammography in women younger than 50 years of age are apparent, and a large number of national and international studies demonstrate a 20% to 40% reduction in breast cancer mortality from annual or biannual screening mammography in women aged 50 to 70 years.

❷ Breast cancer is diagnosed most commonly in early stages, when it is a highly curable malignancy.

❸ Local therapy of early-stage breast cancer consists of modified radical mastectomy or lumpectomy plus external-beam radiation therapy. The surgical approach to the ipsilateral axilla may consist of a full level I/II axillary lymph node dissection or a lymph node mapping procedure with sentinel lymph node biopsy.

❹ Adjuvant endocrine therapy reduces the rates of relapse and death in patients with hormone-receptor-positive early breast cancer tumors. Adjuvant chemotherapy reduces the rates of relapse and death in all patients with early-stage breast cancer.

❺ The choices of chemotherapy regimen, dose, schedule, and duration of therapy, as well as the choice of endocrine therapy, are controversial and rapidly changing as results from ongoing randomized clinical trials are reported.

❻ Neoadjuvant chemotherapy is appropriate for patients with locally advanced or inflammatory breast cancer, followed by local therapy and further adjuvant systemic therapy.

❼ The goal of adjuvant chemotherapy is curative, whereas the goal of chemotherapy in the metastatic setting is palliative.

❽ Initial therapy of metastatic breast cancer in women with hormone-receptor-positive tumors should consist of hormonal therapy.

❾ Women with metastatic breast cancer who have hormone-receptor-positive tumors and respond to an initial hormonal manipulation usually will respond to a second hormonal manipulation.

❿ Approximately 50% to 60% of women who have not received prior chemotherapy for metastatic disease will respond to chemotherapy regimens; doxorubicin- and taxane-containing regimens are the most active.

Although the incidence of breast cancer has been increasing in the United States, the mortality rate has been decreasing over the past two decades. This trend reflects the success of early detection and the development of effective treatment regimens. Treatment for most breast cancer patients includes a combination of pharmacologic and nonpharmacologic therapy.

EPIDEMIOLOGY AND ETIOLOGY

Breast cancer is the most common site of cancer and is second only to lung cancer as a cause of cancer death in American women. It is estimated that 214,640 new cases of breast cancer will be diagnosed and that 41,430 women will die of breast cancer in 2006.[1] Whites account for the largest portion of estimated cases (82%) and deaths (80%). In addition to invasive breast cancers, it is estimated that 61,980 cases of in situ cancer will be diagnosed among women in the United States in 2006. The median age for the diagnosis of breast cancer is between the ages of 60 and 65 years.[2]

Most breast cancers diagnosed are small tumors (less than or equal to 2 cm), and disease is localized in all racial and ethnic groups. However, blacks and other minority women have proportionally more cases of disease diagnosed at more advanced stages compared with white women. This is thought to reflect access to and use of screening mammography and timely treatment.

The etiology of breast cancer is unknown, but a number of factors that increase a woman's chances of developing the disease have been identified. These risk factors, as well as information regarding the biology of the disease, suggest that a complex interplay between hormones, genetic factors, and environmental and lifestyle influences all contribute to the etiology of this disease.

The two variables most strongly associated with the occurrence of breast cancer are gender and age. Although one commonly thinks of breast cancer as a disease confined to women, about 1,720 cases of male breast cancer were projected to be diagnosed in the United States in 2006.[1] When stage and other known prognostic factors are controlled for, men do not fare any differently from their female counterparts and receive similar treatment regimens.

The incidence of breast cancer increases with advancing age. Perhaps the most frequently quoted breast cancer statistic is that one in seven women will develop breast cancer during their lifetime. It should be emphasized that this is a cumulative lifetime risk of developing the disease from birth to age 110 and that the estimates are weighted by the probability of surviving through each decade of life.[3] The one in seven women figure is often misinterpreted by women who assume that it translates into one in seven women being diagnosed with breast cancer each year. Feuer and colleagues developed a more useful method of presenting the risk data based on age intervals.[3] As Table 86–1 demonstrates, the risk of a woman developing breast cancer before the age of 40 years is about 1 in 250. It is apparent from this table that although the cumulative probability of developing breast cancer increases with increasing age, more than half the risk occurs after age 60 years.

TABLE 86–1. Risk of Developing Breast Cancer in SEER Areas, Women, All Races, 1998–2000

Age Interval (years)	Probability (%) of Developing Invasive Breast Cancer During the Interval
30–40	0.40 or 1 in 250
40–50	1.45 or 1 in 69
50–60	2.78 or 1 in 36
60–70	3.81 or 1 in 26
From birth to death	13.51 or 1 in 7

From Ries LAG, Eisner MP, Kosary CL, (eds.) SEER Cancer Statistics Review: 1975–2001. Bethesda, MD, http://seer.cancer.gov/csr/1975–2001/, 2004.

As many as 85% of American women have "lumpy breasts" and may have a clinical diagnosis of fibrocystic breast disease or benign breast disease. Data suggest that benign breast disease or fibrocystic disease is most often not associated with proliferation and that these women are not at an increased risk for developing breast cancer.[4] However, it must be noted that "lumpy breasts" may lead to a delay in diagnosis of breast cancer because of an inability of the patient or physician to detect a true malignant lesion.

Endocrine Factors

A number of endocrine factors have been linked to the incidence of breast cancer.[5,6] Many of these relate to the total duration of menstrual life. Early **menarche** (prior to age 12) and late **menopause** (after age 55) increase a women's breast cancer risk. Similarly, investigators have reported that bilateral **oophorectomy** prior to age 35 reduces the relative risk of developing breast cancer. **Nulliparity** and a late age at first birth (greater than or equal to 30 years) have been reported to increase the lifetime risk of developing breast cancer twofold.

Long-term use of hormone-replacement therapy and concurrent use of progestins appear to contribute to breast cancer risk.[7] The use of postmenopausal estrogen-replacement therapy in women with a history of breast cancer generally is considered contraindicated. However, most experts believe that the safety and benefits of low-dose oral contraceptives currently outweigh the potential risks and that changes in the prescribing practice for the use of oral contraceptives are not warranted. Oral contraceptives are known to reduce the risk of ovarian cancer by about 40% and the risk of endometrial cancer by about 60%.

Genetic Factors

Both personal and family histories influence a woman's risk of developing breast cancer. A past medical history for breast cancer is associated with about a fivefold increased risk of

contralateral breast cancer. Cancer of the uterus and ovary also has been associated with an increased risk of the development of breast cancer.

It has been recognized for some time that a family history of breast cancer is associated rather strongly with a woman's own risk for developing the disease. The percentage of all breast cancers in the population that can be attributed to family history range between 6% and 12%.[8] Empirical estimates of the risks associated with particular patterns of family history of breast cancer indicate the following:[8]

1. Having any first-degree relative with breast cancer increases a woman's risk of breast cancer 1.5- to 3-fold, depending on age.
2. The higher relative risk is associated with breast cancer with onset younger than age 45 years in one or more first-degree relatives.
3. Having multiple first-degree relatives affected has been inconsistently associated with elevated risks.
4. Having a second-degree relative affected increases a woman's risk of developing breast cancer by approximately 50% [relative risk (RR) = 1.5].
5. Affected family members on the maternal side and the paternal side contribute similarly to the risk.

In the early 1990s, the *BRCA1* gene on the long arm of chromosome 17 (17q21) was identified as abnormal in a large percentage of hereditary breast and ovarian cancer patients.[9,10] A second breast cancer gene, called *BRCA2*, has been mapped to chromosome 13. Both genes are tumor suppressors. A woman with a strong family history of breast or ovarian cancer, or both, who carries a germ-line mutation of *BRCA1* faces roughly an 85% lifetime risk of breast cancer and a 60% risk of ovarian cancer.[11] Carriers of the *BRCA2* mutation have similar risks for breast cancer but much lower risks for ovarian cancer. Jewish people of eastern European decent (Ashkenazi Jews) have an unusually high (2.5%) carrier rate of germ-line mutations in *BRCA1* and *BRCA2* compared with the rest of the United States population.

There is a commercially available test for screening that should be done under the guidance of a genetic counselor. To date, there are no clear recommendations for carriers of *BRCA1* and *BRCA2* from high-risk families. **Bilateral** total mastectomy does reduce the risk of breast cancer occurrence; however, both breast and ovarian cancer have been reported in patients who have had prophylactic removal of these organs. In *BRCA* carriers who do not opt for surgical prophylaxis, mammography every 6 months is recommended. Because no effective screening for ovarian cancer exists, most experts recommend bilateral oophorectomy at completion of childbearing.

Environmental and Lifestyle Factors

Experimental and epidemiologic evidence suggests an association between breast cancer and the Western diet (high in calories, fat, and cooked meats). Obesity in postmenopausal women and distribution of body fat around the abdominal region also appear to increase the risk of breast cancer. A recent meta-analysis[12] indicates both a modest positive association between alcohol ingestion and breast cancer and a dose-response relationship. Cigarette smoking and augmentation mammoplasty do not appear to increase the risk of breast cancer. Exercise may provide a modest protection against breast cancer.

Radiation is associated with an increased risk of breast cancer in survivors of the atomic bomb, in patients given radiation for postpartum mastitis, in women receiving multiple fluoroscopic examinations during therapy for tuberculosis, and in patients who receive **mediastinal** radiation for malignancies. Interestingly, this risk appears to be confined to exposure to radiation prior to age 40, which suggests that a "window of initiation" for breast cancer occurs at a relatively early age. Exposure to diagnostic x-rays, including annual screening mammography, does not impart a sufficient dose of radiation for clinical concern.

It should be emphasized that more than 60% of women with breast cancer have no identifiable major risk factor, indicating that the search for the etiology of this disease is largely incomplete.

A number of calculators are available on the Internet to estimate a patient's risk of developing breast cancer. The National Cancer Institute (NCI) has an online version of the Breast Cancer Risk Assessment Tool that is considered to be the most authoritative and accurate standard (www.cancer.gov/ bcrisktool). The Breast Cancer Risk Assessment Tool was designed for health professionals to project a women's individualized risk for invasive breast cancer over a 5-year period and over her lifetime.

Patient Encounter, Part 1

BB is a 65-year-old woman who presents with a history of a small, hard lump in the upper outer quadrant of her right breast. This lump has been there for at least 3 months. She reports having mammograms in the past that were normal, but she has not had one in about 3 years. The lump in her breast is not painful. She has no nipple discharge or drainage from that breast, and the skin appears normal. The left breast is normal. She has a history of hypertension and has been postmenopausal for approximately 10 years. She does not smoke and drinks an occasional glass of wine. She has no family history of breast cancer but does have a sister with ovarian cancer at age 58, and her father had prostate cancer at age 85. She began menses at age 10, had two pregnancies (first at age 25) with two healthy daughters, and has taken Prempro since menopause at age 55 (for 10 years).

- What risk factors for breast cancer does this patient have?

PATHOPHYSIOLOGY

The pathologic evaluation of breast lesions serves to establish the histologic diagnosis and to confirm the presence or absence of other factors believed to influence prognosis. These prognostic factors include the presence of necrosis, lymphatic or vascular invasion, nuclear grade, hormone receptor status, proliferative index, amount of **aneuploidy**, and *HER-2/neu* expression.

Invasive Carcinoma

Invasive breast cancers are a histologically heterogeneous group of lesions. Most breast carcinomas are **adenocarcinomas** and are classified on the basis of their microscopic appearance as either ductal or lobular, corresponding to the ducts and lobules of the normal breast. The various histologic types of breast cancer have different prognoses, but it is unknown whether their response to therapy differs because patients in therapeutic trials typically are not stratified according to histologic type. *Infiltrating lobular carcinoma* commonly metastasizes to **meningeal** and **serosal** surfaces and other unusual sites, whereas other types usually metastasize to the bone, brain, or liver.

Noninvasive Carcinoma

As with invasive carcinoma, the noninvasive lesions may be divided broadly into ductal and lobular categories. The widespread use of screening mammography and subsequent biopsy, coupled with recognition of noninvasive breast carcinoma by pathologists, has resulted in a significant increase in the diagnosis of in situ breast cancer during the past decade. A detailed discussion of the biology and appropriate management of noninvasive breast cancer is beyond the scope of this chapter, but some of the more salient characteristics of ductal carcinoma in situ (DCIS) and lobular carcinoma in situ (LCIS) are described below, and the reader is referred to a number of excellent reviews for a more comprehensive discussion.[13,14]

DCIS is seen more frequently than LCIS. It is important to note that carcinoma in situ is treated as cancer. *Simple* or *total mastectomy* (without lymph node dissection) has been the standard treatment of DCIS for several decades. Breast conservation, i.e., wide local excision followed by irradiation of breast tissue, may be an effective alternative to mastectomy. Although radiation following lumpectomy does not appear to change the survival of patients with DCIS, it significantly reduces the incidence of local recurrences and enhances the breast preservation rate in these women. Axillary dissection generally is not indicated because there is only a 1% incidence of axillary node involvement. There is currently no proven benefit for the use of cytotoxic chemotherapy in patients who receive local therapy for DCIS. However, there are subgroups of patients with DCIS, such as hormone-receptor-positive patients, who may benefit from the addition of tamoxifen to lumpectomy plus radiation.[15]

Clinical Presentation and Diagnosis

Common early symptoms include:

- Painless lump (90% of cases) that is:
  - Solitary
  - Unilateral
  - Solid
  - Hard
  - Irregular
  - Nontender
- Stabbing or aching pain (10% of cases) as the first symptom

Uncommon early symptoms include:

- Nipple discharge (3% of women and 20% of men), retraction, or dimpling
- Eczema appearance of the nipple (Paget's carcinoma)
- Prominent skin edema, redness, warmth, and induration of the underlying tissue (inflammatory carcinoma)

Metastatic symptoms: Tissues most commonly involved with metastases are lymph nodes (other than axillary or internal mammary), skin, bone, liver, lungs, and brain. The following symptoms of metastases will be present in about 10% of patients when they first seek treatment:

- Bone pain
- Difficulty breathing
- Abdominal enlargement
- Jaundice
- Mental status changes

Prevention and Early Detection

Current efforts at breast cancer prevention are directed toward the identification and removal of risk factors. Unfortunately, a number of risk factors associated with the development of breast cancer, such as family history of breast cancer or personal history of breast or other gynecologic malignancies, cannot be modified. Isolation and cloning of breast cancer susceptibility genes now allows screening of women with histories suggestive of "breast cancer families" and identification of appropriate candidates for prophylactic bilateral mastectomy. There are currently no absolute indications for prophylactic bilateral mastectomy. This surgery is considered for women at very high risk for the development of breast cancer, particularly if the women's breasts are difficult to evaluate by both physical examination and mammography, and the women have persistent disabling fears that they will be diagnosed with the disease.

The agent currently being used clinically as a breast cancer chemoprevention agent is tamoxifen. In randomized trials of tamoxifen as an adjuvant treatment for breast cancer, women who received tamoxifen also were found to have a reduced incidence of contralateral primary breast carcinomas.[16] A

recent meta-analysis of these tamoxifen chemoprevention trials indicates a consistent benefit in reducing the incidence of estrogen receptor (ER)–positive breast cancers (48%).[17] Tamoxifen's estrogenic effects on the uterus and the coagulation system increase the risk of serious adverse effects that may be critical for patients taking this agent in the prevention setting. Other agents being studied for breast cancer chemoprevention are raloxifene (currently approved to prevent bone loss in postmenopausal women), aromatase inhibitors, and retinoids (synthetic derivative of vitamin A).

The rationale for early detection of breast cancer is based on the clear relationship between stage of breast cancer at diagnosis and the probability of cure. Thus, if all breast cancers could be detected at a very early stage of the disease (i.e., small primary tumor and negative lymph nodes), then more patients with the disease could be cured. Screening guidelines for early detection of breast cancer have been put forward by the American Cancer Society, the United States Preventive Services Task Force, and the National Cancer Institute[18–20] (Table 86–2). These all include recommendations for women at average risk, with some general statements regarding screening for high-risk women as well. ❶ *Nearly 75% of all breast cancer occurs in women 50 years of age or older, and it has been demonstrated conclusively that regular use of screening mammography can reduce mortality from breast cancer by 20% to 40% in this age group. Controversy regarding the use of screening mammography is largely confined to women younger than 50 years of age. After many years of debate, the three available guidelines discussed here recommend mammograms in this age group of women every 1 to 2 years.*[18–20]

Diagnosis

Initial work-up for a woman presenting with a lesion or symptoms suggestive of breast cancer should include a careful history, physical examination of the breast, three-dimensional mammography, and possibly other breast imaging techniques such as ultrasound. Most (80% to 85%) breast cancers can be visualized on a mammogram as a mass, a cluster of calcifications, or a combination of both. Breast biopsy is indicated for a mammographic abnormality that suggests malignancy or for a palpable mass on physical examination.

Clinical Staging

Stage (anatomic extent of disease) is defined on the basis of the primary tumor size ($T_{1–4}$), presence and extent of lymph node involvement ($N_{1–3}$ or $pN_{1–3}$ if pathologic examination of lymph nodes is conducted), and presence or absence of distant metastases ($M_{0–1}$) (Table 86–3). For a more complete description of the staging system, the reader is referred to the guidelines.[21] Although many possible combinations of T and N are possible within a given stage, simplistically, stage 0 represents carcinoma in situ (T_{is}) or disease that has not invaded the basement membrane. Stage I represents small primary tumor without lymph node involvement, and the majority of stage II disease involves regional lymph nodes. Stages I and II are often referred to as *early breast cancer.* It is in these early stages that the disease is curable. Stage III, also referred to as *locally advanced disease,* usually represents a large tumor with extensive nodal involvement in which either node or tumor is fixed to the chest wall. Stage IV disease is characterized by the presence of metastases to organs distant from the primary tumor and is often referred to as *advanced* or *metastatic disease,* as described earlier. Most cancer today presents in early stages, where the prognosis is favorable (Table 86–4).

Prognostic Factors

A number of potential prognostic factors have been identified for breast cancer. *Prognostic factors* are measurements available at diagnosis or time of surgery that in the absence of adjuvant therapy are associated with recurrence rate, death rate, or other clinical outcome.

- *Patient age.* Patients diagnosed at age younger than 35 years have a worse prognosis.
- *Tumor size.* In general, patients with a larger tumor have a worse prognosis.

TABLE 86–2. Guidelines for Early Detection of Breast Cancer

	American Cancer Society[18]	United States Preventive Services Task Force[19]	National Cancer Institute[20]
BSE	Age greater than or equal to 20: risk/benefit discussion	All ages: ±	NR
CBE	Age 20–30: every 3 years Age greater than or equal to 40: every year	All ages: ± (recommended with mammogram)	All ages: every year
Mammogram	Age greater than or equal to 40: interval not designated	Age greater than or equal to 40: every 1–2 years (with or without CBE)	Age 40–49: every 1–2 years Age greater than or equal to 50: every 1–2 years

BSE, breast self-examination; CBE, clinical breast examination; NR, not recommended; ±, insufficient data to recommend for or against.

TABLE 86–3. TNM Stage Grouping for Breast Cancer

Stage	Grouping		
0	T_{is}	N_0	M_0
I	T_1[a]	N_0	M_0
IIA	T_0	N_1	M_0
	T_1[a]	N_1	M_0
	T_2	N_0	M_0
IIB	T_2	N_1	M_0
	T_3	N_0	M_0
IIIA	T_0	N_2	M_0
	T_1[a]	N_2	M_0
	T_2	N_2	M_0
	T_3	N_1	M_0
	T_3	N_2	M_0
IIIB	T_2	N_0	M_0
	T_2	N_1	M_0
	T_2	N_2	M_0
IIIC	Any T	N_3	M_0
IV	Any T	Any N	M_1

[a]T_1 includes T_1mic; tumor (T)
- T_0 No evidence of tumor
- T_{is} Carcinoma in situ or Paget's disease of the nipple with no tumor
- T_1 less than or equal to 2 cm
- T_2 greater than 2–5 cm
- T_3 greater than 5 cm
- T_4 Any size; direct extension to chest wall (excluding pectoral muscle) or skin infiltration

Regional lymph nodes (pN)
- pN_x Regional lymph nodes cannot be assessed
- pN_0 No regional lymph node metastasis histologically
- pN_1 Metastasis in one to three axillary lymph nodes, and/or in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent**
- pN_2 Metastasis in four to nine axillary lymph nodes, or in clinically apparent* internal mammary lymph nodes in the *absence* of axillary lymph node metastasis
- pN_3 Metastasis in ten or more axillary lymph nodes, or in infraclavicular lymph nodes, or in clinically apparent* ipsilateral internal mammary lymph nodes in the *presence* of 1 or more positive axillary lymph nodes; or in more than 3 axillary lymph nodes with clinically negative microscopic metastasis in internal mammary lymph nodes; or in ipsilateral supraclavicular lymph nodes

* *Clinically apparent* is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination.
***Not clinically apparent* is defined as not detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination.

Metastasis (M)
- M_0 No distant metastases
- M_1 Distant metastasis

TABLE 86–4. Estimated Stage at Presentation and 5-Year Disease-Free Survival (DFS): Breast Cancer

	Percentage of Total Cases	5-Year DFS[a] (%)
Stage I	40	70–90
Stage II	40	50–70
Stage III	15	20–30
Stage IV	5	0–10[b]

[a]With current conventional local and systemic therapy.
[b]Patients in stage IV are rarely free of disease; however, 10% to 20% of these patients may survive with minimal disease for 5 to 10 years.

Patient Encounter, Part 2: Medical History and Physical Examination

PMH
Hypertension for 15 years, currently controlled.

Endocrine History
Menarche age 10; menopause age 55 (natural); first child age 25; $G_2P_2A_0$. Last Pap smear 10 years ago. HRT with Prempro since age 55 (10 years). No other exogenous hormone exposure.

Meds
- Valsartan 160 mg PO daily
- Prempro 1 tablet PO daily

ROS
(+) lump in right breast; otherwise (–).

PE
- **Gen:** Obese 65 year-old Caucasian woman who appears her stated age in NAD.
- **VS:** BP 135/76, P 78, RR 18, T 38.1°C (100.6°F); ht 5 ft, 4 in, wt 100 kg
- **Breast:** Right: Hard 2.4 × 3.0 cm mass in upper outer quadrant without associated erythema, dimpling, or skin changes, not fixed to skin, no ulceration. No palpable lymph nodes in axilla. Left: Without masses or lymphadenopathy.

Labs
All within normal limits.

CXR: Lungs are clear.

- What information is suggestive of breast cancer?
- What other tests do you need to make a diagnosis and develop a treatment plan?

- *Nuclear grade* describes the size and shape of the nucleus in tumor cells and the percentage of tumor cells that are dividing. A high nuclear grade signifies that a tumor is growing quickly and indicates a worse prognosis.
- *Lymph node involvement*. Patients with node-positive disease have a worse prognosis.
- *Hormone-receptor status*. Patients with negative-estrogen-receptor (ER) and negative-progesterone-receptor (PR) tumors have a worse prognosis.
- *HER-2/neu protein expression*. Patients with *HER-2/neu* overexpression have a worse prognosis.

TREATMENT: EARLY BREAST CANCER

Desired Outcome

❷ *Most patients presenting with breast cancer today have either an in situ tumor, a small tumor with negative lymph nodes (stage I), or a small stage II cancer. The goal of therapy in early breast cancer is curative.* Surgery alone can cure most, if not all, patients with in situ cancers and approximately half of all patients with stage II cancers.

Nonpharmacologic Local-Regional Therapy

The choice of surgical procedures has changed drastically over the past 50 years. ❸ *Current surgical management options for early invasive breast cancer include the modified radical mastectomy (also termed total mastectomy with* ***ipsilateral*** *axillary lymph node dissection) and breast conservation*. In the modified radical mastectomy, the pectoralis minor muscle may be excised, divided, or left intact, and more important, there may be variation in the extent of axillary lymph node dissection, ranging from sampling to full dissection. It is important to note that in the elderly, patients with comorbid conditions, patients with particularly favorable tumors, or patients whose adjuvant therapy likely would not be affected by node status, axillary dissection can be considered optional. Breast conservation consists of lumpectomy, also referred to as *segmental mastectomy* or *partial mastectomy,* and is defined as excision of the primary tumor and adjacent breast tissue, followed by radiation therapy to reduce the risk of local recurrence. Removal of level I/II axillary lymph nodes is recommended for completeness of staging and prognostic information. The National Institutes of Health (NIH) Consensus Conference on the Treatment of Early Stage Breast Cancer addressed the roles of modified radical mastectomy versus breast conservation and concluded that primary therapy for breast cancer stages I and II should be *breast conservation.*[22] The reason given for favoring breast conservation therapy is that it achieved similar results to more extensive surgical procedures and had superior results cosmetically.

In most instances, external-beam radiation therapy used in conjunction with breast-conserving procedures involves 4 to 6 weeks of radiation therapy directed to the breast tissue to eradicate residual disease. Complications associated with radiation therapy to the breast are minor and include reddening and erythema of the breast tissue and subsequent shrinkage of total breast mass beyond that predicted on the basis of breast tissue removal. Some clinical situations also require postmastectomy radiation therapy as well (see section on locally advanced breast cancer).

There are several contraindications to breast conservation that must be considered when selecting patients:

- Multiple sites of cancer within the breast
- Pregnancy (patient cannot receive radiation)
- Inability to attain negative pathologic margins on the excised breast specimen
- Preexisting collagen-vascular diseases (e.g., scleroderma and systemic lupus erythematosus)
- Diffuse malignant-appearing microcalcifications on mammogram
- Prior radiation treatment to the breast or chest wall
- Large tumor volume in a woman with small breasts (better cosmetic results often can be obtained with mastectomy and reconstruction)

The importance of stage I/II axillary dissection is being challenged. Although highly accurate, its morbidity is significant, with an acute complication rate as high as 20% to 30% and rates of chronic lymphedema also on the order of 20% to 30%.[23,24] A new procedure involving lymphatic mapping and sentinel lymph node biopsy is becoming more acceptable at many academic centers across the United States.[25] The sentinel lymph node is the first lymph node that drains a cancer. Injection of a dye around the primary breast tumor results in identification of the sentinel lymph node in the majority of patients, and the status of this lymph node may predict the status of the remaining nodes in the nodal basin. A sentinel lymph node can be identified in 90% of patients and can accurately predict the status of the remaining axillary nodes in 95% of patients.[26]

Pharmacologic Systemic Adjuvant Therapy

Unfortunately, breast cancer cells often spread by contiguity, lymph channels, and through the blood to distant sites. This often occurs early in the breast cancer growth, and deposits of tumor cells form in distant sites that cannot be detected with current diagnostic methods and equipment (micrometastases). *Systemic adjuvant therapy* is defined as the administration of systemic therapy following definitive local therapy (i.e., surgery, radiation, or a combination of these) when there is no evidence of metastatic disease but a high likelihood of disease recurrence. ❹ *Most published results confirm that chemotherapy (in all patients), hormonal therapy (in patients with hormone-receptor-positive disease), or both result in improved disease-free survival (DFS) and/or overall survival (OS) for patients with early-stage brease cancer.*

An NIH Consensus Development Conference Statement[22] advises that adjuvant hormonal therapy should be recommended to women whose tumors contain hormone-receptor protein regardless of age, menopausal status, involvement of axillary lymph nodes, or tumor size. They also support a benefit of adjuvant chemotherapy for most women with lymph node metastases or with primary breast cancers larger than 1 cm in diameter (both node-negative and node-positive).[22]

In 2005, a group of international experts in the treatment of breast cancer met at the ninth St. Gallen meeting in Switzerland.[27] At the conclusion of the conference, a consensus panel of experts reviewed and modified its previous guidelines and recommendations for selection of adjuvant systemic therapies. The panel decided that endocrine responsiveness was the most important patient characteristic to consider. They developed three categories: endocrine responsive, endocrine nonresponsive, and tumors of uncertain endocrine responsiveness. These categories then are divided by menopausal status. Finally, the panel divided patients into low-, intermediate- and high-risk categories.

1. *Low risk:* Node-negative and all the following: pathologic tumor size of 2 cm or less, or grade 1, absence of peritumoral vascular invasion, *HER2/neu* gene neither overexpressed nor amplified, and age 35 years or older

2. *Intermediate risk*
   - Node-negative and at least one of the following: pathologic tumor size greater than 2 cm, or grade 2 to 3, presence of peritumoral vascular invasion, *HER2/neu* gene overexpressed or amplified, and age older than 35 years
   - Node positive (1–3 involved nodes) and *HER2/neu* gene overexpressed or amplified
3. *High risk*
   - Node positive (1–3 involved nodes) and *HER2/neu* gene overexpressed or amplified
   - Node positive (4 or more involved nodes)

In general, the panel recommended

1. Chemotherapy for patients with endocrine-nonresponsive disease.
2. Endocrine therapy is primary therapy for endocrine-responsive disease, with chemotherapy being added for some intermediate- and all high-risk patients
3. Both endocrine therapy and chemotherapy are used in patients with an uncertain endocrine response category unless the patients are low risk, in which case they may just try endocrine therapy alone.

The National Comprehensive Cancer Network (NCCN) also has developed practice guidelines for the treatment of breast cancer.[28] Their most recent guidelines differ a bit from the St. Gallen expert consensus guidelines because they stratify selection of adjuvant therapy based on both hormone responsiveness and *HER2/neu* level of expression. For patients who have *HER2/neu* overexpressed tumors, the NCCN guidelines recommend that biologic therapy with trastuzumab be added to the adjuvant regimen.

The use of preoperative systemic therapy is gaining favor in both early-stage and locally advanced breast cancers. This approach to therapy, referred to as *neoadjuvant* or *primary systemic therapy*, most often consists of chemotherapy but in special circumstances also may include hormonal therapy (e.g., in inoperable patients with significant comorbidities). The advantages of preoperative systemic therapy include (1) decrease in the size of the tumor to minimize surgery and (2) to determine response to chemotherapy/hormone therapy in vivo (an important prognostic indicator). While this approach to therapy generally is reserved for patients with inoperable tumors (locally advanced), early-stage breast cancer patients who meet the criteria for breast-conserving therapy except for the size of the tumor may be considered for preoperative systemic therapy in order to decrease the size of the tumor, allowing for less radical surgery and better cosmetic results.

Adjuvant Chemotherapy

❺ *Cytotoxic drugs that have been used alone and in combination as adjuvant therapy in breast cancer include doxorubicin, epirubicin, cyclophosphamide, methotrexate, fluorouracil, paclitaxel, docetaxel, melphalan, prednisone, vinorelbine, and vincristine.* The most common combination chemotherapy regimens employed in the adjuvant and metastatic setting are listed in Table 86–5. The dose-limiting toxicities and other significant toxicities are listed for each chemotherapeutic agent in Table 86–6.

The basic principle of adjuvant therapy for any cancer type is that the regimen with the highest response rate in advanced disease should be the optimal regimen for use in the adjuvant setting. Early administration of effective combination chemotherapy at a time when the tumor burden is low should increase the likelihood of cure and minimize the emergence of drug-resistant tumor cell clones. Anthracyclines (e.g., doxorubicin and epirubicin) historically have been referred to as the most active class of chemotherapy agents in the treatment of metastatic breast cancer. This has led to the assumption that anthracycline-containing regimens are associated with a higher cure rate than non-anthracycline-containing regimens when used in the adjuvant setting.

The taxanes (e.g., paclitaxel and docetaxel) are a newer class of agents that rival the anthracyclines in their activity in metastatic breast cancer, becoming (arguably) the most active class of chemotherapy for this disease.

Although the optimal duration of adjuvant chemotherapy administration is unknown, it appears to be on the order of 12 to 24 weeks and may depend on the regimen being used. Chemotherapy is usually initiated within 3 weeks of surgical removal of the primary tumor. Dose intensity and dose density appear to be critical factors in achieving optimal outcomes in adjuvant breast cancer therapy. *Dose intensity* is defined as the amount of drug administered per unit of time and typically is reported in milligrams per square meter of body surface area per week (mg/m^2 per week). Increasing dose, decreasing time, or both can increase dose intensity. *Dose density* is equivalent to the concept of increasing dose intensity but not by increasing the amount of drug given, as occurs with dose escalation, but instead by decreasing the time between treatment cycles. Reducing the dose for standard treatment regimens should be avoided unless necessitated by severe toxicity. On the other hand, increasing doses beyond those contained in standard treatment regimens does not appear to add benefit because there is a threshold for dosing adjuvant chemotherapy above which only additional toxicity is seen without any improvement in patient outcomes.

The short-term toxic effects of chemotherapy used in the adjuvant setting generally are well tolerated. Although a number of investigators have demonstrated a reduction in quality of life, most patients are able to maintain a reasonable level of function and emotional and social well-being during treatment.[30] In general, supportive therapy of the patient receiving systemic adjuvant chemotherapy has improved in the past decade. Increased attention to the impact of symptoms on quality of life may account for some of this improvement. In addition, serotonin-antagonist antiemetics have become available to assist in

TABLE 86–5. Common Chemotherapy Regimens for Breast Cancer

Adjuvant Chemotherapy Regimens

AC
Doxorubicin 60 mg/m^2 IV, day 1
Cyclophosphamide 600 mg/m^2 IV, day 1
Repeat cycles every 21 days for 4 cycles[a]

FAC[w]
Fluorouracil 500 mg/m^2 IV, days 1 and 4
Doxorubicin 50 mg/m^2 IV continuous infusion over 72 hours[w]
Cyclophosphamide 500 mg/m^2 IV, day 1
Repeat cycles every 21–28 days for 6 cycles[c]

CAF
Cyclophosphamide 600 mg/m^2 IV, day 1
Doxorubicin 60 mg/m^2 IV bolus, day 1
Fluorouracil 600 mg/m^2 IV, days 1 and 8
Repeat cycles every 28 days for 6 cycles[e]

FEC
Fluorouracil 500 mg/m^2 IV, day 1
Epirubicin 100 mg/m^2 IV bolus, day 1
Cyclophosphamide 500 mg/m^2 IV, day 1
Repeat cycle every 21 days for 6 cycles[g]

CEF
Cyclophosphamide 75 mg/m^2 orally on days 1–14
Epirubicin 60 mg/m^2 IV, days 1 and 8
Fluorouracil 600 mg/m^2 IV, days 1 and 8
Repeat cycles every 21 days for 6 cycles (requires prophylactic antibiotics or growth factor support)[i]

AC → paclitaxel (CALGB 9344)
Doxorubicin 60 mg/m^2 IV, day 1
Cyclophosphamide 600 mg/m^2 IV, day 1
Repeat cycles every 21 days for 4 cycles
Followed by:
Paclitaxel 175 mg/m^2 IV over 3 hours
Repeat cycles every 21 days for 4 cycles[b]

TAC (BCIRG 001)
Docetaxel 75 mg/m^2 IV, day 1
Doxorubicin 50 mg/m^2 IV bolus, day 1
Cyclophosphamide 500 mg/m^2 IV, day 1
(Doxorubicin should be given first)
Repeat cycles every 21–28 days for 6 cycles[d]

Paclitaxel → FAC[w]
Paclitaxel 80 mg/m^2 per week IV over 1 hour every week for 12 weeks
Followed by:
Fluorouracil 500 mg/m^2 IV, days 1 and 4
Doxorubicin 50 mg/m^2 IV continuous infusion over 72 hours
Cyclophosphamide 500 mg/m^2 IV, day 1
Repeat cycles every 21–28 days for 4 cycles[n]

CMF
Cyclophosphamide 100 mg/m^2 per day orally, days 1–14
Methotrexate 40 mg/m^2 IV, days 1 and 8
Fluorouracil 600 mg/m^2 IV, days 1 and 8
Repeat cycles every 28 days for 6 cycles[h]
or
Cyclophosphamide 600 mg/m^2 IV, day 1
Methotrexate 40 mg/m^2 IV, day 1
Fluorouracil 600 mg/m^2 IV, days 1 and 8
Repeat cycles every 28 days for 6 cycles[i]

Dose-dense AC → paclitaxel
Doxorubicin 60 mg/m^2 IV bolus, day 1
Cyclophosphamide 600 mg/m^2 IV, day 1
Repeat cycles every 14 days for 4 cycles (must be given with growth factor support)
Followed by:
Paclitaxel 175 mg/m^2 IV over 3 hours
Repeat cycles every 14 days for 4 cycles (must be given with growth factor support)[k]

Metastatic Single-Agent Chemotherapy

Paclitaxel
Paclitaxel 175 mg/m^2 IV over 3 hours
Repeat cycles every 21 days[l]
or
Paclitaxel 80 mg/m^2 per week IV over 1 hour
Repeat dose every 7 days[m]

Docetaxel
Docetaxel 60–100 mg/m^2 IV over 1 hour
Repeat cycles every 21 days[o]
or
Docetaxel 30–35 mg/m^2 per week IV over 30 minutes
Repeat dose every 7 days[p]

Vinorelbine
Vinorelbine 30 mg/m^2 IV, days 1 and 8
Repeat cycles every 21 days
or
Vinorelbine 25–30 mg/m^2 per week IV
Repeat cycles every 7 days (adjust dose based on absolute neutrophil count; see product information)[n]

Gemcitabine
Gemcitabine 600–1000 mg/m^2 per week IV, days 1, 8, and 15
Repeat cycles every 28 days (may need to hold day 15 dose based on blood counts)[q]

(*Continued*)

TABLE 86–5. Common Chemotherapy Regimens for Breast Cancer *(Continued)*

Metastatic Single-Agent Chemotherapy (*continued*)

Capecitabine
Capecitabine 2000–2500 mg/m^2 per day orally, divided twice daily for 14 days
Repeat cycles every 21 days[q,r]

Liposomal doxorubicin
Liposomal doxorubicin 30–50 mg/m^2 IV over 90 minutes
Repeat cycles every 21–28 days[s]

Metastatic Combination Chemotherapy Regimens

Docetaxel + capecitabine
Docetaxel 75 mg/m^2 IV over 1 hour, day 1
Capecitabine 2000–2500 mg/m^2 per day orally divided twice daily for 14 days
Repeat cycles every 21 days[t]

Epirubicin + docetaxel[x]
Epirubicin 70–90 mg/m^2 IV bolus
Followed by:
Docetaxel 70–90 mg/m^2 IV over 1 hour
Repeat cycles every 21 days[v]

Doxorubicin + docetaxel[x]
Doxorubicin 50 mg/m^2 IV bolus, day 1
Followed by:
Docetaxel 75 mg/m^2 IV over 1 hour, day 1
Repeat cycles every 21 days[u]

[w]FAC also may be given with bolus doxorubicin administration, and the fluorouracil dose is then given on days 1 and 8.
[x]Paclitaxel also may be given concurrently with doxorubicin ***or*** epirubicin as a combination regimen. Pharmacokinetic interactions make these regimens more difficult to give.

managing chemotherapy-induced nausea and vomiting, and colony-stimulating factors often are helpful in preventing febrile neutropenia, particularly in elderly patients or patients receiving high-dose and dose-dense chemotherapy regimens. A number of side effects are common with the regimens employed, and patients should be counseled appropriately regarding the likelihood of alopecia, weight gain, and fatigue. Patients who are menstruating usually experience a cessation of menses that may or may not return. Along with cessation of menses are accompanying signs and symptoms of menopause. Deep vein thrombosis has been reported in women receiving combination chemotherapy regimens.[31] A recent study estimated that 1 to 10 of 10,000 patients treated for 6 months with cyclophosphamide-based regimens might be expected to have leukemia within 10 years of diagnosis of breast cancer.[32] Cardiomyopathy induced by doxorubicin occurs less than 1% of the time in women whose total dose of doxorubicin is less than 320 mg/m^2.[33] It should be noted that epirubicin in the adjuvant setting is given at a dose of 100 to 120 mg/m^2.[34] At this dose, epirubicin has an equal chance of causing cardiomyopathy as standard doxorubicin doses when both agents are given as bolus or short infusions. Taxanes often are associated with hypersensitivity reactions, peripheral neuropathy, and/or myalgias and arthralgias for a few days following the infusion.

It is important to note that the magnitude of survival benefit for chemotherapy appears to be small, with an absolute reduction in mortality of only 5% at 10 years for patients with negative axillary lymph nodes and 10% for patients with positive axillary lymph nodes. In addition, there is currently no means to identify patients who will attain this survival benefit. However,

TABLE 86–6. Toxicities of Common Chemotherapies Used for Breast Cancer

Class	Drug	Dose-Limiting Toxicities	Other Toxicities
Anthracyclines	Doxorubicin, epirubicin	Myelosuppression, cardiomyopathy	Alopecia, nausea, vomiting, stomatitis, ulceration & necrosis with extravasation, red-colored urine, radiation-recall effect
	Liposomal doxorubicin	Myelosuppression, palmar-plantar erythrodysesthesia (hand-foot syndrome)	Alopecia, infusion reactions, stomatitis, fatigue, nausea, vomiting
Taxanes	Paclitaxel	Neutropenia, peripheral neuropathy	Alopecia, fluid retention, myalgia, skin reactions, ulceration & necrosis with extravasation, bradycardia, stomatitis, hypersensitivity reactions
	Docetaxel	Myelosuppression, severe fluid retention	Alopecia, fatigue, stomatitis, nausea, vomiting, diarrhea, peripheral neuropathy, nail disorder, skin reactions, hypersensitivity reactions
Antimetabolites	Capecitabine	Diarrhea, palmar-plantar erythrodysesthesias (hand-foot syndrome)	Myelosuppression, stomatitis, nausea, vomiting
	Gemcitabine	Myelosuppression (especially thrombocytopenia)	Flulike syndrome (fever, chills, myalgias, & arthralgias), nausea
	Fluorouracil	Myelosuppression	Stomatitis, diarrhea, alopecia
	Methotrexate	Myelosuppression, stomatitis	Diarrhea, nausea, vomiting, renal toxicity
Vinca alkaloids	Vinorelbine	Myelosuppression	Fatigue, nausea, vomiting, ulceration & necrosis with extravasation
Alkylating agents	Cyclophosphamide	Myelosuppression, hemorrhagic cystitis	Alopecia, stomatitis, amenorrhea, aspermia, secondary leukemias

two investigators report that most patients with breast cancer would accept severe toxicity from treatment to achieve as little as a 1% to 5% improvement in survival.[35,36] Therefore, in the absence of the ability to predict who will benefit, it is likely that most patients with stage I and stage II breast cancer will choose an adjuvant chemotherapy treatment. The optimal chemotherapy regimen for use in the adjuvant setting has yet to be identified and depends on many patient and tumor characteristics.

Adjuvant Biologic Therapy

Trastuzumab is a monoclonal antibody directed against the *HER-2/neu* receptor. *HER-2/neu* is a member of the erbB (or HER) growth factor receptor family and is expressed at low levels in the epithelial cells of normal breast tissue. The overexpression of *HER-2/neu* is associated with increased transmission of growth signals that control aspects of cell growth and division. Most experts would agree that women whose tumors overexpress *HER-2/neu* appear to be relatively resistant to alkylating agent–based adjuvant therapy, and they might derive greater benefit from an anthracycline-based adjuvant therapy regimen.[29] *HER-2/neu* positively predicts response to trastuzumab therapy but is also considered a negative prognostic factor. Currently, the use of trastuzumab is indicated for treatment of adjuvant and metastatic breast cancer in patients who have tumors that overexpress *HER-2/neu*.[28] It is important to note that trastuzumab therapy should not be given concurrently with the anthracyclines because of an increased risk of cardiotoxicity (see section on metastatic breast cancer). Doses and common toxicities for trastuzumab are listed in Table 86–7.

TABLE 86–7. Biologic Therapy Used for Breast Cancer

Drug	Dose	Side Effects
Trastuzumab	4 mg/kg IV over 90 minutes on day 1 followed by 2 mg/kg over 90 minutes (30 minutes if no infusion-related reactions) once weekly ***or*** 8 mg/kg IV over 90 minutes on day 1 followed by 6 mg/kg IV over 90 minutes every 3 weeks	Infusion reactions (fever, chills, rigors), nausea, vomiting, pain at tumor sites, headaches, dizziness, dyspnea, hypotension, heart failure
Bevacizumab	10 mg/kg IV on days 1 and 15, cycled every 28 days (paclitaxel 90 mg/m^2 IV on days 1, 8 and 15)	Hypertension, gastrointestinal perforation, impaired wound healing, bleeding, thromboembolic events, proteinuria

Adjuvant Endocrine Therapy

❺ *Hormonal therapies that have been studied in the treatment of primary or early breast cancer include antiestrogens, oophorectomy, ovarian irradiation, luteinizing hormone–releasing hormone (LHRH) agonists, and aromatase inhibitors.*

Hormone receptors are used clinically as indicators of prognosis and to predict response to hormone therapy. Hormone receptors are cytoplasmic proteins that transmit signals to the nucleus of the cell for growth and proliferation. The hormone receptors clinically useful in discussions of breast cancer include the estrogen receptor (ER) and the progesterone receptor (PR). The presence of these proteins in the primary tumor (or less often metastases) is measured routinely by enzyme-linked immunochemical assays and radioassays (enzyme-linked immunosorbent assay). About 50% to 70% of patients with primary or metastatic breast cancer have hormone-receptor-positive tumors. Hormone-receptor positivity is associated with a superior response to hormone therapy and a longer disease-free interval between primary and subsequent metastatic disease and overall a more favorable prognosis. Hormone-receptor-positive tumors are more common in postmenopausal patients than in premenopausal patients. Many experts suggest that breast cancer in postmenopausal women is substantively different from that occurring in premenopausal women.

Tamoxifen traditionally was the "gold standard" adjuvant hormonal therapy and has been used in the adjuvant setting for three decades. Tamoxifen is antiestrogenic in breast cancer cells, but it appears to have estrogenic properties in other tissues and organs.[37,38] Newer information confirms that tamoxifen and other similar drugs have many estrogenic and antiestrogenic effects that depend on the tissue and the gene in question, and they are more appropriately called *selective estrogen receptor modulators* (SERMs). Women receiving adjuvant tamoxifen therapy have a reduction in recurrence and mortality compared with women not receiving adjuvant tamoxifen therapy.[16] This observation, coupled with evidence of tamoxifen's tolerability, including beneficial estrogenic effects on the lipid profile and bone density, led to tamoxifen being the hormonal agent of choice.

Adjuvant tamoxifen therapy generally is initiated shortly after surgery or as soon as pathology results are known and the decision to administer tamoxifen as adjuvant therapy is made. The administration of tamoxifen should be limited to administration after completion of chemotherapy based on results from a study that randomized patients to receive chemotherapy for six cycles with concurrent tamoxifen, followed by continued tamoxifen for a total of 5 years, or chemotherapy with sequential tamoxifen for 5 years.[39] After a median follow-up of 8.5 years, the administration of sequential tamoxifen resulted in an estimated DFS advantage of 18% [hazard ratio (HR) = 1.18] compared with the concurrent use of tamoxifen with chemotherapy.[39] It is believed the growth-inhibitory effect of tamoxifen therefore may diminish the cytotoxic effect of chemotherapy, resulting in subsequent recurrence of disease in women who received the two agents concurrently.

The optimal duration of tamoxifen therapy (20 mg/day) in the adjuvant setting is currently defined as 5 years. Studies examining prolonged administration (e.g., 10 years) have failed to demonstrate any advantage and may, in fact, be associated with a slightly worse survival.[40] Owing to the potential serious side effects of tamoxifen, all patients must be counseled properly about warning signs of endometrial cancer (i.e., vaginal bleeding or groin pain/pressure) and thromboembolism (i.e., chest pain, trouble breathing, changes in vision, one-sided weakness, or pain/swelling in the legs).

Toremifene is a recently marketed antiestrogen whose primary advantage is a lower estrogenic:antiestrogenic ratio than tamoxifen (based on laboratory data).[41] Toremifene (60 mg orally daily) has been found to have efficacy similar to that of tamoxifen in metastatic disease and a generally similar side-effect profile.[42] Currently, toremifene is indicated as an alternative to tamoxifen in patients with metastatic breast cancer, but studies are ongoing that evaluate its safety and efficacy in the adjuvant setting.

In premenopausal women, the use of LHRH agonists or other means of ovarian ablation have been shown to provide benefit in the adjuvant setting.[43] The use of goserelin (an LHRH agonist), alone or with tamoxifen, has been compared with standard chemotherapy (CMF) for six cycles. As a single agent, goserelin appears to provide similar benefit to CMF for six cycles for node-positive, ER-positive premenopausal breast cancer patients.[44] In another trial, the combination of goserelin and tamoxifen was compared with CMF for six cycles.[45] After a median follow-up of 6 years, this trial demonstrated a significant advantage of endocrine therapy in terms of DFS over chemotherapy alone. Retrospective reviews have found that premenopausal women who cease to menstruate with chemotherapy may have a better survival than women who continue to menstruate.[46] Therefore, the role of an LHRH agonist after chemotherapy in women who continue to menstruate is being investigated.

In postmenopausal women, recently reported evidence supporting the use of aromatase inhibitors in the adjuvant setting is intriguing and may usurp the role of tamoxifen. Three different approaches to therapy have been undertaken with these new agents: (1) direct comparison with tamoxifen for adjuvant hormonal therapy, (2) sequential use after 5 years of adjuvant tamoxifen therapy, and (3) sequential use after 2 to 3 years of adjuvant tamoxifen. Based on results of several studies, it has been concluded that therapy for postmenopausal women with ER-positive breast cancer should include an aromatase inhibitor.[27,47] It is still unclear if the aromatase inhibitor should be used instead of tamoxifen or sequentially after receiving tamoxifen for 2 to 5 years.[27] Concerns surrounding loss of bone density, changes in blood lipids, and cardiac and vascular disease require further study.[27]

Successful coadministration of bisphosphonates with the aromatase inhibitors has been accomplished in many patients in the metastatic setting. The three available aromatase inhibitors are exemestane, anastrozole, and letrozole.

TREATMENT: LOCALLY ADVANCED BREAST CANCER (STAGE III)

Desired Outcome

Locally advanced cancer breast cancer generally refers to breast carcinomas with significant primary tumor and nodal disease but in which distant metastases cannot be documented. A wide variety of clinical scenarios can be seen within this group of patients, including neglected tumors that have spread locally and inflammatory breast cancers that are a unique clinical entity. Many locally advanced breast cancers are diagnosed in patients who have had symptoms for months to years and have neglected to seek medical attention. Patients with inflammatory breast cancer often are treated inappropriately for cellulitis with antibiotics for several weeks to months.

Treatment of stage III breast cancer generally consists of a combination of surgery, radiation, and chemotherapy administered in an aggressive approach. The natural history of locally advanced breast cancer suggested that even when local-regional control was accomplished, systemic relapse and death from breast cancer occurred eventually in most patients.[48] This led to interest in the use of neoadjuvant or primary chemotherapy in locally advanced breast cancer, as discussed previously. This approach to therapy renders inoperable tumors resectable and can increase rates of breast-conserving therapy. Theoretical advantages also include potential benefits related to early initiation of systemic therapy, delivery of drugs through an intact vasculature, in vivo assessment of response to therapy, and the opportunity to study the biologic effects of the systemic treatment. However, this approach to therapy also results in a loss of standard, well-validated pathologic prognostic markers, such as initial tumor size and the number of axillary lymph nodes involved. Also, as discussed earlier, OS with adjuvant compared with neoadjuvant chemotherapy is similar, making either approach reasonable for a patient with operable breast cancer.

Pharmacologic Therapy

❻ *For patients with inoperable breast cancer, including inflammatory breast cancer, the initial approach to therapy should be chemotherapy with the goal of achieving resectability.* After neoadjuvant chemotherapy, most tumors respond with more than a 50% decrease in tumor size; about 70% of patients experience downstaging. Chemotherapy regimens used in this setting are similar to those used in the adjuvant setting. Supporting evidence for each individual regimen differs, but most of the available data support the use of anthracycline-containing regimens, incorporation of the taxanes in some manner, and other approaches to improve dose density or dose intensity. For more details regarding the specific regimens, the reader is referred to a recently published review.[48] Neoadjuvant endocrine therapy may be an option for patients who have unresectable hormone-receptor-positive tumors who are unable to receive chemotherapy (e.g., multiple comorbid conditions). In terms of local therapy, this usually follows chemotherapy, and the extent of surgery will be determined by response to chemotherapy, the wishes of the patient, and the cosmetic results likely to be achieved. Many patients may be able to have breast-conserving surgery if an acceptable response to chemotherapy is achieved. Adjuvant radiation therapy should be administered to all locally advanced breast cancer patients to minimize local recurrences regardless of the type of surgery used for that individual patient (e.g., mastectomy or segmental mastectomy). Inoperable tumors that are unresponsive to systemic chemotherapy may require radiation therapy for local management and may or may not be eligible for surgical resection after that radiation. Such patients are not seen commonly, but they have a very poor prognosis. For most patients in this category, cure is still the primary goal of therapy and can be achieved in a large number of patients when all treatment modalities are employed.

TREATMENT: METASTATIC BREAST CANCER (STAGE IV)

Desired Outcome

The goal of therapy with early and locally advanced breast cancer is to cure the disease. ❼ *Breast cancer is currently incurable after it has advanced beyond local-regional disease. The goal of treatment of metastatic breast cancer is to improve symptoms, maintain quality of life, and extend survival.* Thus it is important to choose therapy with good activity while minimizing toxicities. Treatment of metastatic breast cancer with either cytotoxic or endocrine therapy often results in regression of disease and improvements in quality of life.

General Approach to Treatment

The choice of therapy for metastatic disease is based on the site of disease involvement and presence or absence of certain characteristics (i.e., hormonal status of the primary tumor and disease location). For example, patients who experience a long DFS following local-regional therapy or have disease that is located primarily in the bone or soft tissue likely will respond to endocrine therapy. Patients with asymptomatic visceral involvement (e.g., liver or lung) may be candidates for hormonal therapy depending on the clinical circumstance (generally

hormones work more slowly than chemotherapy). ❽ *Patients who are hormone-receptor-positive generally will receive initial endocrine therapy followed by combination chemotherapy when endocrine therapy fails.* ❾ *Patients who respond to initial endocrine therapy often respond to a second (or even third) hormonal manipulation.* Response rate is lower and duration of response is shorter with second (and third) hormonal manipulations. Patients are treated sequentially with endocrine therapy until their tumors cease to respond, at which time cytotoxic chemotherapy can be given. Between 50% and 60% of ER-positive patients and 75% and 80% of ER- and PR-positive patients will respond to hormonal therapy, whereas those with ER- and PR-negative tumors have a less than 10% response rate. Thus the largest factor determining choice of endocrine versus cytotoxic chemotherapy is the presence of hormone receptors in the primary breast tumor.

Patients who are hormone-receptor-negative with rapidly progressive or symptomatic disease involving the liver, lung, or central nervous system or those having progressed on initial endocrine therapy usually are treated initially with cytotoxic chemotherapy. ❿ *Chemotherapy will result in an objective response in about 50% to 60% of patients previously unexposed to chemotherapy.* Most patients have partial response, and complete disappearance of disease occurs in fewer than 20% of patients treated. Median duration of response is 5 to 12 months, although some patients will have an excellent response to an initial course of chemotherapy and may live 5 to 10 years without evidence of disease. In general, survival of patients after treatment with commonly used drug combinations for metastatic breast cancer is a median of 14 to 33 months. The response rate to second- and third-line combination chemotherapy varies from 20% to 40% depending on the previous chemotherapy regimens the patient has received. Combinations of different hormonal therapies or chemotherapy plus hormones are not employed in the setting of metastatic breast cancer owing to the lack of increased efficacy and evidence of increased toxicity. *Patients with tumors that have HER2/neu overexpression should be considered for treatment with trastuzumab, alone or with chemotherapy.*

Pharmacologic Systemic Therapy

Endocrine Therapy

The pharmacologic goals of endocrine therapy for breast cancer are either to decrease circulating levels of estrogen and/or to prevent the effects of estrogen at the breast cancer cell (targeted therapy) through blocking the hormone receptors or downregulating the presence of those receptors. Achievement of the first goal depends on the menopausal status of the patient, but achievement of the second goal is independent of menopausal status. Many endocrine therapies are available to target either goal of therapy, and combination studies also have been conducted in an attempt to combine differing mechanisms of action and improve outcomes. Unfortunately, combinations have not demonstrated any efficacy benefits but have increased toxicity. Therefore, combinations of endocrine agents for breast cancer are not recommended outside the context of a clinical trial. Patients often are treated with a series of endocrine agents, frequently over several years, before chemotherapy is considered.

Until recently, there was little evidence that the response or survival benefit from one endocrine therapy was clearly superior to that achieved with other therapies. Given this equality in efficacy, the choice of a particular endocrine therapy was based primarily on toxicity (Table 86–8). Based on these criteria, tamoxifen is the preferred initial agent when metastases are present. An exception to this occurs when the patient is receiving adjuvant tamoxifen at the time or within 1 year of occurrence of metastatic disease.

Over the past decade, new information has been published regarding the use of a new generation of aromatase inhibitors. These data have changed the way we treat metastatic breast cancer, as well as early-stage breast cancer (as noted previously). In postmenopausal and castrated women, the main source of estrogen is derived from the peripheral conversion of androstenedione, produced by the adrenal gland, into estrone and estradiol. This conversion requires the enzyme aromatase. Aromatase also catalyzes the conversion of androgens to estrogens in the ovary in premenopausal women and in extraglandular tissue, including the breast itself, in postmenopausal women. Therefore, aromatase inhibitors (e.g., anastrozole, letrozole, and exemestane) effectively reduce the level of circulating estrogens, as well as estrogens in the target organ. Their toxicity profile consists mainly of nausea, hot flashes, arthralgias/myalgias, and mild fatigue. Anastrozole and letrozole are nonsteroidal compounds that exhibit reversible, competitive inhibition of aromatase. Exemestane is a steroidal compound that binds irreversibly to aromatase, forming a covalent bond. There is no clinical evidence that exemestane produces superior results over the other agents in this class.

Aromatase inhibitors are used for first-line therapy for advanced breast cancer in postmenopausal women. Large trials have compared these agents with tamoxifen and have found similar response rates and a longer median time to progression for patients receiving the selective aromatase inhibitor.[49] A consistent finding in these trials was a lower incidence of thromboembolic events and vaginal bleeding in patients who received selective aromatase inhibitors, which, together with the advantage in terms of time to progression, led to the conclusion that the new aromatase inhibitors are superior to tamoxifen as first-line therapy for advanced breast cancer in postmenopausal women. Use of a steroidal aromatase inhibitor (exemestane) after a patient progresses on a nonsteroidal inhibitor (anastrozole or letrozole) may provide some benefit and is a common practice based on small clinical trials investigating this sequential approach to therapy.[49] The opposite sequence also has shown some benefit. Therefore, patients may receive two aromatase inhibitors (first and second line sequentially), especially patients who progress while on adjuvant tamoxifen therapy.

TABLE 86–8. Endocrine Therapies Used for Metastatic Breast Cancer

Class	Drug	Dose	Side Effects
Aromatase Inhibitors			
Nonsteroidal	Anastrozole	1 mg orally daily	Hot flashes, arthralgias, myalgias, headaches, diarrhea, mild nausea, osteoporosis (boneloss)
	Letrozole	2.5 mg orally daily	
Steroidal	Exemestane	25 mg orally daily	
Antiestrogens			
SERMs	Tamoxifen	20 mg orally daily	Hot flashes, vaginal discharge, mild nausea, thromboembolism, endometrial cancer
	Toremifene	60 mg orally daily	
SERDs	Fulvestrant	250 mg IM every 28 days	Hot flashes, injection site reactions, possibly thromboembolism
LHRH Analogs	Goserelin	3.6 mg SC every 28 days	Hot flashes, amenorrhea, menopausal symptoms, injection site reactions
	Leuprolide	7.5 mg IM every 28 days	
	Triptorelin	3.75 mg IM every 28 days	
Progestins	Megestrol acetate	40 mg orally four times daily	Weight gain, hot flashes, vaginal bleeding, edema, thromboembolism
	Medroxyprogesterone	400–1000 mg IM every week	
Androgens	Fluoxymesterone	10 mg orally twice a day	Deepening voice, alopecia, hirsutism, facial/truncal acne, fluid retention, menstrual irregularities, cholestatic jaundice
Estrogens	Diethylstilbestrol	5 mg orally three times daily	Nausea/vomiting, fluid retention, anorexia, thromboembolism, hepatic dysfunction
	Ethinyl estradiol	1 mg orally three times daily	
	Conjugated estrogens	2.5 mg orally three times daily	

SERM, selective estrogen receptor modulator; SERD, selective estrogen receptor downregulator; LHRH, luteinizing hormone–releasing hormone.

As mentioned several times so far, the aromatase inhibitors are only used appropriately in women who are postmenopausal. Pre- or perimenopausal women, whose ovaries are functioning, are not appropriate candidates for these therapies, at least based on the available evidence. Use of the aromatase inhibitors in addition to ovarian ablation (e.g., oophorectomy or LHRH agonists) is currently being investigated. Also, the use of aromatase inhibitors in men with advanced breast cancer should be avoided. Available evidence suggests that use of these agents in men increases circulating levels of testosterone, which may negate the therapeutic effects of the drug.[50]

Antiestrogens bind to estrogen receptors, preventing receptor-mediated gene transcription, and therefore are used to block the effect of estrogen on the end target. This class of agents now is subdivided into two pharmacologic categories, SERMs and pure antiestrogens. SERMs include tamoxifen and toremifene and demonstrate tissue-specific activity, both estrogenic and antiestrogenic, as described previously. The agonistic activity is thought to be responsible for many of the adverse reactions seen with these agents, including the increased risk of endometrial cancer. Research into how to minimize this agonistic activity has lead to the production of pure estrogen-receptor antagonists that lack estrogen agonist activity. Pure antiestrogens are a new class of agents that are also referred to as *selective estrogen receptor downregulators* (SERDs). These molecules bind to the ER, inhibiting estrogen binding, and cause a degradation of the drug-ER complex, decreasing the amount of ER on the tumor cell surface. There is currently only one pure antiestrogen available commercially in the United States, namely, fulvestrant.

Tamoxifen can be used in both premenopausal and postmenopausal women with metastatic breast cancer who have tumors that are hormone-receptor-positive. The toxicities of tamoxifen are described in the section on adjuvant endocrine therapy. The only additional toxicity that one might expect to find in the setting of metastatic breast cancer (specifically bone metastases) is a tumor flare or hypercalcemia, which occurs in approximately 5% of patients following the initiation of any SERM therapy and is not an indication to discontinue SERM therapy. It is generally accepted that this is a positive indication that the patient will respond to endocrine therapy.

Toremifene is another commercially available SERM for the treatment of breast cancer. It exhibits similar efficacy and tolerability to tamoxifen in the metastatic setting. Cross-resistance to toremifene has been demonstrated in patients with tamoxifen-refractory disease.[51] Therefore, toremifene appears to be an alternative to tamoxifen in postmenopausal patients with positive or unknown hormone-receptor status with metastatic breast cancer.

Fulvestrant is a new agent approved for the second-line therapy of postmenopausal metastatic breast cancer patients who have tumors that are hormone-receptor-positive. Studies examining the role of fulvestrant in the treatment of metastatic breast cancer have compared this agent with anastrozole. Given anastrozole's mechanism of action, only postmenopausal women were eligible for these trials. There is no biologic reason why fulvestrant should not produce similar outcomes in premenopausal

women, but no data exist to confirm the safety or efficacy in premenopausal women. In the comparative trials with fulvestrant and anastrozole, similar efficacy and safety were demonstrated with both agents when given after patients progressed on tamoxifen therapy.[52,53] Adverse events related to fulvestrant include injection-site reactions, hot flashes, asthenia, and headaches. This agent is a good option for patients who are unable to take an oral medication because it is given as a intramuscular injection ever 28 days.

Another goal of antitumor treatment is to reduce estrogen production in premenopausal women with surgery, irradiation, or medication. No difference has been found in two randomized trials of the overall response rate between tamoxifen and oophorectomy in premenopausal women. However, the secondary response rate to oophorectomy after tamoxifen treatment was somewhat higher than the response to tamoxifen after primary oophorectomy (33% versus 11%).[54] Some experts interpret this as suggesting that tamoxifen does not completely antagonize available estrogen, particularly in premenopausal women. Ovarian ablation (surgically or chemically) is still used commonly in some parts of the United States and is considered by many specialists to be the endocrine therapy of choice in premenopausal women. The mortality rate with surgical oophorectomy is low, usually less than 2% to 3% in appropriately selected patients. Irradiation of the ovaries was a means of castration many years ago but was associated with multiple complications and is no longer performed for these purposes. Medical castration with LHRH analogs is used increasingly in lieu of oophorectomy in premenopausal women.

Medical castration with LHRH analogs has been used in premenopausal metastatic breast cancer patients and induces remission in about one-third of unselected patients. The mechanism of action of LHRH analogs in breast cancer is thought to result from down-regulation of LHRH receptors in the pituitary. Decreased levels of luteinizing hormone (LH) subsequently lead to a decrease in estrogen to castrated levels. The three agents available in the United States are leuprolide, goserelin, and triptorelin, but only goserelin is approved for the treatment of metastatic breast cancer. These agents are administered as an injection and are associated with minimal side effects, including amenorrhea, hot flashes, and occasionally nausea. A recent meta-analysis was reported on combined tamoxifen and LHRH agonists versus LHRH agonists alone in premenopausal patients with metastatic breast cancer.[55] With a median follow-up of 6.8 years, there was a significant survival benefit and progression-free survival benefit in favor of the combined treatment. The overall response rate was significantly higher on combined endocrine treatment. However, this analysis did not compare tamoxifen alone with the combination of an LHRH agonist with tamoxifen. LHRH agonists also may produce a flare response owing to an initial surge in LH and estrogen production for the first 2 to 4 weeks. This flare response is similar to that seen with tamoxifen, and patients should be monitored for increasing pain and/or hypercalcemia during the initiation period.

Progestins such as megestrol acetate and medroxyprogesterone acetate have been compared with tamoxifen in randomized trials and have been found to yield equal response rates. Although there were no direct comparisons of these two forms of progestational therapy, they appear to be equally effective. Medroxyprogesterone acetate is used more frequently in Europe, and megestrol acetate is used more frequently in the United States. Based on efficacy and tolerability, these agents generally are reserved as third-line therapy after patients have received an aromatase inhibitor and a SERM (i.e., tamoxifen or toremifene). The most common side effect is weight gain, occurring in 20% to 50% of patients. Patients experiencing weight gain may have fluid retention, but fluid retention is not totally responsible for the weight gain. In **cachectic** cancer patients, the weight gain may be desirable, but this is not uniformly true of all patients with metastatic breast cancer. Additional side effects associated with progestins include vaginal bleeding in 5% to 10% of patients, either while patients are taking the progestational agent or when it is discontinued, and somewhat less than a 10% incidence of hot flashes. Thromboembolic complications are also significant with these agents.

High-dose estrogens and androgens are used rarely today because these agents are more toxic than the other hormonal agents discussed thus far. About one-third of patients placed on high-dose estrogens will discontinue them because of side effects, the most important of which are thromboembolic events, vomiting, and fluid retention. Given the recent availability of the aromatase inhibitors, use of androgens and estrogens has become rare.

Cytotoxic Chemotherapy

Cytotoxic chemotherapy is eventually required in most patients with metastatic breast cancer. Patients with hormone-receptor-negative tumors require chemotherapy as initial therapy of symptomatic metastases. Patients who respond initially to hormonal manipulations eventually cease to respond and go on to require chemotherapy. The median duration of response is 5 to 12 months, but some patients will have an excellent response to an initial course of chemotherapy and may live 5 to 10 years or longer without evidence of disease. In general, median survival of patients after treatment with commonly used drug combinations for metastatic breast cancer is 14 to 33 months. The median time to response has ranged from 2 to 3 months in most studies, but this period depends in large part on the site of measurable disease. The median time to appearance of response is between 3 and 6 weeks in patients whose disease is primarily in the skin and lymph nodes, 6 to 9 weeks in patients with metastatic lung involvement, 15 weeks in patients with hepatic involvement, and nearly 18 weeks in patients with bone involvement. Thus it is often the case that an immediate response to therapy is not

apparent, and in general, once a chemotherapy regimen has been initiated, it is continued until there is unequivocal evidence of progressive disease.

There are no well-defined clinical characteristics or established tests to identify patients likely to benefit from chemotherapy. Factors associated with an increased probability of response that have been identified include a good performance status, a limited number (one to two) of disease sites, and patients who respond to chemotherapy or hormonal therapy with a long disease-free interval. Patients who have progressive disease during chemotherapy have a lower probability of response to a different type of chemotherapy. However, this is not necessarily true for patients who are given chemotherapy after some interval during which they have received no chemotherapy. Patients who do not respond to endocrine therapy are as likely to respond to chemotherapy as patients who are treated with chemotherapy as their initial treatment modality. Age, menopausal status, and receptor status have not been associated with favorable or unfavorable response to chemotherapy.

A number of chemotherapeutic agents have demonstrated activity in the treatment of breast cancer, including doxorubicin, epirubicin, paclitaxel, docetaxel, capecitabine, fluorouracil, cyclophosphamide, methotrexate, vinblastine, vinorelbine, gemcitabine, mitoxantrone, mitomycin-C, thiotepa, and melphalan. ❿ *The most active classes of chemotherapy in metastatic breast cancer are the anthracyclines and the taxanes, producing response rates as high as 50% to 60% in patients who have not received prior chemotherapy for metastatic disease.*[56] The most useful weekly dose of paclitaxel in the metastatic setting appears to be 80 mg/m^2 per week with no breaks in therapy. With this approach, the toxicity profile of paclitaxel changes with less myelosuppression and delayed onset of peripheral neuropathy but slightly more fluid retention and skin and nail changes. Patients should be premedicated with a steroid (dexamethasone), H_1 antagonist (diphenhydramine), and H_2 antagonist (ranitidine or famotidine) prior to treatment to minimize hypersensitivity reactions. A randomized study comparing doses of 60, 75, and 100 mg/m^2 docetaxel was published recently and demonstrates a dose-response relationship with regard to response rates only.[57] Time to progression and overall survival were similar among all three dose levels. Therefore, dose remains important for symptomatic patients who require a rapid response to therapy. In asymptomatic patients requiring docetaxel chemotherapy, lower doses may be appropriate. Results from a single randomized trial appear to indicate that docetaxel is associated with less neuropathy, myalgia, and hypersensitivity than paclitaxel given every 3 weeks, but febrile neutropenia, fluid retention, and skin reactions appear to occur more frequently with the newer taxane.[58] The median cumulative docetaxel dose to the onset of fluid retention is 400 mg/m^2 in nonpremedicated patients. Premedication with a steroid (dexamethasone) prior to beginning docetaxel and continued for three days helps to prevent hypersensitivity reactions and fluid retention.

Capecitabine is a novel oral agent approved in the mid-1990s with significant activity in metastatic breast cancer patients who have progressed on an anthracycline-containing regimen as well as a taxane regimen. This agent is a prodrug for fluorouracil with somewhat targeted activity toward malignant cells. The parent compound undergoes a three-step enzymatic conversion to become fluorouracil at the target cell. The third and final step in this conversion is more likely to occur in malignant cells than normal cells owing to the presence of higher levels of the responsible enzyme in malignant tissues. In patients who have been exposed to an anthracycline and a taxane, capecitabine produces response rates of about 25%, which is impressive compared with other tested chemotherapy agents.[59]

Vinorelbine, a microtubule interactive agent, also has shown impressive response rates in metastatic breast cancer.[60] Vinorelbine was approved by the FDA in 1994 for the treatment of non–small cell lung cancer. It is not approved for breast cancer, but response rates to vinorelbine range from 30% to 50%, with an overall 5% complete response rate in phase I and phase II studies in patients with advanced breast cancer. Importantly, paclitaxel, docetaxel, and vinorelbine do not appear to be cross-resistant with anthracyclines, which are arguably considered first-line treatment of metastatic breast cancer.

Gemcitabine is another agent that is used quite frequently in patients who have received the aforementioned chemotherapy regimens, who still have a good performance status, and who may benefit from additional chemotherapy. This is a nucleotide analog that inhibits DNA synthesis. Response rates ranging from 13% to 42% have been reported in a number of phase II trials.[60] In patients who have been exposed to an anthracycline and a taxane, gemcitabine appears to provide similar benefit to capecitabine. This agent appears to affect platelets more frequently than other chemotherapy previously mentioned, and close monitoring is required for patients receiving this agent.

Combination chemotherapy regimens are associated with higher response rates than are single-agent therapies in the treatment of metastatic breast cancer, but the higher response rates usually have not translated into significant differences in time to progression and OS. The use of sequential single-agent chemotherapies versus the combination regimens has been debated widely for metastatic breast cancer. Current consensus is that first-line chemotherapy includes sequential single agents or combination chemotherapy.[28] In the palliative metastatic setting, using the least toxic approach is preferred when efficacy is considered equal. In clinical practice, patients who require a rapid response to chemotherapy (e.g., those with symptomatic bulky metastases) often receive combination therapy despite the added toxicity. This decision is complex and should be made on an individual patient basis.

Because most patients are given adjuvant chemotherapy, regimens chosen for first-line use in the metastatic setting often are

different from those used in the adjuvant setting. If a patient's cancer recurs within 1 year of finishing adjuvant chemotherapy, those chemotherapy agents are not considered effective for treatment of the metastatic disease. However, if the patient recurs more than 1 year after the end of her adjuvant chemotherapy, the same agents also may be helpful in the metastatic setting.

Biologic Therapy

Trastuzumab is a humanized monoclonal antibody that binds with a specific epitope of the *HER-2/neu* protein. Single-agent treatment with trastuzumab has a response rate of 15% to 20% and a clinical benefit rate of nearly 40% in patients with *HER-2/neu*-overexpressing cancers.[61] Trastuzumab has additive and perhaps synergistic activity with other chemotherapeutic agents.[62] In the pivotal trial, patients who received the doxorubicin-trastuzumab combination had a very high incidence of cardiotoxicity (27%), leading to a black-box warning regarding this combination in the product information for trastuzumab. Many investigators are attempting to circumvent this toxicity while giving these two classes of agents together (e.g., liposomal doxorubicin or continuous-infusion doxorubicin). Until further information regarding the safety of these approaches becomes available, this combination should not be given outside the context of a clinical trial. Other chemotherapy agents that are being evaluated in combination with trastuzumab include docetaxel, vinorelbine, gemcitabine, capecitabine, and the platinum agents (e.g., cisplatin and carboplatin).[63]

Trastuzumab is reasonably well tolerated. The most common adverse effects are infusion-related, primarily fever and chills, and occur in about 40% of patients during the initial infusion. Acetaminophen and diphenhydramine may be given and/or the infusion rate reduced to help alleviate the symptoms related to these reactions. A more severe adverse effect consisting of severe hypersensitivity and/or pulmonary reactions has been reported but is rare. It is important to educate patients regarding the pulmonary reactions because these may occur up to 24 hours after the infusion and can be fatal if not treated promptly. Trastuzumab may increase the incidence of infection, diarrhea, and/or other adverse events when given with chemotherapy. As mentioned previously, when given with an anthracycline, the rates of heart failure are unacceptably high, but even when given as a single agent, there is about a 5% incidence of heart failure. Fortunately, the heart failure seen with trastuzumab is somewhat reversible with pharmacologic management, and some patients have continued therapy with trastuzumab after their left ventricular ejection fraction has returned to normal. Close monitoring for clinical signs and symptoms of heart failure is important in order to intervene with appropriate cardiac treatments.

It should be noted that only 20% to 30% of patients with metastatic breast cancer overexpress *HER-2/neu*, and

Patient Encounter, Part 3: Diagnostic Tests

Diagnostic Bilateral Mammogram

- American College of Radiology Category V report highly suspicious for malignancy in right breast. Spiculated mass measuring approximately 2 × 1.8 cm. Recommend biopsy.
- Left breast shows no abnormality.

Unilateral Ultrasound Right Breast and Right Axilla with Biopsy

- Solid-appearing mass favoring malignancy in right upper outer quadrant. This mass measures 1.7 × 1.8 cm in dimension. There is no associated skin thickening or edema. Fine-needle aspiration (FNA) was performed with two passes with preliminary evaluation suggestive of malignancy.
- Abnormal axillary adenopathy. Within the left axillar is a single lymph node that is abnormal in appearance. The node measures 0.8 × 0.9 cm and was sampled with FNA using a 20-gauge needle with two passes without complication. Preliminary cytologic evaluation suggested malignancy.

Fine-Needle Aspiration of Right Breast Mass and Right Axillary Mass

- *Right breast 10 o'clock:* Breast carcinoma, ductal type, modified Black's nuclear grade III (poorly differentiated), ER 50%, PR 30%.
- *Right axillary lymph node:* Metastatic adenocarcinoma; the cytomorphology of the malignant cells in the lymph node aspiration is similar to that seen in the breast aspiration material.

Core Needle Biopsy of Right Breast Mass

Infiltrating ductal carcinoma, modified Black's nuclear grade III (poorly differentiated), *HER2/neu* overexpression 2+ by IHC; *HER2/neu* amplification negative by FISH.

Ultrasound Liver

No lesions suggestive of malignancy.

Bone Scan

No evidence of active osseous metastases.

Echocardiogram

- Left ventricular systolic function is normal. Left ventricular ejection fraction by visual inspection is estimated at 55% to 60%. The left ventricle is grossly normal size.
- The right ventricle is normal in size and function.
- There is mild tricuspid regurgitation.
- Right ventricular systolic pressure is elevated at 30 to 40 mm Hg.
- There is no pericardial effusion.

- Given this information, what is your assessment of the patient's stage and prognosis?
- Identify your treatment goals for the patient.
- What nonpharmacologic and pharmacologic alternatives are available for this patient?

commercially available immunohistochemistry (IHC) tests that are reported back as 2+ for *HER-2/neu* are often negative by the more sensitive and specific fluorescence in situ hybridization (FISH) technique. To date, there is no benefit associated with the administration of trastuzumab to the subset of patients who are *HER-2/neu*-negative and a very questionable benefit associated with administration of trastuzumab to women who are 2+ for *HER-2/neu* by IHC staining alone. The patients who benefit most from trastuzumab therapy include those whose tumors express *HER2* protein at the 3+ level and/or demonstrate gene amplification by FISH testing.

Another monoclonal antibody, bevacizumab, was combined with paclitaxel in a clinical trial for first-line chemotherapy in women with metastic breast cancer. The DFS was improved for the combination regimen over paclitaxel alone.[28] Bevacizumab targets vascular endothelial growth factor (VEGF), thereby preventing angiogenesis, which is a necessary process to support tumor growth and metastasis. Bevacizumab was first approved by the FDA for the treatment of colorectal cancer. Additional studies are being conducted to elucidate bevacizumab's role in the treatment of beast cancer, including combination with trastuzumab.

Bisphosphonates

For women whose breast cancer has metastasized to bone, bisphosphonates are recommended, in addition to chemotherapy or endocrine therapy, to reduce bone pain and fractures.[28,64] Pamidronate (90 mg) and zoledronate (4 mg) can be given intravenously once each month. These bisphosphonates are given in combination with calcium and vitamin D.

Local-Regional Control

Radiation Therapy

Radiation is an important modality in the treatment of symptomatic metastatic disease. The most common indication for treatment with radiation therapy is painful bone metastases or other localized sites of disease refractory to systemic therapy. Radiation therapy gives significant pain relief to approximately 90% of patients who are treated for painful bone metastases. Radiation is also an important modality in the palliative treatment of metastatic brain lesions and spinal cord lesions, which respond poorly to systemic therapy, as well as eye or orbit lesions and other sites where significant accumulation of tumor cells occurs. Skin and/or lymph node metastases confined to the chest wall area also may be treated with radiation therapy for palliation (e.g., open wounds or painful lesions).

Patient Encounter, Part 4: Creating a Care Plan

Based on the information presented, create a care plan for this patient's breast cancer. Your plan should include (1) a statement of the drug-related and non-drug-related needs and/or problems, (2) the goals of therapy, (3) a patient-specific detailed therapeutic plan (including options for local control), and (4) a plan for follow-up to determine whether the goals have been achieved and adverse effects managed adequately.

OUTCOME EVALUATION

Early breast cancer is resected completely with curative intent, and adjuvant chemotherapy and hormonal therapy are initiated to prevent recurrence. During adjuvant chemotherapy, laboratory values to monitor chemotherapy toxicity are obtained prior to each cycle of chemotherapy. After completion of adjuvant therapy, patients are monitored every 3 months for the first few years after diagnosis, with intervals between exams extended as time from diagnosis lengthens.

- Physical examination to detect breast cancer recurrence
- Annual mammography
- Symptom-directed work-up

Locally advanced breast cancer often is treated with neoadjuvant therapy to make the tumor surgically respectable. During neoadjuvant chemotherapy, laboratory values to monitor chemotherapy toxicity are obtained prior to each cycle of chemotherapy, and a physical examination and ultrasound exams to detect size of tumor are performed after the cycles of neoadjuvant therapy are completed. After a complete surgical resection, monitoring proceeds as described earlier for early breast cancer.

Metastatic breast cancer is not curable, and therapy is intended to palliate symptoms. In most cases, hormonal therapy is the mainstay. While on therapy, patients are monitored monthly for signs of disease progression or metastasis to common sites, such as the bones, brain, or liver.

- Pain
- Mental status or other neurological findings
- Laboratory tests
  - Liver function tests
  - Complete blood count
  - Calcium, electrolytes

Patient Care and Monitoring

1. Review the patient's diagnostic information to determine the stage of disease, overall prognosis, and goals of therapy.
2. Obtain a thorough history of prescription, nonprescription, and natural drug product use. Is the patient taking any medications that may contribute to breast cancer and require discontinuation?
3. Review the patient's past medical history to determine the risks associated with any potential therapies and/or surgery and/or radiation therapy.
4. Educate the patient on the chemotherapy or endocrine therapy regimen chosen for the patient, focusing on what adverse events to expect, when to expect them, and how to manage them if they do occur. Also include in the initial education an overall plan of care, including the duration of therapy, other treatment modalities that will follow (e.g., radiation therapy, surgery, endocrine therapy), and when the patient will receive them.
5. Develop a pre- and postmedication plan for the chemotherapy or endocrine therapy regimen chosen based on the patient's risk factors for adverse events, chemotherapy/endocrine therapy drugs chosen, and dose, route, and timing of administration chosen.
6. Develop a plan to assess the effectiveness of the overall treatment plan, focusing on educating the patient on ways to monitor and track adverse events and/or disease-related symptoms throughout therapy.
7. Determine success of the overall treatment plan by obtaining a thorough history of adverse events experienced with the previous chemotherapy/endocrine therapy treatment and objective measures of response to therapy. Assess effects on quality-of-life measures such as physical, psychological, and social function and well-being.
8. Address any adverse events the patient experienced, and alter the pre- and postmedication plan for the next treatment accordingly.
9. Provide follow-up patient education regarding the new plan for side-effect management.
10. Stress the importance of reporting adverse events and adherence with the prescribed medication regimen. Attempt to develop a therapeutic regimen that is easy for the patient to accomplish.

87 Lung Cancer

Val Adams and Justin Balko

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Identify major risk factors for the development of lung cancer.
2. Explain the pathologic progression of lung cancer and its relationship with signs and symptoms of the disease.
3. Make appropriate recommendations for screening or preventative measures in high-risk patients.
4. Understand staging of lung cancer patients and how it influences treatment decisions.
5. List the rationale, advantages, disadvantages, and place in therapy for adjuvant and neoadjuvant chemotherapy
6. Identify the chemotherapeutic regimens of choice for limited and extensive small cell lung carcinoma, as well as local, locally advanced, and advanced non–small cell lung carcinoma.
7. Monitor patients for chemotherapy-associated toxicity, and recommend appropriate management.
8. Distinguish the treatment goals of palliative care versus those of first-line treatment.

Key Concepts

❶ The single most important risk factor for the development of lung cancer is smoking, and the most effective way for high-risk patients to reduce their risk is to stop smoking. Additional recommendations should include an increase in dietary intake of fruits and vegetables.

❷ The signs and symptoms of lung cancer can be classified as pulmonary, extrapulmonary, and paraneoplastic. These classifications relate to disease progression.

❸ Surgical resection of the tumor is the mainstay of treatment in early-stage non–small cell lung cancer and produces the longest survival rates.

❹ The performance status of the patient represents an important aspect of chemotherapy treatment decisions. Patients with a performance status of 0 to 1 may be treated with chemotherapy. Patients with a performance status of 2 may be treated with less aggressive regimens that have a decreased risk of major toxicities, whereas performance status 3 and 4 patients should be treated with supportive care only.

❺ Doublet chemotherapy regimens are superior in response to single-agent regimens and should be used when the patient can tolerate the associated toxicity. Platinum-containing doublets are first-line treatment in most cases.

❻ The treatment goals in lung cancer are cure (early-stage disease), prolongation of survival, and maintenance or improvement of quality of life through alleviation of symptoms.

❼ Knowing how to prevent and treat adverse events from chemotherapy is an important aspect of patient care. Unmanaged events may result in excess morbidity and cause delays in chemotherapy administration and reduced chemotherapy doses and contribute to treatment failure.

Lung cancer has a major health impact both in the United States and worldwide. Prior to 1930, lung cancer was a relatively rare disease, but a sharp incline in industrialization and smoking in the early 1900s has bred an epidemic. Lung cancer has a high mortality rate, and although treatment can cure selected patients, most therapies prolong survival for only months. Recent advances in lung cancer research provide good reason for optimism, although antismoking campaigns still appear to offer the best opportunity to reduce lung cancer incidence and mortality.

EPIDEMIOLOGY AND ETIOLOGY

Incidence and Mortality

Cancer is the second leading cause of death in the United States, and cancers of the lung and bronchus rank first in mortality,

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

comprising over 28% of cancer-related deaths.[1] In 2007, over 213,380 new cases of lung cancer were reported. A close correlation exists between incidence and mortality of lung cancer, reflecting the reality that approximately 85% of lung cancer patients ultimately die of their disease.

Gender

Lung cancer incidence and mortality are slightly higher in males, but the rate in females is expected to match that of males in future years[2] owing to changes in smoking patterns. Typically, women with lung cancer are diagnosed at an earlier age, which has raised the question that there may be inherent genetic differences between males and females in susceptibility to lung cancer. Furthermore, there are differences in the prevalence of histologic types of tumors. Interestingly, historically studies have shown improved prognosis and survival times for women diagnosed with lung cancer.[3]

Race

While no significant difference is noted in incidence or mortality between black and white females, black males have a markedly higher incidence and mortality rate than white males. Smoking habits, including cigarette type (i.e., increased menthol cigarette use) have a proposed contribution to this gap.[2] Black Americans also show a significantly lower 5-year survival rate than white Americans regardless of gender. They present with more advanced disease and are less likely to be treated, which suggests that genetic, psychosocial, and socioeconomic components contribute to this disparity.[4] People of other races, such as Asians, Hispanics, and Native Americans, have lower rates of lung cancer than both Caucasians and African Americans, although it remains a significant health care issue.[5]

Clinical Risk Factors

Smoking

❶ *The single most important risk factor for the development of lung cancer is smoking.* Furthermore, one of the most predictive factors on lung cancer epidemiology is trends in population cigarette smoking. Since lung cancer is a fatal disease in most cases, both incidence and mortality strongly reflect the smoking trends of the population on a 20- to 30-year lag. In other words, decreases in tobacco use now would not be expected to affect lung cancer incidence until approximately 2030. With this knowledge, the current expectation is that lung cancer incidence and mortality will decrease steadily until 2020, reflecting decreases in cigarette smoking between 1970 and 1990. Since smoking has continued at a steady rate since 1990, lung cancer incidence is expect to plateau.[2] Correlation between smoking and lung cancer continues to drive antismoking campaigns and should be considered an investment in the future health care of the nation.[6] Furthermore, smoking cessation plays a important role in reducing lung cancer risk on a patient-to-patient basis, and appropriately guiding such therapy is a crucial part of treating at-risk patients.[7] Total smoke exposure, as well as current use, correlates with the individual's risk of developing malignancy. The risk of lung cancer decreases to near-normal levels 10 to 15 years following successful smoking cessation. Total smoke exposure is reported as pack-years. One pack-year is the equivalent of smoking 1 pack per day for 1 year. A patient who smokes 40 cigarettes per day (2 packs) for 5 years would have a 10 pack-year history (2 packs/day × 5 years).

Other Air-Related Risks

In addition to direct inhalation of cigarette smoke, other environmental factors have been identified as risks for the development of primary lung tumors. Environmental tobacco smoke (ETS) presents a significant occupational hazard for nonsmokers working in environments that have a high smoking population, such as bars or restaurants. Some states have instituted laws banning public smoking in order to protect individuals working in these locations. It is estimated that approximately 3000 cases of lung cancer each year in nonsmokers are due to ETS.[8] Other environmental factors linked to lung cancer include radon, arsenic, nickel, and chloromethyl ethers. Those who live in an urban environment are also at an increased risk for lung cancer owing to exposure to high concentrations of combustion fumes.[5] Asbestos causes a distinct type of lung cancer called **mesothelioma,** which is rare and not discussed in this chapter.

Nutrition

Diet and nutrition have long been suspected to play a role in cancer susceptibility, and many studies have sought to define specific foods or nutrients that influence cancer risk. Since not all heavy smokers develop lung cancer, it is thought that nutritional factors may explain in part this variation. Epidemiologic studies focusing on diet and nutrition in lung cancer have shown reduced rates of lung cancer in individuals who report higher fruit and vegetable consumption. However, studies attempting to identify specific chemical components of fruits and vegetables that are responsible for this effect have not been successful.[9] ❶ *Recommendations to patients who are at risk owing to smoking or other factors or those who are simply interested in reducing their risk of cancer should include an increase in dietary intake of fruits and vegetables.*

Hereditary or Genetic Risk Factors

The majority of people who smoke never develop lung cancer. Genetic risk factors may predispose certain smokers to lung cancer. After adjustments for age, smoke exposure, occupation, and gender, relatives of a lung cancer patient have approximately a twofold risk of developing lung cancer. The

Patient Encounter, Part 1

A 53-year-old African-American man presents at your clinic complaining of new-onset cough. He has had several upper respiratory infections in the last 2 months, with occasional hemoptysis. He has consistently smoked 1.5 packs per day for the last 20 years. He has worked as a bartender at a local restaurant downtown for most of his life.

- What risk factors for lung cancer are present?
- Calculate this patient's pack-year history.

degree of inherited risk correlates with the age of the relative at the time of diagnosis. The relative risk is approximately six-fold higher for first-degree relatives of a lung cancer patient diagnosed between the ages of 40 and 59 years. Familial lung cancer that develops at an early age in nonsmokers fits a Mendelian codominant inheritance model. However, a lung cancer gene has not been identified.[10]

Other genetic links to lung cancer involve metabolic enzymes that process carcinogens. The damaging effects of tobacco smoke are thought be a result of bulky aromatic hydrocarbons that damage DNA. These chemicals are activated by certain phase I metabolic enzymes and are deactivated by phase II conjugating enzymes such as the glutathione-*S*-transferases. People with elevated cytochrome CYP450 2D6, 1A1, or 1A2 have greater risk of DNA damage and subsequent cancer owing to higher formation rates of active carcinogens. Those with deficient phase II metabolism (*GSTM1* or *GSTT1*) similarly may have increased risk owing to lower clearance of these carcinogens.[11–13]

PATHOPHYSIOLOGY

Most lung cancers are derived from the epithelium of the airways and therefore are classified as **carcinomas.** There are four major and several rare histologic types of lung cancer that appear to form through different mutagenic pathways. However, they all appear to transition through a premalignant state. The presence of a transition state from normal tissue to cancerous tissue is important because the premalignant cells contain damage that generally is thought to be reversible. Researchers currently are trying to develop methods to identify people with premalignant lesions as well as drugs that can reverse the damage.

Continued damage to premalignant cells can lead to cancer. The first appearance of cancer cells that have not yet become invasive is referred to as *carcinoma in situ.* Patients are rarely diagnosed with this early stage of cancer owing to a lack of symptoms and relatively rapid progression to larger invasive tumors. As the tumor grows, cells may become dislodged from the tumor bulk and enter the hematologic or lymphatic circulatory systems, where they can travel to either local or distant parts of the body. Hematologic spread usually results in metastatic sites in the bones, liver, and central nervous system.[11] Lymphatic spread is more orderly in nature, with the hilar and mediastinal lymph nodes in the pleural cavity commonly being involved. Once the tumor has spread to multiple locations, curative treatment is rare because surgical excision and radiotherapy cannot remove all or nearly all the cancer cells.

Histologic Classification

Histologic classification of lung cancer involves determining the cellular origin of the tumor. Knowing the histology of the tumor influences treatment decisions as well as prognosis. In order for histologic classification to be carried out, the pathologist must obtain a tissue sample. Methods of tissue sampling are discussed in the section on diagnostic principles.

There are four major histologic types of lung cancer that are divided into two classes based on response to treatment and prognosis: small cell lung cancer (SCLC) and non–small cell lung cancer (NSCLC). However, it is important to note that certain other rare malignancies can be seen as well as mixed-type carcinomas. The four major types of lung cancer are outlined in Table 87–1.

TABLE 87–1. Lung Tumor Histopathology[11]

Tumor Type	Percent of Tumors	Approximate Cell Doubling Time	Sensitivity to Chemotherapy and Radiotherapy	Relative Risk of Metastasis
Small cell	10–15%	30 days	High	High
Non–small cell				
Adenocarcinoma	30–35%	180 days	Low	Medium
Large cell (giant)	9%	100 days	Low	Low
Squamous (epidermoid)	30–35%	180 days	Low	Low

CLINICAL PRESENTATION AND DIAGNOSIS

❷ Clinical Presentation

Signs and symptoms of lung cancer can be classified into three subdivisions: pulmonary, extrapulmonary, and paraneoplastic syndromes. Distinguishing between these classes of symptoms is important because it can aid in determining the severity of the disease, guide treatment options, and affect prognosis.

Pulmonary Symptoms

Symptoms owing to the direct effects of the primary tumor are often the first to appear and are the most common. These include

- Cough
- Chest pain
- SVC obstruction
- Shortness of breath
- Dysphagia
- Hemoptysis
- Pleural effusion

Extrapulmonary Symptoms

Once the tumor invades tissues outside the pleural cavity, it can produce a wide array of symptoms, including

- General bone pain
- Adrenal insufficiency
- Confusion
- Personality changes
- Enlarged lymph nodes
- Weight loss
- Seizures
- Nausea
- Focal neurologic symptoms
- **Horner's syndrome**
- Fatigue
- Headache
- Vomiting
- Subcutaneous skin nodules

Paraneoplastic Syndromes

Symptoms that are not a result of the direct effects of the tumor are termed **paraneoplastic syndromes.** They may be caused by substances secreted by the tumor or in response to the tumor and often occur in tissues far from the site of malignancy. Paraneoplastic syndromes are numerous and affect a wide variety of systems, including the endocrine, neurologic, skeletal, renal, metabolic, vascular, and hematologic systems.

Clinical symptoms are seen not commonly until lung cancer tumors become large and/or have metastasized. This is a key factor in the poor prognosis associated with lung cancer. Patients who are diagnosed at an earlier clinical stage are more likely to respond to treatment than those at later stages. Therefore, diagnosing lung cancer earlier through screening and identification of initial signs and symptoms is important. Since screening techniques have not been refined sufficiently to demonstrate high rates of both sensitivity and specificity, identifying lung cancer patients on symptomatic presentation is of utmost importance.

Chemoprevention

The term **chemoprevention** refers to the use of prophylactic medications to prevent the development of cancer. Many studies of potential chemopreventatives, including nonsteroidal anti-inflammatory drugs (NSAIDs), retinoids (β-carotene), inhaled glucocorticoids, vitamin E, selenium, and green tea extracts, have been conducted, but none has been successful. Large randomized clinical trials have evaluated β-carotene as a lung cancer chemopreventative agent in high-risk patients (older smokers). The trials clearly show that older people who smoke have a higher risk of developing and dying of lung cancer if they take a β-carotene supplement. Nonsmokers do not appear to have an altered risk of lung cancer with β-carotene consumption.[14]

Currently, one of the most promising agents for the prevention of lung cancer is selenium, which appeared to prevent the development of lung tumors in patients with skin cancer.[15] This has not yet been shown in patients without preexisting skin cancer, although studies are underway.

Diagnosis

Diagnosis of lung cancer requires both visualization of the cancerous lesion and tissue sampling for pathologic assessment. Visualization of the suspected tumor provides the clinician with the information necessary to choose the most appropriate sampling technique. While some lung tumors may be very apparent using relatively simple techniques such as a chest x-ray (CXR), many can be either too small to detect or located in an anatomically difficult area to visualize. Therefore, multiple methods of visualization are used often. Once the tumor has been located, sampling provides tissue to confirm malignancy and to determine the histology (i.e., squamous cell, adenocarcinoma, large cell, or small cell). The advantages and disadvantages of various sampling methods must be weighed carefully so that the least invasive procedure can be performed that has a high likelihood of resulting in an accurate diagnosis. Tools used in the diagnosis of lung cancer are outlined in Table 87–2.

TABLE 87–2. Diagnostic Tools

	Technique	Description
Visualization	Chest x-ray	The least expensive visualization method in the diagnosis of lung cancer. Readily accessible and does not require systemic administration of contrast dye. However, it often detects lesions that are not cancerous and is not capable of assessing lymph node status.
	Computed tomography	More accurate when providing information on size, location, and invasion than CXR. It is recommended as part of the standard work-up in most cases.
	PET scanning	Uses a substance called 5-fluorodeoxyglucose (5-FDG) to produce a functional image of the lungs. Cells that are actively growing and dividing use greater amounts of glucose and therefore take up more 5-FDG. Focal regions of fluorescence can be visualized in cancerous lesions. PET scanning combined with a CT scan is more accurate than CT scan alone; however, the exact role of PET scanning in staging and monitoring is unclear. The apparent benefit and common role in staging is to evaluate mediastinal disease when it can influence the tumor resectability.
Tumor Sampling	Fine-needle aspiration	A method of aspirating cells from the tumor via insertion of a small-bore needle into the lesion and aspirating. Commonly used to evaluate lymph nodes or other poorly accessible sites, it has the advantage of being faster and less invasive than other biopsy methods; however, it does not preserve the architecture of the tumor and may return cells that are undergoing cell death, which negates histologic analysis.
	Bronchoscopy	A fiberoptic camera is inserted through the airways to examine the site of the suspected lesion. Once the lesion. Once the lesion is visualized, a tool attached to the camera allows for a tissue biospy.
	Core needle biopsy	A method of obtaining tissue and preserving the tumor architecture. A large-bore needle is inserted into a lesion, where it cuts a core of tissue out that then can be evaluated
	Thoracentesis	Involves removal of fluid in the pleural cavity via a needle. The fluid then is assayed for presence cancerous cells. This procedure has low sensitivity and depends on the presence of a pleural effusion
	Sputum cytology	Detects cancerous cells that become disloged from the airways into the sputum. Sputum cytology is useful because it is not invasive, although it has much lower sensitivity for detecting cancer.

Clinical Staging

Once the diagnosis of lung cancer is confirmed through visualization and biopsy, the extent of disease must be determined. For NSCLC, tumor growth and spread are staged using the American Joint Committee on Cancer (AJCC) tumor, node, and metastasis (TNM) staging system. Small cell lung cancer typically is staged with the Veterans Administration Lung Cancer Study Group method. Clinical staging serves two primary purposes: predicting prognosis and guiding therapy.

Non–Small Cell Lung Cancer

Clinical staging of NSCLC with the TNM system evaluates the size of the tumor, extent of nodal involvement, and presence of metastatic sites. The combination of these three evaluations determines the stage. Clinical stages and associated survival rates are outlined in Table 87–3. Local disease includes tumors that are confined to a single hemithorax and those cancers which have spread to the ipsalateral hilar lymph nodes. Once malignancy invades the mediastinal lymph nodes or contralateral hilar nodes, the disease becomes locally advanced. When signs of cancer are detected outside the pleural cavity, it is classified as advanced disease. Local disease is associated with the highest cure and survival rates, whereas those with advanced disease have less than a 10% 5-year survival rate.

Small Cell Lung Cancer

The most commonly used system of staging SCLC was developed originally by the Veterans Administration Lung Cancer Study Group. This system categorizes SCLC into two classifications: limited and extensive disease.[16]

TABLE 87–3. Clinical Stage and Prognosis[61, 62]

Clinical Stage	TNM staging			Survival Rate	
	Tumor	Node	Metastasis	1 Year	5 Year
Local					
IA	1	0	0	94%	67%
IB	2	0	0	87%	53%
IIA	1	1	0	89%	40%
Locally Advanced					
IIB	2	1	0	73%	30%
	3	0	0		
IIIA	1	2	0	58%	15%
	2	2	0		
	3	1	0		
	3	2	0		
IIIB	Any	3	0	37%	10%
Advanced					
IIIB	4	Any	0	37%	10%
IV	Any	Any	1	18%	Less than 5%

Patient Encounter, Part 2: Medical History, Physical Examination, and Diagnosis

PMH
Significant for COPD (poorly controlled), GERD (controlled with PPIs), and moderate hypertension

FH
Father died of MI, mother living.

Meds
- Lisinopril 20 mg daily
- Lansoprazole 30 mg daily
- Albuterol/ipratropium MDI 2 puffs bid

ROS
(+) light chest pain, shortness of breath, hemoptysis; (–) recent weight loss

PE
VS: BP 135/69, RR 26, P 80, T 99°F (37.2°C)
CV: RRR

Labs
- Slightly elevated ionized calcium and LFTs; all others WNL.
- CXR reveals a solitary nodule in right lower lobe.
- Fine-needle aspiration confirms adenocarcinoma.
- Further evaluation with CT and PET scans reveal a $T_2N_0M_0$ tumor.

- What clinical stage is this patient's disease?
- What is the estimated survival time for this stage of NSCLC?

- When evidence of the tumor is confined to a single hemithorax and can be encompassed by a single radiation port, the disease is considered limited.
- Any progression beyond this point is extensive disease.

TREATMENT

Desired Outcome and General Approach to Patient

The treatment of lung cancer depends on tumor histology, stage of disease, and patient characteristics such as age, gender, history, and performance status. All these aspects must be assessed before appropriate treatment can be recommended. The general approach to treatment of lung cancer is outlined in Fig. 87–1. In the development of a patient care plan, keep in mind the ultimate goals of therapy. ❻ *In patients with early-stage disease, a definitive cure is the primary goal of treatment, although this end point is not always met. Additional goals of treating lung cancer patients include prolongation of survival and improvement of quality of life through alleviation of symptoms.* The goals of treatment must be considered when selecting a therapeutic plan. Some treatments may show prolonged survival by a few months but at the expense of significant decreases in patient quality of life. Treatment decisions must include both the health care team and an informed and well-counseled patient.

Nonpharmacological Therapy

Surgery

❸ *Of all treatment modalities, surgical resection of the affected lobe or lung leads to the greatest improvement in survival for NSCLC patients. If at all possible, surgery should be considered the mainstay of treatment for all patients with early-stage NSCLC (clinical stage IA, IB, or IIA) and locally advanced tumors.*[17] The resectability of the tumor should only be determined by an experienced thoracic surgeon who routinely works with cancer patients.[18] During surgery, peripheral lymph nodes may be removed if they are thought to be involved, and mediastinal nodes often are dissected for biopsy to determine their involvement. Surgery is not curative and as a general approach does not prolong survival in patients with advanced disease; however, it is an important palliative treatment that can improve some patients' quality of life. In this respect, surgery is limited to local sites where the tumor is causing significant morbidity (e.g., spinal cord compression). Patients with small cell carcinomas are treated rarely with surgery because the results of a randomized trial published in 1969 showed that surgery did not result in any 5- or 10-year survivors, whereas radiation produced a 4% survival rate at 5 and 10 years.[19,20] With improved imaging and surgical techniques and the use of effective adjuvant therapy, some clinicians believe that surgery does have a role in early-stage disease; however, this has yet to be proven in a clinical trial.

Radiation

As mentioned earlier, radiation is the treatment of choice for limited-stage small cell lung cancer. It is synergistic with chemotherapy, and optimal patient outcomes are realized when radiation is administered concurrently with chemotherapy. In patients with advanced small cell lung cancer, radiation is limited to palliation of symptoms caused by a local tumor. Patients with localized NSCLC are best treated with surgery; however, many of these patients are inoperable because of comorbidities (e.g., lung disease from smoking). In these situations, radiation therapy can be used in place of surgery with curative intent, although at a success rate approximately 50% that of surgery.[21] Similar to small cell lung cancer, patients with late-stage NSCLC can receive radiation therapy to palliate symptomatic metastases. Although radiation is less invasive than surgery, it can have marked toxicity on normal tissue, and patients may experience esophagitis, pneumonitis, cardiac abnormalities, myelopathies, and skin irritation. These adverse events can be decreased by using stereotactic radiation and/or hyperfractionated administration.[17]

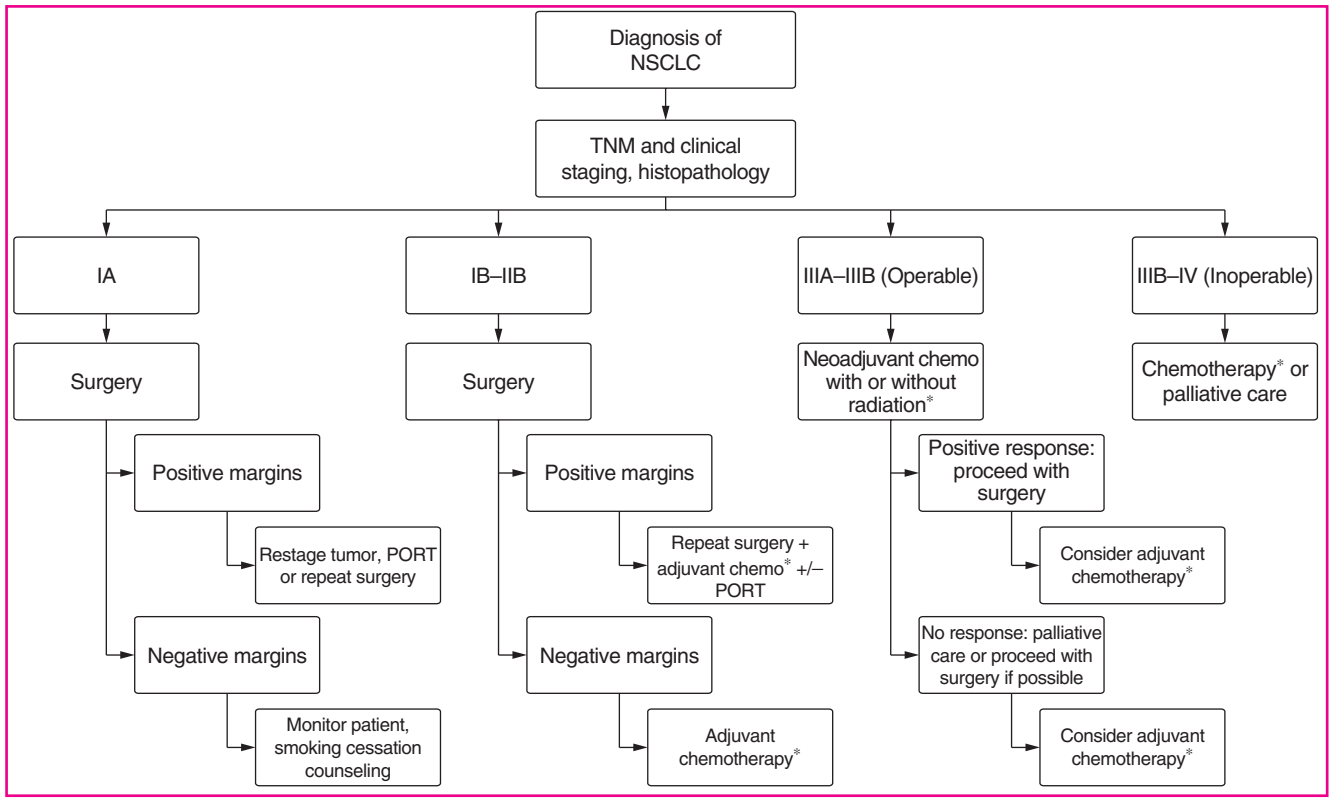

FIGURE 87–1. Clinical pathway for non–small cell lung cancer. *See text for specific treatment recommendations. Chemo, chemotherapy; NSCLC, non–small cell lung cancer; PORT, post operative radiotherapy; TNM, tumor node metastasis.

Pharmacologic Therapy

Chemotherapy

Traditional chemotherapeutic agents interfere with processes during cell division or DNA replication in nondividing cells that result in cell death. Unfortunately, these agents are not specific for cancer cells, and other tissues in the body often are affected as well. Rapidly cycling cells, both tumor and normal tissue such as bone marrow, the epithelial cells of the gastrointestinal tract, and hair follicles, are most susceptible to chemotherapy toxicity. Since the dose of traditional chemotherapy agents is determined in phase I studies where the maximum tolerated dose is considered the best dose, toxicity is seen with all these agents. Preventing and managing chemotherapy toxicity are crucial to optimizing patient outcomes (i.e., curing, prolonging life, or palliating symptoms). Making the decision to start chemotherapy depends greatly on the overall patient picture, with emphasis on performance status (see below) and comorbid conditions. Knowledge of the major adverse effects of individual regimens is important for anticipation and prophylaxis of such toxicities. Many regimens require appropriate premedications and hydration. Furthermore, decisions to start chemotherapy must include the full consent and understanding of risks by the patient. Counseling on the chemotherapy and risk of toxicity is imperative before dosing. Lung cancer regimens and their associated toxicities are shown in Table 87–4.

Performance Status

The performance status of an individual patient predicts response and likelihood of toxicity to chemotherapy as well as overall survival.[22] The performance status scaling system used most frequently was developed by the Eastern Cooperative Oncology Group (ECOG)[23] (Table 87–5). ❹ *Categorizing patients on their ECOG performance status (PS) allows for an objective measure of capability to tolerate systemic therapies that may severely compromise the patient's health. Patients who score well (0–1) are more likely to tolerate intense therapy, whereas patients who score highly (3–4) are considered unfit for chemotherapy or surgery. There is some controversy over whether to treat patients with a PS of 2. At this point, treatment is aimed at treating comorbidities to improve the performance status or the use of palliative symptomatic therapy.* Patients with less advanced disease may be treated more aggressively in this scenario.

Adjuvant Therapy

The term *adjuvant therapy* refers to the use of chemotherapy or radiotherapy following surgical resection of a tumor mass. The rationale behind adjuvant chemotherapy is to eradicate micrometastases or other tumor cells that may have been missed during removal of the primary tumor. The recent results of five relatively large prospective trials (n = 344–1867) suggest that there is benefit from adjuvant chemotherapy. The largest study, the International Adjuvant Lung Trial (IALT),[24] has led to the

TABLE 87–4. Chemotherapy Regimens in Lung Cancer and Associated Toxicities[23,39,44,63–75]

	Dose	Cycle Length	Neutropenia	
			Grade III	Grade IV
Non-Small Cell				
Paclitaxel-carboplatin-bevacizumab	Carboplatin, dose targeted to *AUC* of 6 IV (day 1), paclitaxel 200 mg/m^2 IVover 3 hours (day 1), bevacizumab 15 mg/kg IV (day 1)	21 days	N/A	24%
Cisplatin-paclitaxel	Paclitaxel 135 mg/m^2 IV over 24 hours (day 1) and cisplatin 75 mg/m^2 IV (day 2)	21 days	18%	57%
Cisplatin-docetaxel	Cisplatin 75 mg/m^2 IV (day 1) and docetaxel 75 mg/m^2 IV (day 1)	21 days	21%	48%
Cisplatin-gemcitabine	Cisplatin 100 mg/m^2 IV (day 1) and gemcitabine 1000 mg/m^2 IV (days 1, 8, 15)	28 days	24%	39%
Carboplatin-paclitaxel	Carboplatin, dose targeted to *AUC* of 6 IV (day 1), and paclitaxel 225 mg/m^2 IV over 3 hours (day 1)	21 days	20%	43%
Gemcitabine-paclitaxel	Paclitaxel 200 mg/m^2 IV (day 1) and gemcitabine 1000 mg/m^2 (day 1 and 8)	21 days	10%	5%
Gemcitabine-docetaxel	Gemcitabine 1100 mg/m^2 IV (days 1 and 8) and docetaxel 100 mg/m^2 IV (day 8)	21 days	11%	11%
Gemcitabine	Gemcitabine 1125 mg/m^2 (days 1 and 8)	21 days	19%	
Pemetrexed	Pemetrexed 500 mg/m^2 (day 1), vitamin B_{12} 1 mg IM 1–2 weeks before treatment initiation and every 9 weeks thereafter, folic acid 1 mg daily beginning 3 weeks before treatment initiation	21 days	5–6%	
Paclitaxel	Paclitaxel 200 mg/m^2 IV over 3 hours (day 1)	21 days	34%	3%
Docetaxel	Docetaxel 35 mg/m^2 IV over 1 hour (days 1, 8, 15)	28 days	5%	
Small Cell				
EP	Etoposide 100 mg/m^2 IV (days 1–3) and cisplatin 100 mg/m^2 IV (day 2)	28 days	85%	18%
CAV	Cyclophosphamide 800 mg/m^2 IV (day 1), doxorubicin 50 mg/m^2 (day 1), and vincristine 1.4 mg/m^2 (maximum of 2 mg) IV (day 1)	21–28 days	15%	72%
EC	Etoposide 100 mg/m^2 IV (days 1–3) and carboplatin *AUC* 5–6 IV (day 1)	21 days	10–20%	5–15%
IC	Irinotecan 60 mg/m^2 (days 1, 8, 15) and cisplatin 60 mg/m^2 (day 1)	28 days	40%	25%
Topotecan	Topotecan 1.5 mg/m^2 IV over 30 minutes (days 1–5)	21 days	18%	70%

	Other Significant Toxicities	Nausea and Vomiting Potential
Non–Small Cell		
Paclitaxel-carboplatin-bevacizumab	Diarrhea, fever, headache, hypertension, hemoptysis, infection, leucopenia, nausea, neuropathy, peripheral neuritis, vomiting, thromobocytopenia, thrombotic events	High (day 1 only)
Cisplatin-paclitaxel	Febrile neutropenia, infection, thrombocytopenia, nausea, vomiting, diarrhea, cardiac toxicity, renal toxicity, neuropathy, weakness, hypersensitivity reactions, anemia	High (day 2 only)
Cisplatin-docetaxel	Infection, thromocytopenia, nausea, vomiting, diarrhea, cardiac, renal, neuropathy, weakness, hypersensitivity, anemia	High (day 1 only)
Cisplatin-gemcitabine	Febrile neutropenia, infection, thrombocytopenia, nausea, vomiting, diarrhea, cardiac, renal, neuropathy, weakness, anemia	High (day 1) Mild (days 8 and 15)
Carboplatin-paclitaxel	Infection, thrombocytopenia, nausea, vomiting, diarrhea, cardiac, renal, neuropathy, weakness, hypersensitivity, anemia	High (day 1 only)
Gemcitabine-paclitaxel	Alopecia, nausea and vomiting, neurotoxicity, thrombocytopenia	Moderate
Gemcitabine-docetaxel	Nausea and vomiting, diarrhea, thrombocytopenia, asthenia, neurotoxicity	Moderate
Gemcitabine	Thrombocytopenia	Mild
Pemetrexed	Anemia	Mild
Paclitaxel	Infection, nausea, vomiting, diarrhea, mucositis, arthralgia, asthenia, peripheral neuropathy, alopecia, cardiovascular	Mild (day 1 only)
Docetaxel	Fatigue, nausea, vomiting, skin toxicity, neuropathy, anemia, hypersensitivity, alopecia	Mild (on administration days only)

(Continued)

TABLE 87–4. Chemotherapy Regimens in Lung Cancer and Associated Toxicities[23,39,44,63–75] (*Continued*)

	Other Significant Toxicities	Nausea and Vomiting Potential
Small Cell		
EP	Infection, fever, nausea, vomiting, thrombocytopenia, anemia	High (day 2 only)
CAV	Nausea, vomiting, thrombocytopenia, neuropathy, hepatic, renal, alopecia	High
EC	Infection, thrombocytopenia, alopecia	High (day 1 only)
IC	Fever, infection, thrombocytopenia, anemia, diarrhea, nausea and vomiting, liver enzymes	High (day 1), moderate (days 8 and 15)
Topotecan	Neutropenic fever, neutropenic sepsis, anemia, thrombocytopenia, nausea, fatigue, vomiting, stomatitis, anorexia, diarrhea, fever	Mild (days 1–5)

CAV, cyclophosphamide, doxorubicin, vincristine; EC, etoposide carboplatin; EP, etoposide cisplatin; IC, irinotecan, cisplatin. See Table 87–4 for doses and schedules.

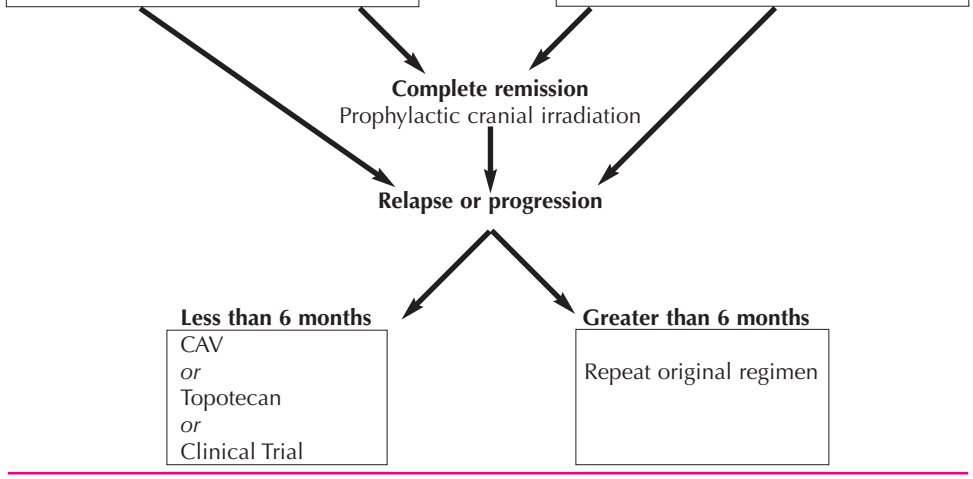
conclusion that adjuvant chemotherapy following surgical resection of non–small cell tumors leads to a 4% improvement in survival. Interestingly, the majority of patients in the IALT trial were treated with a cisplatin and an older agent, which have been proven inferior to combinations of cisplatin and a newer agent in the advanced disease setting. Two studies (Intergroup JBR-10 and CALGB 9633) evaluated cisplatin-vinorelbine and carboplatin-paclitaxel (current standards for advanced-stage disease) and found a survival advantage of 12% to 15%.[25] Consequently, adjuvant therapy has become the standard of care and should be offered to patients after resection,[26] and although the regimen of choice is unclear, carboplatin-paclitaxel and cisplatin-vinorelbine appear to be the regimens with the most evidence.

Adjuvant radiotherapy, or postoperative radiotherapy (PORT), is thought to eliminate remnants of the resected tumor that might be deposited in nearby tissue. Clinical trials have clearly shown that PORT decreases local recurrence; however, a survival benefit has never been shown. A meta-analysis of PORT when used alone suggest that PORT actually may be detrimental to patients with early-stage disease (stage I or II).[27,28] The meta-analysis evaluated older studies that used outdated radiation techniques, and consequently, some argue that the meta-analysis does not apply to current practice.[29] Nonetheless, no studies to date have demonstrated a survival advantage with PORT. In cases where local recurrence is a significant risk, PORT still may be a viable option. In fact, current guidelines recommend that patients with positive surgical margins (i.e., cancerous cells are detected on the surface of the excised tissue) undergo reresection or systemic chemotherapy or PORT.[18] Outside this indication, adjuvant radiotherapy without concurrent chemotherapy is not considered beneficial, especially in early-stage disease.

TABLE 87–5. ECOG Performance Status[33–35]

ECOG Score	Patient Status
0	Unrestricted, asymptomatic
1	Able to complete light work activities but restricted from strenuous tasks. Otherwise ambulatory.
2	Ambulatory for more than 50% of waking hours. Able to care for self completely but unable to complete even light work.
3	Able to care for self on a limited basis, confined to bed or chair more than 50% of time awake. Unable to carry out work activities
4	Completely disabled, confined to bed or chair
5	Deceased

Neoadjuvant Therapy



Neoadjuvant, or *induction*, *therapy* refers to the use of chemotherapy regimens or radiotherapy prior to surgery. The rationale behind neoadjuvant therapy is to decrease the size of the tumor so that it can be extracted more easily with clean margins, as well as to eliminate distant micrometastases before invasive local treatment. Furthermore, patients with marginally resectable or nonresectable tumors may respond sufficiently to induction therapy that surgery becomes an option. Neoadjuvant chemotherapy has been shown to yield benefits in NSCLC (i.e., increase in median survival and disease-free survival and decreased risk of metastasis) for both local and locally advanced disease.[30] However, the toxicity of induction regimens may delay surgery, and if the tumor does not respond to the treatment, there is a risk of disease progression. Nonetheless, current data suggest that over 90% of patients who are treated with neoadjuvant therapy maintain their scheduled surgery.[31] This approach is most common in patients with locally advanced tumors (stage III).[32] Current studies are aimed at comparing neoadjuvant with adjuvant therapy in earlier-stage NSCLC patients.

Small Cell Lung Cancer

Small cell lung cancer typically presents as extensive disease (approximately 60% to 70% of new cases) and progresses very quickly. Small cell carcinomas are very responsive to chemotherapy and radiation. Radiotherapy became the standard in 1969, when a randomized trial showed that it offered the potential for cure, whereas surgery did not.[20] For the vast majority of patients, chemotherapy with or without radiotherapy is the treatment of choice. Even after a complete response to therapy, the cancer usually recurs within 6 to 8 months, and survival time following recurrence is typically short (~4 months). This yields a typical survival rate of 14 to 20 months for limited disease and 8 to 13 months for extensive disease.[33] Table 87–6 illustrates the general treatment path of SCLC.

TABLE 87–6. Small Cell Lung Cancer Treatment Overview[60]

Stage	First Line
Limited	EP × 4 cycles *or* EC × 4 cycles *plus* Concurrent radiation
Extensive	EP × 4–6 cycles *or* EC × 4 cycles *or* IC × 4 cycles

CAV, cyclophosphamide, doxorubicin, vincristine; EC, etoposide carboplatin; EP, etoposide cisplatin; IC, irinotecan, cisplatin. See Table 87–4 for doses and schedules.

Limited Disease

The regimen of choice for limited-disease SCLC is etoposide-cisplatin (EP). Carboplatin may be substituted for cisplatin to reduce nausea and vomiting, nephrotoxicity, or neurotoxicity,[34] although increased myelosuppression in the form of thrombocytopenia may result.[35] In patients who are able to tolerate combined therapy, concomitant chemoradiotherapy offers the most substantial survival benefit. In European countries, a three-drug combination containing an anthracycline has been the mainstay of therapy; however, mounting clinical evidence shows that these regimens are inferior to EP plus concurrent radiation and have more toxicity.[36] Consequently, the guidelines recommend that the EP regimen be used with concurrent radiotherapy.[33] Since patients with small cell lung cancer commonly have a recurrence in the central nervous system (CNS), trials have been performed to evaluate the benefit of prophylactic cranial irradiation (PCI). A pivotal study showed that PCI reduces the incidence of brain metastasis and increases 3-year survival from 15% to 21%.[37,38] Consequently, patients who achieve a complete response with treatment should be offered PCI.

Extensive Disease

Platinum regimens are also the treatment of choice in extensive disease, and many studies have failed to show superiority to the EP regimen as first-line treatment. A combination of irinotecan and cisplatin in one Japanese study demonstrated an increased median survival time by approximately 3 months over the EP regimen. This regimen showed a lower incidence of severe neutropenic side effects but exhibited higher rates of middle- to high-grade diarrhea.[39] However, this study was repeated in the United States and did not show a similar improvement over the EP regimen.[40] Therefore, EP remains the regimen of choice for treating extensive SCLC in the United States. Concurrent radiotherapy is not used routinely in extensive disease.[39]

Recurrent Disease

The treatment of recurrent disease depends on the time to recurrence. If the time to recurrence is less than 6 months, second-line therapy should be considered if the patient has an acceptable performance status (see "Patient Care and Monitoring"). The most widely accepted second-line therapies in SCLC are topotecan alone or CAV [cyclophosphamide, doxorubicin (Adriamycin), vincristine]. Relapses occurring more than 6 months after treatment warrant a repeat of the initial regimen. Poor performance status patients (3–4) typically are treated with palliative care therapies.

Non–Small Cell Lung Cancer

The first step in treatment of NSCLC involves confirmation of the clinical stage and determination of resectability of the tumor. This decision always should be made by a thoracic surgeon who routinely performs lung cancer surgery. Treatment options depend on the advancement of disease (i.e., local, locally advanced, or metastatic).

Local Disease

Local disease encompasses stages IA through IIA and is associated with a favorable prognosis because approximately 40% to 60% of patients are expected to live more than 5 years from diagnosis. Goals of therapy are curative in local disease, and surgery is the mainstay of treatment. Stage IA tumors are seen rarely clinically but may be treated with surgery alone. In this case, neoadjuvant or adjuvant therapy has not been studied adequately to know if it conveys a benefit. If surgical margins are positive, radiotherapy or reresection is recommended.[18] Stage IB, IIA, and IIB disease is treated with adjuvant chemotherapy. Patients who have positive or questionable margins may receive radiation therapy, which typically is administered with the adjuvant chemotherapy. The regimen of choice in this setting is not clear; however, the most benefit seen in clinical trials used carboplatin-paclitaxel or cisplatin-vinorelbine.[18,25]

Locally Advanced Disease

Patients with locally advanced disease (stages IIB and IIIA) still may be considered for surgery. Neoadjuvant chemotherapy with concurrent radiotherapy can be used prior to surgery, although this practice varies from institution to institution. Progression of disease during induction therapy may preclude surgery, and the regimen should be altered if disease progresses in this time. If there is a response, surgery may proceed, preferably with additional adjuvant chemotherapy. Nonresectable locally advanced disease may be treated with both an active platinum-containing regimen and radiotherapy.

Advanced or Metastatic Disease (Stages IIIB and IV)

Advanced disease is treated with chemotherapy if the patient has an acceptable ECOG PS score (0–1). Platinum-containing doublets have produced the highest overall response rates (25% to 35%) and survival times (30% to 40% 1-year survival) in well-performing patients with advanced disease. A platinum agent and one of the newer agents (see below) are superior to a platinum agent and an older agent (e.g., etoposide or vindesine). A number of different platinum doublet treatment regimens which have used in this setting, and no agent appears to be clearly superior to the others. There has been some debate about the equivalence of cisplatin and carboplatin. To address this question, a recent meta-analysis[41] was performed that found that cisplatin is superior to carboplatin when combined with a newer agent in advanced-stage NSCLC. This analysis had some limitations, which leaves clinicians to make their own decision. Additionally, two non-platinum-containing regimens have been shown to have similar response and survival benefits. Both gemcitabine-paclitaxel and gemcitabine-docetaxel have been shown to produce similar response durations and survival times as platinum-containing regimens[42,43] and may be substituted when patients are unlikely to tolerate the toxicity of platinum regimens owing to comorbidities or other factors. NSCLC chemotherapy doublets that are considered generally equivalent include

- Paclitaxel-cisplatin
- Paclitaxel-carboplatin
- Cisplatin-gemcitabine
- Cisplatin-docetaxel
- Carboplatin-docetaxel
- Cisplatin-vinorelbine
- Gemcitabine-paclitaxel
- Gemcitabine-docetaxel

A large randomized trial comparing the first four regimens reported similar response rates and survival with all treatments, although there was less life-threatening toxicity and treatment-related death associated with the administration of paclitaxel-carboplatin. Consequently, one may argue that paclitaxel-carboplatin is the treatment of choice. However, the carboplatin- paclitaxel regimen used in the trial[44] infused paclitaxel over 24 hours, which is uncommon in clinical practice. The most common carboplatin-paclitaxel regimen infuses a higher dose of paclitaxel over 3 hours in the clinic rather than admit patients to the hospital for a 24-hour infusion. It is unfair to extrapolate the toxicity advantage from this trial to the commonly used 3-hour paclitaxel infusion, and consequently, there is truly not a single best regimen.

While it is unclear exactly which platinum combination is the best, new research is being aimed at adding nontraditional agents to platinum regimens. Adding the EGFR tyrosine kinase inhibitors to chemotherapy provides no benefit; however, adding bevacizumab to the carboplatin-paclitaxel (3-hour infusion) regimen increases response rates and prolongs progression-free and overall survival.[45] Consequently, carboplatin-paclitaxel and bevacizumab are arguably the new standard of care. Based on the inclusion/exclusion criteria for this study, bevacizumab is recommended when the patient meets the following criteria:[18]

- Non–squamous cell histology (NSCLC only)
- History negative for hemoptysis
- History negative for CNS metastasis
- No concurrent anticoagulation therapy (i.e., enoxaparin, heparin, or warfarin)
- Chemotherapy regimen that does not have significant (greater than 10%) risk of thrombocytopenia

Treating patients with a PS of 2 is a subject of much debate. While PS 2 patients typically show inferior survival rates and higher toxicity to platinum chemotherapy than higher-performing patients, low-toxicity single-agent regimens may offer a survival advantage in this subset. Use of these regimens also presents a method of providing symptomatic care for advanced-stage patients.[46] Newer third-generation agents such as pemetrexed, gemcitabine, and docetaxel may be used in this scenario. In PS 3 or 4 patients, chemotherapy typically results in high rates of toxicity and fails to convey a survival benefit. Consequently, treatment should be aimed at relief of symptoms instead of a definitive cure.

Patient Encounter, Part 3

The patient's condition has not interfered with his ability to work, and he is able to complete most daily activities. Therefore his ECOG PS score in 0.

- Are there any nonpharmacologic interventions you would suggest?

Recurrent (Progressive) Disease

Although patients may experience a response to initial therapy, disease recurs in many cases. If the recurrence is localized, surgery options may be assessed. If the patient's PS remains acceptable (0–1), second-line systemic chemotherapy has been shown to improve survival. A single-agent therapy with docetaxel, pemetrexed, or erlotinib is recommended at this stage.[47] Recurrences in poorly performing patients (3–4) usually are not treated with chemotherapy and are instead treated with supportive care. Additional recurrences (i.e., third-line therapy) may be treated with erlotinib if not used previously. Otherwise, repeat single-agent therapy or administer best supportive care.

Single-Agent Therapy

First-line therapy for advanced-stage NSCLC and small cell lung cancer is best done with a two-drug regimen. However, patients who have a recurrence after the initial regimen are best treated with a single chemotherapy agent. Single-agent therapy is also acceptable for poor health patients with advanced disease because toxicities tend to be lower with one-drug regimens.[48] Typical agents used in monotherapy in lung cancer include pemetrexed, erlotinib, docetaxel, gemcitabine, paclitaxel, topotecan, and vinorelbine.[10,47–49]

Combination Therapy

❺ *Doublet chemotherapy regimens clearly are superior in response to single-agent regimens and should be used when the patient can tolerate the increased toxicity. Platinum-containing regimens are the mainstay of multidrug regimens.* There are several regimens that contain either cisplatin or carboplatin, and some clinicians feel that they can be substituted for each other; however, it is unclear if cisplatin and carboplatin are equally efficacious. When combined with newer agents (e.g., paclitaxel), both improve survival in patients with advanced-stage NSCLC compared with combinations with older agents (e.g., etoposide). Because of differences in toxicity, many clinicians favor carboplatin over cisplatin.[49] There is also interest in developing non-platinum-containing doublets. Recent studies suggest that gemcitabine combined with paclitaxel or docetaxel is just as effective in advanced-stage NSCLC as a platinum doublet; however, guidelines still suggest that a platinum-containing doublet should be used when feasible.[18] In small cell lung cancer, a platinum agent combined with an older agent (e.g., etoposide) is the treatment of choice. However, there are a number of non-platinum-containing three-drug anthracycline-containing regimens that are equally effective as a platinum doublet, at least in extensive-stage disease. However, the three-drug regimens are more toxic and therefore used rarely in the United States. In limited-stage disease, cisplatin and etoposide are superior to the three-drug anthracycline-containing regimens, and when combined with concurrent radiation, they provide optimal outcomes.[36] A direct comparison of cisplatin and carboplatin combined with etoposide found similar results, and many clinicians consider the agents interchangeable; however, this trial enrolled primarily patients with extensive-stage disease. A direct comparison in patients with limited-stage disease has not been performed, and most clinicians consider cisplatin and etoposide to be the treatment of choice because they have been used in nearly all the large comparative trials.

Monoclonal Antibodies

Bevacizumab and cetuximab are IgG monoclonal antibodies that have activity in NSCLC. Bevacizumab targets vascular endothelial-derived growth factor (VEGF), which is thought to facilitate angiogenesis, a process contributing to growth and maintenance of the tumor environment.[50] Cetuximab targets epidermal growth factor receptor (EGFR), a cytokine receptor on tumor cells that is frequently involved with tumor survival and proliferation. These monoclonal antibodies have different and less extensive toxicity profiles than traditional chemotherapy agents and appear to be synergistic with chemotherapy; hence they have been studied with the most active chemotherapy regimens for lung cancer. At this relatively early point in testing, bevacizumab has been shown to improve survival of advanced-stage NSCLC patients in a large phase III trial[45] and has been incorporated into current guidelines.[18,51,52] Cetuximab appears promising, but no large phase III trials have been completed at this time. Consequently, it is not recommended for use in lung cancer outside a clinical trial.

Tyrosine Kinase Inhibitors

Tyrosine kinase inhibitors (TKIs) work by targeting specific intracellular messenger proteins that transmit growth and survival signals. Two TKIs are currently available for treatment of lung cancer: erlotinib and gefitinib. These agents, like cetuximab, target the EGFR, which has been shown to be mutated or overexpressed in some lung tumors.[53] Both these medications are structurally related and presumably have the same mechanism of action; however, recent data show that erlotinib prolongs survival, whereas gefitinib does not. Consequently, gefitinib availability is restricted until the FDA and the company determine if there is a predictable way to identify patients who will respond to therapy. It appears that certain clinical factors are able to aid in prediction of response to both EGFR inhibitors, such as female gender, Asian ancestry, adenocarcinoma histology, and lack of significant smoking history.[54] However, the fate of gefitinib is undetermined at this time. Currently, several TKIs

that target the EGFR and other cell-signaling cascades are in clinical trials and show promise for the treatment of lung cancer.

PATIENT CARE AND MONITORING

Screening and Early Detection

Overall 5-year survival in lung cancer is only 15%, whereas those who are diagnosed at a localized stage exhibit a 5-year survival rate of 50%. Currently, over three-quarters of newly diagnosed lung cancers present with locally advanced or metastatic disease, and therefore, very few patients are able to undergo surgical resection.[1] In an attempt to identify tumors when they are localized and have higher cure rates, many investigators are evaluating different screening modalities. Effective screening methods have the potential to save thousands of lives. To date, no screening study has demonstrated a benefit in overall survival; however, the use of spiral computed tomographic (CT) scanning has been shown to be sensitive in detecting small nodules. Unfortunately, spiral CT scanning alone is not likely to be of benefit owing to the high rate of false-positive results (i.e., lack of specificity) leading to excessive patient anxiety and work-up, which can have a negative effect on morbidity and mortality. Since lung cancer tumors are hypermetabolic, they typically can be visualized with 5-FDG positron-emission tomographic (PET) scanning. The combination of spiral CT scanning and follow-up PET scanning for positive lesions is currently the most promising method. In a recent study, this combination resulted in 90% specificity and 100% sensitivity for detection of cancer when a 3-month follow-up CT was used after a negative PET scan. Furthermore, 92% of non–small cell tumors were diagnosed at stage IA or IB.[55] Additional studies evaluating the benefits on mortality of this approach are underway. ❼ *Identification and screening of high-risk patients with spiral CT scanning and PET scanning are currently the most promising, and high-risk individuals should be encouraged to enter randomized, controlled trials aimed at demonstrating a survival benefit from screening.*

Management of Toxicity

❽ *Knowing when and how to treat adverse events from chemotherapy is an important aspect of patient care. Unmanaged events may cause delays in chemotherapy administration and reduced chemotherapy doses and may contribute to treatment failure.* Given the fatal nature of untreated lung cancer, patients and health care professionals are willing to tolerate high risks of severe and life-threatening side effects, provided that the therapy has been shown to benefit the patient. There are multiple methods of preventing or reducing toxicity to chemotherapeutic agents. These methods usually are agent-specific but commonly include maintenance of adequate hydration, use of appropriate premedications, dose reduction, and use of growth factors to combat toxicities associated with cytopenias.

Grading Toxicity

In order to standardize grading of adverse events, the National Cancer Institute (NCI) has developed the Common Terminology Criteria for Adverse Events (CTC, V3.0). Toxicities are graded from 1 to 4, where grade 1 toxicity is mild, 2 is moderate, 3 is severe, and 4 is life-threatening. Selected toxicities and their grading scales are listed in Table 87–7. The full version can be accessed at www.ctep.cancer.gov. In most cases, patients who experience grade 3 or 4 toxicity require a change in therapy with the next cycle of treatment. Common changes include a chemotherapy dose reduction or pharmacologic intervention to prevent or treat the toxicity. This grading scale or a similar one is almost always employed in clinical trials and will be published in the research manuscript. This is an invaluable tool to determine what serious toxicity is most likely with a particular regimen, and this improves the pharmacist's ability to counsel the patient, as well as determine appropriate toxicity-prevention measures.

Dose Intensity and Growth Factors

The term *dose intensity* refers to the percent of drug delivered compared with the planned amount as measured by milligrams per meter squared per week. Maintaining dose intensity (i.e., delivering the planned dose, according to the scheduled time course) has been shown to influence survival in some cancers, such as breast cancer; however, the importance of dose intensity in lung cancer is not well established. In order to maintain dose intensity, pharmacologic agents sometimes are used to combat serious toxicities that may prohibit or delay administration of subsequent doses. The most common grade 3 or 4 toxicity associated with most lung cancer chemotherapy regimens is myelosuppression, more specifically, neutropenia. Patients who experience grade 3 or 4 neutropenia are at a high risk of developing a severe or life-threatening bacterial infection. Consequently, patients with neutropenia who develop a fever are empirically given broad-spectrum antibiotics. If a patient experiences neutropenic fever, intervention with growth factors (e.g., filgrastim or sargramostim) to maintain dose intensity or dose reduction should occur prior to the next cycle of chemotherapy. In lung cancer patients, no survival benefit has been demonstrated by using a colony-stimulating factor to maintain dose intensity. ❾ *While some evidence does exist that the use of a colony-stimulating factor reduces the number of neutropenic fever episodes, hospital stay, and antibiotic administration in certain subsets of lung cancer patients, routine front-line (prophylactic) use of a colony-stimulating factor is not recommended owing to lack of a survival benefit.*[56]

Nausea and Vomiting

Platinum agents are the most active lung cancer agents and historically have very high rates of nausea and vomiting. This is particularly true of high-dose cisplatin, which is used in many regimens. Understanding how to prevent and treat

TABLE 87–7. Selected NCI CTC V3.0 (www.cstep.cancer.gov)

Toxicity	Grade 1	Grade 2	Grade 3	Grade 4	Grade 5
General	Mild	Moderate	Severe	Life-threatening	Death
Neutropenia	Lowest baseline: 1500/mm^3 (1.5×10^9/L)	Less than 1500–1000/mm^3 ($1.5–1 \times 10^9$/L)	Less than 1000–500/mm^3 ($1–0.5 \times 10^9$/L)	Less than 500/mm^3 (5×10^9/L)	
Thrombocytopenia	Lowest baseline: 75,000/mm^3 (75×10^9/L)	Less than 75,000–50,000/mm^3 ($75–50 \times 10^9$/L)	Less than 50,000–25,000/mm^3 $50–25 \times 10^9$/L)	Less than 25,000 mm^3 (25×10^9/L)	Death
Diarrhea	Increase of less than 4 stools per day over baseline or mild increase in ostomy output	Increase of 4–6 stools per day over baseline, IV fluids indicated less than 24 hours moderate increase in ostomy output compared with baseline, not interfering with ADL	Increase of greater than or equal to 7 stools per day over baseline, incontinence, IV fluids greater than or equal to 24 hours; hospitalization; severe increase in ostomy output compared to baseline; interfering with ADL	Life-threatening consequences (e.g., hemodynamic collapse)	Death
Esophagitis	Asymptomatic pathologic, radiographic, or endoscopic findings only	Symptomatic altered eating/swallowing IV fluids indicated less than 24 hours	Symptomatic and severely altered eating/swallowing; IV fluids, tube feedings, or TPN indicated greater than or equal to 24 hours	Life-threatening consequences	Death
Nausea	Loss of appetite without alteration in eating habits	Oral intake decreased without significant weight loss, dehydration or malnutrition; IV fluids indicated less than 24 hours	Inadequate oral caloric or fluid intake; IV fluids, tube feedings, or TPN indicated greater than 24 hours	Life-threatening consequences	Death
Vomiting	1 episode in 24 hours	2–5 episodes in 24 hours; IV fluidsindicated less than 24 hours	Greater than or equal to 6 episodes in 24 hours; IV fluids or TPN indicated greater than or equal to 24 hours	Life-threatening consequences	Death

chemotherapy-induced nausea and vomiting (CINV) in lung cancer patients is crucial because nearly all the regimens are highly emetogenic. Although the pathology of CINV is not fully understood, there are three classifications of CINV based on the time of occurrence in relationship to chemotherapy administration: acute CINV (1–24 hours after the dose), delayed (24 hours to 5 days after the dose), and anticipatory (before the dose following one or more previous cycles). Acute CINV appears to be influenced predominantly by serotonin binding to 5-HT_3 receptors on the vagal nerve, where it innervates the GI tract. Delayed CINV has been attributed to a variety of mechanisms but appears to be influenced by substance-P stimulation of neurokinin-1 (NK-1) receptors in the CNS, as well as a corticosteroid-responsive element. Anticipatory CINV is thought to be a learned or conditioned behavior. The major influencing factors appear to be prior acute or delayed CINV and anxiety. Anticipatory CINV may be prevented or treated with benzodiazepines such as lorazepam or alprazolam not because they possess antiemetic properties but rather because they contain amnestic and antianxiety properties.

There are three main drug targets that are antagonized to prevent or treat acute and delayed CINV: 5-HT_3 receptors, dopamine type 2 receptors (D_2), and NK-1 receptors. 5-HT_3-receptor antagonists are the most effective agents for preventing acute CINV. However, they are commonly recommended only for moderate- to high-emetogenic-potential regimens, primarily owing to cost (see Table 87–8 for a comparison of agents). Aprepitant is the only available NK-1-receptor antagonist that is approved to prevent CINV. It has modest but additive activity in acute CINV and appears to be highly active against delayed CINV. It was approved for use in highly emetogenic regimens but also works in patients receiving moderately emetogenic chemotherapy. The use of aprepitant is somewhat limited by the cost. Dopamine type 2 receptor antagonists, which are approved commonly to manage schizophrenia, also have antiemetic activity in both acute and delayed CINV. As a group, these agents do not appear to be as effective as 5-HT_3-receptor antagonist in acute CINV or as effective as aprepitant in delayed CINV. Consequently, their use is limited commonly to patients receiving mild or moderate emetogenic chemotherapy as prevention or as treatment following full-dose 5-HT_3-receptor antagonist and/or aprepitant. They are attractive owing to their relatively low cost but also cause a significant number of side effects. Interestingly, corticosteroids, most commonly dexamethasone, is an active antiemetic agent that can be used as monotherapy to prevent acute CINV in patients receiving mild to moderate emetogenic chemotherapy. They are also synergistic with 5-HT_3-receptor antagonists, aprepitant, and D_2-receptor antagonists in acute and

TABLE 87–8. Pharmacotherapy for Chemotherapy Induced Nausea and Vomiting

Class	Indication	Drug	Dose	Half-life
NK-1 inhibitors	Acute/delayed NAV	Aprepitant	125 mg PO on day 1 80 mg PO daily on days 2–3	9–13 hours
5-HT_3 inhibitors	Acute NAV	Ondansetron	16–24 mg PO or 8–12 mg IV on day 1 16 mg PO daily or 8 mg IV daily on days 2–4	3–6 hours
		Palonosetron	0.25 mg IV on day 1	40 hours
		Granisetron	1–2 mg PO or 0.01 mg/kg IV on days 1–4	4–12 hours
		Dolasetron	100 mg PO or 100 mg IV daily on days 1–4	8 hours (active metabolite)
D_2 antagonists	Acute/delayed NAV, PRN breakthrough treatment	Haloperidol	1–2 mg PO q4–6hours or 1–3 mg IV q4–6hours	20 hours
		Olanzapine	Olanzapine 2.5–5 mg PO bid prn	20–50 hours
Corticosteroids	Adjunctive treatment for acute or delayed NAV	Dexamethasone	12 mg IV or PO on day 1 8 mg IV or PO daily on days 2–4	2–4 hours biologic half-life of 36–54 hours
Benzodiazepines	Anticipatory NAV	Lorazepam	0.5–2 mg PO once on night before and once on morning of treatment	12–16 hours
	Anticipatory NAV	Alprazolam	0.5–2 mg PO tid starting the night prior to treatment	12–16 hours

NAV, nausea and vomiting.

delayed CINV. Although antiemetic choices typically are guided by chemotherapy, patient-specific risk factors that may play a role include the following high-risk features: very young age, very old age, female gender, emesis associated with pregnancy or motion sickness, and those with low alcohol intake.[57]

Diarrhea

Chemotherapy-induced diarrhea can be a significant toxicity in cancer patients and should be managed pharmacologically when necessary. The most common offending agents include irinotecan and fluorouracil. Treatment may include loperamide (4 mg at the onset followed by 2 mg every 2 hours until resolution—may use 4 mg every 4 hours during sleep) or octreotide (starting at 100 mcg subcutaneously every 8 hours and titrated to effect). The goals of therapy are resolution of diarrhea and improvement in quality of life.[58]

Surveillance

Following response to surgery or pharmacologic treatment, the patient should be monitored regularly to detect recurrence. NCCN guidelines suggest a physical examination and chest x-ray every 3 to 4 months for 2 years. If no disease is detected during this time, follow-up frequency can be prolonged to every 6 months for 3 years and then annually. Low-dose spiral CT scanning is also recommended annually. Additionally, smoking-cessation counseling with or without pharmacologic treatment should be a priority.[18–33]

Complications

Cachexia and Anorexia

Cachexia is a severe wasting syndrome that is seen in many cancer patients. Although it is more common in advanced disease, it is often seen in localized disease as well. Cachexia is characterized by a catabolic state that leads to significant loss of body mass, both lean muscle and fat. The causes of cachexia are poorly understood, but it is thought that they involve inflammatory cytokines such as tumor necrosis factor α (originally described as cachexin). **Anorexia** is the patient's loss of appetite or willingness to eat. The presence of anorexia can aggravate cachexia and contribute to morbidity. When anorexia contributes to cachexia, it is important to assess the patient for the underlying cause of the anorexia.

Causes for anorexia in lung cancer patients can be widespread and include CINV, esophagitis and mucosal irritation from combined radiotherapy and chemotherapy, gastrointestinal obstruction owing to tumors, constipation from analgesics, and psychological factors such as anxiety or depression. Many of these issues may be improved with pharmacologic treatment of the underlying cause (i.e., antidepressant therapy for psychological factors) or with palliative treatment of the offending tumor.[59] Additionally, appetite stimulants such as the cannabinoid drobinol (2.5 mg twice daily with meals, titrated to a maximum of 20 mg/day) and megesterol acetate (400–800 mg/day orally) can aid in increasing caloric intake.

Cachexia is more difficult to treat, although it may resolve following treatment of the underlying malignancy. Nutritional consultation may be of aid, although cachexia is thought to be more attributable to internal pathophysiologic processes than malnutrition.

Paraneoplastic Syndromes

Paraneoplastic syndromes are clinical syndromes owing to nonmetastatic systemic effects of cancer. Tumors make and secrete biologically active products that can stimulate or inhibit hormone production, autoimmunity, immune complex production, or immune suppression. Lung cancer, particularly small cell lung cancer, is associated with a high rate of paraneoplastic

Patient Encounter, Part 4

Based on the information provided, develop a care plan for this patient. Include (1) treatment goals, (2) monitoring parameters for anticipated toxicities, and (3) a follow-up plan to determine response to treatment and surveillance.

syndromes. Pharmacologic therapy is necessary when the abnormality causes the patient acute physical or psychological stress or adversely affects his or her health. When possible, therapy should be directed at the primary tumor, and a response often leads to resolution of symptoms.

Palliative Care

Ultimately, most lung cancer patients succumb to their disease. Palliative care involves management of symptoms and improvement of quality of life when curative treatment options are no longer available. Often, problematic metastases can be removed by surgery (depending on location) or can be treated with radiotherapy to reduce the size. In selecting options at this point in treatment, it is important to keep the goals of therapy in mind, those being maximizing the duration and quality of life. Low-toxicity single-agent chemotherapy, targeted therapy, and best supportive care, which includes fatigue and pain management, are commonly the mainstays of palliative care.

OUTCOME EVALUATION

Following treatment, evaluate the goals of therapy versus the response that was achieved. Was there response to treatment or progression of disease? If the patient is being treated with supportive care, then alleviation of symptoms and improvement in quality of life should be of primary importance. Be sure to document objective evaluations of the outcome in the care plan.

TABLE 87–9. RECIST Criteria

Term	Description
Complete response (CR):	Disappearance of all targeted lesions
Partial response (PR):	At least a 30% decrease in the sum of the longest diameter of target lesions from baseline
Progressive disease (PD):	At least a 20% increase in the sum of the longest diameter of target lesions from baseline, including new lesions discovered during treatment
Stable disease (SD):	Neither sufficient shrinkage to qualify for PR nor sufficient increase to qualify for PD

Patient Care and Monitoring

1. Review the patient's medical and social history. Was the patient exposed to clinical risk factors for lung cancer?
2. Verify the histology and clinical stage of disease. Evaluate the patient's performance status. Is the patient a surgical candidate? How does this influence treatment recommendations?
3. Develop a care plan based on treatment goals. If the goal is palliative care, how does treatment-related toxicity influence therapy?
4. If chemotherapy is the treatment of choice, counsel the patient on risks and benefits of undergoing such therapy. Be sure that the patient understands the issues fully before moving forward.
5. Verify dosing of all agents in the chemotherapy regimen. What are the major expected toxicities?
6. Evaluate toxicity as treatment progresses. Is the toxicity severe enough to warrant dose reduction or pharmacologic treatment? Record graded toxicities according to the NCI CTC V3.0 criteria.
7. Evaluate the response to treatment. Did the patient experience a complete response, partial response, stable disease, or disease progression? How does this change future treatment?
8. If the patient is in remission, develop a monitoring plan. What signs or symptoms denote disease progression?
9. Recommend a smoking-cessation program or other risk-reduction plan for the patient.

RECIST Criteria

The RECIST (Response Evaluation Criteria in Solid Tumors) criteria are guidelines that objectively measure a patient's response to a therapeutic intervention. The RECIST criteria define a complete response (CR), partial response (PR), stable disease (SD), and progressive disease (PD) in objective terms.[60] The RECIST guidelines were put into place to standardize reporting of response end points in clinical lung cancer trials. The patient's response to therapy is key because it guides therapy decisions (i.e., continue therapy, change regimens, etc.). These terms are defined in Table 87–9. The full guidelines can be accessed at www.eortc.be/recist.

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Identify the risk factors for colon cancer.
2. Recognize the signs and symptoms of colon cancer.
3. Describe the treatment options for colon cancer based on patient-specific factors, such as stage of disease, age of patient, and previous treatment received.
4. Outline the pharmacologic principles for agents used to treat colon cancer.
5. Develop a monitoring plan to assess the efficacy and toxicity of agents used in colon cancer.
6. Educate patients about the adverse effects of chemotherapy that require specific patient counseling.
7. Outline preventive and screening strategies for individuals at average and high risk for colon cancer.

Key Concepts

❶ Although there are numerous risk factors for developing colon cancer, age is the biggest risk factor.

❷ Dietary and pharmacologic agents influence the risk of colon cancer. Diets high in fat and low in fiber are associated with increased colon cancer risk, whereas the regular use of aspirin (and other NSAIDs) and calcium supplementation may decrease the risk of colon cancer.

❸ Most patients with colon cancer are asymptomatic early but may develop changes in bowel or eating habits, fatigue, abdominal pain, and blood in stool.

❹ The stage of colorectal cancer is determined by the TNM staging system and is the most important prognostic factor for patient survival. Stage I to III disease is curable, whereas patients with stage IV disease are treated with the goal of palliation.

❺ **Adjuvant chemotherapy** is not needed in patients with stage I colon cancer, is controversial in patients with stage II colon cancer, and is standard of care in patients with stage III colon cancer.

❻ 5-Flurouracil-based chemotherapy is the standard regimen used in adjuvant treatment of colon cancer. It is usually given for 6 months with leucovorin, and based on recent clinical trials, oxaliplatin also may be added to the combination.

❼ Triple-drug therapy consisting of 5-fluorouracil and leucovorin with oxaliplatin or irinotecan improves survival compared with 5-fluorouracil plus leucovorin alone and is considered as standard first-line therapy for metastatic disease. Bevacizumab, in combination with 5-fluorouracil-based chemotherapy, is also indicated for initial treatment of metastatic colorectal cancer.

❽ Adjuvant therapy consisting of 5-fluorouracil-based chemotherapy in combination with radiation therapy should be offered to patients with stage II or III cancer of the rectum.

❾ Patients should be evaluated during every treatment visit for the presence of anticipated side effects from their treatment, and health care practitioners should anticipate these adverse reactions and treat them aggressively and attempt to prevent them from occurring.

❿ Effective colorectal cancer screening programs incorporate annual fecal occult blood testing in combination with regular examination of the entire colon starting at age 50 for average-risk individuals and should be recommended by all health care providers.

Colon cancer is one of the three most common cancers diagnosed in the United States and includes cancers of the colon and rectum. In 2007, approximately 153,760 new cases were diagnosed and an estimated 52,180 deaths occurred, making colon cancer the second leading cause of cancer-related deaths in the United States.[1] Patient prognosis is determined primarily by the extent or stage of disease, with most patients with early-stage disease being cured. Treatment for colon cancer

includes surgery, radiation, chemotherapy, and new targeted molecular therapies.

EPIDEMIOLOGY AND ETIOLOGY

Colon cancer occurs at a much higher rate in industrialized parts of the world such as North America and Europe, whereas the lowest rates are seen in less-developed areas, suggesting that environmental and dietary factors influence the development of colon cancer.[2] In addition to these environmental factors, colon cancers are known to develop more frequently in certain families, and genetic predisposition to this cancer is well known.

The incidence of colon cancer is greatest among males, who have an approximately 1.5 times greater risk for developing colorectal cancer than women. Overall, colon and rectal cancers make up approximately 10% of all cancers in men and women in the United States.[1] The median age at diagnosis is 72 years, with very few cases occurring in individuals younger than 45 years of age.[3] ❶ *Age appears to be the biggest risk factor for the development of colon cancer, with 70% of cases diagnosed in adults older than 65 years of age.*

Though still the second leading cause of cancer death, mortality rates for colon cancer have declined over the last 30 years as a result of better and increasingly used screening programs and more effective and better tolerated treatments.

PATHOPHYSIOLOGY

Anatomy and Bowel Function

The large intestine consists of the cecum; the ascending, transverse, descending, and sigmoid colon segments; and the rectum (Fig. 88–1). The function of the large intestine is to receive contents from the ileum. Absorption of materials occurs in segments of the colon proximal to the middle of the transverse colon, with movement and storage of fecal material in the left colon and distal segments of the colon.

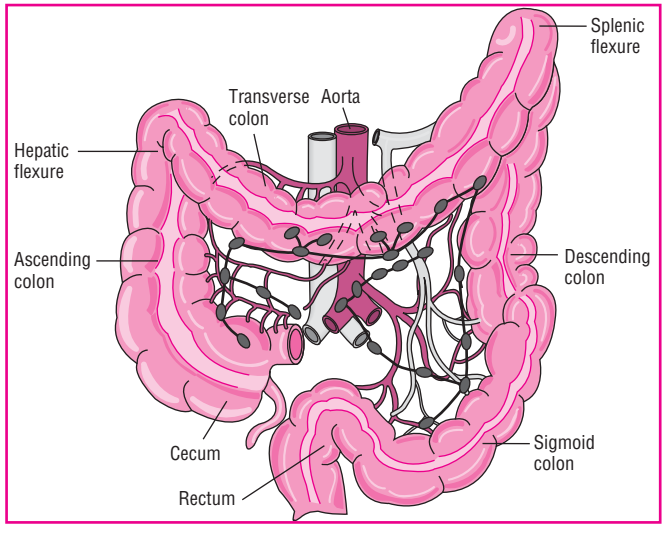

FIGURE 88–1. Colon and rectum anatomy. (From DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: Fig. 127-2.)

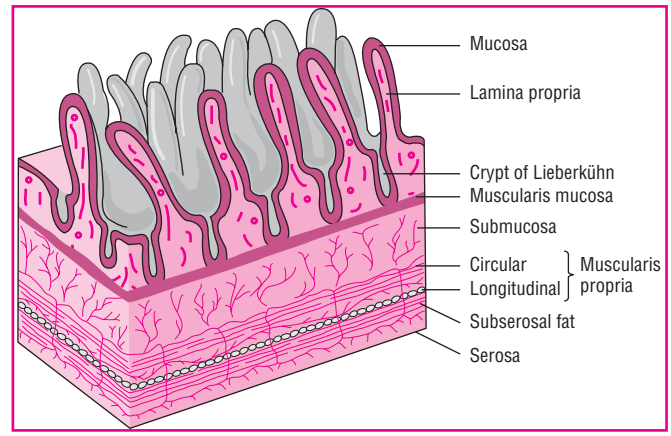

FIGURE 88–2. Cross section of bowel wall. (From DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: Fig. 127-3.)

Four major tissue layers, from the lumen outward, form the large intestine: the mucosa, submucosa, muscularis externa, and serosa (Fig. 88–2). Complete replacement of surface epithelial cells occurs approximately weekly, with the total number of epithelial cells remaining constant in normal colonic tissue. As patients age, abnormal cells accumulate on the surface epithelium and protrude into the stream of fecal matter; their contact with fecal mutagens can lead to further cell mutations and eventual adenoma formation.[4]

Colorectal Tumorigenesis

The development of a colorectal neoplasm is a multistep process of several genetic and phenotypic alterations of normal bowel epithelium structure and function leading to unregulated cell growth, proliferation, and tumor development. A genetic model has been proposed for colorectal tumorigenesis that describes a process of transformation from adenoma to carcinoma. This model of tumor development reflects an accumulation of mutations within colonic epithelium that gives a selective growth advantage to the cancer cells.[4,5] Genetic changes include activating mutations of **oncogenes,** inactivating mutations of **tumor-suppressor genes,** and defects in **DNA mismatch repair genes.**

Additional genes and protein receptors are believed to be important in colorectal tumorigenesis. Cyclooxygenase 2 (COX-2), which is induced in colorectal cancer cells, influences apoptosis and other cellular functions in colon cells, and overexpression of the epidermal growth factor receptor (EGFR), a transmembrane glycoprotein involved

Patient Encounter, Part 1

GW is a 61-year-old man who presents to your clinic with a chief complaint of abdominal discomfort and cramping for the past 3 weeks not relieved with over-the-counter medications. While obtaining your medical history, he states that he also has seen small amounts of blood in his stool on and off for 4 months. He has a past medical history positive for hypertension and obesity. He states that he has smoked 1 pack of cigarettes per day for the past 40 years and drinks 4 to 6 beers every couple of days.

- What risk factors does GW have for colon cancer?
- Does he have clinical symptoms suggestive of colon cancer?
- What additional tests need to be ordered to diagnosis colon cancer?

in signaling pathways that affect cell growth, differentiation, proliferation, and **angiogenesis,** occurs in the majority of colon cancers.[6,7] These mechanisms are potentially important because of the availability of pharmacologic agents targeted to inhibit them.

Over 90% of colon cancers are adenocarcinomas and are assigned a grade of I to III based on how similar they are to normal colon cells. Grade I tumors most closely resemble normal cellular structure, whereas, grade III tumors frequently have lost the characteristics of mature normal cells. Grade III tumors are associated with a worse prognosis than grade I tumors.[8]

RISK FACTORS

Besides age, the development of colorectal cancer appears to be caused by variety of dietary or environmental factors, comorbid disease states, and genetic susceptibility to the disease. Table 88-1 lists well-known risk factors for developing colon cancer. Epidemiologic studies of worldwide incidence of colorectal cancer suggest that dietary habits strongly influence its development.

TABLE 88–1. Risk Factors for Colon Cancer[a]

Dietary
High-fat, low-fiber diets
Lifestyle
Alcohol
Smoking
Obesity/physical inactivity
Comorbid Conditions
Inflammatory bowel disease (ulcerative colitis and Crohn's disease)
Hereditary/Genetic
Familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC)
Family history

[a]Age is the primary risk factor.

❷ *High-fat, low-fiber diets, which usually occur in tandem, have been associated with an increased risk of colon cancer.* The association between red meat consumption and colorectal cancer is strongest, possibly a result of the heterocyclic amines formed during cooking or the presence of specific fatty acids in red meat such as arachidonic acid. While data indicate that animal meat and saturated fat intake are associated with an increased risk of colorectal cancer, the exact increase in risk is unknown. The evidence for low-fiber diets as a risk factor is based on the ingestion of large amounts of dietary fiber being associated with a small, inconsistent reduced colon cancer risk. Foods that are high in fiber include vegetables, fruit, grains, and cereals. The protective effects of fiber[4] may be a result of

- Reduced absorption of carcinogens in the bowel
- Reduced bowel transit time
- Reduced dietary fat intake associated with high-fiber diets

The degree of colorectal cancer risk reduction associated with increased consumption of vegetables and fruit is variable but generally modest and has ranged from no difference to a 25% decrease in cancer risk in prospective studies.[9,10]

❷ The risk of colon cancer appears to be inversely related to calcium and folate intake. Calcium's protective effect may be related to a reduction in mucosal cell proliferation rates or through its binding to bile salts in the intestine, whereas dietary folate helps in maintaining normal bowel mucosa. Additional micronutrient deficiencies have been demonstrated through several studies to increase colorectal cancer risk and include selenium, vitamin C, vitamin D, vitamin E, and β-carotene; however, the benefit of dietary supplementation does not appear to be substantial.[11]

Chronic use of several medications has been shown to influence the risk of developing colon cancer. ❷ *Studies have consistently demonstrated that regular (at least two doses per week) nonsteroidal anti-inflammatory drug (NSAID) or aspirin use is associated with a reduced risk of colorectal cancer.*[4] Additional studies support these findings that regular aspirin or NSAID use may decrease the risk of colorectal cancer by as much as 50%.[12] The potential anticancer mechanism of NSAIDS is inhibition of cyclooxygenase-2 (COX-2). Exogenous hormone use, particularly postmenopausal hormone-replacement therapy, is associated with a significant reduction in colorectal cancer risk in most studies,[4,13] with the greatest benefit in women who are on current hormone-replacement therapy.

Personal attributes such as physical inactivity and elevated body mass index (BMI) are associated with up to a twofold increase in the risk of colon cancer. Decreased bowel

transit time and exercise-induced alterations in body glucose, insulin levels, and perhaps other hormones may reduce tumor cell growth.[4] Type 2 diabetes mellitus, independent of body mass and physical activity level, is also associated with an increased risk of colorectal cancer in women and supports a role for hyperinsulinemia as a possible link between obesity, sedentary lifestyle, diabetes mellitus, and colon cancer.[14] Additional lifestyle choices that increase the risk of colon cancer include alcohol consumption and smoking, which may increase the risk of colon cancer by generating carcinogens or their direct toxic effects on bowel tissue.[11]

Comorbid conditions, such as chronic ulcerative colitis, particularly when it involves the entire large intestine, and to lesser extent Crohn's disease, also increase the risk of colon cancer. Overall, persons diagnosed with either disease constitute about 1% to 2% of all new cases of colorectal cancer each year.

Finally, as many as 10% of cases are thought to be hereditary, resulting from genetic mutations. The two most common forms of hereditary colon cancer are familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC).[5] FAP is a rare autosomal dominant trait that is caused by mutations of the **adenomatous polyposis coli** (***APC***) gene and accounts for 1% of all colorectal cancers. The disease is manifested by hundreds to thousands of **polyps** arising during adolescence.[4,5] The risk of developing colorectal cancer for individuals with untreated FAP is close to 100%, and patients will require early screening for the disease. HNPCC, also an autosomal dominant syndrome, accounts for up to 5% of colon cancer cases.[4,5] In contrast to FAP, polyps occur rarely, and the average age of colorectal cancer in these patients is much older, with most patients diagnosed in their forties. Testing for HNPCC mutations is available but reserved for individuals who meet stringent diagnostic criteria.

Up to 25% of patients who develop colorectal cancer will have a family history of colorectal cancer unrelated to one of the mutations just described. First-degree relatives of patients diagnosed with colorectal cancer have an increased risk of the disease that is at least two to four times that of persons in the general population without a family history.[15]

Summary of Risk Factors

In summary, the true association between most dietary factors and the risk of colon cancer is unclear. The protective effects of fiber, calcium, and a diet low in fat are not completely known. Lifestyle factors such as NSAID use and hormone use appear to decrease the risk of colorectal cancer, whereas physical inactivity, alcohol use, and smoking appear to increase the risk of colon cancer. Clinical risk factors and genetic mutations are well-known risks for colon cancer.

CLINICAL PRESENTATION AND DIAGNOSIS

The signs and symptoms associated with colorectal cancer can be extremely varied, subtle, and nonspecific.

Patients presenting with symptoms suggestive of colon cancer are evaluated by a colonoscopy. If abnormalities in the bowel are identified, a biopsy is performed, and the diagnosis of colon cancer is made by a pathologist. The extent and spread of colon cancer then are evaluated by CT scans and other diagnostic imaging techniques; this evaluation is commonly called *staging*. Staging of patients is required to determine the extent of disease and is necessary in developing treatment options and determining prognosis. The TNM classification system, which takes into account T (tumor size and depth of tumor invasion), N (lymph node involvement), and M (presence or absence of metastases) is used to stage patients from stage I to stage IV. Figure 88–3 depicts how the three categories are used in combination to determine the stage of disease. ❹ *The stage of colorectal cancer on diagnosis is the most important prognostic factor for survival and disease recurrence. Stages I, II, and III disease is considered potentially curable and is treated aggressively in an attempt to cure these patients. Patients who develop stage IV disease are treated to reduce symptoms, avoid disease-related complications, and prolong survival.*

❸ Presentation of Colon Cancer

General
Patients are often asymptomatic in early stages of disease.

Symptoms
Changes in bowel habits, anorexia, nausea and vomiting, weakness (if anemia is severe)

Signs
Blood in stool, weight loss, abdominal pain

Laboratory Tests
- Patients may have a low hemoglobin level from blood loss.
- Positive fecal occult blood test (FOBT)
- Liver function tests [international normalization ratio (INR), activated partial thromboplastin time (aPTT), and bilirubin] may be abnormal if disease has metastasized to the liver.
- **Carcinoembryonic antigen (CEA)** level may be high. Normal level is less than 3 ng/mL (3 mcg/L) in nonsmokers and less than 5 ng/mL (5 mcg/L) in smokers.

Imaging Tests
Chest x-ray, CT scan, or **PET scan** may be positive if cancer has spread to the lungs, liver, or peritoneal cavity.

Patient Encounter, Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH
- Hypertension since age 47, which is not well controlled.
- Obesity; the patient is 65% over his ideal body weight.

FH
Mother and father both dead. Father died of a myocardial infarction at the age of 62. Mother died of colon cancer at the age of 64. Patient states that "many" relatives have cancer in his family.

SH
Works as an auto mechanic. Drinks alcohol frequently, and smokes 1 pack of cigarettes daily. Patient also does no exercise and states that he eats fast food daily. He is married with twin boys aged 29.

Meds
Atenolol 50 mg orally once daily

ROS
(+) abdominal cramping, mild nausea and loss of appetite, blood in stool, fatigue

PE
- **VS:** 153/90, P 78, RR 16, T 37.2°C (99°F), 72 in, 128 kg (282 lbs)
- **Abd:** Distended and tender to touch, (+) bowel sounds, heme (+) stools
- **Labs:** Positive Hemoglobin 11.3 g/dL (113 g/L 7 mmol/L) [decreased from 14.8 g/dL (148 g/L 9.2 mmol/L) last year]

Imaging and Diagnostic Studies
- Colonoscopy revealed multiple polyps in his transverse colon.
- Biopsy revealed three polyps positive for adenocarcinoma of the colon.
- Staging computed tomographic (CT) scan revealed metastatic disease in the liver.
- All other findings negative.

- Since GW has stage IV colon cancer, how does this affect
- your treatment plan compared with stage I–III disease?
- What is your treatment goal for him?
- What nonpharmacologic and pharmacologic options are available to GW?

TREATMENT

Desired Outcome

The treatment approaches for colorectal cancer reflect two primary treatment goals: curative therapy for localized disease (stages I to III) and palliative therapy for metastatic cancer (stage IV). Surgical resection of the primary tumor is the most important part of therapy in patients who clinicians are attempting to cure.[16] Depending on the stage of disease and whether the tumor originated in the colon or rectum, further adjuvant chemotherapy or chemotherapy plus radiation may be needed after surgery to cure these patients. In the metastatic setting, pharmacologic intervention is the main treatment option.

Nonpharmacologic Therapy

Operable Disease (Stages I–III)

Surgery

Individuals with stage I to III colorectal cancer should undergo a complete surgical resection of the tumor mass with removal of regional lymph nodes as a curative approach for

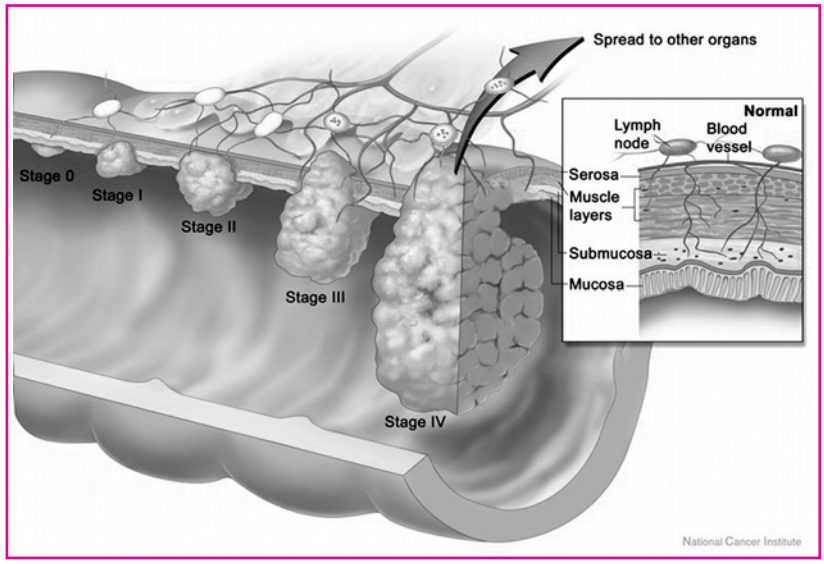

FIGURE 88–3. Stage I: Cancer is confined to the lining of the colon. Stage II: Cancer may penetrate the wall of the colon into the abdominal cavity but does not invade any local lymph nodes. Stage III: Cancer invades one or more lymph nodes but has not spread to distant organs. Stage IV: Cancer has spread to distant locations in the body, which may include the liver, lungs, or other sites. (From www.cancer.gov/cancertopics/pdq/treatment/colon/Patient/page2.)

their disease.[16] Surgery for rectal cancer depends on the region of tumor involvement, with an attempt to retain rectal function a goal of the surgical procedure. Overall, surgery for colorectal cancer is associated with low morbidity and mortality. Common complications associated with colorectal surgery include infection, anastomotic leakage, obstruction, adhesion formation, and malabsorption syndromes.

Radiation Therapy

There is currently no definitive role for adjuvant radiation in colon cancer. However, patients who receive surgery for rectal cancer receive radiation therapy to reduce local tumor recurrence. Adjuvant radiation plus chemotherapy is considered standard treatment for patients with stage II or III rectal cancer after the surgical procedure is complete.[17] Preoperative radiation may be used to reduce the initial size of rectal cancers in order to make the surgical procedure easier.

Metastatic Disease (Stage IV)

Surgery

Unlike stage I to III disease, the benefit of surgical resection in most patients with metastatic disease is limited to symptomatic improvement. Select patients who have from one to three small nodules isolated to the liver, lungs, or abdomen may have a prolongation of survival, although cure is rare. Five-year survival for patients who undergo surgical resection of metastases isolated to the liver is approximately double that of patients who are not surgical candidates.[18]

Alternatives to surgery include destroying the tumor through freezing and thawing (cryoablation), heat (radiofrequency), or alcohol injection, although these appear to be less successful than surgical interventions.[18] Because the majority of these patients will relapse, many practitioners offer adjuvant chemotherapy to selected patients following potentially curative resection, but further studies are needed to determine an optimal treatment regimen.

Radiation

Symptom reduction is the primary goal of radiation for patients with advanced or metastatic disease colorectal cancer.

Pharmacologic Therapy

Tables 88–2 and 88–3 list common chemotherapy regimens and the abbreviations often used in colon cancer.

Operable Disease (Stages I–III)

❺ *Adjuvant chemotherapy is administered after tumor resection to decrease relapse rates and improve survival in patients with colon cancer by eliminating micrometastatic disease that is undetected on imaging studies. Patients diagnosed with stage I colon or rectal cancer usually are cured by surgical resection, and adjuvant chemotherapy is not indicated in these patients.*[16] *The role of adjuvant chemotherapy for stage II colon cancer is controversial.* Adjuvant chemotherapy for patients with stage II disease has not been shown to be superior to surgery alone, with the exception of high-risk patients, who are ill-defined. Consequently, the American Society of Clinical Oncology does not recommend the routine use of adjuvant chemotherapy in the general patient population unless part of a clinical trial.[19] Patients with stage II colon cancer should be enrolled in carefully controlled clinical trials to assess the impact of new agents and prognostic models that predict who may benefit. ❺ *Adjuvant chemotherapy is standard therapy for patients with stage III colon cancer.* The presence of lymph node involvement with tumor places patients with stage III colon cancer at high risk for relapse; the risk of death within 5 years of surgical resection alone is as high as 70%.[16] In this population of patients, adjuvant chemotherapy significantly decreases risk of cancer recurrence and death and is considered standard of care.

❻ *5-Fluorouracil-based chemotherapy is the standard of care for the adjuvant treatment of colorectal cancer either as a single agent or, more commonly, in combination with other agents.* 5-Fluorouracil (5-FU) alone results in a small improvement in survival that can vary based on the method of 5-FU administration. Studies suggest that protracted or continuous intravenous (IV) 5-FU infusion treatment schedules are more effective than bolus therapy.[20]

More often 5-FU is administered as part of a combination regimen. ❻ *The most frequently used combination is 5-FU and leucovorin.* The combination of 5-FU and leucovorin has undergone extensive study in the adjuvant setting, with decreased rates of recurrence and improved survival seen in patients receiving 5-FU and leucovorin compared with surgery alone.[21] The International Multicentre Pooled Analysis of Colon Cancer Trials (IMPACT) demonstrated that recurrence and death rates were reduced by 35% and 22%, respectively, with the combination.[22] 5-FU and leucovorin can be administered in a variety of treatment schedules, but none has proven superior with regard to overall patient survival. In the past, the United States favored bolus regimens based on patient convenience. However, improved availability and comfort in use of portable infusion pumps has led to an increased use of the continuous intravenous schedule of 5-FU commonly advocated in Europe. Patients are treated with 6 months of adjuvant therapy because longer regimens do not improve patient outcomes. No standard exists for the best schedule of 5-FU and leucovorin administration, although continuous infusions may be less toxic and have improved response rates (although no survival advantage) than bolus regimens. Recently, oxaliplatin added to the combination of 5-FU and leucovorin has further improved disease-free survival in the adjuvant setting. ❻ *The MOSAIC trial, conducted in over 2200 patients, demonstrated that the addition of oxaliplatin to 5-FU and leucovorin decreases disease recurrence and improves disease-free survival.*[23] *These results led to the approval of the FOLFOX4 regimen, given for 6 months, for the adjuvant treatment of colon cancer.*

TABLE 88–2. Dosing Schedules of Chemotherapy Regimens for Colon Cancer[a]

Regimen	Dosing
5-Fluorouracil	300 mg/m^2 per day IV infused indefinitely or 250–1000 mg/m^2 per day IV over 24 hours × 5 days
5-Fluorouracil + leucovorin (bolus)	Leucovorin 500 mg/m^2 IV 5-Fluorouracil 500 mg/m^2 IV Every week × 6 weeks, followed by 2-week rest
5-Fluorouracil + leucovorin (continuous infusion)	Leucovorin 200 mg/m^2 IV 5-Fluorouracil 400 mg/m^2 IV bolus and then 600 mg/m^2 of 5-fluorouracil as a 22-hour continuous infusion On days 1 and 2; repeat every 2 weeks
5-Fluorouracil + leucovorin + irinotecan (IFL)	Leucovorin 20 mg/m^2 IV 5-Fluorouracil 500 mg/m^2 IV bolus Irinotecan 125 mg/m^2 IV Every week × 4 weeks, followed by 2-week rest
IFL + bevacizumab	IFL as above plus bevacizumab 5 mg/kg IV every 2 weeks
FOLFIRI	Irinotecan 180 mg/m^2 IV day 1 Folinic acid (leucovorin) 200 mg/m^2 IV day 1 5-Fluorouracil 400–500 mg/m^2 IV bolus, after folinic acid; then 2400–3000 mg/m^2 of 5-fluorouracil IV over 46 hours Repeat every 14 days
FOLFOX4	*Day 1* Oxaliplatin 85 mg/m^2 IV + leucovorin 200 mg/m^2 IV, followed by 5-fluorouracil 400 mg/m^2 IV bolus and then 5-fluorouracil 600 mg/m^2 IV over 22 hours *Day 2* Leucovorin 200 mg/m^2, followed by 5-fluorouracil 400 mg/m^2 IV bolus and then 5-fluorouracil 600 mg/m^2 IV over 22 hours Repeat every 2 weeks
Capecitabine	1250 mg/m^2 twice a day orally for 14 days Repeat every 3 weeks
CAPOX	Capecitabine 1000 mg/m^2 twice a day orally for 14 days Oxaliplatin 130 mg/m^2 IV on day 1 Repeat every 3 weeks
CAPIRI	Capecitabine 1000 mg/m^2 twice a day for 14 days Irinotecan 100 mg/m^2 IV days 1 and 8 Repeat every 22 days

Note: Many variations exist, and current literature should be checked prior to administering any chemotherapy regimen.

TABLE 88–3. Common Regimens Used in Colon Cancer

Acronym	Regimen
5-Fluorouracil	5-Fluorouracil given alone as a bolus or continuous infusion
LV/5-fluorouracil	Leucovorin + 5-fluorouracil given as a bolus or continuous infusion
IFL	Irinotecan + 5-fluorouracil + leucovorin given as IV boluses
IFL + bevacizumab	IFL as above plus bevacizumab
FOLFIRI	Folinic acid (leucovorin) + 5-fluorouracil + Irinotecan given as combined IV boluses and continuous infusions
FOLFOX	Folinic acid (leucovorin) + 5-fluorouracil + oxaliplatin given as combined IV boluses and continuous infusions
CAPOX	Capecitabine + Oxaliplatin given as oral therapy and IV boluses
CAPIRI	Capecitabine + Irinotecan given as oral therapy and IV boluses

Note: Many variations exist, and current literature should be checked prior to administering any chemotherapy regimen.

Capecitabine is an oral prodrug of 5-FU that also is effective in the adjuvant setting and is being evaluated as a replacement for 5-FU for patient convenience and safety reasons. Data suggest that capecitabine is at least equivalent to 5-FU and leucovorin in efficacy and is better tolerated by patients.[24] Consequently, most practitioners feel that capecitabine is an acceptable alternative to IV 5-FU plus leucovorin. However, the role of capecitabine with additional chemotherapy agents such as oxaliplatin requires further study.

Following resection of liver metastases, infusion of chemotherapy through the portal vein provides an additional adjuvant treatment approach. Historically, 5-FU and floxuridine have been the agents used most commonly for hepatic portal vein infusion owing to their high metabolism in the liver. Although some studies demonstrate a decrease in recurrence rates, the value of portal vein infusion of chemotherapy for colon cancer remains to be determined.[25] Table 88–4 summarizes adjuvant treatment recommendations for colon cancer.

TABLE 88–4. Treatment Regimens for Adjuvant Colon Cancer[a]

Stage II[b]	Stage III
High Risk	**Good Performance Status**
• FOLFOX	• FOLFOX
• Capecitabine or 5-fluorouracil plus leucovorin	• Capecitabine or 5-fluorouracil plus leucovorin
Low Risk	**Poor Performance Status**
• Observation or clinical trial	• Capecitabine

[a]CAPOX or CAPIRI may replace FOLFOX or FOLFIRI in select patients.
[b]Individualized assessment of patient risk is necessary to determine if treatment is required.

Metastatic Disease (Stage IV)

Traditional chemotherapy and targeted biologic therapies are the mainstay of treatment for metastatic colon or rectal cancer.[26] Most often a combination of chemotherapy agents with biologic therapies is administered to these patients. Currently, metastatic colorectal cancer is incurable, and treatment goals are to reduce patients' symptoms, improve quality of life, and extend survival. Combination-chemotherapy regimens have been demonstrated to result in prolongation of survival with tolerable adverse effects. Similar to the adjuvant setting, 5-FU plus leucovorin continues to be in most first-line chemotherapy regimens used for metastatic colorectal cancer. A variety of continuous IV infusion 5-FU and bolus regimens can be used, but in comparison with IV bolus 5-FU, response rates with continuous-infusion 5-FU are approximately doubled. In a meta-analysis of six randomized trials evaluating over 1200 patients with advanced colorectal cancer, continuous infusions of 5-FU had a significantly higher tumor response rate, a small increase in survival, and a lower incidence of myelosuppression, diarrhea, and mucositis than bolus regimens.[27]

Additional agents have been added to the 5-FU and leucovorin regimen with superior response and survival rates than the two drugs used alone. The addition of irinotecan to 5-FU plus leucovorin (IFL) significantly improves response rates and survival without adversely affecting quality of life. In a landmark trial, this regimen was superior to 5-FU plus leucovorin with regard to tumor response, survival, and quality of life.[28] As a result, irinotecan received approval from the Food and Drug Administration (FDA) in 2000 as first-line therapy for metastatic colorectal cancer in combination with 5-FU and leucovorin. This regimen was the most commonly administered schedule for irinotecan plus 5-FU and leucovorin in the United States until recently, when oxaliplatin in combination with 5-FU and leucovorin (FOLFOX4) demonstrated improvement in median survival when compared with the IFL regimen described earlier. A comparison of oxaliplatin plus 5-FU and leucovorin (FOLFOX4) with weekly irinotecan plus IV bolus 5-FU and leucovorin (IFL) showed the superior efficacy of FOLFOX4 compared with IFL with regard to response rates and survival.[29] Several study design-questions, including the **crossover design** and differing methods of 5-FU administration led several practitioners to debate the significance of these results. Patients on the IFL arm received weekly IV bolus 5-FU, whereas FOLFOX4 patients received 5-FU as an IV bolus followed by a continuous IV infusion, which is known to increase response rates. A larger European study validated these concerns when it compared a combined bolus and infusional 5-FU regimen plus irinotecan (FOLFIRI) with the FOLFOX regimen (using a slightly different schedule) with crossover to the opposite arm on relapse.[30] No difference in patient survival was seen with either regimen, and toxicity was as expected. Neuropathy and neutropenia were more common with FOLFOX, and diarrhea, nausea, vomiting, dehydration, and febrile neutropenia were more common with FOLFIRI.

The treatment of metastatic colon cancer has been changed with the approval of targeted or biologic agents. Bevacizumab, in combination with intravenous 5-FU-based chemotherapy, is approved by the FDA for the initial treatment of patients with metastatic colorectal cancer and represents an additional regimen for the first-line treatment of these patients. Results from randomized trials show increased benefit compared with chemotherapy alone. One phase III trial of bevacizumab in combination with IFL as first-line therapy in patients with metastatic colorectal cancer also has been completed, with a 5-month increase in median survival seen with the addition of bevacizumab with manageable adverse effects.[31] The results of this study show the relevance of angiogenesis as an important target for the treatment of metastatic colorectal cancer. How the addition of bevacizumab to FOLFOX or the other irinotecan-based combinations is the first-line treatment of metastatic colon cancer remains to be seen.

❼ *In summary, most practitioners select first-line treatment for metastatic colorectal cancer from among these currently approved treatments: oxaliplatin plus 5-FU plus leucovorin (FOLFOX), irinotecan plus 5-FU plus leucovorin (IFL or FOLFIRI), bevacizumab plus 5-FU chemotherapy.* In addition, capecitabine is approved for use in metastatic colon cancer when monotherapy is desired and appears to be an appropriate substitute for intravenous fluorouracil in the combination regimens mentioned earlier. 5-FU plus leucovorin alone is appropriate first-line treatment only for individuals for whom three-drug combination regimens are believed too toxic. The site(s) of tumor involvement, history of prior chemotherapy, and patient-specific factors help to define the appropriate management strategy. The most important factor in patient survival is not the initial regimen but whether or not patients receive all three active chemotherapy drugs (i.e., 5-FU, irinotecan,, and oxaliplatin) at some point in his or her treatment course.[32]

Second-Line Therapy

Treatment options on disease progression following standard initial therapy are based on the type of prior therapy received. Since most patients will have received a combination of 5-FU and either irinotecan or oxaliplatin, second-line therapy with the alternate regimen should be considered.[26,33] If targeted agents such as bevacizumab were not part of the initial regimen, addition to the second-line regimen should be strongly considered.

Patient Encounter, Part 3: Creating a Care Plan

Based on the information presented, create a care plan for this patient's colon cancer. Your plan should include (1) the patient's drug- and non-drug-related needs and problems, (2) the goals of therapy, (3) a treatment plan specific to GW that includes strategies to prevent adverse effects of chemotherapy, (4) a follow-up plan to determine whether the goals have been achieved and the adverse effects of chemotherapy have been minimized, and (5) a plan for treatment options when the initial therapy is no longer achieving the goals of therapy.

An additional option includes the use of cetuximab either alone or in combination with irinotecan-based chemotherapy.[34] Cetuximab is FDA approved for use in EGFR-expressing metastatic colorectal cancer in combination with irinotecan but can be used as a single agent in patients who cannot tolerate irinotecan-based chemotherapy. The results appear to be best when irinotecan is continued owing to synergy demonstrated between the two agents.[26,34] Cetuximab is given as at loading dose of 400 mg/m^2 followed by weekly IV infusions of 250 mg/m^2 until disease progression. The incidence of grade 3 or 4 adverse effects was as anticipated based on previous trials; asthenia and an acne-like rash occurred most commonly with cetuximab alone. The benefit of adding cetuximab to oxaliplatin-based regimens or as part of initial therapy for metastatic colorectal cancer is an area of active investigation. Immunohistochemical evidence of EGFR-positive staining in tumors should be obtained prior to initiating therapy, although the clinical relevance of this is uncertain.

Finally, patients who fail standard treatment for metastatic colorectal cancer should be encouraged to participate in a clinical trial evaluating new treatment approaches for this incurable disease. Table 88–5 lists options for first- and second-line treatment of metastatic colon cancer. Patients with good **performance status** are treated more aggressively than those with poor performance status because of their better ability to tolerate chemotherapy.

TABLE 88–5. Treatment Options for Metastatic Colon Cancer[a]

First-Line Therapy	Second-Line Therapy
Good Performance Status	**If First Line Irinotecan**
• FOLFIRI with or without bevacizumab	• FOLFOX with or without bevacizumab[b]
• FOLFOX with or without bevacizumab	• Irinotecan and cetuximab (if EGFR-positive)
• IFL and bevacizumab	• Capecitabine or 5-fluorouracil plus leucovorin
Poor Performance Status	**If First Line Oxaliplatin**
• Capecitabine or 5-fluorouracil plus leucovorin with or without bevacizumab	• FOLFIRI with or without bevacizumab[b]
	• Irinotecan with or without cetuximab
	• Capecitabine or 5-fluorouracil plus leucovorin

[a]CAPOX or CAPIRI may replace FOLFOX or FOLFIRI in select patients.
[b]Bevacizumab may be given if not part of the first-line therapy.

SPECIFIC AGENTS USED IN COLON CANCER

Table 88–6 lists all FDA-approved drugs used in colon cancer, along with their mechanism of action and common toxicities.

5-Flurouracil

5-Fluorouracil (5-FU) acts as a "false" pyrimidine, inhibiting the formation of the DNA base thymidine.[26,35] The main mechanism by which it accomplishes this is by inhibiting the enzyme thymidylate synthase, the rate-limiting step in thymidine formation. 5-FU first must be metabolized to its active metabolite (F-dUMP). Additionally, metabolites of 5-FU may incorporate into RNA, inhibiting its synthesis.

5-FU is used commonly in the adjuvant and metastatic treatment of colon and rectal cancers. Various dosing administration techniques and schedules have been developed with 5-FU, including an IV bolus every 3 to 4 weeks, an IV continuous infusion, weekly IV boluses, and IV boluses followed by continuous infusions. Clinical studies comparing the efficacy of bolus and continuous-infusion schedules generally favor continuous infusion of 5-FU. This is consistent with evidence that suggests that the duration of infusion may be an important determinant of the biologic activity of 5-FU, particularly because of its short plasma half-life and S-phase specificity and the relatively slow growth of colon tumors.[16,26]

Clinically significant differences in toxicity also are based on the dose, route, and schedule of 5-FU administration. Leukopenia and mucositis are the primary dose-limiting toxicities of bolus 5-FU, whereas palmar-plantar erythrodysesthesia (hand-foot syndrome) and diarrhea occur most frequently with continuous infusions of 5-FU.[36] Health care practitioners can offer valuable patient advice to decrease the impact of these adverse effects. Patients can be informed to suck on ice chips prior to and for up to 30 minutes after 5-FU boluses to decrease the incidence of mucositis. Hand-foot syndrome, characterized by painful swelling and redness of the soles of the feet and palms of the hand, can be minimized with loose-fitting clothing and keeping the skin moist. Additional toxicities include moderate nausea and vomiting, skin discoloration, nail changes, photosensitivity, and neurologic toxicity. 5-FU administered with warfarin can result in significant increases in a patient's INR and requires close monitoring to prevent bleeding.

An additional determinate of 5-FU toxicity, regardless of the method of administration, is related to its catabolism and **pharmacogenomic** factors. Dihydropyrimidine dehydrogenase (DPD) is the main enzyme responsible for the catabolism of 5-FU to inactive metabolites.[37] A pharmacogenetic disorder has been identified in which patients have a complete or near-complete

TABLE 88–6. FDA-Approved Drugs Used in Colon Cancer

Name	Mechanism of Action	Common Toxicities
5-Fluorouracil	Inhibition of the enzyme thymidylate synthase, the rate-limiting step in thymidine formation.	*Dose-limiting* Myelosuppression and mucositis with bolus administration Diarrhea and hand-foot syndrome with continuous infusion *Additional toxicities* Skin discoloration, nail changes, photosensitivity, and neurologic toxicity
Capecitabine (Xeloda®)	Orally active prodrug of 5-fluorouracil. Once activated, the mechanism of action is the same.	Similar to continuous infusion 5-fluorouracil
Irinotecan (Camptosar®)	Topoisomerase inhibitor that forms a complex with the covalently bound DNA topoisomerase enzyme and interferes with the DNA breakage-resealing process.	*Dose-limiting* Early and late diarrhea *Additional toxicities* Neutropenia, nausea, and vomiting
Oxaliplatin (Eloxatin®)	Similar to other platinum analogs (cisplatin) in that it binds to the N-7 position of guanine, which results in cross-linking of DNA and double-stranded DNA breaks.	*Dose-limiting* Acute (within first 2 days) and persistent (greater than 14 days) neuropathies *Additional toxicites* Anaphylactic-like reactions, dyspnea
Bevacizumab (Avastin®)	Monoclonal antibody that binds to vascular endothelial growth factor (VEGF) and inhibits angiogenesis.	*Dose-limiting* Hypertension, bleeding episodes, thrombotic events *Additional toxicities* Rare perforation of the bowel, proteinurea
Cetuximab (Erbitux®)	Binds to the cell surface epidermal growth factor receptor (EGFR), preventing EGF and TGF-α binding. This decreased cell proliferation of cancer cells.	*Dose-limiting* Infusion-related reactions, acneiform skin rash *Additional toxicities* Diarrhea, nausea and vomiting, interstitial lung disease

deficiency of this enzyme. This results in unusually severe toxicity, including death, after the administration of 5-FU. Approximately 3% of patients have a complete lack of DPD activity, with other patients demonstrating a partial deficiency in enzyme activity. Although patients may be tested for their level of DPD activity, it is not done commonly but may be considered in patients who develop severe toxicity after 5-FU administration.

Leucovorin is given commonly with 5-FU. Leucovorin acts to increase the affinity of 5-FU for thymidine synthase, increasing the pharmacologic activity of 5-FU.[16,22] Leucovorin is most effective when administered prior to 5-FU and can be given by IV bolus, continuous infusion, or orally. Health care practitioners also can expect an increase in 5-FU toxicities when leucovorin is given in combination with 5-FU, in particular leukopenia, mucositis, and diarrhea.

Capecitabine

Capecitabine (Xeloda®) is an oral prodrug of 5-FU. Capecitabine undergoes a three-step conversion to 5-FU, the last step being phosphorylation by thymidine phosphorylase (TP). TP levels are reported to be higher in tumor cells than in normal tissues; therefore, the systemic exposure of active drug is minimized, and tumor concentrations of the active drug are optimized.[24,26] Once the drug is converted to 5-FU, it has the same mechanism of action described for that agent. The current FDA-approved indication for capecitabine is for use in metastatic and adjuvant colon cancer when monotherapy is desired, although it is actively being investigated as a replacement for 5-FU in most combination colon and rectal cancer regimens. Capecitabine has been demonstrated to be at least equivalent to IV 5-FU in the metastatic and adjuvant setting with improved patient tolerability.[24,38] Hand-foot syndrome and diarrhea are common with capecitabine because its toxicities (and pharmacologic activity) appear to mimic those of continuous infusions of 5-FU. Both irinotecan and oxaliplatin have been combined with capecitabine, and these combinations appear to be as safe and effective as IV 5-FU in the treatment of colorectal cancer.

The dose of capecitabine begins at 1250 mg/m^2 twice a day when used by itself; lower doses are used often when it is given in combination with irinotecan or oxaliplatin or in patients with renal insufficiency. The dose should be taken on a full stomach with breakfast and dinner. Capecitabine administered with warfarin can result in significant increases in the patient's INR and requires close monitoring to prevent bleeding. The convenience of oral administration and an improvement in toxicity make capecitabine a useful alternative to IV 5-FU both by itself and incorporated into other regimens used in colon cancer.

Irinotecan

Irinotecan (Camptosar®) is a **topoisomerase** I inhibitor that forms a complex with the covalently bound DNA topoisomerase

I enzyme and interferes with the DNA breakage-resealing process.[26] Binding permits uncoiling of the double-stranded DNA, but it prevents subsequent resealing of the DNA, resulting in double-stranded DNA breaks. Irinotecan is a prodrug that is converted by carboxylesterases to its active form SN-38. Irinotecan is indicated for the first-line treatment of metastatic colon cancer in combination with 5-FU and leucovorin or as a single agent in patients who fail first-line therapies. Irinotecan is not recommended as part of the adjuvant treatment of colon cancer at this time.

The major toxicity of irinotecan is diarrhea, which can occur both early and late in therapy.[26] The early diarrhea is a cholinergic reaction that occurs in the first 24 hours (often during the infusion) in up to 10% of patients and responds to atropine 0.25 to 1 mg IV. The late diarrhea seen in a larger percent of patients occurs 7 to 14 days after the irinotecan infusion. Health care practitioners must explain this adverse effect to patients and counsel them on the proper use of antidiarrheals. At the first change in bowel habits, an intensive loperamide regimen should be started by patients (4 mg initially, followed by 2 mg every 2 hours until diarrhea-free for 12 hours). If diarrhea does not stop or worsens, patients should be instructed to call their health care provider immediately. Late-onset diarrhea may require hospitalization or discontinuation of therapy, and fatalities have been reported. Additional toxicities with irinotecan include leukopenia (including neutropenic fever) and moderate nausea and vomiting. Toxicities of irinotecan appear to be greater when the drug is given weekly compared with other administration schedules.

Similar to 5-FU, there is a polymorphism associated with irinotecan toxicity. UDP-glucuronosyltransferase (*UGT1A1*) is an enzyme responsible for the glucuronidation of SN-38 to inactive metabolites, and reduced or deficient levels of this enzyme correlate with irinotecan-induced diarrhea and neutropenia.[39] Recently the FDA approved a blood test that detects variations in this gene. This test will assist health care providers in predicting which patients may develop severe toxicities from "normal" doses of irinotecan and can be ordered prior to patients receiving irinotecan. Irinotecan is administered as an IV bolus over 60 to 90 minutes in a variety dosing schedules.

Oxaliplatin

Oxaliplatin (Eloxatin®) is similar to other platinum analogs (e.g., cisplatin) in that it binds to the N-7 position of guanine, which results in cross-linking of DNA and double-stranded DNA breaks.[26,40] Oxaliplatin differs from cisplatin in that the DNA damage induced by oxaliplatin may not be as easily recognized by DNA repair genes often seen in colorectal cancer. Oxaliplatin, in combination with 5-FU-based regimens, is indicated for the first- and second-line treatment of metastatic colon cancer, as well as the adjuvant treatment of colon cancer.

The dose-limiting toxicity of oxaliplatin is acute and chronic neuropathy.[41] Acute neuropathies occur within 1 to 2 days of dosing, resolve within 2 weeks, and usually occur peripherally. These acute neuropathies occur in almost all patients to some degree and are exacerbated by exposure to cold temperature or cold objects. Health care providers should instruct patients to avoid cold drinks and the use of ice and to cover the skin before exposure to cold or cold objects. In addition, carbamazepine, gabapentin, amifostine, and calcium and magnesium infusions are sometimes used to both prevent and treat oxaliplatin-induced neuropathies, although no strong evidence demonstrating their efficacy exists. Until definitive trials are conducted, calcium and magnesium infusions may be used because they have few adverse effects and are relatively inexpensive. Persistent neuropathies generally occur after eight cycles of oxaliplatin and are characterized by defects that can interfere with daily activities (e.g., writing, buttoning, swallowing, and walking). These neuropathies occur in up to half of patients receiving oxaliplatin but usually resolve with dosage reductions or after oxaliplatin is stopped.[26,41] Oxaliplatin has minimal renal or mylesuppressive effects and nausea/vomiting when compared with other platinum drugs. Oxaliplatin is given intravenously in a variety of dosing schedules, with a typical dose being 85 mg/m^2 IV every 2 weeks.

Bevacizumab

Bevacizumab (Avastin®) is a recombinant humanized monoclonal antibody that inhibits vascular endothelial growth factor (VEGF). VEGF is a proangiogenic growth factor found in many cancers, including colon cancer, and is thought to promote blood vessel formation and metastasis of the tumor by binding to VEGF receptors on tumors. Bevacizumab inhibits circulating VEGF, preventing it from binding to receptors and decreasing the formation of new blood vessels.[26,31] Additionally, bevacizumab may allow for increased concentrations of traditional chemotherapy such as irinotecan to reach the tumor to exert its pharmacologic effect. Bevacizumab is not effective alone and must be used in combination with other agents effective in colorectal cancer. It is indicated for first-line treatment of patients with metastatic colorectal cancer in combination with intravenous 5-FU-based regimens. Bevacizumab also has been shown to increase survival in the second-line setting when used in combination with the FOLFOX regimen in patients who have not yet received bevacizumab.

Adverse effects associated with bevacizumab include dose-limiting hypertension, which is common but manage with oral antihypertensive agents.[42] Thrombotic events (including myocardial infarctions, pulmonary embolisms, and deep vein thromboses) occur more frequently in the elderly patients with cardiovascular risk factors, and the risk/benefit of bevacizumab must be considered. Since bevacizumab interferes with normal wound healing, it should not be given shortly before or after surgical procedures.[42] Initiation within 28 days

of surgery is not recommended to allow for proper would healing and decrease the risk of bleeding. The amount of time needed after bevacizumab discontinuation to perform elective surgical procedures is less clear, but health care providers should take into consideration bevacizumab's half-life of approximately 20 days when making clinical decisions.[42] Patients should have their urine checked for protein prior to each dose of bevacizumab to assess for potential kidney damage. Patients who have a develop 2+ protein on the urinalysis require additional testing prior to receiving therapy. Finally, there is a risk of gastrointestinal perforation, which is rare but potentially fatal. Patients complaining of abdominal pain associated with vomiting or constipation should be counseled to call their physician immediately. Bevacizumab is commonly given at a dose of 5 mg/kg IV every 14 days until disease progression. Once disease progresses and salvage chemotherapy is initiated, the benefit of continuing bevacizumab is unclear.

Cetuximab

Cetuximab (Erbitux®) is a chimeric monoclonal antibody directed against the EGFR. The EGFR is overexpressed in some colon cancers and leads to an increase in tumor proliferation and growth.[26,34] Cetuximab received FDA approval for use in EGFR-expressing metastatic colorectal cancer. Cetuximab should be administered in combination with irinotecan but can be used as a single agent in patients who cannot tolerate irinotecan-based chemotherapy.

Cetuximab is well tolerated, with infusion-related reactions its dose-limiting toxicity. Patients require premedication with acetaminophen and diphenhydramine and may require dose modifications if they develop severe toxicity. An acneiform skin rash and diarrhea are also seen commonly, and health care practitioners should provide counseling to patients about these adverse effects. Treatment options include common medications used to treat acne (doxycycline) and general skin care. A rare (less than 1%) interstitial lung disease is seen with all agents that inhibit the EGFR, and patients should be instructed to report any new-onset shortness of breath. An initial loading dose of 400 mg/m^2 is given as an IV infusion, followed by weekly doses of 250 mg/m^2. At this time, immunohistochemical evidence of EGFR-positive staining should be obtained prior to initiating therapy with cetuximab.

RECTAL CANCER

Although often treated similarly to colon cancer, there are some important differences in the treatment of rectal cancer compared with colon cancer, especially in the adjuvant setting and the role of radiation. Rectal cancer involves tumors found in distal 15 cm of the large bowel and, as such, is very distinct from colon cancer in that it may recur both locally and distally. The higher incidence of local failure and poorer overall prognosis associated with rectal cancer are due to limitations in surgical techniques. Therefore, multimodal therapies with a combination of chemotherapy, radiation, and surgery are at the forefront of the treatment of rectal cancer, with the main goal of survival and quality of life by preserving the function of the anal sphincter. In addition, because treatment with surgery, radiation, or systemic chemotherapy at the time of the recurrence is often suboptimal, adjuvant therapy after tumor resection is an important aspect of treatment of the primary tumor. Similar to adjuvant therapy for colon cancer, 5-FU provides the basis for chemotherapy regimens for rectal cancer. ❽ *For stage II or III rectal cancer, six cycles of 5-FU combined with radiation is standard after surgical resection.*[43] The radiation therapy decreases the rate of local recurrence, whereas the 5-FU decreases the risk of distant tumor recurrence, as well as acting as a radiosensitizer. Toxicities from combined-modality therapy include severe hematologic toxicity, enteritis, and diarrhea. Additional trials have sought to determine optimal combinations of concurrent radiation and 5-FU. Again, similar to tumors in the colon, continuous infusions of 5-FU appear to be superior to bolus doses. However, leucovorin does not appear to improve efficacy of adjuvant treatment for rectal cancer. Use of oral alternatives to 5-FU that are also known to enhance radiation effects, such as capecitabine, are under investigation, with preliminary data suggesting that the combination of capecitabine and radiation will be safe and effective.

Another unique aspect of rectal cancer is the use of **neoadjuvant therapy.** Preoperative radiation with or without chemotherapy is given to downstage the tumor prior to surgical resection to improve sphincter preservation by making the surgical procedure easier to perform. The issue of preoperative versus postoperative radiation is a subject of debate and investigation in the United States and will require further data to determine the superiority of one method over the other.

OUTCOME EVALUATION

Disease Assessment

The goal of monitoring is to evaluate whether the patient is receiving any benefit from the management of the disease, to detect recurrence, and to minimize the adverse effects of treatment. During treatment for active disease, patients should undergo monitoring for measurable tumor response, progression, or new metastases; these tests may include chest CT scans or x-rays, abdominal or pelvic CT scans or x-rays depending on the site of disease being evaluated for response, and CEA measurements every 3 months if the CEA is or was elevated previously.[44] A PET scan can be considered to identify localized sites of metastatic disease in situations where a rising CEA level suggests metastatic disease but CT scans and other imaging studies are negative. Symptoms of recurrence such as pain, changes in bowel habits, rectal bleeding, pelvic masses, anorexia, and weight

Patient Encounter, Part 4: Screening and Preventing Colon Cancer

GW is concerned about his twin boys developing colon cancer given his disease and his family history of cancer. He asks for advice on preventing colon cancer and ways to detect the disease earlier in his children.

- What is the role for chemoprevention for GW's children?
- What are the screening recommendations for colon cancer? Do these change for GW's children?

loss develop in fewer than 50% of patients. Patients who undergo curative surgical resection, with or without adjuvant therapy, require close follow-up because early detection and treatment of recurrence still could result in patient cure. In addition, early treatment for asymptomatic metastatic colorectal cancer appears superior to delayed therapy.[44]

Monitoring of Chemotherapy

Laboratory monitoring is performed before initiating therapy and before each cycle of chemotherapy. A complete blood count should be obtained prior to each course of chemotherapy to ensure that hematologic values are adequate. In particular, white blood cell counts and absolute neutrophil counts can be decreased in patients receiving chemotherapy such as irinotecan and 5-FU and increase the risk of infection. Baseline liver function tests and an assessment of renal function should be done prior to and periodically during therapy. Other selected laboratory tests include checking for the presence of protein in the urine in patients receiving oxaliplatin and bevacizumab.

❾ *Patients should be evaluated during every treatment visit for the presence of anticipated side effects, which generally include loose stools or diarrhea from irinotecan, 5-FU, and capecitabine, hand-foot syndrome from 5-FU and capecitabine, nausea or vomiting from irinotecan, 5-FU, and oxaliplatin, mouth sores from 5-FU, neuropathies from oxaliplatin, bleeding and hypertension from bevacizumab, and skin rash associated with cetuximab. Health care practitioners should anticipate these adverse reactions and treat them aggressively and attempt to prevent them from occurring. Refer to summary section for complete patient care and monitoring recommendations.*

SCREENING

❿ *Health care professionals must be aware of and promote appropriate screening recommendations for colon cancer in their patients.* Proper screening of patients at normal and high risk for colon cancer leads to the detection of smaller, localized lesions and higher cure rates.[45] Screening techniques include a digital rectal examination, fecal occult blood tests (FOBTs), and imaging of the colon. The use of FOBTs annually in combination with digital rectal examinations has led to earlier diagnosis of early stages of disease and may reduce colorectal cancer mortality by up to a third. Two main methods are available to detect occult blood in the feces: guaiac dye and immunochemical methods. The Hemoccult II is the most commonly used FOBT in the United States and is a guaiac-based test. Proper counseling by health care providers is required to receive accurate test results. Table 88–7 lists common reasons for inaccurate results with the guaiac tests, and such results require proper counseling of patients on the use of these tests. Immunochemical tests (InSure® and others), which use antibodies to detect hemoglobin, are also available for use. One advantage of immunochemical tests is that they do not react with dietary factors or medications. Both FOBTs can be recommended in screening protocols for patients.

TABLE 88–7. Common Reasons for Inaccurate Results from Guaiac Stool Tests

False Positives	False Negatives
Red meat, blood soup, blood sausage	Vitamin C
Vegetables with peroxidase activity	Dehydrated samples
Iron	
Gastric irritation (NSAIDs)	
Avoid these foods and medications for 3 days prior to test	

In addition, imaging of the colon with a sigmoidoscopy, colonoscopy, or double-contrast barium enema is required every 5 to 10 years in most individuals over age 50. Colonoscopy is the preferred procedure because it allows for greater visualization of the entire colon and simultaneous removal of lesions found during screening.[45] A sigmoidscope only examines the lower half of the colon, and a double-contrast barium enema (DCBE) requires a supplemental colonoscopy to remove any lesions found during the screening process. ❿ *Table 88–8 is a summary of the current American Cancer Society guidelines for screening and surveillance for early detection of colorectal polyps and cancer.*[45]

TABLE 88–8. Colon Cancer Screening Guidelines

Average risk	Annual DRE after age 50 ***and***
	Annual FOBT after age 50, at the time of DRE, ***and***
	One of the following after age 50:
	Sigmoidoscopy every 5 years
	Colonoscopy every 10 years
	Barium enema every 5–10 years
Family history	Screening at ages 35–40
HNPCC	Screening at age 30
FAP	Screening at ages 10–12

COLORECTAL CANCER PREVENTION

Strategies to prevent colon cancer can be carried out with pharmacologic or surgical interventions and involve either preventing the initial development of colon cancer (primary prevention) or preventing cancer in patients who demonstrate early signs of colon cancer (secondary prevention). The most widely studied agents for the chemoprevention of colorectal cancer are agents that inhibit COX-2 (e.g., aspirin, NSAIDs, and selective COX-2 inhibitors) and calcium supplementation.[46] COX-2 appears to play a role in polyp formation, and COX-2 inhibition suppresses polyp growth. In 1999, the FDA approved the use of celecoxib to reduce the number of colorectal polyps in patients with FAP, as an adjunct to usual care. This may delay the need for surgical intervention in these patients, but the results cannot be extrapolated to the general population. The dose of celecoxib for this indication is 400 mg orally twice daily, and the risk of cardiovascular damage from COX-2 inhibition needs to be assessed carefully in these patients. The use of aspirin as both a primary and a secondary chemoprevention agent also has been studied. In a prospective, randomized trial, low-dose aspirin (81 mg/day) was shown to decrease the incidence of additional polyps by 19% in patients with a previous history of at least one polyp.[47]

Calcium supplementation appears to be associated with a moderate reduction in risk of recurrent colorectal adenomas, with prospective studies demonstrating a nonstatistical decrease in adenoma recurrence, and the role of calcium as a chemoprevention agent remains under investigation.[47]

Additional agents, including selenium, folic acid, and HMG-CoA reductase inhibitors (statins), show promise as chemopreventive agents in colon cancer, and preliminary and confirmatory studies evaluating their effectiveness have been completed or are ongoing, although none of these agents have been approved for the prevention of colon cancer.[46]

Surgical resection remains an option to prevent colon cancer in individuals at extremely high risk for its development, such as patients diagnosed with FAP. Individuals with FAP who are found to have polyps on screening examinations require total abdominal colectomy. In addition, removal of noncancerous polyps detected during screening colonoscopy is considered a standard of care to prevent the progression of premalignant polyps to cancer.

CONCLUSION

Recent advances in the treatment of cancer of the colon and rectum now offer the potential to improve patient survival, but for many patients, improved disease- and progression-free survival represent equally important therapeutic outcomes. In the absence of the ability of a specific treatment to demonstrate improved survival, important outcome measures should include the effects of the treatment on patient symptoms, daily activities, performance status, and other quality-of-life indicators. Individualized patient care to balance the risks associated with treatment with the benefits of a specific treatment regimen is necessary to optimize patient outcomes.

⑨ Patient Care and Monitoring

1. Review any available diagnostic data to determine the status of the colon cancer.
2. Obtain a thorough history of prescription, nonprescription, and natural drug product use.
3. Evaluate patient-specific factors that may dictate treatment regimen. *Does the patient have a known pharmacogenomic deficiency? What lifestyle issues are important to the patient?*
4. Determine if any dose modifications are required in the chemotherapy regimen prescribed. *Does the patient have adequate blood counts to receive chemotherapy?*
5. Educate the patient on drug therapy and possible treatment-related adverse effects, and counsel the patient on appropriate recommendations to prevent or minimize these adverse effects. *What medications are for the treatment of cancer and what medications are to prevent the adverse effects of chemotherapy?*
6. Develop a plan to prevent treatment-related adverse effects. *Are the antiemetics appropriate? Does the patient understand the possible adverse effects and when to call the physician versus when patient-directed care is appropriate?*
7. Warning signs to report to the physician (depends on regimen used) include fever, diarrhea, mucositis, and hand-foot syndrome.
8. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.

ABBREVIATIONS

APC:	adenomatous polyposis coli
BMI:	body mass index
CAPOX:	capecitabine and oxaliplatin
CAPIRI:	capecitabine and irinotecan
CBC:	complete blood count
CEA:	carcinoembryonic antigen
COX-2:	cyclooxygenase-2
CT:	computed tomography
DCBE:	double-contrast barium enema
DPD:	dihydropyrimidine dehydrogenase
DRE:	digital rectal examination
F-dUMP:	fluoro-deoxy-uridine monophosphate
EGFR:	epidermal growth factor receptor
FAP:	familial adenomatous polyposis
FOBT	fecal occult blood test
FOLFIRI:	folinic acid, fluorouracil, and infusional irinotecan
FOLFOX:	folinic acid, fluorouracil, and oxaliplatin
HNPCC:	hereditary nonpolyposis colorectal cancer
IFL:	irinotecan, fluorouracil, and leucovorin
INR:	international normalized ratio
IV:	intravenous
NSAIDs:	nonsteroidal anti-inflammatory drugs
PET:	positron-emission tomography

TGF-α: transforming growth factor α
TNM: tumor, node, metastasis
TP: thymidine phosphorylase
VEG: Fvascular endothelial growth factor

89 Prostate Cancer

Jill M. Kolesar

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Describe the incidence and mortality of prostate cancer.
2. List the risk factors associated with the development of prostate cancer.
3. Understand the pathophysiology underlying the clinical symptoms associated with prostate cancer.
4. Compare placebo versus finasteride for the prevention of prostate cancer.
5. Recommend a prostate cancer screening program for a man based on his age and risk factors.
6. Recommend a treatment for initial treatment of prostate cancer based on stage, Gleason score, age, and symptoms.
7. Compare the efficacy of radiation therapy versus surgical therapy for the initial management of prostate cancer.
8. Outline the role of luteinizing hormone–releasing hormone (LHRH) agonists in the treatment of prostate cancer.
9. Contrast the benefits and risks of luteinizing hormone–releasing hormone (LHRH) single-agent therapy and combined androgen blockade in the first-line therapy of metastatic prostate cancer.
10. Understand the role of chemotherapy in the treatment of metastatic prostate cancer.

Key Concepts

❶ Prostate cancer is the most frequent cancer in United States men. African-American ancestry, family history, and increased age are the primary risk factors for prostate cancer.

❷ Prostate-specific antigen is a useful marker for detecting prostate cancer at early stages, predicting outcome for localized disease, defining disease-free status, and monitoring response to androgen-deprivation therapy or chemotherapy for advanced-stage disease.

❸ The prognosis for prostate cancer patients depends on the histologic grade, the tumor size, and the disease stage. More than 85% of patients with stage A_1 disease but less than 1% of those with stage D_2 can be cured.

❹ Androgen ablation with a luteinizing hormone–releasing hormone (LHRH) agonist plus an antiandrogen should be used prior to radiation therapy for patients with locally advanced prostate cancer to improve outcomes over radiation therapy alone.

❺ Androgen ablation therapy, with either orchiectomy, a luteinizing hormone–releasing hormone (LHRH) agonist alone, or an LHRH agonist plus an antiandrogen (combined hormonal blockade), can be used to provide palliation for patients with advanced (stage D_2) prostate cancer. The effects of androgen deprivation seem most pronounced in patients with minimal disease at diagnosis.

❻ Antiandrogen withdrawal, for patients having progressive disease while receiving combined hormonal blockade with a luteinizing hormone–releasing hormone (LHRH) agonist plus an antiandrogen, can provide additional symptomatic relief. Mutations in the androgen receptor have been documented that cause antiandrogen compounds to act like receptor agonists.

❼ Chemotherapy, with docetaxel and prednisone or docetaxel and estramustine, improves survival in patients with hormone-refractory prostate cancer. Patients with hormone-refractory prostate cancer should be considered for entry into clinical trials investigating new therapies for prostate cancer.

Prostate cancer is the most commonly diagnosed cancer in American men.[1] For most men, prostate cancer has an indolent course, and treatment options for early disease include expectant management, surgery, and radiation. With expectant management, patients are monitored for disease progression or development of symptoms. Localized prostate cancer can be cured by surgery or radiation therapy, but advanced prostate cancer is not yet curable. Treatment for advanced prostate cancer can provide significant disease palliation for many patients for several years after diagnosis. The endocrine dependence of this tumor is well documented, and hormonal manipulation to decrease circulating androgens remains the basis for the treatment of advanced disease.

EPIDEMIOLOGY AND ETIOLOGY

❶ *Prostate cancer is the most frequent cancer among American men and represents the second leading cause of cancer-related deaths in all males.*[1] In the United States alone, it is estimated that 234,460 new cases of prostatic carcinoma will be diagnosed and more than 27,350 men will die from this disease in 2006.[1] Although prostate cancer incidence increased during the late 1980s and early 1990s owing to widespread prostate-specific antigen (PSA) screening, deaths from prostate cancer have been declining continuously since 1995.[1]

Table 89–1 summarizes the possible factors associated with prostate cancer.[2] The only widely accepted risk factors for prostate cancer are age, race/ethnicity, and family history of prostate cancer.[2] The disease is rare under the age of 40 years, but the incidence increases sharply with each subsequent decade, most likely because the individual has had a lifetime exposure to testosterone, a known growth signal for the prostate.[3]

TABLE 89–1. Risk Factors Associated with Prostate Cancer

Factor	Possible Relationship
Probable Risk Factors	
Age	More than 70% of cases are diagnosed in men greater than 65 years old.
Race	African Americans have higher incidence and death rate.
Genetic	Familial prostate cancer is inherited in an autosomal dominant manner.
	Mutations in *p53, Rb*, E-cahedrin, α-catenin, androgen receptor, *KAII*, microsatellite instability, loss of heterozygocity at 1, 2q, 12p, 15q, 16p, and 16q.
	Candidate prostate cancer gene locus identified on chromosome 1.
Possible Risk Factors	
Environmental	Clinical carcinoma incidence varies worldwide.
	Latent carcinoma similar between regions. Nationalized males adopt intermediate incidence rates between that of the United States and their native country.
Occupational	Increased risk associated with cadmium exposure.
Diet	Increased risk associated with high-meat and high-fat diets.
	Decreased intake of 1, 25-dihydroxyvitamin D, vitamin E, lycopene, and β-carotene increases risk.
Hormonal	Does not occur in eunuchs.
	Low incidence in cirrhotic patients.
	Up to 80% are hormonally dependent. African-Americans have 15% increased testosterone.
	Japanese have decreased 5-α-reductase activities.
	Polymorphic expression of the androgen receptor.

Compiled from Carter et al,[2] Hsieh et al,[3] and Ross et al.[4]

Race and Ethnicity

The incidence of clinical prostate cancer varies across geographic regions. Scandinavian countries and the United States report the highest incidence of prostate cancer, whereas the disease is relatively rare in Japan and other Asian countries.[4] African-American men have the highest rate of prostate cancer in the world, and in the United States, prostate cancer mortality in African Americans is more than twice that seen in Caucasian populations.[1] Hormonal, dietary, and genetic differences, as well as differences in access to health care, may contribute to the altered susceptibility to prostate cancer in these populations.[2] Testosterone, commonly implicated in the pathogenesis of prostate cancer, is 15% higher in African American men than in Caucasian males. Activity of 5-α-reductase, the enzyme that converts testosterone to its more active form, dihydrotestosterone (DHT), in the prostate, is decreased in Japanese men compared with African Americans and Caucasians.[2] In addition, genetic variations in the androgen receptor exist. Activation of the androgen receptor is inversely correlated with CAG repeat length. Shorter CAG repeat sequences have been found in African Americans. Therefore, the combination of increased testosterone and increased androgen receptor activation may account for the increased risk of prostate cancer for African-American men.[2] The Asian diet generally is considered to be low in fat and high in fiber with a high concentration of phytoestrogens, potentially explaining the decreased risk in Asians.[4]

Family History

There appears to a be a family prostate cancer syndrome and genome-wide scans have identified potential prostate cancer susceptibility loci on chromosomes 1, 2q, 12p, 15q, 16p, and

16q; however, none of these susceptibility loci have demonstrated linkage to currently known candidate genes.[5]

An alternative explanation for the familial clustering may be **polymorphisms** in genes important for prostate cancer function and development.[5] Candidate polymorphisms include a polymorphism in the androgen receptor, which has two different nucleotide repeat variants, the CAG and the GCC. The CAG repeat varies in repeat number from 11 to 31 repeats in healthy individuals, and the number of repeats is inversely proportional to the activity of the androgen receptor. Some studies have demonstrated that shorter CAG repeats are associated with increased prostate cancer risk. Another candidate polymorphism is *SRD5A2,* which is the gene that codes for 5-α-reductase, the enzyme that converts testosterone to the more active dihydrotestosterone. A variant in *SRD5A2,* the Ala49Thr, increases the activity and may increase prostate cancer risk.[5]

Diet

A number of epidemiologic studies support an association between high fat intake and the risk of prostate cancer. A strong correlation between national per capita fat consumption and national prostate cancer mortality has been reported, and prospective case-control studies suggest that a high-fat diet doubles the risk of prostate cancer.

Other dietary factors implicated in prostate cancer include retinol, carotenoids, lycopene, and vitamin D consumption.[5,6] Retinol, or vitamin A, intake, especially in men older than age 70, is correlated with an increased risk of prostate cancer, whereas intake of its precursor, β-carotene, has a protective or neutral effect. Lycopene, obtained primarily from tomatoes, decreases the risk of prostate cancer in small cohort studies. The antioxidant vitamin E also may decrease the risk of prostate cancer. Men who developed prostate cancer in one cohort study had lower levels of $1,25(OH)_2$-vitamin D than matched controls, although a prospective study did not support this.[2] Clearly, dietary risk factors require further evaluation, but because fat and vitamins are modifiable risk factors, dietary intervention may be promising in prostate cancer prevention.

Other Factors

Benign prostatic hyperplasia (BPH) is one of the most common problems of elderly men, affecting more than 40% of men over age 70. BPH results in the urinary symptoms of hesitancy and frequency. Since prostate cancer affects a similar age group and often has similar presenting symptoms, the presence of BPH often complicates the diagnosis of prostate cancer, although it does not appear to increase the risk of developing prostate cancer.[2,5]

Smoking has not been associated with an increased risk of prostate cancer, but smokers with prostate cancer have an increased mortality resulting from the disease when compared with nonsmokers with prostate cancer [relative risk (RR) = 1.5–2).[2,5] In addition, in a prospective cohort analysis, alcohol consumption was not associated with the development of prostate cancer.

Chemoprevention

Currently, the most promising agent for the prevention of prostate cancer is finasteride, a 5-α-reductase inhibitor used for BPH.[6] When compared with placebo, the point prevalence of prostate cancer was reduced for those on finasteride by 24.8% [95% confidence interval (CI) = 18.6–30.6%; hazard ratio (HR) = 0.75]. However, in those who did develop prostate cancer, there was an increase in the number of high-grade (Gleason grade 7–10) tumors detected at biopsy in the finasteride group. Overall, finasteride did reduce the frequency of prostate cancer, but the prostate cancers that were diagnosed in the finasteride group were more aggressive.

Therefore, the use of finasteride to prevent prostate cancer is currently under debate.[7] Because of its established benefit in treating BPH, the 20% to 30% of men over age 50 with BPH may derive the additional benefit of prostate cancer prevention and should be offered treatment with finasteride. In the 70% to 80% of men without BPH, the benefits, side effects (primarily impotence), and risks of finasteride should be discussed prior to initiating therapy.

Other agents, including selenium, vitamin E, lycopene, green tea, nonsteriodal anti-inflammatory agents, isoflavones, and statins, are under investigsation for prostate cancer and show promise. Selenium is a naturally occurring trace element that is an essential nutrient in the human diet.[8] However, none of these agents is currently recommended for routine use outside a clinical trial.

Screening

Early detection of potentially curable prostate cancers is the goal of prostate cancer screening. For cancer screening to be beneficial, it must reliably detect cancer at an early stage, when intervention would decrease mortality. Whether prostate cancer screening fits these criteria has generated considerable controversy.[9] Digital rectal examination (DRE) has been recommended since the early 1900s for the detection of prostate cancer. The primary advantage of DRE is its specificity, reported at greater than 85%, for prostate cancer. Other advantages of DRE include low cost, safety, and ease of performance. However, DRE is relatively insensitive and is subject to interobserver variability. DRE as a single screening method has poor compliance and has had little effect on preventing metastatic prostate cancer in one large case-control study.[10]

❷ *Prostate-specific antigen (PSA) is a useful marker for detecting prostate cancer at early stages, predicting outcome for localized disease, defining disease-free status, and monitoring response to*

Patient Encounter 1

HG is 46-year-old Caucasian man. He is not overweight and follows a low-fat diet. He does not have any family members with a history of prostate cancer.

- What are his options for prostate cancer screening?
- Is he a candidate for prostate cancer chemoprevention?
- What are his risk factors for prostate cancer?

androgen-deprivation therapy or chemotherapy for advanced-stage disease. PSA is used widely for prostate cancer screening in the United States, with simplicity its major advantage and low specificity its primary limitation.[11] PSA may be elevated in men with acute urinary retention, acute prostatitis, and prostatic ischemia or infarction, as well as BPH, a nearly universal condition in men at risk for prostate cancer. PSA elevations between 4.1 and 10 ng/mL (10 mcg/L) cannot distinguish between BPH and prostate cancer, limiting the utility of PSA alone for the early detection of prostate cancer. Additionally, only 38% to 48% of men with clinically significant prostate cancer have a serum PSA outside the reference range.[12]

Neither DRE nor PSA is sensitive or specific enough to be used alone as a screening test.[12] Although the relative predictability of DRE and PSA is similar, the tumors identified by each method are different. Catalona and associates[13] confirmed that the combination of a DRE and a PSA determination is a better method of detecting prostate cancer than DRE alone.

The common approach to prostate cancer screening today involves offering a baseline PSA and DRE at age 40, with annual evaluations beginning at age 50, to all men of normal risk with a 10-year or greater life expectancy.

Despite this common practice, the benefits of prostate cancer screening are unproven. PSA measurements can identify small, subclinical prostate cancers, where no intervention may be required. Detecting prostate cancer in those not needing therapy not only increases the cost of care through unnecessary screening and work-ups but also increases the toxicity of therapy by subjecting some patients to unnecessary therapy.[14] Currently, the American College of Physicians recommends that rather than screening all men for prostate cancer as a matter of routine, physicians should describe the potential benefits and known risks of screening, diagnosis, and treatment; listen to the patient's concerns; and then decide on an individual's screening method.

PATHOPHYSIOLOGY

The growth and development of the prostate is under control of androgens, and it is well known that men who undergo castration prior to puberty do not develop prostate cancer. The majority of risk factors for prostate cancer are factors that either increase or decrease testosterone exposure. Despite this, serum testosterone or DHT levels obtained at diagnosis are not associated directly with prostate cancer risk, suggesting a multifactorial cause of prostate cancer.[5]

The normal prostate is composed of acinar secretory cells arranged in a radial shape and surrounded by a foundation of supporting tissue. The size, shape, or presence of acini are almost always altered in the gland that has been invaded by prostatic carcinoma. Adenocarcinoma, the major pathologic cell type, accounts for more than 95% of prostate cancer cases.[15] Much rarer tumor types include small cell neuroendocrine cancers, sarcomas, and transitional cell carcinomas.

Prostate cancer can be graded systematically according to the histologic appearance of the malignant cell and then grouped into well, moderately, or poorly differentiated grades.[16] Gland architecture is examined and then rated on a scale of 1 (well differentiated) to 5 (poorly differentiated). Two different specimens are examined, and the score for each specimen is added. Groupings for total Gleason score are 2 to 4 for well-differentiated, 5 or 6 for moderately differentiated, and 7 to 10 for poorly differentiated tumors. Poorly differentiated tumors grow rapidly (poor prognosis), whereas well-differentiated tumors grow slowly (better prognosis).

Metastatic spread can occur by local extension, lymphatic drainage, or hematogenous dissemination.[17] Lymph node metastases are more common in patients with large, undifferentiated tumors that invade the seminal vesicles. The pelvic and abdominal lymph node groups are the most common sites of lymph node involvement (Fig. 89–1). Skeletal metastases from hematogenous spread are the most common sites of distant

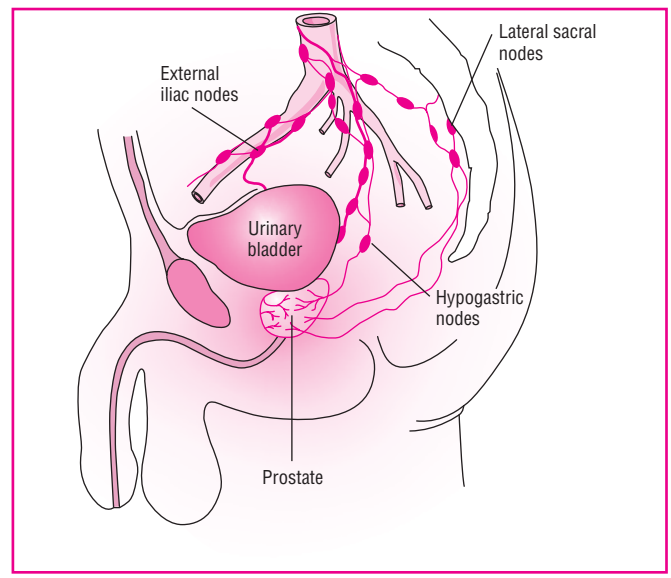

FIGURE 89–1. The prostate gland. (From Kolesar JM. Prostate cancer. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 2423.)

spread. Typically, the bone lesions are osteoblastic or a combination of osteoblastic and osteolytic. The most common site of bone involvement is the lumbar spine. Other sites of bone involvement include the proximal femurs, pelvis, thoracic spine, ribs, sternum, skull, and humerus. The lung, liver, brain, and adrenal glands are the most common sites of visceral involvement, although, these organs usually are not involved initially. About 25% to 35% of patients will have evidence of lymphangitic or nodular pulmonary infiltrates at autopsy. The prostate is a rare site for metastatic involvement from other solid tumors.

The prostate gland is a solid, round, heart-shaped organ positioned between the neck of the bladder and the urogenital diaphragm (see Fig. 89–1). Normal growth and differentiation of the prostate depend on the presence of androgens, specifically DHT.[18] The testes and the adrenal glands are the major sources of circulating androgens. Hormonal regulation of androgen synthesis is mediated through a series of biochemical interactions between the hypothalamus, pituitary, adrenal glands, and testes (Fig. 89–2). Luteinizing hormone–releasing hormone (LHRH) released from the hypothalamus stimulates the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary gland. LH complexes with receptors on the Leydig cell testicular membrane and stimulates the production of testosterone and small amounts of estrogen. FSH acts on the Sertoli cells within the testes to promote the maturation of LH receptors and to produce an androgen-binding protein. Circulating testosterone and estradiol influence the synthesis of LHRH, LH, and FSH by a negative-feedback loop operating at the hypothalamic and pituitary level.[19] Prolactin, growth hormone, and estradiol appear to be important accessory regulators for prostatic tissue permeability, receptor binding, and testosterone synthesis.

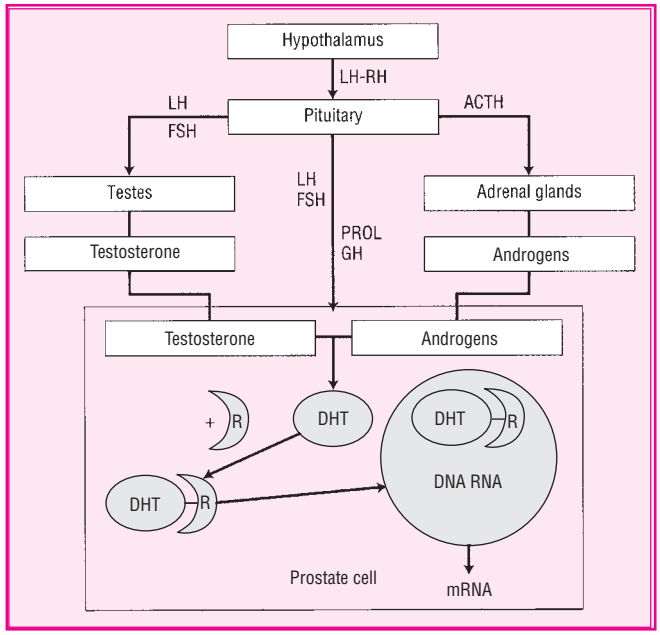

FIGURE 89–2. Hormonal regulation of the prostate gland. ACTH, adrenocorticotropic hormone; DHT, dihydrotestosterone; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; LHRH, luteinizing hormone–releasing hormone; PROL, prolactin; R, receptor. (From Kolesar JM. Prostate cancer. In DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 2424.)

Testosterone, the major androgenic hormone, accounts for 95% of the androgen concentration. The primary source of testosterone is the testes; however, 3% to 5% of the testosterone concentration is derived from direct adrenal cortical secretion of testosterone or C-19 steroids such as androstenedione.[17,18]

Hormonal manipulations to ablate or reduce circulating androgens can occur through several mechanisms[17,18] (Table 89–2). The organs responsible for androgen production can be removed surgically (e.g., orchiectomy, hypophysectomy, or adrenalectomy). Hormonal pathways that modulate prostatic growth can be interrupted at several steps (see Fig. 89–2). Interference with LHRH or LH can reduce testosterone secretion by the testes (e.g., estrogens, LHRH agonists, progestogens, and cyproterone acetate). Estrogen administration reduces androgens by directly inhibiting LH release, by acting directly on the prostate cell, or by decreasing free androgens by increasing steroid-binding globulin levels.[17,18]

Isolation of the naturally occurring hypothalamic decapeptide hormone LHRH has provided another group of effective agents for advanced prostate cancer treatment.[20] The physiologic response to LHRH depends on both the dose and mode of administration. Intermittent pulsed LHRH administration, which mimics the endogenous release pattern, causes sustained release of both LH and FSH, whereas high-dose or continuous intravenous administration of LHRH inhibits gonadotropin release owing to receptor down-regulation.[19] Structural modification of naturally occurring LHRH and innovative delivery have produced a series of LHRH agonists that cause a similar down-regulation of pituitary receptors and a decrease in testosterone production.[19]

TABLE 89–2. Hormonal Manipulations in Prostate Cancer

Androgen synthesis can be inhibited in the testes or in the adrenal gland. Aminoglutethimide inhibits the desmolase-enzyme complex in the adrenal gland, thereby preventing the conversion of cholesterol to pregnenolone. Pregnenolone is the precursor substrate for all adrenal-derived steroids, including androgens, glucocorticoids, and mineralocorticoids.[21] Ketoconazole, an imidazole antifungal agent, causes a dose-related reversible reduction in serum cortisol and testosterone concentration by inhibiting both adrenal and testicular steroidogenesis.[21,22] As a secondary mechanism to its antiandrogen action, megestrol acetate inhibits the synthesis of androgens. This inhibition appears to occur at the adrenal level, but circulating levels of testosterone also are reduced, suggesting that inhibition at the testicular level also may occur.[21]

Antiandrogens inhibit the formation of the DHT-receptor complex and thereby interfere with androgen-mediated action at the cellular level.[22] Megestrol acetate, a progestational agent, also is available and has antiandrogen actions.[21] Finally, the conversion of testosterone to DHT may be inhibited by 5-α-reductase inhibitors.[6]

CLINICAL PRESENTATION, DIAGNOSIS, AND STAGING

The information obtained from the diagnostic tests is used to stage the patient. There are two commonly recognized staging classification systems (Table 89–3). The formal international classification system [tumor, node, metastases (TNM)], adopted by the International Union Against Cancer in 1974, was updated in 1992 in an effort to provide congruence with the classic American Urologic System (AUS) staging system for prostate cancer.[23] The AUS classification is the most commonly used staging system in the United States (see Table 89–3). Patients are assigned to stages A through D and corresponding subcategories based on size of the tumor (T), local or regional extension, presence of involved lymph node groups (N), and presence of metastases (M).[23] Some studies classify patients who have progressed after hormonal therapy as stage D_3.[38] Based on men diagnosed with prostate cancer at Walter Reed Army Medical Center from 1988 to 1998, including over 2042 prostate cancer diagnoses, localized prostate cancer (stage T_1 and T_2) was diagnosed more frequently (89% versus 68%) and advanced disease (stages T_3, T_4, and D) was diagnosed less frequently (11% versus 32%) when comparing the 1998 to the 1988 incidence rates.

Clinical Presentation

Localized Disease
Asymptomatic

Locally Invasive Disease
- Ureteral dysfunction, frequency, hesitancy, and dribbling
- Impotence

Advanced Disease
- Back pain
- Cord compression
- Lower extremity edema
- Pathologic fractures
- Anemia
- Weight loss

Diagnostic and Staging Work-Up for Prostate Cancer

Diagnostic Tests
- Digital rectal examination (DRE)
- Prostate-specific antigen (PSA)
- Transrectal ultrasonography (TRUS) if either DRE is positive or PSA is elevated
- Biopsy

Staging Tests
- Gleason score on biopsy specimen
- Bone scan
- Complete blood count
- Liver function tests
- Serum phosphatases (acid/alkaline)
- Excretory urogram
- Chest x-ray

Additional Staging Tests
- Depends on tumor classification, PSA, and Gleason score.
- Skeletal films
- Lymph node evaluation
  - Pelvic computed tomography
  - ^{111}In-labeled capromab pendetide scan
  - Bipedal lymphangiogram
- Transrectal magnetic resonance imaging

❸ *The prognosis for patients with prostate cancer depends on the histologic grade, the tumor size, and the local extent of the primary tumor.*[16] The most important prognostic criterion appears to be the histologic grade because the degree of differentiation ultimately determines the stage of disease. Poorly differentiated tumors are highly associated with both regional lymph node involvement and distant metastases.[16]

Between 1992 and 1999, 5-year overall survival rates were estimated at 98% for whites and 93% for African Americans.[1] For this same period, the survival rates for localized or regional disease (100%) and distant disease (33%) in white males were about the same as the survival rates for localized or regional disease (100%), and distant disease (26%) in African Americans.[1] A 6.3% decline in age-adjusted mortality has been documented for the period 1991 to 1995.[24] Ten-year cancer-specific survival is estimated as 95% for stage A_1, 80% for stages A_2 to B_2, 60% for stage C, 40% for stage D_1, and 10% for stage D_2.[25] It is estimated that more than 85% of patients with stage A_1 can be cured, whereas fewer than 1% of patients with stage D_2 will be cured.

TABLE 89–3. Staging and Classification Systems for Prostate Cancer

AUS[a] Stage (A–D)	AJC-UICC[b] Classification (TNM)
A (occult, nonpalpable)	$T_xN_xM_x$ (cannot be assessed) $T_0N_0M_0$ (nonpalpable)
A_1: Focal	T_0 : Focal or diffuse
A_2: Diffuse	
B (confined to prostate)	$T_1N_0M_0$, $T_2N_0M_0$
B_1: Single nodule in one lobe, less than 1.5 cm	T_1: (Clinically inapparent tumor not palpable or visible by imaging) T_{1a}: Tumor incidental histologic finding in 5% or less of tissue resected T_{1b}: Tumor incidental histologic finding in 5% or more of tissue resected T_{1c}: Tumor identified by needle biopsy (e.g., because of elevated PSA)
B_2: Diffuse involvement of whole gland, greater than 1.5 cm	T_2: (Tumor confined within the prostate[c]) T_{2a}: Tumor involves half of a lobe or less T_{2b}: Tumor involves more than half a lobe, but not both lobes T_{2c}: Tumor involves both lobes
C (localized to periprostatic area)	$T_3N_0M_0$, $T_4N_0M_0$
C_1: No seminal vesicle involvement, less than 70 g	T_3: (Tumor extends through the prostatic capsule[d]) T_{3a}: Unilateral extracapsular extension T_{3b}: Bilateral extracapsular extension T_{3c}: Tumor invades the seminal vesicle(s)
C_2: Seminal vesicle involvement, greater than 70 g	T_4: (Tumor is fixed or invades adjacent structures other than the seminal vesicles) T_{4a}: Tumor invades any of bladder neck, external sphincter, or rectum T_{4b}: Tumor invades levator muscles and/or is fixed to the pelvic wall
D (metastatic disease)	Any T, $N_{1–4}$, M_0, or $N_{0–4}$, M_1
D_1: Pelvic lymph nodes or ureteral obstruction	N_1: Metastasis in a single lymph node, 2 cm or less in greatest dimension
D_2: Bone, distant lymph node, organ, or soft tissue metastases	N_2: Metastasis in single lymph node more than 2 cm but not more than 5 cm in greatest dimension, or multiple lymph node metastases, none more than 5 cm in greatest dimension N_3: Metastasis in lymph node more than 5 cm in greatest dimension M_{1a}: Nonregional lymph node(s) M_{1b}: Bone(s) M_{1c}: Other site(s)

[a]American Urologic System.
[b]American Joint Committee–International Union Against Cancer.
[c]Tumor found in one or both lobes by needle biopsy but not palpable or visible by imaging is classified as T_{1c}.
[d]Invasion into the prostatic apex or into (but not beyond) the prostatic capsule is not classified as T_3 but as T_2.

TREATMENT

Desired Outcome

The desired outcome in early-stage prostate cancer is to minimize morbidity and mortality owing to prostate cancer.[26] Unfortunately, the most appropriate therapy for early-stage prostate cancer is unknown. Early-stage disease may be treated with surgery, radiation, or watchful waiting. While surgery and radiation are curative, they are associated with significant morbidity and mortality. Since the overall goal is to minimize morbidity and mortality associated with the disease, watchful waiting is appropriate in selected individuals. Advanced prostate cancer (stage D) is not currently curable, and treatment should focus on providing symptom relief and maintaining quality of life.[27]

General Approach to Treatment

The initial treatment for prostate cancer depends primarily on the disease stage, the Gleason score, the presence of symptoms, and the life expectancy of the patient.[15,26] Prostate cancer usually

TABLE 89–4. Initial Management of Prostate Cancer with Low and Intermediate Recurrence Risk

Recurrence Risk	Expected Survival	Initial Therapy
Low	Less than 10 years	Expectant management or RT
$T_{1–2a}$, Gleason 2–6, PSA less than 10	Greater than or equal to 10 years	Expectant management or RP with or without pelvic lymph node dissection or RT
Intermediate	Less than 10 years	EM, RT or RP with or without pelvic lymph node dissection
$T_{2b–2c}$, or Gleason 7, or PSA 10–20	Greater than or equal to 10 years	RP with or without pelvic lymph node dissection or RT

EM = Expectant management; RT = Radiation therapy; RP = Radical prostatectomy; PSA = Prostate specific antigen.

is diagnosed initially by PSA and DRE and confirmed by a biopsy, where the Gleason score is assigned. Asymptomatic patients with a low risk of recurrence, those with a T_1 or T_2 lesion with a Gleason score of 2 through 6 and a PSA of less than 10 ng/mL (10 mcg/L), may be managed by expectant management or radiation[26] (Table 89–4). Since patients with asymptomatic early-stage disease generally have an excellent 10-year survival, immediate morbidities of treatment must be balanced against the likelihood of dying from prostate cancer. In general, more aggressive treatments of early-stage prostate cancer are reserved for younger men, although patient preference is a major consideration in all treatment decisions. In patients with a normal life expectancy of equal to or greater than 10 years, either observation, radiation (external beam or brachytherapy), or radical prostatectomy may be offered. Radical prostatectomy and radiation therapy generally are considered therapeutically equivalent for localized prostate cancer, although neither has been shown to be better than observation alone.[26–28]

Individuals with T_{2b} and T_{2c} disease or a Gleason score of 7 or a PSA ranging from 10 to 20 ng/mL (10 to 20 mcg/L) are considered at intermediate risk for prostate cancer recurrence.[26] Individuals with less than a 10-year expected survival may be offered expectant managment, radiation therapy, or radical prostatectomy, and those with a greater than or equal to 10-year life expectancy may be offered either radical prostatectomy or radiation therapy (Table 89–5).

Patients at high risk of recurrence [stage T_{3b}, a Gleason score ranging from 8 to 10, or a PSA value greater than 20 ng/mL (20 mcg/L)] should be treated with androgen ablation for 2 to 3 years combined with radiation therapy[26] (see Table 89–5). Selected individuals with a low tumor volume may receive a radical prostatectomy or radiation therapy.[29,30]

Patients with T_{3b} and T_4 disease have a very high risk of recurrence and are not candidates for radical prostatectomy because of extensive local spread of disease.[26] ❹ *Androgen ablation with an LHRH agonist plus an antiandrogen should be used prior to radiation therapy for patients with locally advanced prostate cancer to improve outcomes over radiation therapy alone.* Patients should be offered a combination of radiation therapy and androgen ablation. Recent evidence suggests that androgen ablation should be instituted at diagnosis rather than waiting for symptomatic disease or progression to occur. In a randomized clinical trial enrolling 500 men with locally advanced prostate cancer who were randomized to either immediate initiation of androgen ablation with either orchiectomy or androgen ablation or deferred hormonal therapy, individuals with immediate therapy had a median actuarial cause-specific survival duration of 7.5 years, whereas those with deferred treatment had a median actuarial cause-specific survival duration of 5.8 years.[31]

❺ *Androgen ablation therapy, with either orchiectomy, an LHRH agonist alone, or an LHRH agonist plus an antiandrogen (combined hormonal blockade), can be used to provide palliation for patients with advanced (stage D_2) prostate cancer.* The effects of androgen deprivation seem most pronounced in patients with minimal disease at diagnosis.[26] Estrogens were once used widely; however, the primary estrogen, diethylstilbestrol (DES), was withdrawn from the United States market in 1997 owing to increased cardiovascular risk. Secondary hormonal manipulations, cytotoxic chemotherapy, or supportive care is used for the patient who progresses after initial therapy.[21]

TABLE 89–5. Management of Prostate Cancer with High and Very High Recurrence Risk

Recurrence Risk	Initial Therapy
High	
T_{3a}, or Gleason 8–10, or PSA greater than 20 ng/mL	Androgen deprivation for 2 years and RT or RT or RP
Locally advanced	
Very high	RT + androgen deprivation
$T_{3b}–T_4$	or Androgen deprivation
Metastatic	
Any T, N_1	Androgen deprivation or RT
Any T, any N, M_1	Androgen deprivation

Androgen ablation = serum testosterone levels less than 50 ng/mL.
LHRH agonist (medical castrations or surgical are equivalent).
RT = radiation therapy; RP = radical prostatectomy.

Nonpharmacologic Therapy

Expectant Management

Expectant management, also known as *observation* or *watchful waiting,* involves monitoring the course of disease and initiating treatement if the cancer progresses or the patient becomes symptomatic. A PSA determination and DRE are performed every 6 months, with a repeat biopsy at any sign of disease progression. The advantages of expectant management are avoiding the adverse effects associated with definitive therapies such as radiation and radical prostatectomy and minimizing the risk of unnescessary therapies. The major disadvantage of expectant management is the risk that the cancer progresses and requires a more intensive therapy.[26]

Orchiectomy

Bilateral **orchiectomy,** or removal of the testes, rapidly reduces circulating androgens to castrate levels (androstenedione less than 50 ng/mL, 1.7 nmol/L).[15] However, many patients are not surgical candidates owing to their advanced age, and other patients find this procedure psychologically unacceptable.[15] Orchiectomy is the preferred initial treatment in patients with impending spinal cord compression or ureteral obstruction.

Radiation

The two commonly used methods for radiation therapy are **external-beam radiotherapy** and **brachytherapy.**[26] In external-beam radiotherapy, doses of 70 to 75 Gy are delivered in 35 to 41 fractions in patient with low-grade prostate cancer and 75 to 80 Gy for those with intermediate- or high-grade prostate cancer. Brachytherapy involves the permanent implantation of radioactive beads of 145 Gy of ^{125}I or 124 Gy of ^{103}Pd and generally is reserved for individuals with low-risk cancers.

Radical Prostatectomy

Complications from radical **prostatectomy** include blood loss, stricture formation, incontinence, lymphocele, fistula formation, anesthetic risk, and impotence. Nerve-sparing radical prostatectomy can be performed in many patients; 50% to 80% regain sexual potency within the first year. Acute complications from radiation therapy include cystitis, proctitis, hematuria, urinary retention, penoscrotal edema, and impotence (30% incidence).[15] Chronic complications include proctitis, diarrhea, cystitis, enteritis, impotence, urethral stricture, and incontinence.[15] Since radiation and prostatectomy have significant and immediate mortality when compared with observation alone, many patients may elect to postpone therapy until symptoms develop.

Patient Encounter 2

GG is a 72-year-old man with newly diagnosed prostate cancer. He has no symptoms, and he was diagnosed on routine screening. He is stage T_1, his Gleason score is 2, and his PSA is 6 ng/mL (6 mcg/L).

- What treatment options are available to GG?

Pharmacologic Therapy

LHRH Agonists

Luteinizing hormone–releasing hormone (LHRH) agonists are a reversible method of androgen ablation and are as effective as orchiectomy in treating prostate cancer.[32] Currently available LHRH agonists include leuprolide, leuprolide depot, leuprolide implant, and goserelin acetate implant. Leuprolide acetate is administered once daily, whereas leuprolide depot and goserelin acetate implant can be administered either once monthly, once every 12 weeks, or once every 16 weeks (leuprolide depot, every 4 months). The leuprolide depot formulation contains leuprolide acetate in coated pellets. The dose is administered intramuscularly, and the coating dissolves at different rates to allow sustained leuprolide levels throughout the dosing interval. Goserelin acetate implant contains goserelin acetate dispersed in a plastic matrix of D,L-lactic and glycolic acid copolymer and is administered subcutaneously. Hydrolysis of the copolymer material provides continuous release of goserelin over the dosing period. A recently approved leuprolide implant is a mini-osmotic pump that delivers 120 mcg of leuprolide daily for 12 months. After 12 months, the implant is removed, and a different implant can be placed.

Several randomized trials have demonstrated that leuprolide and goserelin are effective agents when used alone in patients with advanced prostate cancer.[19] Response rates around 80% have been reported, with a lower incidence of adverse effects compared with estrogens.[19] There are no direct comparative trials of the currently available LHRH agonists or the dosage formulations, but a recent meta-analysis reported that there is no difference in efficacy or toxicity between leuprolide and goserelin. Therefore, the choice between the two usually is made based on cost and patient and physician preference for a dosing schedule.

The most common adverse effects reported with LHRH agonist therapy include a disease flare-up during the first week of therapy, hot flashes, erectile impotence, decreased libido, and injection-site reactions.[19] The disease flare-up is thought to be caused by initial induction of LH and FSH by the LHRH agonist and manifests clinically as either increased bone pain or increased urinary symptoms.[19] This flare reaction usually resolves after 2 weeks and has a similar onset and duration pattern for the depot LHRH products.[33,34]

LHRH agonist monotherapy can be used as initial therapy, with similar response rates to orchiectomy and estrogen administration expected. There is a lower incidence of cardiovascular-related adverse effects associated with LHRH agonist therapy than with estrogen administration. Patients should be counseled to expect worsening symptoms during the first week of therapy, and caution should be exercised when initiating LHRH agonist therapy in patients with widely metastatic disease involving the spinal cord or having the potential for ureteral obstruction because irreversible complications may occur.

Antiandrogens

Three antiandrogens, flutamide, bicalutamide, and nilutamide, are currently available (Table 89–6). Antiandrogens have been used as monotherapy in previously untreated patients, but a recent meta-analysis determined that monotherapy with antiandrogens is less effective than LHRH agonist therapy.[34] Efficacy of the antiandrogens was similar.[21,35–37] Objective responses are manifested as decreased bone pain, decreased prostate size, decreased PSA, and/or improved performance status. However, for advanced prostate cancer, all currently available antiandrogens are indicated only in combination with androgen-ablation therapy; flutamide and bicalutamide are indicated in combination with an LHRH agonist, and nilutamide is indicated in combination with orchiectomy.[21] The most common antiandrogen-related adverse effects are listed in Table 89–6.

TABLE 89–6. Antiandrogens

Antiandrogen	Usual Dose	Adverse Effects
Flutamide	750 mg/day	Gynecomastia Hot flushes Gastrointestinal disturbances (diarrhea) Liver function test abnormalities Breast tenderness Methemoglobinemia
Bicalutamide	50 mg/day	Gynecomastia Hot flushes Gastrointestinal disturbances (diarrhea) Liver function test abnormalities Breast tenderness
Nilutamide	300 mg/day for first month, then 150 mg/day	Gynecomastia Hot flushes Gastrointestinal disturbances (nausea or constipation) Liver function test abnormalities Breast tenderness Visual disturbances (impaired dark adaptation) Alcohol intolerance Interstitial pneumonitis

Combined Hormonal Blockade

Although up to 80% of patients with advanced prostate cancer will respond to initial hormonal manipulation, almost all patients will relapse within 2 to 4 years of initiating therapy.[15] The rationale for combination hormonal therapy is to interfere with multiple hormonal pathways to completely eliminate androgen action. In clinical trials, combination hormonal therapy, sometimes also referred to as *maximal androgen deprivation* or *total androgen blockade,* has been used. The combination of LHRH agonists or orchiectomy and antiandrogens is the most extensively studied combined androgen-deprivation approach.

Combining an LHRH agonist with flutamide demonstrated response rates greater than 90% in previously untreated patient, and the median survival was 61 months in the combination arm and 41 months in the leuprolide-alone arm in patients with minimal disease.[38] However, in a comparison of goserelin with goserelin and flutamide conducted in 589 patients with 10 years of follow-up, combined androgen blockade (CAB) showed no benefit over goserelin alone.[39]

The most recent meta-analysis of 27 randomized trials in 8275 patients (4803 treated with flutamide, 1683 treated with nilutamide, and 1784 treated with cyproterone) comparing maximal androgen blockade with conventional medical or surgical castration showed a small survival benefit at 5 years for those treated with flutamide or nilutamide (27.6%) compared with those treated with castration alone (24.7%; $p = 0.0005$).[40]

Although some investigators now consider CAB to be the initial hormonal therapy of choice for newly diagnosed patients, the clinician is left to weigh the costs of combined therapy against potential benefits in light of conflicting results in the randomized trials[21] and the modest benefit seen in the meta-analysis.[40] For trials that did show an advantage for CAB, whether these effects are specific to the testosterone-deprivation method (orchiectomy versus leuprolide versus goserelin), the antiandrogen, the duration of therapy, or patient selection is not clear. Until further carefully designed studies that use survival, time to progression, quality of life, patient preference, and cost as end points are conducted, it is appropriate to use either LHRH agonist monotherapy or CAB as initial therapy

Patient Encounter

CC is a 69-year-old man who presents with metastatic prostate cancer. His disease is metastatic to the bones, and his primary symptom is bone pain.

- What treatment options are available?
- Develop a treatment plan including medication and a monitoring plan for both efficacy and toxicity.

for metastatic prostate cancer. CAB may be most beneficial for improving survival in patients with minimal disease and for preventing tumor flare, particularly in those with advanced metastatic disease. All other patients may be started on LHRH agonist monotherapy, and an antiandrogen may be added after several months if androgen ablation is incomplete.

Estrogens

DES was once a mainstay of prostate cancer therapy. While very effective in androgen ablation, DES-treated patients experienced increased cardiovascular mortality.[41] LHRH agonists, with equivalent efficacy and decreased cardiovascular toxicity, supplanted DES as a mainstay of therapy.

Second-Line Therapy

Secondary or salvage therapies for patients who progress after their initial therapy depend on what was used for initial management.[26] For patients diagnosed initially with localized prostate cancer, radiotherapy can be used in the case of failed radical prostatectomy. Alternatively, androgen ablation can be used in patients who progress after either radiation therapy or radical prostatectomy.

Secondary hormonal manipulations, such as adding an antiandrogen to a patient who incompletely suppresses testosterone secretion with an LHRH agonist, or withdrawing antiandrogens in a patient receiving combination therapy, or using agents that inhibit androgen synthesis, can be attempted in patients treated initially with one hormonal modality. Supportive care, chemotherapy, or local radiotherapy can be used in patients who have failed all forms of androgen-ablation manipulations because these patients are considered to have androgen-independent disease.

For patients who initially received an LHRH agonist alone, castration testosterone levels should be documented. Patients with inadequate total testosterone suppression (greater than 20 ng/dL, or 0.694 nmol/L) can be treated by adding an antiandrogen or performing an orchiectomy. If castration testosterone levels have been achieved, the patient is considered to have androgen-independent disease, and palliative androgen-independent salvage therapy can be used.

❻ *Antiandrogen withdrawal, for patients having progressive disease while receiving combined hormonal blockade with an LHRH agonist plus an antiandrogen, can provide additional symptomatic relief. Mutations in the androgen receptor have been documented that cause antiandrogen compounds to act like receptor agonists.*

If the patient initially received combined androgen blockade with an LHRH agonist with an antiandrogen, then androgen withdrawal is the first salvage manipulation.[42] Objective and subjective responses have been noted following the discontinuation of flutamide, bicalutamide, or nilutamide in patients receiving these agents as part of combined androgen ablation with an LHRH agonist. Mutations in the androgen receptor have been demonstrated that allow antiandrogens such as flutamide, bicalutamide, and nilutamide (or their metabolites) to become agonists and activate the androgen receptor. Patient responses to androgen withdrawal manifest as significant PSA reductions and improved clinical symptoms. Androgen withdrawal responses lasting 3 to 14 months have been noted in up to 35% of patients, and predicting response seems to be related most closely to longer androgen exposure times.[42] Incomplete cross-resistance has been noted in some patients who received bicalutamide after they had progressed while receiving flutamide.[35] Adding an agent that blocks adrenal androgen synthesis, such as aminoglutethimide, at the time that androgens are withdrawn may produce a better response than androgen withdrawal alone. Because of the potential for response immediately after antiandrogen withdrawal, a sufficient observation and assessment period (usually 4–6 weeks) is required before a patient can be enrolled on a clinical trial evaluating a new agent or therapy for advanced prostate cancer.

Androgen synthesis inhibitors, such as aminoglutethimide and ketoconazole, can provide symptomatic relief for a short time in approximately 50% of patients with progressive disease despite previous androgen-ablation therapy.[21] Adverse effects during aminoglutethimide therapy occur in approximately 50% of patients.[21] Central nervous system effects that include lethargy, ataxia, and dizziness are the major adverse reactions. A generalized morbilliform, pruritic rash has been reported in up to 30% of patients treated. The rash is usually self-limiting and resolves within 5 to 8 days with continued therapy. Adverse effects from ketoconazole include gastrointestinal intolerance, transient rises in liver and renal function tests, and hypoadrenalism.

After all hormonal manipulations are exhausted, the patient is considered to have androgen-independent disease, and chemotherapy or palliative supportive therapy is appropriate.[26] Palliation can be achieved by pain management, using radioisotopes for bone-related pain, analgesics, corticosteroids, bisphosphonates,[43] and local radiotherapy.[26] Data are emerging that demonstrate that bisphosphonates such as pamidronate and zoledronic acid may prevent skeletal morbidity, such as pathologic fractures and spinal cord compression, in men with hormone-refractory prostate cancer; however, other studies have shown no benefit. The early use of bisphosphonates also has been shown to prevent bone loss owing to androgen deprivation therapy. The usual dose of pamidronate is 90 mg every month, and the usual dose of zoledronic acid is 4 mg every 3 to 4 weeks. A trial of pamidronate or zoledronic acid can be initiated in prostate cancer patients with bone pain; if no benefit is observed, the drug may be discontinued.[44]

❼ *Chemotherapy, with docetaxel and prednisone or docetaxel and estramustine, improves survival in patients with hormone-refractory prostate cancer. Patients with hormone-refractory prostate cancer also may be considered for entry into clinical*

trials investigating new therapies for prostate cancer. Docetaxel 75 mg/m^2 every 3 weeks and prednisone 5 mg twice a day improve survival in hormone-refractory metastatic prostate cancer.[45,46] (Table 89–7). The most common adverse events reported with this regimen are nausea, alopecia, and bone marrow suppression. In addition, fluid retention and peripheral neuropathy, known effects of docetaxel, are observed. The combination of estramustine (280 mg three times a day on days 1–5) and docetaxel 60 mg/m^2 on day 2 every 3 weeks also improves survival in hormone refractory metastatic prostate cancer. Estramustine causes a decrease in testosterone and a corresponding increase in estrogen; therefore, the adverse effects of estramustine include an increase in thromboembolic events and gynecomastia and decreased libido. Estramustine is an oral capsule and should be refridgerated. Calcium inhibits the absorption or estramustine, so concurrent administration should be avoided. While both the docetaxel-prednisone and the docetaxel-estramustine regimens are effective in hormone-refractory prostate cancer, most clinicians prefer the docetaxel-prednisone regimen because of the cardiovascular adverse effects associated with estramustine. In addition, androgen ablation usually is continued when chemotherapy is initiated.[26]

OUTCOME EVALUATION

Monitoring of prostate cancer depends on the stage of the cancer.[26] When definitive, curative therapy is attempted, objective parameters to assess tumor response include assessment of the primary tumor size, evaluation of involved lymph nodes, and the response of tumor markers such as PSA to treatment. Following definitive therapy, the PSA level is checked every 6 months for the first 5 years and then annually. Local recurrence in the absence of a rising PSA may occur, so DRE is also performed. In the metastatic setting, clinical-benefit responses can be documented by evaluating performance status changes, weight changes, quality of life, and analgesic requirements, in addition to the PSA or DRE at 3-month intervals.

Patient Care and Monitoring

1. Men, starting at age 40, should be offered a baseline PSA determination and DRE, with annual screening offered starting at age 50.
2. There are no currently recommended prostate cancer chemoprevention agents.
3. The diagnosis of prostate cancer is made by biopsy.
4. Prostate cancer treatment depends on the stage, age, Gleason score, and PSA concentration. Treatment options include expectant management, radiation therapy, radical prostatectomy, hormonal therapy, and chemotherapy.
5. While receiving treatment for prostate cancer, patients should be monitored for efficacy and toxicity.
6. Measures of efficacy include disappearance of tumor or decrease in tumor, resolution of symptoms, or a decline in the PSA.
7. Measures of toxicity vary by the treatment; work with patients to ensure that they understand the expected toxicities of their regimen and that they should report them.
8. Counsel patients to be compliant with all treatment regimens and appointments.

90 Malignant Lymphomas

Chris Fausel

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Discuss the underlying pathophysiologic mechanisms of the lymphomas and how they relate to presenting symptoms of the disease.
2. Differentiate the pathologic findings of Hodgkin's lymphoma, follicular indolent non-Hodgkin's lymphoma, and diffuse aggressive non-Hodgkin's lymphoma and how this information yields a specific diagnosis.
3. Describe the general staging criteria for the lymphomas and how they relate to prognosis, and evaluate the role of the International Prognostic Index (IPI) in providing prognostic information for non-Hodgkin's lymphoma patients.
4. Contrast the treatment for early- and advanced-stage disease for Hodgkin's lymphoma.
5. Delineate the clinical course of follicular indolent and diffuse aggressive non-Hodgkin's lymphoma and the implications for disease classification schemes and treatment goals.
6. Outline the general treatment approach to follicular indolent and diffuse aggressive non-Hodgkin's lymphoma for localized and advanced disease.
7. Interpret the current role for monoclonal antibody therapy in non-Hodgkin's lymphoma.
8. Assess the role of autologous hematopoietic stem cell transplantation in relapsed Hodgkin's lymphoma and non-Hodgkin's lymphoma.

Key Concepts

❶ B and T cells can undergo neoplastic transformation that is governed by specific mutations in their chromosomes that result in populations of malignant lymphoma cells.

❷ Specific pathologic characteristics distinguishing Hodgkin's lymphoma from non-Hodgkin's lymphoma include morphology, cell surface antigens, and chromosomal mutations.

❸ Classic signs and symptoms of the lymphomas include lymphadenopathy and B-symptoms (i.e., fever, night sweats, and weight loss).

❹ The diagnosis of malignant lymphomas is established by tumor biopsy sample, analysis of the biopsy tissue, and determination of the extent of the disease in the patient.

❺ The goal of treatment of Hodgkin's lymphoma is cure for all stages of disease and the first relapse.

❻ Follicular indolent non-Hodgkin's lymphoma is incurable, so therapy goals focus on inducing and maintaining remission duration while minimizing treatment-related toxicities.

❼ Diffuse, aggressive non-Hodgkin's lymphoma centers on curative-intent therapy using anthracyline-based combination chemotherapy and high-dose chemotherapy with autologous stem cell transplantation for relapsed disease.

❽ The recombinant monoclonal antibody rituximab is an effective treatment option for some patients with non-Hodgkin's lymphoma as a single agent and enhances the efficacy of combination chemotherapy regimens.

The malignant lymphomas are hematologic cancers that consist of a cluster of diseases of the lymphoid tissue. The primary malignant cells for lymphomas are lymphocytes of B-cell, T-cell, and NK-cell origin. These cells originate from a small population of

lymphocytes that have undergone malignant transformation secondary to a series of genetic mutations. Lymphoma cells predominate in the lymph nodes; however, they can infiltrate other tissues, such as the bone marrow, central nervous system (CNS), gastrointestinal (GI) tract, liver, mediastinum, skin, and spleen. A diagrammatic overview of the lymph node regions is depicted in Fig. 90–1. Lymphoma is categorized into two general headings: Hodgkin's lymphoma (HL) and non-Hodgkin's lymphoma (NHL), both containing numerous histologic subtypes that are pathologically distinct disease entities. HL is distinguished from NHL by the presence of the pathognomonic Reed-Sternberg (RS) cell. Other lymphoma disease entities without the RS cells are classified as types of NHL.

The clinical course varies widely among these histologies of HL and NHL. Most lymphoma subtypes are highly proliferating tumor cells that require aggressive therapeutic intervention with chemotherapy, radiation therapy, or both. By contrast, certain subtypes of non-Hodgkin's lymphoma are characterized by a disease course that flares and remits intermittently over a period of several years either with or without treatment.

Patient Encounter, Part 1

A 22-year-old female college student with no remarkable medical history notes shortness of breath when she takes her daily 5-mile run, which has worsened progressively over the past 3 weeks. On review of systems, it is discovered that she has experienced intermittent sensations of chest tightness over the past 2 months that she ascribed to pollen allergies, and 3 days prior to presentation she experienced an episode of hemoptysis. Her only medication is oral contraceptives, and she reports no known drug allergies. A chest x-ray is remarkable for a 10 × 12 cm mediastinal mass.

- What is necessary to establish a diagnosis for this patient?
- Is this age group at risk for a particular malignant diagnosis that presents as a mediastinal mass?

EPIDEMIOLOGY AND ETIOLOGY

Hodgkin's Lymphoma

Approximately 7500 new cases of HL are diagnosed each year in the United States, with 1400 deaths attributed to the disease. The age-specific incidence of HL is bimodal, with its greatest peak in the third decade of life and a smaller peak in the fifth decade of life.[1] The precise cause of HL is unknown, but certain associations have been noted to provide insight about possible etiologic factors. Viruses, such as the Epstein-Barr virus (EBV), have been implicated by epidemiologic, serologic, and molecular studies. The EBV genome has been detected in RS cells in up to 50% of cases in developed countries and more in developing nations. To date, no conclusive studies have correlated HL with human immunodeficiency virus (HIV). Other possible risk factors identified include woodworking and familial factors such as same-sex siblings with HL.[2]

Non-Hodgkin's Lymphoma

There are approximately 55,000 cases of NHL in the United States each year, with the number of deaths approaching 20,000. The incidence of the disease is increasing 4% per year, which has doubled the number of cases in the United States since 1950.[3] This increase is related to the development of aggressive NHL in 20- to 40-year-old men with HIV, although the overall increase is independent of HIV disease, particularly for patients older than 65 years of age. The median age

for diagnosis is 50 years, although children and young adults may be affected. The etiology of certain aggressive NHL subtypes is related to specific endemic geographic factors. Follicular or low-grade lymphoma is more common in the United States and Europe and is relatively uncommon in the Caribbean, Far East, Middle East, or Africa. The human T-cell leukemia virus I (HTLV-I) induces T-cell lymphoma/leukemia in both Japan and the Caribbean. Kaposi's sarcoma–associated herpes virus, or human herpes virus 8 (HHV-8), and hepatitis C have been implicated in inducing NHL. Lymphomas of the gastrointestinal tract are more prevalent in patients with celiac sprue, inflammatory bowel disease, or *Helicobacter pylori* infection. The incidence of Burkitt's NHL is 7 cases per 100,000 population in Africa, compared with 0.1 per 100,000 in the United States. Malaria or EBV is thought to contribute to the chronic B-lymphocyte stimulation that leads to malignant transformation. EBV has been shown to transform lymphocytes in vitro to a monoclonal malignant population, which is believed to drive the development of disease in patients who have received a solid-organ transplant or bone marrow transplant or have other chronic immunosuppressed states. Patients with congenital diseases such as Wiskott-Aldrich syndrome, common-variable hypogammaglobinemia, X-linked lymphoproliferative syndrome, and severe combined immunodeficieny are also at risk.[4]

Environmental factors have been identified as contributing to the development of NHL. Certain occupations such as wood and forestry workers, butchers, exterminators, grain millers, machinists, mechanics, painters, printers, and industrial workers have a higher prevalence of disease. Industrial chemicals such as pesticides, herbicides, organic chemicals (e.g., benzene), solvents, and wood preservatives are also associated with NHL.

PATHOPHYSIOLOGY

Pluripotent stem cells in the bone marrow are able to differentiate to both lymphoid and myeloid progenitor cells. Lymphoid progenitor cells undergo gene rearrangement to yield either B-cell or T-cell lineage precursor cells. Normal maturation for naive B cells includes expression of cell surface antibody or the cells typically undergo **apoptosis,** or programmed cell death. These cells are differentiated from other B cells, such as memory cells, by virtue of cell surface antigen (CD5+ or CD5– and CD27–) and bound antibody (IgM+ and IgD+). Once naive B cells recognize antigen with their cell surface antibody, they accumulate in the lymph nodes, spleen, or other lymphoid tissue. The DNA of these B cells is susceptible to three different types of genetic modification: **receptor editing, somatic hypermutation,** and **class switching** within the germinal center of the lymph node. Germinal centers are microanatomic structures located within lymph nodes that develop with clonal B-cell expansion secondary to antigen stimulation. Under normal circumstances, these genetic changes allow for adaptation of the immune system to the repeated exposure to environmental antigens.

Hodgkin's Lymphoma

The pathophysiology of HL is defined by the presence of the RS cell in a grouping of lymph nodes. The RS cell is a large cell morphologically with a multinucleated structure with pronounced eosinophilic nucleoli.[5] In the affected lymph nodes, the RS cells are contained in a reactive milieu of T lymphocytes, eosinophils, histiocytes, and plasma cells, which makes them difficult to distinguish from these background cells. The natural course of the disease, if left untreated, is less than a 5% probability of surviving 5 years.

RS cells are genetically derived preapoptotic germinal center B cells. There is evidence to suggest that a protein called c-FLIP that inhibits apoptosis garners protection for RS cells. RS cells express cell-surface antigens CD30 and CD15 while lacking other common B-cell antigens such as CD20. RS cells lack the expression of surface immunoglobulin likely owing to the lack of immunoglobulin transcription factors in normal B cells. The overexpression of a proproliferative and antiapoptotic transcription factor NF-κB is believed to contribute to the expansion and survival of RS cells.[6]

HL is classified into disease subtypes based on the number and morphologic appearance of RS cells and the background cellular milieu. These are listed in the WHO classification of lymphoid neoplastic diseases in Table 90–1.[7] Nodular sclerosing HL is the most common form of HL, representing 70% of cases. It is more common in young adults and is marked by the presence of the RS variant cell, the lacunar cell. The second most common form of HL, accounting for approximately 25% of cases, is the mixed-cellularity variant, with others accounting for less than 5% of cases. Factors identified as negative disease prognostic indicators are listed in Table 90–2.[8]

Non-Hodgkin's Lymphoma

The pathophysiology of NHL is governed by numerous environmental and genetic events culminating with a monoclonal population of malignant lymphocytes. B cells represent the cells of origin in excess of 90% of cases of NHL. Figure 90–2 outlines normal B-cell maturation with accompanying cell-surface antigens. ❶ *Evolving data are correlating chromosomal mutations with specific disease subtypes. Cytogenetic abnormalities involving translocations of antigen receptor genes are prevalent in NHL*. These include T-cell receptor genes in T-cell lymphomas and immunoglobulin genes in B-cell lymphomas. The principal defect appears to be an error in the assembly of the regulatory gene segment of an antigen receptor gene, resulting in inappropriate binding to an **oncogene.** This results in dysregulaton of cell growth and proliferation, giving rise to the malignant clone of

TABLE 90–1. WHO Classification of Lymphoid Neoplasms

B-Cell Neoplasms
Precursor B-cell neoplasm
Precursor B-lymphoblastic leukemia/lymphoma
Mature (peripheral) B-cell neoplasms

Lymphocyte depletion Hodgkin's lymphoma

TABLE 90–2. Negative Prognostic Factors for Hodgkin's Lymphoma and Non-Hodgkin's Lymphoma

International Prognostic Score—Advanced Hodgkin's Lymphoma
Albumin less than 4 g/dL (40 g/L)
Hemoglobin less than 10.5 g/dL (6.5 mmol/L)
Male sex
Age greater than 45 years
Stage IV disease
White blood cell count greater than or equal to 15,000 mm^3 (15×10^9/L)
Lymphocytopenia [count less than 600 mm^3 (0.6×10^9/L) or less than 8% (0.08) of white blood cell count or both]
International Prognostic Index—Diffuse, Aggressive Non-Hodgkin's Lymphoma
Age greater than 60 years
Stage III/IV disease
Extranodal disease greater than 1 site
ECOG performance status 2 or greater
Serum LDH greater than 1 × normal limit

lymphocytes. Oncogenes that have been identified in different lymphomatous diseases include *c-myc*, a regulator of gene transcription; *bcl-1*, important in the regulation of mitosis; *bcl-2*, a regulator of apoptosis; and *bcl-3*, *NF-κB*, and *bcl-6*, which regulate cell differentiation.[9] Classic translocations for NHL include t(8;14) in Burkitt's lymphoma, t(14;18) in follicular lymphomas, t(11;14) mantle cell lymphoma, and t(11;18)/t(1;14) in mucosal-associated lymphomas (MALT).

❷ *Characterization of the* ***morphology*** *of the lymphocytes, the reactivity of the other cells in the lymph node, and the lymph node architecture is essential in obtaining a diagnosis and predicting disease course.* The nodal presentation of NHL is divided into two main categories: follicular, corresponding with low-grade disease, and diffuse, corresponding with aggressive disease. A follicular disease pattern in the inspected lymph node is indicative of a more indolent or low-grade disease progression that has survival measured in years if left untreated. In contrast, a diffuse pattern of lymph node infiltration is a marker of highly aggressive disease, resulting in death within weeks to months if left untreated. Follicular NHL is the most common indolent sub-type, comprising 22% of NHL cases, where diffuse, large B-cell lymphoma is the most common aggressive histology in 31% of cases. The cells of origin for follicular NHL tend to be more mature, nondividing lymphocytes, whereas aggressive NHL is derived from rapidly dividing lymphoid precursors, such as immunoblasts, lymphoblasts, and centroblasts. B cells at the end of germinal center maturation and small, naive B lymphocytes are transformed neoplastic cells for the indolent NHL subtypes follicular lymphoma and small lymphocytic lymphoma, respectively. Lymphoblastic lymphoma/leukemia is believed to originate from lymphoblasts in which diffuse, large B-cell lymphomas form germinal center centroblasts. A unique feature of the biology of NHL is that follicular low-grade histologies can undergo further malignant transformation, and a segment of malignant lymphocytes transforms further into a diffuse, large B-cell lymphoma population. This syndrome, called *Richter's transformation*, may occur in up to 20% of follicular low-grade lymphoma patients and involves multiple genetic events, including abnormalities of chromosomes 11 and 12 and tumor-suppressor genes.[10]

The classification of NHL has undergone several revisions as the histology, molecular biology, and clinical course of the disease have been better defined. Classification schemes such as the *Working Formulation* categorize disease on aggressiveness into three general categories: low grade—survival estimated in years without treatment; intermediate grade—survival estimated in

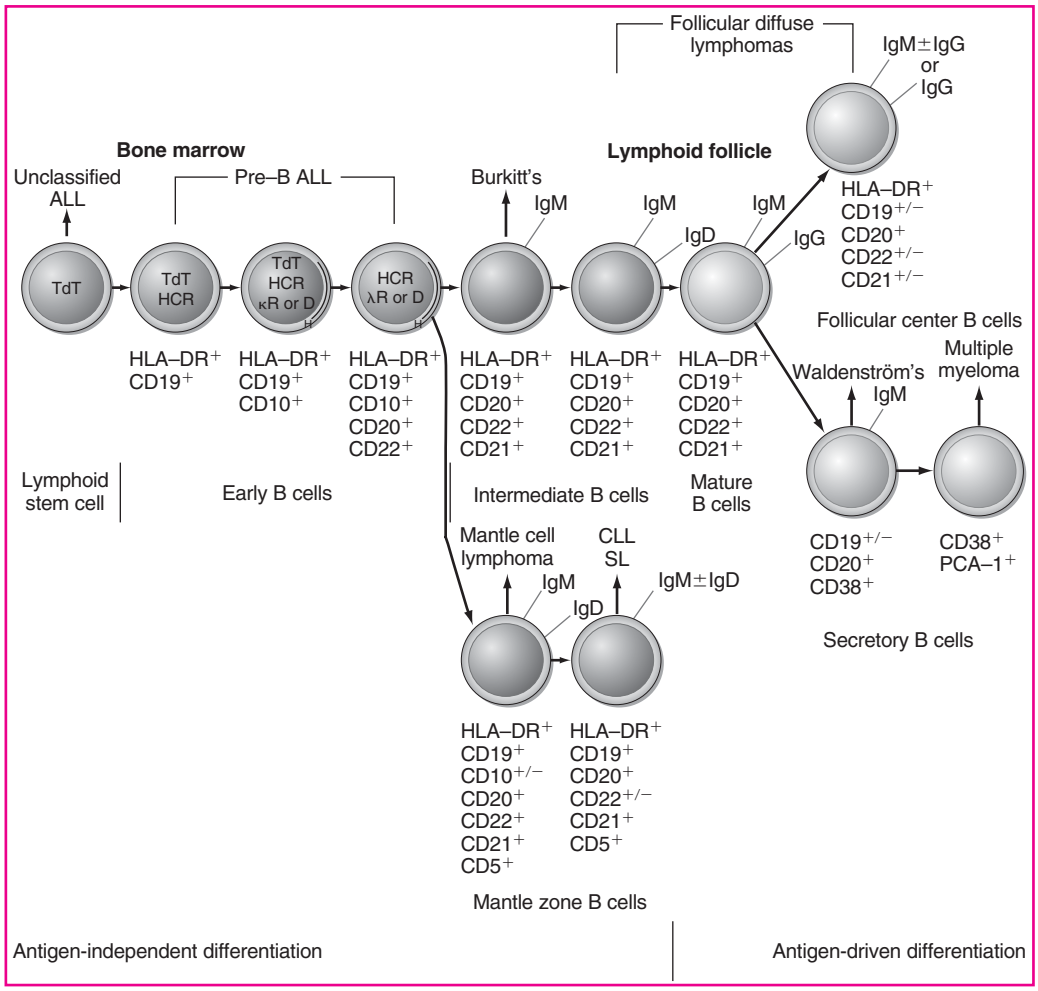

FIGURE 90–2. Pathway of normal B-cell differentiation and relationship to B-cell lymphocytes. (Reproduced from Armitage JO, Longo DL. Malignancies in lymphoid cells. In: Kasper DL, Braunwald E, Fauci AS, et al, (eds.) Harrison's Principles of Internal Medicine. 16th ed. New York: McGraw-Hill; 2005: 544.)

Clinical Presentation and Diagnosis

General

Nonspecific; can range from an asymptomatic patient with a less aggressive lymphoma to a patient that is gravely ill with advanced disease

❸ Symptoms

- Lymphadenopathy, generally in the cervical, axillary, supraclavicular, or inguinal lymph nodes
- Splenomegaly
- Shortness of breath, dry cough, chest pressure (patients with mediastinal mass)
- Gastrointestinal complications (e.g., nausea, vomiting, early satiety, constipation, and diarrhea)
- Back, chest, or abdominal pain

Signs

- Fever
- Night sweats
- Weight loss greater than 10% within last 6 months (These three are known collectively as *B-symptoms*.)
- Pruritus

Laboratory Tests

- LDH
- ESR
- Serum chemistries
- CBC with differential

❹ Other Diagnostic Tests

- Physical examination with careful attention to lymph node inspection
- Imaging: Chest x-ray, chest CT scan, abdominal/pelvic CT scan; PET scan or gallium scan may be used to confirm presence of active disease after treatment.
- Bone marrow biopsy
- *Biopsy of suspected lymph node(s)—either open lymph node biopsy or core biopsy preferred over fine-needle aspiration.*
- *Hematopathology evaluation of biopsy specimen—morphologic inspection, immunohistochemistry for cell-surface antigens to characterize lymphoma cells,* ***cytogenetic analysis***

PE
VSS temp 38.0ºC (100.4ºF)
Labs: WNL, except LDH 2302 units/L (38.4 µkat/L)
Chest x-ray: As mentioned previously
Patient is seen by a hematologist who recommends an open-lung biopsy by a cardiothoracic surgeon. The biopsy is conducted, and pathology assessment shows nodular sclerosing Hodgkin's disease. The hematologist then conducts a staging work-up with computed tomographic (CT) scans of the chest, abdomen, and pelvis and performs a bone marrow biopsy.

• What therapy is appropriate for this patient?

months without treatment; and high grade—survival measured in days to weeks for untreated disease. This scheme is limited in its clinical applicability because the large number of distinct clinical disease entities are not categorized by this classification. The Working Formulation classification of NHL and diseases unclassifiable by that system are presented in Table 90–3. The World Health Organization (WHO) has updated a classification scheme published in 1994 by the International Lymphoma Study Group called the *Revised European American Classification of Lymphoid Neoplasms* (REAL) that broadly categorizes histologic subtypes into B- and T-cell subtypes. This newer classification incorporates immunologic, morphologic, genetic, and clinical attributes of various NHL histologies.

Prognosis with NHL is based on both histology and morphology of the lymphomatous cells. Patients with low-grade lymphomas may remain virtually free of symptoms and able to lead normal lives for many years with minimal intervention, whereas patients with intermediate- and high-grade lymphomas have survival measured in months and weeks, respectively, with untreated disease. Additional prognostic factors present at diagnosis have been identified. Age, presence of B-symptoms, performance status, number of nodal and extranodal sites, lactate dehydrogenase (LDH) concentration, bulky disease (greater than 10 cm), advanced stage, and

TABLE 90–3. Working Formulation for Non-Hodgkin's Lymphoma

Classification	Immunophenotype
Low Grade	
A. Small lymphocytic	100% B cell
B. Follicular, small cleaved cell	100% B cell
C. Follicular, mixed small cleaved cell and large cell	100% B cell
Intermediate Grade	
D. Follicular, large cell	100% B cell
E. Diffuse, small cleaved cell	75% B cell, 20% T cell, 5% null cell
F. Diffuse, mixed small and large cell	75% B cell, 20% T cell, 5% null cell
G. Diffuse, large cell	70% B cell, 20% T cell, 10% null cell
High Grade	
H. Immunoblastic	50% B cell, 50% T cell
I. Lymphoblastic	5% B cell, 95% T cell
J. Diffuse, small noncleaved cell	100% B cell

Lymphomas not included in Working Formulation: mycosis fungoides, mantle cell lymphoma, monocytoid B-cell lymphoma, mucosa-associated lymphoid tissue (MALT), anaplastic large cell lymphoma, angiocentric lymphoma, angioimmunoblastic lymphadenopathy (AILD), Castleman's disease, adult T-cell leukemia/lymphoma.

β_2-microglobulin concentration have been correlated with survival. The *International Index* is a predictive model for aggressive NHL to be treated with doxorubicin-containing chemotherapy regimens.[11] This index is used as a tool for selecting therapy for patients who may warrant a more intense treatment regimen based on known poor prognostic factors.

TREATMENT OF HODGKIN'S LYMPHOMA

Desired Outcome

Staging of HL with a standard staging classification is necessary to guide appropriate treatment with chemotherapy, radiotherapy, or both. The number of involved sites, disease involvement on one or both sides of the diaphragm, localized or disseminated extranodal disease, and B-symptoms are factors in assignment of stage. The Cotswald staging system, a revision of the original Ann Arbor classification, is outlined in Table 90–4.[12]

❺ *The principal goal in treating HL is to cure the patient of the primary malignancy*. HL is a disease sensitive to both radiation and chemotherapy, resulting in an 80% rate of cure with modern therapy. Treatment strategy generally is divided into approaches for early stage I/II localized disease and stage III /IV advanced disease. Regardless of the stage of the disease, all patients are treated with curative intent. Other goals during treatment include:

• Complete resolution of symptoms of disease
• Minimization of acute treatment-related toxicity
• Minimization of long-term treatment-related toxicity

TABLE 90–4. Cotswald Staging Classification for Hodgkin's Disease (1989 Revision of Ann Arbor Staging)

Stage	Description
I	Involvement of a single lymph node region of lymphoid structure (e.g., spleen, thymus, Waldeyer's ring).
II	Involvement of two or more lymph node regions on the same side of the diaphragm. The number of anatomic sites is indicated by a subscript.
III	Involvement of lymph node regions or structure on both sides of the diaphragm.
	III_1: With or without involvement of splenic, hilar, celiac, or portal nodes.
	III_2: Involvement of para-aortic,iliac, or mesenteric.
IV	Involvement of extranodal sites(s) beyond that designated E.
Designations applicable to all stages:	
A	No symptoms
B	Fever, night sweats, and weight loss
X	Bulky disease: greater than 1/3 the width of the mediastinum or greater than 10 cm maximal dimension of nodal mass
E	Involvement of a single extranodal site, contiguous or proximal to a known nodal site
CS	Clinical stage
PS	Pathologic stage

- Provision of high-level supportive care to ameliorate the toxicities of chemotherapy and/or radiation therapy to optimize quality of life during treatment
- Selection of palliative therapy for disease that has become refractory to all curative therapies

Nonpharmacologic Therapy

Patients presenting with stage I/II disease generally are curable with subtotal lymphoid irradiation, which involves treatment of the mantle and paraaortic fields. This therapeutic modality has yielded an overall 90% cure rate, with over a decade of follow-up. However, up to one-third of patients will relapse at the site of original disease presentation. If a patient relapses, then it likely will occur in the first 3 years after therapy has been completed. Fortunately, most of these patients are still curable with salvage chemotherapy.

Standard doses of radiotherapy for HL generally total 3600 cGy to each field in daily fractions of 180 cGy over 4 weeks. Clinically involved areas are given boost doses of 550 to 900 cGy in three to five fractions, resulting in a total dose to the involved area of upwards of 4500 cGy. Radiation may be given as consolidation following completion of a complete course of chemotherapy in patients with advanced HL.[13,14] This treatment typically is reserved for patients who have an unconfirmed response to chemotherapy or who have bulky disease on presentation.

Treatment with these doses of radiotherapy involves toxicity. Both acute and late effects of radiotherapy occur. Acute effects of mantle-field irradiation include nausea, vomiting, anorexia, xerostomia, dysguesia, pharyngitis, dry cough, fatigue, diarrhea, and rash. Prophylaxis with antiemetics such as dexamethasone or prochlorperazine help to prevent or treat nausea. These effects generally are transient and resolve shortly following completion of treatment. Delayed effects from radiotherapy are more concerning in that they may be permanent and present months to years after therapy is complete. Pneumonitis, pericarditis, hypothyroidism, infertility (with pelvic field irradiation), coronary artery disease, deformities in bone and muscle growth in adolescents and children, herpes-zoster reactivation, **Lhermitte's sign,** and secondary malignancies are not uncommon. Patients cured with radiotherapy are at increased risk for breast cancer, lung cancer (particularly in smokers), stomach cancer, melanoma, and non-Hodgkin's lymphoma.

Pharmacologic Therapy

Chemotherapy compared with radiotherapy for stage I or II nonbulky HL has produced equivocal results in major clinical trials.[15] A National Cancer Institute (NCI) trial comparing MOPP (mechlorethamine, vincristine, procarbazine, and prednisone) and radiotherapy showed no overall difference in survival. However, an Italian randomized trial comparing radiotherapy and chemotherapy in early-stage HL showed a significant survival advantage for the radiotherapy arm. This difference has been attributed to the higher salvage rate for patients who relapsed in the radiotherapy arm and received subsequent treatment with salvage chemotherapy. A complete listing of chemotherapy regimens used in HL with drugs, dosing, administration, and treatment interval is presented in Table 90–5.

In an attempt to reduce relapse rate and late toxicity, combined-modality therapy using lower doses of radiation and an abbreviated course of chemotherapy has been evaluated.[16] The goal of decreased relapse rate has been achieved, but no overall survival benefit has been documented. A limitation of this approach is exposing patients to the additive toxicities of chemotherapy. Trials that have investigated this approach typically have incorporated between two and four cycles of a standard regimen for HL, such as ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) with involved-field radiation. At present, combined-modality therapy is considered to be a standard of care for stage I/II HL.

Advanced Disease

Treatment of advanced-stage (stage III–IV) HL is focused on the use of multiagent chemotherapy for six to eight total cycles. MOPP is of historical significance because it was the first chemotherapy regimen to cure HL when it was introduced in the 1960s. However, the significant toxicity, including sterility and secondary leukemia, prompted investigators to evaluate other regimens. ABVD was compared with MOPP or ABVD alternating with MOPP.[17] This pivotal phase III Cancer and Leukemia Group B (CALGB) trial comparing these regimens in 361 patients with stage III or IV HL documented a higher complete response (CR) in the ABVD arms (82% and 83%) versus MOPP (65%). There was increased

TABLE 90–5. Common Treatment Programs in Hodgkin's Lymphoma

MOPP—every 28 days
Mechlorethamine 6 mg/m^2 IV × 1, days 1, 8
Vincristine 1.4 mg/m^2 IV × 1, days 1, 8
Procarbazine 100 mg PO daily, days 1–14
Prednisone 40 mg PO daily, days 1–14

ABVD—every 28 days
Doxorubicin 25 mg/m^2 IV × 1, days 1, 15
Bleomycin 10 units IV × 1, days 1, 15
Vinblastine 6 mg/m^2 × 1, days 1, 15
Dacarbazine 375 mg/m^2 IV, days 1, 15

MOPP/AVD hybrid—every 28 days
Mechlorethamine 6 mg/m^2 IV × 1; day 1
Vincristine 1.4 mg/m^2 IV × 1; day 1
Procarbazine 100 mg PO daily, days 1–7
Prednisone 40 mg PO daily, days 1–14
Doxorubicin 35 mg/m^2 IV × 1; day 8
Bleomycin 10 units IV × 1; day 8
Vinblastine 6 mg IV × 1; day 8

ChlVPP—every 28 days
Chlorambucil 6 mg PO daily, days 1–14
Vinblastine 6 mg/m^2 IV × 1, days 1–8
Procarbazine 100 mg PO daily, days 1–14
Prednisone 40 mg PO daily, days 1–14

BEACOPP (escalated)—every 21 days
Bleomycin 10 mg/m^2 IV, day 8
Etoposide 200 mg/m^2 IV daily, days 1–3
Doxorubicin 35 mg/m^2, day 1
Cyclophosphamide 1200 mg/m^2 IV, day 1
Vincristine 1.4 mg/m^2 IV, day 8
Procarbazine 100 mg/m^2 PO daily, days 1–14
Prednisone 40 mg PO daily, days 1–5
Gemcitabine 1250 mg/m^2 IV × 1; days 1, 8, every 21 days

BCV (high-dose with autologous stem cell transplant)[a]
Carmustine 400 mg/m^2 IV × 1 day
Etoposide 800 mg/m^2 IV daily × 3 days
Cyclophosphamide 1800 mg/m^2 IV daily × 4 days

BEAM (high-dose with autologous stem cell transplant)[a]
Carmustine 300 mg/m^2 IV × 1 day
Etoposide 800 mg/m^2 IV × 1 day
Cytarabine 1600 mg/m^2 IV × 1 day
Melphalan 140 mg/m^2 IV × 1 day

[a]Used for both Hodgkin's lymphoma and non-Hodgkin's lymphoma.

hematologic toxicity in the MOPP arm. A recent update of the data shows the 8-year freedom from progression of 37% in the MOPP arm and about 50% in the ABVD arms. A survival advantage has yet to be demonstrated. ABVD is now considered standard therapy for initial treatment of stage III or IV HL. Further information on ABVD may be found in Table 90–6.

More recently, a German study compared a dose-escalated regimen of BEACOPP (with filgrastim support) with standard-dose bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone, gemcitabine (BEACOPP) and COPP alternating with ABVD (C—cyclophosphamide instead of mechlorethamine for MOPP).[18] The escalated BEACOPP was superior to the other arms in freedom from treatment failure at 5 years and was superior to COPP alternating with ABVD in overall survival at 5 years. The escalated BEACOPP regimen had a higher number of cases of secondary leukemia, and the procarbazine increases the risk of infertility. Currently, this regimen has not been adopted widely in the United States, but considerable interest has been generated in evaluating it in patients with advanced-stage HL with a high number of poor prognostic factors.

Relapse in HL is associated with a significant potential for cure with chemotherapy for both localized and advanced HL. For patients with early-stage HL, the chance of relapse is about 10% to 30%. Advanced-stage HL patients, who have approximately a one-third chance of relapse within the first 3 years of therapy, still retain a chance for cure. Management of relapsed HL can be broadly subcategorized into three different categories: relapse after treatment for early-stage disease, relapse after treatment with chemotherapy for advanced disease, and relapse in patients with advanced disease who do not achieve a remission. For these patients, the definitive therapy is high-dose chemotherapy with autologous stem cell transplant (SCT).[19] This treatment offers a cure rate of approximately 40%.

The role of SCT in HL has evolved from data with conventional four-drug regimens demonstrating that patients with lower dose intensity had a higher rate of relapse. Data comparing high-dose chemotherapy with lower doses of the same regimen yielded a significant benefit in the high-dose arm, leading to early closure of the study. High-dose chemotherapy is given to patients who are in first relapse with encouraging results. A series of 58 patients had a progression-free survival of over 60% with a median follow-up of 2.3 years. The safety profile of autologous SCT continues to improve as improvements in supportive care are realized, and current estimates of mortality from autologous SCT for HL approximate 5%. Morbidity commonly associated with the preparative regimens in HL, aside from infectious and bleeding complications, includes the additive pulmonary toxicity of bleomycin coupled with carmustine in inducing potentially fatal pulmonary pneumonitis.

Patients who are not deemed candidates for high dose chemotherapy with autologous SCT may receive multiagent salvage chemotherapy, such as etoposide methylprednisolone cytarabine cisplatin (ESHAP) or Dexamethasine Cytarabine Cisplatin (DHAP). If less aggressive therapy is desired, patients can be offered palliation with single-agent gemcitabine or vinblastine.[20]

Patient Encounter, Part 3: Creating a Care Plan

Based on the information presented, create a care plan for this patient, including goals of therapy, antineoplastic therapy plan, and necessary supportive care.

TABLE 90–6. Practical Information for ABVD and CHOP

Regimen	Drug Class	Phamacokinetics	Unique Toxicities
ABVD			
Doxorubicin	Anthracycline	Hepatic metabolism	Cardiomyopathy
Bleomycin	Antitumor antibiotic	Renal clearance	Pulmonary fibrosis
Vinblastine	Vinca alkaloid	CYP 3A4/5 metabolism	Neuropathy, constipation
Dacarbazine	Alkylating agent	Hepatic metabolism	Myelosuppression
CHOP			
Cyclophosphamide	Alkylating agent	Prodrug; CYP 3A4/5, 2D6	Hemorrhagic cystitis
Doxorubicin	Anthracycline	Hepatic metabolism	Cardiomyopathy
CYP 3A4/5 metabolism	Vinca alkaloid	CYP 3A4/5	Neuropathy, constipation
Prednisone	Corticosteroid	100% oral bioavailability	Hyperglycemia, osteopenia

TREATMENT OF NON-HODGKIN'S LYMPHOMA

Desired Outcome

Treatment of NHL depends primarily on histologic sub-type (follicular low grade versus diffuse aggressive) and staging (local stage I/II versus advanced stage III/IV) to guide appropriate treatment strategy with observation, chemotherapy, radiotherapy, or chemotherapy and radiation. As with HL, the number of involved sites, disease involvement on one or both sides of the diaphragm, localized or disseminated extranodal disease, and B-symptoms are factors in staging assignment. The Ann Arbor staging system is outlined in Table 90–7.[21]

Treatment goals for NHL depend on the presence of follicular low-grade versus diffuse aggressive disease. For follicular low-grade NHL, the disease is considered to be incurable with standard therapies There is a small prospect for cure using allogeneic SCT owing to the graft-versus-lymphoma effect of donor T cells. Many patients with follicular low-grade NHL are older than 60 years of age, making allogeneic SCT impractical owing to the high treatment-related mortality for older patients.

TABLE 90–7. Ann Arbor Staging of Non-Hodgkin's Lymphoma

Stage	Description
I	Involvement of a single lymph node region (1) or a single extralymphatic organ or site (IE)
II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ or site (IIE)
III	Involvement of lymph node regions on both sides of the diaphragm (III) or localized involvement of an extralymphatic organ or site (IIIE) or spleen (IIIS) or both (IIISE)
IV	Diffuse or disseminated involvement of one or more extranodal organs with or without associated lymph node involvement
Designations applicable to all stages:	
A	No symptoms
B	Fever, nights sweats, and weight loss (greater than 10%)

❻ *The treatment goals for low-grade NHL include:*

- *Observation of the disease until the patient exhibits obvious progression that limits functional capacity or is life-threatening for low-grade NHL*
- *Treatment that induces the disease into remission with resolution of disease symptoms and minimal toxicity*
- *Judicious selection of treatment options to avoid long-term toxicity because patients may require several different chemotherapy treatment regimens over a period of years for low-grade NHL*
- *Prevention of infectious complications of treatment*

The treatment aim for patients with aggressive histologies is cure of the malignancy. There are some histologic subtypes that exhibit an aggressive clinical course that are not considered to be curable. These patients are still treated with curative-intent chemotherapy or may be considered for a clinical trial.

Nonpharmacologic Therapy

For patients with low-grade follicular NHL, deferring initiation of therapy until progression of disease is standard. The median survival is 6 to 10 years, with some patients waiting several years before the disease becomes symptomatic, making observation a reasonable front-line therapy for most of these patients. Radiation therapy has a limited role in NHL relative to HL. NHL is a systemic disease, and radiation typically has been reserved for consolidation therapy following chemotherapy in patients presenting with a large extranodal mass.

For early-stage diffuse, aggressive NHL, combined-modality therapy was tested versus a longer course of chemotherapy.[22] Overall survival favored the CHOP/radiation arm for 5 years (82% versus 72%). There was a trend toward increased toxicity, particularly hematologic and cardiac toxicity, in the CHOP alone arm. The results of this trial have established combined-modality therapy as first-line treatment for early-stage NHL. Unique presentations of NHL, such as CNS primary disease, may incorporate radiation into treatment algorithms.[23]

Pharmacologic Therapy

Follicular Low-Grade NHL

The management of low-grade lymphomas is an area of controversy. Chemotherapy such as single-agent oral cyclophosphamide or fludarabine is often offered initially. In patients in whom a more rapid response is desired, multiagent chemotherapy such as cyclophosphamide vincristine prednisone (CVP) or cyclophosphamide doxorubicin vincristine prednisone (CHOP) may be used. None of these therapies is associated with an overall survival benefit, making it impossible to select an unequivocal first-line regimen.[24–26] These regimens are detailed in Table 90–8. Introduction of the monoclonal antibody rituximab has prompted interest in a novel modality of therapy for this disease. Rituximab is a chimeric murine/human monoclonal antibody that binds specifically to the antigen CD20 expressed on pre-B and mature B lymphocytes.[27] NHL of B-cell origin expresses CD20 in greater than 90% of cases. CD20 is believed to play a role in early differentiation and activation of the cell cycle. After the Fab domain of rituximab binds to CD20, the Fc domain acts to recruit complement and other components of the immune system to induce cell-mediated cytotoxicity with subsequent lysis of the bound lymphocytes. Rituximab also may produce apoptosis of the bound lymphocyte with the act of binding to the CD20 receptor. Rituximab has specific affinity for binding to lymphocytes and lymphoid tissue, begins depleting B lymphocytes with the first dose, and results in sustained suppression for 6 to 9 months with as few as three doses. B-cell recovery begins 6 months following administration of the drug. The drug has a half-life of 60 hours with the first dose that increases with subsequent dosing to approximately 150 hours, allowing for weekly dosing. The initial clinical experience with rituximab involved 166 patients with CD20+ low-grade lymphoma treated with four doses of 375 mg/m^2 of rituximab weekly.[28] The overall response rate was 48%, with 6% representing complete responses and the remainder representing partial responses. The median follow-up of 12 months demonstrated a median time to progression of 13 months by intention-to-treat analysis. Most adverse events were related to intolerance of the first infusion with hypotension, fever, chills, nausea, and bronchospasm. These data established the role of rituximab as a viable treatment option in patients with indolent follicular NHL.

Novel strategies for treatment of low-grade lymphomas include the combination of monoclonal antibodies directed against CD20 with a radioactive moiety attached. Two such entities are now approved by the Food and Drug Administration (FDA): ibritumomab-yttrium^{90} (Zevalin) and tositumomab-iodine^{131} (Bexxar). Both agents are active in disease that has become refractory to rituximab. The radiation component necessitates compounding both medications in a nuclear medicine pharmacy. High-dose chemotherapy is being evaluated for low-grade follicular NHL, but its role is currently limited to clinical trials.

TABLE 90–8. Treatment Programs for Low-Grade, Follicular Non-Hodgkin's Lymphomas

Cyclophosphamide 100 mg/m^2 PO daily Fludarabine 25 mg/m^2 IV daily, days 1–5 Rituximab 375 mg/m^2 IV, day 1, given weekly for 4 or 8 weeks
CVP—every 21 days Cyclophosphamide 800 mg/m^2 IV, day 1 Vincristine 1.4 mg/m^2 IV, day 1 Prednisone 100 mg PO daily, days 1–5
rCVP—every 21 days Rituximab 375 mg/m^2 IV, day 1 Cyclophosphamide 800 mg/m^2 IV, day 1 Vincristine 1.4 mg/m^2 IV, day 1 Prednisone 100 mg PO daily, days 1–5
CHOP—every 21 days Cyclophosphamide 750 mg/m^2 IV, day 1 Doxorubicin 50 mg/m^2 IV, day 1 Vincristine 1.4 mg/m^2 IV, day 1 Prednisone 100 mg PO daily, days 1–5
rCHOP—every 21 days Rituximab 375 mg/m^2 IV, day 1 Cyclophosphamide 750 mg/m^2 IV, day 1 Doxorubicin 50 mg/m^2 IV, day 1 Vincristine 1.4 mg/m^2 IV, day 1 Prednisone 100 mg PO daily, days 1–5

Diffuse, Aggressive NHL

? *The mainstay of therapy for diffuse, aggressive NHL has been the administration of anthracycline-based combination chemotherapy, which generally consists of programs of four or more drugs.* Therapy options for intermediate- and high-grade NHL generally are segregated between localized (stage I/II) and disseminated (stage III/IV) disease. As mentioned previously, combined-modality therapy with CHOP and radiation is considered a standard of care for stage I/II disease.

For disseminated disease, the approach has centered on the administration of multiagent chemotherapy. The standard therapy in this disease since the 1970s has been CHOP. This regimen conferred a response of 50% to 60%, with a long-term survival of approximately 30%. However, the 1980s were notable for the development of newer combination drug programs that incorporated increasing numbers of agents with varying schedules. More complex chemotherapy regimens were shown in phase II trials to have higher response rates than CHOP. The CALGB designed a phase III randomized four-arm trial to assess the impact on survival of three more intensive regimens compared with CHOP.[29] This phase III cooperative group trial randomized 899 patients with intermediate- or high-grade (Working Formulation classification) NHL to CHOP or one of the three more intensive advanced-generation regimens just mentioned. There were no significant differences in response rate or overall survival, which was consistent among all subgroups. Severe toxicity and death were higher in the advanced-generation treatment programs relative to CHOP. This pivotal trial has cemented CHOP's position as front-line therapy in diffuse NHL.

The next hypothesis tested was whether combining monoclonal antibody therapy with chemotherapy could increase

activity against diffuse, aggressive NHL. A French study randomized patients 60 to 80 years of age with newly diagnosed diffuse, large B-cell NHL to either CHOP for eight cycles or CHOP plus rituximab for eight cycles.[30] At relatively early follow-up of 2 years, the combination arm had a superior complete response rate (76% versus 63%) and event-free survival (57% versus 38%), with comparable toxicity in each arm. Similar findings in younger patients have been reported recently, making CHOP plus rituximab first-line therapy for advanced-stage diffuse, aggressive NHL (Table 90–9). Alternative approaches that have shown promise are the inclusion of etoposide in the CHOP regimen or shortening the treatment interval from 21 days and supporting the white blood cell count with filgrastim, otherwise known as *dose-dense therapy.*[31]

There are certain histologic subtypes of diffuse, aggressive NHL that respond less well to treatment with conventional regimens such as CHOP. Burkitt's lymphoma, lymphoblastic lymphoma, mantel cell lymphoma, and primary CNS lymphoma are examples of disease that benefit from more intensive therapy. Regimens such as hyper-CVAD, which alternate cycles of hyperfractionated cyclophosphamide, doxorubicin, vincristine, and dexamethasone with high-dose cytarabine and methotrexate, often are substituted for CHOP. Intrathecal therapy with methotrexate is indicated with documented CNS infiltration of tumor or involvement of the sinuses. The recent appreciation of the etiology of *Helicobacter pylori* in the etiology of peptic ulcer disease and the association between colonization and mucosal-associated lymphoma (MALT) has spurred

TABLE 90–9. Treatment Regimens for Diffuse, Aggressive Non-Hodgkin's Lymphomas

CHOP—every 21 days
Cyclophosphamide 750 mg/m^2 IV, day 1
Doxorubicin 50 mg/m^2 IV, day 1
Vincristine 1.4 mg/m^2 IV, day 1
Prednisone 100 mg PO daily, days 1–5

rCHOP—every 21 days
Rituximab 375 mg/m^2 IV, day 1
Cyclophosphamide 750 mg/m^2 IV, day 1
Doxorubicin 50 mg/m^2 IV, day 1
Vincristine 1.4 mg/m^2 IV, day 1
Prednisone 100 mg PO daily, days 1–5

CHOP-14—every 14 days (with filgrastim support days 4–13)
Cyclophosphamide 750 mg/m^2 IV, day 1
Doxorubicin 50 mg/m^2 IV, day 1
Vincristine 1.4 mg/m^2 IV, day 1
Prednisone 100 mg PO daily, days 1–5

CHOEP-21—every 21 days
Cyclophosphamide 750 mg/m^2 IV, day 1
Doxorubicin 50 mg/m^2 IV, day 1
Vincristine 1.4 mg/m^2 IV, day 1
Etoposide 100 mg/m^2 IV daily, days 1–3
Prednisone 100 mg PO daily, days 1–5

m-BACOD—every 21 days
Methotrexate 200 mg/m^2 IV, days 8, 15
Bleomycin 4 mg/m^2 IV, day 1
Doxorubicin 45 mg/m^2, day 1
Cyclophosphamide 600 mg/m^2 IV, day 1
Vincristine 1.4 mg/m^2 IV, day 1
Dexamethasone 6 mg PO daily, days 1–5
Leucovorin 10 mg PO q6hours, 24 hours following methotrexate × 8 doses

ProMACE-CytaBOM—every 28 days
Prednisone 60 mg PO daily, days 1–14
Doxorubicin 25 mg/m^2 IV, day 1
Cyclophosphamide 650 mg/m^2 IV, day 1
Etoposide 120 mg/m^2 IV, day 1
Cytarabine 300 mg/m^2 IV, day 8
Bleomycin 5 units IV, day 8
Vincristine 1.4 mg/m^2 IV, day 8
Methotrexate 120 mg/m^2, day 8
Leucovorin 25 mg/m^2 IV q6hours, 24 hours following methotrexate × 5 doses

MACOP-B
Methotrexate 400 mg/m^2 IV, day 8
Doxorubicin 50 mg/m^2 IV, days 1, 15
Cyclophosphamide 350 mg/m^2 IV, days 1, 15
Vincristine 1.4 mg/m^2 IV, days 8, 15
Prednisone 75 mg PO daily, × 12 weeks
Bleomycin 10 units IV, day 28
Leucovorin 15 mg PO q6hours, 24 hours following methotrexate × 6 doses

Hyper-CVAD
Cyclophosphamide 300 mg/m^2 IV q12hours, days 1–3 (with mesna)
Doxorubicin 50 mg/m^2 IV, day 1
Vincristine 1.4 mg/m^2 IV, days 1, 11
Dexamethasone 40 mg PO qday, days 1–4, 11–14
Methotrexate 15 mg intrathecal, day 2

Cytarabine 30 mg intrathecal, day 2
Hydrocortisone 15 mg intrathecal, day 2
Above drugs given on courses 1, 3, 5, 7
Methotrexate 1000 mg/m^2 IV over 24 hours, day 1
Cytarabine 3000 mg/m^2 IV q12hours, days 2, 3
Leucovorin 25 mg IV × 1, then 25 mg PO q6hours for 7 doses
Methotrexate 15 mg intrathecal, day 2
Above drugs given on courses 2, 4, 6, 8
Relapsed Disease

ESHAP
Etoposide 40 mg/m^2 IV per day continuous infusion, days 1–4
Cisplatin 25 mg/mm^2 IV per day continuous infusion, days 1–4
Cytarabine 2000 mg/m^2 IV × 1, day 5
Methylprednisone 250 mg IV q12hours, days 1–4

DHAP
Dexamethasone 40 mg PO or IV daily, days 1–4
Cisplatin 100 mg/m^2 IV continuous infusion, day 1
Cytarabine 2000 mg/m^2 IV q12hours for 2 doses, day 2

ICE
Etoposide 100 mg/m^2 IV daily, days 1–3
Carboplatin *AUC* 5 (max dose 800 mg) IV, day 2
Ifosfamide 5000 mg/m^2 IV continuous infusion × 1 on day 2 (with 100% replacement with mesna)

the more aggressive treatment of this organism with antibiotics. Generally, 7 to 14 days of combinations of either omeprazole, clarithromycin, and amoxicillin or tetracycline, metronidazole, and bismuth subsalicylate have been shown to provide rates of *H. pylori* clearance near 90%.

With over half of patients expected to relapse with disease, salvage therapy plays a major role in the attempt to cure patients with recurrence. Multiple drug programs such as ESHAP and DHAP can induce a complete response, but the long-term cure rates with these regimens are less than 10%. Further salvage therapy could induce remissions, but with each subsequent relapse, the chance for a CR and the duration of remission decreased. Therefore, the approach of high-dose chemotherapy was attempted with autologous SCT.[32] The best-studied indication for SCT is for patients with intermediate- or high-grade disease that fails to respond to conventional therapy. A 3- to 5-year survival of upwards of 40% is achieved in patients who have good performance and disease that demonstrates a significant response to one or two cycles of salvage chemotherapy. The procedure-related mortality has ranged from 5% to 10% in published reports. However, as with HL, with more broad application of peripheral blood stem cells and improved supportive care, this figure continues to decline. The role of allogeneic bone marrow transplantation (BMT) in this setting is considered investigational at this time owing to the undefined significance of a graft-versus-lymphoma effect and the high treatment-related morbidity and mortality.

Patients with HIV-related lymphoma represent a therapeutic dilemma in that many have high-grade disease of B-cell origin. A common presentation is that of extranodal disease, frequently in the GI tract, CNS, and bone marrow. Therapy for this population thus far has fared poorly, with a median survival of 6 to 12 months, which decreases to 3 months with CNS involvement.[33] It remains to be seen if improved antiretroviral therapy will have an impact on the incidence and treatment options for these patients.

The addition of rituximab to chemotherapy has an adverse effect on outcome in this patient population.

OUTCOME EVALUATION

Treatment success in lymphoma is measured in successive stages, the first being inducing tumor regression and the degree of that regression: complete response (CR) versus partial response (PR) versus stable disease (SD) versus progressive disease (PD). The RECIST criteria, a uniform criteria assessing tumor response, are considered a standard of care. Both HL and NHL may have residual masses following completion of treatment, adding to the difficulty in establishing a definitive remission from treatment. Ongoing clinical trials are evaluating the value of PET scans and gallium scans to rule out whether residual tumor masses following treatment contain viable tumor. PET scans hold the promise of a future role because the 2-fluoro-2deoxyglucose contrast material is taken up more avidly by metabolically active tumor cells relative to fibrosis.

Long-term follow-up monitors patients for continued disease remission or relapse with careful physical examination of the lymph nodes and sites of prior disease involvement and imaging studies. Patients will have routine chest x-rays and CT scans administered to screen for recurrence of disease. Patients require long-term monitoring for toxicities of their primary treatment, either chemotherapy or radiation therapy.
