Pharmacotherapy
Principles & Practice

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the editors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Pharmacotherapy Principles & Practice

Editors

Marie A. Chisholm-Burns, PharmD, FCCP, FASHP

Professor and Head
Department of Pharmacy Practice and Science
The University of Arizona College of Pharmacy
Tucson, Arizona

Barbara G. Wells, PharmD, FASHP, FCCP, BCPP

Professor and Dean
Executive Director, Research Institute of Pharmaceutical Sciences
School of Pharmacy
The University of Mississippi
University, Mississippi

Terry L. Schwinghammer, PharmD, FCCP, FASHP, BCPS

Professor and Chair
Department of Clinical Pharmacy
West Virginia University
School of Pharmacy
Morgantown, West Virginia

Patrick M. Malone, PharmD, FASHP

Professor and Assistant Dean, Internal Affairs
School of Pharmacy
University of Findlay
Findlay, Ohio

Jill M. Kolesar, PharmD, BCPS, FCCP

Associate Professor
University of Wisconsin School of Pharmacy
Faculty Supervisor
Analytical Instrumentation Laboratory
Madison, Wisconsin

John C. Rotschafer, PharmD, FCCP

Professor
Department of Experimental and Clinical Pharmacology
College of Pharmacy
University of Minnesota
Minneapolis, Minnesota

Joseph T. DiPiro, PharmD, FCCP

Professor and Executive Dean
South Carolina College of Pharmacy
University of South Carolina, Columbia
Medical University of South Carolina
Charleston, South Carolina

Contributors *ix*
Reviewers *xxi*
Preface *xxxix*

PART ONE. BASIC CONCEPTS OF PHARMACOTHERAPY PRINCIPLES AND PRACTICE **1**

1. Introduction 3
Jack E. Fincham

PART TWO. DISORDERS OF ORGAN SYSTEMS **7**

***Section 1.* Cardiovascular Disorders** **9**

2. Hypertension 9
Robert J. Straka, R. Todd Burkhardt, and David Parra

3. Heart Failure 33
Orly Vardeny and Tien M. H. Ng

4. Ischemic Heart Disease 63
Larisa H. Cavallari and Robert J. DiDomenico

5. Acute Coronary Syndromes 83
Sarah A. Spinler and Simon de Denus

6. Arrhythmias 107
James E. Tisdale

7. Venous Thromboembolism 133
Stuart T. Haines and Edith A. Nutescu

8. Stroke 161
Susan R. Winkler

9. Hyperlipidemia 175
Matthew K. Ito

10. Hypovolemic Shock 195
Bradley A. Boucher and G. Christopher Wood

***Section 2.* Respiratory Disorders** **209**

11. Asthma 209
W. Greg Leader

12. Chronic Obstructive Pulmonary Disease 231
Tara R. Whetsel and Nicole D. Verkleeren

13. Cystic Fibrosis 245
Kimberly J. Novak

***Section 3.* Gastrointestinal Disorders** **257**

14. Gastroesophageal Reflux Disease 257
Dianne B. Williams and Marie A. Chisholm-Burns

15. Peptic Ulcer Disease 269
Jeffrey J. Fong and John W. Devlin

16. Inflammatory Bowel Disease 281
Brian A. Hemstreet

17. Nausea and Vomiting 295
Sheila Wilhelm

18. Constipation, Diarrhea, and Irritable Bowel Syndrome 307
Beverly C. Mims and Clarence E. Curry, Jr.

19. Portal Hypertension and Cirrhosis 323
Laurajo Ryan

20. Pancreatitis 337
Joseph J. Kishel

21. Viral Hepatitis 345
Juliana Chan

***Section 4.* Renal Disorders** **361**

22. Acute Renal Failure 361
Mary K. Stamatakis

23. Chronic and End-Stage Renal Disease 373
Kristine S. Schonder

24. Fluids and Electrolytes 403
Mark A. Malesker and Lee E. Morrow

25. Acid-Base Disturbances 419
Lee E. Morrow and Mark A. Malesker

Section 5. Neurologic Disorders

26. Multiple Sclerosis 431
Melody Ryan

27. Epilepsy 443
Timothy E. Welty and Edward Faught

28. Status Epilepticus 461
Gretchen M. Brophy and Eljim P. Tesoro

29. Parkinson's Disease 473
Mary L. Wagner

30. Pain Management 487
Christine K. O'Neil

31. Headache 501
Leigh Ann Ross and Brendan S. Ross

Section 6. Psychiatric Disorders

32. Alzheimer's Disease 513
Gary M. Levin, Toya M. Bowles, and Megan J. Ehret

33. Substance-Related Disorders 525
Sally K. Guthrie, Kirk J. Brower, and Maher Karam-Hage

34. Schizophrenia 549
Deanna L. Kelly and Elaine Weiner

35. Major Depressive Disorder 569
Marshall Cates, Angela Ann Boggs, and Jacqueline Feldman

36. Bipolar Disorder 585
Brian L. Crabtree and Martha J. Faulkner

37. Generalized Anxiety Disorder, Panic Disorder, and Social Anxiety Disorder 605
Sheila Botts, Tawny Bettinger, and Brian Greenlee

38. Sleep Disorders 621
John M. Dopp and Bradley G. Phillips

39. Attention-Deficit Hyperactivity Disorder 633
Kevin W. Cleveland and John Erramouspe

Section 7. Endocrinologic Disorders

40. Diabetes Mellitus 643
Christopher L. Cook, John T. Johnson, and William E. Wade

41. Thyroid Disorders 667
Michael D. Katz

42. Adrenal Gland Disorders 685
Devra K. Dang, Judy T. Chen, Frank Pucino, Jr., and Karim Anton Calis

43. Pituitary Gland Disorders 701
Judy T. Chen, Devra K. Dang, Frank Pucino, Jr., and Karim Anton Calis

Section 8. Gynecologic and Obstetric Disorders

44. Pregnancy and Lactation: Therapeutic Considerations 721
Deborah Sturpe and Kari Alperovitz-Bichell

45. Contraception 737
Julie M. Koehler and Kathleen B. Haynes

46. Menstruation-Related Disorders 751
Elena M. Umland, Lara C. Weinstein, and Abby Morris

47. Hormone-Replacement Therapy in Menopause 765
Nicole S. Culhane and Melissa A. Somma

Section 9. Urologic Disorders

48. Erectile Dysfunction 779
Cara Liday and Catherine Heyneman

49. Benign Prostatic Hyperplasia 791
Mary Lee and Roohollah Sharifi

50. Urinary Incontinence and Pediatric Enuresis 803
David R.P. Guay

Section 10. Immunologic Disorders

51. Allergic and Pseudoallergic Drug Reactions 819
J. Russell May and Philip H. Smith

52. Solid-Organ Transplantation 829
Steven Gabardi and Ali J. Olyaei

Section 11. Bone and Joint Disorders 853

53. Osteoporosis 853
Beth Bryles Phillips

54. Rheumatoid Arthritis 867
Susan P. Bruce

55. Osteoarthritis 879
Benjamin J. Epstein, John G. Gums, and Karen Hall

56. Gout and Hyperuricemia 891
Geoffrey C. Wall

57. Musculoskeletal Disorders 899
Jill S. Burkiewicz

Section 12. Disorders of the Eyes, Ears, Nose, and Throat 909

58. Glaucoma 909
Mikael D. Jones

59. Allergic Rhinitis 925
Kristi N. Hofer and Michelle W. McCarthy

60. Minor Ophthalmic Disorders 935
Kendra J. Grande

Section 13. Dermatologic Disorders 949

61. Psoriasis 949
Rebecca M.T. Law

62. Common Skin Disorders 959
Angie L. Goeser

Section 14. Hematologic Disorders 975

63. Anemia 975
Edward C. Li and James M. Hoffman

64. Coagulation Disorders 987
Alma Hamidovic

65. Sickle Cell Disease 1003
Tracy M. Hagemann and Teresa V. Lewis

Section 15. Diseases of Infectious Origin 1019

66. Antimicrobial Regimen Selection 1019
Catherine M. Oliphant and Karl Madaras-Kelly

67. Central Nervous System Infections 1033
S. Diane Goodwin and Charles E. Hartis

68. Lower Respiratory Tract Infections 1049
Diane M. Cappelletty

69. Upper Respiratory Tract Infections 1061
Heather L. VandenBussche

70. Skin and Soft Tissue Infections 1075
A. Christie Graham and Randy Wesnitzer

71. Infective Endocarditis 1089
Ronda L. Akins

72. Tuberculosis 1105
Charles A. Peloquin and Rocsanna Namdar

73. Gastrointestinal Infections 1117
Elizabeth D. Hermsen and Ziba Jalali

74. Intraabdominal Infections 1129
Joseph T. DiPiro and Thomas R. Howdieshell

75. Parasitic Diseases 1139
J.V. Anandan

76. Urinary Tract Infection 1151
Brian A. Potoski

77. Sexually Transmitted Infections 1159
Marlon Honeywell and Michael Thompson

78. Osteomyelitis 1177
Melinda M. Neuhauser and Susan L. Pendland

79. Sepsis and Septic Shock 1185
S. Scott Sutton

80. Superficial Fungal Infections 1199
Lauren S. Schlesselman

81. Invasive Fungal Infections 1211
Russell E. Lewis and P. David Rogers

82. Antimicrobial Prophylaxis in Surgery 1231
Jeremy A. Schafer and John C. Rotschafer

83. Vaccines and Toxoids 1239
Marianne Billeter

84. Human Immunodeficiency Virus Infection 1253
Amanda Corbett, Rosa Yeh, Julie Dumond, and Angela D.M. Kashuba

Section 16. Oncologic Disorders *1277*

85. Cancer Chemotherapy and Treatment 1277
Dianne Brundage

86. Breast Cancer 1303
Kristine Hahn and Laura Boehnke Michaud

87. Lung Cancer 1323
Val Adams and Justin Balko

88. Colorectal Cancer 1341
Patrick J. Medina

89. Prostate Cancer 1357
Jill M. Kolesar

90. Malignant Lymphomas 1371
Chris Fausel

91. Ovarian Cancer 1385
Judith A. Smith

92. Acute Leukemias 1397
Nancy Heideman

93. Chronic Leukemias and Multiple Myeloma 1415
Amy M. Pick and Timothy R. McGuire

94. Skin Cancer 1425
Trinh Pham

95. Hematopoietic Cell Transplantation 1447
Jeannine S. McCune

96. Oncologic Emergencies 1467
Brad L. Stanford

Section 17. Nutrition and Nutritional Disorders *1493*

97. Parenteral Nutrition 1493
Michael D. Kraft and Imad F. Btaiche

98. Enteral Nutrition 1511
Sarah J. Miller

99. Overweight and Obesity 1529
Maqual R. Graham and Cameron C. Lindsey

Appendices *1541*

Appendix A: Conversion Factors and Anthropometrics 1541

Appendix B: Common Laboratory Tests 1545

Appendix C: Common Medical Abbreviations 1553

Appendix D: Glossary 1559

Index *1581*

CONTRIBUTORS

Val R. Adams, PharmD
Associate Professor
University of Kentucky
Oncology Clinical Specialist
Markey Cancer Center
Lexington, Kentucky
Chapter 87: Lung Cancer

Ronda L. Akins, PharmD
Assistant Professor–Infectious Diseases
University of Louisiana at Monroe
College of Pharmacy
Monroe, Louisiana
Chapter 71: Infective Endocarditis

Kari Alperovitz-Bichell, MD, MPH
Assistant Professor
Family Medicine
University of Maryland School of Medicine
University of Maryland Medical System
Baltimore, Maryland
Chapter 44: Pregnancy and Lactation: Therapeutic Considerations

J. V. Anandan, PharmD
Adjunct Associate Professor of Pharmacy
Eugene Applebaum College of Pharmacy and Health Sciences
Wayne State University
Pharmacy Specialist
Henry Ford Hospital
Detroit, Michigan
Chapter 75: Parasitic Diseases

Justin M. Balko, PharmD
Graduate Student
University of Kentucky
Pharmacist
UK Chandler Medical Center
Lexington, Kentucky
Chapter 87: Lung Cancer

Tawny L. Bettinger, PharmD
Assistant Professor
University of Texas at Austin
College of Pharmacy
Austin, Texas
Chapter 37: Generalized Anxiety Disorder, Panic Disorder, and Social Anxiety Disorder

Marianne Billeter, PharmD, BCPS
Clinical Pharmacy Specialist
Infectious Diseases
Ochsner Clinic Foundation
New Orleans, Louisiana
Chapter 83: Vaccines and Toxoids

Angela Ann Boggs, PharmD
Clinical Pharmacist
University of Maryland
Baltimore, Maryland
Chapter 35: Major Depressive Disorder

Sheila R. Botts, PharmD, BCPP
Assistant Professor
University of Kentucky College of Pharmacy
Clinical Pharmacy Specialist
Psychiatry
Lexington Veterans Affairs Medical Center
Lexington, Kentucky
Chapter 37: Generalized Anxiety Disorder, Panic Disorder, and Social Anxiety Disorder

Bradley A. Boucher, PharmD, FCCP, FCCM
Professor of Pharmacy
Department of Pharmacy
University of Tennessee Health Science Center
Clinical Pharmacist
Regional Medical Center at Memphis
Memphis, Tennessee
Chapter 10: Hypovolemic Shock

Toya M. Bowles, PharmD, BCPP
Senior Medical Science Manager
Organon USA
Hallandale Beach, Florida
Chapter 32: Alzheimer's Disease

Gretchen M. Brophy, PharmD, BCPS, FCCP, FCCM
Associate Professor of Pharmacy and Neurosurgery
Clinical Specialist
Neuroscience Intensive Care Unit
Virginia Commonwealth University
Medical College of Virginia Campus
Richmond, Virginia
Chapter 28: Status Epilepticus

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

Kirk J. Brower, MD
Associate Professor of Psychiatry
University of Michigan Medical School
Executive Director
Chelsea Arbor Addiction Treatment Center
Ann Arbor, Michigan
Chapter 33: Substance-Related Disorders

Susan P. Bruce, PharmD, BCPS
Associate Professor of Pharmacy Practice
Albany College of Pharmacy
Clinical Pharmacist
The Center for Rheumatology
Albany, New York
Chapter 54: Rheumatoid Arthritis

Dianne Brundage, PharmD, FCCP, BCPS, BCOP
Oncology Clinical Pharmacy Specialist
Methodist Hospital/Park Nicollet Health Services
Minneapolis, Minnesota
Chapter 85: Cancer Chemotherapy and Treatment

Imad F. Btaiche, BS, PharmD, BCNSP
Clinical Associate Professor of Pharmacy
Department of Clinical Sciences
University of Michigan College of Pharmacy
Clinical Pharmacist
University of Michigan Hospitals and Health Centers
Ann Arbor, Michigan
Chapter 97: Parenteral Nutrition

R. Todd Burkhardt, PharmD
Research Fellow
Cardiovascular Pharmacotherapy
Experimental and Clinical Pharmacology Department
University of Minnesota
Minneapolis, Minnesota
Chapter 2: Hypertension

Jill S. Burkiewicz, PharmD, BCPS
Associate Professor and Director
Primary Care Residency Program
Midwestern University Chicago College of Pharmacy
Clinical Pharmacist
Mercy Family Health Center–Chicago
Chicago, Illinois
Chapter 57: Musculoskeletal Disorders

Karim Anton Calis, PharmD, MPH, BCPS, BCNSP, FASHP, FCCP
Professor
Virginia Commonwealth University
Clinical Professor
University of Maryland and Shenandoah University
Clinical Specialist, Endocrinology and Women's Health
Director, Drug Information Service, NIH Clinical Center
National Institutes of Health
Bethesda, Maryland
Chapter 42: Adrenal Gland Disorders
Chapter 43: Pituitary Gland Disorders

Diane M. Cappelletty, PharmD
Associate Professor of Pharmacy Practice
The University of Toledo
Adjunct Assistant Professor
Department of Medicine
Medical University of Ohio
Toledo, Ohio
Chapter 68: Lower Respiratory Tract Infections

Marshall E. Cates, PharmD, BCPP, FASHP
Professor of Pharmacy Practice
Samford University McWhorter School of Pharmacy
Clinical Pharmacist
Department of Psychiatry and Behavorial Neurobiology
University of Alabama at Birmingham
Birmingham, Alabama
Chapter 35: Major Depressive Disorder

Larisa H. Cavallari, PharmD
Assistant Professor
Department of Pharmacy Practice
University of Illinois at Chicago College of Pharmacy
Chicago, Illinois
Chapter 4: Ischemic Heart Disease

Juliana Chan, PharmD
Clinical Assistant Professor
Department of Pharmacy Practice
College of Pharmacy
Department of Medicine
Sections of Digestive Diseases and Nutrition
Section of Hepatology
University of Illinois at Chicago
Chicago, Illinois
Chapter 21: Viral Hepatitis

Judy T. Chen, PharmD, BCPS
Assistant Professor of Pharmacy Practice
Purdue University
School of Pharmacy and Pharmaceutical Sciences
Pharmacotherapist
Tippecanoe Community Health Clinic
West Lafayette, Indiana
Chapter 42: Adrenal Gland Disorders
Chapter 43: Pituitary Gland Disorders

Marie A. Chisholm-Burns, PharmD, FCCP, FASHP
Professor and Head
Department of Pharmacy Practice and Science
The University of Arizona College of Pharmacy
Tucson, Arizona
Chapter 14: Gastroesophageal Reflux Disease

Kevin W. Cleveland, PharmD
Clinical Assistant Professor
College of Pharmacy
Idaho State University
Pocatello, Idaho
Chapter 39: Attention-Deficit Hyperactivity Disorder

Christopher L. Cook, PharmD, PhD
Clinical Assistant Professor
University of Georgia College of Pharmacy
Athens, Georgia
Chapter 40: Diabetes Mellitus

Amanda H. Corbett, PharmD, BCPS
Clinical Assistant Professor
School of Pharmacy
University of North Carolina
Clinical Pharmacist
University of North Carolina Health Care
Infectious Disease Clinic
Chapel Hill, North Carolina
Chapter 84: Human Immunodeficiency Virus Infection

Brian L. Crabtree, PharmD, BCPP
Associate Professor of Pharmacy Practice
Clinical Associate Professor of Psychiatry,
University of Mississippi School of Pharmacy
University of Mississippi Medical Center
School of Medicine
Psychopharmacologist
Mississippi State Hospital
Whitfield, Mississippi
Chapter 36: Bipolar Disorder

Nicole S. Culhane, PharmD, BCPS
Associate Professor
Pharmacy Practice
Wilkes University
Nesbitt College of Pharmacy and Nursing
Clinical Pharmacist Faculty
Wyoming Valley Family Practice Residency
Wilkes-Barre, Pennsylvania
Chapter 47: Hormone Replacement Therapy in Menopause

Clarence E. Curry, Jr., PharmD
Associate Professor
School of Pharmacy
CPNAHS
Howard University
Clinical Pharmacist
Ambulatory Care
Howard University Hospital Clinics
Washington, DC
Chapter 18: Constipation, Diarrhea, and Irritable Bowel Syndrome

Devra K. Dang, PharmD
Assistant Clinical Professor
University of Connecticut School of Pharmacy
Clinical Faculty
St. Francis Hospital/UCONN Primary Care Center
at Burgdorf Health Center
Instructor
Department of Medicine
University of Connecticut School of Medicine
Hartford, Connecticut
Chapter 42: Adrenal Gland Disorders
Chapter 43: Pituitary Gland Disorders

Simon de Denus, BPharm, MSc
Assistant Professor
Faculty of Pharmacy
University of Montreal Pharmacy Department
Fellow in Cardiovascular Research
Montreal Heart Institute
Montreal
Quebec, Canada
Chapter 5: Acute Coronary Syndromes

John W. Devlin, PharmD, BCPS, FCCM
Associate Professor
Northeastern University School of Pharmacy
Clinical Pharmacist
Medical Intensive Care Unit
Tufts-New England Medical Center
Boston, Massachusetts
Chapter 15: Peptic Ulcer Disease

Robert J. DiDomenico, PharmD
Clinical Associate Professor
Department of Pharmacy Practice
University of Illinois
Cardiovascular Clinical Pharmacist
University of Illinois Medical Center at Chicago
Chicago, Illinois
Chapter 4: Ischemic Heart Disease

Joseph T. DiPiro, PharmD, FCCP
Professor and Executive Dean
South Carolina College of Pharmacy
University of South Carolina
Columbia
Medical University of South Carolina
Charleston, South Carolina
Chapter 74: Intraabdominal Infections

John M. Dopp, PharmD
Assistant Professor
University of Wisconsin-Madison School of Medicine
Clinical Pharmacist
University of Wisconsin Sleep Disorders Center
Madison, Wisconsin
Chapter 38: Sleep Disorders

Julie Dumond, PharmD
University of North Carolina–Chapel Hill
School of Pharmacy
Chapel Hill, North Carolina
Chapter 84: Human Immunodeficiency Virus Infection

Megan J. Ehret, PharmD
Assistant Professor
University of Connecticut
School of Pharmacy
Storrs, Connecticut
Chapter 32: Alzheimer's Disease

Benjamin J. Epstein, PharmD, BCPS
Clinical Assistant Professor
Departments of Pharmacy Practice and Internal Medicine
Colleges of Pharmacy and Medicine
University of Florida
Gainesville, Florida
Chapter 55: Osteoarthritis

John Erramouspe, PharmD, MS
Professor
Idaho State University College of Pharmacy
Pocatello, Idaho
Chapter 39: Attention-Deficit Hyperactivity Disorder

Edward Faught, MD
Professor of Neurology
University of Alabama School of Medicine
Director
University of Alabama at Birmingham Epilepsy Center
Birmingham, Alabama
Chapter 27: Epilepsy

Martha J. Faulkner, BSN, MSW, MSN, LISW, CNP
Nurse Practitioner
University of New Mexico
Albuquerque, New Mexico
Chapter 36: Bipolar Disorder

Christopher A. Fausel, PharmD, BCOP
Adjunct Associate Professor of Medicine
Indiana University Cancer Center
Indianapolis, Indiana
Chapter 90: Malignant Lymphomas

Jacqueline Maus Feldman, MD
Patrick H. Linton Professor
University of Alabama School of Medicine
Director
Division of Public Psychiatry
Community Psychiatry Program
Birmingham, Alabama
Chapter 35: Major Depressive Disorder

Jack E. Fincham, BS, PhD
Professor of Pharmacy Practice
School of Pharmacy
University of Missouri-Kansas City
Kansas City, Missouri
Chapter 1: Introduction

Jeffrey J. Fong, PharmD
Critical Care Fellow
Northeastern University School of Pharmacy
Tufts-New England Medical Center
Boston, Massachusetts
Chapter 15: Peptic Ulcer Disease

Steven Gabardi, PharmD, BCPS
Renal Transplant Clinical Specialist
Department of Pharmacy Services
Brigham and Women's Hospital
Assistant Professor
Northeastern University
Boston, Massachusetts
Chapter 52: Solid Organ Transplantation

Angie L. Goeser, PharmD
Assistant Professor
Department of Pharmacy Practice
Creighton University School of Pharmacy and Health Professions
Omaha, Nebraska
Chapter 62: Common Skin Disorders

S. Diane Goodwin, PharmD, FCCP
Clinical Pharmacist
Rex Healthcare
Raleigh, North Carolina
Chapter 67: Central Nervous System Infections

A. Christie Graham, PharmD
Clinical Assistant Professor
University of Wyoming School of Pharmacy
Laramie, Wyoming
Chapter 70: Skin and Soft Tissue Infections

Maqual R. Graham, PharmD
Associate Professor of Pharmacy Practice
University of Missouri–Kansas City
Clinical Pharmacy Specialist
Veterans Affairs Medical Center–Kansas City
Kansas City, Missouri
Chapter 99: Overweight and Obesity

Kendra J. Grande, RPh
Consultant Pharmacist
Abelian Consulting
Stevensville, Maryland
Chapter 60: Minor Ophthalmic Disorders

Brian A. Greenlee, MD
Assistant Professor of Psychiatry
Neuropsychiatry Clinic Director
University of Kentucky
Lexington, Kentucky
Chapter 37: Generalized Anxiety Disorder, Panic Disorder, and Social Anxiety Disorder

David R. P. Guay, PharmD, FCCP
Professor
Department of Experimental and Clinical Pharmacology
College of Pharmacy
University of Minnesota
Consultant
Division of Geriatrics
HealthPartners Inc.
Minneapolis, Minnesota
Chapter 50: Urinary Incontinence and Pediatric Enuresis

John G. Gums, PharmD
Professor of Pharmacy and Medicine
Departments of Pharmacy Practice and Community Health and Family Medicine
University of Florida
Gainesville, Florida
Chapter 55: Osteoarthritis

Sally K. Guthrie, PharmD
Associate Professor of Pharmacy
College of Pharmacy and Department of Psychiatry
The University of Michigan
The University of Michigan Hospitals
Ann Arbor, Michigan
Chapter 33: Substance-Related Disorders

Tracy M. Hagemann, PharmD
Associate Professor of Pharmacy Practice
University of Oklahoma College of Pharmacy
Clinical Pediatric Specialist
Oklahoma City, Oklahoma
Chapter 65: Sickle Cell Disease

Kristine Hahn, PharmD
Postdoctoral Fellow
University of Wisconsin Comprehensive Cancer Center
Madison, Wisconsin
Chapter 86: Breast Cancer

Stuart T. Haines, PharmD, FCCP, FASHP
Professor and Vice Chair
Pharmacotherapy Specialist
University of Maryland Department of Pharmacy Practice and Science
University of Maryland Medical Center-Antithrombosis Services
Baltimore, Maryland
Chapter 7: Venous Thromboembolism

Karen L. Hall, MD
Associate Professor and Residency Program Director
Department of Community Health and Family Medicine
University of Florida
Gainesville, Florida
Chapter 55: Osteoarthritis

Alma Hamidovic, PharmD
Postdoctoral Oncology Fellow
University of Wisconsin Comprehensive Cancer Center
Madison, Wisconsin
Chapter 64: Coagulation Disorders

Charles Hartis, PharmD
Antibiotic Management/Clinical Improvement Pharmacist
Forsyth Medical Center
Winston-Salem, North Carolina
Chapter 67: Central Nervous System Infections

Kathleen B. Haynes, PharmD, BCPS
Disease Management Pharmacist
VEI/Community Health Network
Carmel, Indiana
Chapter 45: Contraception

Nancy Heideman, PharmD, BCPS
Assistant Professor of Pharmacy Practice
University of New Mexico College of Pharmacy
Albuquerque, New Mexico
Chapter 92: Acute Leukemias

Brian A. Hemstreet, PharmD, BCPS
Assistant Professor
University of Colorado School of Pharmacy
Denver, Colorado
Chapter 16: Inflammatory Bowel Disease

Elizabeth D. Hermsen, PharmD, MBA
Antimicrobial Specialist
The Nebraska Medical Center
Adjunct Assistant Professor
University of Nebraska Medical Center College of Pharmacy
Omaha, Nebraska
Chapter 73: Gastrointestinal Infections

Catherine A. Heyneman, MS, PharmD
Associate Professor of Pharmacy Practice
Idaho State University College of Pharmacy
Director of Idaho Drug Information Service
Pocatello, Idaho
Chapter 48: Erectile Dysfunction

Kristi N. Hofer, PharmD
Scientific Project Manager
ASHP Advantage
Charlottesville, Virginia
Chapter 59: Allergic Rhinitis

James M. Hoffman, PharmD, MS
Medication Outcomes Coordinator
Pharmaceutical Department
St. Jude Children's Research Hospital
Memphis, Tennessee
Chapter 63: Anemias

Marlon Honeywell, PharmD
Associate Professor of Pharmacy Practice
Florida A&M University
Clinical Pharmacist
Bond Community Health Center
Tallahassee, Florida
Chapter 77: Sexually Transmitted Infections

Thomas R. Howdieshell, MD, FACS, FCCP
Associate Professor of Surgery
Department of Surgery
University of New Mexico Health Science Center
Division of Trauma/Surgical Critical Care
Albuquerque, New Mexico
Chapter 74: Intraabdominal Infections

Matthew K. Ito, PharmD, FCCP, BCPS
Chair, Department of Pharmacy Practice
Professor of Pharmacy Practice
College of Pharmacy
Oregon State University
Portland, Oregon
Chapter 9: Hyperlipidemia

Ziba Jalali, MD
Assistant Professor
University of Nebraska Medical Center
College of Medicine
Omaha, Nebraska
Chapter 73: Gastrointestinal Infections

John T. Johnson, PharmD, CDE
Clinical Associate Professor
University of Georgia College of Pharmacy
Athens Primary Care
Mercy Health Center
Athens, Georgia
Chapter 40 : Diabetes Mellitus

Mikael D. Jones, PharmD, BCPS
Assistant Professor
College of Pharmacy and Nursing
University of Kentucky
Lexington, Kentucky
Chapter 58: Glaucoma

Maher Karam-Hage, MD
Assistant Professor, Addiction Psychiatrist
Medical Director Tobacco Treatment Program (TTP)
University of Texas
MD Anderson Cancer Center
Houston, Texas
Chapter 33: Substance-Related Disorders

Angela D. M. Kashuba, BScPharm, PharmD, DABCP
Associate Professor
School of Pharmacy
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina
Chapter 84: Human Immunodeficiency Virus Infection

Michael D. Katz, PharmD
Associate Professor and Coordinator, International Education
University of Arizona College of Pharmacy
Department of Pharmacy Practice and Science
Tucson, Arizona
Chapter 41: Thyroid Disorders

Deanna L. Kelly, PharmD, BCPP
Associate Professor
University of Maryland
Maryland Psychiatric Research Center
Baltimore, Maryland
Chapter 34: Schizophrenia

Joseph J. Kishel, Jr., PharmD, BCPS
Adjunct Instructor of Pharmacology
Penn State College of Medicine
Clinical Pharmacy Specialist–Infectious Diseases
M.S. Hershey Medical Center
Hershey, Pennsylvania
Chapter 20: Pancreatitis

Julie M. Koehler, PharmD
Associate Professor and Chair of Pharmacy Practice
Butler University College of Pharmacy and Health Sciences
Clinical Pharmacist
Family Medicine
Clarian Health Partner and the Indiana University-Methodist
Family Residency Program
Indiana University School of Medicine
Indianapolis, Indiana
Chapter 45: Contraception

Jill M. Kolesar, PharmD, BCPS, FCCP
Associate Professor
School of Pharmacy
University of Wisconsin
Madison, Wisconsin
Chapter 89: Prostate Cancer

Michael D. Kraft, PharmD
Clinial Assistant Professor
University of Michigan College of Pharmacy
Clincial Coordinator and Clinical Pharmacist-Surgery/Nutrition Support
University of Michigan Health System
Ann Arbor, Michigan
Chapter 97: Parenteral Nutrition

Rebecca M. T. Law, BScPharm, PharmD
Associate Professor
School of Pharmacy
Memorial University of Newfoundland
Newfoundland, Canada
Chapter 61: Psoriasis

Cara Lawless-Liday, PharmD
Associate Professor
Idaho State University
Intermountain Medical Clinic
Pocatello, Idaho
Chapter 48: Erectile Dysfunction

W. Greg Leader, PharmD
Associate Dean
Academic Affairs
University of Louisiana Monroe
College of Pharmacy
Monroe, Louisiana
Chapter 11: Asthma

Mary Lee, PharmD, BCPS, FCCP
Dean and Professor
Midwestern University Chicago College of Pharmacy
Chicago, Illinois
Chapter 49: Benign Prostatic Hyperplasia

Gary M. Levin, PharmD, BCPP, FCCP
Dean and Professor
LECOM-Bradenton
School of Pharmacy
Bradenton, Florida
Chapter 32: Alzheimer's Disease

Russell E. Lewis, PharmD
Associate Professor
University of Houston College of Pharmacy
Clinical Pharmacy Specialist
Infectious Diseases
Department of Infectious Diseases
The University of Texas M.D. Anderson Cancer Center
Houston, Texas
Chapter 81: Invasive Fungal Infections

Teresa V. Lewis, PharmD
Pediatric Pharmacotherapy Fellow
University of Oklahoma College of Pharmacy
Oklahoma City, Oklahoma
Chapter 65: Sickle Cell Disease

Edward C. Li, PharmD
Assistant Professor
Wilkes University
Nesbitt College of Pharmacy and Nursing
Wilkes-Barre, Pennsylvania
Chapter 63: Anemias

Cameron C. Lindsey, PharmD, BC-ADM
Associate Professor of Pharmacy Practice
University of Missouri–Kansas City School of Pharmacy
Clinical Pharmacy Specialist
Veterans Affairs Medical Center–Kansas City
Kansas City, Missouri
Chapter 99: Overweight and Obesity

Karl Madaras-Kelly, PharmD, MPH
Associate Professor
College of Pharmacy
Idaho State University
Boise, Idaho
Chapter 66: Antimicrobial Regimen Selection

Mark A. Malesker, PharmD, FCCP
Associate Professor of Pharmacy Practice and Medicine
Clinical Pharmacy Specialist
Creighton University Medical Center
Omaha, Nebraska
Chapter 24: Fluids and Electrolytes
Chapter 25: Acid-Base Disturbances

J. Russell May, PharmD, FASHP
Clinical Professor
University of Georgia College of Pharmacy
Clinical Pharmacist
Medical College of Georgia Health System
Augusta, Georgia
Chapter 51: Allergic and Pseudoallergic Drug Reactions

Michelle W. McCarthy, PharmD
Drug Information Specialist
University of Virginia Health System
Charlottesville, Virginia
Chapter 59: Allergic Rhinitis

Jeannine S. McCune, PharmD
Associate Professor
University of Washington
Affiliate Investigator
Fred Hutchinson Cancer Research Center
Seattle, Washington
Chapter 95: Hematopoietic Cell Transplantation

Timothy R. McGuire, BS, PharmD, FCCP
Associate Professor
Pharmacy Practice
University of Nebraska Medical Center
College of Pharmacy
Omaha, Nebraska
Chapter 93: Chronic Leukemias and Multiple Myeloma

Patrick J. Medina, PharmD, BCOP
Associate Professor
University of Oklahoma College of Pharmacy
Oklahoma City, Oklahoma
Chapter 88: Colorectal Cancer

Laura Boehnke Michaud, PharmD
Clinical Pharmacy Specialist
The University of Texas M.D. Anderson Cancer Center
Houston, Texas
Chapter 86: Breast Cancer

Sarah J. Miller, PharmD, BCNSP
Professor, Pharmacy Practice
University of Montana Skaggs School of Pharmacy
Pharmacy Clinical Coordinator
Saint Patrick Hospital
Missoula, Montana
Chapter 98: Enteral Nutrition

Beverly Mims, PharmD
Associate Professor of Pharmacy Practice
Howard University School of Pharmacy
Clinical Pharmacist
Howard University Hospital
Washington, DC
Chapter 18: Constipation, Diarrhea, and Irritable Bowel Syndrome

Abby Morris, MD
Family Medicine Resident
Thomas Jefferson University Hospital
Philadelphia, Pennsylvania
Chapter 46: Menstruation-Related Disorders

Lee E. Morrow, MD, MS
Assistant Professor of Medicine
Creighton University Medical Center
Omaha, Nebraska
Chapter 24: Fluids and Electrolytes
Chapter 25: Acid-Base Disturbances

Rocsanna Namdar, PharmD
Assistant Professor
University of New Mexico
College of Pharmacy
Albuquerque, New Mexico
Chapter 72: Tuberculosis

Melinda Margaret Neuhauser, PharmD
Clinical Pharmacy Specialist
Infectious Diseases
U.S. Department of Veterans Affairs
Pharmacy Benefits Management Strategic Health Care Group
Hines, Illinois
Chapter 78: Osteomyelitis

Tien M. H. Ng, PharmD, BCPS
Assistant Professor of Clinical Pharmacy and Pharmaceutical Economics and Policy
Department of Pharmacy
University of Southern California
Los Angeles, California
Chapter 3: Heart Failure

Kimberly J. Novak, PharmD
Adjunct Clinical Assistant Professor
The Ohio State University College of Pharmacy
Clinical Pharmacy Specialist/Pediatric
Pulmonary Medicine
Children's Hospital
Columbus, Ohio
Adjunct Assistant Professor
West Virginia University School of Pharmacy
Morgantown, West Virginia
Chapter 13: Cystic Fibrosis

Edith A. Nutescu, PharmD
Clinical Associate Professor
Department of Pharmacy Practice
Director
Antithrombosis Center
University of Illinois at Chicago College of Pharmacy
Chicago, Illinois
Chapter 7: Venous Thromboembolism

Catherine M. Oliphant, PharmD
Associate Professor of Pharmacy Practice
Idaho State University College of Pharmacy
Clinical Pharmacist
St. Luke's Internal Medicine
Boise, Idaho
Chapter 66: Antimicrobial Regimen Selection

Ali J. Olyaei, PharmD, BCPS
Associate Professor
Nephrology and Hypertension
Oregon Health and Sciences University
Clinical Pharamcotherapist
University Hospital
Portland, Oregon
Chapter 52: Solid Organ Transplantation

Christine K. O'Neil, PharmD, BCPS, CGP, FCCP
Associate Professor
Duquesne University
Mylan School of Pharmacy
Director
Center for Pharmacy Care
Pittsburgh, Pennsylvania
Chapter 30: Pain Management

David Parra, PharmD, BCPS
Clinical Pharmacy Specialist in Cardiology
Department of Cardiology
Veterans Affairs Medical Center
Clinical Assistant Professor
Experimental and Clinical Pharmacology Department
University of Minnesota
Minneapolis, Minnesota
Chapter 2: Hypertension

Charles A. Peloquin, PharmD
Clinical Professor of Pharmacy and Medicine
University of Colorado
Director
Infectious Disease Pharmacokinetics Laboratory
National Jewish Medical and Research Center
Denver, Colorado
Chapter 72: Tuberculosis

Susan L. Pendland, MS, PharmD
Adjunct Associate Professor of Pharmacy Practice
University of Illinois at Chicago
Chicago, Illinois
Chapter 78: Osteomyelitis

Trinh Pham, PharmD, BCOP
Assistant Clinical Professor
University of Connecticut, School of Pharmacy
Assistant Clinical Professor
Yale New Haven Hospital
New Haven, Connecticut
Chapter 94: Skin Cancer

Beth Bryles Phillips, PharmD, BCPS
Assistant Professor (Clinical)
University of Iowa College of Pharmacy
Clinical Pharmacy Specialist
Ambulatory Care
University of Iowa Hospitals and Clinics
Iowa City, Iowa
Chapter 53: Osteoporosis

Bradley G. Phillips, PharmD
Associate Professor
University of Iowa
College of Pharmacy
Iowa City, Iowa
Chapter 38: Sleep Disorders

Amy M. Pick, PharmD
Assistant Professor of Pharmacy Practice
Creighton University
Oncology Clinical Pharmacist
Nebraska Methodist Hospital
Omaha, Nebraska
Chapter 93: Chronic Leukemias and Multiple Myeloma

Brian A. Potoski, PharmD
Assistant Professor
Department of Pharmacy and Therapeutics
University of Pittsburgh School of Pharmacy
Clinical Specialist
Antibiotic Management Program
University of Pittsburgh Medical Center
Presbyterian University Hospital
Pittsburgh, Pennsylvania
Chapter 76: Urinary Tract Infection

Frank Pucino, Jr., PharmD, BCPS, FASHP, FDPGEC
Ambulatory Care Clinical Pharmacy Team Leader
National Institutes of Health Clinical Center
Bethesda, Maryland
Chapter 42: Adrenal Gland Disorders
Chapter 43: Pituitary Gland Disorders

Phillip David Rogers, PharmD, PhD, FCCP
First Tennessee Chair of Excellence in Pediatric Clinical Pharmacy
Associate Professor and Vice Chair for Research
Department of Clinical Pharmacy
Associate Professor, Departments of Pharmaceutical Sciences, Molecular Sciences, and Pediatrics
University of Tennessee Health Science Center
Memphis, Tennessee
Chapter 81: Invasive Fungal Infections

Leigh Ann Ross, PharmD, BCPS, CDE
Assistant Professor
University of Mississippi School of Pharmacy
Director
Pharmaceutical Care Services
University of Mississippi Medical Center
Jackson, Mississippi
Chapter 31: Headache

Brendan S. Ross, MD
Assistant Professor
University of Mississippi School of Pharmacy
Staff Physician
G. V. (Sonny) Montgomery Veterans Affairs Medical Center
Jackson, Mississippi
Chapter 31: Headache

John C. Rotschafer, PharmD, FCCP
Professor
Department of Experimental and Clinical Pharmacology
College of Pharmacy
University of Minnesota
Minneapolis, Minnesota
Chapter 82: Antimicrobial Prophylaxis in Surgery

Laurajo Ryan, PharmD, BCPS, CDE
Clinical Assistant Professor
University of Texas at Austin
University of Texas Health Science Center San Antonio
San Antonio, Texas
Chapter 19: Portal Hypertension and Cirrhosis

Melody Ryan, PharmD
Associate Professor
University of Kentucky College of Pharmacy
Clinical Specialist in Neurology
Veterans Affairs Medical Center
Lexington, Kentucky
Chapter 26: Multiple Sclerosis

Jeremy A. Schafer, PharmD
Senior Clinical Pharmacist
Prime Therapeutics
Eagan, Minnesota
Chapter 82: Antimicrobial Prophylaxis in Surgery

Lauren S. Schlesselman, PharmD
Assistant Clinical Professor
University of Connecticut School of Pharmacy
Department of Pharmacy Practice
Storrs, Connecticut
Chapter 80: Superficial Fungal Infections

Kristine S. Schonder, PharmD
Assistant Professor
University of Pittsburgh School of Pharmacy
Clinical Specialist
Thomas E. Starzl Transplantation Institute
Pittsburgh, Pennsylvania
Chapter 23: Chronic and End-Stage Renal Disease

Roohollah Sharifi, MD, FACS
Professor of Urology
University of Illinois at Chicago
College of Medicine
Section Chief of Urology
Westside Veterans Administration Hospital
Chicago, Illinois
Chapter 49: Benign Prostatic Hyperplasia

Judith A. Smith, PharmD, BCOP
Assistant Professor
University of Texas M.D. Anderson Cancer Center
Houston, Texas
Chapter 91: Ovarian Cancer

Philip H. Smith, MD, FAAAAI, FACAAI
Assistant Professor of Medicine
Allergy and Immunology
Medical College of Georgia
Assistant Professor
Medical College of Georgia
Childrens' Medical Center
Augusta, Georgia
Chapter 51: Allergic and Pseudoallergic Drug Reactions

Melissa A. Somma, PharmD, CDE
Assistant Professor of Pharmacy and Family Medicine
University of Pittsburgh Schools of Pharmacy and Medicine
Director
University of Pittsburgh/Rite Aid Patient Care Initiative
Rite Aid Corporation
Pittsburgh, Pennsylvania
Chapter 47: Hormone Replacement Therapy in Menopause

Sarah A. Spinler, PharmD, FCCP
Professor of Clinical Pharmacy
Residency and Fellowship Program Coordinator
Philadelphia College of Pharmacy
University of the Sciences in Philadelphia
Philadelphia, Pennsylvania
Chapter 5: Acute Coronary Syndromes

Mary K. Stamatakis, BS, PharmD
Associate Dean and Associate Professor
West Virginia University School of Pharmacy
Morgantown, West Virginia
Chapter 22: Acute Renal Failure

Brad L. Stanford, PharmD, BCOP
Assistant Professor of Pharmacy Practice
Texas Tech University Health Sciences Center
School of Pharmacy
Lubbock, Texas
Chapter 96: Oncologic Emergencies

Robert J. Straka, PharmD, FCCP
Associate Professor
Department of Experimental and Clinical Pharmacology
College of Pharmacy
University of Minnesota
Minneapolis, Minnesota
Chapter 2: Hypertension

Deborah Sturpe, PharmD, BCPS
Assistant Professor
University of Maryland School of Pharmacy
Baltimore, Maryland
Chapter 44: Pregnancy and Lactation: Therapeutic Considerations

S. Scott Sutton, PharmD, BCPS
Associate Clinical Professor
South Carolina College of Pharmacy
University of South Carolina
Clinical Pharmacist
WJB Dorn Veterans Affairs Medical Center
Columbia, South Carolina
Chapter 79: Sepsis and Septic Shock

Eljim P. Tesoro, PharmD
Clinical Assistant Professor
University of Illinois at Chicago
Pharmacotherapist
Department of Neurosurgery
University of Illinois at Chicago Medical Center
Chicago, Illinois
Chapter 28: Status Epilepticus

Michael D. Thompson, PharmD, BCNSP
Assistant Dean for Clinical Affairs and Professor
Florida A&M University
Residency Coordinator and Clinical Pharmacy Director
American Home Patient
Tallahassee, Florida
Chapter 77: Sexually Transmitted Infections

James E. Tisdale, PharmD
Professor
School of Pharmacy and Pharmaceutical Sciences
Purdue University
Adjunct Professor
School of Medicine
Indiana University
Indianapolis, Indiana
Chapter 6: Arrhythmias

Elena M. Umland, BS, PharmD
Associate Dean for Academic Affairs
Associate Professor of Clinical Pharmacy
Jefferson School of Pharmacy
Jefferson College of Health Professions
Thomas Jefferson University
Philadelphia, Pennsylvania
Chapter 46: Menstruation-Related Disorders

Heather L. VandenBussche, PharmD
Associate Professor of Pharmacy Practice
Ferris State University College of Pharmacy
Kalamazoo, Michigan
Chapter 69: Upper Respiratory Tract Infections

Orly Vardeny, PharmD
Assistant Professor
Pharmacy Practice Division
University of Wisconsin–Madison
School of Pharmacy
Madison, Wisconsin
Chapter 3: Heart Failure

Nicole D. Verkleeren, PharmD
Adjunct Clinical Professor
West Virginia University School of Pharmacy
Pharmacy Practice Resident
West Virginia University Hospitals
Morgantown, West Virginia
Clinical Pharmacist
The Western Pennsylvania Hospital
Forbes Regional Campus
Monroeville, Pennsylvania
Chapter 12: Chronic Obstructive Pulmonary Disease

William E. Wade, PharmD
Professor and Associate Head
College of Pharmacy
University of Georgia
Clinical Pharmacist
Saint Mary's Health Care Systems
Athens, Georgia
Chapter 40: Diabetes Mellitus

Mary Louise Wagner, MS, PharmD
Associate Professor
Ernest Mario School of Pharmacy
Rutgers–State University of New Jersey
Piscataway, New Jersey
Chapter 29: Parkinson's Disease

Geoffrey C. Wall, PharmD, BCPS
Associate Professor of Pharmacy Practice
Drake University
College of Pharmacy and Health Sciences
Internal Medicine Clinical Pharmacist
Iowa Methodist Medical Center
Des Moines, Iowa
Chapter 56: Gout and Hyperuricemia

Elaine Weiner, MD
Assistant Professor
University of Maryland Medical School
Medical Director
Maryland Psychiatric Research Center
Outpatient Research Program
Catonsville, Maryland
Chapter 34: Schizophrenia

Lara Carson Weinstein, MD
Instructor
Department of Family and Community Medicine
Jefferson Medical College
Thomas Jefferson University
Jefferson Family Medicine
Philadelphia, Pennsylvania
Chapter 46: Menstruation-Related Disorders

Timothy E. Welty, PSPharm, MA, PharmD
Professor
McWhorter School of Pharmacy
Samford University
Adjunct Associate Research Professor
Department of Neurology
University of Alabama Birmingham
Birmingham, Alabama
Chapter 27: Epilepsy

Randy Wesnitzer, BS Pharm, PharmD
Clinical Coordinator
Wyoming Medical Center
Department of Pharmacy
Casper, Wyoming
Chapter 70: Skin and Soft Tissue Infections

Tara Whetsel, PharmD
Clinical Assistant Professor
West Virginia University School of Pharmacy
Morgantown, West Virginia
Chapter 12: Chronic Obstructive Pulmonary Disease

Sheila Wilhelm, PharmD
Assistant Professor
Wayne State University
Clinical Pharmacy Specialist
Internal Medicine
Harper University Hospital
Detroit, Michigan
Chapter 17: Nausea and Vomiting

Dianne B. Williams, PharmD, BCPS
Clinical Assistant Professor
University of Georgia College of Pharmacy
Drug Information and Formulary Coordinator
MCG Health, Inc.
Augusta, Georgia
Chapter 14: Gastroesophageal Reflux Disease

Susan R. Winkler, PharmD, BCPS
Clinical Associate Professor
Pharmacy Practice
Assistant Director
Ambulatory Clinical Services
Department of Pharmacy Practice
University of Illinois at Chicago College of Pharmacy
Chicago, Illinois
Chapter 8: Stroke

G. Christopher Wood, PharmD
Associate Professor of Pharmacy
University of Tennessee Health Science Center
Clinical Pharmacist
Regional Medical Center at Memphis
Memphis, Tennessee
Chapter 10: Hypovolemic Shock

Rosa F. Yeh, PharmD
Assistant Professor
University of Houston College of Pharmacy
Houston, Texas
Chapter 84: Human Immunodeficiency Virus Infection

Reviewers

Beth Alexander, PharmD, BCPS
Associate Professor of Physician Assistant Studies
Augsburg College
Minneapolis, Minnesota

Rita Alloway, PharmD, BCPS
Research Professor

Victor A. Padron, RPh, PhD
Associate Professor
Department of Pharmacy Sciences
Creighton University
Omaha, Nebraska

Amy Pakyz, PharmD, MS
Assistant Professor
Virginia Commonwealth University School
of Pharmacy/Medical College of Virginia Campus
Richmond, Virginia

Cynthia Pentz, EdD, PA-C
Director
Physician Assistant Program
University of Findlay
Findlay, Ohio

Todd Pillen, PA-C/SA, MPAS
Manager
Solid Organ Transplant
Children's Healthcare of Atlanta-Egleston
and Emory University Hospital
Atlanta, Georgia

Therese I. Poirier, PharmD, MPH, BCPS, FASHP, FCCP
Professor and Associate Dean
Academic Affairs
Southern Illinois University-Edwardsville
Edwardsville, IIllinois

Jane Pruemer, PharmD, BCOP, FASHP
Associate Professor of Clinical Pharmacy Practice
University of Cincinnati College of Pharmacy
Cincinnati, Ohio

Edward W. Randell, PhD, DCC, FCACB
Chief
Division of Biochemical Pathology Health Sciences Centre
Associate Professor
Laboratory Medicine
Faculty of Medicine
Memorial University of Newfoundland
St. John's, Newfoundland, Canada

Mette Rasmussen, PhD
Professor
Faculty of Pharmaceutical Sciences
Department of Pharmacology and Pharmacotherapy
Section of Clinical pharmacy
University of Copenhagen
Copenhagen, Denmark

Michael D. Reed, PharmD, FCCP, FCP
Director
Pediatric Clinical Pharmacology and Toxicology
Rainbow Babies and Children's Hospital and Professor of Pediatrics
School of Medicine
Case Western Reserve University
Cleveland, Ohio

Kathleen Reeve, DrPH, AOCN, ANP
Associate Professor of Clinical Nursing
The University of Texas Health Science Center at Houston
Houston, Texas

Suzanne Reich, PA-C, MPAS
Assistant Professor
Department of Physician Assistant Studies
Wake Forest University School of Medicine
Winston-Salem, North Carolina

Warren Richards, BSPharm, MBA, PhD
Associate Professor
Lloyd L. Gregory School of Pharmacy
Palm Beach Atlantic University School of Pharmacy
West Palm Beach, Florida

Keith A. Rodvold, PharmD
Professor of Pharmacy Practice & Associate Professor
of Medicine in Pharmacy
University of Illinois at Chicago
Chicago, Illinois

Carol J. Rollins, MS, RD, PharmD, BCNSP
Program Director: Nutrition Support Pharmacy Practice
Arizona Health Sciences Center
Clinical Associate Professor
College of Pharmacy
University of Arizona
Tucson, Arizona

Wendella Rose-Facey, APRN, CCRN, FNP, MSN
Adjunct Professor
Adelphi University
Critical Care Specialist at Kingsbrook Jewish Medical Center
Brooklyn, New York

Elaine Rosenblatt, MSN, APRN, BC
Clinical Professor
University of Wisconsin
Director of Health Services and Quality Improvement
University of Wisconsin Medical Foundation
Madison, Wisconsin

Polly Royal, MS, RN-BC
Clinical Assistant Professor
Purdue University School of Nursing
West Lafayette, Indiana

Michael Rybak, PharmD, MPH
Associate Dean for Research & Professor of Pharmacy and Medicine
Director of Anti-Infective Research Laboratory
Wayne State University College of Pharmacy & Health Sciences
Detroit, Michigan

Kiranpal S. Sangha, PharmD
Clinical Pharmacy Specialist-CNS
The University Hospital
Cincinnati, Ohio
Adjunct Assistant Professor of Clinical Pharmacy
The University of Cincinnati College of Pharmacy
Cincinnati, Ohio

JoAnne M. Saxe, RN, MS, ANP
Clinical Professor & Director of the Adult Nurse
Practitioner Program
University of California
San Francisco School of Nursing
San Francisco, California

Dana Sayre-Stanhope, EdD, PA-C
Associate Professor
Saint Louis University
Doisy College of Health Sciences
St. Louis, Missouri

Sarah L. Scarpace, PharmD, BCOP
Assistant Professor
Albany College of Pharmacy
Albany, New York

Denise Schentrup, MN, ARNP, BC
Clinical Assistant Professor
University of Florida
College of Nursing
Gainesville, Florida

Karin Schurrer-Erickson, MA, RN, CNP
Teaching Specialist
University of Minnesota School of Nursing
Minneapolis, Minnesota

Catherine Shull, PA-C, MPAS
Instructor
Department of Physician Assistant Studies
Wake Forest University School of Medicine
Winston-Salem, North Carolina

Susan M. Stein, MS, RPh
Assistant Dean for Clinical Education and Student Development
Pacific University School of Pharmacy
Hillsboro, Oregon

Henry Stoll, PA-C
Senior Lecturer
University of Washington School of Medicine
Seattle, Washington

Marc A. Sweeney, RPh, MDiv, PharmD
Chair & Associate Professor
Pharmacy Practice
The University of Findlay School of Pharmacy
Findlay, Ohio

Mohammad J. Tafreshi, PharmD, BCPS
Associate Professor
Midwestern University College of Pharmacy-Glendale
Glendale, Arizona

Brenda J. J. Talarico, MPAS, PA-C
Assistant Professor
Department of Physician Assistant Studies
Augsburg College
Minneapolis, Minnesota

Candace Smith, PharmD
Associate Clnical Professor
St. John's University College of Pharmacy
& Allied Health Professions
Jamaica, New York

Christopher J. Sullivan, MD, FACP
Adjunct Professor of Pharmacy
University of Minnesota
Birchwood Village, Minnesota

Damary Castanheira Torres, PharmD, BCOP
Associate Clinical Professor
St. John's University College of Pharmacy
& Allied Health Professions
Jamaica, New York

Mary Fran Tracy, PhD, RN, CCRN, CCNS, FAAN
Critical Care Clinical Nurse Specialist
University of Minnesota Medical Center
Fairview
Minneapolis, Minnesota

Marianne Vail, MS, PA-C
Department of Physician Assistant Studies
Massachusetts College of Pharmacy & Health Sciences
Boston, Massachusetts

Lee Vermeulen, RPh, MS, FCCP
Director
Center for Drug Policy
University of Wisconsin Hospital and Clinics
Madison, Wisconsin

Angie Veverka, BS, PharmD
Assistant Professor of Pharmacy
Wingate University School of Pharmacy
Wingate, North Carolina

Heather Vezina, PharmD
Assistant Professor
University of Minnesota School of Medicine & College of Pharmacy
Minneapolis, Minnesota

Vicki Waters, MS, PA-C
Assistant Director for Experiential Learning
Physician Assistant Program
School of Allied Health Sciences
Baylor College of Medicine
Houston, Texas

Christine Werner, PA-C, PhD
Assistant Professor
Saint Louis University
Doisy College of Health Sciences
St. Louis, Missouri

Thomas White, JD, PA-C
Academic Coordinator
Physician Assistant Program
University of New Mexico School of Medicine
Albuquerque, New Mexico

Siu-Fun Wong, PharmD, FASHP, FCSHP
Associate Professor of Pharmacy Practice
Western University of Health Sciences
Faculty-in-Residence
Hematology-Oncology Medical Group of Orange County, Inc.
Pomona, California

Daniel Wood, MPAS, PA-C
Clinical Assistant Professor
University of Texas Health Science Center at San Antonio
San Antonio, Texas

Kathleen Woodruff, MS, CRNP
Instructor
The Johns Hopkins University School of Nursing
Baltimore, Maryland

Monty Yoder, PharmD, BCPS
Pharmaceutical Care Coordinator
Wake Forest University Baptist Medical Center
Winston-Salem, North Carolina

Dawn Zwick, MSN, CRNP
Lecturer
College of Nursing
Kent State University
Kent, Ohio

Continuing Education Credits

Chap. 1 – Introduction

Chap. 2 – Hypertension
Universal Program Number:
014-999-07-014-H04
Three (3.0) contact hours (0.30 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 3 – Heart Failure
Universal Program Number:
014-999-07-015-H04
Four (4.0) contact hours (0.40 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 4 – Ischemic Heart Disease
Universal Program Number:
014-999-07-016-H06
Three (3.0) contact hours (0.30 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 5 – Acute Coronary Syndromes
Universal Program Number:
014-999-07-017-H04
Two and half (2.5) contact hours (0.25 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 6 – Arrhythmias
Universal Program Number:
014-999-07-018-H04
Three and half (3.5) contact hours (0.35 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 7 – Venous Thromboembolism
Universal Program Number:
014-999-07-019-H04
Three and half (3.5) contact hours (0.35 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 8 – Stroke
Universal Program Number:
014-999-07-020-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 9 – Hyperlipidemia
Universal Program Number:
014-999-07-021-H04
Two and half (2.5) contact hours (0.25 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 10 – Hypovolemic Shock
Universal Program Number:
014-999-07-022-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 11 – Asthma
Universal Program Number:
014-999-07-025-H04
Three (3.0) contact hours (0.30 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 12 – Chronic Obstructive Pulmonary Disease
Universal Program Number:
014-999-07-026-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 13 – Cystic Fibrosis
Universal Program Number:
014-999-07-027-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 14 – Gastroesophageal Reflux Disease
Universal Program Number:
014-999-07-028-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 15 – Peptic Ulcer Disease
Universal Program Number:
014-999-07-029-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 16 – Inflammatory Bowel Disease
Universal Program Number:
014-999-07-030-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 17 – Nausea and Vomiting
Universal Program Number:
014-999-07-031-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 18 – Constipation, Diarrhea, and Irritable Bowel Syndrome
Universal Program Number:
014-999-07-032-H04
Two and half (2.5) contact hours (0.25 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 19 – Portal Hypertension and Cirrhosis
Universal Program Number:
014-999-07-033-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 20 – Pancreatitis
Universal Program Number:
014-999-07-034-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 21 – Viral Hepatitis
Universal Program Number:
014-999-07-035-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 22 – Acute Renal Failure
Universal Program Number:
014-999-07-036-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 23 – Chronic and End-Stage Renal Disease
Universal Program Number:
014-999-07-037-H04
Four (4.0) contact hours (0.40 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 24 – Fluids and Electrolytes
Universal Program Number:
014-999-07-038-H01
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 25 – Acid-Base Disturbances
Universal Program Number:
014-999-07-039-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 26 – Multiple Sclerosis
Universal Program Number:
014-999-07-040-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 27 – Epilepsy
Universal Program Number:
014-999-07-041-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 28 – Status Epilepticus
Universal Program Number:
014-999-07-042-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 29 – Parkinson's Disease
Universal Program Number:
014-999-07-043-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 30 – Pain Management
Universal Program Number:
014-999-07-044-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 31 – Headache
Universal Program Number:
014-999-07-047-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 32 – Alzheimer's Disease
Universal Program Number:
014-999-07-048-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 33 – Substance-Related Disorders
Universal Program Number:
014-999-07-049-H04
Three (3.0) contact hours (0.30 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 34 – Schizophrenia
Universal Program Number:
014-999-07-050-H04
Two and half (2.5) contact hours (0.25 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 35 – Major Depressive Disorder
Universal Program Number:
014-999-07-051-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 36 – Bipolar Disorder
Universal Program Number:
014-999-07-052-H04
Two and half (2.5) contact hours (0.25 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 37 – Generalized Anxiety Disorder, Panic Disorder, and Social Anxiety Disorder
Universal Program Number:
014-999-07-053-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 38 – Sleep Disorders
Universal Program Number:
014-999-07-054-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 39 – Attention-Deficit Hyperactivity Disorder
Universal Program Number:
014-999-07-055-H04
Half (0.5) contact hours (0.05 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 40 – Diabetes Mellitus
Universal Program Number:
014-999-07-056-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 41 – Thyroid Disorders
Universal Program Number:
014-999-07-057-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 42 – Adrenal Gland Disorders
Universal Program Number:
014-999-07-058-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 43 – Pituitary Gland Disorder
Universal Program Number:
014-999-07-123-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 44 – Pregnancy and Lactation: Therapeutic Considerations
Universal Program Number:
014-999-07-059-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 45 – Contraception
Universal Program Number:
014-999-07-060-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 46 – Menstruation-Related Disorders
Universal Program Number:
014-999-07-061-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 47 – Hormone-Replacement Therapy in Menopause
Universal Program Number:
014-999-07-062-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 48 – Erectile Dysfunction
Universal Program Number:
014-999-07-063-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 49 – Benign Prostatic Hyperplasia
Universal Program Number:
014-999-07-064-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 50 – Urinary Incontinence and Pediatric Enuresis
Universal Program Number:
014-999-07-065-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 51 – Allergic and Pseudoallergic Drug Reactions
Universal Program Number:
014-999-07-066-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 52 – Solid-Organ Transplantation
Universal Program Number:
014-999-07-067-H04
Two and half (2.5) contact hours (0.25 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 53 – Osteoporosis
Universal Program Number:
014-999-07-068-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 54 – Rheumatoid Arthritis
Universal Program Number:
014-999-07-069-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 55 – Osteoarthritis
Universal Program Number:
014-999-07-070-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 56 – Gout and Hyperuricemia
Universal Program Number:
014-999-07-071-H04
Half (0.5) contact hours (0.05 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 57 – Musculoskeletal Disorders
Universal Program Number:
014-999-07-072-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 58 – Glaucoma
Universal Program Number:
014-999-07-073-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 59 – Allergic Rhinitis
Universal Program Number:
014-999-07-074-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 60 – Minor Ophthalmic Disorders
Universal Program Number:
014-999-07-075-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 61 – Psoriasis
Universal Program Number:
014-999-07-076-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 62 – Common Skin Disorders
Universal Program Number:
014-999-07-077-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 63 – Anemia
Universal Program Number:
014-999-07-078-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 64 – Coagulation Disorders
Universal Program Number:
014-999-07-079-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 65 – Sickle Cell Disease
Universal Program Number:
014-999-07-080-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 66 – Antimicrobial Regimen Selection
Universal Program Number:
014-999-07-081-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 67 – Central Nervous System Infections
Universal Program Number:
014-999-07-082-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 68 – Lower Respiratory Tract Infections
Universal Program Number:
014-999-07-083-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 69 – Upper Respiratory Tract Infections
Universal Program Number:
014-999-07-084-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 70 – Skin and Soft Tissue Infections
Universal Program Number:
014-999-07-085-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 71 – Infective Endocarditis
Universal Program Number:
014-999-07-086-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 72 – Tuberculosis
Universal Program Number:
014-999-07-087-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 73 – Gastrointestinal Infections
Universal Program Number:
014-999-07-088-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 74 – Intraabdominal Infections
Universal Program Number:
014-999-07-089-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 75 – Parasitic Diseases
Universal Program Number:
014-999-07-090-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 76 – Urinary Tract Infection
Universal Program Number:
014-999-07-091-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 77 – Sexually Transmitted Infections
Universal Program Number:
014-999-07-092-H04
Two and half (2.5) contact hours (0.25 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 78 – Osteomyelitis
Universal Program Number:
014-999-07-093-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 79 – Sepsis and Septic Shock
Universal Program Number:
014-999-07-094-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 80 – Superficial Fungal Infections
Universal Program Number:
014-999-07-095-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 81 – Invasive Fungal Infections
Universal Program Number:
014-999-07-096-H04
Two and half (2.5) contact hours (0.25 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 82 – Antimicrobial Prophylaxis in Surgery
Universal Program Number:
014-999-07-097-H01
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 83 – Vaccines and Toxoids
Universal Program Number:
014-999-07-098-H01
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 84 – Human Immunodeficiency Virus Infection
Universal Program Number:
014-999-07-099-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 85 – Cancer Chemotherapy and Treatment
Universal Program Number:
014-999-07-100-H01
Three (3.0) contact hours (0.30 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 86 – Breast Cancer
Universal Program Number:
014-999-07-101-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 87 – Lung Cancer
Universal Program Number:
014-999-07-102-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 88 – Colorectal Cancer
Universal Program Number:
014-999-07-103-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 89 – Prostate Cancer
Universal Program Number:
014-999-07-104-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 90 – Malignant Lymphomas
Universal Program Number:
014-999-07-105-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 91 – Ovarian Cancer
Universal Program Number:
014-999-07-106-H04
Half (0.5) contact hours (0.05 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 92 – Acute Leukemias
Universal Program Number:
014-999-07-107-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 93 – Chronic Leukemias and Multiple Myeloma
Universal Program Number:
014-999-07-108-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 94 – Skin Cancer
Universal Program Number:
014-999-07-109-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 95 – Hematopoietic Cell Transplantation
Universal Program Number:
014-999-07-110-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 96 – Oncologic Emergencies
Universal Program Number:
014-999-07-111-H04
Two and half (2.5) contact hours (0.25 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 97 – Parenteral Nutrition
Universal Program Number:
014-999-07-112-H04
Two (2.0) contact hours (0.20 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 98 – Enteral Nutrition
Universal Program Number:
014-999-07-113-H04
One and half (1.5) contact hours (0.15 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Chap. 99 – Overweight and Obesity
Universal Program Number:
014-999-07-114-H04
One (1.0) contact hours (0.10 CEUs) will be awarded and statements issued for successful program completion and request for continuing education.

Continuing Education

Pharmacists, physicians, physician assistants, and nurse practitioners can earn valuable continuing education credit based on the content of Pharmacotherapy Principles & Practice. For details visit: www.pharmacotherapyprinciples.com

Accreditation

This activity has been planned and implemented in accordance with the Essential Areas and policies of the Accreditation Council for Continuing Medical Education through the joint sponsorship of the Medical College of Georgia School of Medicine and The University of Georgia College of Pharmacy.

The Medical College of Georgia School of Medicine is accredited by the Accreditation Council for Continuing Medical Education to provide continuing medical education for physicians.

The Medical College of Georgia is an approved provider of continuing nursing education by the Georgia Nurses Association, an accredited approver by the American Nurses Credentialing Center's Commission on Accreditation.

The University of Georgia College of Pharmacy is accredited by the Accreditation Council for Pharmacy Education as a provider of continuing pharmacy education.

Designation

The Medical College of Georgia School of Medicine designates this educational activity for a maximum of 170 *AMA PRA Category 1 Credits*.™ Physicians (and other qualified participants) should only claim credit commensurate with the extent of their participation in the activity.

The University of Georgia College of Pharmacy designates this on-line educational series for a maximum of 170 contact hours (17.0 CEUs). A Request for CE must be made for EACH offering and continuing education credit will be awarded and statements issued on-line for successful completion of materials and assessment.

For details visit: www.pharmacotherapyprinciples.com

PREFACE

Practitioners who design, implement, monitor, and evaluate medication therapy bear an important responsibility to their patients and society. Development of these abilities requires an integration of knowledge, skills, attitudes, and values that can be acquired only through a structured learning process that includes classroom work, independent study, hands-on practice, and, ultimately, involvement with actual patients.

Pharmacotherapy Principles & Practice is designed to meet the classroom and independent study needs of today's learners in the health professions. Chapters are written or reviewed by pharmacists, nurse practitioners, physician assistants, and physicians who are authorities in their fields and were subjected to rigorous review by experts. The book is written in a concise style that facilitates an in-depth level of understanding of the essential concepts. The disease states covered and the drugs discussed in the text focus on those disorders most often seen in actual practice.

Each chapter reviews etiology, epidemiology, pathophysiology, and disease presentation, followed by clear therapeutic recommendations for drug selection, dosing, and patient monitoring. The learning features used in *Pharmacotherapy Principles & Practice* were designed in collaboration with educational design specialists to enhance learning and retention. These features include:

- *Structured learning objectives.* These are listed at the beginning of each chapter, and information in the text that corresponds to each learning objective is identified by a vertical rule in the margin, which allows the reader to find content related to each objective quickly.
- *Key concepts related to patient assessment and treatment.* Designed to help focus learning, these key concepts are listed at the beginning of each chapter. Textual material that develops these concepts is easily identified by numbered icons throughout the chapter.
- *Patient encounter vignettes.* Distributed throughout each chapter, these case scenarios facilitate critical thinking skills and lend clinical relevance to the scientific foundation provided.
- *Patient care and monitoring guidelines.* This section, placed near the end of each chapter, is designed to assist students in their general approach to assessing, treating, and monitoring patients for therapeutic response and adverse events.
- *Up-to-date literature citations.* A comprehensive reference list for each chapter is provided on the Online Learning Center to substantiate treatment recommendations.
- *Key references and readings.* Placed at the end of each chapter, this list provides a mechanism to acquire a deeper understanding of the subject matter.
- *Generous use of tables, figures, text boxes, and algorithms.* These visual features enhance understanding of pathophysiology, clinical presentation, drug selection, pharmacokinetics, and patient monitoring.
- *Medical abbreviations and their meanings.* Placed at the end of each chapter, these lists facilitate learning the accepted shorthand used in real-world medical practice.
- *Glossary of medical terms.* The glossary is one of the appendices at the end of the book; the first use of each glossary term in a chapter appears in bold font.
- *Self-assessment questions and answers for each chapter.* Located in the Online Learning Center, these questions are designed to evaluate student learning and may be used to obtain approximately 170 hours of continuing education credit for licensed pharmacists, nurse practitioners, physicians, and physician assistants.
- *Laboratory values expressed as both conventional units and Systemè International (SI) units.* Including both units of measurement facilitates use of this book throughout the world.
- *Appendices useful to students and practitioners.* These appendices include: 1) conversion factors and anthropometrics; 2) common laboratory tests and their reference ranges; and 3) common medical abbreviations.

An electronic version of *Pharmacotherapy Principles & Practice* can be downloaded to a desktop or laptop computer using the access number that appears on the card inserted in the middle of this book. The Online Learning Center at www.ChisholmPharmacotherapy.com provides complete reference lists, self-assessment questions, a testing center that has the ability to grade and provide immediate feedback on the self-assessment questions as well as reporting capabilities, and other features designed to support learning.

Pharmacotherapy Principles & Practice is a valuable and unique learning tool that combines state-of-the-art, comprehensive, yet concise chapters, unique learning features, and the Online Learning Center.

1 Introduction

Jack E. Fincham

The prescribing of a drug is the most common outcome of a patient visit to a physician; 60% of physician visits result in a prescription or injection for patients. It is incumbent on health professionals to ensure that this process of receiving and taking medications benefits and does not harm patients. Clinicians are often called upon to identify, resolve, and prevent problems that occur due to undertreatment, overtreatment, or inappropriate treatment. Problems occurring with the use of drugs can include:

- Suboptimal drug, dose, regimen, dosage form, and duration of use;
- Unnecessary drug therapy;
- Therapeutic duplication;
- Drug-drug, drug-disease, drug-food, or drug-nutrient interactions;
- Drug allergies; or
- Adverse drug effects, some of which are preventable.

The readers of this book can help to reverse these problems, improve outcomes of care both clinically and economically, and enable drug use to meet stated goals and objectives. This text provides a thorough analysis and summary of treatment options for commonly occurring diseases and the medications or alternative therapies used to successfully treat these conditions.

The use of drugs as a form of medical treatment in the United States is an enormously complex process. Individuals can purchase medications through numerous outlets. Over-the-counter (OTC) medications can be purchased in pharmacies, grocery stores, supermarkets, convenience stores, via the Internet, and through any number of additional outlets. OTCs are widely used by all age groups. Prescriptions can be purchased through traditional channels (community chain and independent pharmacies), from mail order pharmacies, through the Internet, from physicians, from health care institutions, and elsewhere. Herbal remedies are marketed and sold in numerous outlets. The monitoring of the positive and negative outcomes of the use of these drugs, both prescription and OTC, can be disjointed and incomplete. Clinicians and health professions students need to take ownership of these problems and improve patient outcomes resulting from drug use.

It is important to realize that although clinicians are the gatekeepers for patients to obtain prescription drugs, patients can obtain prescription medications from numerous sources. Patients may also borrow from friends, relatives, or even casual acquaintances. In addition, patients obtain OTC medications from physicians through prescriptions, on advice from pharmacists and other health professionals, through self-selection, or through the recommendations of friends or acquaintances. Through all of this, it must be recognized that there are both formal (structural) and informal (word of mouth) components at play. Health professionals may or may not be consulted regarding the use of medications, and in some cases are unaware of the drugs patients are taking. In addition, herbal remedies or health supplements may be taken without the knowledge or input of a health professional.

External variables may greatly influence patients and their drug-taking behaviors. Coverage for prescribed drugs allows those with coverage to obtain medications with varying cost sharing requirements. However, many do not have insurance coverage for drugs or other health-related needs. With the advent of Medicare coverage for prescription medications, more of the elderly will have access to needed therapy—more than ever before.[1]

SELF-MEDICATION

Self-medication can be broadly defined as a decision made by a patient to consume a drug with or without the approval or direction of a health professional. The self-medication activities of patients have increased dramatically in the late twentieth and early twenty-first centuries. Many factors affecting patients have continued to fuel this increase in self-medication. There are ever increasing ways to purchase OTC medications. There have been many prescription items switched to OTC classification in the last 50 years. In addition, patients are increasingly becoming comfortable with self-diagnosing and self-selection of OTC remedies. The number of switched products is dramatically and significantly fueling the rapid expansion of OTC drug usage. Dean[2] noted in the past that in many studies, self-medication with nonprescribed therapies exceeds the use of prescription medications.

Patients' use of self-selected products has the potential to bring enormous benefits to patients, as well as others.[3] Through the rational use of drugs, patients may avoid more costly therapies or expenditures for other professional services. Self-limiting conditions and even some chronic health conditions (e.g., allergies and dermatologic conditions), if appropriately treated through patient self-medication, allow the patient to have a degree of autonomy in health care decisions. This book provides a thorough analysis of common disease states, discussion of therapies to treat these conditions, and specific advice to provide to patients to help them self-medicate when appropriate and safe to do so.

COMPLIANCE WITH MEDICATION REGIMENS

Both self-medication and patient compliance behaviors are exceedingly complex. McDonald and colleagues[4] point out that patient interventions to impact compliance are complex, labor intensive, and not particularly effective. McDonald and colleagues[4] further suggest that more convenient care, reminders, self-monitoring by patients, reinforcement, family therapy, and additional attention may need to be in play for compliance to improve. Meredith[5] notes that a focus on the individual, rather than a general approach, is more likely to be successful. Haynes and colleagues[6] call for better approaches to enhance compliance that are more efficient and more effective.

For the most part, with regard to compliance-enhancing strategies, the more things that can be done the better the chances of success. Enhancing compliance is more art than science, and more trial and error than precisely delineated. Success may be frustratingly difficult to achieve, but enhanced and suitable patient compliance should be the ultimate goal of the prescribing, dispensing, and therapeutic monitoring process. Clinicians can have no more rewarding, yet vexing, opportunity than trying and succeeding in helping patients comply with medication regimens and achieve treatment goals.

Compliance Issues

Patient noncompliance with prescription regimens is one of the most understated problems in the health care system. The effects of noncompliance have enormous ramifications for patients, caregivers, and health professionals. Compliance with medications is a worldwide problem, and measures that are effective in one country may not have work elsewhere.

In the recently released book on worldwide compliance issues (*Adherence to Long-term Therapies, Evidence for Action*),[7] published by the World Health Organization, researchers indicate that the problem of noncompliance is worse in countries in the developing world than in countries in the industrialized world. Many parts of the United States have similar morbidity and mortality rates as countries in the Third World.[8] Specific disease states may have significant additional noncompliance ramifications due to the development of drug-resistant strains of bacteria.[9] Many times what is necessary is referral to specific clinicians for individualized treatment and monitoring to enhance compliance. The case histories provided in this text will allow you to follow what others have done in similar situations to optimally help patients succeed in improving compliance rates and subsequent positive health outcomes.

DRUG COSTS

Spending for prescription drugs in the United States has skyrocketed in the recent past. Between 1990 and 2003, the amount spent on prescription drugs in the United States quadrupled, far outstripping the increase in cost of other commodities in the United States health care system.[10] This large increase in spending has stressed financing of the health care system. Americans pay the highest prices for prescription drugs in the world.[11] United States prices are 72% higher than those in Canada, and 102% higher than those in Mexico.[11] An increase of 25% in the percentage of expenditures for prescription drugs as a percentage of all health care costs has occurred over the past 5 years.

Numerous types of marketing have impacted the usage of prescription drugs, and marketing has come under increasing scrutiny as one reason for the use of costly alternatives rather than less expensive therapies that might be equally efficacious. More and more of these types of comparisons are appearing in the lay press (magazines and newspapers). A good share of the success of the pharmaceutical industry is due to lobbying efforts, which have been substantive and effective. Knowledgeable clinicians can counter the misleading marketing that sometimes occurs, and in doing so provide a significant service that improves the prescribing and drug use process.

DRUG USE BY THE ELDERLY

Various components of drug use in the elderly are worth noting. Problems with health literacy (i.e., the understanding of medical

terminology and directions from providers) are more common among the elderly.[12] The burgeoning population of the elderly coupled with their lack of health literacy means that this issue will become even more problematic in the future.[12]

Over the next decade, seniors will spend $1.8 trillion on prescription medications. Medicare proposals to provide a drug benefit for seniors have been suggested to cost $400 billion over a 10-year period. Thus, the most elaborate of the current drug programs will pay only 22% of seniors' drug costs. Enhanced use of pharmacoeconomic tenets to select appropriate therapy while considering cost and therapeutic benefits for seniors and others will become even more crucial for clinicians in the future.

IMPACTING THE PROBLEMS OF DRUG USE

Medication Errors

Brass,[13] commenting on the change from prescription to over-the-counter status of many medications, notes increasing problems with polypharmacy. This is no surprise to anyone considering the several classes of drugs that can cause problems. These problem drugs include analgesics, sleep preparations, pseudoephedrine, caffeine, cough and cold preparations, and laxatives. The problems with these drugs have been also noted in studies elsewhere.[14] Inaccurate self-diagnosis leads to suboptimal therapy, high patient cost, and more adverse effects and/or drug interactions.[13]

Elsewhere, it was found that errors by physicians and others is often not reported to patients, and surprisingly, 23% of physicians and 11% of patients in one study did not feel that physicians should report such errors to patients.[15] Clinicians in the future will be expected to interact more, and more effectively, with patients. These expectations for improved interaction with patients will help both clinicians and patients to reach their therapeutic goals. The authors of the chapters in this text have worked through patient care problems that are commonly seen in practice, and the reader will benefit by using similar tactics to help their patients.

Health Literacy and Indigent Care

The negative influence of health illiteracy on all affected patients has tangible outcomes, namely higher rates of hospitalization with lower rates of health literacy.[16] Much of the elaborate technology used by the United States health care system is not accessible to the uninsured. It is estimated that $1.1 billion per year in additional expenditures are needed to deal with undertreatment of myocardial infarction, cataracts, and depression.[17] As governmental programs expand to provide drug coverage for more seniors in Medicare Part D, and for patients shifted from drug coverage under Medicaid to Medicare coverage, the impacts of health illiteracy and the need for clinicians to provide interventions that will enhance drug use will dramatically increase.

Health professionals are at a crucial juncture as we face an uncertain, yet promising future. Technological advances, including electronic prescribing, may stem the tide of medication errors and inappropriate prescribing. Pilot studies have implemented these technological enhancements for physician order entry (via personal data assistants or through web access to pharmacies) in order to reduce drug errors. The skills and knowledge that enable effective pharmacotherapy practice have never been more daunting among the numerous health professions. Sophisticated computer technology can further empower health professionals to play an ever increasing and effective role in helping patients and fellow health professionals to practice safe and effective medicine.

This book, which incorporates materials written by some of the finest minds in pharmacy practice and education, can enable the reader to play a crucial role in improving the drug use process for patients, providers, payers, and society. The purpose of this book is to help hone your skills so you can make a real improvement in the therapies you provide to your patients. Current and future clinicians can rely on the information laid out here to enhance your knowledge and allow you to assist your patients with the sound advice that they expect you to provide. Use the text, case histories, and numerous examples detailed here to expand your therapeutic skills, and to help positively impact your patients in the years to come.

2 Hypertension

Robert J. Straka, R. Todd Burkhardt, and David Parra

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Classify blood pressure levels and treatment goals.
2. Recognize the underlying causes and contributing factors in the development of hypertension.
3. Describe the appropriate measurement of blood pressure.
4. Recommend appropriate lifestyle modifications and pharmacotherapy for patients with hypertension.
5. Identify populations requiring special consideration when designing a treatment plan.
6. Construct an appropriate monitoring plan to assess hypertension treatment.

Key Concepts

❶ Hypertension is widely prevalent and accounts for significant morbidity and mortality, as well as billions of dollars in direct and indirect costs.

❷ The cause of hypertension is unknown in the majority of cases (primary hypertension), but for those with secondary hypertension, specific causes are indicated.

❸ Patients failing to achieve goal blood pressure despite maximum doses of three antihypertensives including a diuretic should be carefully screened for resistant hypertension.

❹ The pathophysiology of primary hypertension is heterogeneous, but ultimately exerts its effects through the two primary determinants of blood pressure: cardiac output and peripheral resistance.

❺ Appropriate technique in measuring blood pressure is a vital component to the diagnosis and continued management of hypertension in the outpatient setting.

❻ Drug selection for the management of patients with hypertension should be considered as adjunctive to nonpharmacologic approaches for blood pressure lowering, and ultimately the attainment of target blood pressure in many cases may be more important than the antihypertensive agent used.

❼ Implementation of lifestyle modifications successfully lowers blood pressure, often with results similar to those of therapy with a single antihypertensive agent.

❽ An approach to selection of drugs for the treatment of patients with hypertension should be evidence-based with considerations regarding the individual's co-existing disease states, co-prescribed medications, and practical patient-specific issues including costs.

❾ While the main goal of antihypertensive therapy is to achieve target blood pressures, the selection of agents for an individual should also account for certain special considerations and a patient's comorbidities. Specific antihypertensive therapy is warranted for certain patients with comorbid conditions that may elevate their level of risk for cardiovascular disease.

❿ The frequency of follow-up visits for patients with hypertension will vary based on individual cases, but will be influenced by severity of hypertension, comorbidities, and choice of agent selected.

National and international trends over the past 15 years depict modest improvements in the treatment and/or control of blood pressure (BP) for hypertensive patients. This observation is made despite efforts to promote awareness, treatment, and the means available to aggressively manage high blood pressure. Over 65 million Americans have hypertension, which was listed as the primary cause of death for over 261,000 individuals in the United States in 2002.[1] Hypertension is also a significant cause of end-stage renal disease and heart failure. National and international organizations continually refine their recommendations of how

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

clinicians should approach the management of patients with high blood pressure, including methods of measurement, patient education, medication adherence, and overall benefits of reduced blood pressure. Although approaches vary to some degree, there are clear themes that emerge regardless of which national or international organization's algorithm is followed. The purpose of this chapter is to provide a summary of key issues associated with the management of patients with hypertension. We will discuss the basic approach to treating patients with hypertension and provide a functional summary of the currently prevailing themes of national guidelines, including their grounding in relevant landmark trials. Finally, we will summarize salient pharmacotherapeutic issues essential for clinicians to consider when managing patients with hypertension.

Various algorithms recommending nonpharmacologic and pharmacologic management for typical and atypical patients are proposed, with the underlying theme that achievement of blood pressure targets mitigate end-organ damage, leading to substantial reductions in stroke, myocardial infarction, and heart failure. Although references to other algorithms will be mentioned, this chapter will focus primarily on the *Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure,* more commonly referred to as the JNC 7 report.[2]

The JNC 7 report describes four stages of blood pressure classification and provides guidance on nonpharmacologic and pharmacologic approaches to managing patients with hypertension. The four stages of blood pressure classification include normal, prehypertension, stage 1 hypertension, and stage 2 hypertension (Table 2–1). These stages are defined as such to connote a level of risk and thus the need for varying intensities of intervention with drug therapy (Fig. 2–1). With the exception of individuals with "compelling indications," recommendations for drug therapy typically begin with one or two (in the case of stage 2) antihypertensive drugs as an initial step. Specific drug selection is guided by the presence of compelling indications—specific comorbid conditions. These compelling indications, such as heart failure, diabetes, and chronic kidney disease (CKD), represent specific conditions for which explicit evidence in the literature exists to document the utility of a particular agent or class of agents. Selection of drug therapy consequently involves an iterative process of considering multiple antihypertensive drugs as needed to achieve target blood pressures of less than 140/90 mm Hg for all patients, with more aggressive targets of less than 130/80 mm Hg for patients with diabetes or chronic kidney disease.[3] Treatment with drug therapy should be done in combination with recommended lifestyle modifications to manage hypertension and minimize risk.

EPIDEMIOLOGY

❶ *Hypertension is widely prevalent and accounts for significant morbidity and mortality, as well as billions of dollars in direct and indirect costs.* Worldwide prevalence of hypertension is estimated to include 1 billion individuals. There are an estimated 7 million deaths per year that may be related to the diagnosis of hypertension.[4] The prevalence of hypertension in the United States is estimated to include 65 million individuals and accounts for an estimated 59.7 billion dollars annually in direct and indirect costs.[1]

The prevalence of hypertension differs based on age, sex, and ethnicity. As individuals become older, their risk of high blood pressure increases. Individuals 55 years of age who do not have hypertension are estimated to have a lifetime risk of 90% of eventually developing hypertension. The National Health and Nutrition Examination Survey from 1999 to 2000 indicated that hypertension is slightly more prevalent in men (30.1%) than women (27.1%). However, the prevalence increased by 5.6% in women and has remained unchanged in men from 1988 to 2000.[5] Hypertension prevalence is highest in African-Americans when compared to non-Hispanic whites and Mexican-Americans.[1]

Hypertension is strongly associated with type 2 diabetes.[6] The added comorbidity of hypertension in diabetes leads to a higher risk of cardiovascular disease (CVD), stroke, renal disease, and diabetic retinopathy leading to greater health care costs.[7]

TABLE 2–1. Classification of Blood Pressure (BP) in Children, Adolescents, and Adults Defined as 18 Years Old or Greater[2,70]

BP Classification	Adult SBP (mm Hg)	Adult DBP (mm Hg)	Children/Adolescents SBP or DBP Percentile[a]
Normal	Less than 120	and less than 80	Less than 90th
Prehypertension	120–139	or 80–89	90–95th or 120/80 mm Hg
Stage 1 hypertension	140–159	or 90–99	95–99th + 5 mm Hg[b]
Stage 2 hypertension	Greater than or equal to 160	Greater than or equal to 100	Greater than 99th + 5 mm Hg[c]

[a]Tables contain the 50th, 90th, and 99th percentiles of systolic blood pressure (SBP) and diastolic blood pressure (DBP) standards based on percentile height by age and sex, which is used to compare the child's measured blood pressure on three separate occasions. The difference in blood pressure of the 95th and 99th percentiles are 7–10 mm Hg which requires an adjustment of 5 mm Hg to accurately categorize stage 1 or 2 hypertension. If the systolic and diastolic percentile categories are different, then classify hypertension by the higher blood pressure value.
[b]Children and adolescents' stage 1 hypertension is classified by blood pressure levels that range from the 95th percentile to 5 mm Hg above the 99th percentile.
[c]Children and adolescents' stage 2 hypertension is classified by blood pressure levels that are greater than 5 mm Hg above the 99th percentile.

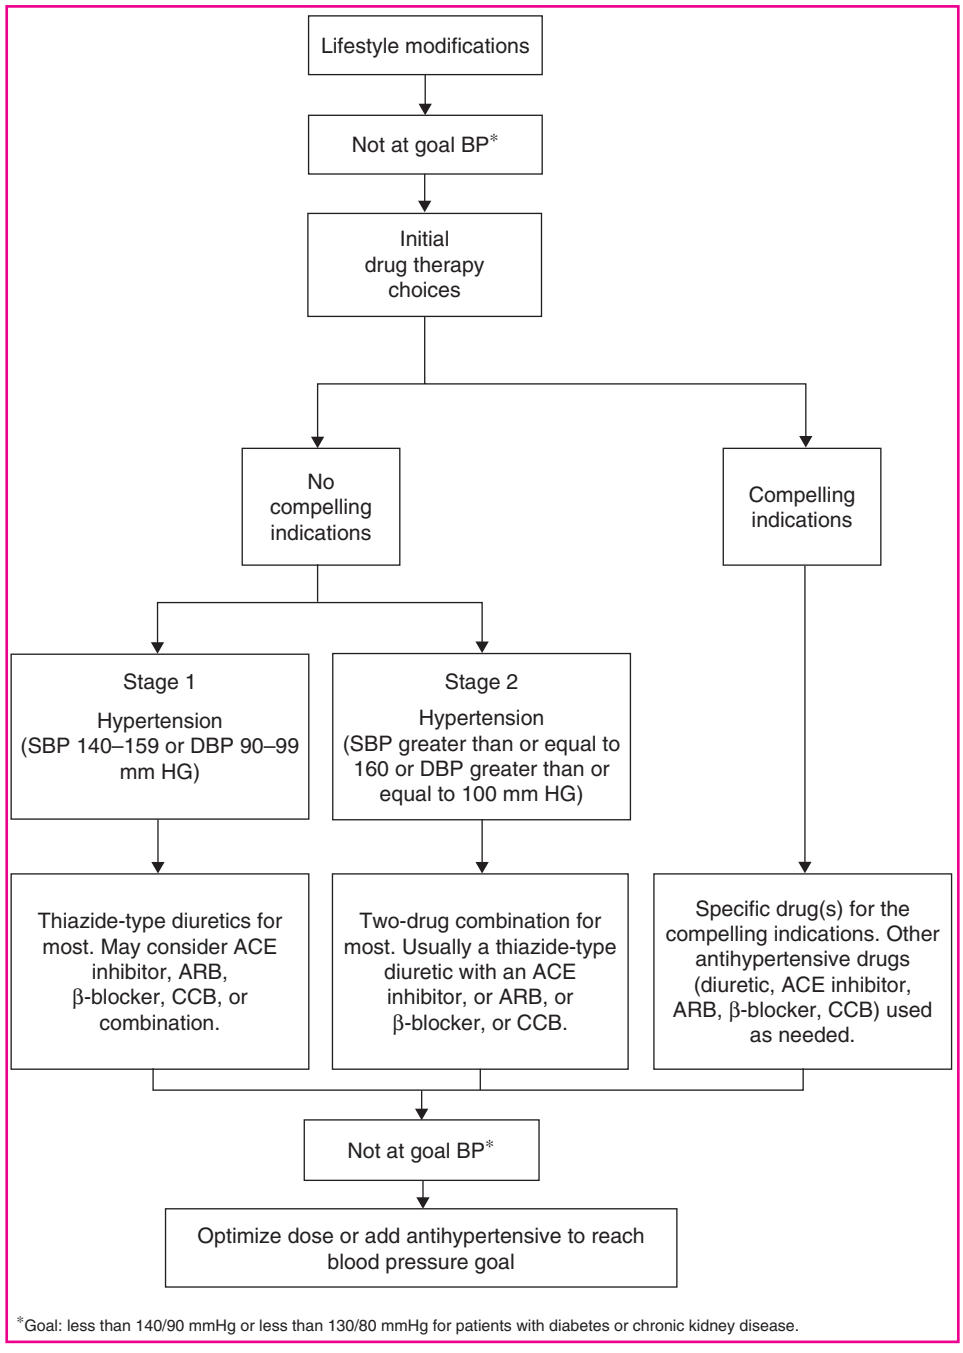

FIGURE 2–1. Algorithm for treatment of hypertension when patients are not at their goal blood pressure. Compelling indications refer to specific indications where the selection of a particular antihypertensive drug class for a defined high-risk population is highly recommended. These recommendations are usually based on results from landmark randomized placebo-controlled outcome trials or consensus statements from clinical guidelines and are usually based on findings documenting superior outcomes in terms of morbidity and mortality. ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; BP, blood pressure; CCB, calcium channel blocker agent; DBP, diastolic blood pressure; SBP, systolic blood pressure. (Adapted from JNC 7; Modified from Saseen JJ, Carter BL. Hypertension. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 194, with permission.)

ETIOLOGY

❷ *In the majority of patients, up to 95%, the cause of hypertension is unknown and it is referred to as essential, or more appropriately, as primary hypertension.*[8] *However, in some patients there is an identifiable cause of which the most common are:*[2]

- *Chronic kidney disease*
- *Coarctation of the aorta*
- *Cushing's syndrome and other glucocorticoid excess states*
- *Drug induced/related (Table 2–2)*
- *Pheochromocytoma*
- *Primary aldosteronism and other mineralocorticoid excess states*
- *Renovascular hypertension*
- *Sleep apnea*
- *Thyroid or parathyroid disease*

Hypertension caused by any of these conditions is referred to as secondary hypertension. Identification of a secondary cause of hypertension is often not initially pursued unless suggested by routine clinical and laboratory evaluation of the patient, or failure to achieve blood pressure control.

TABLE 2–2. Causes of Resistant Hypertension[2]

Improper blood pressure measurement
Volume overload
• Excess sodium intake
• Volume retention from kidney disease
• Inadequate diuretic therapy
Ineffective cardiac pump function
• Diastolic dysfunction
Drug-induced
• Non-steroidal anti-inflammatory drugs; cyclooxygenase 2 inhibitors
• Cocaine, amphetamines, and other illicit drugs
• Sympathomimetics (decongestants, anorectics, and stimulants)
• Oral contraceptive hormones
• Adrenal steroid hormones
• Cyclosporine and tacrolimus
• Erythropoietin
• Licorice (including some chewing tobacco)
• Select over-the-counter dietary supplements and non-traditional medicines (e.g., ephedra, ma huang, and bitter orange)
Therapeutic circumstances
• Failure to receive or take antihypertensive medications
• Inadequate doses (sub-therapeutic)
• Improper antihypertensive selection or combination
• Drug-drug or drug-food interactions
Associated conditions
• Obesity
• Excess alcohol intake

In addition to primary and secondary hypertension, the clinician may encounter what is referred to as resistant hypertension. ❸ *Patients failing to achieve goal blood pressure despite maximum doses of three antihypertensives including a diuretic should be carefully screened for resistant hypertension.* Several causes of resistant hypertension are listed in Table 2–2 and should be carefully considered in such patients.

PATHOPHYSIOLOGY

❹ *The pathophysiology of primary hypertension is heterogeneous, but ultimately exerts its effects through the two primary determinants of blood pressure:* ***cardiac output*** *and* ***peripheral resistance.*** The processes influencing these two determinants are numerous and complex (Fig. 2–2).[9] The underlying cause of primary hypertension is unknown and most likely multifactorial. Although several hypotheses exist, we will limit our discussion to a few while recognizing that only a minority of patients with hypertension may have an identifiable cause. For a detailed discussion of the pathophysiology behind these secondary causes, the reader is referred to additional texts.[10,11] Discussion of the management of patients with select secondary causes are found elsewhere in this chapter.

Genetics

Multiple genetic polymorphisms have been associated with hypertension. It is estimated that up to 30% to 50% of variability in blood pressure may have a genetic basis.[12] The majority of these polymorphisms appear to be involved directly or indirectly in renal sodium reabsorption, which may represent future therapeutic drug targets.[13] In addition, the identification of genetic factors contributing to variability in response to drug therapy should allow for specific tailoring of individual patient therapy, thereby optimizing the effectiveness of antihypertensive therapy while minimizing costs and adverse events.

Cardiac Output

Cardiac output is an important determinant of blood pressure. Factors which elevate cardiac output may, in theory, contribute to the development of primary hypertension. Increases in cardiac output and subsequent blood pressure may arise from factors that increase preload (fluid volume) or contractility

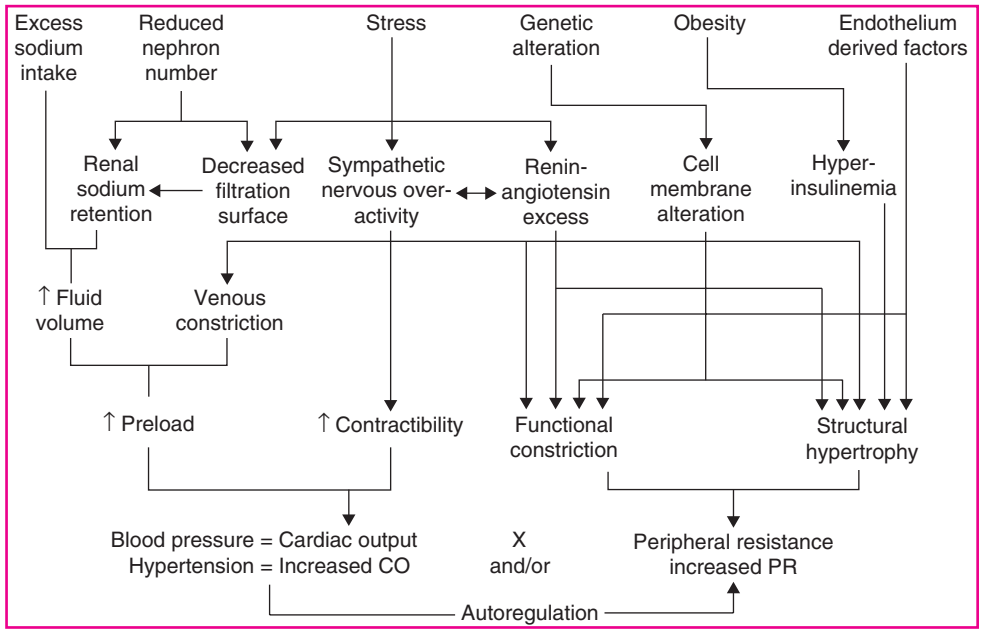

FIGURE 2–2. Factors which are involved in the pathogenesis of hypertension are summarized. Some of the factors involved in the control of blood pressure affect the basic equation: blood pressure = cardiac output × peripheral resistance. The figure depicts the complex nature of various factors which may play a role in the development of hypertension. Each of these factors may individually or collectively modulate blood pressure through their actions upon various physiologic systems at the cellular, organ, and organ system level. CO, cardiac output; PR, peripheral resistance. (From Kaplan NM. Primary hypertension: Pathogenesis. In: Kaplan's Clinical Hypertension. 8th ed. Philadelphia: Lippincott Williams & Wilkins; 2002: 63, with permission.)

of the heart. Nonetheless, even if increased cardiac output may be involved in the development of primary hypertension, these increases do not appear to persist over time. As a consequence, elevated cardiac output is not considered a hemodynamic hallmark of established primary hypertension.

Sodium Regulation

The contribution of sodium to the development of primary hypertension is related to excess sodium intake and/or abnormal sodium excretion by the kidneys. It is generally accepted that dietary salt is associated with increases in blood pressure that can be lowered with reduction of sodium intake.[2,14] There appears to be a threshold effect of sodium intake in the range of 50 to 100 mmol/day [1.2 to 2.4 grams of sodium per day is equivalent to 3 to 6 grams of sodium chloride per day (50 to 100 mmol/day)] and its impact on blood pressure. The mean sodium intake per day is 175 mmol (4.1 grams) for men and 120 mmol (2.7 grams) for women in the United States, with the majority derived from processed foods.[2] However, not all individuals appear to be susceptible to a high sodium intake, with about 50% of hypertensive patients being classified as sodium-sensitive. The proposed mechanisms behind high sodium intake and blood pressure include increases in intracellular calcium, insulin resistance, paradoxical rise in **atrial natriuretic peptide,** and other pressor effects.[9] Proposed mechanisms behind salt sensitivity include a defect in renal sodium excretion and an increased rate of proximal sodium reabsorption, among others.[9]

In addition to excess sodium intake, abnormal renal sodium retention may be the primary event in the development of hypertension, and it includes abnormalities in the pressure-natriuresis mechanism. In hypertensive individuals, this theory proposes a shift in the control mechanism preventing the normalization of blood pressure. The mechanisms behind the resetting of the pressure-natriuresis curve may include afferent arteriolar vasoconstriction, decreased glomerular ultrafiltration, or an increase in tubular sodium reabsorption.[4] Other theories supporting abnormal renal sodium retention suggest a congenital reduction in the number of nephrons, enhanced renin secretion from nephrons that are ischemic, or an acquired compensatory mechanism for renal sodium retention.[9]

Given that the majority of patients with hypertension have no recognizable etiology for their elevated blood pressure, it is important to understand systems involved in blood pressure regulation as a means to employ drug therapy to affect these systems. One such system which is central to the understanding of hypertension and drug therapies is the renin-angiotensin-aldosterone system (RAAS).

Renin-Angiotensin-Aldosterone System

Since the discovery of renin over 100 years ago, the RAAS has been extensively studied as a prime target or site of action for many effective antihypertensives.[15] Renin is produced and stored in the juxtaglomerular cells of the kidney, and its release is stimulated by impaired renal perfusion, salt depletion, and β_1-adrenergic stimulation. The release of renin is the rate-limiting step in the eventual formation of angiotensin II, which is primarily responsible for the pressor effects mediated by the RAAS (Fig. 2–3). Evidence indicates that renin's pressor effects occur at the cellular level (autocrine), the local environment (paracrine), and throughout the systemic circulation (endocrine).[16] The role of the RAAS in primary hypertension is supported by the presence of high levels of renin, suggesting that the system is inappropriately activated. Proposed mechanisms behind this inappropriate activation include increased sympathetic drive, defective regulation of the RAAS (non-modulation), and the existence of a sub-population of ischemic nephrons which release excess renin.[9] However, there are also patients with primary hypertension and low levels of renin. This observation suggests that alternate mechanisms for hypertension unrelated to renin levels or activity may be in play.[17]

Sympathetic Overactivity

Overactivation of the sympathetic nervous system (SNS) may also play a role in the development and maintenance of primary hypertension for some individuals. Among other effects, direct activation of the SNS may lead to enhanced sodium retention, insulin resistance, and baroreceptor dysfunction.[9] Regardless of which mechanism(s) underlie the role the SNS may play in the development of primary hypertension, the SNS remains a target of many antihypertensive agents.

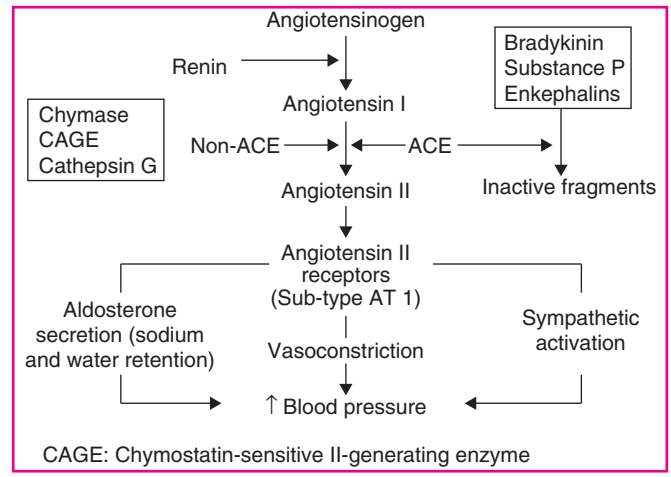

FIGURE 2–3. Diagram of the renin-angiotensin-aldosterone system. The renin-angiotensin-aldosterone system is a key system involved in the modulation of blood pressure. The diagram depicts the pathways involved in the action of various antihypertensives including ACE inhibitors, ARBs, diuretics, and aldosterone antagonists. By inhibiting the action of angiotensin-converting enzyme, ACE inhibitors reduce both the formation of the vasoconstrictor angiotensin II, and the degradation of vasodilating substances including bradykinin. ARBs primarily act through inhibition of the action of angiotensin II on the angiotensin-1 receptors which modulate vasoconstriction. Aldosterone antagonists directly inhibit the actions of aldosterone while diuretics affect sodium and water retention at a renal level. ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blockers; AT1, angiotensin-1.

Peripheral Resistance

Elevated peripheral arterial resistance is a hallmark of primary hypertension. The increase in peripheral resistance typically observed may be due to a reduction in the arterial lumen size as a result of vascular remodeling. This remodeling, or change in vascular tone, may be modulated by various endothelium-derived vasoactive substances, growth factors, and cytokines. This increase in arterial stiffness or reduced compliance results in the observed increase in systolic blood pressure.[9]

Other Contributing Processes and Factors

Obesity appears to promote the development of primary hypertension via activation of the SNS and the RAAS and is well-recognized as a global risk factor for CVD. Given the rapid increase in the prevalence of obesity worldwide and its association with insulin resistance, diabetes, and dyslipidemia, weight loss should be a prime target of interventions aimed at reducing overall cardiovascular risk.

Many other processes are proposed to contribute to the development of hypertension, including physical inactivity, insulin resistance, potassium and magnesium depletion, chronic moderate alcohol consumption, and transient effects of cigarette smoking and caffeine intake.[9] Ultimately, the management of global cardiovascular risk suggests addressing each one of these factors where relevant in all patients while pursuing target blood pressures through nonpharmacologic and pharmacologic means.

CLINICAL PRESENTATION AND CO-EXISTING RISK FACTORS

Presentation of Primary (Essential) Hypertension

General

Age: prevalence of hypertension is likely to be highest with middle-age or older patients.
Sex: men have a higher prevalence of hypertension than women until age 55.

Symptoms The primary hypertension patient may be asymptomatic or may have major cardiovascular disease risk factors.

Signs Adult patients with an average of two or more previous blood pressure readings (systolic, SBP; diastolic, DBP) indicating either:

	SPB (mm Hg)	DBP (mm Hg)
Normal	Less than 120	or less than 80
Pre-hypertension	120–139	or 80–89
Stage 1 hypertension	140–159	or 90–99
Stage 2 hypertension	Greater than or equal to 160	or greater than or equal to 100

Laboratory Tests (Not necessarily indicative of hypertension, but may be seen in hypertensive patients)
Fasting lipid panel
- Low-density lipoprotein greater than 160 mg/dL (4.14 mmol/L)
- Total cholesterol greater than 240 mg/dL (6.22 mmol/L)
- High-density lipoprotein less than 40 mg/dL (1.04 mmol/L)
- Triglycerides greater than 200 mg/dL (2.26 mmol/L)

Fasting blood serum or plasma glucose
- Impaired fasting glucose of 100–125 mg/dL (5.55–6.94 mmol/L)
- Diagnose diabetes with glucose greater than or equal to 126 mg/dL (7 mmol/L)

Abnormal test may indicate hypertension-related damage.
- Serum creatinine elevated (greater than 1.2 mg/dL [106 µmol/L])
- **Microalbuminuria** (protein in urine which is excreted at a rate of 30–300 mg per 24 hours or 20–200 mcg/minute)

Presentation of Hypertension and Co-existing Risk Factors in a Diabetic Patient

General (Not necessarily indicative of hypertension, but may be seen in hypertensive patients)
Hypertension is a common comorbidity in diabetics.
Insulin resistance (metabolic syndrome)
Dyslipidemia
Microalbuminuria
Family history
Central obesity
Physical inactivity
Tobacco use

Symptoms Many patients who are hypertensive also have diabetes. The diabetic patient may be asymptomatic or may have ischemic heart disease.

Signs Patient has previous blood pressure measurements indicating SBP greater than 130 or DBP greater than 80 mm Hg in clinic, or is currently taking antihypertensive medication(s).

Laboratory Tests The following tests may indicate additional cardiovascular risk factors or poor control of diabetes.
- Elevated fasting lipid panel
- Elevated fasting blood glucose
- Hemoglobin A_{1c} greater than 7.0%

Abnormal test may indicate hypertension related to kidney damage
- Elevated blood urea nitrogen
- Elevated serum creatinine
- Microalbuminuria/proteinuria

Target Organ Damage
Eyes (retinopathy)
Heart (angina, coronary artery disease, myocardial infarction, or heart failure)
Kidney (chronic kidney disease)
Brain (transient ischemic attack, stroke)

Regardless of the initiating process or processes leading to the development of hypertension, the ultimate goal is to reduce the risk of cardiovascular events and minimize target organ damage. This clearly requires the early identification of risk factors and treatment of patients with hypertension.

❺ *Appropriate technique in measuring blood pressure is a vital component to the diagnosis and continued management of hypertension in the outpatient setting.* Accurate measurement of a patient's blood pressure identifies and controls for factors that may influence the variability in the measure. Failure to consider how each of these factors may influence blood pressure measurement results in significant variation in measurements, leading to misclassification or inaccurate assessments of risk. Factors including body position, cuff size, device selection, auscultatory technique, and dietary intake prior to the clinic visit may contribute to such inaccuracies. Clinicians should instruct patients to avoid exercise, alcohol, caffeine, or nicotine consumption 30 minutes before blood pressure measurement. Patients should be sitting comfortably with their back supported and arm free of constrictive clothing with legs uncrossed for a minimum of 5 minutes before the first reading. In addition to these important positions, patients should have their feet uncrossed and flat on the floor.

The selection of blood pressure cuff size based on a patient's arm circumference is crucial for the accurate measurement of blood pressure. Systolic and diastolic blood pressure tend to increase when the cuff size is too small relative to the patient's arm circumference. This circumstance is important due to the increasing prevalence of obesity in developed nations. Currently, the guidelines of the American College of Cardiology/American Heart Association (ACC/AHA) Blood Pressure Measurement in Humans recommends cuff sizes for small, standard, and large adults with an optimal 2:1 ratio of cuff length/width based on arm circumference.[18]

Mercury sphygmomanometers are recommended for routine office measurements, but concerns of patient exposure and environmental contamination of mercury has fostered the development of other devices to measure blood pressure. However, there is no general concensus among health care providers as to an acceptable replacement for mercury sphygmomanometers.

To reduce deviations in blood pressure measurement in the clinic, the patient and clinician should not talk during blood pressure readings. The measurement arm is supported and positioned at heart level with the blood pressure cuff encircling at least 80% of arm circumference. If a mercury or aneroid device is used, then the palpatory method must be used first to estimate the systolic blood pressure.[18] If an automated device is used, this is not necessary. After the patient's cuff is inflated above the systolic pressure, the mercury column should drop at a rate of 2 to 3 mm per second. A stethoscope placed over the brachial artery in the antecubital fossa identifies the first and last audible **Korotkoff sounds,** which should be taken as systolic and diastolic pressure, respectively. A minimum of two readings at least 1 minute apart are then averaged. If measurements vary by more than 5 mm Hg between the two readings, then one or two additional blood pressure measurements are collected and the multiple readings averaged. Details and further recommendations for accurate measurement of blood pressure in special populations can be reviewed in the ACC/AHA Blood Pressure Measurement in Humans statement for health care professionals.[18]

Finally, the measurement of clinic or office blood pressures is poorly correlated with assessments of blood pressure in other settings. Because of this, the use of a 24-hour ambulatory blood pressure monitoring device has become more common. The device can be useful in identifying patients with **white coat hypertension** or with elevations of blood pressure during the nighttime (non-dippers). Its use has also aided in the management of refractory hypertensives with minor target organ damage, those with suspected autonomic neuropathy, and patients with large differences between home and clinic blood pressure measurements. The prognostic significance of an average level with ambulatory blood pressure monitoring may be that this measure is better at predicting cardiovascular risk than clinic blood pressure.

TREATMENT

Desired Outcomes

Hypertension management by nonpharmacologic and pharmacologic therapies has proven useful in reducing the risk of heart attack, heart failure, stroke, and kidney disease morbidity and mortality. For every 20 mm Hg systolic or 10 mm Hg diastolic increase in blood pressure, there is a doubling of mortality for both ischemic heart disease and stroke.[19] The goal of blood pressure management is to reduce the risk of cardiovascular disease and target organ damage.

General Approach to Treatment

❻ *As is the case with dyslipidemia and other cardiovascular conditions, drug selection for the management of patients with hypertension should be considered as adjunctive to nonpharmacologic approaches for blood pressure lowering. Previous clinical research has established the relative value of using individual antihypertensive drugs versus placebo to achieve reduction in morbidity and mortality by lowering blood pressure. However, as newer antihypertensive agents are developed by pharmaceutical companies, it is difficult to ethically justify the comparison of newer agents to placebo. Consequently, there have been attempts to conduct large outcome-based, multi-center trials comparing one specific agent versus another antihypertensive pharmacologic agent. These "head-to-head" comparisons and meta-analyses of multidrug regimen trials have provided convincing evidence supporting the position that the overall importance of which drug to initiate therapy with is less important than the achievement of targeted blood pressure goals.* Inherent in this position is the

realization that nonpharmacologic approaches alone are rarely successful in attaining target blood pressures, and multidrug therapy (sometimes as many as three or more agents) is necessary for most patients with hypertension.[20] Furthermore, JNC 7 continues to focus on targeting blood pressure goals in contrast to the European Society of Cardiology, which utilizes a broader approach such as the Systematic Coronary Risk Evaluation (SCORE) system.[21] In spite of global variance in approaches, this chapter will focus on the importance of advocating nonpharmacologic approaches and provide specific guidance on these steps, keeping in mind the JNC 7 theme that achievement of blood pressure goals should remain the focus.

Nonpharmacologic Treatment: Lifestyle Modifications

Therapeutic lifestyle modifications consisting of nonpharmacologic approaches to blood pressure reduction should be an active part of all treatment plans for patients with hypertension. The most widely studied interventions demonstrating effectiveness include:

- Weight reduction in overweight or obese individuals
- Adoption of a diet rich in potassium and calcium
- Dietary sodium restriction
- Physical activity
- Moderation of alcohol consumption

❼ *Implementation of these lifestyle modifications successfully lowers blood pressure (Table 2–3), often with results similar to those of therapy with a single antihypertensive agent.*[22] Combinations of two or more lifestyle modifications can have even greater effects with blood pressure lowering. Weight reduction in overweight individuals would ideally lead to attainment and maintenance of a normal body weight and should be encouraged. Blood pressure lowering in overweight patients may be seen by a weight loss of as few as 10 pounds (4.5 kilograms). The Dietary Approaches to Stop Hypertension (DASH) trial demonstrated that a diet high in fruits, vegetables, and low-fat dairy products, along with a reduced intake of total and saturated fat, significantly reduced blood pressure in as little as 8 weeks.[22] Sodium restriction in moderate amounts lowers blood pressure, is generally well-accepted, and is free of adverse effects. Restriction of sodium intake to 2.4 grams (100 mmol) of elemental sodium [6 grams of sodium chloride (100 mmol) or 1 teaspoon of table salt] should be easily achievable in most patients simply by avoidance of highly salted processed foods.[23] Simple dietary advice and instructions on reading packaging labels should be introduced to the patient initially and assessed and reinforced at subsequent office visits. As is

TABLE 2–3. Lifestyle Modifications to Manage Hypertension[2,a,b]

Modification	Recommendation	Approximate Systolic BP Reduction, Range
Weight reduction	Maintain normal body weight (body mass index 18.5–24.9 kg/m^2)	5–20 mm Hg/10 kg
Adopt DASH eating plan	Consume a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat	8–14 mm Hg
Dietary sodium restriction	Reduce dietary sodium intake to no more than 100 mmol per day (2.4 g sodium or 6 g sodium chloride)	2–8 mm Hg
Physical activity	Engage in regular aerobic physical activity such as brisk walking (at least 30 minutes per day, most days of the week)	4–9 mm Hg
Moderation of alcohol consumption	Limit consumption to no more than 2 drinks [e.g., 24 oz (710 mL) beer, 10 oz (296 mL) wine, or 3 oz (89 mL) 80-proof whiskey] per day in most men and to no more than 1 drink per day in women and lighter weight persons	2–4 mm Hg

BP, blood pressure; DASH, Dietary Approaches to Stop Hypertension.
[a] For overall cardiovascular risk reduction, stop smoking.
[b] The effects of implementing these modifications are dose- and time-dependent and could be greater for some individuals.

the case with weight loss, changes in physical activity do not need to be profound in order to have a significant effect on blood pressure. It is generally accepted that 30 minutes of moderately intense aerobic activity (e.g., brisk walking) most days of the week will lower blood pressure.[24] While most patients can safely engage in moderately intense aerobic activity, individuals with known cardiovascular disease, multiple risk factors with symptoms, or selected diabetic patients should undergo medical examination, possibly including exercise testing, prior to participation.[25,26] The effects of alcohol on blood pressure are variable. Initially, acute ingestion leads to a fall in blood pressure followed by a rise several hours later,[27] and binge drinking is associated with a higher risk of stroke. Furthermore, abstinence from alcohol in heavy drinkers leads to a reduction in blood pressure.[28] Alcohol also attenuates the effects of antihypertensive therapy, which is mostly reversible within 1 to 2 weeks with moderation of intake.

In addition to their beneficial effects on lowering blood pressure, lifestyle modifications also have a favorable effect on other risk factors such as dyslipidemia and insulin resistance, which are commonly encountered in the hypertensive population, and lifestyle modifications should be encouraged for this reason as well. Smoking cessation should also be encouraged for overall cardiovascular health despite its lack of chronic effects on blood pressure.[29,30] Although lifestyle modifications have never been documented to reduce cardiovascular morbidity and mortality in patients with hypertension, they do effectively lower blood pressure to some extent in most hypertensive patients. This may obviate the need for drug therapy in those with mild elevations in blood pressure or minimize the doses or number of antihypertensive agents required in those with greater elevations in blood pressure.

Patient Encounter 1

RS, a 67-year-old Hispanic man, comes to your clinic with results from a health fair he attended last week. He is concerned because his blood pressure at that time was 150/70 mm Hg, and when repeated was 154/68 mm Hg. Upon examination, seated blood pressure is 134/82 mm Hg in the left arm and 136/80 mm Hg in the right arm. Repeat measurements 5 minutes later are 142/84 and 138/76 mm Hg in the left and right arms, respectively.

- Based on the above information, should RS be classified as having hypertension?
- What factors may have contributed to the discrepancy between the health fair and office-based blood pressure readings?
- What additional information do you need to know before creating a treatment plan for RS?

Pharmacologic Treatment

8 *An approach to selection of drugs for the treatment of patients with hypertension should be evidence-based decision making with considerations regarding the individual's co-existing disease states, co-prescribed medications, and practical patient-specific issues including cost. The current JNC 7 report recommends drug therapy that is largely grounded in the best available evidence for superiority in outcomes—specifically morbidity and mortality.[2] The approach is often tempered with practical considerations relating to competing options for specific comorbidities and practical issues regarding a patient's experience or tolerance for side effects, and in some cases, the cost of medications.*

Although landmark trials, such as the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), have provided some objective basis for comparisons between initiating antihypertensive drug therapy with one class of antihypertensives versus another, there is room for criticism of these studies.[20,31,32] Consequently, practical interpretations of their conclusions must always leave room for individualization based on clinical judgment. Overall, JNC 7 provides a reasonable basis for guiding the selection of drug classes for individuals based on their stage of hypertension, comorbidities, and special circumstances. The following section will summarize key features of specific drug classes and summarize the JNC 7–based recommendations for patients with hypertension. Finally, an overview of the specific oral antihypertensive drug classes in common use is summarized in Table 2–4.

Diuretics

Many authorities recognize the value of diuretics as first-line agents for the majority of patients with hypertension. Extensive experience with using diuretics, as well as their practical attributes (acquisition cost and availability as combination agents), make thiazide-type diuretics a seemingly attractive selection as first-line agents. The endorsement by JNC 7 as an initial drug therapy selection for stage 1 and stage 2 hypertensive patients without compelling indications is based on a litany of placebo-controlled studies, and in no small way, on the results of active controlled outcome studies such as ALLHAT.[20] This landmark double-blind study attempted to test the hypothesis that newer antihypertensive agents would outperform thiazide-type diuretics when selected as initial drug therapy. After 4.9 years of follow-up in over 42,000 patients, the primary endpoint of fatal coronary heart disease and non-fatal myocardial infarction was indistinguishable between chlorthalidone versus either amlodipine or lisinopril. A fourth arm examining doxazosin was terminated early based on a higher risk of heart failure for doxazosin compared with chlorthalidone.[33] In spite of these findings for the primary endpoint, differences in outcomes for select secondary endpoints demonstrated superiority of chlorthalidone over either of the two remaining comparison groups. These observations, along with perceived cost-effectiveness

TABLE 2–4. Oral Antihypertensive Drugs by Pharmacologic Class[2]

Class	Drug Name and Oral Dose (mg/day)	Compelling Indications[2]	Clinical Trials	Select Adverse Events	Comments
Diuretics					
	Chlorthalidone (Hygroton) 6.25–25	Heart failure stage A (chlorthalidone)	ALLHAT[20]	Hypokalemia; Negative effect on glucose and lipids	Monitor electrolytes (e.g., decreased potassium)
		High coronary disease risk (chlorthalidone)	ALLHAT[20]		Chlorthalidone is about twice as potent as hydrochlorothiazide
		Diabetes (chlorthalidone)	ALLHAT[20]		
	Indapamide (Lozol) 2.5–5	Stroke (perindopril + indapamide)	PROGRESS[53]		
	Hydrochlorothiazide (Microzide) 12.5–50				
Aldosterone Antagonists					
	Spironolactone (Aldactone) 25–50	Heart failure (spironolactone)	RALES[73]	Hyperkalemia; Gynecomastia (spironolactone)	Monitor electrolytes (e.g., increased potassium)
	Eplerenone (Inspra) 50–100	Heart failure post-MI (eplerenone)	EPHESUS[42]		Eplerenone contraindicated in patients with estimated creatinine clearance less than 50 mL/minute or serum creatinine greater than 1.8 mg/dL (159.12 mmol/L) in women or greater than 2 mg/dL (176.8 mmol/L) in men
β-Blockers					
	Metoprolol extended-release (Toprol XL) 50–200	Heart failure (metoprolol XL, carvedilol)	MERIT-HF[74]	Bradycardia; Heart block; Fatigue	Caution with heart rate less than 60 bpm
	Carvedilol (Coreg) 12.5–50	Heart failure post-MI (carvedilol)	COPERNICUS[75] CAPRICORN[76]		Selectivity of β_1 agents is diminished at higher doses
	Propranolol (Inderal) 160–480	Post-MI (propranolol, β_1-antagonists)	BHAT[77]		Abrupt discontinuation may cause rebound hypertension
	Propranolol long-acting (Inderal LA, InnoPran XL) 80–320	High coronary disease risk			
	Metoprolol (Lopressor) 50–200				
	Atenolol (Tenormin) 25–100	Diabetes (atenolol)	UKPDS 33[78]		

Calcium Channel Blockers					
	Verapamil sustained-release (Calan SR, Isoptin SR, Verelan) 180–480 Amlodipine (Norvasc) 5–10 Nifedipine long-acting (Adalat CC, Procardia XL) 30–90 Diltiazem sustained-release (Cardizem SR) 180–360	High coronary disease risk (verapamil) Diabetes	INVEST[79]	Peripheral edema (amlodipine)	Caution with heart rate less than 60 bpm (verapamil, diltiazem) Extended-release formulations are preferred for once- or twice-daily medication administration
Angiotensin-Converting Enzyme Inhibitors					
	Benazepril (Lotensin) 10–40 Captopril (Capotan) 12.5–150 Enalapril (Vasotec) 5–40 Fosinipril (Monopril) 10–40 Lisinopril (Priniril, Zestril, Various) 10–40 Moexipril (Univasc) 7.5–30 Perindopril (Aceon) 4–16 Quinapril (Accupril) 10–80 Ramipril (Altace) 2.5–10 Trandolapril (Mavik) 1–4	Heart failure (enalapril) High coronary disease risk (ramipril, trandolapril) Heart failure post-MI (ramipril, trandolapril) Post-MI (captopril) Diabetes (captopril) Chronic kidney disease (captopril, ramipril) High coronary disease risk (perindopril) Stroke (perindopril + indapamide)	SOLVD[80] HOPE[65] AIRE[81] TRACE[82] SAVE[83] UKPDS 33[78] Captopril Trial[50] EUROPA[64] PROGRESS[53]	Hyperkalemia; Cough	Monitor electrolytes (e.g., increased potassium) Monitor rental function with serum creatinine Contraindicated in pregnancy, do not use
Angiotensin Receptor Blockers					
	Valsartan (Diovan) 80–320 Candesartan (Atacand) 4–32 Losartan (Cozarr) 25–100 Irbesartan (Avapro) 150–300	Heart failure (valsartan, candesartan) High coronary disease risk (losartan) Diabetes Chronic kidney disease (irbesartan, losartan)	ValHEFT[84] CHARM[54] LIFE[58] RENAAL[58] IDNT[57] IRMA-II[60]	Hyperkalemia	Monitor electrolytes (e.g., increased potassium) Monitor renal function with serum creatinine Contraindicated in pregnancy, do not use May use when patient develops cough with ACE inhibitor
α_1-Blockers					
	Doxazosin (Cardura) Terazosin (Hytrin) Prazosin (Minipress)	No recommendations at this time		Syncope Dizziness Palpitations	May be used in elderly males with prostatism

TABLE 2–4. Oral Antihypertensive Drugs by Pharmacologic Class[2] (*Continued*)

Class	Drug Name and Oral Dose (mg/day)	Compelling Indications[2]	Clinical Trials	Select Adverse Events	Comments
Central α_2-Agonists					
	Methyldopa Clonidine (Catapres) Guanabenz Guanfacine (Tenex) Guanadrel	No recommendations at this time		Transient sedation initially	First-line in pregnancy (methyldopa)
Direct Vasodilators					
	Isosorbide dinitrate 20 mg and hydralazine 37.5 (BiDil) 1–2 tablets three times a day Minoxidil (Loniten) Hydralazine	Heart failure (isosorbide dinitrate + hydralazine in African-Americans)	A-HeFT[66]	Edema (minoxidil) Tachycardia Lupus-like syndrome (hydralazine)	
Other Agents					
	Reserpine	No recommendations at this time		Mental depression	May be used in resistant hypertension when combined with a thiazide

Antihypertensive drug name and dose is associated with compelling indications which are based on benefits from outcome studies or clinical guidelines. For example, the drug class aldosterone antagonists have eplerenone dosed at 25–50 mg per day which is indicated for heart failure patients after an MI and supported by the EPHESUS trial.

A-HeFT, African-American Heart Failure trial; AIRE, Acute Infarction Ramipril Efficacy Study; ALLHAT, Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial; BHAT, Beta-Blocker Heart Attack Trial; bpm, beats per minute; CAPRICORN, Carvedilol Post-Infarct Survival Control in Left Ventricular Dysfunction Trial; Captopril Trial, Collaborative Study Captopril Trial ("The Effect of Angiotensin-Converting Enzyme Inhibition on Diabetic Nephropathy"); CHARM, Candesartan in Heart Failure Assessment of Reduction in Morbidity and Mortality Trial; COPERNICUS, Carvedilol Prospective Randomized Cumulative Survival Trial; EPHESUS, Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study; EUROPA, European Trial on Reduction of Cardiac Events with Perindopril in Stable Coronary Artery Disease Trial; HOPE, Heart Outcomes Prevention Evaluation Study; IDNT, Irbesartan Diabetic Nephropathy Trial; INVEST, International Verapamil-Trandolapril Study; IRMA-II, Irbesartan in Patients with Type 2 Diabetes and Microalbuminuria study; ISA, intrinsic sympathomimetic activity; LIFE, Losartan Intervention For Endpoint reduction in hypertension study; MERIT-HF, Metoprolol CR/XL Randomised Intervention Trial in Congestive Heart Failure; MI, myocardial infarction; PROGRESS, Perindopril Protection Against Recurrent Stroke Study; RALES, Randomized Aldactone Evaluation Study; RENAAL, Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan study; SAVE, Survival and Ventricular Enlargement trial; SOLVD, Studies of Left Ventricular Dysfunction; TRACE, Trandolapril Cardiac Evaluation; UKPDS, UK Prospective Diabetes Study; VALUE, Valsartan Antihypertensive Long-term Use Evaluation; ValHEFT, Veterans Affairs Cooperative I study.

(which was not specifically evaluated in this study), led the authors and JNC 7 to endorse diuretics as keys to initial drug therapy for most patients with hypertension. Nonetheless, substantial criticism of this trial has undermined some of the enthusiasm for diuretics in some clinicians' minds as well as international guideline committees.[34] Criticism of the differential blood pressures achieved in the various treatment groups, the artificial construct guiding the use of add-on drugs to base therapy, and the overrepresentation of African-Americans exhibiting select endpoints have weakened the interpretability of the authors' conclusions. Furthermore, other contemporary studies[31,35] have also challenged the status of diuretics as ideal baseline choices for initial antihypertensive drug therapy for all patients. Specifically, the Australian-New Zealand Blood Pressure-2 (ANBP2) Study[35] seemingly demonstrated (in particular for the male cohort) a superior outcome for angiotensin-converting enzyme (ACE) inhibitor–based therapy versus diuretic-based therapy in over 6,000 relatively older patients treated for over 4 years. Similarly, the Anglo-Scandinavian Cardiac Outcomes Trial-Blood Pressure Lowering Arm (ASCOT-BPLA)[31] study demonstrated in over 19,000 patients treated for approximately 5 years more favorable outcomes for the dual therapy of a calcium channel blocker agent (CCBA)/ACE inhibitor–based approach versus a β-blocker/ diuretic–based approach. Needless to say, all three of these major trials are subject to significant criticism related to study design issues, including inequities of achievement in blood pressure targets between groups for the ALLHAT and ASCOT-BPLA studies.[36] Nonetheless, diuretics continue to receive support for use as baseline initial therapy for most hypertensive patients who do not have compelling indications.[37]

Key features of diuretics that must be kept in mind, along with evidence from outcome-based studies, include the diversity between the sub-types of diuretics and their corresponding diversity of pharmacologic actions. The four sub-types include thiazides, loop diuretics, potassium-sparing agents, and aldosterone antagonists. The latter will be discussed as a separate entity. Each sub-type has clinically based properties which distinguish their roles in select patient populations. Thiazide diuretics are by far the most commonly prescribed sub-type with the greatest number of outcome-based studies supporting their use. In the United States, hydrochlorothiazide and chlorthalidone represent the most commonly prescribed thiazide-type diuretics and have been the subject of the majority of large outcome-based studies. Although subtle differences in pharmacokinetics between these agents exist, practical differences are limited to their relative diuretic potency. Chlorthalidone is considered approximately 1.5 to 2 times more potent than hydrochlorothiazide for blood pressure reduction.[38] Since the relationship between antihypertensive efficacy and metabolic/electrolyte-related side effects of thiazide diuretics is considered to be dose-related, attention to this differential in potency may be important. Specifically, select metabolic effects (hyperlipidemic and hyperglycemic) and electrolyte-related effects (hypokalemic, hypomagnesemic, hyperuricemic, and hypercalcemic) seem to increase with higher doses. This has led to national guidelines[2] recommending doses not exceeding 6.25 to 25 mg/day for chlorthalidone versus 12.5 to 50 mg/day for hydrochlorothiazide. These metabolic effects may clearly complicate the management of higher-risk patients with common comorbidities such as dyslipidemia or diabetes, or even those likely to be sensitive to the potassium- or magnesium-wasting effects of diuretics (patients with dysrhythmias or those taking digoxin). While rates of diabetes are higher following administration of thiazides, there is plenty of evidence that this can be greatly minimized by keeping potassium in the high normal range (i.e., above 4.0 mEq/L [4 mmol/L]).[39] Nonetheless, clinicians should rarely approach the upper limits of these dosage ranges without careful assessment of their metabolic effects or potential to induce electrolyte disturbances. In this way, optimization of blood pressure lowering potential may be achieved while minimizing potential adverse outcomes.

Another key feature of the thiazide-type diuretics is their limited efficacy in patients whose estimated renal function is reduced, such as the elderly. For example, patients with estimates of reduced renal function, such as those with a glomerular filtration rate (GFR) below 30 mL/minute, should be considered for more potent loop type diuretics such as furosemide. Clinicians often fail to either reconsider the role of thiazide diuretics prescribed to individuals whose renal function has been declining or fail to recognize the likely prevalence of renal compromise in the elderly to begin with.

Renal function is often estimated by formulas that attempt to predict GFR. As stated above, when predicted GFR is less than 30 mL/minute, the natural course of action would be to consider more potent diuretics. The loop diuretics, such as furosemide, bumetanide, torsemide, and ethacrynic acid, have a common site of action in the thick ascending limb of the loop of Henle.[40] Responsible for reabsorption of over 65% of the filtered sodium, their diuretic activity is clearly greater than that of the thiazides, potassium-sparing diuretics, and mineralocorticoid-acting agents. Practically speaking, furosemide is the most common agent used as a functional alternative for patients whose renal compromise precludes effective diuresis from thiazide-type agents. In situations in which a patient has poor renal function, a loop diuretic should be given at least twice a day, with the exception of furosemide to augment blood pressure control with combination antihypertensive therapy. Diuretic resistance may result from extended use of loop diuretics. In these circumstances, the addition of a thiazide to a loop diuretic may dramatically enhance overall diuresis. The most significant adverse effects related to loop diuretic use concern their potential for excessive diuresis leading to hyponatremia or hypotension. Additionally, hypokalemia, hypomagnesemia, and hypocalcemia may develop over time and contribute to the potential for cardiac arrhythmias. Overall relevance of drug-drug interactions and potential for aggravating select conditions (hyperglycemia, dyslipidemias, and hyperuricemia)

should be routinely considered in the monitoring plan for those taking loop diuretics for extended periods of time.

Potassium-sparing diuretics that do not act through mineralocorticoid receptors include triamterene and amiloride. These agents are often prescribed with potassium-wasting diuretics in an attempt to mitigate the loss of potassium. When administered as a single entity or as one component of a combination product, these agents result in moderate diuresis. Potassium-sparing diuretics act on the late distal tubule and collecting duct and thereby have limited ability to affect sodium reabsorption, which translates into modest diuresis. The most important adverse effects associated with these agents are their potential to contribute to hyperkalemia. This is especially relevant in the context of those patients receiving other agents with potassium-sparing properties, such as ACE inhibitors, angiotensin receptor blockers (ARBs), and potassium supplements, as well nonsteroidal anti-inflammatory drugs (NSAIDs), in those with mild to moderate renal impairment.

Aldosterone Antagonists

Aldosterone antagonism has recently been recognized as more than an alternate means of achieving diuresis. Indeed, spironolactone, and more recently eplerenone in the RAAS system (Fig. 2–3), have been recognized as important modulators of vascular tone through a variety of mechanisms. These inhibitors of aldosterone are commonly used in patients as components of select combination drug therapies to balance the potassium-wasting effects of more potent diuretics, such as thiazide or loop diuretics, as well as for their direct antihypertensive effects through aldosterone modulation. Patients with resistant hypertension with and without primary aldosteronism had significant additive blood pressure reductions when adding low-dose spironolactone (12.5 to 50 mg/day) to diuretics, ACE inhibitors, and ARBs.[41] Although functional for these purposes, it is important to recognize their potential to cause hyperkalemia when used in conjunction with other select agents or in patients with comorbidities resulting in reduced renal function. Classic examples include co-administration with ACE inhibitors and ARBs, known for their potassium-sparing effects, as well as agents that may directly or indirectly alter renal potassium load (e.g., potassium supplements) or potassium excretory function (e.g., NSAIDs). The most commonly used potassium-sparing diuretic is spironolactone; however, eplerenone has been increasingly used in patients with heart failure following acute myocardial infarction.[42] Although spironolactone is commonly associated with gynecomastia, eplerenone rarely causes this complication.[43] The risk of hyperkalemia is also more commonly reported with patients on spironolactone.[44]

Beta-Blockers

The JNC 7 identifies β-blockers as agents appropriate for first-line therapy for many individuals with hypertension. Based on JNC 7, the role of β-blockers in patients with select comorbidities is extensive (Table 2–5). Patients with comorbidities such as heart failure, recent myocardial infarction, and diabetes represent opportunities for β-blocker use on the basis of proven outcome-based studies. The role of β-blockers for patients with ischemic conditions including acute myocardial infarction is based on their hemodynamic effects on heart rate, blood pressure, and cardiac output, as well as their possibly antiarrhythmic properties.[40] Given their reputation for negative inotropic and chronotropic effects, any role of β-blockers in heart failure would at first appear counterintuitive. This is based on the fact that heart failure patients with systolic dysfunction would seem to be poor candidates for therapeutic agents that reduce inotropicity or contractility. Nonetheless, in the long run β-blockers, when judiciously used in patients with heart failure, have consistently been shown to reduce morbidity and mortality relative to standard heart failure therapies. Similarly, given their effects on pancreatic β-cell release of insulin and metabolic effects, such as reducing gluconeogenesis and glycogenolysis, their role in managing diabetic patients would also seem illogical. However, randomized trials strongly support β-blockers in both of these populations. In contrast, a meta-analysis by Lindholm and associates[45] has shown a higher risk of stroke with β-blocker treatment compared to other antihypertensive therapy in the treatment of patients with primary hypertension. The drug with the most prominent difference in the increased risk of stroke between the three β-blocker subgroups was atenolol. Moreover, Messerli and colleagues[46] showed that

TABLE 2–5. Compelling Indications for Individual Drug Classes

	Recommended Drug Class						
Compelling Indication	**Diuretic**	**Ald Ant**	**BB**	**CCBA**	**ACE-I**	**ARB**	**Dir Vaso**
Heart failure	•	•	•		•	•	•
Post-myocardial infarction		•	•		•		
High coronary disease risk	•		•		•		
Diabetes	•		•	•	•	•	
Chronic kidney disease				•	•	•	
Recurrent stroke prevention	•				•		

ACE-I, angiotensin-converting enzyme inhibitor; Ald Ant, aldosterone antagonist; ARB, angiotensin receptor blocker; BB, beta-blocker; CCBA, calcium channel blocking agent; Dir Vaso, direct vasodilator.

β-blocker therapy was ineffective in preventing coronary heart disease, cardiovascular mortality, and all-cause mortality when compared to diuretics for elderly patients (60 years of age or greater) treated for primary hypertension. Clearly, the effects of β-blockers on blood pressure are complex and difficult to ascribe to one or two mechanisms. Rather, the varied effects of negative chronotropic and inotropic properties along with reduced renin levels (Fig. 2–3) appear to result in an overall reduction in cardiac output and/or reduction in peripheral resistance.

The specific pharmacologic properties of various β-blockers are varied and diverse. An understanding of these properties may be useful in order to prioritize selection of one agent over others given a patient's specific condition(s). One of these properties is cardioselectivity—the property of some β-blockers that preferentially block β_1- versus β_2-receptors. Another property exhibited by some β-blockers is membrane stabilization activity, which relates to the propensity of the β-blocker to possess some capacity for antiarrhythmic properties, in addition to β-receptor blocking properties. Some β-blockers (Fig. 2–4) possess properties referred to as intrinsic sympathomimetic activity (ISA). β-Blockers possessing this property effectively block the β-receptor at higher circulating catecholamine levels, such as during exercise, while having modest β-blocking activity at times of lower catecholamine levels, such as at rest.[47]

Each of these properties may be exploited to some extent when prescribing a β-blocker, while others (membrane stabilization activity and ISA) are more of theoretical interest, with less relative value in clinical practice. For example, consider a patient with mild asthma, chronic obstructive pulmonary disease, or peripheral vascular disease (intermittent claudication). A β-blocker with relative cardioselectivity to block β_1-receptors may be more desirable in such a patient, while a nonselective β-blocker (Fig. 2–4) may be potentially disadvantageous. In such a patient, low doses of cardioselective β-blockers may achieve adequate blockade of β_1-receptors in the heart and kidneys while minimizing the undesirable effects of β_2-receptor blockade on the smooth muscle lining the bronchioles. In doing so, hypertension may be managed while avoiding complications of the co-existing reactive airway disease, which is mediated by β_2-receptor stimulation. Similarly, either because of a reduction in the β_2-mediated vascular blood flow or by enhanced unopposed β-agonist–mediated vasoconstriction, a patient with peripheral vascular disease (intermittent claudication) may experience a worsening of symptoms with use of a nonselective β-blocker (Fig. 2–4). It is important to remember that cardioselectivity is dependent upon dose, with diminished selectivity exhibited with higher doses.

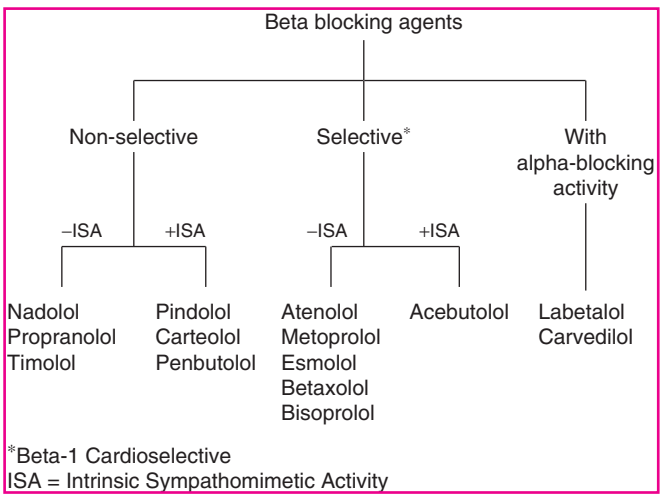

FIGURE 2–4. Flowchart listing various β-blocking agents separated by β-receptor activity and intrinsic sympathomimetic activity.

Membrane stabilization activity and ISA are two pharmacologic properties of some β-blockers whose value in the clinical setting is less well established. Generally, membrane stabilization activity may correlate with antiarrhythmic properties, while β-blockers with ISA properties have the theoretical advantage of mitigating reductions in resting heart rate while acting as classic β-blockers, at higher sympathetic tone.[40] Since neither has directly proven value in the clinical setting, they will not be discussed further other than to point out that β-blockers with ISA are not recommended for use in the post–myocardial infarction patient.[48]

A limited number of β-blockers possess properties that block β-receptors and antagonize α-receptors (Fig. 2–4). β-Blockers with α-receptor–blocking activity also have a clinical role that is theoretically beneficial, yet somewhat difficult to prove as a clinical advantage. Such is the case for carvedilol and labetalol. Both these β-blockers possess α-receptor–blocking activity in addition to their β-receptor–blocking properties. In the case of carvedilol, reductions in peripheral resistance through α-receptor–mediated blockade, in addition to β-blockade, may be thought of as a benefit for patients with hypertension. Such a combination should theoretically contribute to enhanced reductions in vascular tone. Nonetheless, there has been no proven evidence of superior outcome from the use of β-blockers with α-blocking activity compared to those with only β-blocking activity. Blocked α-receptors may represent a theoretical disadvantage for carvedilol when used to manage patients with chronic heart failure. In such patients, when recommended therapy is prescribed,[49] there is often a risk of lowering peripheral vascular resistance too much (through α- and β-receptor blockade) in such patients, who may have precious little reserve blood pressure. Nonetheless, carvedilol has enjoyed considerable clinical and proven success as a mainstay of managing patients with chronic heart failure.[49]

The adverse effects of β-blockers logically follow their pharmacology. Initiating β-blockers for hypertension in all patients may have the potential to precipitate bradycardia, various degrees of heart block, or signs and symptoms of heart failure. The latter is usually limited to those with a subclinical diagnosis and should be considered in the elderly or those with documented reductions in left ventricular function. Conversely, abrupt discontinuation of β-blockers has been cited as a precipitating factor in the development of ischemic syndromes—especially for those patients in whom β-blockers were used for extended periods of time or at higher doses, In such cases, the dose of these agents should be reduced (tapered) over a period of several days to perhaps 1 or even 2 weeks depending on patient-related factors.

Calcium Channel Blocking Agents

Exhibiting considerable interclass diversity, calcium channel blocking agents (CCBAs) have been recognized as effective antihypertensives, for the elderly in particular. Earlier trials demonstrated effective event reduction for patients with isolated systolic hypertension and clearly established the effectiveness of the blood pressure–lowering effects of dihydropyridine CCBAs. Comparative data between specific CCBAs as part of combination drug therapy versus other combination regimens have been forthcoming as of late. Specifically, the Valsartan Antihypertensive Long-term Use Evaluation (VALUE) trial compared valsartan-based therapy to amlodipine-based therapy in over 15,000 patients who were at high risk for cardiac events. In spite of an attempt to achieve identical blood pressure reductions, differences were noted early and sustained throughout the 4.2-year length of the study. Overall the primary endpoint (composite cardiac mortality and morbidity) was not statistically significantly different between the groups, but cause-specific outcomes did favor the regimen affording the achievement of lower blood pressures—namely the amlodipine-based therapy. This theme of unequal reductions in BP accounting for differences in cause-specific outcomes was shared by the findings of the ASCOT-BPLA study, which compared amlodipine-based therapy versus atenolol-based therapy in over 19,000 hypertensives for 5.5 years. Again although no statistically significant reduction in the primary endpoint was observed, the study was stopped prematurely because of fewer individuals achieving the primary endpoint while receiving the amlodipine-based regimen compared to those taking the atenolol-based regimen. These observations appear to confirm a critical theme that regardless of the agents used, the overwhelming evidence appears to indicate that the amount of blood pressure lowering achieved has more to do with event reduction than with the agents or combinations of agents used to achieve them. Primary endpoints aside, certain secondary endpoints demonstrated differences between regimens. Protection from the development of new-onset diabetes over the duration of the study was noted for the amlodipine-based therapy in the ASCOT-BPLA study and favored the ARB-based regimen over the CCBA-based regimen in the VALUE study.

Often used to augment blood pressure lowering, CCBAs are most commonly used as add-on therapy for patients who are in need of further blood pressure lowering above and beyond that afforded by diuretics or other antihypertensives. Nonetheless, they have demonstrated their efficacy in select patient populations as very effective blood pressure lowering agents.

The diversity of pharmacologic properties within the CCBA class is significant. Knowledge of their subclass helps the clinician to recognize their predominant effects on the cardiovascular system and probable side-effect profile. Dihydropyridine CCBAs such as amlodipine are commonly associated with edema, especially when used at higher doses. Phenylalkylamine-verapamil and benzothiazepine-diltiazem are more commonly recognized for their effects on the cardiac conduction system and their propensity to be negative inotropes and negative chronotropes. Many of these pharmacologic properties are exploited for their specific clinical utility. Given that verapamil and diltiazem (both are nondihydropyridine CCBAs) effectively block cardiac conduction through the atrioventricular node, their value in the management of patients with atrial fibrillation in addition to hypertension is obvious. In contrast, the dihydropyridine subclass of agents has no utility in managing atrial dysrhythmias. Similarly, all three subclasses of CCBAs possess some coronary vasodilating properties and hence may be used in select patients for the management of patients with angina, in addition to their antihypertensive benefits.

ACE Inhibitors

ACE inhibitors are a key class of antihypertensive agents used in a vast array of patients with or without comorbidities and/or cardiovascular risk factors. As the target agents of choice for numerous outcome trials, they have been extensively studied across a wide variety of patient types and thus have considerable applicability to a wide array of potential patients. This broad utility extends to the list of compelling indications (Table 2–5) for patients as described in JNC 7. These compelling indications include their qualified role in managing patients with hypertension who have type 1 diabetes,[50] heart failure,[49] post–myocardial infarction,[48] type 2 diabetes,[3] chronic kidney disease,[51,52] or recurrent stroke prevention.[53] Comparative trials between ACE inhibitors and various other agents as initial drug therapy have also demonstrated some differences in outcomes for this class. In the case of ALLHAT,[20] ACE inhibitors appeared to perform less well than diuretics in terms of incidence of combined cardiovascular disease and heart failure. On the other hand, the ANBP2 trial[35] seemed to suggest that ACE inhibitors may be equivalent to diuretics in terms of overall outcomes. Since there are legitimate criticisms of both these trials, it may only be safe to conclude that both diuretics and ACE inhibitors represent formidable agents as either first- or second-line hypertensive

therapies that effectively achieve a target blood pressure goal for most patients with or without comorbidities.

Although generally well-tolerated by most, classic side effects associated with ACE inhibitors include their potential to cause hyperkalemia and a persistent dry cough. Modest elevations in serum potassium should be anticipated. This is particularly true in patients with compromised renal function, those receiving concurrent NSAIDs, or those taking potassium supplementation. The elevations in potassium should be anticipated if not prospectively considered when starting or increasing the dose of an ACE inhibitor. Hyperkalemia is rarely a reason for discontinuation of this otherwise reasonably well-tolerated class of agents. Nonetheless, periodic monitoring of serum potassium is prudent for patients receiving ACE inhibitors.

Another effect of ACE inhibitors includes their propensity to cause a dry cough. This cough is thought to be caused by accumulation of bradykinin resulting from a direct effect of inhibiting ACE. It can be a troubling source of nonadherence to this class of agents. Although mild forms are tolerable, should cough become the source of poor compliance with the agent, ARBs should be considered as possible alternative agents. This is particularly true for patients in whom there is a need for RAAS inhibition.

In general, the effects of ACE inhibitors on diminished renal function and potassium can be predicted given an understanding of their pharmacologic actions (Fig. 2–3). Inhibition of the generation of angiotensin II through ACE inhibition (or direct blockage of the angiotensin II receptor by angiotensin II receptor blockers) naturally would reduce the efferent renal artery tone thereby changing the intraglomerular pressure. Although changes in the afferent renal artery tone also occur, the overall effects usually translate into a reduction in GFR[52] with resulting elevations of up to 30% in serum creatinine values. It is important to recognize that such elevations in serum creatinine are not usually indications to discontinue use of the ACE inhibitor. Rather, possible dose reduction and continued monitoring for further increases in serum creatinine remains prudent. Alternatively, should elevations in serum creatinine exceed 30%, discontinuation is prudent until further evaluation can be made.

More rare forms of adverse effects of ACE inhibitors include blood dyscrasias, angioedema, and more serious effects of ACE inhibitors on renal function such as acute renal failure in those with preexisting kidney dysfunction or renal artery stenosis. With incidences usually less than 1%, these adverse effects are rarely seen by many clinicians. Nonetheless, given their potential for serious consequences, they remain important to consider given the widespread use of ACE inhibitors for a variety of cardiovascular conditions. Specifically, the insidious nature of the development of neutropenia and agranulocytosis and the acute effects of lip and tongue swelling accompanying angioedema or acute renal failure in a patient with bilateral renal artery stenosis can have potentially life-threatening complications.

Angiotensin Receptor Blockers

ARBs are another key class of agents whose role in managing patients with hypertension has been further defined by recently completed studies. ARBs are inhibitors of the angiotensin-1 (AT1) receptors (Fig. 2–3). AT1 receptor stimulation evokes a pressor response via a host of accompanying effects on catecholamines, aldosterone, and thirst.[40] Consequently, inhibition of AT1 receptors directly prevents this pressor response and results in up-regulation of the RAAS. Up-regulation of the RAAS results in elevated levels of angiotensin II, which have the added effect of stimulating the angiotensin-2 (AT2) receptors. AT2-receptor stimulation is generally associated with antihypertensive activity; however, long-term effects of AT2-receptor stimulation that involve cellular growth and repair are relatively unknown. What is clear is that ARBs differ from ACE inhibitors in that the former cause up-regulation of the RAAS while the latter blocks the breakdown of bradykinin. The therapeutic relevance resulting from these pharmacologic differences has yet to be fully evaluated through long-term clinical comparative trials.

At this point, ARBs have emerged as an effective class of antihypertensives whose low incidence of side effects and demonstrated clinical role in patients with specific comorbidities have afforded them an attractive position in the antihypertensive armamentarium. Like ACE inhibitors, the antihypertensive effectiveness of ARBs is greatly enhanced by combining them with diuretics. Furthermore, they have proven their value as well-tolerated alternatives to ACE inhibitors for patients with chronic kidney disease, diabetes mellitus, and post–acute myocardial infarction (AMI) (Table 2–5). As of late, the addition of ARBs to standard therapy for patients with congestive heart failure (CHF), including ACE inhibitors, have demonstrated additional incremental benefits for patients with systolic dysfunction[54] or diastolic dysfunction[55] or as alternatives to ACE inhibitors when ACE inhibitors are not tolerated.[56] Comparative studies with alternate (non-ACE inhibitors) antihypertensive regimens in patients with type 2 diabetes[57,58] and left ventricular hypertrophy[59] have demonstrated their usefulness as effective antihypertensives in these special populations. Studies (the Irbesartan Diabetic Nephropathy Trial [IDNT] and Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan [RENAAL]) have demonstrated superiority of delaying progression toward renal dysfunction for ARBs relative to alternative antihypertensives in type 2 diabetics.[57,58] Their use in treatment of diabetic nephropathy and proteinuria in patients with type 2 diabetes mellitus and hypertension has been supported by their Food and Drug Administration (FDA) approval for use in this population and inclusion in national guidelines.[3] The Irbesartan in Patients with Type 2 Diabetes and Microalbuminuria (IRMA II)[60] study demonstrated the dose dependency of these outcomes in type 2 diabetics, while the IDNT study suggested a relative superiority over alternative antihypertensives, namely CCBAs. Although

Patient Encounter 2

JT, a 55-year-old African-American woman, comes to your clinic with a recent diagnosis of hypertension. She is 5′5″ (165 cm) tall and weighs 160 pounds (72.7 kg) with a body mass index (BMI) of 26.6 kg/m^2. JT does not use tobacco or drink alcohol, and exercises about once a week. Physical exam was unremarkable, but an electrocardiogram revealed left ventricular hypertrophy. Baseline laboratory tests were significant for fasting blood glucose of 124 mg/dL (6.88 mmol/L), serum creatinine of 1.5 mg/dL (133 mmol/L), total cholesterol of 200 mg/dL (5.18 mmol/L), high-density lipoprotein cholesterol of 40 mg/dL (1.04 mmol/L), triglycerides of 200 mg/dL (2.26 mmol/L), and low-density lipoprotein cholesterol of 120 mg/dL (3.11 mmol/L). Urinalysis was positive for microalbuminuria. Blood pressure today was 165/86 mm Hg.

- What signs of target organ damage does JT exhibit?
- Is more extensive testing for identifiable causes of hypertension indicated at this time?
- Based on the information presented, create a care plan for JT's hypertension. This should include (1) goals of therapy, (2) a patient-specific therapeutic plan, and (3) a plan for appropriate monitoring to achieve goals and avoid adverse effects.

better tolerated than ACE inhibitors, ARBs have not been shown to demonstrate superiority of outcomes relative to ACE inhibitors. This key observation, in addition to their relatively higher acquisition cost, has mitigated the growth of ARB use relative to ACE inhibitors.

Alpha-Blockers

Generally, α_1-blockers are considered as second-line agents to be added on to most other agents when hypertension is not adequately controlled. They may have a specific role in the antihypertensive regimen for elderly males with prostatism; however, their use is often curtailed by complaints of syncope, dizziness, or palpitations following the first dose and orthostatic hypotension with chronic use. The roles of doxazosin, terazosin, and prazosin in the management of patients with hypertension are limited due to the paucity of outcome data and the absence of a unique role for special populations or compelling indications from JNC 7.

Central Alpha2-Agonists

Also limited by their tendency to cause orthostasis, sedation, dry mouth, and vision disturbances, clonidine, methyldopa, and guanabenz represent rare choices in contemporary treatment of patients with hypertension. Their central α_2-adrenergic stimulation is thought to reduce sympathetic outflow and enhance parasympathetic activity thereby reducing heart rate, cardiac output, and total peripheral resistance. Occasionally used for cases of resistant hypertension, these agents may have a role when other more conventional therapies appear ineffective. The availability of a transdermal clonidine patch that is applied once weekly may offer an alternative to hypertensive patients with adherence problems.

Other Agents

Direct vasodilators such as hydralazine and minoxidil represent additional alternative agents used rarely for patients with resistant hypertension. Primarily acting to relax smooth muscles in arterioles and activate baroreceptors, use of these agents in the absence of concurrently administered β-blockers and diuretics is uncommon. This is due to the need to offset their tendency to cause reflex tachycardia and fluid retention. Other more rare adverse effects include hydralazine-induced lupus-like syndrome and hypertrichosis from minoxidil. Finally, reserpine, although slow to act, represents another rarely used alternative agent for those who are recalcitrant to more standard therapy. This agent is a long-acting depleter of the catecholamine norepinephrine, which causes reduced sympathetic tone leading to reductions in peripheral resistance. Reserpine's association with numerous side effects including gastric ulceration, depression, and sexual side effects has limited its usefulness in all but the more rare cases of patients with resistant hypertension. However, the Systolic Hypertension in the Elderly (SHEP) trial[61] demonstrated the blood pressure lowering effectiveness of reserpine (0.05 mg per day) when combined with a diuretic, and similar cardiopulmonary and psychosocial side effects between the treatment and placebo groups.

SPECIAL PATIENT POPULATIONS

Compelling Indications and Special Considerations

❾ *While the main goal of antihypertensive therapy is to achieve target blood pressures, the selection of agents for an individual should also account for certain special considerations and a patient's comorbidities. Specific antihypertensive therapy is warranted for certain patients with comorbid conditions that may elevate their level of risk for cardiovascular disease.* Clinical conditions for which there is compelling evidence supporting one or more classes of drug therapy include:[2]

- Ischemic heart disease
- Heart failure

- Diabetes
- Chronic kidney disease
- Cerebrovascular disease

Compelling indications for specific drug therapies are summarized in Table 2–5.[62] In patients with hypertension and chronic stable angina, β-blockers and long-acting calcium channel blockers are indicated due to their antihypertensive and antianginal effects.[2,63] In patients at high risk of ischemic heart disease, such as diabetic patients with additional cardiovascular risk factors or chronic coronary artery or vascular disease, ACE inhibitors are particularly useful in reducing the risk of cardiovascular events regardless of whether the patient carries a concurrent diagnosis of hypertension.[2,64,65]

β-Blockers and ACE inhibitors are also indicated for post–myocardial infarction for the reduction of cardiovascular morbidity and mortality, as are aldosterone antagonists, in post–myocardial infarction patients with reduced left ventricular systolic function and diabetes or signs and symptoms of heart failure.[2,48]

Patients with asymptomatic left ventricular systolic dysfunction and hypertension should be treated with β-blockers and ACE inhibitors. Those with heart failure secondary to left ventricular dysfunction and hypertension should be treated with drugs proven to also reduce the morbidity and mortality of heart failure, including β-blockers, ACE inhibitors, ARBs, aldosterone antagonists, and diuretics for symptom control as well as antihypertensive effect. In African-Americans with heart failure and left ventricular systolic dysfunction, combination therapy with nitrates and hydralazine not only affords a morbidity and mortality benefit, but may also be useful as antihypertensive therapy if needed.[66] The dihydropyridine calcium channel blockers amlodipine or felodipine may also be used in patients with heart failure and left ventricular systolic dysfunction for uncontrolled blood pressure, although they have no effect on heart failure morbidity and mortality in these patients.[49] For patients with heart failure and preserved ejection fraction, antihypertensive therapies that should be considered include β-blockers, ACE inhibitors, ARBs, calcium channel blockers (including nondihydropyridine agents), diuretics, and others as needed to control blood pressure.[2,49]

Patients with diabetes and hypertension should initially be treated with either β-blockers, ACE inhibitors, ARBs, diuretics, or calcium channel blockers. There is a general consensus that therapy focused on RAAS inhibition by ACE inhibitors or ARBs may be optimal if the patient has additional cardiovascular risk factors such as left ventricular hypertrophy or chronic kidney disease.[2,3,59,67]

In patients with chronic kidney disease and hypertension, ACE inhibitors and ARBs are preferred, usually in combination with a diuretic.[67] ACE inhibitors in combination with a thiazide diuretic are also preferred in patients with a history of prior stroke or transient ischemic attack. This therapy reduces the risk of recurrent stroke, making it particularly attractive in these patients for blood pressure control.[53]

There are several situations in the management of hypertension requiring special considerations including, but not limited to:

- Hypertensive crisis
- Elderly populations
- Isolated systolic hypertension
- Minority populations
- Pregnancy
- Pediatrics

Hypertensive crisis can be divided into hypertensive emergencies and hypertensive urgencies. A hypertensive emergency occurs when severe elevations in blood pressure are accompanied by acute or life-threatening target organ damage such as acute myocardial infarction, unstable angina, encephalopathy, intracerebral hemorrhage, acute left ventricular failure with pulmonary edema, dissecting aortic aneurysm, rapidly progressive renal failure, accelerated malignant hypertension with papilledema, and eclampsia among others. Blood pressure is generally greater than 220/140 mm Hg, although a hypertensive emergency can occur at lower levels, particularly in individuals without previous hypertension. The goal in a hypertensive emergency is to reduce mean arterial pressure by up to 25% to the range of 160/100 to 110 mm Hg in minutes to hours.[2,68] Intravenous therapy is generally required and may consist of the agents listed in Table 2–6.[62] A hypertensive urgency is manifested as a severe elevation in blood pressure without evidence of acute or life-threatening target organ damage. In these individuals, blood pressure can usually be managed with orally administered short-acting medications (i.e., captopril, clonidine, or labetalol) and observation in the emergency department over several hours, with subsequent discharge on oral medications and follow-up in the outpatient setting within 24 hours.[2,62]

The treatment of elderly patients with hypertension, as well as those with isolated systolic hypertension, should follow the same approach as with other populations with the exception that lower starting doses may be warranted to avoid symptoms and with special attention paid to postural hypotension. This should include a careful assessment of orthostatic symptoms, measurement of blood pressure in the upright position, and caution to avoid volume depletion and rapid titration of antihypertensive therapy.[2] In individuals with isolated systolic hypertension, the optimal level of diastolic pressure is not known, and although treated patients who achieve diastolic pressures less than 60 to 70 mm Hg had poorer outcomes in a landmark trial, their cardiovascular event rate was still lower than those receiving placebo.[69]

TABLE 2–6. Parenteral Antihypertensive Agents for Hypertensive Emergency[a]

Drug	Dose	Onset of Action	Duration of Action	Adverse Effects[b]	Special Indications
Vasodilators					
Sodium nitroprusside	0.25–10 mcg/kg/minute as IV infusion[c]	Immediate	1–2 minutes	Nausea, vomiting, muscle twitching, sweating, thiocyanate and cyanide intoxication	Most hypertensive emergencies; use with caution with high intracranial pressure or azotemia
Nicardipine hydrochloride	5–15 mg/hour IV	5–10 minutes	15–30 minutes, may exceed 4 hours	Tachycardia, headache, flushing, local phlebitis	Most hypertensive emergencies except acute heart failure; use with caution with coronary ischemia
Fenoldopam mesylate	0.1–0.3 mcg/kg/minute as IV infusion[c]	Less than 5 minutes	30 minutes	Tachycardia, headache, nausea, flushing	Most hypertensive emergencies; use with caution with glaucoma
Nitroglycerin	5–100 mcg/kg/minute as IV infusion	2–5 minutes	5–10 minutes	Headache, vomiting, methemoglobinemia, tolerance with prolonged use	Coronary ischemia
Enalaprilat	1.25–5 mg every 6 hours	15–30 minutes	6–12 hours	Precipitous fall in pressure in high-renin states; variable response	Acute left ventricular failure; avoid in acute myocardial infarction
Hydralazine hydrochloride	10–20 mg IV 10–40 mg IM	10–20 minutes 20–30 minutes	1–4 hours IV 4–6 hours IM	Tachycardia, flushing, headache, vomiting, aggravation of angina	Eclampsia
Adrenergic Inhibitors					
Labetalol hydrochloride	20–80 mg IV bolus every 10 minutes	5–10 minutes	3–6 hours	Vomiting, scalp tingling, dizziness, bronchoconstriction, nausea, heart block, orthostatic hypotension	Most hypertensive emergencies except acute heart failure
Esmolol hydrochloride	250–500 mcg/kg/minute IV bolus, then 50–100 mcg/kg/minute by infusion; may repeat bolus after 5 minutes or increase infusion to 300 mcg/minute	1–2 minutes	10–30 minutes	Hypotension, nausea, asthma, first-degree heart block, heart failure	Aortic dissection, perioperative
Phentolamine	5–15 mg IV bolus	1–2 minutes	10–30 minutes	Tachycardia flushing, headache	Catecholamine excess

IM, intramuscular; IV, intravenous.
[a]These doses may vary from those in the Physicians' Desk Reference (51st ed.).
[b]Hypotension may occur with all agents.
[c]Requires special delivery system.

Patient Encounter 3

DW, a 78-year-old Caucasian man, presents to the emergency room with complaints of a headache persisting over the last 3 days. Repeated blood pressure measurements average 200/110 mm Hg. He reports no other symptoms and physical examination and laboratory tests are unremarkable as is his past medical history with the exception of hypertension diagnosed in his early 60s. DW reports that he is struggling on a fixed retirement income with no prescription coverage and takes "what I can afford." Blood pressure medications are carvedilol 25 mg twice daily, amlodipine 10 mg once daily, torsemide (Demadex®) 10 mg once daily, and valsartan 320 mg once daily.

- What type of hypertensive crisis is DW experiencing?
- What are likely causes of DW's loss of blood pressure control?
- Create a care plan for DW's hypertensive crisis. This should include (1) acute goals of therapy, (2) a patient-specific therapeutic plan to achieve goals, and (3) a plan for appropriate outpatient follow-up including recommendations for changes, if any, to current medications.

TABLE 2–7. Treatment of Chronic Hypertension in Pregnancy[2]

Agent	Comments
Methyldopa	Preferred first-line therapy on the basis of long-term follow-up studies supporting safety after exposure in utero. Surveillance data do not support an association between drug and congenital defects when the mother took the drug early in the first trimester.
Labetalol	Increasingly preferred to methyldopa because of reduced side effects. The agent does not seem to pose a risk to the fetus, except possibly in the first trimester.
β-Blockers	Generally acceptable on the basis of limited data. Reports of intrauterine growth restriction with atenolol in the first and second trimesters.
Clonidine	Limited data; no association between drug and congenital defects when the mother took the drug early in the first trimester, but number of exposures is small.
Calcium antagonists	Limited data; nifedipine in the first trimester was not associated with increased rates of major birth defects, but animal data were associated with fetal hypoxemia and acidosis. This agent should probably be limited to mothers with severe hypertension.
Diuretics	Not first-line agents; probably safe; available data suggest that throughout gestation a diuretic is not associated with an increased risk of major fetal anomalies or adverse fetal-neonatal events.
Angiotensin-converting enzyme inhibitors and angiotensin II receptor antagonists	Contraindicated; reported fetal toxicity and death.

While the treatment approach of hypertension in minority populations is similar, special consideration should be paid to socioeconomic and lifestyle factors that may be important barriers to blood pressure control. In addition, in patients of African origin, diminished blood pressure responses have been seen with ACE inhibitors and ARBs compared to diuretics or calcium channel blockers.[2] Hypertension in pregnancy is a major cause of maternal, fetal, and neonatal morbidity and mortality. There are many categories of hypertension in pregnancy; however, preexisting hypertension and preeclampsia are treated differently. The therapeutic selection of an oral antihypertensive agent (Table 2–7) in a pregnant patient with chronic hypertension is determined with regard to fetal safety. Therapeutic options for acute severe hypertension in pre-eclampsia may be reviewed in JNC 7.[2]

Similar to the JNC 7 criteria (which has four stages for blood pressure classification in adults), the measurement of three or more blood pressures in children and adolescents are compared to tables listing the 90th, 95th, and 99th percentile blood pressures based on age, height, and gender that classify blood pressure as normal, prehypertension, and stage 1 and stage 2 hypertension (Table 2–1).[70] The prevalence of hypertension in adolescent populations is increasing and is associated with obesity, sedentary lifestyle, or a positive family history, which increases the risk of cardiovascular disease. The clinician should be aware that secondary causes are common in adolescent hypertension and the identification and aggressive modification of risk factors with nonpharmacologic and pharmacologic interventions is paramount for risk reduction of target organ damage. The 2004 National High Blood Pressure Education Program (NHBPEP) Working Group Report on Hypertension in Children and Adolescents has recommendations to modify and treat risk factors.[70] The Nelson Textbook of Pediatrics is also recommended for a comprehensive review of treatment of congenital and pediatric hypertension.[71]

PATIENT CARE AND MONITORING

⓾ *The frequency of follow-up visits for patients with hypertension will vary based on individual cases, but will be influenced by severity of hypertension, comorbidities, and choice of agent selected. However, generally speaking, assessment of response to medications may be prudent at 1-month intervals.*[2] *For patients with stage 2 hypertension or those with comorbidities (e.g., diabetes, vascular disease, CHF, or CKD) shorter time frames of 2 weeks or less may be more appropriate.*[51] Annual or semiannual monitoring for changes in serum biochemistries such as serum creatinine or potassium are recommended.[2] However, for patients with CHF, CKD, or diabetes, more frequent monitoring will be necessary to adequately control comorbid conditions. Another aspect to monitoring relates to the importance of medication adherence. Confirmation of continued use of antihypertensive medications should be considered in the routine monitoring of patients on numerous medications for hypertension. Evaluation of side effects, lab abnormalities, and/or progression to target organ damage should also be considered at appropriate intervals. Given the asymptomatic nature of hypertension, patient motivation to adhere to prescribed medications becomes a key tool in controlling hypertension.[2]

Given the chronic nature of hypertension, parsimony of medication regimens is a virtue of a good therapeutic plan. Minimizing the number of medications a patient is required to take has the potential to enhance adherence and mitigate cost. Often, control of blood pressure is achieved by use of two or even three or more antihypertensives.[20,72] Many combination products contain a diuretic as one of their active components. However, combination therapy may limit the ability of the clinician to titrate the dose of a specific agent. As such, the number of medications ("pill count") may often be reduced through use of combination products. This inherently simplifies the number of medications and co-pays a patient may have to endure to achieve effective blood pressure control. These practicalities, although obvious, go a long way to optimize compliance, another challenge to maximizing therapy effectiveness.

Patient Care and Monitoring

1. Measure patient blood pressure twice, at least 1 minute apart in a sitting position, and then average the readings to determine if blood pressure is adequately controlled.
2. Conduct a medical history. Does the patient have any compelling indications? Is the patient pregnant?
3. Conduct a medication history (prescription, over-the-counter, and dietary supplements) to determine conditions or causes of hypertension. Does the patient take any medications, supplements, herbal products, or foods that may elevate SBP or DBP? Does the patient have drug allergies?
4. Review available laboratory tests to examine electrolyte balance and renal function.
5. Discuss lifestyle modifications that may reduce blood pressure with the patient. Determine what non-pharmacologic approaches might be or have been helpful to the patient.
6. Evaluate the patient if pharmacologic treatment has reached the target blood pressure goal. If the patient is at the goal, skip to step 8.
7. If patient is not at goal BP, assess efficacy, safety, and compliance of the antihypertensive regimen to determine if a dose increase or additional antihypertensive agent (step 8) is needed to achieve goal blood pressure.
8. Select an agent to minimize adverse drug reactions and interactions when additional drug therapy is needed. Does the patient have prescription coverage or is the recommended agent in the formulary?
9. Open a dialogue to address patient concerns about hypertension and management of the condition.
10. Provide a plan to assess the effectiveness and safety of therapy. Follow-up in 2 to 4 weeks if the medication regimen has changed, otherwise semi-annual or annual clinic visits to assess blood pressure, electrolyte balance, and renal function should occur.

OUTCOME EVALUATION

- Short-term goals are to safely achieve reduction in blood pressure through the iterative process of employing drug therapy, along with non-drug therapy or lifestyle changes.
- Lifestyle changes should address other risk factors for cardiovascular disease including obesity, physical inactivity, insulin resistance, dyslipidemia, smoking cessation, and others.
- Monitoring for efficacy, adverse events, and adherence to therapy is key to achieving the long-term goals of reducing the risk of morbidity and mortality associated with cardiovascular disease.

3 Heart Failure

Orly Vardeny and Tien M. H. Ng

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Differentiate between the common underlying etiologies of heart failure, including ischemic, non-ischemic, and idiopathic causes.
2. Describe the pathophysiology of heart failure as it relates to neurohormonal activation of the renin-angiotensin-aldosterone system and the sympathetic nervous system.
3. Identify signs and symptoms of heart failure and classify a given patient by the New York Heart Association Functional Classification and American College of Cardiology/American Heart Association Heart Failure Staging.
4. Describe the goals of therapy for a patient with acute or chronic heart failure.
5. Develop a nonpharmacologic treatment plan which includes patient education for managing heart failure.
6. Develop a specific evidence-based pharmacologic treatment plan for a patient with acute or chronic heart failure based on disease severity and symptoms.
7. Formulate a monitoring plan for the nonpharmacologic and pharmacologic treatment of a patient with heart failure.

Key Concepts

❶ The most common causes of heart failure are coronary artery disease (CAD), hypertension, and dilated cardiomyopathy.

❷ Development and progression of heart failure involves activation of neurohormonal pathways, including the sympathetic nervous system and the renin-angiotensin-aldosterone system (RAAS).

❸ The clinician must identify potential reversible causes of heart failure exacerbations including prescription and nonprescription drug therapies, dietary indiscretions, and medication non-adherence.

❹ Symptoms of left-sided heart failure include dyspnea, orthopnea, and paroxysmal nocturnal dyspnea (PND), whereas symptoms of right-sided heart failure include fluid retention, gastrointestinal bloating, and fatigue.

❺ Therapeutic goals focus on alleviating symptoms, slowing or preventing disease progression, maintaining quality of life, and improving patient survival.

❻ Nonpharmacologic treatment involves dietary modifications such as sodium and fluid restriction, risk factor reduction including smoking cessation, timely immunizations, and supervised regular physical activity.

❼ Diuretics are used for relief of acute symptoms of congestion and maintenance of euvolemia.

❽ Agents with proven benefits in improving symptoms, slowing disease progression, and improving survival in chronic heart failure target neurohormonal blockade; these include angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs), β-adrenergic blockers, and aldosterone antagonists.

❾ Combination therapy with hydralazine and isosorbide dinitrate is an appropriate substitute for angiotensin II antagonism in those unable to tolerate an ACE inhibitor or ARB, or as add-on therapy in African-Americans.

❿ Treatment of acute heart failure targets relief of congestion and optimization of cardiac output utilizing oral or intravenous diuretics, intravenous vasodilators, and when appropriate, inotropes.

Heart failure (HF) is defined as the inadequate ability of the heart to pump enough blood to meet the blood flow and metabolic demands of the body.[1] High-output HF is characterized by an inordinate increase in the body's metabolic demands, which outpaces an increase in **cardiac output** (CO) of a generally normally functioning heart. More commonly, HF is a result of low CO secondary to impaired cardiac function. The term "heart failure" will refer to low-output HF for purposes of this chapter.

Heart failure is a clinical syndrome characterized by a history of specific signs and symptoms related to congestion and hypoperfusion. As HF can occur in the presence or absence of fluid overload, the term "heart failure" is preferred over the former term "congestive heart failure." Heart failure results from any structural or functional cardiac disorder that impairs the ability of the ventricle to fill with or eject blood.[1] Many disorders such as those of the pericardium, epicardium, endocardium, or great vessels may lead to HF, but most patients develop symptoms due to impairment in left ventricular (LV) myocardial function.

The phrase "acute heart failure" (AHF) is used to signify either an acute decompensation of a patient with a history of chronic heart failure or to refer to a patient presenting with new-onset HF symptoms. Terms commonly associated with HF, such as cardiomyopathy and LV dysfunction, are not equivalent to HF but describe possible structural or functional reasons for the development of HF.

EPIDEMIOLOGY AND ETIOLOGY

Epidemiology

Heart failure is a major public health concern affecting approximately five million people in the United States. An additional 550,000 new cases are diagnosed each year. Heart failure manifests most commonly in adults over the age of 60.[2] The growing prevalence of HF corresponds to: (1) better treatment of patients with acute myocardial infarctions (MIs) who will survive to develop HF later in life, and (2) the increasing proportion of older adults due to the aging "baby boomer" population. The relative incidence of HF is lower in women compared to men, but there is a greater prevalence in women overall due to their longer life expectancy. Acute heart failure accounts for 12 to 15 million office visits per year and 6.5 million hospitalizations annually.[2] According to national registries, patients presenting with AHF are older (mean age 75 years) and have numerous comorbidities such as CAD, renal insufficiency, and diabetes.[2]

Total estimated direct and indirect costs for managing both chronic and acute HF in the United States for 2005 was approximately $27.9 billion. Medications account for approximately 10% of that cost.[3] Heart failure is the most common hospital discharge diagnosis for Medicare patients and is the most costly diagnosis in this population.

The prognosis for patients hospitalized for AHF remains poor. Average hospital length of stay is estimated to be between 4 to 6 days, a number which has remained constant over the past decade.[3] The in-hospital mortality rate has been estimated at approximately 4%, but ranges from 2% to 20% depending on the report.[4] In-hospital mortality increases to an average of 10.6% in patients requiring an intensive care unit admission. Readmissions are also high, with up to 30% to 60% of patients readmitted within 6 months of their initial discharge date.[4] The 5-year mortality rate for chronic HF remains greater than 50%. Survival strongly correlates with severity of symptoms and functional capacity. Sudden cardiac death is the most common cause of death, occurring in approximately 40% of patients with HF.[2] Although therapies targeting the up-regulated neurohormonal response contributing to the pathophysiology of HF have clearly impacted morbidity and mortality, long-term survival remains low.

Etiology

Heart failure is the eventual outcome of numerous cardiac diseases or disorders (Table 3–1).[5] Heart failure can be classified by the primary underlying etiology as ischemic or non-ischemic, with 70% of HF related to ischemia. ❶ *The most common causes of HF are CAD, hypertension, and dilated cardiomyopathy*. Coronary artery disease resulting in an acute MI and reduced ventricular function is a common presenting history. Non-ischemic etiologies include hypertension, viral illness, thyroid disease, excessive alcohol use, illicit drug use, pregnancy-related heart disease, familial congenital disease, and valvular disorders such as mitral or tricuspid valve regurgitation or stenosis.

TABLE 3–1. Causes of Heart Failure

Systolic Dysfunction (Decreased Contractility)
- Reduction in muscle mass (e.g., myocardial infarction)
- Dilated cardiomyopathies
- Ventricular hypertrophy
  - Pressure overload (e.g., systemic or pulmonary hypertension, aortic or pulmonic valve stenosis)
  - Volume overload (e.g., valvular regurgitation, shunts, high-output states)

Diastolic Dysfunction (Restriction in Ventricular Filling)
- Increased ventricular stiffness
- Ventricular hypertrophy (e.g., hypertrophic cardiomyopathy, other examples above)
- Infiltrative myocardial diseases (e.g., amyloidosis, sarcoidosis, endomyocardial fibrosis)
- Myocardial ischemia and infarction
- Mitral or tricuspid valve stenosis
- Pericardial disease (e.g., pericarditis, pericardial tamponade)

From Parker RB, Patterson JH, Johnson JA. Heart failure. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 220, with permission.

Heart failure can also be classified based on the main component of the cardiac cycle leading to impaired ventricular function. A normal cardiac cycle is dependent on two components: systole and diastole. Expulsion of blood occurs during systole or contraction of the ventricles, while diastole relates to filling of the ventricles. **Ejection fraction** (EF) is the fraction of the volume present at the end of diastole that is pushed into the aorta during systole. Abnormal ventricular filling (**diastolic dysfunction**) and/or ventricular contraction (**systolic dysfunction**) can result in a similar decrease in CO and cause HF symptoms. Most HF is associated with evidence of LV systolic dysfunction (evidenced by a reduced EF) with or without a component of diastolic dysfunction, which coexists in up to two-thirds of patients. Isolated diastolic dysfunction, occurring in approximately one-third of HF patients, is diagnosed when a patient exhibits impaired ventricular filling with or without accompanying HF symptoms but normal systolic function. Long-standing hypertension is the leading cause of diastolic dysfunction. Ventricular dysfunction can also involve either the left or right chamber of the heart or both. This has implications for symptomatology, as right-sided failure manifests as systemic congestion whereas left-sided failure results in pulmonary symptoms.

PATHOPHYSIOLOGY

A basic grasp of normal cardiac function sets the stage for understanding the pathophysiologic processes leading to HF and selecting appropriate therapy for HF. Cardiac output is defined as the volume of blood ejected per unit of time (liters per minute) and is a major determinant of tissue perfusion. Cardiac output is the product of heart rate (HR) and stroke volume (SV): $CO = HR \times SV$. The following describes how each parameter relates to CO.

Heart rate is controlled by the autonomic nervous system, where sympathetic stimulation of β-adrenergic receptors results in an increase in HR and CO. Stroke volume is the volume of blood ejected with each systole. Stroke volume is determined by factors regulating preload, afterload, and contractility. **Preload** is a measure of ventricular filling pressure, or the volume of blood in the left ventricle (also known as LV end-diastolic volume). Preload is determined by venous return as well as atrial contraction. An increase in venous return to the left ventricle results in the stretch of cardiomyocyte sarcomeres (or contractile units) and a subsequent increase in the number of cross-bridges formed between actin and myosin myofilaments. This results in an increase in the force of contraction based on the **Frank-Starling mechanism**.[6] **Afterload** is the resistance to ventricular ejection and is regulated by ejection impedence, wall tension, and regional wall geometry. Thus, elevated aortic and systemic pressures result in an increase in afterload and reduced SV. Contractility, also known as the **inotropic** state of the heart, is an intrinsic property of cardiac muscle incorporating fiber shortening and tension development. Contractility is influenced to a large degree by adrenergic nerve activity and circulating catecholamines such as epinephrine and norepinephrine.

Compensatory Mechanisms

In the setting of a sustained loss of myocardium, a number of mechanisms aid the heart when faced with an increased hemodynamic burden and reduced CO. They include the following: the Frank-Starling mechanism, tachycardia and increased afterload, and cardiac hypertrophy and remodeling (Table 3–2).[5,7]

Preload and the Frank-Starling Mechanism

In the setting of a sudden decrease in CO, the natural response of the body is to decrease blood flow to the periphery in order to maintain perfusion to the vital organs such as the heart and brain. Therefore, renal perfusion is compromised due to both the decreased CO, as well as shunting of blood away from peripheral tissues. This results in activation of the renin-angiotensin-aldosterone system (RAAS). The decrease in renal perfusion is sensed by the juxtaglomerular cells of the kidneys leading to the release of renin and initiation of the cascade for production of angiotensin II. Angiotensin II stimulates the synthesis and release of aldosterone, which stimulates sodium and water retention in an attempt to increase intravascular volume and hence preload. In a healthy heart, a large increase in CO is usually accomplished with just a small change in preload. However, in a failing heart, alterations in the contractile filaments reduce the ability of cardiomyocytes to adapt to increases in preload. Thus, an increase in preload actually impairs contractile function in the failing heart and results in a further decrease in CO.

Tachycardia and Increased Afterload

Another mechanism to maintain CO when contractility is low is to increase heart rate. This is achieved through sympathetic nervous system (SNS) activation and the agonist effect of norepinephrine on β-adrenergic receptors in the heart. Sympathetic activation also enhances contractility by increasing cytosolic calcium concentrations. SV is relatively fixed in HF, thus HR becomes the major determinant of CO. Although this mechanism increases CO acutely, the **chronotropic** and inotropic responses to sympathetic activation increase myocardial oxygen demand, worsen underlying ischemia, contribute to proarrhythmia, and further impair both systolic and diastolic function.

Activation of both the RAAS and the SNS also contribute to vasoconstriction in an attempt to redistribute blood flow from peripheral organs such as the kidneys to coronary and cerebral circulation.[7] However, arterial vasoconstriction leads to impaired forward ejection of blood from the heart due to an increase in afterload. This results in a decrease in CO and continued stimulation of compensatory responses, creating a vicious cycle of neurohormonal activation.

TABLE 3–2. Beneficial and Detrimental Effects of the Compensatory Responses in Heart Failure

Compensatory Response	Beneficial Effects of Compensation	Detrimental Effects of Compensation
Increased preload (through sodium and water retention)	Optimize stroke volume via Frank-Starling mechanism	Pulmonary and systemic congestion and edema formation Increased MVO_2
Vasoconstriction	Maintain blood pressure and perfusion in the face of reduced cardiac output	Increased MVO_2 Increased afterload decreases stroke volume and further activates the compensatory responses
Tachycardia and increased contractility (due to SNS activation)	Increase cardiac output	Increased MVO_2 Shortened diastolic filling time β_1-Receptor down-regulation, decreased receptor sensitivity Precipitation of ventricular arrhythmias Increased risk of myocardial cell death
Ventricular hypertrophy and remodeling	Maintains cardiac output Reduces myocardial wall stress Decreases MVO_2	Diastolic dysfunction Systolic dysfunction Increased risk of myocardial cell death Increased risk of myocardial ischemia Increased arrhythmia risk

MVO_2, myocardial oxygen consumption; SNS, sympathetic nervous system.

Cardiac Hypertrophy and Remodeling

Ventricular hypertrophy, an adaptive increase in ventricular muscle mass due to growth of existing myocytes, occurs in response to an increased hemodynamic burden such as volume or pressure overload.[5] Hypertrophy can be concentric or eccentric. Concentric hypertrophy occurs in response to pressure overload such as in long-standing hypertension or pulmonary hypertension, whereas eccentric hypertrophy occurs after an acute myocardial infarction. Eccentric hypertrophy involves an increase in myoctye size in a segmental fashion, as opposed to the global hypertrophy occurring in concentric hypertrophy. Although hypertrophy helps to reduce cardiac wall stress in the short term, continued hypertrophy accelerates myocyte cell death through an overall increase in myocardial oxygen demand.

Cardiac remodeling occurs as a compensatory adaptation to a change in wall stress and is largely regulated by neurohormonal activation, with angiotensin II and aldosterone being key stimuli.[7] The process entails changes in myocardial and extracellular matrix composition and function which results in both structural and functional alterations to the heart. In HF, the changes in cardiac size, shape, and composition are pathologic and detrimental to heart function. In addition to myocyte size and extracellular matrix changes, heart geometry shifts from an elliptical to a less efficient spherical shape. Even after remodeling occurs, the heart can maintain CO for many years. However, heart function will continue to deteriorate until progression to clinical HF. The timeline for remodeling varies depending on the cardiac insult. For example, in the setting of an acute MI, remodeling starts within a few days.[5] Chronic remodeling, however, is what progressively worsens HF and therefore is a major target of drug therapy.

Models of Heart Failure

Earlier models of HF focused on the hemodynamic consequences of volume overload from excess sodium and water retention, decreased CO secondary to impaired ventricular function, and vasoconstriction.[8] Congestion was a result of fluid backup due to inadequate pump function. Therefore, drug therapy was focused on relieving excess volume using diuretics, improving pump function with inotropic agents, and alleviating vasoconstriction with vasodilators. Although these agents improved HF symptoms, they did little to slow the progressive decline in cardiac function or to improve survival.

Neurohormonal Model

❷ *Development and progression of HF involves activation of neurohormonal pathways including the sympathetic nervous system and the renin-angiotensin-aldosterone system (RAAS).* This model begins with an initial precipitating event or myocardial injury resulting in a decline in CO, followed by the compensatory mechanisms previously discussed. This includes activation of neurohormonal pathways with pathologic consequences including the RAAS, SNS, endothelin and vasopressin, and those with counterregulatory properties such as the natriuretic peptides and nitric oxide. This model currently guides our therapy for chronic HF in terms of preventing disease progression and mortality.

Angiotensin II

Angiotensin II is a key neurohormone in the pathophysiology of HF. The vasoconstrictive effects of angiotensin II lead to an increase in systemic vascular resistance (SVR) and blood pressure. The resulting increase in afterload contributes to an increase in myocardial oxygen demand and opposes the desired increase in SV. In the kidneys, angiotensin II enhances renal function acutely by raising intraglomerular pressure through constriction of the efferent arterioles.[6] However, the increase in glomerular filtration pressure may be offset by a reduction in renal perfusion secondary to angiotensin II's influence over the release of other vasoactive neurohormones such as vasopressin and endothelin-1 (ET-1). Angiotensin II also potentiates the release of aldosterone from the adrenal glands and norepinephrine from adrenergic nerve terminals. Additionally, angiotensin II induces vascular hypertrophy and remodeling in both cardiac and renal cells. Clinical studies show that blocking the effects of the RAAS in HF is associated with improved cardiac function and prolonged survival. Thus, angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are the cornerstone of HF treatment.

Aldosterone

Aldosterone's contribution to HF pathophysiology is also multifaceted. Renally, aldosterone causes sodium and water retention in an attempt to enhance intravascular volume and CO. This adaptive mechanism has deleterious consequences since excessive sodium and water retention worsen the already elevated ventricular filling pressures. Aldosterone also contributes to electrolyte abnormalities seen in HF patients. Hypokalemia and hypomagnesemia contribute to the increased risk of arrhythmias. In addition, evidence supports the role of aldosterone as an etiologic factor for myocardial fibrosis and cardiac remodeling.[6] Elevated aldosterone concentrations have been associated with more severe cardiac disease and a poorer prognosis in HF. Thus, aldosterone antagonism has become an important therapeutic target for improvement of long-term prognosis.

Norepinephrine

Norepinephrine is a classic marker for SNS activation. It plays an adaptive role in the failing heart by stimulating HR and myocardial contractility to augment CO and by producing vasoconstriction to maintain organ perfusion. However, excess levels are directly cardiotoxic. In addition, sympathetic activation increases the risk for arrhythmias, ischemia, and myocyte cell death through increased myocardial workload and accelerated **apoptosis** (i.e., programmed cell death). Ventricular hypertrophy and remodeling are also influenced by norepinephrine.[8]

Plasma norepinephrine concentrations are elevated proportionally to HF severity, with highest levels correlating to the poorest prognosis. Several mechanisms relate to diminished responsiveness to catecholamines (e.g., norepinephrine) as cardiac function declines.[6] Adrenergic receptor desensitization and **down-regulation** (decreased receptor number and post-receptor responses and signaling) occurs under sustained sympathetic stimulation. The desensitization contributes to further release of norepinephrine.[5] β-Adrenergic blocking agents, although intrinsically negatively inotropic, have become an essential therapy for chronic HF.

Endothelin

Endothelin-1, one of the most potent physiologic vasoconstrictors, is an important contributor to HF pathophysiology.[9] Endothelin-1 binds to two G-protein coupled receptors, endothelin-A (ET-A) and endothelin-B (ET-B). Endothelin-A receptors mediate vasoconstriction and are prevalent in vascular smooth muscle and cardiac cells. Endothelin-B receptors are expressed on the endothelium and in vascular smooth muscle, and receptor stimulation mediates vasodilation. Levels of ET-1 correlate with HF functional class and mortality.

Arginine Vasopressin

Higher vasopressin concentrations are linked to dilutional hyponatremia and a poor prognosis in HF. Vasopressin exerts its effects through vasopressin type 1a (V_{1a}) and vasopressin type 2 (V_2) receptors.[5,7] Vasopressin type 1a stimulation leads to vasoconstriction, while actions on the V_2 receptor cause free water retention through aquaporin channels in the collecting duct. Vasopressin increases preload, afterload, and myocardial oxygen demand in the failing heart.

Counterregulatory Hormones (Natriuretic Peptides, Bradykinin, and Nitric Oxide)

Atrial natriuretic peptide (ANP) and B-type (formerly brain) natriuretic peptide (BNP) are endogenous neurohormones that regulate sodium and water balance. Natriuretic peptides decrease sodium reabsorption in the collecting duct of the kidney.[10] Natriuretic peptides also cause vasodilation through the cyclic guanosine monophosphate (cGMP) pathway. Atrial natriuretic peptide is synthesized and stored in the atria, while BNP is produced mainly in the ventricles. Release of ANP and BNP is stimulated by increased cardiac chamber wall stretch usually indicative of volume load. Higher concentrations of natriuretic peptides correlate with a more severe HF functional class and prognosis. BNP is sensitive to volume status; thus, the plasma concentration can be used as a diagnostic marker in HF.[10]

Bradykinin is part of the kallikrein-kinin system, which shares a link to the RAAS through angiotensin-converting enzyme. Bradykinin is a vasodilatory peptide that is released in response to a variety of stimuli, including neurohormonal and inflammatory mediators known to be activated in HF.[9] As a

consequence, bradykinin levels are elevated in HF patients and thought to partially antagonize the vasoconstrictive peptides.

Nitric oxide, a vasodilatory hormone released by the endothelium, is found in higher concentrations in HF patients and provides two main benefits in HF: vasodilation and neurohormonal antagonism of endothelin.[9] Nitric oxide's production is affected by the enzyme inducible nitric oxide synthetase (iNOS), which is up-regulated in the setting of HF, likely due to increased levels of angiotensin II, norepinephrine, and multiple cytokines. In HF, the physiologic response to nitric oxide appears to be blunted, which contributes to the imbalance between vasoconstriction and vasodilation.

Cardiorenal Model

There is growing evidence of a link between renal disease and HF.[8] Renal insufficiency is present in one-third of HF patients and is associated with a worse prognosis. In hospitalized HF patients, the presence of renal insufficiency is associated with longer lengths of stay, increased in-hospital morbidity and mortality, and detrimental neurohormonal alterations. Conversely, renal dysfunction is a common complication of HF or results from its treatment. Renal failure is also a common cause for HF decompensation.

Proinflammatory Cytokines

Inflammatory cytokines have been implicated in the pathophysiology of HF.[9] Several proinflammatory (e.g., tumor necrosis factor-α [TNF-α], interleukin-1, interleukin-6, and interferon-γ) and anti-inflammatory cytokines (e.g., interleukin-10) are overexpressed in the failing heart. The most is known about TNF-α, a pleiotrophic cytokine that acts as a negative inotrope, stimulates cardiac cell apoptosis, uncouples β-adrenergic receptors from adenylyl cyclase, and is related to **cardiac cachexia**. The exact role of cytokines and inflammation in HF pathophysiology continues to be studied.

Precipitating and Exacerbating Factors in Heart Failure

Heart failure patients exist in one of two clinical states. When a patient's volume status and symptoms are stable, their HF condition is said to be "compensated." In situations of volume overload or other worsening symptoms, the patient is considered "decompensated." Acute decompensation can be precipitated by numerous etiologies that can be grouped into cardiac, metabolic, or patient-related causes (Table 3–3).[5]

❸ *The clinician must identify potential reversible causes of HF exacerbations including prescription and non-prescription drug therapies, dietary indiscretions, and medication non-adherence. Non-adherence with dietary restrictions or chronic HF medications deserves special attention, as it is the most common cause of acute decompensation and can be prevented. As such, an accurate history regarding diet, food choices, and the patient's knowledge regarding sodium and fluid intake (including alcohol) is valuable in assessing dietary indiscretion.* Non-adherence with medical recommendations such as laboratory and other appointment follow-up can also be indicative of non-adherence with diet or medications.

TABLE 3–3. Exacerbating or Precipitating Factors in Heart Failure

Cardiac	Metabolic	Patient-Related
Acute ischemia	Anemia	Dietary/fluid non-adherence
Arrhythmia	Hyperthyroidism/ thyrotoxicosis	HF therapy non-adherence
Endocarditis	Infection	Use of cardiotoxins (cocaine, chronic alcohol, amphetamines, sympathomimetics)
Myocarditis	Pregnancy	Offending medications (NSAIDs, COX-2 inhibitors, steroids, lithium, β-blockers, calcium channel blockers, anti-arrhythmics, alcohol, thiazolidinediones)
Pulmonary embolus	Worsening renal function	
Uncontrolled hypertension		
Valvular disorders		

COX-2, cyclooxygenase-2; HF, heart failure; NSAID, non-steroidal anti-inflammatory drug.

Patient Encounter, Part 1

BE is a 62-year-old female with a history of known coronary artery disease and type 2 diabetes mellitus who presents for a belated follow-up clinic visit (her last visit was 2 years ago). She states that she used to be able to walk over one-half mile (0.8 km) and two flights of stairs before experiencing chest pain and becoming short of breath. Since her last visit, she has had increasing symptoms and has now progressed to shortness of breath (SOB) with walking only half a block and doing chores around the house. She also notes her ankles are always swollen and her shoes no longer fit, therefore she only wears slippers. Additionally, her appetite is decreased, and she often feels bloated. She also feels full after eating only a few bites of each meal.

- What information is suggestive of a diagnosis of heart failure?
- What additional information do you need to know before creating a treatment plan for BE?

CLINICAL PRESENTATION AND DIAGNOSIS OF CHRONIC HEART FAILURE

In low-output HF, symptoms are generally related to either congestion behind the failing ventricle(s), or hypoperfusion (decreased tissue blood supply), or both. Congestion is the most common symptom in HF, followed by symptoms related to decreased perfusion to peripheral tissues including decreased renal output, mental confusion, and cold extremities. Activation of the compensatory mechanisms occurs in an effort to increase CO and preserve blood flow to vital organs. However, the increase in preload and afterload in the setting of a failing ventricle leads to elevated filling pressures and further impairment of cardiac function, which manifests as systemic and/or pulmonary congestion. It is important to remember that congestion develops behind the failing ventricle, caused by the inability of that ventricle to eject the blood that it receives from the atria and venous return. As such, signs and symptoms may be classified as left-sided or right-sided. ❹ *Symptoms of left-sided HF include dyspnea,* ***orthopnea****, and paroxysmal nocturnal dyspnea (PND), whereas symptoms of right-sided HF include fluid retention, gastrointestinal bloating, and fatigue. Although most patients initially have left ventricular failure (LVF; pulmonary congestion), the ventricles share a septal wall, and because LVF increases the workload of the right ventricle, both ventricles eventually fail and contribute to the HF syndrome. Because of the complex nature of this syndrome, it has become exceedingly more difficult to attribute a specific sign or symptom as caused by either right ventricular failure (RVF; systemic congestion) or LVF. Therefore, the numerous signs and symptoms associated with this disorder are collectively attributed to HF rather than to dysfunction of a specific ventricle.*

General Signs and Symptoms

Hypoperfusion of skeletal muscles leads to fatigue, weakness, and exercise intolerance. Decreased perfusion of the central nervous system (CNS) is related to confusion, hallucinations, insomnia, and lethargy. Peripheral vasoconstriction due to SNS activity causes pallor, cool extremities, and cyanosis of the digits. Tachycardia is also common in these patients and may reflect increased SNS activity. Patients will often exhibit **polyuria** and **nocturia**. Polyuria is a result of increased release of natriuretic peptides caused by volume overload. Nocturia occurs due to increased renal perfusion as a consequence of reduced SNS renal vasoconstrictive effects at night. In chronic severe HF, unintentional weight loss can occur which leads to a syndrome of cardiac cachexia. This results from several factors, including loss of appetite, malabsorption due to gastrointestinal edema, elevated metabolic rate, and elevated levels of proinflammatory cytokines.

Clinical Presentation and Diagnosis of Heart Failure

General

Patient presentation may range from asymptomatic to cardiogenic shock.

Symptoms

- Dyspnea, particularly on exertion
- Orthopnea
- Shortness of breath (SOB)
- Paroxysmal nocturnal dyspnea
- Exercise intolerance
- Tachypnea
- Cough
- Fatigue
- Nocturia and/or polyuria
- Hemoptysis
- Abdominal pain
- Anorexia
- Nausea
- Bloating
- Ascites
- Mental status changes
- Weakness
- Lethargy

Signs

- Pulmonary rales
- Pulmonary edema
- S_3 gallop
- Pleural effusion
- **Cheyne-Stokes respiration**
- Tachycardia
- Cardiomegaly
- Peripheral edema (e.g., pedal edema, which is swelling of feet and ankles)
- Jugular venous distension (JVD)
- **Hepatojugular reflex** (HJR)
- Hepatomegaly
- Cyanosis of the digits
- Pallor or cool extremities

Laboratory Tests

- BNP greater than 100 pg/mL (greater than 100 ng/L) or N-terminal proBNP (NT-proBNP) greater than 300 pg/mL (greater than 300 ng/L or greater than 35.4 pmol/L)
- Electrocardiogram (ECG): May be normal or could show numerous abnormalities including acute ST-T–wave changes from myocardial ischemia, atrial fibrillation, bradycardia, and LV hypertrophy.
- Serum creatinine: May be increased owing to hypoperfusion; preexisting renal dysfunction can contribute to volume overload.
- Complete blood count: Useful to determine if heart failure is due to reduced oxygen-carrying capacity.
- Chest x-ray: Useful for detection of cardiac enlargement, pulmonary edema, and pleural effusions.
- Echocardiogram: Used to assess LV size, valve function, pericardial effusion, wall motion abnormalities, and ejection fraction.

Patients can experience a variety of symptoms related to buildup of fluid in the lungs. Dyspnea, or shortness of breath, can result from pulmonary congestion or systemic hypoperfusion due to LVF. Exertional dyspnea occurs when patients describe breathlessness induced by physical activity or a lower level of activity than previously known to cause breathlessness. Patients often state that activities such as stair climbing, carrying groceries, or walking a particular distance cause shortness of breath. Severity of HF is inversely proportional to the amount of activity required to produce dyspnea. In severe HF, dyspnea will be present even at rest.

Orthopnea is dyspnea that is positional. Orthopnea is present if a patient is unable to breathe while lying flat on a bed (i.e., in the recumbent position). It manifests within minutes of a patient lying down and is relieved immediately when the patient sits upright. Patients can relieve orthopnea by elevating their head and shoulders with pillows. The practitioner should inquire as to the number of pillows needed to prevent dyspnea as a marker of worsening HF. Paroxysmal nocturnal dyspnea occurs when patients awaken suddenly with a feeling of breathlessness and suffocation. Paroxysmal nocturnal dyspnea is caused by increased venous return and mobilization of interstitial fluid from the extremities, leading to alveolar edema and usually occurs within 1 to 4 hours of sleep. In contrast to orthopnea, PND is not relieved immediately by sitting upright and often takes up to 30 minutes for symptoms to subside.

Pulmonary congestion may also cause a non-productive cough that occurs at night or with exertion. Cheyne-Stokes respiration, or periodic breathing, is common in advanced HF. It is usually associated with low-output states and may be perceived by the patient as either severe dyspnea or transient cessation of breathing. In cases of pulmonary edema, the most severe form of pulmonary congestion, patients may produce a pink, frothy sputum and experience extreme breathlessness and anxiety due to feelings of suffocation and drowning. If not treated aggressively, patients can become cyanotic and acidotic. Severe pulmonary edema can progress to respiratory failure, necessitating mechanical ventilation.

Systemic venous congestion results mainly from right ventricular failure. A clinically validated assessment of the jugular venous pressure (JVP) is performed by examining the right internal jugular vein for distention or elevation of the pulsation while reclining at a 45 degree angle. A JVP more than 4 cm above the sternal angle is indicative of elevated right atrial pressure. Jugular venous pressure may be normal at rest, but if application of pressure to the abdomen can elicit a sustained elevation of JVP, this is defined as hepatojugular reflux (HJR). A positive finding of HJR indicates hepatic congestion and results from displacement of volume from the abdomen into the jugular vein because the right atrium is unable to accept this additional blood. Hepatic congestion can cause abnormalities in liver function, which can be evident in liver function tests and/or clotting times. Development of hepatomegaly occurs infrequently and is caused by long-term systemic venous congestion. Intestinal or abdominal congestion can also be present, but usually doesn't lead to characteristic signs unless overt ascites is evident. In advanced RVF, evidence of pulmonary hypertension may be present (e.g., right ventricular heave).

The most recognized finding of systemic congestion is peripheral edema. It usually occurs in dependent areas of the body, such as the ankles (pedal edema) for ambulatory patients, or the sacral region for bedridden patients. Weight gain often precedes signs of overt peripheral edema. Therefore, it is crucial for patients to weigh themselves daily even in the absence of symptoms to assess fluid status.

Patients may complain of swelling of their feet and ankles, which can extend up to their calves or thighs. Abdominal congestion may cause a bloated feeling, abdominal pain, early satiety, nausea, anorexia, and constipation. Often patients may have difficulty fitting into their shoes or pants due to edema.

Patient History

A thorough history is crucial to identify cardiac and non-cardiac disorders or behaviors that may lead to or accelerate the development of HF. Past medical history, family history, and social history are important for identifying comorbid illnesses that are risk factors for the development of HF or underlying etiologic factors. A complete medication history (including prescription and non-prescription drugs, herbal therapy, and vitamin supplements) should be obtained each time a patient is seen to evaluate adherence, to assess appropriateness of therapy, to eliminate drugs that may be harmful in HF (Table 3–4), and to determine additional monitoring requirements. For newly

TABLE 3–4. Drugs That May Precipitate or Exacerbate Heart Failure

Agents Causing Negative Inotropic Effect
Antiarrhythmics (e.g., disopyramide, flecainide, and others)
β-Blockers (e.g., propranolol, metoprolol, atenolol, and others)
Calcium channel blockers (e.g., verapamil and others)
Itraconazole
Terbinafine
Rosiglitazone
Cardiotoxic Agents
Doxorubicin
Daunomycin
Cyclophosphamide
Agents Causing Sodium and Water Retention
Non-steroidal anti-inflammatory drugs
COX-2 inhibitors
Glucocorticoids
Androgens
Estrogens
Salicylates (high-dose)
Sodium-containing drugs (e.g., carbenicillin disodium, ticarcillin disodium)
Thiazolidinediones (e.g., rosiglitazone, pioglitazone)

COX-2, cyclooxygenase-2.

diagnosed HF, previous use of chemotherapeutic agents as well as current or past use of alcohol and illicit drugs should be assessed. In addition, for patients with a known history of HF, questions related to symptomatology and exercise tolerance are essential for assessing any changes in clinical status that may warrant further evaluation or adjustment of the medication regimen.

Heart Failure Classification

There are two common systems for categorizing patients with HF. The New York Heart Association (NYHA) Functional Classification (FC) system is based on the patient's activity level and exercise tolerance. It divides patients into one of four classes, with functional class I patients exhibiting no symptoms or limitations of daily activities, and functional class IV patients who are symptomatic at rest (Table 3–5). The NYHA FC system reflects a subjective assessment by a health care provider and can change frequently over short periods of time. Functional class correlates poorly with EF; however, EF is one of the strongest predictors of prognosis. In general, anticipated survival declines in conjunction with a decline in functional ability.

The American College of Cardiology/American Heart Association (ACC/AHA) has proposed another system based on the development and progression of the disease. Instead of classifications, patients are placed into stages A through D (Table 3–5).[11] Stage A encompasses patients who carry risk factors for the development of HF, such as CAD, hypertension, and diabetes mellitus. Stage B includes high-risk patients with documented structural heart disease (LV hypertrophy or impaired LV function). Stage C denotes patients with current or past symptoms of HF and underlying structural heart disease. Stage D is reserved for those with refractory or end-stage HF in whom special interventions may be indicated, such as mechanical circulatory support. Since the staging system is related to development and progression of HF, it also proposes management strategies for each stage including risk factor modification. The staging system is meant to complement the NYHA FC system; however, patients can move between NYHA functional classes as symptoms improve with treatment, whereas HF staging does not allow for patients to move to a lower stage (e.g., patients cannot be categorized as stage C and move to stage B after treatment). Currently, patients are categorized based on both systems. Functional classification and staging are useful from a clinician's perspective, allowing for a longitudinal assessment of a patient's risk and progress, requirements for nonpharmacologic interventions, response to medications, and overall prognosis.

TABLE 3–5. New York Heart Association (NYHA) Functional Classification and American College of Cardiology/American Heart Association (ACC/AHA) Staging

NYHA Functional Class	ACC/AHA Stage	Description
N/A	A	Patients at high risk for heart failure but without structural heart disease or symptoms of heart failure.
I	B	Patients with cardiac disease but without limitations of physical activity. Ordinary physical activity does not cause undue fatigue, dyspnea, or palpitation.
II	C	Patients with cardiac disease that results in slight limitations of physical activity. Ordinary physical activity results in fatigue, palpitations, dyspnea, or angina.
III	C	Patients with cardiac disease that results in marked limitation of physical activity. Although patients are comfortable at rest, less than ordinary activity will lead to symptoms.
IV	C, D	Patients with cardiac disease that results in an inability to carry on physical activity without discomfort. Symptoms of heart failure are present at rest. With any physical activity, increased discomfort is experienced. Stage D refers to end-stage heart failure patients.

Patient Encounter, Part 2

BE's Medical History, Physical Exam, and Diagnostic Tests

PMH
Type 2 diabetes mellitus × 15 years
Coronary artery disease × 10 years (MIs in 1999 and 2002)
Tobacco use
History of back surgery in 2001

Allergies
No known drug allergies

Meds
Diltiazem CD 240 mg once daily
Nitroglycerin 0.4 mg sublingual (SL) as needed (last use yesterday after showering)
Ibuprofen 600 mg twice daily for arthritis pain
Vitamin B_{12} once daily
Multivitamin daily
Aspirin 325 mg once daily

FH
Significant for early heart disease in father (MI at age 53)

SH
She is disabled from a previous accident; she is married, has 6 children, and runs her own business; she does not drink alcohol and smokes one to two packs of cigarettes per day.

PE
Blood pressure 126/70 mm Hg, pulse 60 bpm and regular, respiratory rate 16/minute, Ht 5′8″ (173 cm), Wt 251 lb (114 kg), body mass index (BMI): 38.2 kg/m^2

(*Continued*)

Patient Encounter, Part 2 (*Continued*)

Lungs are clear to auscultation with a prolonged expiratory phase; rales are present bilaterally

CV: Regular rate and rhythm with normal S_1 and S_2; there is an S_3 and a soft S_4 present; there is a 2/6 systolic ejection murmur heard best at the left lower sternal border; point of maximal impulse is within normal limits at the midclavicular line; there is no JVD

Abd: Soft, non-tender, and bowel sounds are present; 2+ pitting edema of extremities extending to below the knees is observed

Chest x-ray: Bilateral pleural effusions and cardiomegaly

Echocardiogram: EF = 35%

Laboratory Values

Hct: 41.1%	WBC: $5.3 \times 10^3/\mu L$ ($5.3 \times 10^9/L$)
Sodium: 132 mEq/L (132 mmol/L)	Potassium: 3.2 mEq/L (3.2 mmol/L)
Bicarb: 30 mEq/L (30 mmol/L)	Chloride: 90 mEq/L (90 mmol/L)
Magnesium: 1.5 mEq/L (0.8 mmol/L)	Fasting blood sugar: 120 mg/dL (6.7 mmol/L)
Uric acid: 8 mg/dL (476 µmol/L)	Blood urea nitrogen (BUN): 40 mg/dL (14 mmol/L)
SCr: 0.8 mg/dL (71 µmol/L)	Alk Phos: 120 IU/L (2 µKat/L)

Aspartate aminotransferase: 100 IU/L (1.7 µKat/L)

- What other laboratory or other diagnostic tests are required for assessment of BE's condition?
- How would you classify BE's NYHA functional class and ACC/AHA heart failure stage?
- Identify exacerbating or precipitating factors that may worsen BE's heart failure.
- What are your treatment goals for BE?

TREATMENT OF CHRONIC HEART FAILURE

Desired Therapeutic Outcomes

There is no cure for HF. ❺ *The general management goals for chronic HF include preventing the onset of clinical symptoms or reducing symptoms, preventing or reducing hospitalizations, slowing progression of the disease, improving quality of life, and prolonging survival.* The ACC/AHA staging system described earlier provides a guide for application of these goals based on the clinical progression of HF for a given patient. The goals are additive as one moves from stage A to stage D.[1,11] For stage A, risk factor management is the primary goal. Stage B includes the addition of pharmacologic therapies known to slow the progression of the disease in an attempt to prevent the onset of clinical symptoms. Stage C involves the use of additional therapies aimed at controlling symptoms and decreasing morbidity. Finally, in stage D, the goals shift toward quality-of-life related issues. Only with aggressive management throughout all the stages of the disease will the ultimate goal of improving survival be realized. The attainment of these goals is based on designing a therapeutic approach that encompasses strategies aimed at control and treatment of contributing disorders, nonpharmacologic interventions, and optimal use of pharmacologic therapies.[12,13]

Control and Treatment of Contributing Disorders

All causes of HF must be investigated to determine the etiology of cardiac dysfunction in a given patient. Since the most common etiology of HF in the United States is ischemic heart disease, coronary angiography is warranted in the majority of patients with a history suggestive of underlying CAD. Revascularization of those with significant CAD may help restore some cardiac function in patients with reversible ischemic defects. Aggressive control of hypertension, diabetes, and obesity is also essential since each of these conditions can cause further cardiac damage. Surgical repair of valvular disease or congenital malformations may be warranted if detected. Since clinical HF is partly dependent on metabolic processes, correction of imbalances such as thyroid disease and anemia is required. Other more rare causes such as autoimmune disorders or acquired illnesses may have specific treatments. Identifying and discontinuing medications that can exacerbate HF is also an important intervention.

Nonpharmacologic Interventions

It is imperative that patients recognize the role of self-management in HF. ❻ *Nonpharmacologic treatment involves dietary modifications such as sodium and fluid restriction, risk factor reduction including smoking cessation, timely immunizations, and supervised regular physical activity. Patient education regarding monitoring symptoms, dietary and medication adherence, exercise and physical fitness, risk factor reduction, and immunizations are important for prevention of AHF exacerbations.*

Patients should be encouraged to become involved in their own care through several avenues, the first of which is self-monitoring. A general explanation of symptoms associated with HF should be included at the initiation of treatment. Home monitoring should include daily assessment of weight and exercise tolerance. Daily weights should be done first thing in the morning upon arising and before any food intake to maintain consistency. Patients should record their weight daily in a journal and bring this log to each clinic or office visit. Changes in weight can indicate fluid retention and congestion prior to onset of peripheral or pulmonary symptoms. Individuals who have an increase of 2 to 3 pounds (0.91 to 1.36 kg) in a single day or 5 pounds (2.27 kg) over 5 days should be referred to their HF care provider. Some patients may be educated about self-adjusting diuretic doses based on daily weights.

In addition to weight changes, a marked decline in exercise tolerance should also be reported to the HF care provider.

Non-adherence is an important issue as it relates to acute exacerbations of HF. Ensuring an understanding of the importance of each medication used to treat HF, proper administration, and potential adverse effects may improve adherence. Stressing the rationale for each medication is important, especially for NYHA FC I or ACC/AHA stage B patients who are asymptomatic, yet started on drugs that may worsen symptoms initially. A clinician's involvement in emphasizing medication adherence, offering adherence suggestions such as optimal timing of medications or use of weekly pill containers, and providing intensive follow-up care has been shown to reduce AHF hospitalizations.

Dietary modifications in HF consist of initiation of an AHA step II diet as part of cardiac risk factor reduction, sodium restriction, and sometimes fluid restriction. As sodium and water retention is a compensatory mechanism that contributes to volume overload in HF, salt and fluid restriction is often necessary to help avoid or minimize congestion. The normal American diet includes 3 to 6 grams of sodium per day. Most patients with HF should limit salt intake to a maximum of 2 grams per day. Patients should be educated to avoid cooking with salt and to limit intake of foods with high salt content, such as fried or processed food (lunchmeats, soups, cheeses, salted snack foods, canned food, and some ethnic food). Salt restriction can be challenging for many patients. The clinician should assess a patient's salt consumption habits and counsel to restrict salt slowly over time. Drastic dietary changes may lead to nonadherence due to an unpalatable diet. Substituting spices to flavor food is a useful recommendation. Salt substitutes should be used judiciously, as many contain large amounts of potassium which can increase the risk of hyperkalemia. Fluid restriction may not be necessary in many patients. When applicable, a general recommendation is to limit fluid intake from all sources to less than 2 liters per day.

Exercise, while discouraged when the patient is acutely decompensated to ease cardiac workload, is recommended when patients are stable. The heart is a muscle that requires activity to prevent atrophy. In addition, exercise improves peripheral muscle conditioning and efficiency, which may contribute to better exercise tolerance despite the low CO state. Regular low intensity, aerobic exercise that includes walking, swimming, or riding a bike is encouraged, while heavy weight training is discouraged. The prescribed exercise regimen needs to be tailored to the individual's functional ability, and thus it is suggested that patients participate in cardiac rehabilitation programs, at least initially. It is important that patients not overexert themselves to fatigue or exertional dyspnea.

Modification of classic risk factors, such as tobacco and alcohol consumption, is important to minimize the potential for further aggravation of heart function. Data from observational studies suggest that patients with HF who smoke have a mortality rate 40% higher than those who do not consume tobacco products.[1] All HF patients who smoke should be counseled on the importance of tobacco cessation and offered a referral to a cessation program. Patients with an alcoholic cardiomyopathy should abstain from alcohol. Whether all patients with other forms of HF should abstain from any alcohol intake remains controversial. Proponents of moderation of alcohol base their rationale on the potential cardioprotective effects. However, opponents to any alcohol intake point out that alcohol is cardiotoxic and should be avoided.

In general, it is suggested that patients remain up to date on standard immunizations. Patients with HF should be counseled to receive yearly influenza vaccinations. Additionally, a pneumococcal vaccine is recommended. Usually only one pneumonia vaccination is necessary unless a patient is vaccinated before age 65. In that case, a booster vaccination is suggested 5 years after the initial vaccination.

Pharmacologic Treatment

In addition to determining therapeutic goals, the ACC/AHA staging system delineates specific therapy options based on disease progression.[1,11] For patients in stage A, every effort is made to minimize the impact of diseases that can injure the heart. Antihypertensive and lipid-lowering therapies should be utilized when appropriate to decrease the risk for stroke, MI, and HF. ACE inhibitors should be considered in high-risk vascular disease patients. For stage B patients, the goal is to prevent or slow disease progression by interfering with neurohormonal pathways that lead to cardiac damage and mediate pathologic remodeling. The goal is to prevent the onset of HF symptoms. The backbone of therapy in these patients includes ACE inhibitors or ARBs and β-blockers. In stage C patients with symptomatic LV systolic dysfunction (EF less than 40%), the goals focus on alleviating fluid retention, minimizing disability, slowing disease progression, and reducing long-term risk for hospitalizations and death. Treatment entails a strategy that combines diuretics to control intravascular fluid balance with neurohormonal antagonists to minimize the effects of the RAAS and SNS. Aldosterone antagonists and digoxin are often added as cardiac function continues to decline. Patients with advanced stage D disease are offered more modest goals, such as improvement in quality of life. Enhancing quality of life is often achieved at the expense of expected survival. Treatment options include mechanical support, transplantation, and continuous use of intravenous vasoactive therapies, in addition to maintaining an optimal regimen of chronic oral medications.

Diuretics

Diuretics have been the mainstay for HF symptom management for many years. ❼ *Diuretics are used for relief of acute symptoms of congestion and maintenance of euvolemia.* These agents interfere with sodium retention by increasing urinary sodium and free water excretion. No prospective data exist on the effects of diuretics on patient outcomes.[14] Therefore, the

primary rationale for the use of diuretic therapy is to maintain euvolemia in symptomatic or stages C and D heart failure. Diuretic therapy is recommended for all patients with clinical evidence of fluid overload retention.[15,16] In more mild HF, diuretics may be used on an as-needed basis. However, once the development of edema is persistent, regularly scheduled doses will be required.

Two types of diuretics are used for volume management in HF: thiazides and loop diuretics. Thiazide diuretics such as hydrochlorothiazide, chlorthalidone, and metolazone block sodium and chloride reabsorption in the distal convoluted tubule. Thiazides are weaker than loop diuretics in terms of effecting an increase in urine output and therefore are not utilized frequently as monotherapy in HF. They are optimally suited for patients with hypertension who have mild congestion. Additionally, the action of thiazides is limited in patients with renal insufficiency (creatinine clearance less than 30 mL/minute) due to reduced secretion into their site of action. An exception is metolazone, which retains its potent action in patients with renal dysfunction. Metolazone is often used in combination with loop diuretics when patients exhibit diuretic resistance, defined as edema unresponsive to loop diuretics alone.

Loop diuretics are the most widely used diuretics in HF. These agents, including furosemide, bumetanide, and torsemide, exert their action at the thick ascending loop of Henle. Loop diuretics are not filtered through the glomerulus, but instead undergo active transport into the tubular lumen via the organic acid pathway. As a result, drugs that compete for this active transport (e.g., probenecid and organic by-products of uremia) can lower efficacy of loop diuretics. Loop diuretics increase sodium and water excretion and induce a prostaglandin-mediated increase in renal blood flow which contributes to their natriuretic effect. Unlike thiazides, they retain their diuretic ability in patients with poor renal function. The various loop diuretics are equally effective when used at equipotent doses, although there are intrinsic differences in pharmacokinetics and pharmacodynamics (Table 3–6).[5] The choice of which loop diuretic to use and the route of administration depends on clinical factors, such as presence of intestinal edema and rapidity of desired effect. Oral diuretic efficacy may vary based on differing bioavailability, which is almost complete for torsemide and bumetanide, but averages only 50% for furosemide. Therefore, oral torsemide can be considered an alternative to the intravenous route of administration for patients who do not respond to oral furosemide in the setting of profound edema. The onset of effect is slightly delayed after oral administration but occurs within a few minutes with intravenous dosing. Consequently, bioequivalent doses of intravenous furosemide are half the oral dose, whereas bumetanide and torsemide intravenous doses are generally equivalent to the oral doses.

In patients with evidence of mild to moderate volume overload, diuretics should be initiated at a low dose and titrated to achieve a weight loss of up to 2 pounds (0.91 kg) per day. Patients with severe volume overload should be managed in an inpatient setting. Once diuretic therapy is initiated, dosage adjustments are based on symptomatic improvement and daily body weight. As body weight changes are a sensitive marker of fluid retention or loss, patients should continue to weigh themselves daily. Once a patient reaches a euvolemic state, diuretics may be cautiously tapered and then withdrawn in appropriate patients. In stable, educated, and compliant patients, another option is self-adjusted diuretic dosing. Based on daily body weight, patients may temporarily increase their diuretic regimen in order to reduce the incidence of overt edema. This also avoids overuse of diuretics and possible complications of over-diuresis such as hypotension, fatigue, and renal impairment.

TABLE 3–6. Loop Diuretics Used in Heart Failure

	Furosemide	Bumetanide	Torsemide
Usual daily dose (oral)	20–160 mg	0.5–4 mg	10–80 mg
Ceiling dose:			
Normal renal function	80–160 mg	1–2 mg	20–40 mg
CrCL 20–50 mL/minute	160 mg	2 mg	40 mg
CrCL less than 20 mL/minute	400 mg	8–10 mg	100 mg
Bioavailability	10–100% (average 50%)	80–90%	80–100%
Affected by food	Yes	Yes	No
Half-life	0.3–3.4 hours	0.3–1.5 hours	3–4 hours

CrCL, creatinine clearance.

The maximal response to diuretics is reduced in HF, creating a "ceiling dose" above which there is limited added benefit. This diuretic resistance is due to a compensatory increase in sodium reabsorption in the proximal and distal tubules, which decreases the effect of blocking sodium reabsoption in the loop of Henle.[17] In addition, there is a simultaneous increase in the reabsorption of sodium from the proximal tubule, allowing less to reach the site of action for loop diuretics. Apart from increasing diuretic doses, strategies to improve diuretic efficacy include increasing the frequency of dosing to two or three times daily, utilizing a continuous infusion of a loop diuretic, and/or combining a loop diuretic with a thiazide diuretic.[17,18] The latter strategy theoretically prevents sodium and water reabsorption at both the loop of Henle and the compensating distal convoluted tubule. Metolazone is used most often for this purpose, as it retains its activity in settings of a low creatinine clearance. Metolazone can be dosed daily or as little as once weekly. This combination is usually maintained until the patient reaches his or her baseline weight.

Diuretics cause numerous adverse effects and metabolic abnormalities, with severity linked to diuretic potency. A particularly worrisome adverse effect in the setting of HF is

hypokalemia. Low serum potassium can predispose patients to arrhythmias and sudden death. Hypomagnesemia often occurs concomitantly with diuretic-induced hypokalemia, and therefore both should be assessed and replaced in patients needing correction of hypokalemia. Magnesium is an essential co-factor for movement of potassium intracellularly to restore body stores. Patients taking diuretics are also at risk for renal insufficiency due to overdiuresis and reflex activation of the renin-angiotensin system. The potential reduction in renal blood flow and glomerular pressure is amplified by concomitant use of ACE inhibitors or ARBs.

Neurohormonal Blocking Agents

❽ *Agents with proven benefits in improving symptoms, slowing disease progression, and improving survival in chronic HF target neurohormonal blockade. These include ACE inhibitors, ARBs, β-adrenergic blockers, and aldosterone antagonists.*

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors are the cornerstone of treatment for HF. ACE inhibitors decrease neurohormonal activation by blocking the conversion of angiotensin I (AT_1) to angiotensin II (AT_2), a potent mediator of vasoconstriction and cardiac remodeling. The breakdown of bradykinin is also reduced. Bradykinin enhances the release of vasodilatory prostaglandins and histamines. These effects result in arterial and venous dilatation, and a decrease in myocardial workload through reduction of both preload and afterload. ACE inhibitors demonstrate favorable effects on cardiac hemodynamics, such as long-term increases in **cardiac index** (CI), stroke work index, and SV index, as well as significant reductions in LV filling pressure, SVR, mean arterial pressure, and HR.

There is extensive clinical experience with ACE inhibitors in systolic HF. Numerous clinical studies show ACE inhibitor therapy is associated with improvements in clinical symptoms, exercise tolerance, NYHA functional class, LV size and function, and quality of life as compared with placebo.[18–21] ACE inhibitors significantly reduce hospitalization rates and mortality regardless of underlying disease severity or etiology. ACE inhibitors are also effective in preventing HF development in high-risk patients. Studies in acute MI patients show a reduction in new-onset HF and death with ACE inhibitors whether they are initiated early (within 36 hours) or started later. In addition, ACE inhibition decreases the risk of HF hospitalization and death in patients with asymptomatic LV dysfunction. The exact mechanisms for decreased HF progression and mortality are postulated to involve both the hemodynamic improvement and the inhibition of angiotensin II's growth promoting and remodeling effects. All patients with documented LV systolic dysfunction, regardless of existing HF symptoms, should receive ACE inhibitors unless a contraindication or intolerance is present.

There is no evidence to suggest that one ACE inhibitor is preferred over another. ACE inhibitors should be initiated using low doses and titrated up to target doses over several weeks depending on tolerability (adverse effects and blood pressure). The ACC/AHA 2005 guidelines advocate using the doses that were proven to decrease mortality in clinical trials as the target doses (Table 3–7).[1] If the target dose cannot be attained in a given patient, the highest tolerated dose should be used chronically. Although there is incremental benefit with higher doses of ACE inhibitors, it is accepted that lower doses provide substantial if not the majority of the effect.[22] Since ACE inhibitors are only one component of a mortality-reducing treatment plan in HF, targeting a high ACE inhibitor dose should not interfere with starting a β-blocker or aldosterone antagonist. Specifically, higher ACE inhibitor dosing may accentuate the hypotensive effects. Higher ACE inhibitor dosing may also limit tolerability of a regimen which also includes β-blockers and aldosterone antagonists.

Despite their clear benefits, ACE inhibitors are still underutilized in HF. One reason is undue concern or confusion regarding absolute versus relative contraindications for their use. Absolute contraindications include a history of angioedema, bilateral renal artery stenosis, and pregnancy. Relative contraindications include unilateral renal artery stenosis, renal insufficiency, hypotension, hyperkalemia, and cough. Relative contraindications provide a warning that close monitoring is required, but they do not necessarily preclude their use.

Clinicians are especially concerned about the use of ACE inhibitors in patients with renal insufficiency. It is important to recognize that ACE inhibitors can potentially contribute to preservation or decline in renal function depending on the clinical scenario. Through preferential efferent arteriole vasodilation, ACE inhibitors can reduce intraglomerular pressure. Reduced glomerular pressures are renoprotective chronically; however, in situations of reduced or fixed renal blood flow, this leads to a reduction in filtration. In general, ACE inhibitors can be used in patients with serum creatinine less than 2.5 to 3 mg/dL (221 to 265 μmol/L). In HF, their addition can result in improved renal function through an increase in CO and renal perfusion. Some data suggest that ACE inhibitors are especially beneficial in those with renal dysfunction. Although a small increase in serum creatinine (less than 0.5 mg/dL [44 μmol/L]) is possible with the addition of an ACE inhibitor, it is usually transient or becomes the patient's new serum creatinine baseline level. However, ACE inhibition can also worsen renal function since glomerular filtration is maintained in the setting of reduced CO through angiotensin II's constriction of the efferent arteriole. Patients most dependent on angiotensin II for maintenance of glomerular filtration pressure, and hence most susceptible to ACE inhibitor worsening of renal function, include those with hyponatremia, severely depressed LV function, or dehydration. It is important to note that the most common reason for creatinine elevation in a patient without a history of renal dysfunction is overdiuresis. Therefore, clinicians should consider decreasing or holding diuretic doses if an elevation in serum creatinine occurs concomitantly with a rise in blood urea nitrogen.

TABLE 3–7. Dosing and Monitoring for Neurohormonal Blocking Agents

Drug	Initial Daily Dose	Target or Maximum Daily Dose	Monitoring
ACE Inhibitors			
Captopril	6.25 mg 3 times	50 mg 3 times	BP
Enalapril	2.5 mg twice	10–20 mg twice	Electrolytes (K^+, BUN, SCr) at baseline, 2 weeks, and after dose titration, CBC periodically
Fosinopril	5–10 mg once	40 mg once	
Lisinopril	2.5–5 mg once	20–40 mg once	
Perindopril	2 mg once	8–16 mg once	
Quinopril	5 mg once	20 mg twice	Adverse effects: cough, angioedema
Ramipril	1.25–2.5 mg once	10 mg once	
Trandolapril	1 mg once	4 mg once	
Angiotensin Receptor Blockers			
Candesartan	4–8 mg once	32 mg once	BP
Losartan	25–50 mg once	50–100 mg once	Electrolytes (K^+, BUN, SCr) at baseline, 2 weeks, and after dose titration, CBC periodically
Valsartan	20–40 mg once	160 mg twice	Adverse effects: cough, angioedema
Aldosterone Antagonists			
Spironolactone	12.5–25 mg once	25 mg once or twice	BP
Eplerenone	25 mg once	50 mg once	Electrolytes (K^+) at baseline and within 1 week of initiation and dose titration
			Adverse effects: gynecomastia or breast tenderness, menstrual changes, hirsutism
β-Blockers			
Bisoprolol	1.25 mg once	10 mg once	BP, HR baseline and after each dose titration, ECG
Carvedilol	3.125 mg twice	25 mg twice (50 mg twice for patients greater than 85 kg or 187 lbs)	Adverse effects: worsening HF symptoms (edema, SOB, fatigue), depression, sexual dysfunction
Metoprolol succinate	12.5–25 mg once	200 mg once	

BP, blood pressure; BUN, blood urea nitrate; CBC, complete blood cell count; ECG, electrocardiogram; HF, heart failure; HR, heart rate; K^+, potassium; SCr, serum creatinine; SOB, shortness of breath.

Hypotension occurs commonly at the initiation of therapy or with dosage increases but may happen anytime during therapy. Hypotension can manifest as dizziness, lightheadedness, presyncope, or syncope. The risk of hypotension due to possible volume depletion increases when ACE inhibitors are initiated or used concomitantly in patients on high diuretic doses. Therefore, in euvolemic patients, diuretic doses may often be decreased or withheld during ACE inhibitor dose titration. Initiating at a low dose and titrating slowly can also minimize hypotension. It may be advisable to initiate therapy with a short-acting ACE inhibitor, such as captopril, and subsequently switch to a longer-acting agent, such as lisinopril or enalapril, once the patient is stabilized.

Hyperkalemia results from reduced angiotensin II–stimulated aldosterone release. The risk of hyperkalemia with ACE inhibitors is also increased in HF due to a propensity for impaired renal function and additive effects with aldosterone antagonists. To minimize hyperkalemia, patients should be counseled to avoid foods high in potassium such as certain salt substitutes. ACE inhibitor dose may need to be decreased or held if serum potassium increases above 5 mEq/L (5 mmol/L). Persistent hyperkalemia in the setting of renal insufficiency may preclude the use of an ACE inhibitor.

Cough is commonly seen with ACE inhibitors (5% to 15%) and may be related to accumulation of tissue bradykinins.[5] It can be challenging to distinguish an ACE inhibitor–induced cough from cough caused by pulmonary congestion. A productive or wet cough usually signifies congestion, whereas a dry, hacking cough is more indicative of a drug-related etiology. If a cough is determined to be ACE inhibitor–induced, its

severity should be evaluated before deciding on a course of action. If the cough is truly bothersome, a trial with a different ACE inhibitor or switching to an ARB is warranted.

Angiotensin Receptor Blockers

Angiotensin receptor blockers selectively antagonize the effects of angiotensin II directly at the AT_1 receptor. AT_1 receptor stimulation is associated with vasoconstriction, release of aldosterone, and cellular growth promoting effects, while angiotensin receptor type 2 (AT_2) stimulation causes vasodilation. By selectively blocking AT_1 but leaving AT_2 unaffected, ARBs block the detrimental AT_1 effects on cardiac function while allowing AT_2-mediated vasodilation and inhibition of ventricular remodeling. Angiotensin receptor blockers are considered an equally effective replacement for ACE inhibitors in patients who are intolerant or have a contraindication to an ACE inhibitor.

It was hoped that the more complete blockade of angiotensin II's AT_1 effects would confer greater long-term efficacy with ARBs compared to ACE inhibitors. However, prospective, randomized trials suggest that the clinical efficacy of ARBs is similar to that of ACE inhibitors for reduction of hospitalizations for HF, sudden cardiac death, and all cause mortality.[23–25] Despite poorer suppression of AT_2, comparable efficacy of ACE inhibitors may be due to the additional effects on the kallikrein-kinin system. Although ARBs produce hemodynamic and neurohormonal effects similar to those of ACE inhibitors, they are considered second-line therapy due to the overwhelming clinical trial experience with ACE inhibitors.

Since the mechanism for long-term benefit appears different for ACE inhibitors and ARBs, the combination has been studied for additive benefits. One study evaluated the addition of the ARB candesartan versus placebo in three distinct groups of HF patients: systolic dysfunction intolerant to an ACE inhibitor, systolic dysfunction currently on ACE inhibitor therapy, and patients with preserved systolic function.[25] Candesartan reduced the combined incidence of cardiovascular death and hospitalization for HF in all three groups, with the greatest benefit being seen in those not on an ACE inhibitor. Candesartan significantly decreased mortality compared to placebo when all three groups were combined. Based on this study, the addition of an ARB to ACE inhibitor therapy can be considered in patients with evidence of disease progression despite optimal ACE inhibitor therapy.[1] This study also demonstrates the importance of having some form of angiotensin II antagonism as part of a treatment regimen.

Angiotensin receptor blockers show similar tolerability to ACE inhibitors with regard to hypotension and hyperkalemia, but they do not induce cough since ARBs do not cause an accumulation of bradykinin. Angiotensin receptor blockers can be considered in patients with ACE inhibitor–induced angioedema, but they should be initiated cautiously, as cross-reactivity has been reported. Many of the other considerations for the use of ARBs are similar to those of ACE inhibitors, including the need for monitoring renal function, blood pressure, and potassium. Bilateral renal artery stenosis is an absolute contraindication to ARB therapy unless it has been corrected. Neither ACE inhibitors nor ARBs should be used in patients who are pregnant or actively trying to become pregnant because of associated teratogenicity. In patients truly intolerant or contraindicated to ACE inhibitors or ARBs, the combination of hydralazine and isosorbide dinitrate should be considered.

Hydralazine and Isosorbide Dinitrate

Complementary hemodynamic actions originally led to the combination of nitrates with hydralazine. Nitrates reduce preload by causing primarily venous vasodilation through activating guanylate cyclase and a subsequent increase in cyclic guanosine monophosphate (cGMP) in vascular smooth muscle. Hydralazine reduces afterload through direct arterial smooth muscle relaxation via an unknown mechanism. More recently, nitric oxide has been implicated in modulating numerous pathophysiologic processes in the failing heart, including inflammation, cardiac remodeling, and oxidative damage. Supplementation of nitric oxide via administration of nitrates has also been proposed as a mechanism for benefit from this combination therapy. The beneficial effect of an external nitric oxide source may be more apparent in the African-American population, which appears to be predisposed to having an imbalance in nitric oxide production. In addition, hydralazine may reduce the development of nitrate tolerance when nitrates are given chronically.

The combination of hydralazine and isosorbide dinitrate was the first therapy shown to improve long-term survival in patients with systolic HF, but has largely been supplanted by angiotensin II antagonist therapy (ACE inhibitors and ARBs).[27,28] Therefore, until recently, this combination therapy was reserved for patients intolerant to ACE inhibitors or ARBs secondary to renal impairment, angioedema, or hyperkalemia. New insight into the pathophysiologic role of nitric oxide has reinvigorated research into this combination therapy.

The nitrate-hydralazine combination was first shown to improve survival compared to placebo.[27] Subsequently, the combination of isosorbide dinitrate 40 mg and hydralazine 75 mg, both given four times daily, was compared to the ACE inhibitor enalapril.[28] Enalapril produced a 28% greater decrease in mortality. Therefore, the combination is considered a third-line vasodilatory option for patients truly intolerant of ACE inhibitors and ARBs.

More recently, the value of adding the combination of isosorbide dinitrate 40 mg and hydralazine 75 mg three times daily to therapy including ACE inhibitors, β-blockers, digoxin, and diuretics was evaluated in a prospective, randomized trial.[26] The study enrolled only African-American patients and demonstrated a significant reduction in mortality, as well as first hospitalization for HF. Quality-of-life scores were also improved over placebo. ❾ *Combination therapy with hydralazine and isosorbide dinitrate is an appropriate substitute for angiotensin II antagonism*

in those unable to tolerate an ACE inhibitor or ARB or as add-on therapy in African-Americans. The ACC/AHA HF guidelines now recommend considering the addition of isosorbide dinitrate and hydralazine in African-Americans already on ACE inhibitors or ARBs.[1] Combination therapy with isosorbide dinitrate and hydralazine should be initiated and titrated as are other neurohormonal agents such as ACE inhibitors and β-blockers. Low doses are used to initiate therapy with subsequent titration of the dose toward target doses based on tolerability. Adverse effects such as hypotension and headache cause frequent discontinuations in patients taking this combination, and full doses often cannot be tolerated. Patients should be monitored for headache, hypotension, and tachycardia. Hydralazine is also associated with a dose-dependent risk for lupus.

The frequent dosing of isosorbide dinitrate (e.g. 3–4 times daily) is not conducive to patient adherence; therefore, a once-daily isosorbide mononitrate is commonly substituted for isosorbide dinitrate to simplify the dosing regimen. A nitrate-free interval is still required when using nitrates for HF.

Beta-Adrenergic Antagonists

Beta-adrenergic antagonists, or β-blockers, competitively block the influence of the SNS at β-adrenergic receptors. As recently as 15 years ago, β-adrenergic blockers were thought to be detrimental in HF due to their negative inotropic actions, which could potentially worsen symptoms and cause acute decompensations. Since then, the benefits of inhibiting the SNS have been recognized as far outweighing the acute negative inotropic effects. Chronic β-blockade reduces ventricular mass, improves ventricular shape, and reduces LV end-systolic and diastolic volumes.[6,8] β-Blockers also exhibit antiarrhythmic effects, slow or reverse catecholamine-induced ventricular remodeling, decrease myocyte death from catecholamine-induced necrosis or apoptosis, and prevent myocardial fetal gene expression. Consequently, β-blockers improve EF, reduce all-cause and HF-related hospitalizations, and decrease all-cause mortality in patients with systolic HF.[29–33]

The ACC/AHA recommends that β-blockers be initiated in all patients with NYHA FC I to IV or ACC/AHA stages B through D heart failure if clinically stable.[1] To date, only three β-blockers have been shown to reduce mortality in systolic HF, including the selective β_1-antagonists bisoprolol and metoprolol succinate, and the non-selective β_1-, β_2-, and α_1-antagonist carvedilol.[29–33] The positive findings should not be extrapolated to be indicative of a class effect, as bucindolol did not exhibit a beneficial effect on mortality when studied for HF, and there is limited information with propranolol and atenolol.

Controversy surrounds the selection of a β-blocker for HF management. First, although metoprolol and carvedilol are the most commonly used β-antagonists in HF, it remains controversial as to whether one agent should be considered first-line. Carvedilol exhibits several pharmacologic properties that theoretically would confer superior efficacy, since carvedilol: (1) provides blockade at multiple adrenergic receptors, which translates into vasodilatory effects and theoretically more complete antagonism of sympathetic stimulation, and (2) has in vitro antioxidant activity that could reduce vascular and cardiac oxidative damage. Several smaller studies and a meta-analysis suggested that carvedilol increased left ventricular ejection fraction (LVEF), improved cardiac hemodynamics, and slowed remodeling to a greater extent than metoprolol tartrate. To compare their relative effects on patient outcomes, one study compared immediate-release metoprolol tartrate to carvedilol in 3,000 patients with mild to severe HF.[33] Carvedilol lowered all-cause mortality significantly more than metoprolol tartrate. However, the controversy remains, as proponents for metoprolol question: (1) the validity of using immediate-release metoprolol tartrate as the comparison agent in this study, and (2) the low average dose of metoprolol tartrate achieved in the study. It also remains controversial as to whether metoprolol tartrate should be used in HF since the only trial demonstrating a mortality benefit with metoprolol used the sustained-release succinate dosage form.

The key to utilizing β-blockers in systolic HF is initiation with low doses and slow titration to target doses over weeks to months. It is important that the β-blocker be initiated when a patient is clinically stable and euvolemic. Volume overload at the time of β-blocker initiation increases the risk for worsening symptoms. β-Blockade should begin with the lowest possible dose (Table 3–7), after which the dose may be doubled every 2 to 4 weeks depending on patient tolerability. β-Blockers may cause an acute decrease in LVEF and short-term worsening of HF symptoms upon initiation and at each dosage titration. After each dose titration, if the patient experiences symptomatic hypotension, bradycardia, orthostasis, or worsening symptoms, further increases in dose should be withheld until the patient stabilizes. After stabilization, attempts to increase the dose should be reinstituted. If mild congestion ensues as a result of the β-blocker, an increase in diuretic dose may be warranted. If moderate or severe symptoms of congestion occur, a reduction in β-blocker dose should be considered along with an increase in diuretic dose. Dose titration should continue until target clinical trial doses are achieved (Table 3–7) or until limited by repeated hemodynamic or symptomatic intolerance. Patient education regarding the possibility of acutely worsening symptoms but improved long-term function and survival is essential to ensure adherence.

Apart from possible clinical differences between the β-blockers approved for HF, selection of a β-blocker may also be affected by pharmacologic differences. Carvedilol exhibits a more pronounced blood pressure lowering effect and thus causes more frequent dizziness and hypotension as a consequence of its α_1-receptor blocking activity. Therefore, in patients predisposed to symptomatic hypotension, such as those with advanced LV dysfunction (LVEF less than 20%) who normally exhibit low systolic blood pressures, metoprolol succinate may be the most desirable first-line β-blocker. In patients with uncontrolled hypertension, carvedilol may provide additional antihypertensive efficacy.

β-Blockers may be used by those with reactive airway disease or peripheral vascular disease, but should be used with considerable caution or avoided if patients display active respiratory symptoms. Care must also be used in interpreting shortness of breath in these patients, as the etiology could be either cardiac or pulmonary. A selective β_1-blocker such as metoprolol is a reasonable option for patients with reactive airway disease. The risk versus benefit of using any β-blocker in peripheral vascular disease must be weighed based on the severity of the peripheral disease.

Both metoprolol and carvedilol are metabolized by the liver through cytochrome P-450 (CYP450)2D6 and undergo extensive first-pass metabolism. Bisoprolol is not as commonly used since it is not Food and Drug Administration (FDA)-approved for this use.

Aldosterone Antagonists

Currently, the aldosterone antagonists available are spironolactone and eplerenone. Both agents are inhibitors of aldosterone that produce weak diuretic effects while sparing potassium concentrations. Eplerenone is selective for the mineralocorticoid receptor and hence does not exhibit the endocrine adverse-effect profile commonly seen with spironolactone. The initial rationale for specifically targeting aldosterone for treatment of HF was based on the knowledge that ACE inhibitors do not suppress the chronic production and release of aldosterone. Aldosterone is a key pathologic neurohormone which exerts multiple detrimental effects in HF. Through the kidneys, aldosterone promotes fluid retention and electrolyte abnormalities. Aldosterone is another neurohormone known to mediate pathologic ventricular remodeling by causing increased extracellular matrix collagen deposition and cardiac fibrosis. Aldosterone potentially contributes to disease progression via sympathetic potentiation and ventricular remodeling. In addition, the combination of these multiple effects is likely responsible for the increased risk of sudden cardiac death attributed to aldosterone. Similar to norepinephrine and angiotensin II, aldosterone levels are increased in HF and have been shown to correlate with disease severity and patient outcomes.

Each agent (spironolactone and eplerenone) has been studied in a defined population of patients with HF. One study established efficacy with low-dose spironolactone in NYHA FC III and IV heart failure patients in reducing HF hospitalizations, improving functional class, reducing sudden cardiac death, and improving all-cause mortality.[34] Another study investigated the use of eplerenone in patients within 14 days of MI and LVEF less than 40%.[35] Eplerenone was found to decrease mortality as well as cardiovascular death and related hospitalization, mainly due to reducing occurrence of sudden cardiac death. Based on these two studies, the ACC/AHA guidelines recommend that the addition of spironolactone be considered in NYHA FC III and IV (ACC/AHA stages C and D) patients, and eplerenone in directly post-MI patients with evidence of LV dysfunction.[1]

The major risk related to aldosterone antagonists is hyperkalemia. Therefore, the decision for use of these agents should balance the benefit of decreasing death and hospitalization from HF and the potential risks of life-threatening hyperkalemia. Before and within one week of initiating therapy, two parameters must be assessed: serum potassium and creatinine clearance (or serum creatinine). Aldosterone antagonists should not be initiated in patients with potassium concentrations greater than 5.5 mEq/L (5.5 mmol/L). Likewise, these agents should not be given when creatinine clearance is less than 30 mL/minute or serum creatinine is greater than 2.5 mg/dL (221 μmol/L).

In patients without contraindications, spironolactone is initiated at a dose of 12.5 to 25 mg daily, or occasionally on alternate days for patients with baseline renal insufficiency. Eplerenone is used at a dose of 25 mg daily, with the option to titrate up to 50 mg daily. Doses should be halved or switched to alternate-day dosing if creatinine clearance falls below 50 mL/minute. Potassium supplementation is often decreased or stopped after aldosterone antagonists are initiated, and patients should be counseled to avoid high-potassium foods. At any time after initiation of therapy, if potassium concentrations exceed 5.5 mEq/L (5.5 mmol/L), the dose of the aldosterone antagonist should be reduced or discontinued. Patients receiving concomitant potassium supplements should have these discontinued. In addition, worsening renal function dictates consideration for stopping the aldosterone antagonist. Other adverse effects observed mainly with spironolactone include gynecomastia for men and breast tenderness and menstrual irregularities for women. Gynecomastia leads to discontinuation in up to 10% of patients on spironolactone. Eplerenone is a CYP3A4 substrate and should not be used concomitantly with strong inhibitors of 3A4.

Digoxin

Digoxin has been used for several decades in the treatment of HF. Traditionally, it was considered useful for its positive inotropic effects, but more recently its benefits are thought to be related to neurohormonal modulation. Digoxin exerts positive inotropic effects through binding to sodium- and potassium-activated adenosine triphosphate (ATP) pumps, leading to increased intracellular sodium concentrations and subsequently more available intracellular calcium during systole. The mechanism of digoxin's neurohormonal blocking effect is less well understood, but may be related to restoration of baroreceptor sensitivity and reduced central sympathetic outflow.[5]

The exact role of digoxin in therapy remains controversial largely due to disagreement on the risk versus benefit of routinely using this drug in patients with systolic HF. Digoxin was shown to decrease HF-related hospitalizations but did not decrease HF progression or improve survival.[36] Moreover, digoxin was associated with an increased risk for concentration related toxicity and numerous adverse effects. Post-hoc study analyses demonstrated a clear relationship between digoxin plasma concentration and outcomes. Concentrations below 1.2 mg/dL (1.5 nmol/L) were associated with no apparent

adverse effect on survival, whereas higher concentrations increased the relative risk of mortality.[37,38]

Current recommendations are for the addition of digoxin for patients who remain symptomatic despite an optimal HF regimen consisting of an ACE inhibitor or ARB, β-blocker, and diuretic. In patients with concomitant atrial fibrillation, digoxin may be added to slow ventricular rate regardless of HF symptomology.

Digoxin is initiated at a dose of 0.125 to 0.25 mg daily depending on age, renal function, weight, and risk for toxicity. The lower dose should be used if the patient satisfies any of the following criteria: over 65 years of age, creatinine clearance less than 60 mL/minute, or ideal body weight less than 70 kg (154 lb). The 0.125 mg daily dose is adequate in the majority of patients. The desired concentration range for digoxin is 0.5 to 1.2 ng/mL (0.64 to 1.5 nmol/L), preferably with concentrations at or less than 0.8 ng/mL (1 nmol/L). Routine monitoring of serum drug concentrations is not required but recommended in those with changes in renal function, suspected toxicity, or after addition or subtraction of an interacting drug.

Digoxin toxicity may manifest as non-specific findings such as fatigue or weakness, and other CNS effects such as confusion, delirium, and psychosis. Gastrointestinal manifestations include nausea, vomiting, or anorexia, and visual disturbances may occur such as halos, photophobia, and color perception problems (red-green or yellow-green vision). Cardiac findings include numerous types of arrhythmias related to enhanced automaticity, slowed or accelerated conduction, or delayed afterdepolarizations. These include ventricular tachycardia and fibrillation, atrioventricular nodal block, and sinus bradycardia. Risk of digoxin toxicity, in particular the cardiac manifestations, are increased with electrolyte disturbances such as hypokalemia, hypercalcemia, and hypomagnesemia. To reduce the proarrhythmic risk of digoxin, serum potassium and magnesium should be monitored closely to ensure adequate concentrations (potassium greater than 4.0 mEq/L [4.0 mmol/L] and magnesium greater than 2.0 mEq/L [1 mmol/L]). In patients with life-threatening toxicity due to cardiac or other findings, administration of digoxin-specific Fab antibody fragments usually reverses adverse effects within an hour in most cases.

Calcium Channel Blockers

Treatment with nondihydropyridine calcium channel blockers (diltiazem and verapamil) may worsen HF and increase the risk of death in patients with advanced LV dysfunction due to their negative inotropic effects. Conversely, dihydropyridine calcium channel blockers, although negative inotropes in vitro, do not appear to decrease contractility in vivo. Amlodipine and felodipine are the two most extensively studied dihydropyridine calcium channel blockers for systolic HF.[39,40] These two agents have not been shown to affect patient survival, either positively or negatively. As such, they are not routinely recommended as part of a standard HF regimen; however, amlodipine and felodipine can safely be used in HF patients to treat uncontrolled hypertension or angina once all other appropriate drugs are maximized.

Antiplatelets and Anticoagulation

Patients with HF are at an increased risk of thromboembolic events secondary to a combination of hypercoagulability, relative stasis of blood, and endothelial dysfunction. However, the role of antiplatelets and anticoagulants remains debatable due to a lack of prospective clinical trials.

Aspirin is generally used in HF patients with an underlying ischemic etiology, a history of ischemic heart disease, or other compelling indications such as history of embolic stroke. Routine use in non-ischemic cardiomyopathy patients is currently discouraged because of a lack of data supporting any long-term benefit, as well as the potential negative drug-drug interaction with ACE inhibitors and ARBs. If aspirin is indicated, the preference is to use a low dose (81 mg daily).[41] Although no data are available with clopidogrel, it may become the antiplatelet agent of choice in HF because it has not been shown to adversely affect the actions of ACE inhibitors or ARBs.

Current consensus recommendations support the use of warfarin in patients with reduced LV systolic dysfunction and a compelling indication such as atrial fibrillation or prosthetic heart valves.[42] In addition, warfarin is empirically used in patients with echocardiographic evidence of a mural thrombus or severely depressed (LVEF less than 20%) LV function.[43] However, there are no prospective data and only limited observational data supporting the use of empiric warfarin based on these echocardiographic findings. Patients with HF often have difficulty maintaining a therapeutic International Normalized Ratio (INR) due to fluctuating volume status and varying drug absorption. Therefore, the benefit of using warfarin should be evaluated in the context of the risk for major and minor bleeding.

Heart Failure with Preserved Left Ventricular Ejection Fraction

It is now recognized that a significant number of patients exhibiting HF symptoms have normal systolic function or preserved LVEF (40% to 60%). It is believed that the primary defect in these patients is impaired ventricular relaxation and filling, commonly referred to as diastolic dysfunction or diastolic HF. Heart failure with preserved EF is more prevalent in older women and is closely associated with hypertension or diabetes, and to a lesser extent, CAD and atrial fibrillation.[44] Morbidity in HF patients with preserved EF is comparable to those with depressed EF, as both are characterized by frequent, repeated hospitalizations.[44] However, HF with preserved EF is associated with better survival. The diagnosis is based on findings of typical signs and symptoms of HF, in conjunction with echocardiographic evidence of normal LV systolic function and no valvular disease.

Unlike systolic HF, few prospective trials have evaluated the safety and efficacy of various cardiac medications in patients with diastolic HF or preserved ejection fraction. The Candesartan in Heart Failure Assessment of Reduction in Mortality and Morbidity (CHARM) study demonstrated that angiotensin receptor blockade with candesartan resulted in beneficial effects on HF morbidity in patients with preserved LVEF similar to those seen in depressed LV function.[25]

In the absence of more landmark clinical studies, the current treatment approach for diastolic dysfunction or preserved LVEF is: (1) correction or control of underlying etiologies (including optimal treatment of hypertension and CAD and maintenance of normal sinus rhythm); (2) reduction of cardiac filling pressures at rest and during exertion; and (3) increased diastolic filling time. Diuretics, ACE inhibitors, and ARBs are frequently used to control congestion. Angiotensin receptor blockers may also slow disease progression. β-Blockers and calcium channel blockers can theoretically improve ventricular relaxation through negative inotropic and chronotropic effects. Unlike in systolic HF, nondihydropyridine calcium channel blockers (diltiazem and verapamil) may be especially useful in improving diastolic function by limiting the availability of calcium that mediates contractility. The role of digoxin for symptom management and HR control in these patients is not well established.

Special Populations and Patients with Concomitant Disorders

Ethnic and Genetic Considerations

Heart failure is more prevalent and associated with a worse prognosis in African-Americans compared to the general population.[1] Unfortunately, deficiencies in disease prevention, detection, and access to treatment are well documented in minority populations. African-Americans and other races are underrepresented in clinical trials, compromising the extrapolation of results from these studies to ethnic subpopulations. The influence of race on efficacy and safety of medications used in HF treatment has received additional attention with the advent of pharmacogenomics (the influence of genetics on drug response). The application of race and genetics to pharmacotherapeutic decision making for HF is in the early stages. However, these concepts are being applied to the use of hydralazine and isosorbide dinitrate in African-American patients.[26] It is anticipated that further investigation will lead to better insight relating to the clinical applicability of genetic variations to drug responses.

Peripartum Cardiomyopathy and Pregnancy

Peripartum cardiomyopathy (PPCM) is currently defined as clinical and echocardiographic evidence for new-onset HF occurring during pregnancy and up to 6 months after delivery, with other etiologies excluded. Although PPCM is not well understood, it manifests in pregnant women of all ages, but the risk is elevated in women older than 30 years of age.[45] The true incidence of idiopathic PPCM is debatable, with reported rates for peripartum HF at 1 case per 100 to 4,000 deliveries.[46] The leading hypothesis for PPCM pathogenesis is myocarditis caused by a viral infection or an abnormal immune response to pregnancy. Heart failure may persist after delivery but can be reversible (with partial or full recovery of cardiac function) in many cases.[45]

The clinical presentation of peripartum HF is indistinguishable from that of other types of HF. Initial treatment is also similar, with the exception of ACE inhibitors and ARBs being contraindicated during the antepartum period. Treatment includes reducing preload by sodium restriction and diuretics, afterload reduction with vasodilators, and sometimes inotropic support with digoxin. Hydralazine is utilized frequently in pregnancy and is classified as FDA pregnancy category C. Labetalol is used for acute parenteral control of blood pressure, but long-term β-blocker use corresponds with low birth weight infants. Management of the cardiomyopathy after delivery includes use of ACE inhibitors and β-blockers, although these treatment guidelines have been extrapolated from studies in patients with idiopathic dilated cardiomyopathy rather than specific trials in PPCM. Patients with PPCM also have a high rate of thromboembolism. Treatment options during pregnancy are limited to unfractionated heparin and low-molecular-weight heparin since warfarin is contraindicated. After delivery, anticoagulation is recommended in patients with LVEF less than 20%.[46]

Patient Encounter, Part 3

Based on the information presented and your problem-based assessment, create a care plan for BE's heart failure. Your plan should include:

- Nonpharmacologic treatment options.
- Acute and chronic treatment plans to address BE's symptoms and prevent disease deterioration.
- Monitoring plan for acute and chronic treatments.

OUTCOME EVALUATION OF CHRONIC HEART FAILURE

- The evaluation of therapy is influenced by the ability of treatment to successfully reduce symptoms, improve quality of life, decrease frequency of hospitalizations for AHF, reduce disease progression, and prolong survival (Fig. 3–1).
- The major outcome parameters focus on: (1) volume status; (2) exercise tolerance; (3) overall symptoms/quality of life; (4) adverse drug reactions; and (5) disease progression and

cardiac function. Assess quality of life by evaluating patients' ability to continue their activities of daily living.

- Assess symptoms of HF such as dyspnea on exertion, orthopnea, weight gain, and edema, and abdominal manifestations such as nausea, bloating, and loss of appetite.
- If diuretic therapy is warranted, monitor for therapeutic response by assessing weight loss and improvement of fluid retention, as well as exercise tolerance and presence of fatigue.
- Once therapy for preventing disease progression is initiated, monitoring for symptomatic improvement continues.
- It is important to keep in mind that patients' symptoms of HF can worsen with β-blockers, and it may take weeks or months before patients notice improvement.
- Monitor blood pressure to evaluate for hypotension caused by drug therapy.
- To assess for prevention of disease progression, practitioners may utilize serial echocardiograms every 6 months to assess cardiac function and evaluate the effects of drug therapy.
- Occasional exercise testing is conducted in order to ascertain disease prognosis or suitability for heart transplant. Even though these tests can demonstrate improvement in heart function and therefore slowed disease progression, patient symptoms may not improve.

ACUTE AND ADVANCED HEART FAILURE

Clinical Presentation and Diagnosis of Acute Heart Failure

Patients with acute heart failure (AHF) present with symptoms of worsening fluid retention or decreasing exercise tolerance and fatigue (typically worsening of symptoms presented in the chronic heart failure clinical presentation text box). These symptoms reflect congestion behind the failing ventricle and/or hypoperfusion. Patients can be categorized into hemodynamic subsets based on assessment of physical signs and symptoms of congestion and/or hypoperfusion.[47] Patients can be described as "wet" or "dry" depending on volume status, as well as "warm" or "cool" based on adequacy of tissue perfusion. "Wet" refers to patients with volume/fluid overload [e.g., edema and jugular venous distention (JVD)], whereas "dry" refers to euvolemic patients. "Warm" refers to patients with adequate CO to perfuse peripheral tissues (and hence the skin will be warm to touch), whereas "cool" refers to patients with evidence of hypoperfusion (skin cool to touch with diminished pulses). Additionally, invasive hemodynamic monitoring can be used to provide

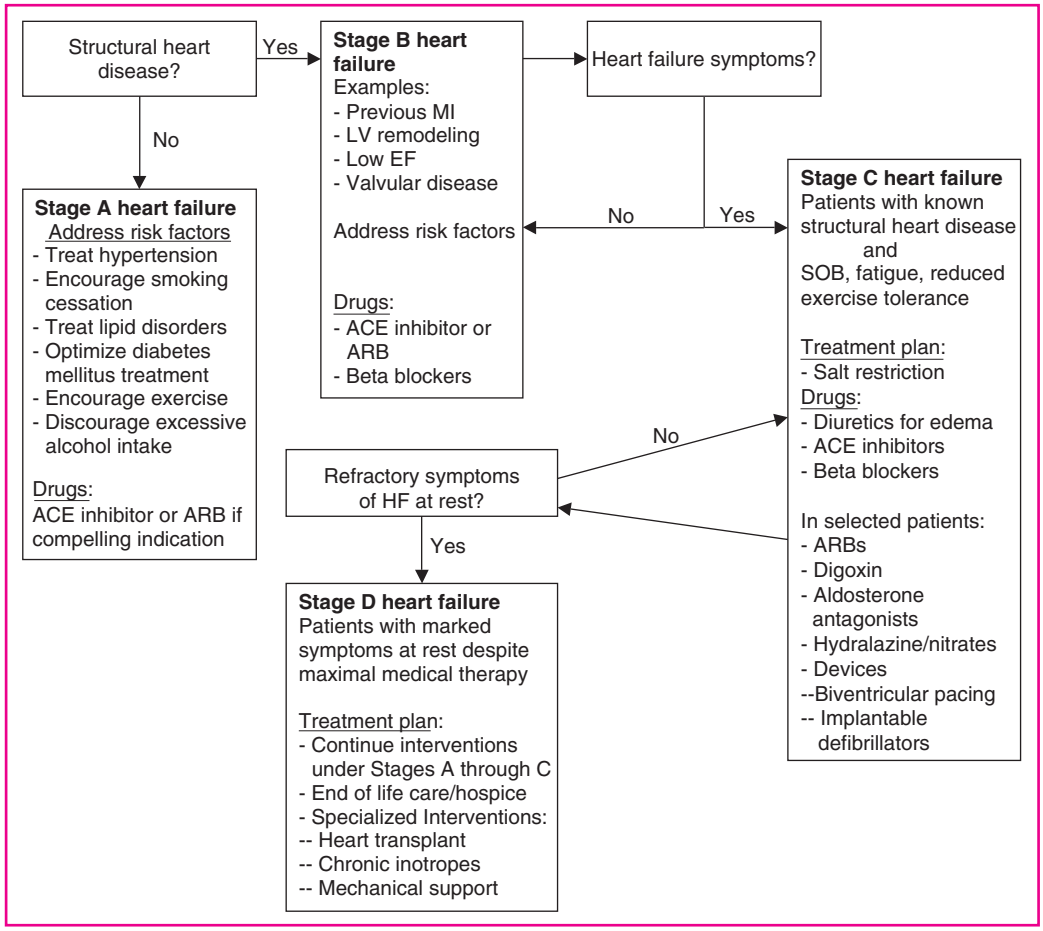

FIGURE 3–1. Treatment algorithm for chronic heart failure. ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; EF, ejection fraction; HF, heart failure; LV, left ventricular; MI, myocardial infarction; SOB: shortness of breath. Table 3–5 describes staging of heart failure.

objective data for assessing volume status [pulmonary capillary wedge pressure (PCWP)] and perfusion (CO). A CI below 2.2 L/minute per square meter is consistent with hypoperfusion and reduced contractility, and a PCWP above 18 mm Hg correlates with congestion and an elevated preload. The four possible hemodynamic subsets a patient may fall into are: "warm and dry," "warm and wet," "cool and dry," or "cool and wet."

Clinical Presentation of Acute Heart Failure

Subset I (Warm and Dry)
- Cardiac index (CI) *greater than* 2.2 L/minute per square meter, pulmonary capillary wedge pressure (PCWP) *less than* 18 mm Hg
- Patients considered well compensated and perfused, without evidence of congestion
- No immediate interventions necessary except optimizing oral medications and monitoring

Subset II (Warm and Wet)
- CI *greater than* 2.2 L/minute per square meter, PCWP *greater than* or equal to 18 mm Hg
- Patients adequately perfused and display signs and symptoms of congestion
- Main goal is to reduce preload (PCWP) carefully with loop diuretics and vasodilators

Subset III (Cool and Dry)
- CI *less than* 2.2 L/minute per square meter, PCWP *less than* 18 mm Hg
- Patients are inadequately perfused and not congested
- Hypoperfusion leads to increased mortality, elevating death rates four-fold compared to those who are adequately perfused
- Treatment focuses on increasing CO with positive inotropic agents and/or replacing intravascular fluids
- Fluid replacement must be performed cautiously, as patients can rapidly become congested

Subset IV (Cool and Wet)
- CI *less than* 2.2 L/minute per square meter, PCWP *greater than* 18 mm Hg
- Patients are inadequately perfused and congested
- Classified as the most complicated clinical presentation of AHF with the worst prognosis
- Most challenging to treat; therapy targets alleviating signs and symptoms of congestion by increasing CI as well as reducing PCWP, while maintaining adequate mean arterial pressure
- Treatment involves a delicate balance between diuretics, vasodilators, and inotropic agents
- Use of vasopressors is sometimes necessary to maintain blood pressure

Clinical Assessment and Diagnosis

Precipitating Factors

❸ *It is important for the clinician to identify the cause(s) of AHF in order to maximize treatment efficacy and reduce future disease exacerbations. Cardiovascular, metabolic, and lifestyle factors can all precipitate AHF.* The most common precipitating factors for acute decompensation and how they contribute pathophysiologically are listed in Table 3–3.

Laboratory Assessment

Routine laboratory testing of patients with AHF includes electrolytes and blood glucose, as well as serum creatinine and blood urea nitrogen to assess renal function. Complete blood cell count is measured to determine if anemia or infection is present. Creatine kinase and/or troponin concentrations are used to diagnose ischemia, and hepatic transaminases are measured to help rule out hepatic congestion (in other words, until it is determined that it is not hepatic congestion). Thyroid function tests are measured to assess hyperthyroidism or hypothyroidism as causes of AHF. A urinalysis is attained in patients with an unknown history of renal disease to rule out nephrotic syndrome. Lastly, a toxicology screen is obtained in patients in whom use of illicit drugs is suspected.

Assays measuring BNP and its degradation product NT-proBNP have been developed and are being used with greater frequency in clinical practice.[10] B-type natriuretic peptide is synthesized, stored, and released from the ventricles in response to increased ventricular filling pressures. Hence, plasma levels of BNP can be used as a marker for volume overload. The most widely accepted indication for BNP measurement is as an adjunctive aid for diagnosing a cardiac etiology for dyspnea.[10] Although there is evidence to support a prognostic role for BNP concentrations in HF and MI, widespread clinical application has yet to occur. Current trials are also testing whether serial BNP monitoring can be used to guide therapy.

The current values for ruling out a cardiac etiology for dyspnea are a BNP less than 100 pg/mL (100 ng/L) or an NT-proBNP less than 300 pg/mL (300 ng/L or 35.4 pmol/L). BNP measurements require cautious interpretation, as numerous conditions can also elevate BNP concentrations. These include older age, renal dysfunction, pulmonary embolism, and chronic pulmonary disease. Nesiritide, a recombinant BNP drug, has an identical structure to native BNP and will interfere with the commercial BNP assay, resulting in a falsely elevated level. Therefore, blood for BNP determination should be obtained 2 hours after the end of a nesiritide infusion, or alternatively the NT-proBNP assay should be utilized.

Other diagnostic tests should also be obtained in order to rule out precipitating factors (chest radiograph) and to evaluate cardiac function (ECG).

Invasive hemodynamic monitoring in patients with HF entails placement of a right heart or pulmonary artery catheter (PAC). The catheter is inserted percutaneously through a central vein and advanced through the right side of the heart to the

TABLE 3–8. Hemodynamic Monitoring: Normal Values

Hemodynamic Variable	Normal Value
Central venous (right atrial) pressure, mean	Less than 5 mm Hg
Right ventricular pressure	25/0 mm Hg
Pulmonary artery pressure	25/10 mm Hg
Pulmonary artery pressure, mean	Less than 18 mm Hg
Pulmonary artery occlusion pressure, mean	Less than 12 mm Hg
Systemic arterial pressure	120/80 mm Hg
Mean arterial pressure	90–120 mm Hg
Cardiac index	2.8–4.2 L/minute per square meter
Stroke volume index	30–65 mL/beat per square meter
Systemic vascular resistance	900–1.400 dyn·s·m^{-5}
Pulmonary vascular resistance	150–250 dyn·s·m^{-5}
Arterial oxygen content	20 mL/dL
Mixed venous oxygen content	15 mL/dL
Arteriovenous oxygen content difference	3–5 mL/dL

pulmonary artery. Inflation of a balloon proximal to the end port allows the catheter to "wedge," yielding the PCWP, which estimates pressures in the left ventricle during diastole. Additionally, CO can be estimated and SVR calculated (Table 3–8).

There are no universally accepted guidelines dictating when invasive monitoring in HF is required. The use of a PAC remains an essential component of management and monitoring of patients in cardiogenic shock; however, the use of inotropic agents does not mandate invasive monitoring. Invasive hemodynamic monitoring is most commonly used to aid in the assessment of hemodynamics when there is disagreement between signs and symptoms and clinical response. In addition, invasive monitoring is helpful in guiding ongoing therapy for AHF. Invasive monitoring offers the advantage of immediate hemodynamic assessment of an intervention, allowing for prompt adjustments. Risks with PACs include infection, bleeding, thrombosis, catheter malfunction, and ventricular ectopy. A recent randomized trial of PAC use in HF demonstrated a neutral effect on patient mortality.

TREATMENT OF ACUTE HEART FAILURE

Desired Therapeutic Outcomes

The goals of therapy for AHF are to: (1) correct the underlying precipitating factor(s); (2) relieve the patient's symptoms; (3) improve hemodynamics; (4) optimize a chronic oral medication regimen; and (5) educate the patient, reinforcing adherence to lifestyle modifications and the drug regimen. The ultimate goal for a patient hospitalized for AHF is the return to a compensated HF state and discharge to the outpatient setting on oral medications. Only through aggressive management to achieve all of these goals will a patient's prognosis be improved and future hospitalizations for acute decompensations prevented.

Removal or control of precipitating factors is essential for an optimal response to pharmacologic therapy. Relief of symptoms should occur rapidly to minimize length of hospitalization. Although a rapid discharge from the hospital is desirable, a patient should not be discharged before ensuring that he or she is in a euvolemic, or nearly euvolemic, state with a body weight and functional capacity similar to before the acute decompensation. Oral agents such as β-blockers, ACE inhibitors or ARBs, and aldosterone antagonists should be initiated as soon as possible during the hospitalization. These chronic oral medications not only improve mortality and prevent readmissions, acutely they also contribute to improvement in hemodynamics. Patient education prior to discharge from the hospital is recommended to assist in minimizing adverse effects and non-adherence. Dissemination of written information, in addition to verbal information, is helpful for patient comprehension and retention. This can include therapy goals, lifestyle modifications, drug regimen, dosage information, and relevant adverse effects, as well as symptom and diary cards.

Pharmacologic Approaches to Treatment

⑩ *Treatment of AHF targets relief of congestion and optimization of CO utilizing oral or intravenous diuretics, intravenous vasodilators, and when appropriate inotropes, based on presenting hemodynamics. Current treatment strategies in AHF target improving hemodynamics while preserving organ function.* A specific treatment approach is formulated depending on the patient's symptoms (congestion versus hypoperfusion) and hemodynamic indices (CI and PCWP).[48,49] If the patient primarily exhibits signs and symptoms of congestion, treatment entails use of diuretics as first-line agents to decrease PCWP. Additionally, intravenous vasodilators are added to provide rapid relief of congestion and additional reductions in PCWP. By reducing congestion in the heart, cardiac contractile function may improve, which results in an increase in SV and CO, and hence perfusion to vital organs. For patients primarily displaying symptoms of hypoperfusion, treatment relies on use of agents that increase cardiac contractility, known as positive inotropes. Some patients display both symptoms of congestion as well as hypoperfusion and thus require use of combination therapies. One of the current challenges to the treatment of AHF is achieving hemodynamic improvement without adversely affecting organ function. In the case of inotropes, the increased contractility occurs at the expense of an increase in cardiac workload and proarrhythmia. In addition, high-dose diuretic therapy is associated with worsened renal function and possibly neurohormonal activation.

Diuretics

Loop diuretics, including furosemide, bumetanide, and torsemide are the diuretics of choice in the management of

TABLE 3–9. Intravenous Diuretics Used to Treat Heart Failure–Related Fluid Retention

	Onset of Action (minutes)	Duration of Action (hours)	Relative Potency	Intermittent Bolus Dosing (mg)	Continuous Infusion Dosing (bolus/infusion)
Furosemide	2–5	6	40	20–200+	20–40/2.5–10
Torsemide	Less than 10	6–12	20	10–100	20/2–5
Bumetanide	2–3	4–6	0.5	1–10	1–4/0.5–1
Ethacrynic acid	5–15	2–7		0.5–1 mg/kg per dose up to 100 mg/dose	

AHF. Furosemide is the most commonly used agent. Diuretics decrease preload by functional venodilation within 5 to 15 minutes of administration and subsequently by an increase in sodium and water excretion. This provides rapid improvement in symptoms of pulmonary congestion. Diuretics reduce PCWP but do not increase CI like positive inotropes and arterial vasodilators. Patients who have significant volume overload often have impaired absorption of oral loop diuretics because of intestinal edema or altered transit time. Therefore, doses are usually administered via intravenous boluses, given either at the same dose as the home oral dose for those taking diuretics regularly or at lower doses for diuretic-naïve patients (Table 3–9). Higher doses may be required for patients with renal insufficiency due to decreased drug delivery to the site of action in the loop of Henle.

There is a paucity of clinical trial evidence comparing the benefit of diuretics to other therapies for symptom relief or long-term outcomes. Additionally, excessive preload reduction can lead to a decrease in CO resulting in reflex increase in sympathetic activation, renin release, and the expected consequences of vasoconstriction, tachycardia, and increased myocardial oxygen demand. Careful use of diuretics is recommended to avoid overdiuresis. Monitor serum electrolytes such as potassium, sodium, and magnesium frequently to identify and correct imbalances. Monitor serum creatinine and blood urea nitrogen daily at a minimum to assess volume depletion and renal function.

Occasionally, patients with HF do not respond to a diuretic, defined as failure to achieve a weight reduction of at least 0.5 kg (or negative net fluid balance of at least 500 mL) after several increasing bolus doses.[17]

Several strategies are employed to overcome diuretic resistance. These include using larger oral doses, converting to intravenous dosing, or increasing the frequency of administration. Small studies using low-dose continuous infusions of furosemide and torsemide have shown an increase in urine output compared to intermittent bolus dosing.[50] Continuous infusions may provide a theoretical advantage of continuous presence of high drug levels within the tubular lumen, causing a sustained natriuresis. Most regimens include a bolus dose followed by a maintenance infusion (Table 3–9).[51] Another useful strategy is to combine two diuretics with different sites of action within the nephron. The most common combination is the use of a loop diuretic with a thiazide diuretic such as metolazone. Combining diuretics should be used with caution due to an increased risk for cardiovascular collapse due to rapid intravascular volume depletion. Strict monitoring of electrolytes, vital signs, and fluid balance is warranted.

Finally, poor CO may contribute to diuretic resistance. In these patients, it may become necessary to add vasodilators or inotropes to enhance perfusion to the kidneys. Care must be taken, as vasodilators can decrease renal blood flow despite increasing CO through dilation of central and peripheral vascular beds.

Vasodilators

Intravenous vasodilators cause a rapid decrease in arterial tone, resulting in a decrease in SVR and a subsequent increase in SV and CO. Additionally, vasodilators reduce ventricular filling pressures (PCWP) within 24 to 48 hours, reduce myocardial oxygen consumption, and decrease ventricular workload. Vasodilators are commonly used in patients presenting with AHF accompanied by moderate to severe congestion. This class includes nitroglycerin, nitroprusside, and nesiritide. Hemodynamic effects and dosages for these agents are included in Tables 3–10 and 3–11, respectively. Although vasodilators are generally safe and effective, identification of the proper patient for use is important to minimize the risk of

TABLE 3–10. Usual Hemodynamic Effects of Commonly Used Intravenous Agents for Treatment of Acute or Severe Heart Failure

Drug	CO	PCWP	SVR	BP	HR
Diuretics	↑/↓/0	↓		↓	0
Nitroglycerin	↑	↓↓	↓	↓↓	↑/0
Nitroprusside	↑	↓↓↓	↓↓↓	↓↓↓	↑
Nesiritide	↑	↓↓	↓↓	↓↓	0

significant hypotension. In addition, vasodilators are contraindicated in patients whose cardiac filling (and hence CO) depends on venous return or intravascular volume, as well as patients who present with shock.

Nitroglycerin

Nitroglycerin acts as a source of nitric oxide, which induces smooth muscle relaxation in venous and arterial vascular beds. Nitroglycerin is primarily a venous vasodilator at lower doses, but exerts potent arterial vasodilatory effects at higher doses. Thus, at lower doses, nitroglycerin causes decreases in preload (or filling pressures) and improved coronary blood flow. At higher doses (greater than 100 mcg/minute), additional reduction in preload is achieved, along with a decrease in afterload and subsequent increase in SV and CO. Intravenous nitroglycerin is primarily used as a preload reducer for patients exhibiting pulmonary congestion or in combination with inotropes for congested patients with severely reduced CO.[52]

Continuous infusions of nitroglycerin should be initiated at a dose of 5 to 10 mcg/minute and increased every 5 to 10 minutes until symptomatic or hemodynamic improvement. Effective doses range from 35 to 200 mcg/minute. The most common adverse events reported are headache, dose-related hypotension, and tachycardia. A limitation to nitroglycerin's use is the development of tachyphylaxis, or tolerance to its effects, which can be evident within 12 hours after initiation of continuous infusion and necessitate additional titrations to higher doses.

Nitroprusside

Nitroprusside, like nitroglycerin, causes the formation of nitric oxide and vascular smooth muscle relaxation. In contrast to nitroglycerin, nitroprusside is both a venous and arterial vasodilator regardless of dosage. Nitroprusside causes a pronounced decrease in PCWP, SVR, and blood pressure, with a modest increase in CO. Nitroprusside has been studied to a limited extent in AHF and no studies have evaluated its effects on mortality.[48] Nitroprusside is initiated at 0.1 to 0.25 mcg/kg per minute, followed by dose adjustments in 0.1 to 0.2 mcg/kg per minute increments if necessary to achieve desired effect. Because of its rapid onset of action and metabolism, nitroprusside is administered as a continuous infusion that is easy to titrate and provides predictable hemodynamic effects. Nitroprusside requires strict monitoring of blood pressure and HR. Nitroprusside's use is limited in AHF due to recommended hemodynamic monitoring with an arterial line and mandatory intensive care unit admission at many institutions. Abrupt withdrawal of therapy should be avoided, as rebound neurohormonal activation may occur. Therefore, the dose should be tapered slowly. Nitroprusside has the potential to cause cyanide and thiocyanate toxicity, especially in patients with renal insufficiency. Toxicity is most common with use longer than 3 days and with higher doses. Nitroprusside should be avoided in patients with active ischemia, because its powerful afterload-reducing effects within the myocardium can "steal" coronary blood flow from myocardial segments that are supplied by epicardial vessels with high-grade lesions.

Nesiritide

B-type natriuretic peptide is an endogenous neurohormone that is synthesized and released from the ventricles in response to chamber wall stretch or increased filling pressures. Recombinant BNP, or nesiritide, is the newest compound developed for AHF. Nesiritide binds to guanylate cyclase receptors in vascular smooth muscle and endothelial cells, causing an increase in cGMP concentrations leading to vasodilation (venous and arterial) and natriuresis. Nesiritide also antagonizes the effects of the RAAS and endothelin. Nesiritide reduces PCWP, right atrial pressure, and SVR. Consequently, it also increases SV and CO without affecting heart rate. Continuous infusions result in sustained effects for 24 hours without tachyphylaxis, although experience with its use beyond 72 hours is limited.

Nesiritide has been shown to improve symptoms of dyspnea and fatigue. In a randomized clinical trial, the safety and efficacy of adding nesiritide to standard care was compared to placebo and nitroglycerin.[53] Nesiritide was found to significantly decrease PCWP more than nitroglycerin and placebo over 3 hours. Nesiritide improved patients' self-reported

dyspnea scores compared to placebo at 3 hours, but there was no difference compared to nitroglycerin. There are no prospective mortality studies with nesiritide in AHF.

Currently, nesiritide is indicated for patients with AHF exhibiting dyspnea at rest or with minimal activity. The recommended dose regimen is a bolus of 2 mcg/kg, followed by a continuous infusion for up to 24 hours of 0.01 mcg/kg per minute. Because nesiritide's effects are predictable and sustained at the recommended dosage, titration of the infusion rate (maximum of 0.03 mcg/kg per minute) is not commonly required nor is invasive hemodynamic monitoring. Nesiritide should be avoided in patients with systolic blood pressure less than 90 mm Hg. Although nesiritide's place in AHF therapy is not firmly defined, it is used as one of the first-line agents (in combination with diuretics) for the majority of patients presenting in moderate to severe decompensation, mainly due to its proven benefits and unique mechanism of action. One potential disadvantage compared to other vasodilators is its longer half-life. If hypotension occurs, the effect can be prolonged (2 hours). There are also concerns relating to elevations in serum creatinine observed with nesiritide; however, whether this effect is clinically relevant remains unanswered.

Inotropic Agents

Currently available positive inotropic agents act via increasing intracellular cyclic adenosine monophosphate (cAMP) concentrations through different mechanisms. β-Agonists activate adenylate cyclase through stimulation of β-adrenergic receptors, which subsequently catalyzes the conversion of adenosine triphosphate (ATP) to cAMP. In contrast, phosphodiesterase inhibitors reduce degradation of cAMP. The resulting elevation in cAMP levels leads to enhanced phospholipase activity, which then increases the rate and extent of calcium influx during systole, thereby enhancing contractility. Additionally, during diastole, cAMP promotes uptake of calcium by the sarcoplasmic reticulum which improves cardiac relaxation. The inotropes approved for use in AHF are discussed in the following sections.

Dobutamine

Dobutamine has historically been the inotrope of choice for AHF. As a synthetic catecholamine, it acts as an agonist mainly on β_1- and β_2-receptors and minimally on α_1-receptors. The resulting hemodynamic effects are due to both receptor- and reflex-mediated activities. These effects include: increased contractility and HR through β_1- (and β_2-) receptors and vasodilation through a relatively greater effect on β_2- than α_1-receptors. Dobutamine can increase, decrease, or cause little change in mean arterial pressure depending on whether the resulting increase in CO is enough to offset the modest vasodilation. Although dobutamine displays a half life of approximately 2 minutes, its positive hemodynamic effects can be observed for several days to months after administration. The use of dobutamine is supported by several small studies documenting improved hemodynamics, but large-scale clinical trials in AHF are lacking.[54]

Dobutamine is initiated at a dose of 2.5 to 5 mcg/kg per minute, which can be gradually titrated to 20 mcg/kg per minute based on clinical response. There are several practical considerations to dobutamine therapy in AHF. First, owing to its vasodilatory potential, monotherapy with dobutamine is reserved for patients with systolic blood pressures greater than 90 mm Hg. However, it is commonly used in combination with vasopressors in patients with lower systolic blood pressures. Second, due to down-regulation of β_1-receptors or uncoupling of β_2- receptors from adenylate cyclase with prolonged exposure to dobutamine, attenuation of hemodynamic effects has been reported to occur as early as 48 hours after initiation of a continuous infusion, although tachyphylaxis is more evident with use spanning longer than 72 hours. Full sensitivity to dobutamine's effects can be restored 7 to 10 days after the drug is withdrawn. Third, many patients with AHF will be taking β-blockers on a chronic basis. Because of β-blockers' high affinity for β-receptors, the effectiveness of β-agonists such as dobutamine will be reduced. In patients on β-blocker therapy, it is recommended that consideration be given to the use of phosphodiesterase inhibitors such as milrinone, which are not dependent on β-receptors for effect.[55,56] Although commonly practiced, use of high doses of dobutamine to overcome the β-blockade should be discouraged, as this negates any of the protective benefits of the β-blocker.

Dopamine

Dopamine is most commonly reserved for patients with low systolic blood pressures and those approaching cardiogenic shock. It may also be used in low doses (less than 3 mcg/kg per minute) to improve renal function in a patient with inadequate urine output despite high filling pressures and volume overload, although this indication is controversial.

Dopamine exerts its effects through direct stimulation of adrenergic receptors, as well as release of norepinephrine from adrenergic nerve terminals. Dopamine produces hemodynamic effects that differ based on dosing. At lower doses, dopamine stimulates dopamine type 1 (D1) receptors and thus increases renal perfusion. Positive inotropic effects are more pronounced at doses of 3 to 10 mcg/kg per minute. Cardiac index is increased due to increased SV and HR. At doses higher than 10 mcg/kg per minute, chronotropic and α_1-mediated vasoconstriction effects are evident. This causes an increase in mean arterial pressure due to higher CI and SVR. The ultimate effect on cardiac hemodynamics will depend largely on the dosage prescribed and must be individually tailored to the patient's clinical status. Dopamine is generally associated with an increase in CO and blood pressure, with a concomitant increase in PCWP. Dopamine increases myocardial oxygen demand and may decrease coronary blood flow through vasoconstriction and increased wall tension. As with other inotropes, dopamine is associated with a risk for arrhythmias.

Phosphodiesterase Inhibitors

Milrinone and inamrinone work by inhibiting phosphodiesterase III, the enzyme responsible for the breakdown of cAMP. The increase in cAMP levels leads to increased intracellular calcium concentrations and enhanced contractile force generation. Milrinone has replaced inamrinone as the phosphodiesterase inhibitor of choice due to the higher frequency of thrombocytopenia seen with inamrinone.

Milrinone has both positive inotropic and vasodilating properties and as such is referred to as an "inodilator." Its vasodilating activities are especially prominent on venous capacitance vessels and pulmonary vascular beds, although a reduction in arterial tone is also noted. Intravenous administration results in an increase in SV and CO, and usually only minor changes in heart rate. Milrinone also lowers PCWP through venodilation. Routine use of milrinone during acute decompensations in NYHA FC II to IV HF is not recommended, and milrinone use remains limited to patients who require inotropic support.[57]

Dosing recommendations for milrinone include a loading dose of 50 mcg/kg, followed by an infusion beginning at 0.5 mcg/kg per minute (range 0.23 mcg/kg per minute for patients with renal failure up to 0.75 mcg/kg per minute). A loading dose is not necessary if immediate hemodynamic effects are not required or if patients have low systolic blood pressures (less than 90 mm Hg). Decreases in blood pressure during an infusion may necessitate dose reductions as well.

Milrinone is a good option for patients requiring an inotrope who are also chronically receiving β-blockers, as the inotropic effects are achieved independent of β-adrenergic receptors. However, milrinone exhibits a long distribution and elimination half-life compared to β-agonists, thus requiring a loading dose when an immediate response is desired. Potential adverse effects include hypotension, arrhythmias, and less commonly, thrombocytopenia. Milrinone should not be used in patients in whom vasodilation is contraindicated.

Mechanical, Surgical, and Device Therapies

Implantable Cardioverter Defibrillators

Implantable cardioverter defibrillators (ICDs) are the most effective modality for primary and secondary prevention of sudden cardiac death in patients with LV dysfunction. Studies universally demonstrate greater efficacy compared to antiarrhythmic therapy and a significant reduction in mortality compared to placebo.[58–60] Recent studies have expanded the eligible patient populations beyond classic indications, such as prior MI and non-sustained ventricular tachycardia or non-suppressible ventricular tachycardia during an electrophysiologic study. A clear advantage of implanting ICDs in all symptomatic patients with LVEF less than 35% regardless of etiology or other cardiac parameters has been demonstrated.[60] Since ICD implantation and follow-up is associated with a significant economic burden, the cost-effectiveness of widespread ICD use continues to be debated. Defining subgroups that

Patient Encounter, Part 4

After 6 months, BE returns to clinic complaining of extreme SOB with any activity, including dressing and showering, as well as at rest. She sleeps sitting up due to severe orthopnea, is unable to eat without nausea, and states she has gained 22 lb (10 kg) from her baseline weight. She also states that she does not feel her furosemide therapy is working, She is admitted to the cardiology unit.

SH

BE admits to resuming smoking after quitting for 2 months; additionally, she has been eating out in restaurants more often in the past 2 weeks.

Meds

Lisinopril 10 mg once daily
Furosemide 80 mg twice daily
Nitroglycerin 0.4 mg sublingual (SL) as needed
Multivitamin daily
Aspirin 325 mg daily

VS: blood pressure 146/94 mm Hg, pulse 102 bpm and regular, respiratory rate 22/minute, temperature 37°C (98.6°F), Wt 271 lb (123 kg), BMI 41.2

Lungs: There are rales present bilaterally

CV: Regular rate and rhythm with normal S_1 and S_2; there is an S_3 and an S_4; a 4/6 systolic ejection murmur is present and heard best at the left lower sternal border; point of maximal impulse is displaced laterally; jugular veins are distended, JVP is 11 cm above sternal angle; a positive HJR is observed

Abd: Hard, tender, and bowel sounds are absent; 3+ pitting edema of extremities is observed

CXR: Bilateral pleural effusions and cardiomegaly

Echo: EF = 20%

Pertinent labs

BNP 740 pg/mL (740 ng/L), K: 4.2 mEq/L (4.2 mmol/L), BUN 64 mg/dL (23 mmol/L), SCr 2.4 mg/dL (212 mmol/L), Mg 1.8 mEq/L (0.9 mmol/L)

A pulmonary catheter is placed, revealing the following: PCWP 37 mm Hg; cardiac index 2.2 L/minute per square meter

- What NYHA functional class, ACC/AHA stage, and hemodynamic subset is BE currently in?
- What are your initial treatment goals?
- What pharmacologic agents are appropriate to use at this time?
- Identify a monitoring plan to assess for efficacy and toxicity of the recommended drug therapy.
- Once BE's symptoms are improved, how would you optimize her oral medication therapy for heart failure?

would derive the greatest benefit and determining the optimal ICD configuration will aid in improving the potential costs compared to benefits.

Cardiac Resynchronization Therapy

Dyssynchronous contraction, as a reflection of intra- and interventricular conduction delays between chambers of the heart, is common in advanced HF patients. Dyssynchrony contributes to diminished cardiac function and unfavorable myocardial energetics through altered filling times, valvular dysfunction, and wall motion defects. Cardiac resynchronization therapy (CRT) with biventricular pacing devices improves cardiac function, quality of life, and mortality in patients with NYHA FC III or IV HF, evidence of intraventricular conduction delay (QRS greater than 120 ms), depressed LV function (LVEF less than 35%), and on an optimal pharmacologic regimen. A recent study also showed that the addition of an ICD to CRT with biventricular pacing further reduced hospitalizations and mortality.[61]

Intra-aortic Balloon Counterpulsation

Intra-aortic balloon counterpulsation (IABC) or intra-aortic balloon pumps (IABPs) are one of the most widely used mechanical circulatory assistance devices for patients with cardiac failure who do not respond to standard therapies. An IABP is placed percutaneously into the femoral artery and advanced to the high descending thoracic aorta. Once in position, the balloon is programmed to inflate during diastole and deflate during systole. Two main beneficial mechanisms are: (1) inflation during diastole increases aortic pressure and perfusion of the coronary arteries, and (2) deflation just prior to the aortic valve opening reduces arterial impedence (afterload). As such, IABC increases myocardial oxygen supply and decreases oxygen demand. This device has many indications, including cardiogenic shock, high-risk unstable angina in conjunction with percutaneous interventions, preoperative stabilization of high-risk patients prior to surgery, and in patients who cannot be weaned from cardiopulmonary bypass. Possible complications include infection, bleeding, thrombosis, limb ischemia, and device malfunction. The device is typically useful for short-term therapy due to the invasiveness of the device, the need for limb immobilization, and the requirement for full anticoagulation.

Ventricular Assist Device

The ventricular assist device (VAD) is a surgically implanted pump that reduces or replaces the work of the right, left, or both ventricles. Ventricular assist devices are currently indicated for short-term support in patients refractory to pharmacologic therapies, as long-term bridge therapy (a temporary transition treatment) in patients awaiting cardiac transplant, or in some instances, as the destination therapy (treatment for patients in lieu of cardiac transplant for those who are not appropriate candidates for transplantation).[1] The most common complications are infection and thromboembolism. Other adverse effects include bleeding, air embolism, device failure, and multiorgan failure.

Surgical Therapy

Heart transplantation represents the final option for refractory, end-stage HF patients who have exhausted medical and device therapies. Heart transplantation is not a cure, but should be considered a trade between a life-threatening syndrome and the risks associated with the operation and long-term immunosuppression. Assessment of appropriate candidates includes comorbid illnesses, psychosocial behavior, available financial and social support, and patient willingness to adhere to lifelong therapy and close medical follow-up.[1] Overall, the transplant recipient's quality of life may be improved, but not all patients receive this benefit. Posttransplant survival continues to improve due to advances in immunosuppression, treatment and prevention of infection, and optimal management of patient comorbidities.

Investigational Therapies

Clinical trials are currently investigating new agents for the treatment of AHF. These compounds offer unique mechanisms of action by targeting different neurohormonal receptors (vasopressin, endothelin, atrial natriuretic peptide, and adenosine) or through completely novel pharmacologic profiles (levosimendan). Some agents or drug classes being studied include: tolvaptan, a V_2-selective vasopressin antagonist; various ET-A selective and non-selective antagonists; and an adenosine-1 receptor agonist.

OUTCOME EVALUATION OF ACUTE HEART FAILURE

- Focus on: (1) acute improvement of symptoms and hemodynamics due to intravenous therapies; (2) criteria for a safe discharge from the hospital; and (3) optimization of oral therapy.
- Initially, monitor patients for rapid relief of symptoms related to the chief complaint on admission. This includes improvement of dyspnea, oxygenation, fatigue, JVD, and other markers of congestion or distress.
- Monitor for adequate perfusion of vital organs through assessment of mental status, creatinine clearance, liver function tests, and a stable HR between 50 and 100 beats per minute. Additionally, adequate skin and muscle blood perfusion and normal pH is desirable.
- Monitor changes in hemodynamic variables if available. Cardiac index should increase, with a goal to maintain it above 2.2 L/minute per square meter. Pulmonary capillary wedge pressure should decrease in volume overloaded patients to a goal of less than 18 mm Hg.
- Closely monitor blood pressures and renal function while decreasing preload with diuretics and vasodilators.

- Ensure patients are euvolemic or nearly euvolemic prior to discharge.
- Since oral therapies can both improve symptoms and prolong survival, optimizing outpatient HF management is a priority when preparing a patient for hospital discharge. Ensure that the patient's regimen includes a vasodilator, β-blocker, a diuretic at an adequate dose to maintain euvolemia, and digoxin or aldosterone antagonist if indicated.

Patient Care and Monitoring

1. Assess the severity and duration of the patient's symptoms including limitations in activity. Rule out potential exacerbating factors.
2. Obtain a thorough history of prescription, nonprescription, and herbal medication use. Is the patient taking any medications that can exacerbate HF?
3. Review available diagnostic information from the chest radiograph, ECG, and echocardiogram.
4. Review the patient's lifestyle habits including salt and alcohol intake, tobacco product use, and exercise routine.
5. If unknown, investigate the patient's underlying etiology of HF. Verify that comorbidities that lead to or worsen HF are optimally managed with appropriate drug therapy.
6. Educate the patient on lifestyle modifications such as salt restriction (maximum 2 to 4 grams per day), fluid restriction if appropriate, limitation of alcohol, tobacco cessation, participation in a cardiac rehabilitation and exercise program, and proper immunizations such as the pneumococcal vaccine and yearly influenza vaccine.
7. Develop a treatment plan to alleviate symptoms and maintain euvolemia with diuretics. Daily weights to assess fluid retention are recommended.
8. Develop a medication regimen to slow the progression of HF with the use of neurohormonal blockers such as vasodilators (ACE inhibitors, ARBs, or hydralazine/isosorbide dinitrate), β-blockers, and aldosterone antagonists. Utilize digoxin if the patient remains symptomatic despite optimization of the above therapies.
   - Is the patient at goal or maximally tolerated doses of vasodilator and β-blocker therapy?
   - Are aldosterone antagonists utilized in appropriate patients with proper electrolyte and renal function monitoring?
9. Stress the importance of adherence to the therapeutic regimen and lifestyle changes for maintenance of a compensated state and slowing of disease progression.
10. Evaluate the patient for presence of adverse drug reactions, drug allergies, and drug interactions.
11. Provide patient education with regard to disease state and drug therapy, and reinforce self-monitoring for symptoms of HF that necessitate follow-up with a health care practitioner.

4 Ischemic Heart Disease

Larisa H. Cavallari and Robert J. DiDomenico

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Identify risk factors for the development of ischemic heart disease.
2. Recognize the symptoms and diagnostic criteria of ischemic heart disease in a specific patient.
3. Differentiate between the pathophysiology of chronic stable angina and acute coronary syndromes.
4. Identify the treatment goals of ischemic heart disease and appropriate lifestyle modifications and pharmacologic therapy to address each goal.
5. Design an appropriate therapeutic regimen for the management of ischemic heart disease based on patient-specific information.
6. Formulate a monitoring plan to assess effectiveness and adverse effects of an ischemic heart disease drug regimen.

Key Concepts

❶ Ischemic heart disease results from an imbalance between myocardial oxygen demand and oxygen supply that is most often due to coronary atherosclerosis. Common clinical manifestations of ischemic heart disease include chronic stable angina and the acute coronary syndromes of unstable angina, non–ST-segment elevation myocardial infarction, and ST-segment elevation myocardial infarction.

❷ Early detection and aggressive modification of risk factors is one of the primary strategies for delaying ischemic heart disease progression and preventing ischemic heart disease–related events including death.

❸ Patients with chest pressure or heaviness that is provoked by activity and relieved with rest should be assessed for ischemic heart disease. Sharp pain is not a typical symptom of ischemic heart disease. Some patients may experience discomfort in the neck, jaw, shoulder, or arm rather than, or in addition to, the chest. Pain may be accompanied by nausea, vomiting, or diaphoresis.

❹ The major goals for the treatment of ischemic heart disease are to prevent acute coronary syndromes and death, alleviate acute symptoms of myocardial ischemia, prevent recurrent symptoms of myocardial ischemia, and avoid or minimize adverse treatment effects.

❺ Both 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins) and angiotensin-converting enzyme inhibitors are believed to provide vasculoprotective effects, and in addition to antiplatelet agents, have been shown to reduce the risk of acute coronary events as well as mortality in patients with ischemic heart disease. Angiotensin receptor blockers may be used in patients who cannot tolerate angiotensin-converting enzyme inhibitors because of side effects (e.g., chronic cough). β-Blockers have been shown to decrease morbidity and improve survival in patients who have suffered a myocardial infarction.

❻ Antiplatelet therapy with aspirin should be considered for all patients without contraindications, particularly in patients with a history of myocardial infarction. Clopidogrel may be considered in patients with allergies or intolerance to aspirin. In some patients, combination antiplatelet therapy with aspirin and clopidogrel may be used.

❼ To control risk factors and prevent major adverse cardiac events, statin therapy should be considered in all patients with ischemic heart disease, particularly in those with elevated low-density lipoprotein cholesterol. In the absence of contraindications, angiotensin-converting enzyme inhibitors should be considered in ischemic heart disease patients who also have diabetes mellitus, left ventricular dysfunction, history of myocardial infarction, or any combination of these. Angiotensin receptor blockers

may be used in patients who cannot tolerate angiotensin-converting enzyme inhibitors because of side effects.

8 All patients with a history of angina should have sublingual nitroglycerin tablets or spray to relieve acute ischemic symptoms. Patients should be instructed to use one dose (tablet or spray) every 5 minutes until pain is relieved and to call 911 if pain is unimproved or worsens 5 minutes after the first dose.

9 β-Blockers are first-line therapy for preventing ischemic symptoms, particularly in patients with a history of myocardial infarction. Long-acting calcium channel blockers and long-acting nitrates may be added for refractory symptoms or substituted if a β-blocker is not tolerated.

10 Patients should be monitored to assess for drug effectiveness, adverse drug reactions, and potential drug-drug interactions. Patients should be assessed for adherence to their pharmacotherapeutic regimens and lifestyle modifications.

Ischemic heart disease (IHD) is also called coronary heart disease (CHD) or coronary artery disease. The term "ischemic" refers to a decreased supply of oxygenated blood, in this case to the heart muscle. Ischemic heart disease is caused by the narrowing of one or more of the major coronary arteries that supply blood to the heart, most commonly by atherosclerotic plaques. Atherosclerotic plaques may impede coronary blood flow to the extent that cardiac tissue distal to the site of the coronary artery narrowing is deprived of sufficient oxygen in the face of increased oxygen demand. 1 *Ischemic heart disease results from an imbalance between myocardial oxygen supply and oxygen demand (Fig. 4–1). Common clinical manifestations of IHD include chronic stable angina and the* ***acute coronary syndromes*** *(ACS) of unstable angina, non–ST-segment elevation myocardial infarction (MI), and ST-segment elevation MI.*

Angina pectoris, or simply angina, is the most common symptom of IHD. Angina is discomfort in the chest that occurs when the blood supply to the myocardium is compromised. Chronic stable angina is defined as a chronic and predictable occurrence of chest discomfort due to transient myocardial ischemia with physical exertion or other conditions that increase oxygen demand. The primary focus of this chapter is on the management of chronic stable angina. However, some information is also provided related to ACS, given the overlap between the two disease states. The American College of Cardiology and the American Heart Association have jointly published practice guidelines for the management of patients with chronic stable angina, and the reader is referred to these guidelines for further information.[1]

EPIDEMIOLOGY AND ETIOLOGY

Ischemic heart disease affects over 13 million Americans and is the leading cause of death for both men and women in the United States.[2] The incidence of IHD is higher in middle-aged men compared to women. However, the rate of IHD increases

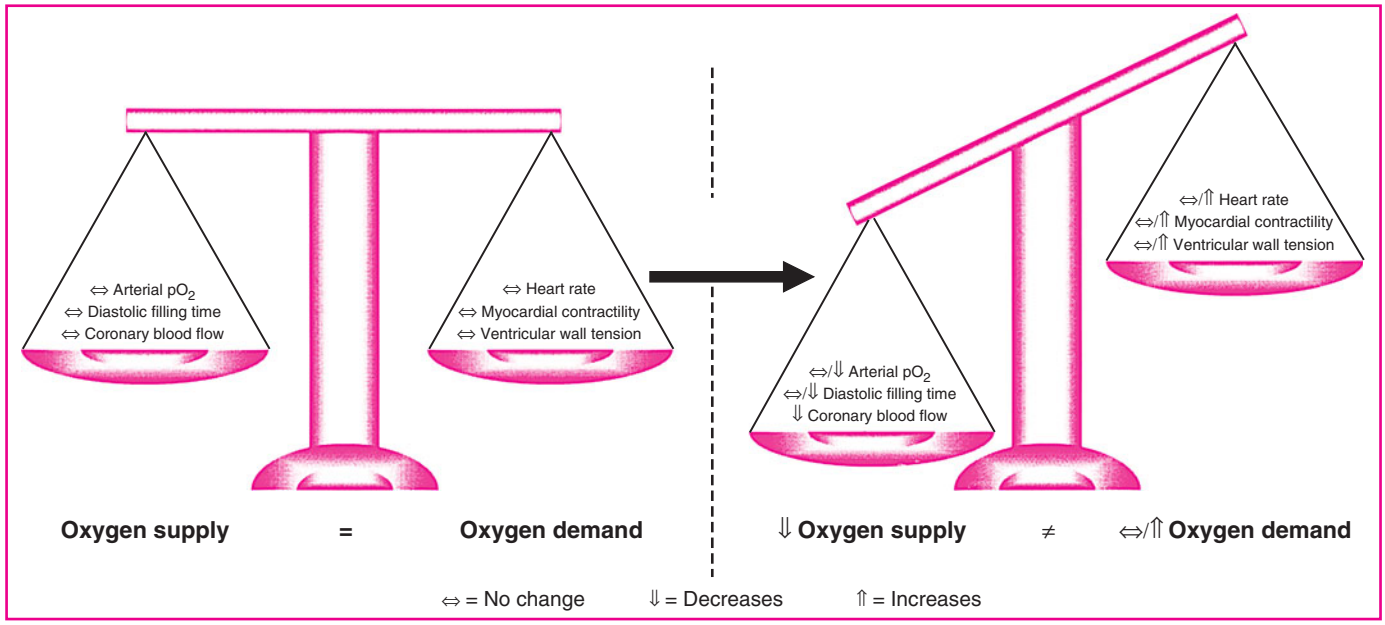

FIGURE 4–1. This illustration depicts the balance between myocardial oxygen supply and demand and the various factors that affect each. It should be noted that diastolic filling time is not an independent predictor of myocardial oxygen supply per se, but rather a determinant of coronary blood flow. On the left is myocardial oxygen supply and demand under normal circumstances. On the right is the mismatch between oxygen supply and demand in patients with ischemic heart disease. In patients without ischemic heart disease, coronary blood flow increases in response to increases in myocardial oxygen demand. However, in patients with ischemic heart disease, coronary blood flow cannot sufficiently increase (and may decrease) in response to increased oxygen demand resulting in angina. IHD, ischemic heart disease; pO_2, partial pressure of oxygen.

two- to three-fold in women after menopause. Chronic stable angina is the initial manifestation of IHD in about 50% of patients. In other patients, unstable angina or MI is the first sign of IHD. Chronic stable angina is associated with considerable patient morbidity, with many affected patients eventually requiring hospitalization for ACS.[3] In addition, chronic stable angina has a major negative impact on health-related quality of life.[4] Thus, in patients with chronic stable angina, it is important to optimize pharmacotherapy to reduce symptoms, improve quality of life, slow disease progression, and prevent ACS.

Conditions Associated with Angina

Figure 4–2 shows the anatomy of the coronary arteries. The major epicardial coronary arteries are the left main, left anterior descending, left circumflex, and right coronary arteries. **Atherosclerosis** involving one or more of the major coronary arteries or their principal branches is the major cause of angina. **Vasospasm** at the site of an atherosclerotic plaque may contribute to angina by further restricting blood supply to the distal myocardium. Less commonly, vasospasm in coronary arteries with no or minimal atherosclerotic disease can produce angina and even precipitate ACS. This type of vasospasm is referred to as variant or **Prinzmetal's angina**.

Non-ischemic cardiac conditions, such as aortic dissection (tear in the wall of the aorta leading to bleeding into the media layer of vessel and separation or dissecting of media from the outer layer of the aorta) and **pericarditis**, can cause chest discomfort that resembles angina. Non-cardiac conditions involving the pulmonary, gastrointestinal, and psychological systems can also cause angina-like symptoms. Table 4–1 lists specific conditions other than atherosclerosis that can precipitate angina-like symptoms. It is important to differentiate the etiology of chest discomfort since treatment varies depending on the underlying disease process.

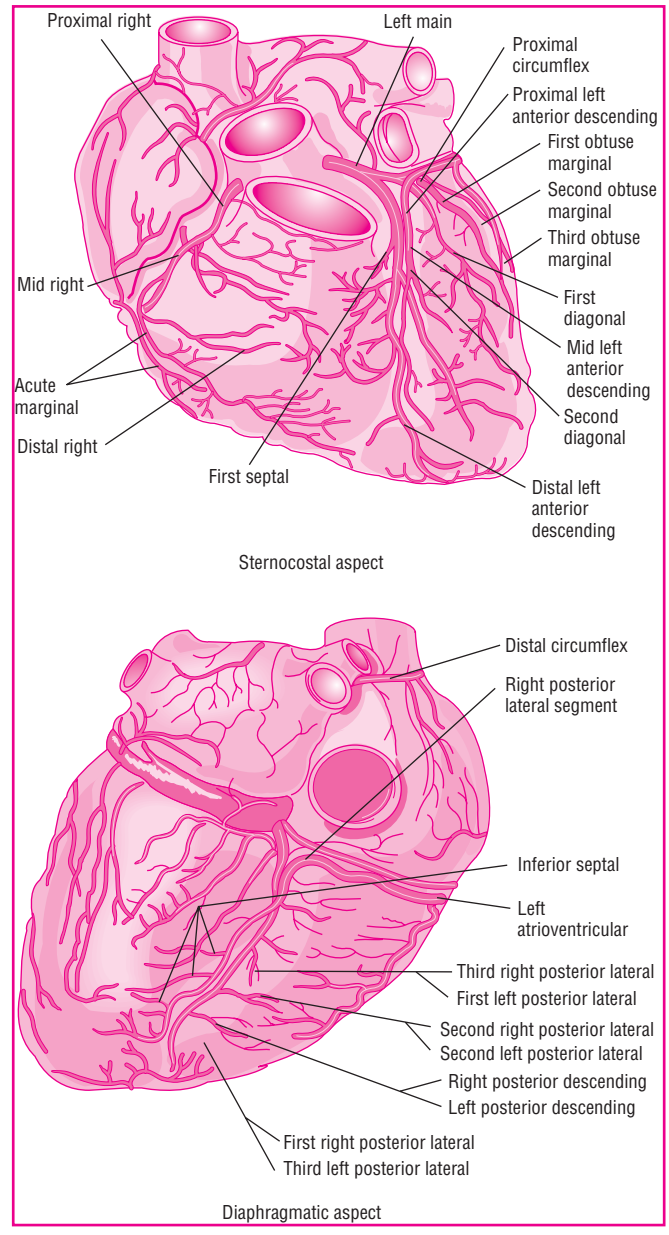

FIGURE 4–2. Coronary artery anatomy with sternocostal and diaphragmatic views. (Reproduced from Talbert RL. Ischemic heart disease. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 263, with permission.)

Risk Factors

Factors that predispose an individual to IHD are listed in Table 4–2. Hypertension, diabetes, **dyslipidemia**, and cigarette smoking are associated with endothelial dysfunction and potentiate atherosclerosis of the coronary arteries. The risk for IHD increases two-fold for every 20 mm Hg increment in systolic blood pressure and up to eight-fold in the presence of diabetes.[5,6] Physical inactivity and obesity independently increase the risk for IHD, in addition to predisposing individuals to other cardiovascular risk factors (e.g., hypertension, dyslipidemia, and diabetes).

Patients with multiple risk factors, particularly those with diabetes, are at the greatest risk for IHD. Metabolic syndrome is a constellation of cardiovascular risk factors related to hypertension, abdominal obesity, dyslipidemia, and insulin resistance. The risk of developing IHD and related complications is two-fold higher in patients with metabolic syndrome.[7] Therefore, detection and appropriate management of these patients is important. While there are several criteria used to diagnose metabolic syndrome, those endorsed by the National Cholesterol Education Program are probably the most widely

TABLE 4–1. Non-atherosclerotic Conditions that Can Cause Angina-like Symptoms

Organ System	Condition
Cardiac	Aortic dissection, coronary artery vasospasm, pericarditis, valvular heart disease
Non-cardiac	Anemia, anxiety disorders, carbon monoxide poisoning, cocaine use, esophageal reflux, peptic ulcer, pleuritis, pneumonia, **pneumothorax**, pulmonary embolus, pulmonary hypertension, **thyrotoxicosis**

accepted.[8] To diagnose metabolic syndrome, patients must meet at least three of the following criteria:

- Increased waist circumference (greater than 40 inches or 102 cm in males and greater than 35 inches or 89 cm in females).
- Triglycerides of 150 mg/dL (1.70 mmol/L) or greater or active treatment to lower triglycerides.
- Low high-density lipoprotein (HDL) cholesterol (less than 40 mg/dL or 1.04 mmol/L in males and less than 50 mg/dL or 1.3 mmol/L in females) or active treatment to raise HDL cholesterol.
- Blood pressure of 130/85 mm Hg or greater or active treatment with antihypertensive therapy.
- Fasting blood glucose of 100 mg/dL (5.55 mmol/L) or greater or active treatment for diabetes.

❷ *Early detection and aggressive modification of risk factors are among the primary strategies for delaying IHD progression and preventing IHD-related events including death.*

PATHOPHYSIOLOGY

The determinants of oxygen supply and demand are shown in Fig. 4–1. Increases in heart rate, left ventricular wall tension, and cardiac contractility increase the rate of myocardial oxygen consumption (MVO_2). Left ventricular wall tension is a function of blood pressure, left ventricular end-diastolic volume, and ventricular wall thickness. Physical exertion increases heart rate, blood pressure, and cardiac contractility, and commonly precipitates ischemia and symptoms of angina in patients with significant coronary atherosclerosis. Medications that reduce heart rate, cardiac contractility, and/or ventricular wall tension are commonly prescribed to prevent ischemic symptoms in patients with chronic stable angina.

TABLE 4–2. Major Risk Factors for Ischemic Heart Disease

Modifiable	Non-modifiable
Cigarette smoking	Age 45 years or greater for males, age 55 years or greater for females
Dyslipidemia	Gender (men and postmenopausal women)
• Elevated LDL or total cholesterol	Family history of premature cardiovascular disease, defined as cardiovascular disease in a male first-degree relative (i.e., father or brother) younger than 55 years old or a female first-degree relative (i.e., mother or sister) younger than 65 years
• Reduced HDL cholesterol	
Diabetes mellitus	
Hypertension	
Physical inactivity	
Obesity (body mass index greater than or equal to 30 kg/m^2)	

HDL, high-density lipoprotein; LDL, low-density lipoprotein

Reductions in coronary blood flow (secondary to atherosclerotic plaques, vasospasm, or **thrombus** formation) and arterial oxygen content (secondary to hypoxia) decrease myocardial oxygen supply. Because the coronary arteries fill during diastole, decreases in diastolic filling time (e.g., tachycardia) can also reduce coronary perfusion and myocardial oxygen supply. In chronic stable angina, atherosclerotic plaques are the most common cause of coronary artery narrowing and reductions in coronary blood flow. In contrast, in ACS, disruption of an atherosclerotic plaque with subsequent thrombus (blood clot) formation causes abrupt reductions in coronary blood flow and oxygen supply. Anemia, carbon monoxide poisoning, and cyanotic congenital heart disease are examples of conditions that reduce the oxygen-carrying capacity of the blood, potentially causing ischemia in the face of adequate coronary perfusion. Interventional procedures to compress or bypass atherosclerotic plaques are effective methods of improving myocardial oxygen supply in patients with IHD.

Coronary Atherosclerosis

The normal arterial wall consists of the intima, media, and adventitia, as illustrated in Fig. 4–3A. The endothelium is located in the intima and consists of a layer of endothelial cells that line the lumen of the artery and form a selective barrier between the vessel wall and blood contents. The internal elastic lamina separates the intima and media, where vascular smooth muscle cells are found. The vascular adventitia comprises the artery's outer layer. Atherosclerotic lesions form in the subendothelial space between the endothelial cells and internal elastic lamina.

Dysfunction of the endothelium allows lipoproteins, predominantly low-density lipoprotein (LDL) cholesterol, and inflammatory cells, namely monocytes and T lymphocytes, to migrate from the plasma to the sub-endothelial space. Monocyte-derived macrophages ingest lipoproteins to form foam cells. Macrophages also secrete growth factors that promote smooth muscle cell migration from the media to the intima. A fatty streak consists of lipid-laden macrophages and smooth muscle cells and is the earliest type of atherosclerotic lesion.

Lipid-laden macrophages, smooth muscle cells, and necrotic debris from the death of foam cells accumulate in the subendothelial space, leading to enlargement of the fatty streak. A collagen matrix forms a fibrous cap that covers the lipid core of the lesion to establish a fibrous plaque called an atherosclerotic plaque. Initially, the diameter of the coronary artery lumen is

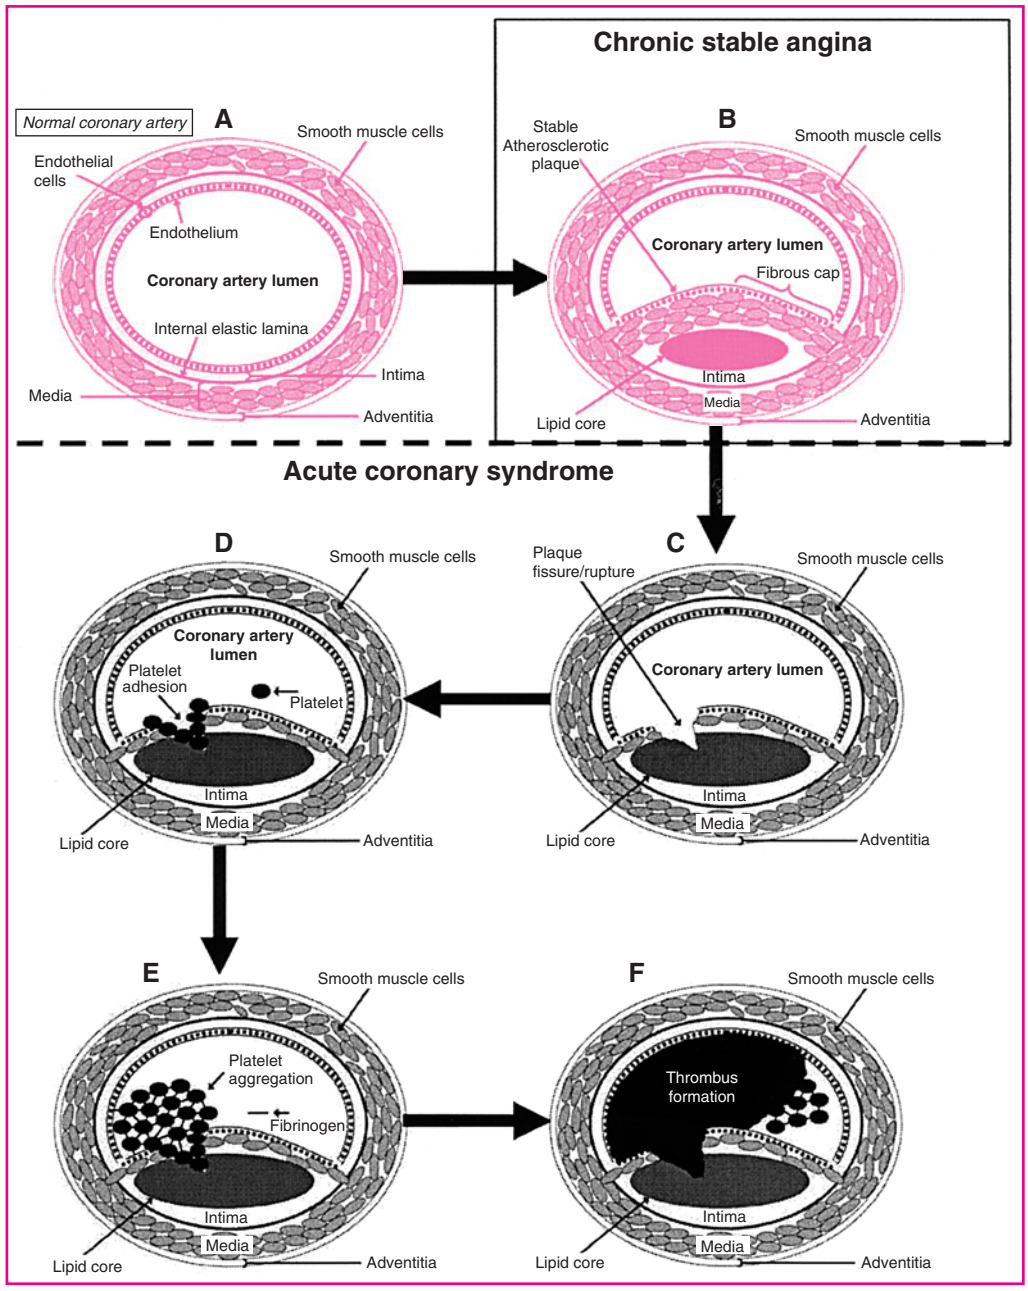

FIGURE 4–3. Pathophysiology of chronic stable angina versus acute coronary syndromes. Panel A depicts the cross-section of a normal coronary artery. Panel B depicts the cross-section of a coronary artery with a stable atherosclerotic plaque. Note that the lipid core is relatively small in size and the fibrous cap is made up of several layers of smooth muscle cells. Panel C depicts an unstable atherosclerotic plaque with a larger lipid core, and a thin fibrous cap comprised of a single layer of smooth muscle cells with a fissure or rupture. Panel D depicts platelet adhesion in response to the fissured plaque. Platelet activation may ensue leading to platelet aggregation as fibrinogen binds platelets to one another to form a meshlike occlusion in the coronary lumen (Panel E). At this stage, patients may experience symptoms of acute coronary syndrome. If endogenous anticoagulant proteins fail to halt this process, platelet aggregation continues and fibrinogen is converted to fibrin, resulting in an occlusive thrombus (Panel F).

maintained as the plaque grows outward (external to the lumen) in a process referred to as arterial remodeling.[9] However, with significant plaque progression, the atherosclerotic plaque begins to protrude into the artery lumen and impede blood flow. When the plaque occludes 70% or more of the artery, the patient may begin to experience angina during activities that increase myocardial oxygen demand (i.e., chronic stable angina).

Stable versus Unstable Atherosclerotic Plaques

The hallmark feature in the pathophysiology of chronic stable angina is an established atherosclerotic plaque that impedes coronary blood flow to the extent that myocardial oxygen supply can no longer meet increases in myocardial oxygen demand. Over time, an established plaque may become unstable and rupture, leading to an ACS. Atherosclerotic plaque rupture with subsequent thrombus formation is the hallmark feature in the pathophysiology of unstable angina and MI and is depicted in Fig. 4–3. Plaque rupture refers to fissuring or erosion of the fibrous cap that covers the lipid core and exposure of the plaque contents to elements in the blood. Plaque composition, rather than the degree of coronary stenosis, determines the stability of the plaque and the likelihood of plaque rupture and ACS. Specifically, a stable lesion consists of

a small lipid core that is surrounded by a thick fibrous cap that protects the lesion from the shear stress of blood flow (Fig. 4–3B). In contrast, an unstable plaque consists of a thin, weak cap in combination with a large, rich lipid core that renders the plaque vulnerable to rupture (Fig. 4–3C). The transformation of a stable plaque into an unstable plaque involves the degradation of the fibrous cap by substances released from macrophages and other inflammatory cells. An unstable plaque often produces minimal occlusion of the coronary vessel, and the patient remains asymptomatic until the plaque ruptures. In fact, the majority of MIs arise from vulnerable plaques that occlude less than 50% of the coronary lumen.[10] As a result, unstable angina or MI is the initial manifestation of IHD in about one-half of affected patients.

Atherosclerotic Plaque Rupture

Following plaque rupture, exposure of the blood to the thrombogenic contents of the plaque stimulates platelet adhesion and activation of the coagulation cascade. Platelets adhere to the site of rupture, aggregate, and generate thrombin (Fig. 4–3D, E, and F). Thrombin converts fibrinogen to fibrin to form a fibrin clot. Coronary thrombi extend into the vessel lumen, where they either partially or completely occlude blood flow, resulting in unstable angina or MI.

Coronary Artery Vasospasm

Prinzmetal's or variant angina results from spasm (or contraction) of a normal or diseased coronary artery. In contrast to chronic stable angina, diseased arteries in variant angina contain lesions that do not obstruct blood flow. While vasospasm is generally transient, in some instances vasospasm may persist long enough to infarct the myocardium. Variant angina usually occurs at rest, especially in the early morning hours. Patients with variant angina are typically younger than those with chronic stable angina and often do not possess the classic risk factors for IHD. The cause of variant angina is unclear but appears to involve endothelial dysfunction and paradoxical response to agents that normally cause vasodilation. Precipitants of variant angina include cigarette smoking, cocaine use, hyperventilation, and exposure to cold temperatures. The management of variant angina differs from that of classic angina, and thus it is important to distinguish between the two.

CLINICAL PRESENTATION AND DIAGNOSIS

History

The evaluation of a patient with suspected IHD begins with a detailed history of anginal symptoms. The five components commonly used to characterize chest pain are quality, location, duration of pain, factors that provoke pain, and factors

❸Clinical Presentation and Diagnosis of Ischemic Heart Disease

General

- Patients with chronic stable angina will generally be in no acute distress. In patients presenting in acute distress, the clinician should be suspicious of ACS.

Symptoms of Angina Pectoris

- Patients typically describe pain as a sensation of pressure, heaviness, or squeezing in the anterior chest area. Sharp pain is not a typical symptom of IHD.
- Pain may radiate to the neck, jaw, shoulder, back, or arm.
- Pain may be accompanied by dyspnea, nausea, vomiting, or **diaphoresis.**
- Symptoms are often provoked by exertion (e.g., walking, climbing stairs, and doing yard or house work) or emotional stress and relieved within minutes by rest or nitroglycerin. Other precipitating factors include exposure to cold temperatures and heavy meals. Pain that occurs at rest (without provocation) or that is prolonged and unrelieved by nitroglycerin is indicative of an ACS. Some patients, most commonly women and patients with diabetes, present with atypical symptoms of ischemia including indigestion, gastric fullness, and shortness of breath.

Signs

- Findings on the physical exam are often normal in patients with chronic stable angina. However, during episodes of ischemia, patients may present with abnormal heart sounds, such as paradoxical splitting of the second heart sound, a third heart sound, or a loud fourth heart sound.

Laboratory Tests

- Biochemical markers (creatine kinase [CK], CK-MB fraction, troponin I and troponin T) are elevated in MI (ST-segment elevation MI and non–ST-segment elevation MI), but normal in chronic stable angina and unstable angina.

Other Diagnostic Tests

- A 12-lead electrocardiogram (ECG) recorded during rest is often normal in patients with chronic stable angina in the absence of active ischemia. Significant Q waves indicate prior MI. ST-segment or T-wave changes during symptoms of angina support the diagnosis of IHD. ST-segment depression or T-wave inversion is typically observed in chronic stable angina, unstable angina, and non–ST-segment elevation MI, whereas ST-segment elevation occurs with ST-segment elevation MI and Prinzmetal's (variant) angina.
- Treadmill or bicycle exercise ECG, commonly referred to as a "stress test," is considered positive for IHD if the ECG shows at least a 1 mm deviation of the ST-segment (depression or elevation).
- Wall motion abnormalities or left ventricular dilation with stress echocardiography are indicative of IHD.
- Stress myocardial perfusion imaging with the radionuclides technetium-99m sestamibi or thallium-201 allows for the identification of multivessel disease and assessment of myocardial viability.

(*Continued*)

- Coronary angiography detects the location and degree of coronary atherosclerosis and is used to evaluate the potential benefit from revascularization procedures. Stenosis of at least 70% of the diameter of at least one of the major epicardial arteries on coronary angiography is indicative of significant IHD.

that relieve pain. The classic presentation of angina is described in the Clinical Presentation and Diagnosis box. In some cases, ischemia may not produce any symptoms and is termed "silent ischemia." Patients with diabetes may experience associated symptoms, such as dyspnea and diaphoresis, without having any of the classic chest pain symptoms.

Non-cardiac conditions, such as gastroesophageal reflux disease, may cause chest pain that is difficult to distinguish from angina. A detailed history and risk factor assessment may help to clarify the diagnosis. For example, pain that is sharp or stabbing, occurs randomly (not provoked by exertion or stress), is tender to palpation, changes with position or respiration, responds variably to nitroglycerin, or lasts for hours is atypical of angina and suggestive of a non-cardiac etiology. The diagnosis of IHD is also less likely in a patient with atypical symptoms who has no known risk factors for IHD.

The Canadian Cardiovascular Society Classification System

The Canadian Cardiovascular Society Classification System (Table 4–3) is commonly used to assess the degree of disability resulting from IHD. Patients are categorized into one of four classes depending on the extent of activity that produces angina. Grouping patients according to this or a similar method is commonly used to assess changes in IHD severity over time and the effectiveness of pharmacologic therapy.

Patient Encounter, Part 1

RJ is a 47-year-old man with a history of hypertension who presents to your clinic complaining of chest pain that occurred several times over the past few weeks. RJ describes his chest pain as "a heaviness." He states that it first occurred while he was mowing the grass. He later felt the same heavy sensation while raking leaves and again while carrying some boxes. The pain was located in the substernal area and radiated to his neck. The pain resolved after about 5 minutes of rest.

- Are RJ's symptoms consistent with angina?
- What tests would be beneficial in establishing a diagnosis?
- What additional objective information do you need in order to create a treatment plan for this patient?

TABLE 4–3. The Canadian Cardiovascular Society Classification System of Angina[49]

Class	Description
I	Able to perform ordinary physical activity (e.g., walking and climbing stairs) without symptoms. Strenuous, rapid, or prolonged exertion causes symptoms.
II	Symptoms slightly limit ordinary physical activity. Walking rapidly or for more than two blocks, climbing stairs rapidly or climbing more than one flight of stairs causes symptoms.
III	Symptoms markedly limit ordinary physical activity. Walking less than two blocks or climbing one flight of stairs causes symptoms.
IV	Angina may occur at rest. Any physical activity causes symptoms.

Distinguishing Characteristics of Chronic Stable Angina and Unstable Angina

Chronic stable angina should be distinguished from unstable angina since the latter is associated with a greater risk for MI and death and requires more aggressive treatment. Because the pathophysiology of chronic stable angina is due primarily to increases in oxygen demand, not acute changes in oxygen supply, symptoms are typically reproducible and reversible. Specifically, a patient will generally experience a similar pattern of discomfort (i.e., same quality, location, and accompanying symptoms) with a similar level of exertion with each angina attack. Chronic stable angina is usually relieved within minutes by rest or sublingual nitroglycerin. In contrast, unstable angina is due to an acute decrease in coronary blood flow leading to insufficient oxygen supply. Consequently, unstable angina is marked by prolonged symptoms (greater than or equal to 20 minutes) or an escalation in the frequency or severity of angina over a short period of time. Unstable angina frequently occurs at rest without any precipitating factors, whereas chronic stable angina usually occurs with exertion. Unstable angina may be less responsive to rest or medication. The presentation of unstable angina is described in greater detail in Table 4–4.

Physical Findings and Laboratory Analysis

A thorough medical history and physical exam are necessary to ascertain cardiovascular risk factors and to exclude non-ischemic

TABLE 4–4. Presentations of Unstable Angina[50]

- Angina at rest that is prolonged in duration, usually lasting over 20 minutes.
- Angina of recent onset (within 2 months) that markedly limits usual activity.
- Angina that increases in severity (i.e., by Canadian Cardiovascular Society Classification System Class of one level or greater), frequency, or duration, or that occurs with less provocation over a short time period (i.e., within 2 months).

and non-cardiac conditions that could cause angina-like symptoms. Cardiac findings on the physical exam are often normal in patients with chronic stable angina. However, findings such as **carotid** bruits or abnormal peripheral pulses would indicate atherosclerosis in other vessel systems and raise the suspicion for IHD.

Laboratory analysis and cardiac testing are other important components of the evaluation of the patient with chest pain. Usual laboratory tests include hemoglobin, fasting glucose, and fasting lipid profile (total cholesterol, LDL cholesterol, HDL cholesterol, and triglycerides) to assess for cardiovascular risk factors and comorbid conditions. Biochemical markers of myocardial necrosis (i.e., cardiac enzymes), including creatine kinase (CK)-MB fraction and cardiac troponin (I or T), are acutely elevated after MI but normal in chronic stable angina and unstable angina. Therefore serial measurements of cardiac enzymes (usually three measurements within 24 hours) are used to exclude the diagnosis of MI.

Diagnostic Tests

A resting ECG is indicated in all patients with angina-like symptoms. A 12-lead ECG should be done within 10 minutes of presentation to the emergency department in patients with symptoms of ischemia. Electrocardiographic findings indicative of myocardial ischemia include ST-segment elevation, ST-segment depression, and T-wave abnormalities in two or more contiguous leads. It is important to promptly identify patients with ST-segment elevation, as these patients are at the highest risk of death and need interventions to restore blood flow to the myocardium as quickly as possible. In patients without ST-segment elevation, biochemical markers are used to distinguish between unstable angina and non–ST-segment elevation MI.

Exercise ECG testing using either a treadmill (most commonly) or bicycle ergometer is a common non-invasive test to evaluate the patient with suspected IHD. "Stress" testing increases myocardial oxygen demand and often precipitates angina in patients with IHD. Approximately 50% of patients with IHD who have a normal ECG at rest will develop ECG changes with exercise. Pharmacologic stressors are used for patients who are unable to exercise. Dobutamine is commonly used with stress echocardiography, whereas adenosine or dipyridamole are used for nuclear imaging studies. Coronary angiography (also referred to as a cardiac catheterization or "cardiac cath") is considered the gold standard for the diagnosis of IHD and is indicated when stress testing results are abnormal or symptoms of angina are poorly controlled. Angiography involves catheter insertion, usually into the femoral artery, and advancement into the aorta and into the coronary arteries. Contrast medium is injected through the catheter into the coronary arteries allowing visualization of the coronary anatomy by fluoroscopy.

Patient Encounter, Part 2: Medical History, Physical Exam, and Diagnostic Tests

PMH
Hypertension, diagnosed 7 years ago

FH
Father with coronary artery disease, had a myocardial infarction at age 50 years
Mother alive and well

SH
Smokes $^1/_2$ to 1 pack per day
Denies alcohol and illicit drug use
No regular exercise program

Meds
Hydrochlorothiazide 25 mg PO once daily
Nifedipine XL 60 mg PO once daily
No known drug allergies

PE
VS: Blood pressure = 154/90 mm Hg
Heart rate = 84 beats per minute, respirations = 16
Temperature = 37°C (98.6°F)
Height = 5′10″ (178 cm), weight = 230 lb (104.6 kg)
Cardiovascular: Regular rate and rhythm, normal S_1 and S_2, no S_3 or S_4; no murmurs, rubs, gallops
Lungs: Clear to auscultation and percussion
Abd: Nontender, nondistended, + bowel sounds

Labs
Fasting lipid profile: total cholesterol 233 mg/dL (6.03 mmol/L), HDL cholesterol 30 mg/dL (0.78 mmol/L), LDL cholesterol 165 mg/dL (4.27 mmol/L), triglycerides 188 mg/dL (2.12 mmol/L); other labs within normal limits

Exercise treadmill test: positive for ischemia

- Identify RJ's risk factors for ischemic heart disease.
- How might RJ's current drug regimen adversely affect his ischemic heart disease?
- What therapeutic alternatives are available to manage RJ's ischemic heart disease?

TREATMENT

Desired Outcomes

Once the diagnosis of IHD is established in a patient, the clinician should provide counseling on lifestyle modifications, institute appropriate pharmacologic therapy, and evaluate the need for surgical revascularization. ❹ *The major goals for the treatment of IHD are to:*

- *Prevent acute coronary syndromes and death;*
- *Alleviate acute symptoms of myocardial ischemia;*

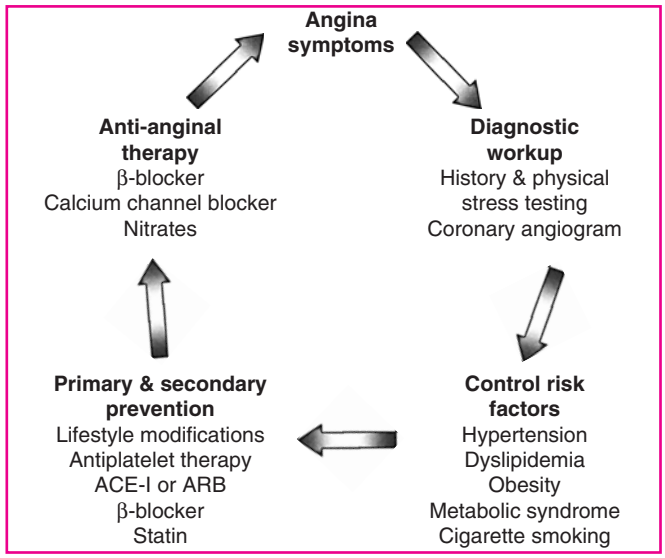

FIGURE 4–4. General treatment strategies for angina follow in clockwise fashion from the top center. ACE-I, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker.

- *Prevent recurrent symptoms of myocardial ischemia; and*
- *Avoid or minimize adverse treatment effects.*

The treatment approach to address these goals is illustrated in Fig. 4–4.

General Approach to Treatment

The primary strategies for preventing ACS and death are to:

- Modify cardiovascular risk factors;
- Slow the progression of coronary atherosclerosis; and
- Stabilize existing atherosclerotic plaques.

The treatment algorithm in Fig. 4–5 summarizes the appropriate management of IHD. Risk factor modification is accomplished through lifestyle changes and pharmacologic therapy. ❺ *Both 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (HMG-CoA reductase inhibitors or statins) and angiotensin-converting enzyme (ACE) inhibitors are believed to provide vasculoprotective effects (properties that are generally protective of the vasculature, which may include anti-inflammatory effects, antiplatelet effects, improvement in endothelial function, and improvement in arterial compliance and tone), and in addition to aspirin, have been shown to reduce the risk of acute coronary events as well as mortality in patients with IHD. Angiotensin receptor blockers (ARBs) may be used in patients who cannot tolerate ACE inhibitors because of side effects (e.g., chronic cough). β-Blockers have been shown to decrease morbidity and improve survival in patients who have suffered an MI.*

Therapies to alleviate and prevent angina are aimed at improving the balance between myocardial oxygen demand and supply. Since angina usually results from increased myocardial oxygen demand in the face of a relatively fixed reduction in oxygen supply, drug treatment is primarily aimed at reducing oxygen demand. Short-acting nitrates are indicated to acutely relieve angina. β-Blockers, calcium channel blockers (CCBs), and long-acting nitrates are traditionally used to reduce the frequency of angina and improve exercise tolerance. In most patients with IHD, the most effective treatments to improve myocardial oxygen supply are invasive mechanical interventions: **percutaneous coronary intervention (PCI)** and **coronary artery bypass graft (CABG) surgery**. Percutaneous coronary intervention involves the threading of a catheter to the site of an atherosclerotic lesion in a coronary artery. Then, either a balloon on the tip of the catheter is inflated to compress the plaque against the arterial wall (balloon angioplasty) or a device is used to cut away the plaque. Often, a stent (a wire mesh tube resembling a spring) is placed at the site of balloon angioplasty to hold the vessel open. Coronary artery bypass graft surgery involves using a leg vein or mammary artery to form a conduit around an atherosclerotic plaque.

Adverse treatment effects can largely be averted by avoiding drug interactions and the use of drugs that may have unfavorable effects on comorbid diseases. For example, β-blockers may exacerbate preexisting bronchospasm. β-Blockers are not absolutely contraindicated in bronchospastic disease, but should be avoided in patients with poorly controlled symptoms. While patients often require combination anti-anginal therapy, there is a potential pharmacodynamic drug interaction with the concurrent use of β-blockers and nondihydropyridine calcium channel blockers. Since both drug classes slow electrical conduction through the atrioventricular (AV) node, serious bradycardia or heart block may result with their concomitant use. Appropriate drug dosing and monitoring also reduces the risk for adverse treatment effects. Drugs should be initiated in low doses, with careful up-titration as necessary to control symptoms of angina and cardiovascular risk factors.

Lifestyle Modifications

Lifestyle modifications include smoking cessation, dietary modifications, increased physical activity, and weight loss. Lifestyle modifications reduce cardiovascular risk factors, slow the progression of IHD, and decrease the risk for IHD-related complications. Cigarette smoking is the single most preventable cause of IHD. Smoking cessation substantially reduces the risk of death from IHD.[11] The clinician should ascertain smoking status on the patient's initial clinic visit and provide counseling on the importance of smoking cessation at each subsequent visit for patients who continue to smoke. There are several pharmacologic aids for smoking cessation. Transdermal nicotine replacement therapy has been shown to be safe in patients with IHD.[12]

Weight loss, through caloric restriction and increased physical activity, should be encouraged in patients who have a body mass index greater than 25 kg/m^2. Dietary modification is important for risk factor management, and dietary counseling

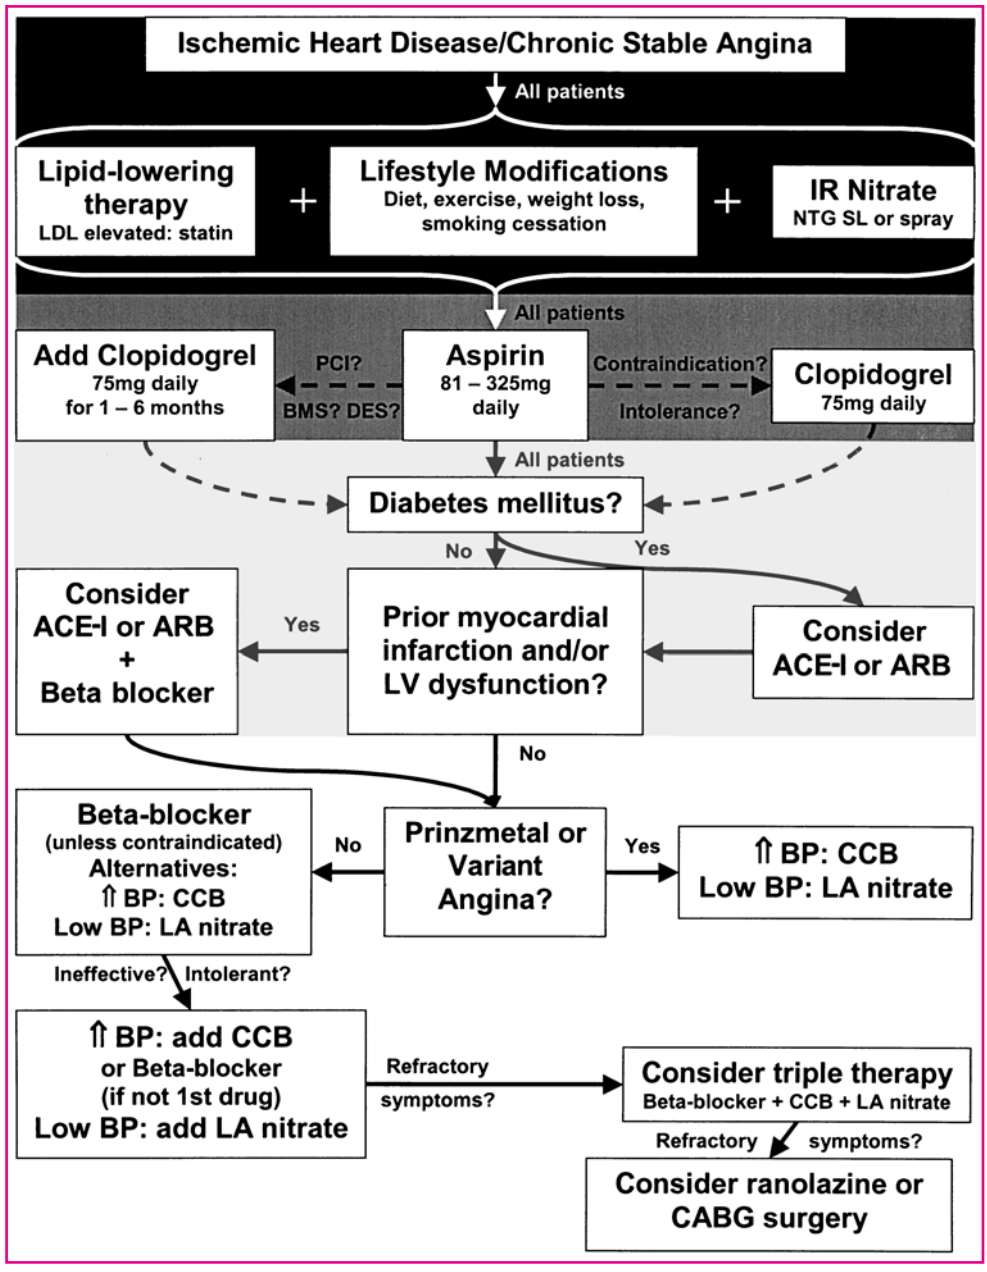

FIGURE 4–5. The treatment algorithm for ischemic heart disease. It begins at the top (black section), which suggests risk factor modifications as the first treatment modality. Moving down to the dark gray section, appropriate antiplatelet therapy is selected. The light gray section identifies patients at high-risk for major adverse cardiac events and suggests appropriate drug therapy to decrease cardiovascular risk. The white section at the bottom recommends appropriate anti-anginal therapy. ACE-I, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BMS, bare metal stent; BP, blood pressure; CABG, coronary artery bypass graft; CCB, calcium channel blocker; DES, drug-eluting stent; IR, immediate-release; LA, long-acting; LDL, low-density lipoprotein; LV, left ventricular; NTG, nitroglycerin; PCI, percutaneous coronary intervention; SL, sublingual.

should be provided to all patients with newly diagnosed angina regardless of weight. The American Heart Association recommends a diet that includes a variety of fruits, vegetables, grains, low-fat or non-fat dairy products, fish, legumes, poultry, and lean meats.[13] Fatty fish, such as salmon and herring, are high in omega-3 fatty acids, which have been shown to reduce triglyceride concentrations and slow atherosclerotic plaque progression.[13] A Mediterranean diet rich in fish in addition to fruit, cooked and raw vegetables, and olive oil has been shown to reduce mortality after MI.[14] Specific dietary recommendations for patients with IHD should include the following:[13]

- Limit fat intake to less than 30% of total caloric consumption.
- Limit cholesterol intake to less than 200 mg per day.
- Limit consumption of saturated fat found in fatty meats, full-fat dairy products, and hydrogenated vegetable oils to less than 7% of total calories.
- Consume at least two servings of fish per week.
- Consume at least six servings of grains, five servings of fruits and vegetables, and two servings of non-fat or low-fat dairy products per day.
- Limit daily sodium intake to 2.4 grams (6 grams of salt) for blood pressure control.

Exercise facilitates both weight loss and blood pressure reduction. In addition, regular exercise improves functional capacity and symptoms in chronic stable angina.[1] Once drug therapy for IHD is instituted, patients should be encouraged

to begin a low level of exercise for 20 to 30 minutes at a time, with increases in exercise duration and intensity as symptoms allow.[15]

Interventional Approaches

Percutaneous Coronary Intervention

When drug therapy fails or if extensive coronary atherosclerosis is present, PCI is often performed to restore coronary blood flow, relieve symptoms, and prevent major adverse cardiac events. Patients with one or more critical coronary stenoses (i.e., greater than 70% occlusion of the coronary lumen) detected during coronary angiography may be candidates for PCI. Several catheter-based interventions may be used during PCI, including:

- Percutaneous transluminal coronary angioplasty (PTCA);
- Intracoronary bare metal stent placement;
- Intracoronary drug-eluting stent placement; and
- Rotational atherectomy.

During PCI, a catheter is advanced into the blocked coronary artery, as described for cardiac catheterization. If PTCA (i.e., balloon angioplasty) is performed, a balloon at the end of the catheter is inflated inside the artery at the site of the critical stenosis. When inflated, this balloon catheter displaces the atherosclerotic plaque out of the lumen of the artery, restoring normal myocardial blood flow. In addition to angioplasty, most PCI procedures involve the insertion of an intracoronary stent. In this case, a special balloon catheter containing a small wire stent (similar in size and shape to the spring at the tip of a ball point pen) is used. When the balloon is inflated, the wire stent (bare metal stent) is deployed in the wall of the coronary artery, forming a sort of bridge to maintain normal coronary blood flow. While bare metal stents are very effective in restoring coronary blood flow, restenosis (re-narrowing of the coronary artery after a PCI to improve coronary blood flow) at the site of stent deployment is common, requiring additional PCI. Drug-eluting stents have thus been developed to reduce the incidence of restenosis and are commonly used in patients undergoing PCI. These stents are impregnated with low concentrations of antiproliferative medications, such as paclitaxel or sirolimus, which are slowly released locally within the coronary artery over several weeks. The antiproliferative effects of these drugs significantly inhibit restenosis, decreasing the need for repeated PCI procedures. Despite the effectiveness of both bare metal and drug-eluting stents, acute thrombotic occlusion is still possible. Therefore, following PCI with either type of stent, combination antiplatelet therapy (discussed later) is required for at least 1 month and perhaps indefinitely to reduce this risk. Lastly, rotational atherectomy may be performed wherein a special catheter is used to essentially cut away the atherosclerotic plaque, restoring coronary blood flow.

Coronary Artery Bypass Graft Surgery

As an alternative to PCI, CABG surgery, or open-heart surgery, may be performed if the patient is found to have extensive coronary atherosclerosis (generally greater than 70% occlusion of three or more coronary arteries) or is refractory to medical treatment. In the former case, CABG surgery has been shown to reduce mortality from IHD. During CABG surgery, veins from the leg or arteries on the inside of the chest wall (i.e., internal mammary arteries) are surgically removed. In the case of venous conduits, one end of the removed blood vessel is attached to the aorta, and the other end is attached to the coronary artery distal to the atherosclerotic plaque. However, when internal mammary arteries are used, the distal end of the artery is detached from the chest wall and anastomosed to the coronary artery distal to the plaque. A median sternotomy, in which an incision the length of the sternum is made, is commonly required to gain access to the thoracic cavity and expose the heart. As the "new" blood vessels are being engrafted, the patient is typically placed on cardiopulmonary bypass (i.e., heart-lung machine) to maintain appropriate myocardial and systemic perfusion. Because of the extremely invasive nature of this surgery, CABG surgery is often a treatment of last resort in patients with IHD.

Pharmacologic Therapy

Pharmacotherapy to Prevent Acute Coronary Syndromes and Death

Antiplatelet Agents

Platelets play a major role in the pathophysiology of ACS. Specifically, platelets adhere to the site of atherosclerotic plaque rupture where they become activated, aggregate, and stimulate thrombus formation and ACS. Thromboxane is a potent platelet activator. Aspirin inhibits cyclooxygenase, an enzyme responsible for the production of thromboxane. Through its effects on thromboxane, aspirin inhibits platelet activation and aggregation. ❺ *In patients with stable or unstable angina, aspirin has been consistently shown to reduce the risk of major adverse cardiac events, particularly MI.*[16–18] ❻ *Antiplatelet therapy with aspirin should be considered for all patients without contraindications, particularly in patients with a history of myocardial infarction.* Aspirin doses of 75 to 325 mg daily have been shown to be cardioprotective. If aspirin is contraindicated (e.g., aspirin allergy, active peptic ulcer disease, or active internal bleeding) or is not tolerated by the patient, other antiplatelet agents such as clopidogrel should be considered.

Recent studies have suggested that combination antiplatelet therapy may be synergistic in reducing the risk of IHD-related events. In patients with ACS, the combination of aspirin and clopidogrel 75 mg daily for up to 9 months was more effective than aspirin alone in decreasing the risk of

death, MI, and stroke.[19] This combination also prevents complications following PCI.[20] The American College of Chest Physicians recommends the combination of aspirin and clopidogrel for 9 to 12 months in patients with IHD who have undergone PCI.[21] For isolated PCI procedures, the recommended duration of combination aspirin and clopidogrel therapy is as follows:

- At least 2 weeks for bare metal stent placement.
- At least 2 to 3 months for sirolimus-eluting stent placement.
- At least 6 months following paclitaxel-eluting stent placement.

Statins

Over the last decade, several studies in tens of thousands of patients have revealed that lowering cholesterol, specifically lowering LDL cholesterol with statins, is effective for both primary and secondary prevention of IHD-related events. Statins shown to decrease morbidity and mortality associated with IHD include lovastatin, simvastatin, pravastatin, and atorvastatin.[22,23] A recent meta-analysis showed that the risk of major adverse cardiac events is reduced by 21% with the use of statins in patients at high risk for IHD-related events.[23]

Several studies have investigated whether statins possess pharmacologic properties in addition to their LDL cholesterol–lowering effect that may confer additional benefits in IHD.[24] These studies were prompted by evidence that patients with "normal" LDL cholesterol derived benefit from statins. Statins have been shown to modulate the following characteristics thought to stabilize atherosclerotic plaques and contribute to the cardiovascular risk reduction seen with these drugs:

- Shift LDL cholesterol particle size from predominantly small, dense, highly atherogenic particles to larger, less atherogenic particles.
- Improve endothelial function leading to more effective vasoactive response of the coronary arteries.
- Prevent or inhibit inflammation by lowering C-reactive protein and other inflammatory mediators thought to be involved in atherosclerosis.
- Possibly improving atherosclerotic plaque stability.

❼ *In summary, to control risk factors and prevent major adverse cardiac events, statin therapy should be considered in all patients with ischemic heart disease, particularly in those with elevated low-density lipoprotein cholesterol. Statins are potent lipid-lowering agents, possess non–lipid-lowering effects that may provide additional benefit to patients with IHD, and have been shown to reduce morbidity and mortality in patients with IHD. Based on these benefits, statins are generally considered the drugs of choice in patients with dyslipidemias. Moreover, based on evidence that statins improve outcomes in patients with IHD and "normal" LDL cholesterol concentration, statins should be considered in all patients with IHD at high risk of major adverse cardiac events, regardless of baseline LDL cholesterol.*

ACE Inhibitors and Angiotensin Receptor Blockers

Angiotensin II is a neurohormone produced primarily in the kidney. It is a potent vasoconstrictor and stimulates the production of aldosterone. Together, angiotensin II and aldosterone increase blood pressure and sodium and water retention (increasing ventricular wall tension), cause endothelial dysfunction, promote blood clot formation, and cause myocardial fibrosis.

Angiotensin-converting enzyme (ACE) inhibitors antagonize the effects of angiotensin II and have consistently been shown to decrease morbidity and mortality in patients with heart failure or a history of MI.[25,26] A recent meta-analysis of 22 clinical trials with ACE inhibitors in post-MI patients found that ACE inhibitors reduced 1-year mortality by 16% to 32% percent, and the mortality-reducing effects were sustained for up to 4 years.[25] In addition, there is evidence that ACE inhibitors reduce the risk of vascular events in patients with chronic stable angina or risk factors for IHD.[27,28] Specifically, in nearly 10,000 patients with vascular disease (including IHD) or risk factors for vascular disease, such as diabetes, ramipril reduced the risk of death, acute MI, and stroke by 22% compared to placebo after an average of 5 years of treatment.[27] Similar results have been demonstrated with perindopril in patients with IHD.[28]

❼ *In the absence of contraindications, ACE inhibitors should be considered in ischemic heart disease patients who also have diabetes mellitus, left ventricular dysfunction, history of myocardial infarction, or any combination of these.[1] In addition, they should also be considered in all patients with IHD and in patients at high-risk for developing IHD based on findings from the studies summarized above. Angiotensin receptor blockers may be used in patients who cannot tolerate ACE inhibitors due to side effects (e.g., chronic cough).* Angiotensin receptor blockers also antagonize the effects of angiotensin II. In one large trial, valsartan was as effective as captopril at reducing morbidity and mortality in post-MI patients.[26] However, there are far more data supporting the use of ACE inhibitors in IHD. Therefore, ACE inhibitors should remain first-line in patients with a history of MI, diabetes, or left ventricular dysfunction. The ACE inhibitors and ARBs with indications for patients with or at risk for IHD or IHD-related complications are listed in Table 4–5.

Control of Risk Factors

A major component of any IHD treatment plan is control of modifiable risk factors, including dyslipidemia, hypertension, and diabetes. Treatment strategies for dyslipidemia and hypertension in the patient with IHD are summarized in the following paragraphs. Visit chapters in this textbook on the management of hypertension and dyslipidemia for further information.

Because lipoprotein metabolism and the pathophysiology of atherosclerosis are closely linked, treatment of dyslipidemias is critical for both primary and secondary prevention of IHD-related cardiac events. In 2001, the Adult Treatment Panel III of the National Cholesterol Education Program

TABLE 4–5. Doses of ACE inhibitors and Angiotensin Receptor Blockers Indicated in Ischemic Heart Disease (IHD).

Drug	Indications	Usual Dosage in IHD
Angiotensin-Converting Enzyme Inhibitors		
Captopril	HTN, HF, post-MI, diabetic nephropathy	6.25–50 mg 3 times daily
Enalapril	HTN, HF	2.5–40 mg daily in 1–2 divided doses
Fosinopril	HTN, HF	10–80 mg daily in 1–2 divided doses
Lisinopril	HTN, HF, post-MI	2.5–40 mg daily
Perindopril	HTN, IHD	4–8 mg daily
Quinapril	HTN, HF, post-MI	5–20 mg twice daily
Ramipril	HTN, high-risk for IHD, HF, post-MI	2.5–10 mg daily in 1–2 divided doses
Trandolapril	HTN, HF, post-MI	1–4 mg daily
Angiotensin Receptor Blockers		
Candesartan	HTN, HF	4–32 mg daily
Valsartan	HTN, HF, post-MI	80–320 mg daily in 1–2 divided doses

HF, heart failure; HTN, hypertension; MI, myocardial infarction.

issued guidelines for the management of dyslipidemia and recommended an LDL cholesterol goal of less than 100 mg/dL (2.59 mmol/L) for patients with documented IHD or IHD risk equivalents such as diabetes or other vascular disease.[8] Statins are the preferred drugs to achieve this goal based on their potency in lowering LDL cholesterol and efficacy in preventing cardiac events. Since the publication of these guidelines, new evidence from several primary and secondary prevention trials suggests that there are additional clinical benefits from further reduction in LDL cholesterol.[29] In response to this evidence, more aggressive cholesterol-lowering goals were established for patients at *very high risk* for developing IHD-related events.[29] Patients with both known IHD and at least one of the following are considered very high risk:

- Multiple major risk factors for IHD, especially diabetes.
- Severe and poorly controlled risk factors, particularly smoking.
- Multiple risk factors of the metabolic syndrome.
- Patients with ACS.

The following modifications were made to the National Cholesterol Education Program treatment guidelines in patients at high or very high risk for IHD-related events:

- If LDL cholesterol is 100 mg/dL (2.59 mmol/L) or greater, statin or other LDL-lowering therapy is indicated along with lifestyle modifications.
- Intensity of LDL-lowering therapy should be sufficient to decrease LDL cholesterol by 30% to 40%.
- Goal LDL cholesterol in patients at very high risk may be decreased to less than 70 mg/dL (1.81 mmol/L).

Like dyslipidemia, hypertension is a major, modifiable risk factor for the development of IHD and related complications. Unfortunately, awareness, treatment, and control of blood pressure are not nearly enough.[30] Aggressive identification and control of hypertension is warranted in patients with IHD to minimize the risk of major adverse cardiac events. Goal blood pressure in patients with IHD is less than 140/90 mm Hg or less than 130/80 mm Hg in patients with diabetes. Because of their cardioprotective benefits, β-blockers and ACE inhibitors (or ARBs in ACE-inhibitor-intolerant patients), either alone or in combination, are appropriate for most patients with both hypertension and IHD.

Nitroglycerin to Relieve Acute Symptoms

Short-acting nitrates are first-line treatment to terminate acute episodes of angina. ❽ *All patients with a history of angina should have sublingual nitroglycerin tablets or spray to relieve acute ischemic symptoms.* Nitrates undergo biotransformation to nitric oxide. Nitric oxide activates soluble guanylate cyclase and leads to increased intracellular concentrations of cyclic guanosine monophosphate, and ultimately, to smooth muscle relaxation. Nitrates primarily cause venodilation, leading to reductions in preload. The resultant decrease in ventricular volume and wall tension leads to a reduction in myocardial oxygen demand. In higher doses, nitrates may also cause arterial dilation and reduce afterload. In addition to reducing oxygen demand, nitrates increase myocardial oxygen supply by dilating the epicardial coronary arteries and collateral vessels, as well as relieving vasospasm.

Short-acting nitrates are available in tablet and spray formulations for sublingual administration. Sublingual nitroglycerin tablets are most commonly used to alleviate angina and are less expensive than the spray. However, the spray is preferred for patients who have difficulty opening the tablet container or produce insufficient saliva for rapid dissolution of sublingual tablets. ❽ *At the onset of an angina attack, a 0.3 to 0.4 mg dose of nitroglycerin (tablet or spray) should be administered sublingually, and repeated every 5 minutes until symptoms resolve. Sitting or standing enhances venous pooling and the effectiveness of nitroglycerin. Sublingual nitroglycerin can also be used to prevent effort-induced angina (i.e., angina that occurs with exertion). In this case, the patient should use sublingual nitroglycerin 2 to 5 minutes prior to an activity known to cause angina, with the effects persisting for approximately 30 minutes.* Isosorbide dinitrate, also available in a sublingual form, has a longer half-life with anti-anginal effects lasting up to 2 hours. The use of short-acting nitrates alone, without concomitant long-acting anti-anginal therapy, may be acceptable for patients who experience angina symptoms once every few days. However, for patients with more frequent attacks, long-acting anti-anginal therapy with β-blockers, calcium channel blockers, or long-acting nitrates is recommended.

Phosphodiesterase type 5 inhibitors are commonly prescribed for erectile dysfunction and include sildenafil, vardenafil,

and tadalafil. Phosphodiesterase degrades cyclic guanosine monophosphate (GMP), which is responsible for the vasodilatory effects of nitrates. Concomitant use of nitrates and phosphodiesterase type 5 inhibitors enhances cyclic GMP-mediated vasodilation and can result in serious hypotension and even death. Therefore, the use of nitrates within 24 hours of sildenafil or vardenafil and within 48 hours of tadalafil is contraindicated.

All patients with IHD should receive a prescription for short-acting nitrates and education regarding their use. Points to emphasize when counseling a patient on nitroglycerin use include:

- The seated position is generally preferred when using nitroglycerin since the drug may cause dizziness.
- Call 911 if symptoms are unimproved or worsen 5 minutes after the first dose.
- Keep nitroglycerin tablets in the original glass container and close the cap tightly after use.
- Nitroglycerin should not be stored in the same container as other medications since this may reduce nitroglycerin's effectiveness.
- Repeated use of nitroglycerin is not harmful or addictive and does not result in any long-term side effects. Patients should not hesitate to use nitroglycerin whenever needed.
- Nitroglycerin should not be used within 24 hours of taking sildenafil or vardenafil or within 48 hours of taking tadalafil because of the potential for life-threatening hypotension.

Pharmacotherapy to Prevent Recurrent Ischemic Symptoms

The overall goal of anti-anginal therapy is to allow patients with IHD to resume normal activities without symptoms of angina and to experience minimal to no adverse drug effects. The drugs traditionally used to prevent ischemic symptoms are β-blockers, calcium channel blockers, and nitrates. These drugs exert their anti-anginal effects by improving the balance between myocardial oxygen supply and demand, with specific effects listed in Table 4–6. β-Blockers, calcium channel blockers, and nitrates decrease the frequency of angina and delay the onset of angina during exercise. However, there is no evidence that any of these agents prevent ACS or improve survival in patients with chronic stable angina. Recently, the Food and Drug Administration (FDA) approved ranolazine, a new molecular entity, for the treatment of chronic stable angina in patients unresponsive to traditional anti-anginal medications. Combination therapy with two or three anti-anginal drugs is often needed.

TABLE 4–6. Effects of Anti-anginal Medications on Myocardial Oxygen Demand and Supply

	Oxygen Demand			
Anti-anginal Agent	Heart Rate	Wall Tension	Cardiac Contractility	Oxygen Supply
β-Blockers	↓	↔ or ↑	↓	↔
Calcium channel blockers				
Verapamil, diltiazem	↓	↓	↓	↑
Dihydropyridines	↔ or ↑	↓	↓	↑
Nitrates	↑	↓	↔	↑

↓, decreases; ↔, no change; ↑, increases.

Beta-Blockers

Stimulation of the β_1- and β_2-adrenergic receptors in the heart increases heart rate and cardiac contractility. β-Blockers antagonize these effects and decrease myocardial oxygen demand. β-Blockers may also reduce oxygen demand by lowering blood pressure and ventricular wall tension. However, with marked reductions in heart rate, β-blockers may actually increase ventricular wall tension. This is because slower heart rates allow the ventricle more time to fill during diastole, leading to increased left ventricular volume, end diastolic pressure, and wall tension. However, the net effect of β-blockade is usually a reduction in myocardial oxygen demand. β-Blockers do not improve myocardial oxygen supply.

The properties and recommended doses of various β-blockers are summarized in Table 4–7. β-Blockers with intrinsic sympathomimetic activity have partial β-agonist effects and cause lesser reductions in heart rate at rest. As a result, β-blockers with intrinsic sympathomimetic activity may produce lesser reductions in myocardial oxygen demand and should be avoided in patients with IHD. Other β-blockers appear equally effective at controlling symptoms of angina. The frequency of dosing and drug cost should be taken into consideration when choosing a particular drug. Agents that can be dosed once or twice daily are preferred. Most β-blockers are available in inexpensive generic versions. β-Blockers should be initiated in doses at the lower end of the usual dosing range, with titration according to symptom and hemodynamic response. The β-blocker dose is commonly titrated to achieve the following:

- Resting heart rate between 50 and 60 beats per minute.
- Maximum heart rate with exercise of 100 beats per minute or less or 20 beats per minute above the resting heart rate.

❾ *β-Blockers are first-line therapy for preventing ischemic symptoms, particularly in patients with a history of myocardial infarction. In the absence of contraindications, β-blockers are preferred for several reasons. First, β-blockers may prevent cardiac arrhythmias by decreasing the rate of spontaneous depolarization of ectopic pacemakers. Second, in several large randomized trials, β-blockers were shown to prevent target organ damage, particularly stroke and heart failure, in patients with hypertension.*[31] *Finally, while the long-term effects of β-blockers on morbidity and mortality in patients with chronic stable angina are largely unknown, certain β-blockers have been shown to decrease the risk for reinfarction and improve survival in patients who have suffered*

TABLE 4–7. Properties and Dosing of β-Blockers in Ischemic Heart Disease

Drug	Receptor Affinity	Intrinsic Sympathomimetic Activity	Usual Dose Range
Acebutolol	β_1-Selective	Yes	100–400 mg twice daily
Atenolol	β_1-Selective	No	25–100 mg once daily
Betaxolol	β_1-Selective	No	5–20 mg once daily
Bisoprolol	β_1-Selective	No	2.5–10 mg once daily
Carvedilol	α_1, β_1, and β_2	No	6.25–25 mg twice daily
Labetalol	α_1, β_1, and β_2	Yes, at β_2-receptors	100–400 mg twice daily
Metoprolol	β_1-Selective	No	50–100 mg twice daily (once daily for extended-release)
Nadolol	β_1 and β_2	No	40–120 mg once daily
Penbutolol	β_1 and β_2	Yes	10–40 mg once daily
Pindolol	β_1 and β_2	Yes	10–40 mg twice daily
Propranolol	β_1 and β_2	No	20–80 mg twice daily (60–180 mg once daily for long-acting formulation)
Timolol	β_1 and β_2	No	10–20 mg twice daily

an MI.[32] Specific β-blockers associated with mortality reductions in clinical trials include metoprolol, propranolol, and carvedilol.[32,33] In a meta-analysis of 82 clinical trials investigating the use of β-blockers in patients following MI, the relative risk of death was reduced by 23% in patients treated with β-blockers compared to control subjects.[32] Long-term therapy (for at least 6 months) was associated with greater mortality benefit compared to short-term β-blockade (6 weeks or less).

β-Blockers are contraindicated in patients with severe bradycardia (heart rate less than 50 beats per minute) or AV conduction defects in the absence of a pacemaker. β-Blockers should be used with particular caution in combination with other agents that depress AV conduction (e.g., digoxin, verapamil, and diltiazem) because of increased risk for bradycardia and heart block. Relative contraindications include asthma, bronchospastic disease, severe depression, and peripheral vascular disease. β_1-Selective blockers are preferred in patients with asthma or chronic obstructive pulmonary disease. However, selectivity is dose dependent, and β_1-selective agents may induce bronchospasm in higher doses. Calcium channel blockers are preferred in patients with severe peripheral vascular disease who experience symptoms at rest.

There are several precautions to consider with the use of β-blockers in patients with diabetes or heart failure. All β-blockers may mask the tachycardia and tremor (but not sweating) that commonly accompany episodes of hypoglycemia in diabetes. In addition, non-selective β-blockers may alter glucose metabolism and slow recovery from hypoglycemia in insulin-dependent diabetes. β_1-Selective agents are preferred because they are less likely to prolong recovery from hypoglycemia. Importantly, β-blockers should not be avoided in patients with IHD and diabetes, particularly in patients with a history of MI who are at a high risk for recurrent cardiovascular events. β-Blockers are negative inotropes (i.e., they decrease cardiac contractility). Cardiac contractility is impaired in patients with left ventricular dysfunction. Therefore, β-blockers may worsen symptoms of heart failure in patients with left ventricular dysfunction (i.e., ejection fraction less than 35%). When used for management of IHD in a patient with heart failure, β-blockers should be initiated in very low doses with slow up-titration to avoid worsening heart failure symptoms.

Other potential adverse effects from β-blockers include fatigue, sleep disturbances, malaise, depression, and sexual dysfunction. Abrupt β-blocker withdrawal may increase the frequency and severity of angina, possibly because of increased receptor sensitivity to catecholamines after long-term β-blockade. If the decision is made to stop β-blocker therapy, the dose should be tapered over several days to weeks to avoid exacerbating angina.

Calcium Channel Blockers

Calcium channel blockers (CCBs) inhibit calcium entry into vascular smooth muscle and cardiac cells, resulting in the inhibition of the calcium-dependent process leading to muscle contraction. Inhibition of calcium entry into the vascular smooth muscle cells leads to systemic vasodilation and reductions in afterload. Inhibition of calcium entry into the cardiac cells leads to reductions in cardiac contractility. Thus, CCBs reduce myocardial oxygen demand by lowering both wall tension (through reductions in afterload) and cardiac contractility. In addition, the nondihydropyridine CCBs verapamil and diltiazem further decrease myocardial oxygen demand by slowing cardiac conduction through the AV nodes and lowering heart rate. In contrast, dihydropyridine calcium channel blockers, nifedipine in particular, are potent vasodilators that can cause baroreflex-mediated increases in sympathetic tone and heart rate. Because of their negative **chronotropic** effects, verapamil and diltiazem are generally more effective anti-anginal agents than the dihydropyridine CCBs. In addition to decreasing myocardial oxygen demand, all CCBs increase myocardial oxygen supply by dilating coronary arteries, thus increasing coronary blood flow and relieving vasospasm.

In randomized, controlled, clinical trials, calcium channel blockers were as effective as β-blockers at preventing ischemic symptoms. ❾ *Calcium channel blockers are recommended as initial treatment in IHD when β-blockers are contraindicated or not tolerated. In addition, CCBs may be used in combination with β-blockers when initial treatment is unsuccessful.* However, the combination of a β-blocker with either verapamil or diltiazem should be used with extreme caution since all of these drugs decrease AV nodal conduction, increasing the risk for severe bradycardia or AV block when used together. If combination therapy is warranted, a long-acting dihydropyridine CCB is preferred. β-Blockers will prevent reflex increases in sympathetic tone and heart rate with the use of calcium channel blockers with potent vasodilatory effects.

There are several precautions to consider with the use of CCBs. Since verapamil and diltiazem slow conduction through the AV node, these agents are contraindicated in patients with bradycardia and preexisting conduction disease. Verapamil and diltiazem should also be used with particular caution in combination with β-blockers as well as with digoxin, which also depresses AV nodal conduction, since the combination may cause bradycardia or heart block. Calcium channel blockers have negative **inotropic** effects that may be deleterious in patients with preexisting left ventricular systolic dysfunction. However, the degree of negative inotropy varies among agents. Amlodipine and felodipine possess less negative inotropic effects and appear to be safe in patients with left ventricular systolic dysfunction.[34,35] However, other calcium channel blockers may cause or exacerbate heart failure in patients with systolic dysfunction and should be avoided in this population. Finally, there is some evidence that short-acting calcium channel blockers (particularly short-acting nifedipine and nicardipine) may increase the risk of cardiovascular events.[31] Therefore, short-acting agents should be avoided in the management of IHD.

Long-Acting Nitrates

Nitrate products are available in both oral and transdermal formulations for chronic use. Commonly used products are listed in Table 4–8. All nitrate products are equally effective at preventing the recurrence of angina when used appropriately.

The major limitation of nitrate therapy is the development of tolerance with continuous use. The loss of anti-anginal effects may occur within the first 24 hours of continuous nitrate therapy. While the cause of tolerance is unclear, several mechanisms have been proposed. These include depletion of the sulfhydryl groups necessary for the conversion of nitrates to nitric oxide, activation of neurohormonal systems, increased intravascular volume, and generation of free radicals that degrade nitric oxide. The most effective method to avoid tolerance and maintain the anti-anginal efficacy of nitrates is to allow a daily nitrate-free interval of at least 8 to 12 hours. Nitrates do not provide protection from ischemia during the nitrate-free period. Therefore, the nitrate-free interval should occur when the patient is least likely to experience angina. Generally, angina is less common during the nighttime hours when the patient is sleeping and myocardial oxygen demand is reduced. Thus, it is common to dose long-acting nitrates so that the nitrate-free interval begins in the evening. For example, isosorbide dinitrate is typically dosed on awakening and again 7 hours later.

TABLE 4–8. Nitrate Formulations and Dosing for Chronic Use

Formulation	Dose
Oral	
Nitroglycerin extended-release capsules	2.5 mg 3 times daily initially, with up-titration according to symptoms and tolerance; allow a 10–12 hour nitrate-free interval
Isosorbide dinitrate tablets	5–20 mg 2–3 times daily, with a daily nitrate-free interval of at least 14 hours
Isosorbide dinitrate slow-release capsules	40 mg 1–2 times daily, with a daily nitrate-free interval of at least 18 hours
Isosorbide mononitrate tablets	20 mg 2 times daily, with doses 7 hours apart
Isosorbide mononitrate extended-release tablets	30–120 mg once daily
Transdermal	
Nitroglycerin extended-release film	0.2–0.8 mg/hour, on for 12–14 hours, off for 10–12 hours

Monotherapy with nitrates for the prevention of ischemia should generally be avoided for a couple of reasons. First, reflex increases in sympathetic activity and heart rate, with resultant increases in myocardial oxygen demand, may occur secondary to nitrate-induced venodilation. Second, patients are unprotected from ischemia during the nitrate-free interval. β-Blockers and calcium channel blockers are dosed to provide 24-hour protection from ischemia. ❾ *Treatment with long-acting nitrates should be added to baseline therapy with either a β-blocker or calcium channel blocker or a combination of the two.* β-Blockers attenuate the increase in sympathetic tone and heart rate that occurs during nitrate therapy. In turn, nitrates attenuate the increase in wall tension during β-blocker therapy. As a result, the combination of β-blockers and nitrates is particularly effective at preventing angina and provides greater protection from ischemia than therapy with either agent alone. Monotherapy with nitrates may be appropriate in patients who have low blood pressure at baseline or who experience symptomatic hypotension with low doses of β-blockers or calcium channel blockers.

Common adverse effects of nitrates include postural hypotension, flushing, and headache secondary to venodilation. Headache often resolves with continued therapy and may be treated with acetaminophen. Hypotension is generally

of no serious consequence. However, in patients with hypertrophic obstructive cardiomyopathy or severe aortic valve stenosis, nitroglycerin may cause serious hypotension and syncope. Therefore, long-acting nitrates are relatively contraindicated in these conditions. Because life-threatening hypotension may occur with concomitant use of nitrates and phosphodiesterase type 5 inhibitors, nitrates should not be used within 24 hours of taking sildenafil or vardenafil or within 48 hours of taking tadalafil. Skin erythema and inflammation may occur with transdermal nitroglycerin administration and may be minimized by rotating the application site.

Ranolazine

Although the exact mechanism of action for ranolazine is unknown, it may be related to partial inhibition of fatty acid oxidation and enhanced generation of adenosine triphosphate. Ultimately, ranolazine may improve energy efficiency, thus reducing the amount of oxygen supply necessary to meet an increase in oxygen demand. In clinical trials, ranolazine at a dose of 750 to 1000 mg twice daily improved angina and increased exercise capacity when added to standard therapy with a β-blocker or calcium channel blocker.[36] Ranolazine has the potential to prolong the QT interval and increase the risk for the life-threatening arrhythmia, torsades de pointes. Therefore, ranolazine should be reserved for patients who do not respond to traditional anti-anginal medications. Common adverse effects with ranolazine include dizziness, headache, constipation, and nausea.

Pharmacotherapy with No Benefit or Potentially Harmful Effects

Hormone Replacement Therapy

Hormone replacement therapy (HRT) has favorable effects on lipoprotein cholesterol concentrations. Data from several observational studies suggested that HRT might reduce the risk of cardiovascular events in women with IHD. However, subsequent randomized controlled studies failed to demonstrate a benefit with HRT in postmenopausal women.[37–39] In fact, HRT appeared to be harmful in this patient population. In one randomized controlled trial with HRT, more women receiving HRT had thromboembolic events and developed gallbladder disease than those on placebo.[37] Similarly, the Women's Health Initiative study found no reduction in the risk for IHD in healthy postmenopausal women receiving either estrogen plus progesterone or estrogen alone.[38,39] In addition, compared to placebo, the risks of thromboembolic events and breast cancer were higher with estrogen plus progesterone. The risk for stroke was higher with estrogen alone. Based on these findings, current guidelines recommend against the use of hormone replacement therapy to reduce cardiovascular risk.[1] Furthermore, the clinician should consider discontinuing hormone replacement therapy in women who suffer an acute coronary event while receiving such therapy.

Antioxidants

Oxidization of LDL-cholesterol is believed to play a significant role in the atherosclerotic process. The antioxidant vitamins, vitamin E and vitamin C, protect LDL cholesterol from oxidation. Evidence from observational and animal studies suggested that increased intake of antioxidant vitamins might inhibit the formation of atherosclerotic lesions and decrease the risk for cardiovascular events.[40] However, several large, randomized, prospective studies found no beneficial effect of vitamin E or other antioxidants on cardiovascular outcomes in patients with IHD or IHD risk factors.[41,42] Based on this evidence, current guidelines do not recommend supplementation with vitamin E or other antioxidants for the sole purpose of preventing cardiovascular events.

Folic Acid

Elevated homocysteine concentrations have been associated with an increased risk for cardiovascular disease in both epidemiologic and clinical studies.[43] Several studies have evaluated the benefit of lowering homocysteine levels with folic acid supplementation. One study reported a reduction in major cardiac events with the combination of folic acid, vitamin B_{12}, and vitamin B_6 following PCI.[44] However, a more recent study found an increased risk of instent restenosis and the need for target-vessel revascularization with folate supplementation following coronary stent placement.[45] The role of folate in the management of IHD is currently unclear.

Herbal Supplements

Herbal products are widely used for their purported cardiovascular benefits; examples of such products include danshen, dong quai, feverfew, garlic, hawthorn, and hellebore.[46] However, strong evidence supporting their benefits in cardiovascular disease is generally lacking. While there are data from small randomized controlled trials supporting the benefits of some herbal supplements, the potential for drug interactions and the lack of product standardization limits the products' usefulness in clinical practice. Safety with herbal supplements in patients with IHD is a major concern. Unlike prescription and over-the-counter (OTC) medicines, the FDA does not require manufacturers of herbal products to submit proof of safety prior to product marketing. Numerous case reports of adverse cardiovascular events, including stroke, MI, and lethal cardiac arrhythmias with ephedra-based products (e.g., Ma huang) led the FDA to ban ephedra-containing products in 2004. However, other herbal supplements with potentially serious adverse cardiovascular effects remain easily accessible to the consumer. Some herbal supplements may interact with antiplatelet and antithrombotic therapy and increase bleeding risk. Others may reduce the effectiveness of anti-anginal medications. Thus, it is important to assess the use of herbal products in patients with IHD and to counsel patients about the potential for drug interactions and adverse events with herbal therapies.

Patient Encounter, Part 3: Creating a Care Plan

Based on the information presented, create a specific plan for the management of RJ's ischemic heart disease. Your plan should include: (1) the goals of therapy; (2) specific nonpharmacologic and pharmacologic interventions to address these goals; and (3) a plan for follow-up to assess drug tolerance and whether the therapeutic goals have been achieved.

Cyclooxygenase-2 (COX-2) Inhibitors and Non-steroidal Anti-Inflammatory Drugs (NSAIDs)

Recent data suggest that COX-2 inhibitors, including rofecoxib, valdecoxib, and celecoxib, may increase the risk for MI and stroke.[47] There is also some evidence that the non-selective NSAIDs may increase the risk for cardiovascular events.[47,48] Rofecoxib was withdrawn from the market in late 2004 because of safety concerns. The FDA requested the withdrawal of valdecoxib from the market in 2005. The FDA also asked the manufacturers of celecoxib and non-selective NSAIDs (prescription and over-the-counter) to include information about the potential adverse cardiovascular effects of these drugs in their product labeling. The cardiovascular risk with COX-2 inhibitors and NSAIDs may be greatest in patients with a history of, or with risk factors for, cardiovascular disease. The American Heart Association recommends that the use of COX-2 inhibitors be limited to low-dose, short-term therapy in patients for whom there is no appropriate alternative.[48] Patients with cardiovascular disease should consult a clinician before using over-the-counter NSAIDs.

SPECIAL POPULATIONS

Variant Angina

Vasospasm as the sole etiology of angina (Prinzmetal's or variant angina) is relatively uncommon. As a result, treatment options are not well studied. Nevertheless, based on the pharmacology of available drugs, several recommendations can be made. First, β-blockers should be avoided in patients with variant angina because of their potential to worsen vasospasm due to unopposed α-adrenergic receptor stimulation. In contrast, both calcium channel blockers and nitrates are effective in relieving vasospasm and are preferred in the management of variant angina. Nitrates have several limitations outlined above, most notably the need for an 8- to 12-hour nitrate-free interval. Therefore, the role of monotherapy with long-acting nitrates as prophylaxis for anginal attacks due to vasospasm is limited. However, immediate-release nitroglycerin is effective at terminating acute anginal attacks due to vasospasm. Therefore, all patients diagnosed with variant angina should be prescribed immediate-release nitroglycerin. Calcium channel blockers are effective for monotherapy of variant angina. Since short-acting calcium channel blockers have been associated with increased risk of adverse cardiac events, they should be avoided.[31] Long-acting nitrates may be added to CCB therapy if needed.

Elderly Patients with IHD

Elderly patients are more likely than younger patients to have other comorbidities that may influence drug selection for the treatment of angina. As a result, polypharmacy is more common in elderly patients, increasing the risk of drug-drug interactions, and perhaps decreasing medication adherence. Additionally, elderly patients are often more susceptible to adverse effects of anti-anginal therapies, particularly the negative chronotropic and inotropic effects of β-blockers and CCBs. Therefore, drugs should be initiated in low doses with close monitoring of elderly patients with IHD.

Acute Coronary Syndrome

The management of ACS is discussed in further detail in the chapter on acute coronary syndromes. It is important to educate patients with IHD on the signs of ACS and what to do if they appear. Importantly, patients should be instructed to seek emergent care if symptoms of angina last longer than 20 to 30 minutes, do not improve after 5 minutes of using sublingual nitroglycerin, or worsen after 5 minutes of using sublingual nitroglycerin. In patients with a history of ACS, it is crucial to select appropriate pharmacotherapy to prevent recurrent ACS and death. Appropriate pharmacotherapy for patients with a history of ACS includes aspirin, ACE inhibitors or ARBs, β-blockers, and statins. In addition, determining appropriate goals and instituting appropriate therapy to meet the goals for cardiovascular risk factors (e.g., dyslipidemia, hypertension, and diabetes) is critical.

OUTCOME EVALUATION

Assessing for Drug Effectiveness and Safety

- ⓫ *Monitor symptoms of angina at baseline and at each clinic visit for patients with IHD to assess the effectiveness of anti-anginal therapy. In particular, assess the frequency and intensity of anginal symptoms.* Determining the frequency of sublingual nitroglycerin use is helpful in making this assessment. If angina is occurring with increasing frequency or intensity, adjust anti-anginal therapy and refer the patient for additional

diagnostic testing (e.g., coronary angiography) and possibly for coronary interventions (e.g., PCI or CABG surgery).

- Assess the patient for IHD-related complications, such as heart failure. The presence of new comorbidities may indicate worsening IHD requiring additional workup or pharmacologic therapy.
- ⑩ *Hemodynamic parameters should be routinely monitored to assess drug tolerance. Assess blood pressure at baseline, after drug initiation and dose titration, then periodically thereafter in patients treated with β-blockers, CCBs, nitrates, ACE inhibitors, and/or ARBs.*
- Blood pressure reduction may be particularly pronounced after initiation and dose titration of β-blockers that also possess α-blocking effects (e.g., labetalol and carvedilol).
- Because of the potential for postural hypotension, warn patients that dizziness, presyncope, and even syncope may result from abrupt changes in body position during initiation or up-titration of drugs with α-blocking effects.
- ⑩ *Closely monitor heart rate in patients treated with drugs that have negative chronotropic effects (e.g., β-blockers, verapamil, or diltiazem) or drugs that may cause reflex tachycardia (e.g., nitrates or dihydropyridine CCBs).*
- Treatment with β-blockers, verapamil, or diltiazem can usually be continued in patients with asymptomatic bradycardia. However, reduce or discontinue treatment with these agents in patients who develop symptomatic bradycardia or serious conduction abnormalities.
- Control of existing risk factors and the presence of new risk factors for IHD should also be assessed regularly. Routine screening for the presence of metabolic syndrome will help in assessing the control of known major risk factors and identifying new risk factors. If new risk factors are identified and/or the presence of metabolic syndrome is detected, modify the pharmacotherapy regimen, as discussed previously, to control these risk factors and lower the risk of IHD and IHD-related adverse events.

Duration of Therapy

- Drugs that modify platelet activity, lipoprotein concentrations, and neurohormonal systems reduce the risk for coronary events and death. However, these therapies do not cure IHD.
- Treatment with antiplatelet (aspirin or clopidogrel), lipid-lowering, and neurohormonal-modifying therapy for IHD is generally lifelong. Similarly, anti-anginal therapy with a β-blocker, CCB, and/or nitrate is usually long-term.
- A patient with severe symptoms managed with combination anti-anginal drugs who undergoes successful coronary revascularization may be able to reduce anti-anginal therapy. However, treatment with at least one agent that improves the balance between myocardial oxygen demand and supply is usually warranted.

Patient Care and Monitoring

1. Assess the patient's symptoms to determine whether the patient should be evaluated by a physician.
   - Determine the quality, location, and duration of pain.
   - Determine factors that provoke and relieve pain.
   - Are symptoms characteristic of angina?
2. Identify risk factors for IHD.
   - Are there any modifiable risk factors?
3. Obtain a thorough history of prescription drug, nonprescription drug, and herbal product use.
   - Is the patient taking any medications/supplements that may exacerbate angina or interact with anti-anginal drug therapy?
4. Educate the patient on lifestyle modifications to control risk factors for IHD.
5. Is the patient taking appropriate drug therapy to prevent ACS and death? If not, why?
6. Is the patient taking appropriate anti-anginal therapy? If not, why?
7. Develop a plan to assess effectiveness of anti-ischemic therapy after 1 to 2 weeks.
8. Evaluate the patient to assess for adverse drug reactions, drug intolerance, and drug interactions.
9. Stress the importance of adherence with the therapeutic regimen, including lifestyle modifications.
10. Provide patient education regarding disease state, lifestyle modifications, and drug therapy:
    - What are the consequences of untreated IHD?
    - What lifestyle modifications should the patient follow?
    - When should the patient take his or her medications?
    - What potential adverse drug effects may occur?
    - Teach the patient how to monitor heart rate and blood pressure to assess tolerance to anti-anginal therapy.
    - Which drugs may interact with therapy or worsen IHD?
    - What should the patient do when chest pain or its equivalent occurs?
    - When should the patient seek emergent care?

ABBREVIATIONS

ACE:	angiotensin-converting enzyme
ACE-I:	angiotensin-converting enzyme inhibitor
ACS:	acute coronary syndrome
ARB:	angiotensin receptor blocker
AV:	atrioventricular

5 Acute Coronary Syndromes

Sarah A. Spinler and Simon de Denus

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Define the role of an atherosclerotic plaque, platelets, and coagulation system in an acute coronary syndrome.
2. Describe the onset, peak, and duration of elevation of troponin and creatine kinase myocardial band in acute myocardial infarction.
3. List key electrocardiographic and clinical features identifying a patient with non–ST-segment elevation acute coronary syndrome who is at high risk of myocardial infarction or death.
4. Devise a pharmacotherapy treatment plan for a patient undergoing primary percutaneous coronary intervention in ST-segment elevation myocardial infarction given patient-specific data.
5. Devise a pharmacotherapy treatment plan for a patient with ST-segment elevation myocardial infarction given patient-specific data.
6. List the quality indicators of care for myocardial infarction and explain the rationale behind each indicator.
7. Formulate a monitoring plan for a patient with ST-segment elevation acute coronary syndrome receiving fibrinolytics, aspirin, unfractionated heparin, intravenous nitroglycerin, intravenous β-blockers followed by oral β-blockers, an angiotensin-converting enzyme inhibitor, and a statin.
8. Devise a pharmacotherapy treatment and monitoring plan for a patient with non–ST-segment elevation acute coronary syndrome given patient-specific data.
9. Devise a pharmacotherapy and risk-factor modification treatment plan for secondary prevention of coronary heart disease events in a patient following myocardial infarction.

Key Concepts

❶ The cause of an acute coronary syndrome is the rupture of an atherosclerotic plaque with subsequent platelet adherence, activation, and aggregation, and the activation of the clotting cascade. Ultimately, a clot forms composed of fibrin and platelets.

❷ The American Heart Association and the American College of Cardiology recommend strategies, or guidelines, for acute coronary syndrome patient care for ST-segment and non–ST-segment elevation acute coronary syndrome.

❸ Patients with ischemic chest discomfort and suspected acute coronary syndrome are risk-stratified based upon a 12-lead electrocardiogram, past medical history, and results of the creatine kinase myocardial band and troponin tests. The diagnosis of myocardial infarction is confirmed based on the results of the creatine kinase myocardial band and troponin tests.

❹ Early reperfusion therapy with either primary percutaneous coronary intervention or administration of a fibrinolytic agent within 3 hours of symptom onset is the recommended therapy for patients presenting with ST-segment elevation acute coronary syndrome.

❺ The most recent non–ST-segment elevation American College of Cardiology/American Heart Association clinical practice guidelines recommend coronary angiography with either percutaneous coronary intervention or coronary artery bypass graft surgery revascularization as an early treatment (early invasive strategy) for high-risk and moderate-risk non–ST-segment elevation acute coronary syndrome patients.

❻ According to the American College of Cardiology/American Heart Association ST-segment elevation acute coronary syndrome practice guidelines, in addition to reperfusion therapy, early pharmacotherapy of ST-segment elevation should include intranasal oxygen (if oxygen saturation is less than 90%), sublingual nitroglycerin followed by intravenous nitroglycerin, aspirin, an intravenous β-blocker, unfractionated heparin, and fibrinolysis in eligible candidates.

❼ According to the American College of Cardiology/American Heart Association non–ST-segment elevation acute coronary syndrome practice guidelines, in the absence of contraindications, early pharmacotherapy of non–ST-segment elevation should include intranasal oxygen (if oxygen saturation is low), sublingual nitroglycerin followed by intravenous nitroglycerin, aspirin, an intravenous β-blocker, and unfractionated heparin or low-molecular-weight heparin. Most patients should receive additional therapy with clopidogrel. High-risk patients should also receive a glycoprotein IIb/IIIa receptor blocker.

❽ Guidelines from the American College of Cardiology/American Heart Association suggest that, in the absence of contraindications, following myocardial infarction from either ST-segment elevation acute coronary syndrome or non–ST-segment elevation coronary syndrome, patients should receive indefinite treatment with aspirin, a beta-blocker, and an angiotensin-converting enzyme inhibitor.[2,3] For non–ST-segment elevation acute coronary syndrome, most patients should receive clopidogrel, in addition to aspirin, for up to 9 months. Most patients will receive a statin to reduce low-density lipoprotein cholesterol to less than 100 mg/dL.

❾ Secondary prevention of death, reinfarction, and stroke is more cost effective than primary prevention of coronary heart disease events.

Cardiovascular disease (CVD) is the leading cause of death in the United States and one of the major causes of death worldwide. **Acute coronary syndromes** (ACS), including unstable angina (UA) and myocardial infarction (MI), are a form of coronary heart disease (CHD) that comprises the most common cause of CVD death.[1] ❶ *The cause of an acute coronary syndrome is the rupture of an atherosclerotic plaque with subsequent platelet adherence, activation, and aggregation and the activation of the clotting cascade. Ultimately, a clot forms composed of fibrin and platelets.* ❷ *The American Heart Association (AHA) and the American College of Cardiology (ACC) recommend strategies, or guidelines, for ACS patient care for ST-segment and non–ST-segment elevation ACS.* These joint practice guidelines are based upon a review of available clinical evidence, have graded recommendations based upon evidence, and are updated periodically. These guidelines form the cornerstone for quality care of the ACS patient.[2,3]

EPIDEMIOLOGY

Each year, more than one million Americans will experience an ACS and 239,000 will die of an MI.[1] In the United States, more than 7.6 million living persons have survived an MI.[1] Chest discomfort is the most frequent reason for patient presentation to emergency departments, with up to 7 million, or approximately 3%, of all emergency department visits linked to chest discomfort and possible ACS. Coronary heart disease is the leading cause of premature, chronic disability in the United States. The risks of CHD events, such as death, recurrent MI, and stroke, are higher for patients with established CHD and a history of MI than for patients with no known CHD. The cost of CHD is high, with more than $10 billion being paid to Medicare beneficiaries in 1999, or more than $10,000 per MI hospital stay, with the average length of hospital stay for MI in 1999 being 5.6 days.[1]

In patients with **ST-segment elevation** (STE) ACS, in-hospital death rates are approximately 7% for patients who are treated with fibrinolytics and 16% for patients who do not receive reperfusion therapy. In patients with **non–ST-segment elevation** (NSTE) MI, in-hospital mortality is less than 5%. In-hospital and 1-year mortality rates are higher for women and elderly patients. In the first year following MI, 38% of women and 25% of men will die, most from recurrent **infarction**.[1] At 1 year, rates of mortality and reinfarction are similar between STE and NSTE MI.

Because reinfarction and death are major outcomes following ACS, therapeutic strategies to reduce morbidity and mortality, particularly utilization of coronary angiography, revascularization, and pharmacotherapy, will have a significant impact on the social and economic burden of CHD in the United States.

ETIOLOGY

Endothelial dysfunction, inflammation, and the formation of fatty streaks contribute to the formation of atherosclerotic coronary artery plaques, the underlying cause of coronary artery disease (CAD). ❶ *The predominant cause of ACS, in more than 90% of patients, is atheromatous plaque rupture, fissuring, or erosion of an unstable atherosclerotic plaque that occludes less than 50% of the coronary lumen prior to the event, rather than a more stable 70% to 90% stenosis of the coronary artery.*[3] Stable stenoses are characteristic of stable angina.

PATHOPHYSIOLOGY

Spectrum of Acute Coronary Syndromes

Acute coronary syndromes is a term that includes all clinical syndromes compatible with acute myocardial ischemia resulting from an imbalance between myocardial oxygen demand and supply.[3] In contrast to stable angina, an ACS results primarily from diminished myocardial blood flow secondary to an occlusive or partially occlusive coronary artery thrombus. Acute coronary syndromes are classified according to electrocardiogram (ECG) changes into STE ACS (STE MI) or NSTE ACS (NSTE MI and unstable angina) (Fig. 5–1). An STE MI, formerly

known as Q-wave or transmural MI, typically results in an injury that transects the thickness of the myocardial wall. Following an STE MI, pathologic Q waves are frequently seen on the ECG, indicating transmural myocardial infarction, while such an ECG manifestation is seen less commonly in patients with NSTE MI.[4] Non–ST-segment elevation MI, formerly known as non–Q-wave or non-transmural MI, is limited to the sub-endocardial myocardium. Patients in this case do not usually develop a pathologic Q wave on the ECG. Moreover, an NSTE MI is smaller and not as extensive as an STE MI. Non–ST-elevation MI differs from unstable angina in that ischemia is severe enough to produce myocardial necrosis resulting in the release of a detectable amount of biochemical markers (intracellular macromolecules released into the peripheral circulation from necrotic myocytes as a result of myocardial cell death or infarction), mainly **troponins T** or **I** or **creatine kinase (CK) myocardial band (MB)** from the necrotic myocytes in the bloodstream.[3] The clinical significance of serum markers will be discussed in greater detail in later sections of this chapter.

Plaque Rupture and Clot Formation

Following plaque rupture, a clot (a partially occlusive or completely occlusive thrombus), forms on top of the ruptured plaque. The thrombogenic contents of the plaque are exposed to blood elements. Exposure of collagen and tissue factor induce platelet adhesion and activation, which promote the release of platelet-derived vasoactive substances including adenosine diphosphate (ADP) and thromboxane A_2 (TXA_2).[5] These produce vasoconstriction and potentiate platelet activation. Furthermore, during platelet activation, a change in the conformation in the glycoprotein IIb/IIIa surface receptors of platelets occurs which cross-links platelets to each other through fibrinogen bridges. This is considered the final common pathway of platelet aggregation. Inclusion of platelets gives the clot a white appearance. Simultaneously, the extrinsic coagulation cascade pathway is activated as a result of exposure of blood components to the thrombogenic lipid core and endothelium, which are rich in tissue factor. This leads to the production of thrombin (factor IIa), which converts fibrinogen to fibrin through enzymatic activity.[5] Fibrin stabilizes the clot and traps red blood cells, which give the clot a red appearance. Therefore, the clot is composed of cross-linked platelets and fibrin strands.[8]

Ventricular Remodeling Following an Acute Myocardial Infarction

Ventricular remodeling is a process that occurs in several cardiovascular conditions including heart failure and following an MI. It is characterized by left ventricular dilation and reduced pumping function of the left ventricle leading to cardiac failure.[6] Because heart failure represents one of the principal causes of mortality and morbidity following an MI, preventing ventricular remodeling is an important therapeutic goal.[6]

Angiotensin-converting enzyme (ACE) inhibitors, β-blockers, and aldosterone antagonists are all agents that slow down or reverse ventricular remodeling through neurohormonal blockage and/or through improvement in hemodynamics (decreasing preload or afterload).[6] These agents also improve survival and will be discussed in more detail in subsequent sections of this chapter.

Complications

This chapter will focus on management of the uncomplicated ACS patient. However, it is important for clinicians to recognize complications of MI, since MI is associated with increased mortality. The most serious complication of MI is cardiogenic shock, occurring in approximately 10% of hospitalized MI patients. Mortality in cardiogenic shock patients with MI is high, approaching 60%.[7] Other complications which may result from MI are heart failure, valvular dysfunction, ventricular and atrial tachyarrhythmias, bradycardia, heart block, pericarditis, stroke secondary to left ventricular thrombus embolization, venous thromboembolism, and left ventricular free wall rupture.[8] In fact, more than one-quarter of MI patients die, presumably from ventricular fibrillation, prior to reaching the hospital.[1]

Symptoms and Physical Examination Findings

The classic symptom of an ACS is midline anterior anginal chest discomfort, most often occurring when an individual is at rest, as a severe new onset, or as an increasing angina that is at least 20 minutes in duration. The chest discomfort may radiate to the shoulder, down the left arm, and to the back or to the jaw. Associated symptoms which may accompany the chest discomfort include nausea, vomiting, **diaphoresis**, or shortness of breath. While similar to stable angina, the duration may be longer and the intensity greater. On physical examination, no specific features are indicative of ACS.

12-Lead Electrocardiogram

❸ *There are key features of a 12-lead ECG that identify and risk-stratify a patient with an ACS. Within 10 minutes of presentation to an emergency department with symptoms of ischemic chest discomfort, a 12-lead ECG should be obtained and interpreted. If available, a prior 12-lead ECG should be reviewed to identify whether or not the findings on the current ECG are new or old, with new findings being more indicative of an ACS. Key findings on review of a 12-lead ECG that indicate myocardial ischemia or infarction are STE, ST-segment depression, and T-wave inversion* (Fig. 5–1). ST-segment and/or T-wave changes in certain groupings of leads help to identify the location of the coronary artery that is the cause of the ischemia or infarction. In addition, the appearance of a new left bundle-branch block accompanied by chest discomfort is highly specific for acute MI. About one-half of patients

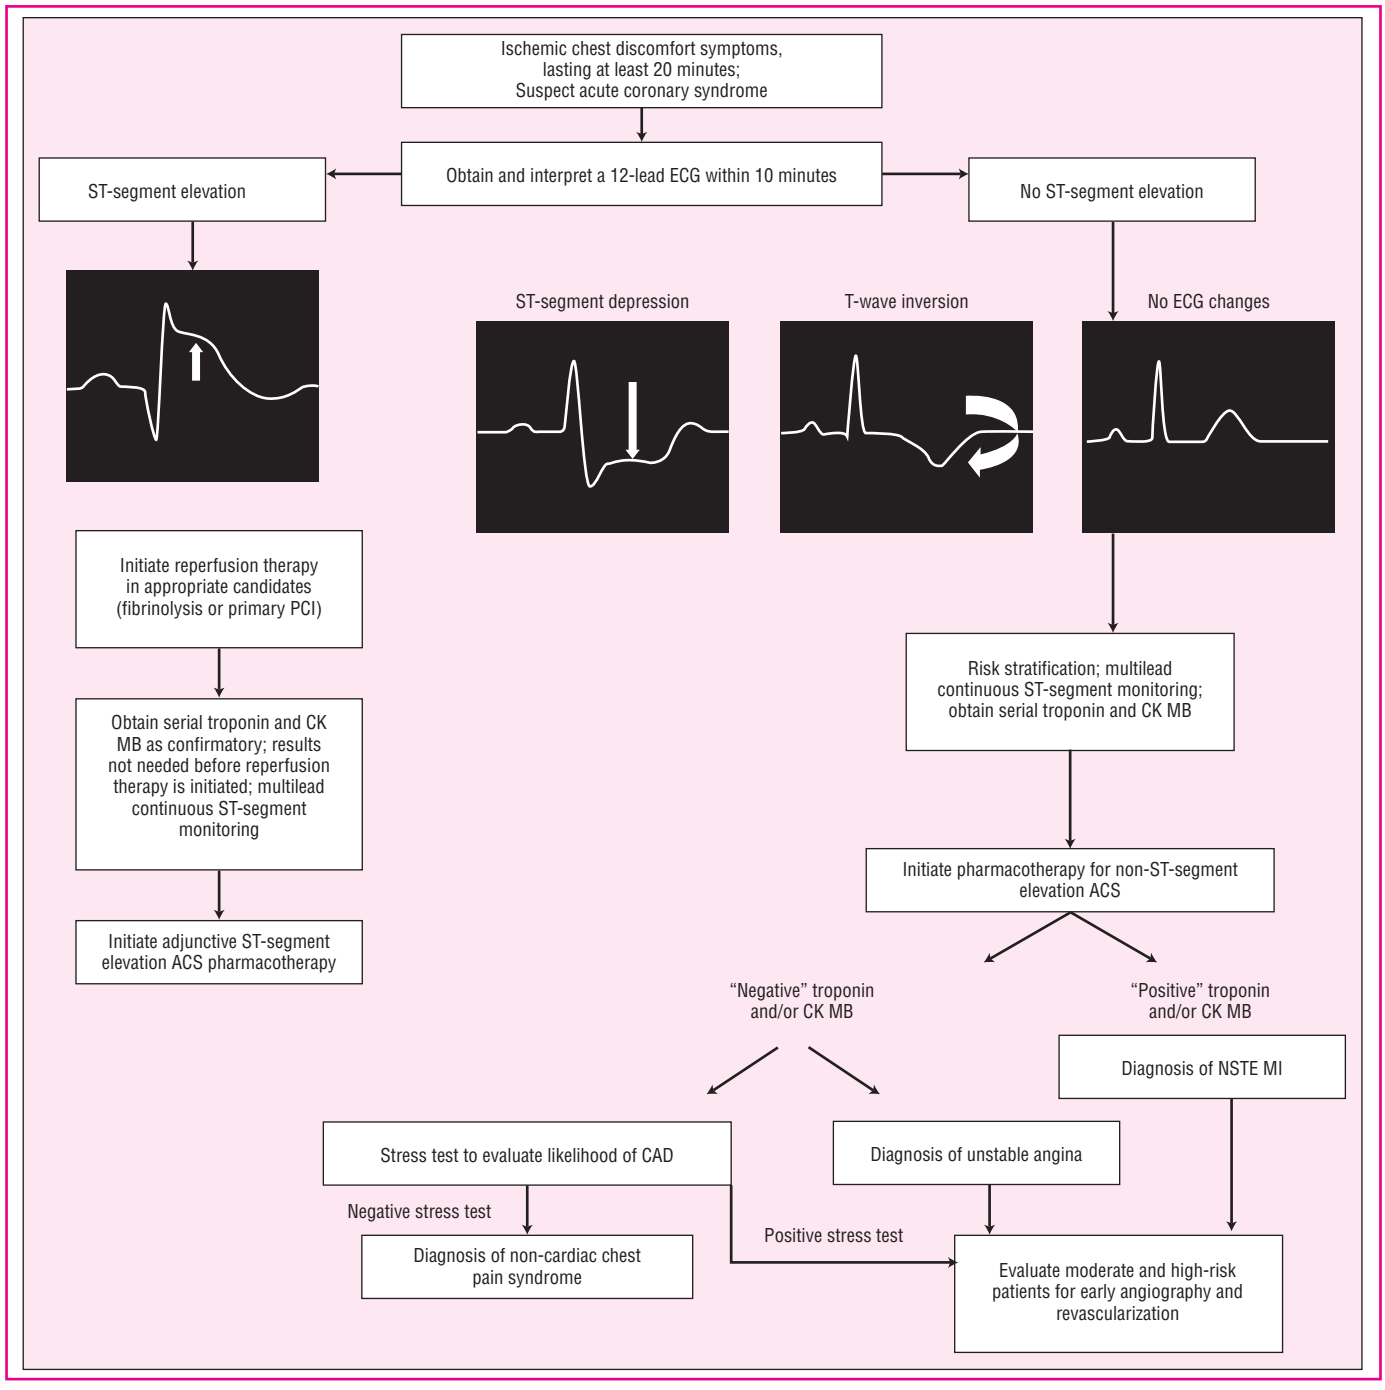

FIGURE 5–1. Evaluation of the acute coronary syndrome patient. (Reprinted from Spinler SA, de Denus S. Acute Coronary Syndromes. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 293, with permission.) ACS, acute coronary syndromes; CAD, coronary artery disease; CKMB, creatine kinase myocardial band; ECG, electrocardiogram; NSTE, non-ST elevation; PCI, percutaneous coronary intervention. Refer to Chapter 6, Figure 6–2 (page 109) for further details regarding ECG interpretation.

diagnosed with MI present with ST-segment elevation on their ECG, with the remainder having ST-segment depression, T-wave inversion, or in some instances, no ECG changes. Some parts of the heart are more "electrically silent" than others, and myocardial ischemia may not be detected on a surface ECG. Therefore, it is important to review findings from the ECG in conjunction with biochemical markers of myocardial necrosis, such as troponin I or T, and other risk factors for CHD to determine the patient's risk for experiencing a new MI or having other complications.

Clinical Presentation and Diagnosis

General
- The patient is typically in acute distress and may develop or present with cardiogenic shock.

Symptoms
- The classic symptom of ACS is midline anterior chest discomfort. Accompanying symptoms may include arm, back, or jaw pain, nausea, vomiting, or shortness of breath.
- Patients less likely to present with classic symptoms include elderly patients, diabetic patients, and women.

Signs
- No signs are classic for ACS.
- However, patients with ACS may present with signs of acute heart failure including jugular venous distention and an S_3 sound on auscultation.
- Patients may also present with arrhythmias and therefore may have tachycardia, bradycardia, or heart block.

Laboratory Tests
- Troponin I or T and CK-MB are measured.
- Blood chemistry tests are performed with particular attention given to potassium and magnesium, which may affect heart rhythm.
- The serum creatinine is measured to identify patients who may need dosing adjustments for some medications, as well as those who are at high risk of morbidity and mortality.
- Baseline complete blood count (CBC) and coagulation tests (activated partial thromboplastin time and International Normalized Ratio) should be obtained, as most patients will receive antithrombotic therapy, which increases the risk for bleeding.
- Fasting lipid panel.

Other Diagnostic Tests
- The 12-lead ECG is the first step in management. Patients are risk-stratified into two groups: ST-segment elevation ACS and suspected non–ST-segment elevation ACS.
- During hospitalization, a measurement of left ventricular function, such as an echocardiogram, is performed to identify patients with low ejection fractions (less than 40%) who are at high risk of death following hospital discharge.
- Selected low-risk patients may undergo early stress testing.

(Adapted from Spinler SA, de Denus S. Acute Coronary Syndromes. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 294, with permission.)

Biochemical Markers/Cardiac Enzymes

Biochemical markers of myocardial cell death are important for confirming the diagnosis of MI. ❸ *The diagnosis of myocardial infarction is confirmed based upon the results of the creatine kinase myocardial band and troponin tests. Evolving MI is defined by the ACC as "typical rise and gradual fall (troponin) or more rapid rise and fall (CK-MB) of biochemical markers of myocardial necrosis."*[9] *Troponin and CK-MB rise in the blood following the onset of complete coronary artery occlusion subsequent to myocardial cell death.* Their time course is depicted in Fig. 5–2. Typically, blood is obtained from the patient three times, once in the emergency department and two additional times over the next 12 to 24 hours in order to measure troponin and CK-MB. A single measurement of a biochemical marker is not adequate to exclude a diagnosis of MI, as up to 15% of values which were initially below the level of detection (a "negative" test) rise to the level of detection (a "positive" test) in subsequent hours. An MI is identified if at least one troponin value is greater than the MI decision limit (set by the hospital laboratory) or two CK-MB results are greater than the MI decision limit (set by the hospital laboratory). While troponins and CK-MB appear in the blood within 6 hours of infarction, troponins stay elevated for up to 10 days while CK-MB returns to normal values within 48 hours. Therefore, if a patient is admitted with elevated troponins and CK-MB and several days later experiences recurrent chest discomfort, the troponin will be less sensitive to detect new myocardial damage because it will still be elevated. If early reinfarction is suspected, CK-MB is the preferred diagnostic test.[9]

Risk Stratification

Patient symptoms, past medical history, ECG, and troponin and/or CK-MB are utilized to stratify patients into low, medium, or high risk of death, MI, or likelihood of failing pharmacotherapy and needing urgent coronary angiography and **percutaneous coronary intervention** (PCI). ❸❹ *Initial treatment according to risk stratification is depicted in Fig. 5–1. Patients with ST-segment elevation are at the highest risk of death.* Initial treatment of ST-segment elevation ACS should proceed without evaluation of the troponin or CK-MB, as these patients have a greater than 97% chance of having an MI subsequently diagnosed with biochemical markers. The ACC/AHA defines a target time to initiate reperfusion treatment as within 30 minutes of hospital presentation for fibrinolytics (e.g., streptokinase, alteplase, reteplase, and tenecteplase) and within 90 minutes or less from presentation for primary PCI.[3] The sooner the infarct-related coronary artery is opened for these patients, the lower their mortality and the greater the amount of myocardium that is preserved.[10,11] While all patients should be evaluated for reperfusion therapy, not all patients may be eligible. Indications and contraindications for fibrinolytic therapy are described in the treatment section of this chapter. Less than 20% of hospitals in the United States. are equipped to perform primary PCI. If

Patient Encounter, Part 1

SD is a 55-year-old, 85 kg (187 lb) male who developed chest tightness while in a store in Sun Valley, Idaho, after 4 hours of skiing. SD developed substernal chest tightness at 2030 hours that radiated into his left arm following an altercation with another patron in the men's room. He became short of breath and diaphoretic. Local paramedics were summoned and he was given three 0.4 mg sublingual nitroglycerin tablets by mouth, 325 mg aspirin by mouth, and 5 mg metoprolol IV push without relief of chest discomfort. SD presented to St. Matthew's Hospital in Sun Valley at 2115 hours. St. Matthew's does not have a cardiac catheterization laboratory and transport time to St. Matthew's in Boise is 1.5 hours door to door via air transport.

PMH
Hypertension (HTN) × 10 years
Dyslipidemia × 6 months
Two-vessel coronary artery disease (60% right coronary artery [RCA] and 80% left anterior descending artery [LAD] occlusion) after intracoronary CYPHER™ stent placement to the mid-LAD artery lesion 10 months ago.

FH
Father with myocardial infarction at age 65; mother alive and well; one sibling with hypertension

SH
Smoked 1 pack per day × 30 years, quit 10 weeks ago

Allergies
No known drug allergies

Meds
Metoprolol 25 mg by mouth twice daily
ASA 325 mg by mouth once daily
Lovastatin 20 mg by mouth once daily at bedtime
Enalapril 5 mg by mouth once daily

ROS
7/10 chest pain/squeezing, diaphoretic

PE
Head, ears, eyes, nose and throat: normocephalic atraumatic
Cardiovascular: regular rate and rhythm S_1, S_2, $-S_3$, $+S_3$, $+S_4$, no murmurs or rubs

VS: Blood pressure 110/70; heart rate 98 beats per minute; temperature 37°C (98.6°F)
Lungs: rales bilaterally $^1/_4$ way up
Abd: non-tender, non-distended
Gastrointestinal: normal bowel sounds
Genitourinary: stool guaiac negative
Exts: no bruits, pulses 2+, femoral pulse present, good range of motion
Neurologic: alert and oriented × 3, cranial nerves intact

Labs
Sodium 138 mEq/L (138 mmol/L), potassium 4.2 mEq/L (4.2 mmol/L), chloride 105 mEq/L (105 mmol/L), bicarbonate 24 mEq/L (24 mmol/L), serum creatinine 1.0 mg/dL (88.4 µmol/L), glucose 95 mg/dL (5.27 mmol/L), white blood cell count $9.9 \times 10^3/mm^3$ (9.9×10^9/L), hemoglobin 15.7 g/dL (157 g/L or 9.7 mmol/L), hematocrit 47%, platelets $220 \times 10^3/mm^3$ (220×10^9/L), brain natriuretic peptide 3238 pg/mL (3238 ng/L), troponin I 16 ng/mL (16 mcg/L), oxygen saturation 99% on room air

ECG: normal sinus rhythm, PR 0.16 s, QRS 0.08 s, QT_c 0.38 s, occasional polymorphic premature ventricular contractions, 3 mm ST-segment elevation anterior leads

CXR: congestive heart failure, borderline upper normal heart size

Echocardiogram: hypocontractile left ventricle, akinesis of anterior apical wall, ejection fraction 20%

- What information is suggestive of acute MI?
- What complications of MI are present?

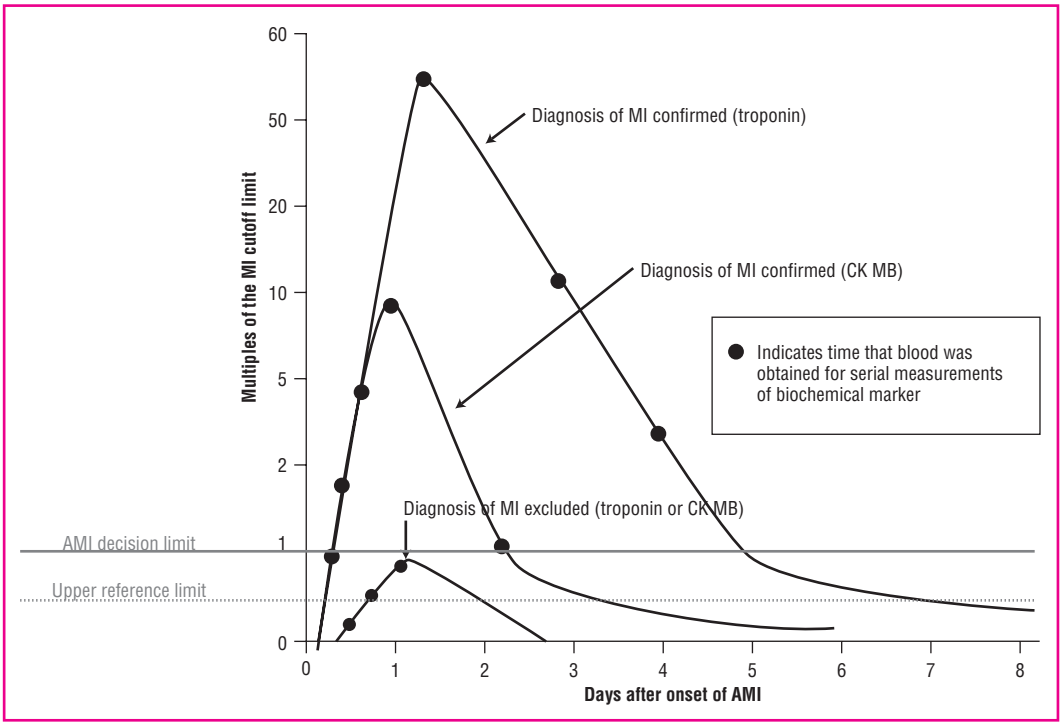

FIGURE 5–2. Biochemical markers in suspected acute coronary syndromes. (Reprinted from Spinler SA, de Denus S. Acute Coronary Syndromes. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 295, with permission.) AMI, acute myocardial infarction; CKMB, creatine kinase myocardial band; MI, myocardial infarction.

patients are not eligible for reperfusion therapy, additional pharmacotherapy for STE patients should be initiated in the emergency department and the patient transferred to a coronary intensive care unit. The typical length of stay for a patient with uncomplicated STE MI is 3 to 5 days.

Risk-stratification of the patient with NSTE ACS is more complex, as in-hospital outcomes for this group of patients varies with reported rates of death of 0% to 12%, reinfarction rates of 0% to 3%, and recurrent severe ischemia rates of 5% to 20%.[12] Not all patients presenting with suspected NSTE ACS will even have CAD. Some will eventually be diagnosed with non-ischemic chest discomfort. ❸ *In general, among NSTE patients, those with ST-segment depression (Fig. 5–1) and/or elevated troponin and/or CK-MB are at higher risk of death or recurrent infarction.*

Patient Encounter, Part 2: Treatment

- Identify your acute treatment goals for SD.
- Is reperfusion therapy with fibrinolysis indicated at this time?
- What adjunctive pharmacotherapy should be administered to SD in the emergency department?
- What additional pharmacotherapy should be initiated on the first day of SD's hospitalization?

TREATMENT

Desired Outcomes

Short-term desired outcomes in a patient with ACS are: (1) early restoration of blood flow to the infarct-related artery to prevent infarct expansion (in the case of MI) or prevent complete occlusion and MI (in unstable angina); (2) prevention of death and other complications; (3) prevention of coronary artery reocclusion; and (4) relief of ischemic chest discomfort.

Long-term desired outcomes are control of risk factors, prevention of additional cardiovascular events, and improvement in quality of life.

General Approach to Treatment

General treatment measures for all STE ACS and high- and intermediate-risk NSTE patients include admission to hospital, oxygen administration (if oxygen saturation is low, less than 90%), continuous multi-lead ST-segment monitoring for arrhythmias and ischemia, frequent measurement of vital signs, bed rest for 12 hours in hemodynamically stable patients, avoidance of Valsalva maneuver (prescribe stool softeners routinely), and pain relief (Fig. 5–3).

Because risk varies and resources are limited, it is important to triage and treat patients according to their risk category. Initial approaches to treatment of STE and NSTE ACS patients are outlined in Fig. 5–1. Patients with STE are at high risk of death, and efforts to re-establish coronary perfusion,

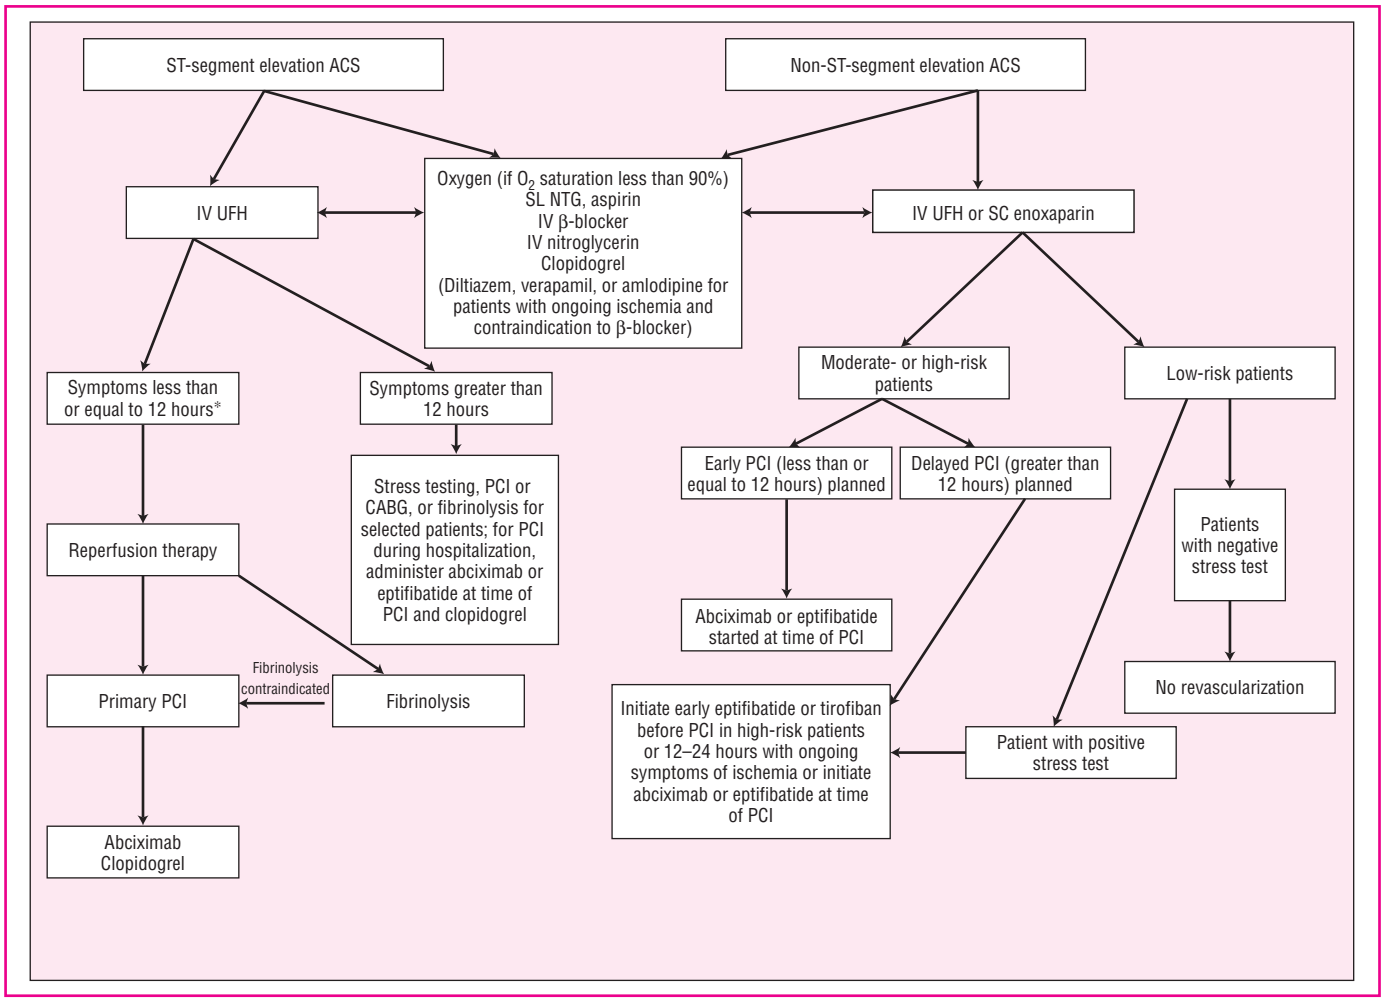

FIGURE 5–3. Initial pharmacotherapy for acute coronary syndromes. (Adapted from Spinler SA, de Denus S. Acute Coronary Syndromes. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 298, with permission.) *Or 12 to 24 hours with ongoing symptoms of ischemia. ACS, acute coronary syndromes; CABG, coronary artery bypass graft; IV, intravenous; NTG, nitroglycerin; PCI, percutaneous coronary intervention; SC, subcutaneous; SL, sublingual; UFH, unfractionated heparin.

as well as adjunctive pharmacotherapy, should be initiated immediately.

❸ *Features identifying low-, moderate-, and high-risk NSTE ACS patients are described using the thrombolysis in myocardial infarction (TIMI) risk score in Table 5–1.*[13]

Nonpharmacologic Therapy

Primary Percutaneous Coronary Intervention for ST-Segment Elevation Acute Coronary Syndromes

❹ *Early reperfusion therapy with either primary percutaneous coronary intervention or administration of a fibrinolytic agent within 3 hours of symptom onset is the recommended therapy for patients presenting with STE ACS.*[3] For primary PCI, the patient is taken from the emergency department to the cardiac catheterization laboratory and undergoes coronary angiography with either balloon angioplasty or placement of a bare metal or drug-eluting intracoronary stent. Results from a recent meta-analysis of trials comparing fibrinolysis to primary PCI indicate a lower mortality rate with primary PCI.[14] One reason for the superiority of primary PCI compared to fibrinolysis is that more than 90% of occluded infarct-related coronary arteries are opened with primary PCI compared to fewer than 60% of coronary arteries opened with currently available fibrinolytics.[15] In addition, intracranial hemorrhage and major bleeding risks from primary PCI are lower than the risks of severe bleeding events following fibrinolysis. An invasive strategy of primary PCI is generally preferred in patients presenting to institutions with skilled interventional cardiologists and a catheterization laboratory immediately available, in patients in cardiogenic shock, those with contraindications to fibrinolytics, and those presenting with symptom onset greater than 3 hours ago.[3] A quality indicator (quality indicators are measures of health care performance developed from practice guidelines intended to permit the quality of patient care to be assessed and ultimately improved)

TABLE 5–1. TIMI Risk Score for Non–ST-Segment Elevation Acute Coronary Syndromes[2,17]

Past Medical History	Clinical Presentation
• Age 65 years or older • Three or more risk factors for CAD: Hypercholesterolemia HTN DM Smoking Family history of premature CHD • Known CAD (50% or greater stenosis of a coronary artery) • Use of aspirin within the past 7 days	• ST-segment depression (0.5 mm or greater) • Two or more episodes of chest discomfort within the past 24 hours • Positive biochemical marker for infarction[a]

Using the TIMI Risk Score

One point is assigned for each of the seven medical history and clinical presentation findings. The point total is calculated and the patient is assigned a risk for experiencing the composite endpoint of death, myocardial infarction, or urgent need for revascularization as follows:

High-Risk	Medium-Risk	Low-Risk
TIMI risk score 5–7 points	TIMI risk score 3–4 points	TIMI risk score 0–2 points

Other Ways to Identify High-Risk Patients

Other findings that alone or in combination may identify a high-risk patient:

- ST-segment depression
- Positive biochemical marker for infarction
- Deep symmetric T-wave inversions (2 mm or greater)
- Acute heart failure
- DM
- Chronic kidney disease
- Refractory chest discomfort despite maximal pharmacotherapy for ACS
- Recent MI within the past 2 weeks

[a]A positive biochemical marker for infarction is a value of troponin I, troponin T, or creatine kinase MB of greater than the MI detection limit.
ACS, acute coronary syndromes; CAD, coronary artery disease; CHD, coronary heart disease; DM, diabetes mellitus; HTN, hypertension; MI, myocardial infarction; TIMI, Thrombolysis in Myocardial Infarction.
(Reprinted from Spinler SA, de Denus S. Acute Coronary Syndromes. In DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 296, with permission.)

in the care of MI patients with ST-segment elevation is the time from hospital presentation to the time that the occluded artery is opened with PCI. This "door-to-primary PCI" time should be equal to or less than 90 minutes.[3,16] Unfortunately, most hospitals do not have interventional cardiology services capable of performing primary PCI 24 hours a day. Therefore, only 7% of MI patients are currently treated with primary PCI.

Percutaneous coronary intervention during hospitalization for STE MI may also be appropriate in other patients following STE MI, such as those in whom fibrinolysis is not successful, those presenting later in cardiogenic shock, those with life-threatening ventricular arrhythmias, and those with persistent rest ischemia or signs of ischemia on stress testing following MI.[3,15]

Percutaneous Coronary Intervention in Non–ST-Segment Elevation Acute Coronary Syndromes

❺ *The most recent non–ST-segment elevation ACC/AHA clinical practice guidelines recommend coronary angiography with either PCI or* ***coronary artery bypass graft (CABG) surgery*** *revascularization as an early treatment (early invasive strategy) for high-risk and moderate-risk NSTE ACS patients.*[2] Several recent clinical trials support an "early invasive" strategy with PCI or CABG versus a "medical stabilization" management strategy, whereby coronary angiography with revascularization is reserved for patients with symptoms refractory to pharmacotherapy and patients with signs of ischemia on stress testing.[17] An "early invasive" approach results in fewer MIs, less need for additional revascularization procedures over the next year following hospitalization, and less cost than the conservative "medical stabilization" approach.[17] All patients undergoing PCI should receive aspirin therapy indefinitely. Clopidogrel is administered (concomitantly with aspirin) for at least 30 days and up to 12 months following PCI[18] (Table 5–2).

Additional Testing and Risk Stratification

At some point during hospitalization but prior to discharge, patients with MI should have their left ventricular function (LVF) evaluated for risk stratification.[2,3] The most common way LVF is measured is using an echocardiogram to calculate the patient's left ventricular ejection fraction (LVEF). Left ventricular function is the single best predictor of mortality following MI. Patients with LVEFs less than 40% are at highest risk of death. Patients with ventricular fibrillation or sustained ventricular tachycardia occurring more than 2 days following MI and those with LVEF less than 30% (measured at least 1 month after STE MI and 3 months after coronary artery revascularization with either PCI or CABG) benefit from placement of an implantable cardioverter defibrillator (ICD).[3]

Pre-discharge from the hospital stress testing (Fig. 5–3) may be indicated in: (1) moderate- or low-risk patients in order to determine who would benefit from coronary angiography to establish the diagnosis of CAD and (2) patients following MI to predict intermediate- and long-term risk of recurrent MI and death.[19] In most cases, patients with a positive stress test indicating coronary ischemia will then undergo coronary angiography and subsequent revascularization of significantly occluded coronary arteries. If a patient has a negative exercise stress test for ischemia, the patient is at lower risk for subsequent CHD events.

Early Pharmacologic Therapy for ST-Segment Elevation Acute Coronary Syndromes

Pharmacotherapy for early treatment of ACS is outlined in Fig. 5–3. ❻ *According to the ACC/AHA ST-segment elevation ACS practice guidelines, in addition to reperfusion therapy, early pharmacotherapy of STE should include intranasal oxygen*

TABLE 5–2. Pharmacotherapy for Acute Coronary Syndromes (ST-Segment Elevation and Non–ST-Segment Elevation)[2,3,20,21,22]

Drug	Clinical Condition and ACC/AHA Guideline Recommendation	Contraindications[a]	Dose
Aspirin	STE ACS, class I recommendation[b] for all patients. NSTE ACS, class I recommendation for all patients.	• Hypersensitivity • Active bleeding • Severe bleeding risk	• 160–325 mg on hospital day 1 • 75–162 mg daily starting hospital day 2 and continued indefinitely
Clopidogrel	STE ACS, class I recommendation in patients allergic to aspirin. NSTE ACS, class I recommendation for all hospitalized patients in whom a non-interventional approach is planned. In PCI in STE and NSTE ACS, class I recommendation. In STE ACS with fibrinolytics, large randomized trial data published after 2004 guidelines.	• Hypersensitivity • Active bleeding • Severe bleeding risk	• 300–600 mg loading dose on hospital day 1 followed by a maintenance dose of 75 mg orally once daily starting on hospital day 2; no data on loading dose in patients greater than 75 years old • Administer indefinitely in patients with an aspirin allergy (class I recommendation) • Administer for at least 9 months in medically managed patients with NSTE ACS (class I recommendation) • Administer for at least 30 days to 1 year in patients with STE or NSTE ACS (class I recommendation) undergoing PCI • Administer for a minimum of 6 months in patients receiving a paclitaxel-eluting stent during PCI • Administer for a minimum of 3 months in patients receiving a tacrolimus-eluting stent during PCI • If possible, withhold for at least 5 days in patients in whom CABG is planned to decrease bleeding risk (class I recommendation)
Unfractionated heparin (UFH)	STE ACS, class I recommendation in patients undergoing PCI, and for those patients treated with alteplase, reteplase, or tenecteplase; class IIa recommendation for patients not treated with fibrinolytic therapy. NSTE ACS, class I recommendation in combination with aspirin. PCI, class I recommendation.	• Active bleeding • History of heparin-induced thrombocytopenia • Severe bleeding risk • Recent stroke	• For STSE ACS administer 60 units/kg IV bolus (maximum 4000 units) followed by a constant IV infusion at 12 units/kg/hour (maximum 1000 units/hour) • For NSTE ACS administer 60–70 units/kg IV bolus (maximum 5000 units) followed by a constant IV infusion of 12–15 units/kg/hour (maximum 1000 units/hour) • Titrated to maintain aPTT between 1.5 and 2.5 times control for NSTE ACS and 1.5–2 times control (approximately 50–70 seconds) in STE ACS • The first aPTT should be measured at 4–6 hours for NSTE ACS and STE ACS in patients not treated with thrombolytics • The first aPTT should be measured at 3 hours in patients with STE ACS who are treated with thrombolytics
Low-molecular-weight heparin	STE ACS, class IIb recommendation for patients less than 75 years old treated with fibrinolytics, class III for patients greater than 75 years old treated with thrombolytics, and class IIa for patients not undergoing reperfusion therapy. NSTE ACS, class I recommendation in combination with aspirin, class IIa recommendation over UFH in patients without renal failure who are not anticipated to undergo CABG surgery within 24 hours.	• Active bleeding • History of heparin-induced thrombocytopenia • Severe bleeding risk • Recent stroke • CrCl less than 10 mL/minute (enoxaparin) • CrCl less than 30 mL/minute (dalteparin)	• Enoxaparin 1 mg/kg SC every 12 hours (CrCl greater than or equal to 30 mL/minute) • Enoxaparin 1 mg/kg SC every 24 hours (CrCl 10–29 mL/minute) • Dalteparin 120 IU/kg SC every 12 hours (maximum single bolus dose of 10,000 units) • Administer 30 mg IV bolus for STE ACS patients age less than 75 years • For STE ACS, first 2 subcutaneous doses should be 100 mg for patients weighing equal to or greater than 100 kg (220 lb)

Fibrinolytics	STE ACS, class I recommendation in patients presenting within 12 hours following the onset of symptoms, class IIa in patients presenting between 12–24 hours following the onset of symptoms with continuing signs of ischemia. NSTE ACS: class III recommendation.	• Absolute and relative contraindications per Table 5–3	Streptokinase: 1.5 million units IV over 60 minutes Alteplase: 15 mg IV bolus followed by 0.75 mg/kg IV over 30 minutes (max 50 mg) followed by 0.5 mg/kg (max 35 mg) over 60 minutes (max dose = 100 mg) Reteplase: 10 units IV × 2, 30 minutes apart Tenecteplase: less than 60 kg = 30 mg IV bolus 60–69.9 kg = 35 mg IV bolus 70–79.9 kg = 40 mg IV bolus 80–89.9 kg = 45 mg IV bolus greater than or equal to 90 kg = 50 mg IV bolus
Glycoprotein IIb/IIIa receptor blockers	NSTE ACS, class IIa recommendation for either tirofiban or eptifibatide for patients with either continuing ischemia, elevated troponin or other high-risk features, class I recommendation for patients undergoing PCI, class IIb recommendation for patients without high-risk features who are not undergoing PCI. STE ACS, class IIa for abciximab for primary PCI and class IIb for either tirofiban or eptifibatide for primary PCI, class III in combination with a fibrinolytic agent	• Active bleeding • Prior stroke • Thrombocytopenia	**Drug with/without PCI** / **Dose for PCI** / **Dose for NSTE ACS** / **Adjustment for renal insufficiency or obesity** Abciximab: 0.25 mg/kg IV bolus followed by 0.125 mcg/kg/minute (maximum 10 mcg/minute) for 12 hours / Not recommended / None Eptifibatide: 180 mcg/kg IV bolus × 2, 10 minutes apart with an infusion of 2 mcg/kg/minute started after the first bolus for 18–96 hours / 180 mcg/kg IV bolus followed by an infusion of 2 mcg/kg/minute for 18–96 hours / Reduce maintenance infusion to 1 mcg/kg/minute for patients with CrCl less than 50 mL/minute; not recommended for patients with serum creatinine greater than 4 mg/dL (354 µmol/L); patients weighing greater than or equal to 121 kg (266 lbs) should receive a maximum infusion rate of 22.6 mg per bolus and a maximum infusion rate of 15 mg/hour Tirofiban: Not recommended / 0.4 mcg/kg IV infusion for 30 minutes followed by an infusion of 0.1 mcg/kg/minute for 18–96 hours / Reduce bolus dose to 0.2 mcg/kg/minute and the maintenance infusion to 0.05 mcg/kg/minute for patients with CrCl less than 30 mL/minute

TABLE 5–2. Pharmacotherapy for Acute Coronary Syndromes (ST-Segment Elevation and Non-ST-Segment Elevation)[2,3,20,21,22] (*Continued*)

Drug	Clinical Condition and ACC/AHA Guideline Recommendation	Contraindications[a]	Dose
Nitroglycerin	STE and NSTE ACS, class I indication in patients with ongoing ischemic discomfort, control of hypertension or management of pulmonary congestion.	• Hypotension • Sildenafil or vardenafil within 24 hours or tadalafil within 48 hours	• 0.4 mg SL, repeated every 5 minutes × 3 doses • 5 to 10 mcg/minute by continuous infusion • Titrated up to 75–100 mcg/minute until relief of symptoms or limiting side-effects (headache or hypotension with a systolic blood pressure less than 90 mm Hg or more than 30% below starting mean arterial pressure levels if significant hypertension is present) • Topical patches or oral nitrates are acceptable alternatives for patients without ongoing or refractory symptoms
β-Blockers[c]	STE and NSTE ACS, class I recommendation in all patients without contraindications for oral β-blockers, class I (NSTE ACS) and IIa (STE ACS) for IV β-blockers, class IIb recommendation for patients with moderate left ventricular failure with signs of heart failure provided they can be closely monitored.	• PR ECG segment greater than 0.24 seconds • Second- or third-degree AV block • Heart rate less than 60 beats per minute • Systolic blood pressure less than 90 mm Hg • Shock • Left ventricular failure with congestive heart failure • Severe reactive airway disease	*Target resting heart rate 50–60 beats per minute* ***Metoprolol*** • 5 mg increments by slow (over 1–2 minutes) intravenous administration • Repeated every 5 minutes for a total initial dose of 15 mg • Followed in 1–2 hours by 25–50 mg by mouth every 6 hours • If a very conservative regimen is desired, initial doses can be reduced to 1–2 mg • Alternatively, initial intravenous therapy can be omitted ***Propranolol*** • 0.5–1 mg intravenous dose • Followed in 1–2 hours by 40–80 mg by mouth every 6–8 hours • Alternatively, initial intravenous therapy can be omitted ***Atenolol*** • 5 mg IV dose • Followed 5 minutes later by a second 5 mg IV dose then 50–100 mg orally every day initiated 1–2 hours after the intravenous dose • Alternatively, initial intravenous therapy can be omitted ***Esmolol*** • Starting maintenance dose of 0.1 mg/kg/minute IV • Titration in increments of 0.05 mg/kg/minute every 10–15 minutes as tolerated by blood pressure until the desired therapeutic response has been obtained, limiting symptoms develop, or a dose of 0.20 mg/kg/minute is reached • Optional loading dose of 0.5 mg/kg may be given by slow IV administration (2–5 minutes) for more rapid onset of action
Calcium channel blockers	STE ACS class IIa recommendation and NSTE ACS class I recommendation for patients with ongoing ischemia who are already taking adequate doses of nitrates and β-blockers or in patients with contraindications to or intolerance to β-blockers (diltiazem or verapamil for STE ACS and diltiazem, verapamil, or amlodipine for NSTE ACS). NSTE ACS, class IIb recommendation for diltiazem for patients with AMI.	• Pulmonary edema • Evidence of left ventricular dysfunction • Systolic blood pressure less than 100 mm Hg • PR ECG segment greater than 0.24 seconds for diltiazem or verapamil • Second- or third-degree AV block for diltiazem or verapamil • Heart rate less than 60 beats per minute for diltiazem or verapamil	• Diltiazem 120–360 mg controlled-release once daily • Verapamil 180–480 mg sustained-release per day • Nifedipine 30–90 mg sustained-release once daily • Amlodipine 5–10 mg once daily

ACE inhibitors	STE ACS, class I recommendation within the first 24 hours after hospital presentation for patients with anterior wall infarction, clinical signs of heart failure and those with EF less than 40% in the absence of contraindications, class IIa recommendation for all other patients in the absence of contraindications. NSTE ACS, class I recommendation for patients with heart failure, left ventricular dysfunction, and EF less than 40%, hypertension, or type 2 diabetes mellitus. Consider in all patients with CAD. Indicated indefinitely for all post-AMI patients.	• Systolic blood pressure less than 100 mm Hg • History of intolerance to an ACE inhibitor • Bilateral renal artery stenosis • Serum potassium greater than 5.5 mEq/L (5.5 mmol/L)	**Drug** — **Initial Dose (mg)** — **Target Dose (mg)** Captopril — 6.25–12.5 — 50 twice daily to 50 three times daily Enalapril — 2.5–5 — 10 twice daily Lisinopril — 2.5–5 — 10–20 daily Ramipril — 1.25–2 — 5 twice daily or 10 mg once daily Trandolapril — 1 — 4 mg once daily
Angiotensin receptor blocker	STE ACS, class I recommendation in patients with clinical signs of heart failure or EF less than 40% and intolerant of an ACE inhibitor, class IIa in patients with clinical signs of heart failure or EF less than 40% and no documentation of ACE inhibitor intolerance.	• Systolic blood pressure less than 100 mm Hg • Bilateral renal artery stenosis • Serum potassium greater than 5.5 mEq/L (5.5 mmol/L)	**Drug** — **Initial Dose (mg)** — **Target Dose (mg)** Candesartan — 4–8 mg — 32 mg once daily Valsartan — 40 mg — 160 mg twice daily
Aldosterone antagonists	STE ACS, class I recommendation for patients with MI and EF less than 40% and either diabetes mellitus or heart failure symptoms who are already receiving an ACE inhibitor.	• Hypotension • Hyperkalemia; serum potassium greater than 5.5 mEq/L (5.5 mmol/L) • Serum creatinine greater than 2.5 mg/dL (221 mmol/L)	**Drug** — **Initial Dose (mg)** — **Maximum Dose (mg)** Eplerenone — 25 mg — 50 mg once daily Spironolactone — 12.5 mg — 25–50 mg once daily
Morphine sulfate	STE and NSTE ACS, class I recommendation, for patients whose symptoms are not relieved after three serial sublingual nitroglycerin tablets or whose symptoms recur with adequate anti-ischemic therapy.	• Hypotension • Respiratory depression • Confusion • Obtundation	• 2–5 mg IV dose • May be repeated every 5–30 minutes as needed to relieve symptoms and maintain patient comfort

[a]Allergy or prior intolerance contraindication for all categories of drugs listed in this chart.
[b]Class I recommendations are conditions for which there is evidence and/or general agreement that a given procedure or treatment is useful and effective.
Class II recommendations are those conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a procedure or treatment. For Class IIa recommendations, the weight of the evidence/opinion is in favor of usefulness/efficacy. Class IIb recommendations are those for which usefulness/efficacy is less well established by evidence/opinion.
[c]Choice of the specific agent is not as important as ensuring that appropriate candidates receive this therapy. If there are concerns about patient intolerance due to existing pulmonary disease, especially asthma, selection should favor a short-acting agent, such as propranolol or metoprolol or the ultra-short-acting agent esmolol. Mild wheezing or a history of chronic obstructive pulmonary disease should prompt a trial of a short-acting agent at a reduced dose (e.g., 2.5 mg IV metoprolol, 12.5 mg oral metoprolol, or 25 mcg/kg/minute esmolol as initial doses) rather than complete avoidance of β-blocker therapy.

(if oxygen saturation is less than 90%), sublingual (SL) nitroglycerin (NTG) followed by intravenous (IV) NTG, aspirin, an IV β-blocker, unfractionated heparin (UFH), and fibrinolysis in eligible candidates. Recent results from two clinical trials in patients with STE ACS indicate that clopidogrel should be administered along with aspirin to patients receiving fibrinolytics to reduce mortality and reinfarction as well as to improve the patency of the infarcted artery.[20,21] Morphine is administered to patients with refractory angina as an analgesic and a venodilator that lowers preload. These agents should be administered early, while the patient is still in the emergency department. Dosing and contraindications for SL and IV NTG, aspirin, IV β-blockers, UFH, clopidogrel, and fibrinolytics are listed in Table 5–2.[2,3,22]

Fibrinolytic Therapy

Administration of a fibrinolytic agent is indicated in patients with STE ACS who present to the hospital within 24 hours of the onset of chest discomfort and have at least a 1 mm STE in two or more contiguous ECG leads.[3] The mortality benefit of fibrinolysis is highest with early administration and diminishes after 12 hours. The use of fibrinolytics between 12 and 24 hours after symptom onset should be limited to patients with ongoing ischemia. Fibrinolytic therapy is preferred over primary PCI in patients presenting within 3 hours of symptom onset where there is a delay in "door-to-primary PCI" less than 90 minutes. Other indications and contraindications for fibrinolysis are listed in Table 5–3.[3] It is not necessary to obtain the results of biochemical markers before initiating fibrinolytic therapy. Because administration of fibrinolytics result in clot lysis, patients who are at high-risk of major bleeding (including intracranial hemorrhage) have either a relative or absolute contraindication to fibrinolytic therapy. Patients presenting with an absolute contraindication will likely not receive fibrinolytic therapy, as primary PCI is preferred. Patients with a relative contraindication may receive fibrinolytic therapy if the perceived risk of death from the MI is higher than the risk of major hemorrhage.

Comparative pharmacology of commonly prescribed fibrinolytics is described in Table 5–4.[26] According to the ACC/AHA STE ACS practice guidelines, a more fibrin-specific agent such as alteplase, reteplase, or tenecteplase, is preferred over a non–fibrin-specific agent, such as streptokinase.[3] Fibrin-specific fibrinolytics open a greater percentage of infarcted arteries. In a large clinical trial, administration of alteplase reduced mortality by 1% (absolute reduction) and costs about $30,000 per year of life saved compared to streptokinase.[23] Two other trials compared alteplase to reteplase and alteplase to tenecteplase and found similar mortality between agents.[24,25] Therefore, either alteplase, reteplase, or tenecteplase are acceptable as first-line agents. Intracranial hemorrhage and major bleeding are the most serious side effects of fibrinolytic agents (Table 5–4). The risk of intracranial hemorrhage is higher with fibrin-specific agents than with streptokinase. However, the risk of systemic bleeding other than intracranial hemorrhage is higher with streptokinase than with other, more fibrin-specific agents.[23]

Twenty to 40 percent of patients presenting with STE ACS receive fibrinolysis compared with 7% receiving primary PCI.[26,27] Therefore, many patients do not receive early reperfusion therapy. The primary reason for lack of reperfusion therapy is that most patients present more than 12 hours after the time of symptom onset.[27] The percentage of eligible patients who receive reperfusion therapy is a quality indicator of care in

TABLE 5–3. Indications and Contraindications to Fibrinolytic Therapy per ACC/AHA Guidelines for Management of Patients with ST-Segment Elevation Myocardial Infarction[3]

Indications

1. Ischemic chest discomfort at least 20 minutes in duration but 12 hours or less since symptom onset
   and
   ST-segment elevation of at least 1 mm in height in two or more contiguous leads, or new or presumed new left bundle-branch block
2. Ongoing ischemic chest discomfort at least 20 minutes in duration 12–24 hours since symptom onset
   and
   ST-segment elevation of at least 1 mm in height in two or more contiguous leads

Absolute Contraindications

- Active internal bleeding (not including menses)
- Previous intracranial hemorrhage at any time; ischemic stroke within 3 months
- Known intracranial neoplasm
- Known structural vascular lesion (e.g., arteriovenous malformation)
- Suspected aortic dissection
- Significant closed head or facial trauma within 3 months

Relative Contraindications

- Severe, uncontrolled hypertension on presentation (blood pressure greater than 180/110 mm Hg)
- History of prior ischemic stroke greater than 3 months ago, dementia, or known intracranial pathology not covered above under absolute contraindications
- Current use of anticoagulants
- Known bleeding diathesis
- Traumatic or prolonged (greater than 10 minutes) CPR or major surgery (less than 3 weeks ago)
- Non-compressible vascular puncture (such as a recent liver biopsy or carotid artery puncture)
- Recent (within 2–4 weeks) internal bleeding
- For streptokinase administration, previous streptokinase use (greater than 5 days) or prior allergic reactions
- Pregnancy
- Active peptic ulcer
- History of severe, chronic, poorly controlled hypertension

TABLE 5–4. Comparison Between Fibrinolytic Agents

Agent	Fibrin Specificity	TIMI-3 Blood Flow Complete Perfusion at 90 Minutes	Systemic Bleeding Risk/ICH Risk	Administration	Average Wholesale Price[3]	Other Approved Uses
Streptokinase	+	35%	+++/+	Infusion over 60 minutes	$613	Pulmonary embolism, deep vein thrombosis, arterial thromboembolism, clearance of an occluded arteriovenous catheter
Alteplase (rt-PA)	+++	50–60%	++/++	Bolus followed by infusions over 90 minutes; weight-based dosing	$2,750	Pulmonary embolism, stroke, clearance of an occluded arteriovenous catheter
Reteplase (rPA)	++	50–60%	++/++	Two bolus doses, 30 minutes apart	$2,974	
Tenecteplase (TNK-tPA)	++++	50–60%	+/++	Single bolus dose; weight-based dosing	$2,833	

ICH, intracranial hemorrhage; TIMI, Thrombolysis in Myocardial Blood Flow (TIMI-3 blood flow indicates complete perfusion of the infracted artery). (Reprinted from Spinler SA, de Denus S. Acute Coronary Syndromes. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 303, with permission.)

patients with MI.[23] The "door-to-needle time", the time from presentation to start of fibrinolytic therapy, is another quality indicator.[23] While the ACC/AHA guidelines recommend a "door-to-needle time" of less than 30 minutes, the average time in the United States is approximately 37 minutes.[27] Therefore, strategies to shorten administration times should be implemented.

Aspirin

Aspirin has become the preferred antiplatelet agent in the treatment of all ACS.[2,3] Aspirin administration to all patients who don't have contraindications to aspirin therapy within the first 24 hours of hospital admission is a quality care indicator.[23] The antiplatelet effects of aspirin are mediated by inhibiting the synthesis of TXA_2 through an irreversible inhibition of platelet cyclooxygenase-1. In patients undergoing PCI, aspirin prevents acute thrombotic occlusion during the procedure. In patients receiving fibrinolytics, aspirin reduces mortality, and its effects are additive to fibrinolysis alone.[28]

Although an initial dose of 160 to 325 mg is required to achieve rapid platelet inhibition, long-term therapy with doses of 75 to 150 mg daily are as effective as higher doses. In addition, doses of less than 325 mg daily are associated with a lower rate of bleeding.[29,30] The major bleeding rate associated with chronic aspirin administration in doses less than 100 mg per day is 1.6%, whereas the rate with doses more than 100 mg per day is 2.3%.[30] Therefore, a daily maintenance dose of 75 to 160 mg is recommended.[2]

Other gastrointestinal disturbances, including dyspepsia and nausea, are infrequent when low-dose aspirin is used. Aspirin therapy should be continued indefinitely.

Thienopyridines

Administration of clopidogrel is recommended for all patients with STE ACS (Table 5–2).[3] Clopidogrel blocks adenosine diphosphate receptors on platelets, preventing the expression of glycoprotein IIb/IIIa receptors and thus platelet activation and aggregation.

Clopidogrel reduces death, MI, or stroke in patients with NSTE ACS when combined with aspirin.[31] It also reduces death, MI, or stroke in secondary prevention of vascular events in patients with a recent MI, stroke, or symptomatic peripheral vascular disease.[32] Most recently, early therapy with clopidogrel 75 mg once daily in patients with STE ACS reduced mortality and reinfarction in patients treated with fibrinolytics without increasing the risk of major bleeding.[21] Therefore, the combination of clopidogrel and aspirin is indicated for all patients with ACS. For PCI, clopidogrel is administered as a 300 to 600 mg loading dose followed by a 75 mg per day maintenance dose, in combination with aspirin, to prevent subacute stent thrombosis and long-term events, such as the composite endpoint of death, myocardial infarction, or need to undergo repeat PCI.[2,18] The most frequent side effect of clopidogrel is rash or gastrointestinal events (nausea, vomiting, or diarrhea). Rarely, thrombotic thrombocytopenic purpura has been reported with clopidogrel. The most serious side effect of clopidogrel is bleeding, which will be discussed in more detail in the section on pharmacotherapy for NSTE ACS.

Glycoprotein IIb/IIIa Receptor Inhibitors

Abciximab is a first-line glycoprotein IIb/IIIa receptor inhibitor for patients undergoing primary PCI[3,15,18] who have not received fibrinolytics. It should not be administered for

medical management of the STE ACS patient who will not be undergoing PCI. Abciximab, in combination with aspirin, a thienopyridine, and UFH (administered as an infusion for the duration of the procedure), is preferred over eptifibatide and tirofiban in this setting because abciximab is the most common glycoprotein IIb/IIIa receptor inhibitor studied in primary PCI trials, and a meta-analysis of trials demonstrated a reduction in short- and long-term mortality.[3,18,33]

Dosing and contraindications for abciximab are described in Table 5–2. Glycoprotein IIb/IIIa receptor inhibitors block the final common pathway of platelet aggregation; namely, cross-linking of platelets by fibrinogen bridges between the glycoprotein IIb and IIIa receptors on the platelet surface. Administration of a glycoprotein IIb/IIIa receptor inhibitor increases the risk of bleeding, especially if it is given in the setting of recent (less than 4 hours) administration of fibrinolytic therapy.[31,33] An immune-mediated thrombocytopenia occurs in approximately 5% of patients receiving abciximab.[34]

Anticoagulants

Unfractionated heparin, administered as a continuous infusion, is a first-line anticoagulant for treatment of patients with STE ACS, both for medical therapy and for patients undergoing PCI.[3,15,18] Unfractionated heparin binds to antithrombin and then to clotting factors Xa and IIa (thrombin). Anticoagulant therapy should be initiated in the emergency department and continued for 48 hours or longer in patients who will be bridged over to receive chronic warfarin anticoagulation following acute MI.[3] In the United States, UFH is typically continued until the patient has undergone PCI during hospitalization for STE ACS. Unfractionated heparin dosing is described in Table 5–2. The dose of the UFH infusion is adjusted frequently to a target activated partial thromboplastin time (aPTT) (Table 5–2). When co-administered with a fibrinolytic, aPTTs above the target range are associated with an increased rate of bleeding, while aPTTs below the target range are associated with increased mortality and reinfarction.[35] Unfractionated heparin is discontinued immediately after the PCI procedure.

A meta-analysis of small randomized studies from the 1970s and 1980s suggests that UFH reduces mortality by approximately 17%.[3] Other beneficial effects of anticoagulation are prevention of cardioembolic stroke, as well as venous thromboembolism in MI patients.[3] Besides bleeding, the most frequent adverse effect of UFH is an immune-mediated clotting disorder, **heparin-induced thrombocytopenia**, which occurs in up to 5% of patients treated with UFH. Heparin-induced thrombocytopenia is less common in patients receiving low-molecular-weight heparins (LMWHs), such as enoxaparin or dalteparin.

Low-molecular-weight heparins have not been studied in the setting of primary PCI. Low-molecular-weight heparins, like UFH, bind to antithrombin and inhibit both factor Xa and IIa. However, because their composition contains mostly short saccharide chain lengths, they preferentially inhibit factor Xa over factor IIa, which requires larger chain lengths for binding and inhibition. Limited data, primarily with enoxaparin, suggests that LMWHs may be an alternative to UFH in STE ACS.[36] A larger trial evaluating enoxaparin versus UFH in combination with fibrinolytics for STE ACS is ongoing.

Nitrates

One sublingual nitroglycerin tablet should be administered every 5 minutes for up to three doses in order to relieve myocardial ischemia. If patients have been previously prescribed sublingual NTG and ischemic chest discomfort persists for more than 5 minutes after the first dose, the patient should be instructed to contact emergency medical services before self-administering subsequent doses in order to activate emergency care sooner. Intravenous nitroglycerin should then be initiated in all patients with an ACS who do not have a contraindication and who have persistent ischemia, heart failure, or uncontrolled blood pressure. Intravenous nitroglycerin should be continued for approximately 24 hours after ischemia is relieved (Table 5–2). Nitrates promote the release of nitric oxide from the endothelium, which results in venous and arterial vasodilation. Venodilation lowers preload and myocardial oxygen demand. Arterial vasodilation may lower blood pressure, thus reducing myocardial oxygen demand. Arterial vasodilation also relieves coronary artery vasospasm, dilating coronary arteries to improve myocardial blood flow and oxygenation. Although used to treat ACS, nitrates have been suggested to play a limited role in the treatment of an ACS patient, as two large, randomized clinical trials failed to show a mortality benefit for IV nitrate therapy followed by oral nitrate therapy in acute MI.[37,38] The most significant adverse effects of nitrates are tachycardia, flushing, headache, and hypotension. Nitrate administration is contraindicated in patients who have received oral phosphodiesterase 5 inhibitors, such as sildenafil and vardenafil, within the past 24 hours, and tadalafil within the past 48 hours.[3]

Beta-Blockers

Intravenous or oral doses of a β-blocker should be administered early in the care of a patient with STE ACS, and then oral agents should be continued indefinitely. Early administration of a β-blocker to patients lacking a contraindication within the first 24 hours of hospitalization is a quality care indicator.[2,3] In ACS the benefit of β-blockers mainly results from the competitive blockade of β_1-adrenergic receptors located on the myocardium. β_1-Blockade produces a reduction in heart rate, myocardial contractility, and blood pressure, decreasing myocardial oxygen demand. As a result of these effects, β-blockers reduce the risk for recurrent ischemia, increase in infarct size and risk of reinfarction, and occurrence of ventricular arrhythmias in the hours and days following MI.[39]

Landmark clinical trials have established the role of early β-blocker therapy in reducing MI mortality, reinfarction, and arrhythmias. Most of these trials were performed in the 1970s and 1980s before routine use of early reperfusion therapy.[40,41] However, data regarding the acute benefit of β-blockers in MI

in the reperfusion era is derived mainly from a recently reported large clinical trial, which suggests that there may be an early risk of cardiogenic shock when initiating intravenous β-blockers followed by oral β-blockers early in the course of STE MI, especially in patients presenting with pulmonary congestion.[42] Therefore, a low dose of an oral β-blocker should be initiated, followed by careful assessment for signs of hypotension and heart failure prior to any dose titration in patients with STE MI. Early administration of β-blockers (to patients without contraindications) within the first 24 hours of hospital admission is a standard of quality patient care.[3] However, the AHA is currently undertaking a re-evaluation of this practice guideline recommendation given the results of the aforementioned trial reporting adverse effects associated with β-blocker use in certain MI populations.

The most serious side effects of β-blocker administration early in ACS are hypotension, bradycardia, and heart block. While initial, acute administration of β-blockers is not appropriate for patients who present with decompensated heart failure, initiation of β-blockers may be attempted before hospital discharge in the majority of patients following treatment of acute heart failure. β-Blockers are continued indefinitely.

Calcium Channel Blockers

Calcium channel blockers in the setting of STE ACS are used for relief of ischemic symptoms in patients who have contraindications to β-blockers. Patients prescribed calcium channel blockers for treatment of hypertension who were not receiving and do not have any contraindications to β-blockers should have the calcium channel blocker discontinued and a β-blocker initiated. Although all calcium channel blockers produce coronary vasodilatation and decrease blood pressure, other effects are more heterogeneous between these agents. Dihydropyridine calcium channel blockers (e.g., amlodipine, felodipine, and nifedipine) primarily produce their anti-ischemic effects through peripheral vasodilatation with no clinical effects on AV node conduction and heart rate. The nondihydropyridine calcium channel blockers (e.g., diltiazem and verapamil), on the other hand, have additional anti-ischemic effects by reducing contractility, AV nodal conduction, and slowing heart rate.

Current data suggest little benefit on clinical outcomes beyond symptom relief for calcium channel blockers in the setting of ACS.[43] Moreover, the use of first-generation short-acting dihydropyridines, such as nifedipine, should be avoided because they appear to worsen outcomes through their negative inotropic effects, induction of reflex sympathetic activation, tachycardia, and increased myocardial ischemia.[43] Therefore, calcium channel blockers should be avoided in the acute management of MI unless there is a clear symptomatic need or a contraindication to β-blockers.

Adverse effects and contraindications of calcium channel blockers are described in Table 5–2. Verapamil, diltiazem, and first-generation dihydropyridines should also be avoided in patients with acute decompensated heart failure or left ventricular dysfunction because they can worsen heart failure and potentially increase mortality secondary to their negative inotropic effects. In patients with heart failure requiring treatment with a calcium channel blocker, amlodipine, a second-generation dihydropyridine that does not cause reflex tachycardia, is the preferred agent.[44]

Early Pharmacotherapy for Non–ST-Segment Elevation Acute Coronary Syndromes

In general, early pharmacotherapy of NSTE ACS (Fig. 5–3) is similar to that of STE ACS with three exceptions: (1) fibrinolytic therapy is not administered; (2) glycoprotein IIb/IIIa receptor blockers are administered to high-risk patients for medical therapy as well as to PCI patients; and (3) at this time, there are no standard quality indicators for patients with NSTE ACS who are not diagnosed with MI.

❼ *According to the ACC/AHA non–ST-segment elevation ACS practice guidelines, in the absence of contraindications, early pharmacotherapy of NSTE ACS should include intranasal oxygen (if oxygen saturation is low), SL NTG followed by IV NTG, aspirin, an IV β-blocker, and UFH or LMWH. Most patients should receive additional therapy with clopidogrel. High-risk patients should also receive a glycoprotein IIb/IIIa receptor blocker.* Morphine is also administered to patients with refractory angina as described previously. These agents should be administered early, while the patient is still in the emergency department. Dosing and contraindications for SL and IV NTG (for selected patients), aspirin, IV β-blockers, UFH, and LMWHs are listed in Table 5–2.[2,22]

Fibrinolytic Therapy

Fibrinolytic therapy is not indicated in any patient with NSTE ACS, as increased mortality has been reported with fibrinolytics compared to controls in clinical trials in which fibrinolytics have been administered to patients with NSTE ACS (patients with normal or ST-segment depression ECGs).[10]

Aspirin

Aspirin reduces the risk of death or developing MI by about 50% (compared to no antiplatelet therapy) in patients with NSTE ACS.[29] Therefore, aspirin remains the cornerstone of early treatment for all ACS. Dosing of aspirin for NSTE ACS is the same as that for STE ACS (Table 5–2). Aspirin is continued indefinitely.

Thienopyridines

For patients with NSTE ACS, clopidogrel started on the first day of hospitalization as a 300 to 600 mg loading dose and followed the next day by 75 mg orally per day is recommended for most patients.[2] Although the use of aspirin in ACS is the mainstay of antiplatelet therapy, morbidity and mortality following an ACS remain high. Clopidogrel, administered as a 300 mg loading dose followed by 75 mg once daily for 9 to

12 months, reduces the combined risk of death from cardiovascular causes, non-fatal MI, or stroke by 20%.[45] Administration of clopidogrel for at least 30 days in patients undergoing intracoronary stenting is the standard of care. Recently, the combination of clopidogrel with aspirin has been extended to 3 months for sirolimus-eluting stents and at least 6 months for patients with paclitaxel-eluting stents.[18] Because of the potential for increased risk of bleeding, clopidogrel should be discontinued for at least 5 days before elective CABG surgery.[2]

Glycoprotein IIb/IIIa Receptor Inhibitors

Administration of tirofiban or eptifibatide is recommended for high-risk NSTE ACS patients as medical therapy without planned revascularization and for patients with continued or recurrent ischemia despite treatment with aspirin and an anticoagulant. In these patients, the benefit of glycoprotein IIb/IIIa inhibitors appears to be limited to those undergoing PCI.[18,46] Patients undergoing PCI in these trials received several hours to days of pre-treatment with the glycoprotein IIb/IIIa receptor blocker before proceeding to PCI. Abciximab should not be used in this setting, because its use in such a setting has not been shown to be beneficial.

In patients with NSTE ACS scheduled for early PCI, administration of either abciximab or eptifibatide (double bolus) is recommended. The use of tirofiban in these patients is not recommended, because it has been shown to be inferior to abciximab.[2] Medical therapy with glycoprotein IIb/IIIa receptor inhibitors in patients not undergoing PCI is reserved for higher-risk patients, such as those with positive troponin or ST-segment depression, and patients who have continued or recurrent ischemia despite other antithrombotic therapy.[2]

Doses and contraindications to glycoprotein IIb/IIIa receptor blockers are described in Table 5–2. Major bleeding and rates of transfusion are increased with administration of a glycoprotein IIb/IIIa receptor inhibitor in combination with aspirin and an anticoagulant,[30] but there is no increased risk of intracranial hemorrhage in the absence of concomitant fibrinolytic treatment. The risk of thrombocytopenia with tirofiban and eptifibatide appears lower than that with abciximab. Bleeding risks appear similar between agents.

Anticoagulants

Either UFH or LMWH should be administered to patients with NSTE ACS. Therapy should be continued for up to 48 hours or until the end of the angiography or PCI procedure. In patients initiating warfarin therapy, UFH or LMWHs should be continued until the International Normalized Ratio (INR) with warfarin is in the therapeutic range for 2 consecutive days. The addition of UFH to aspirin reduces the rate of death or MI in patients with NSTE ACS.[47] Enoxaparin was mentioned as "preferred" over UFH in the 2002 ACC/AHA clinical practice guidelines, as two large clinical trials found a reduction in the combined endpoint of death, MI, or need for PCI in patients primarily treated with a medical management strategy.[2] However, in patients with NSTE ACS undergoing early PCI, similar rates of death or MI and a slightly higher bleeding rate with enoxaparin was found in a large trial comparing enoxaparin and UFH. This trial, however, was confounded by a large number of patients who received both UFH and enoxaparin. Therefore, either enoxaparin or UFH may be administered, but switching between UFH and enoxaparin should be avoided as it appears to increase bleeding rates.[48] In some clinical trials, the risk of heparin-induced thrombocytopenia has been shown to be lower with LMWHs compared to UFH. Dosing information and contraindications are described in Table 5–2.

Nitrates

Sublingual NTG followed by intravenous NTG should be administered to patients with NSTE ACS and ongoing ischemia (Table 5–2). The mechanism of action, dosing, contraindications, and adverse effects are the same as those described in the section on early pharmacologic therapy for STE ACS. Intravenous NTG is typically continued for approximately 24 hours following ischemia relief.

Beta-Blockers

Intravenous β-blockers followed by oral β-blockers should be administered to all patients with NSTE ACS in the absence of contraindications. Benefits of β-blockers in this patient group are assumed to be similar to those seen in patients with STE ACS. β-Blockers are continued indefinitely.

Calcium Channel Blockers

As described in the previous section, calcium channel blockers should not be administered to most patients with ACS. Their role is a second-line treatment for patients with certain contraindications to β-blockers and those with continued ischemia despite β-blocker and nitrate therapy. Administration of either amlodipine, diltiazem, or verapamil is preferred.[2] Agent selection is based on heart rate and left ventricular dysfunction (diltiazem and verapamil are contraindicated in patients with bradycardia, heart block, or systolic heart failure). Dosing and contraindications are described in Table 5–2.

Patient Encounter, Part 3: Secondary Prevention of MI

- Identify the long-term treatment goals for SD.
- What additional pharmacotherapy should be initiated prior to hospital discharge?
- Create a care plan for SD for hospital discharge which includes pharmacotherapy, desired treatment outcomes, and monitoring for efficacy and adverse effects.

Secondary Prevention Following Myocardial Infarction

The long-term goals following MI are to: (1) control modifiable CHD risk-factors, (2) prevent the development of systolic heart failure, (3) prevent recurrent MI and stroke, and (4) prevent death, including sudden cardiac death. Pharmacotherapy, which has been proven to decrease mortality, heart failure, reinfarction, or stroke, should be initiated prior to hospital discharge for secondary prevention. ❽ *Guidelines from the ACC/AHA suggest that in the absence of contraindications, following MI from either STE ACS or NSTE ACS, patients should receive indefinite treatment with aspirin, a β-blocker, and an ACE inhibitor.*[2,3] *For NSTE ACS, most patients should receive clopidogrel, in addition to aspirin, for up to 9 months.*[2] *Most patients will receive a statin to reduce low-density lipoprotein cholesterol to less than 100 mg/dL. Selected patients will also be treated with long-term warfarin anticoagulation. Newer therapies include eplerenone, an aldosterone antagonist. For all ACS patients, treatment and control of modifiable risk factors such as hypertension, dyslipidemia, and diabetes mellitus is essential.* Benefits and adverse effects of long-term treatment with these medications are discussed in more detail below.

❾ *Because the costs for chronic preventative pharmacotherapy are the same for primary and secondary prevention, while the risk of events is higher with secondary prevention, secondary prevention is more cost effective than primary prevention of CHD.* Pharmacotherapy demonstrating cost effectiveness to prevent death in the ACS and post-MI patient includes fibrinolytics ($2,000 to $33,000 cost per year of life saved), aspirin, glycoprotein IIb/IIIa receptor blockers ($13,700 to $16,500 per year of life added), β-blockers (less than $5,000 to $15,000 cost per year of life saved), ACE inhibitors ($3,000 to $5,000 cost per year of life saved), eplerenone ($15,300 to $32,400 per year of life gained), statins ($4,500 to $9,500 per year of life saved) and gemfibrozil ($17,000 per year of life saved).[49–58] Because cost-effectiveness ratios of less than $50,000 per added life-year are considered economically attractive from a societal perspective,[49] pharmacotherapy described above for ACS and secondary prevention are standards of care because of their efficacy and cost attractiveness to payors.

Aspirin

Aspirin decreases the risk of death, recurrent infarction, and stroke following myocardial infarction. Aspirin prescription at hospital discharge is a quality care indicator in MI patients.[3] All patients should receive aspirin indefinitely; those patients with a contraindication to aspirin should receive clopidogrel.[2,3]

The risk of major bleeding from chronic aspirin therapy is approximately 2% and is dose-related. Aspirin doses higher than 75 to 81 mg are no less effective than doses of 160 to 325 mg, but do have lower rates of bleeding. Therefore, chronic doses of aspirin should not exceed 81 mg.

Clopidogrel

For patients with either STE or NSTE ACS, clopidogrel decreases the risk of death, MI, or stroke.[21,45] The ACC/AHA guidelines suggest a minimum therapy duration of 9 months in patients following NSTE ACS.[2] In patients receiving clopidogrel for STE MI who do not undergo PCI, clopidogrel should be administered for at least 14 to 28 days.[21] Patients who have undergone a PCI with stent implantation may receive clopidogrel for up to 12 months.[18] Because of the risk of bleeding with concomitant therapy of clopidogrel and aspirin at doses greater than 100 mg, low-dose aspirin should be administered with clopidogrel.[59] Although not specifically studied, longer duration of therapy with clopidogrel plus aspirin may be considered for patients with many recurrent vascular events such as stroke, MI, or recurrent ACS.

Anticoagulation

Warfarin should be considered in selected patients following an ACS, including patients with a left ventricular thrombus, patients demonstrating extensive ventricular wall motion abnormalities on cardiac echocardiogram, a history of thromboembolic disease, or chronic atrial fibrillation.[3] A meta-analysis of 10 clinical trials of secondary prevention with aspirin, warfarin, and the combination of the two suggested that warfarin plus low-dose aspirin reduced the rate of MI and stroke, but did not reduce mortality. The risk of major bleeding was increased more than two-fold.[60] Many consider these benefits to be small in comparison with the large management issues related to warfarin therapy, such as INR monitoring and drug interactions. Furthermore, because a large proportion of ACS patients in North America undergo coronary revascularization with subsequent stent implantation, patients require a combination of aspirin and clopidogrel to prevent stent thrombosis, a platelet-dependent phenomenon that warfarin does not effectively prevent.[61] Therefore, because of the complexity of managing current anticoagulants, the use of warfarin is unlikely to gain wide acceptance. Despite the superiority of warfarin plus aspirin over aspirin alone, it is not currently the preferred antithrombotic agent recommended by any professional association practice guidelines in the absence of the conditions for select patients outlined previously.

Beta-Blockers, Nitrates, and Calcium Channel Blockers

Current treatment guidelines recommend that following an ACS, patients should receive a β-blocker indefinitely[2,3] whether they have residual symptoms of angina or not.[62] β-Blocker prescription at hospital discharge in the absence of contraindications is a quality care indicator.[3] Overwhelming data support the use of β-blockers in patients with a previous MI. Currently, there are no data to support the superiority of one β-blocker over another, although the only β-blocker with intrinsic sympathomimetic activity that has been shown to be beneficial following MI is acebutolol.[63]

Although β-blockers should be avoided in patients with decompensated heart failure from left ventricular systolic dysfunction complicating an MI, clinical trial data suggest that it is safe to initiate β-blockers prior to hospital discharge in these patients once heart failure symptoms have resolved.[64] These patients may actually benefit more than those without left ventricular dysfunction.[65] In patients who cannot tolerate or have a contraindication to a β-blocker, a calcium channel blocker can be used to prevent anginal symptoms, but should not be used routinely in the absence of such symptoms.[2,3,62]

Finally, all patients should be prescribed short-acting, sublingual NTG or lingual NTG spray to relieve any anginal symptoms when necessary and instructed on its use.[2,3] Chronic long-acting nitrate therapy has not been shown to reduce CHD events following MI. Therefore, intravenous NTG is not routinely followed by chronic, long-acting oral nitrate therapy in ACS patients who have undergone revascularization, unless the patient has chronic stable angina or significant coronary stenoses that were not revascularized.[62]

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

Angiotensin-converting enzyme inhibitors should be initiated in all patients following MI to reduce mortality, decrease reinfarction, and prevent the development of heart failure.[2,3] Dosing and contraindications are described in Table 5–2. The benefit of ACE inhibitors in patients with MI most likely comes from their ability to prevent cardiac remodeling. The largest reduction in mortality is observed in patients with left ventricular dysfunction (low LVEF) or heart failure symptoms. Early initiation (within 24 hours) of an *oral* ACE inhibitor appears to be crucial during an acute MI, as 40% of the 30-day survival benefit is observed during the first day, 45% from days 2 to 7, and approximately 15% from days 8 to 30.[66] However, current data do not support the early administration of *intravenous* ACE inhibitors in patients experiencing an MI, as mortality may be increased.[67] Administration of ACE inhibitors should be continued indefinitely. Hypotension should be avoided, as coronary artery filling may be compromised. Additional trials suggest that most patients with CAD, not just ACS or heart failure patients, benefit from ACE inhibitors. Therefore, ACE inhibitors should be considered in all patients following an ACS in the absence of a contraindication.

Many patients cannot tolerate chronic ACE inhibitor therapy secondary to adverse effects outlined below. Alternatively, the angiotensin receptor blockers (ARBs), candesartan and valsartan, have been documented in trials to improve clinical outcomes in patients with heart failure.[68,69] Therefore, either an ACE inhibitor or candesartan or valsartan are acceptable choices for chronic therapy for patients who have a low ejection fraction (EF) and heart failure following MI. Since more than five different ACE inhibitors have proven benefits in MI while only two ARBs have been studied, the benefits of ACE inhibitors are generally considered a class effect while the benefits of ARBs are still under study. Angiotensin-converting enzyme inhibitor prescription (or alternatively an ARB) at hospital discharge following MI, in the absence of contraindications, to patients with depressed LVF (EF less than 40%) is currently a quality care indicator, and there are plans to make administration of an ACE inhibitor in all patients without contraindications a quality care indicator.[3]

Besides hypotension, the most frequent adverse reaction to an ACE inhibitor is cough, which may occur in up to 30% of patients. Patients with an ACE inhibitor cough and either clinical signs of heart failure or LVEF less than 40% may be prescribed an ARB.[3] Other, less common but more serious adverse effects to ACE inhibitors and ARBs include acute renal failure, hyperkalemia, and angioedema.

Aldosterone Antagonists

To reduce mortality, administration of an aldosterone antagonist, either eplerenone or spironolactone, should be considered within the first 2 weeks following MI in all patients who are already receiving an ACE inhibitor (or ARB) and have an EF of equal to or less than 40% and either heart failure symptoms or diagnosis of diabetes mellitus.[3] Aldosterone plays an important role in heart failure and in MI because it promotes vascular and myocardial fibrosis, endothelial dysfunction, hypertension, left ventricular hypertrophy, sodium retention, potassium and magnesium loss, and arrhythmias. Aldosterone antagonists have been shown in experimental and human studies to attenuate these adverse effects.[70] Spironolactone decreases all-cause mortality in patients with stable, severe heart failure.[71]

Eplerenone, like spironolactone, is an aldosterone antagonist that blocks the mineralocorticoid receptor. In contrast to spironolactone, eplerenone has no effect on the progesterone or androgen receptor, thereby minimizing the risk of gynecomastia, sexual dysfunction, and menstrual irregularities.[70] In a recent clinical trial,[72] eplerenone significantly reduced mortality, as well as hospitalization for heart failure in post-MI patients with an EF less than 40% and symptoms of heart failure at any time during hospitalization. The risk of hyperkalemia, however, was increased. Therefore, patients with a serum creatinine (SCr) greater than 2.5 mg/dL (221 μmol/L) or creatinine clearance less than 50 mL/minute or serum potassium concentration of greater than 5.0 mmol/L (5.0 mEq/L) should not receive eplerenone (in addition to either an ACE inhibitor or ARB). Currently, there are no data to support that the more selective, more expensive eplerenone is superior to, or should be preferred to, the less expensive generic spironolactone unless a patient has experienced gynecomastia, breast pain, or impotence while receiving spironolactone. Finally, it should be noted that hyperkalemia is just as likely to appear with both of these agents.

Lipid-Lowering Agents

There are now overwhelming data supporting the benefits of statins in patients with CAD in prevention of total mortality, cardiovascular mortality, and stroke. According to the National

TABLE 5–5. Therapeutic Drug Monitoring for Adverse Effects of Pharmacotherapy for Acute Coronary Syndromes

Drug	Adverse Effects	Monitoring
Aspirin	Dyspepsia, bleeding, gastritis	Clinical signs of bleeding,[a] gastrointestinal upset; baseline CBC and platelet count; CBC platelet count every 6 months
Clopidogrel	Bleeding, TTP (rare)	Clinical signs of bleeding[a]; baseline CBC and platelet count; CBC and platelet count every 6 months following hospital discharge
Unfractionated heparin	Bleeding, heparin-induced thrombocytopenia	Clinical signs of bleeding[a]; baseline CBC and platelet count; aPTT every 6 hours until target then every 24 hours; daily CBC; platelet count every 2 days (minimum, preferably every day)
Low-molecular-weight heparins	Bleeding, heparin-induced thrombocytopenia	Clinical signs of bleeding[a]; baseline CBC and platelet count; daily CBC, platelet count every 2 days (minimum, preferably every day); SCr daily
Fibrinolytics	Bleeding, especially intracranial hemorrhage	Clinical signs of bleeding[a]; baseline CBC and platelet count; mental status every 2 hours for signs of intracranial hemorrhage; daily CBC
Glycoprotein IIb/IIIa receptor blockers	Bleeding, acute profound thrombocytopenia	Clinical signs of bleeding[a]; baseline CBC and platelet count; daily CBC; platelet count at 4 hours after initiation then daily
Intravenous nitrates	Hypotension, flushing, headache, tachycardia	BP and HR every 2 hours
β-Blockers	Hypotension, bradycardia, heart block, bronchospasm, heart failure, fatigue, depression, sexual dysfunction, nightmares, masking hypoglycemia symptoms in diabetics	BP, RR, HR, 12-lead ECG and clinical signs of heart failure every 5 minutes during bolus intravenous dosing; BP, RR, HR, and clinical signs of heart failure every shift during oral administration during hospitalization, then BP and HR every 6 months following hospital discharge
Diltiazem and verapamil	Hypotension, bradycardia, heart block, heart failure, gingival hyperplasia	BP and HR every shift during oral administration during hospitalization then every 6 months following hospital discharge; dental exam and teeth cleaning every 6 months
Amlodipine	Hypotension, dependent peripheral edema, gingival hyperplasia	BP every shift during oral administration during hospitalization, then every 6 months following hospital discharge; dental exam and teeth cleaning every 6 months
Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers	Hypotension, cough (with ACE inhibitors), hyperkalemia, prerenal azotemia, angioedema (ACE inhibitors more so than ARBs)	BP every 2 hours × 3 for first dose, then every shift during oral administration during hospitalization, then once every 6 months following hospital discharge; baseline SCr and potassium; daily SCr and potassium while hospitalized then every 6 months (or 1–2 weeks after each outpatient dose titration); closer monitoring required in selected patients using spironolactone or eplerenone or if renal insufficiency; counsel patient on throat, tongue, and facial swelling
Aldosterone antagonists	Hypotension, hyperkalemia, increased serum creatinine	BP and HR every shift during oral administration during hospitalization, then once every 6 months; baseline SCr and serum potassium concentration; SCr and potassium at 48 hours, at 7 days, then monthly for 3 months, then every 3 months thereafter following hospital discharge
Warfarin	Bleeding, skin necrosis	Clinical signs of bleeding[a]; baseline CBC and platelet count; CBC and platelet count every 6 months following hospital discharge; baseline aPTT and INR; daily INR until two consecutive INRs are within the target range then once weekly × 2 weeks, then every month
Morphine	Hypotension, respiratory depression	BP and RR 5 minutes after each bolus dose

[a]Clinical signs of bleeding include bloody stools, melena, hematuria, hematemesis, bruising, and oozing from arterial or venous puncture sites.
ACE, angiotensin-converting enzyme; aPTT, activated partial thromboplastin time; ARB, angiotensin receptor blocker; BP, blood pressure; CBC, complete blood count; ECG, electrocardiogram; HR, heart rate; INR, International Normalized Ratio; RR, respiratory rate; SCr, serum creatinine, TTP, thrombotic thrombocytopenic purpura.

Cholesterol Education Program (NCEP) Adult Treatment Panel recommendations, all patients with CAD should receive dietary counseling and pharmacologic therapy in order to reach a low-density lipoprotein (LDL) cholesterol of less than 100 mg/dL (2.59 mmol/L), with statins being the preferred agents to lower LDL cholesterol.[73] Results from landmark clinical trials have unequivocally demonstrated the value of statins in secondary prevention following MI in patients with moderate to high cholesterol.[73,74] Although the primary effect of statins is to decrease LDL cholesterol, statins are believed to produce many non–lipid-lowering or "pleiotropic" effects such as anti-inflammatory and antithrombotic properties. Newer recommendations from the NCEP give an optional LDL cholesterol goal of less than 70 mg/dL (1.81 mmol/L).[75,76] In patients with an ACS, statin therapy initiation should not be delayed and statins should be prescribed at or prior to discharge in most patients.[77]

A fibrate derivative or niacin should be considered in select patients with a low high-density lipoprotein (HDL) cholesterol less than 40 mg/dL (1.04 mmol/L) and/or a high triglyceride level greater than 200 mg/dL (2.26 mmol/L). In a large randomized trial in men with established CAD and low levels of HDL cholesterol, the use of gemfibrozil (600 mg twice daily) significantly decreased the risk of non-fatal myocardial infarction or death from coronary causes.[78]

Other Modifiable Risk Factors

Smoking cessation, managing hypertension, weight loss, and tight glucose control for patients with diabetes mellitus, in addition to treatment of dyslipidemia, are important treatments for secondary prevention of CHD events.[3] Smoking cessation counseling at the time of discharge following MI is a quality care indicator.[3] The use of nicotine patches or gum, or of bupropion alone or in combination with nicotine patches, should be considered in appropriate patients.[3] Hypertension should be strictly controlled according to published guidelines.[79] Patients who are overweight should be educated on the importance of regular exercise, healthy eating habits, and reaching and maintaining an ideal weight.[80] Finally, because diabetics have up to a four-fold increased risk of mortality compared to non-diabetics, the importance of tight glucose control, as well as other CHD risk factor modifications, cannot be overstated.[81]

OUTCOME EVALUATION

- To determine the efficacy of nonpharmacologic and pharmacotherapy for both STE and NSTE ACS, monitor patients for: (1) relief of ischemic discomfort; (2) return of ECG changes to baseline; and (3) absence or resolution of heart failure signs.
- Monitoring parameters for recognition and prevention of adverse effects from ACS pharmacotherapy are described in Table 5–5. In general, the most common adverse reactions from ACS therapies are hypotension and bleeding. To treat for bleeding and hypotension, discontinue the offending agent(s) until symptoms resolve. Severe bleeding resulting in hypotension secondary to hypovolemia may require blood transfusion.

Patient Care and Monitoring

For patients in acute distress and ACS is suspected:

- Follow recommendations in Fig. 5–1, Table 5–2, and Fig. 5–3. Also incorporate into your plan the recommendations detailed below under "For patients diagnosed with ACS."

For patients diagnosed with ACS:

1. Review patient's medical record to determine indications for each medication.
2. Review patient's medical record to determine contraindications for each medication. For aspirin, β-blockers, ACE inhibitors, and ARBs, document contraindications in patient's medical record.
3. Review doses of medications for appropriateness. Aspirin dose should be less than 160 mg/day. Titration toward target doses of ACE inhibitors and β-blockers should be in progress.
4. Interview the patient to assess complementary or alternative medication use. Counsel appropriately based on indications and drug interactions.
5. Evaluate the patient's medical record and medication history, and conduct a patient interview to assess for the presence of drug allergies, adverse drug reactions, and drug interactions.
6. Educate the patient on lifestyle modifications, including smoking cessation, diet, weight loss, and exercise. For patients with diabetes mellitus, tight glucose control should be emphasized.
7. Provide patient education with regard to CAD, MI, indications for medications, and potential adverse effects and drug interactions.
   - What is CAD?
   - How can the progression of CAD and MI be prevented?
   - How does each medication benefit the patient?
   - Why is adherence important?
   - What potential adverse effects may occur?
   - What potential drug interactions may occur?
   - Warning signs to report to the physician or emergency medical services include chest squeezing, burning, or pain; jaw pain; pain radiation down the arm; bleeding; and loss of consciousness.
   - Dial 911 if there is no chest discomfort relief after one sublingual NTG tablet.
   - Important to train caregiver or relative to administer cardiopulmonary resuscitation (CPR).
8. Document smoking cessation counseling and patient receipt of discharge instructions in the patient's medical record.

6 ARRHYTHMIAS

James E. Tisdale

LEARNING OBJECTIVES

UPON COMPLETION OF THE CHAPTER, THE READER WILL BE ABLE TO:

1. Describe the phases of the cardiac action potential, compare and contrast the cellular ionic changes corresponding to each phase, and explain the relationship between the cardiac action potential and the electrocardiogram (ECG).
2. Describe the modified Vaughan-Williams classification of antiarrhythmic drugs, and compare and contrast the effects of available antiarrhythmic drugs on ventricular conduction velocity, refractory period, automaticity, and inhibition of specific myocardial ion channels.
3. Compare and contrast the risk factors for and the features, mechanisms, etiologies, symptoms, and goals of therapy of: (1) sinus bradycardia; (2) atrioventricular (AV) nodal blockade; (3) atrial fibrillation (AF); (4) paroxysmal supraventricular tachycardia (PSVT); (5) ventricular premature depolarizations (VPDs); (6) ventricular tachycardia (VT, including torsades de pointes); and (7) ventricular fibrillation (VF).
4. Compare and contrast appropriate nonpharmacologic and pharmacologic treatment options for sinus bradycardia and AV nodal blockade.
5. Compare and contrast the mechanisms of action of drugs used for ventricular rate control, conversion to sinus rhythm and maintenance of sinus rhythm in patients with AF, and explain the importance of anticoagulation for patients with AF.
6. Compare and contrast the mechanisms of action of drugs used for acute termination of PSVT.
7. Compare and contrast the role of drug therapy versus nonpharmacologic therapy for long-term prevention of recurrence of PSVT.
8. Describe the role of drug therapy for management of asymptomatic and symptomatic VPDs.
9. Compare and contrast the mechanisms of action of drugs used for the treatment of acute episodes of VT (including torsades de pointes), and describe options and indications for nonpharmacologic treatment of VT and VF.
10. Design individualized drug therapy treatment plans for patients with: (1) sinus bradycardia; (2) AV nodal blockade; (3) AF; (4) PSVT; (5) VPDs; (6) VT (including torsades de pointes); and (7) VF.

KEY CONCEPTS

❶ Cardiac arrhythmias may be caused by abnormal impulse formation (automaticity), abnormal impulse conduction (reentry), or both.

❷ Numerous drugs (β-blockers, diltiazem, verapamil, digoxin, and amiodarone) can cause bradyarrhythmias (sinus bradycardia and AV nodal blockade).

❸ The goals of treatment of AF are: (1) ventricular rate control with drugs that inhibit AV nodal conduction; (2) restoration

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

of sinus rhythm with direct current cardioversion or antiarrhythmic drugs (commonly referred to as "cardioversion" or "conversion to sinus rhythm"); (3) maintenance of sinus rhythm/reduction in the frequency of episodes using antiarrhythmic drugs; and (4) prevention of stroke.

❹ Antiarrhythmic drug therapy for maintenance of sinus rhythm/reduction in frequency of episodes of AF should be initiated only in patients in whom symptoms persist despite maximal doses of drugs for ventricular rate control.

❺ The majority of patients with AF should receive warfarin therapy (titrated to an International Normalized Ratio of 2 to 3) for stroke prevention, particularly if they have other risk factors for stroke.

❻ Adenosine is the drug of choice for termination of paroxysmal supraventricular tachycardia.

❼ Asymptomatic ventricular premature depolarizations should not be treated with antiarrhythmic drug therapy.

❽ Implantable cardioverter-defibrillators are more effective than antiarrhythmic drugs for reduction in the risk of sudden cardiac death due to VT or VF.

❾ The purpose of drug therapy for VF is facilitation of electrical defibrillation; in the absence of electrical defibrillation, drug therapy alone will not terminate VF.

❿ Drugs with the potential to cause QT interval prolongation and torsades de pointes should be avoided or used with extreme caution in patients with other risk factors for torsades de pointes.

NORMAL AND ABNORMAL CARDIAC CONDUCTION AND ELECTROPHYSIOLOGY

The heart functions via both mechanical and electrical activity. The mechanical activity of the heart refers to atrial and ventricular contraction, the mechanism by which blood is delivered to tissues. When deoxygenated blood returns to the heart via the venous circulation, the blood enters the right atrium. Right atrial contraction and changes in right ventricular pressure result in delivery of blood to the right ventricle through the tricuspid valve. Right ventricular contraction pumps blood through the pulmonic valve through the pulmonary arteries to the lungs, where the blood becomes oxygenated. The blood then flows through the pulmonary veins into the left atrium. Left atrial contraction and changes in left ventricular (LV) pressure result in delivery of blood through the mitral valve into the left ventricle. Contraction of the left ventricle results in pumping of blood through the aortic valve and to the tissues of the body.

The mechanical activity of the heart (contraction of the atria and ventricles) occurs as a result of the electrical activity of the heart. The heart possesses an intrinsic electrical conduction system (Fig. 6–1).[1] Normal myocardial contraction cannot occur without proper and normal function of the heart's electrical conduction system. Electrical depolarization of the atria results in atrial contraction, and ventricular depolarization is followed by ventricular contraction. Malfunction of the heart's electrical conduction system may result in dysfunctional atrial and/or ventricular contraction.

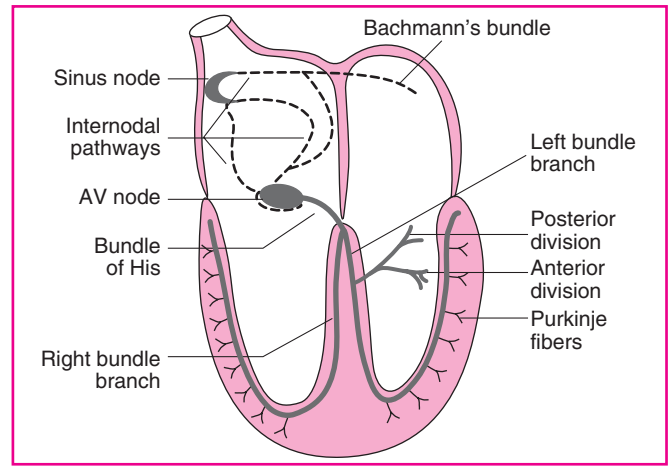

FIGURE 6–1. The cardiac conduction system. AV, atrioventricular. (Reprinted with permission from Cummins RO, (ed.) ACLS Provider Manual. Dallas: American Heart Association; 2003:253.)

The Cardiac Conduction System

Under normal circumstances, the sinoatrial (SA) node (also known as the sinus node), located in the upper portion of the right atrium, serves as the **pacemaker** of the heart and generates the electrical impulses that subsequently result in atrial and **ventricular depolarization** (Fig. 6–1).[1] The SA node serves as the heart's pacemaker because it has the greatest degree of **automaticity,** which is defined as the ability of a cardiac fiber or tissue to initiate depolarizations spontaneously. In adults at rest, the normal intrinsic depolarization rate of the SA node is 60 to 100 per minute. Other cardiac fibers also possess the property of automaticity, but normally the intrinsic depolarization rates are slower than that of the SA node. For example, the normal intrinsic depolarization rate of the atrioventricular (AV) node is 40 to 60 per minute, while that of the ventricular tissue is 30 to 40 per minute. Therefore, because of greater automaticity, the SA node normally serves as the pacemaker of the heart. However, if the SA node fails to generate depolarizations at a rate faster than that of the AV node, the AV node may take over as the pacemaker. Similarly, if the SA node and AV node fail to generate depolarizations at a rate greater than 30 to 40 per minute, ventricular tissue may take over as the pacemaker.

Following initiation of the electrical impulse from the SA node, the impulse travels through the internodal pathways of the specialized atrial conduction system and Bachmann's bundle (Fig. 6–1).[1] The atrial conducting fibers do not traverse the entire breadth of the left and right atria, as impulse conduction occurs across the internodal pathways, and when the impulse reaches the end of Bachmann's bundle, atrial depolarization spreads as a wave similar to that which occurs upon throwing a

pebble into water. As the impulse is conducted across the atria, each depolarized cell excites and depolarizes the surrounding connected cells, until both atria have been completely depolarized. Atrial contraction follows normal atrial depolarization.

Following atrial depolarization, impulses are conducted through the AV node, located in the lower right atrium (Fig. 6–1).[1] The impulse then enters the bundle of His, and is conducted through the ventricular conduction system, consisting of the left and right bundle branches. The left ventricle requires a larger conduction system than the right ventricle due to its larger mass; therefore, the left bundle branch bifurcates into the left anterior and posterior divisions (also commonly known as "fascicles"). The bundle branches further divide into the **Purkinje fibers,** through which impulse conduction results in ventricular depolarization, after which ventricular contraction occurs.

The Ventricular Action Potential

The ventricular **action potential** is depicted in Fig. 6–2.[2] Myocyte resting membrane potential is usually –70 to –90 mV, due to the action of the sodium-potassium adenosine triphosphatase (ATPase) pump, which maintains relatively high extracellular sodium concentrations and relatively low extracellular potassium concentrations. During each action potential cycle, the potential of the membrane increases to a threshold potential, usually –60 to –80 mV. When the membrane potential reaches this threshold, the fast sodium channels open, allowing sodium ions to rapidly enter the cell. This rapid influx of positive ions creates a vertical upstroke of the action potential, such that the potential reaches 20 to 30 mV. This is phase 0, which represents ventricular depolarization. At this point, the fast sodium channels become inactivated, and ventricular repolarization begins. The remaining phases of the action potential, 1 through 4, represent ventricular repolarization. Phase 1 repolarization occurs primarily as a result of an efflux of potassium ions (Fig. 6–2).[2] During phase 2 repolarization, potassium ions continue to exit the cell, but the membrane potential is balanced by an influx of calcium and sodium ions, transported through slow calcium and slow sodium channels, resulting in a plateau. During phase 3, the efflux of potassium ions greatly exceeds calcium and sodium influx, resulting in the major component of ventricular repolarization. During phase 4, sodium ions are actively pumped out of the myocyte via the sodium-potassium ATPase pump, resulting in restoration of membrane potential to its resting value. An understanding of the ionic fluxes that are responsible for each phase of the action potential facilitates understanding of the effects of specific drugs on the action potential. For example, drugs that primarily inhibit ion flux through sodium channels influence phase 0 (ventricular depolarization), while drugs that primarily inhibit ion flux through potassium channels influence the repolarization phases, particularly phase 3.

The Electrocardiogram

The **electrocardiogram** (ECG) is a non-invasive means of measuring the electrical activity of the heart. The relationship

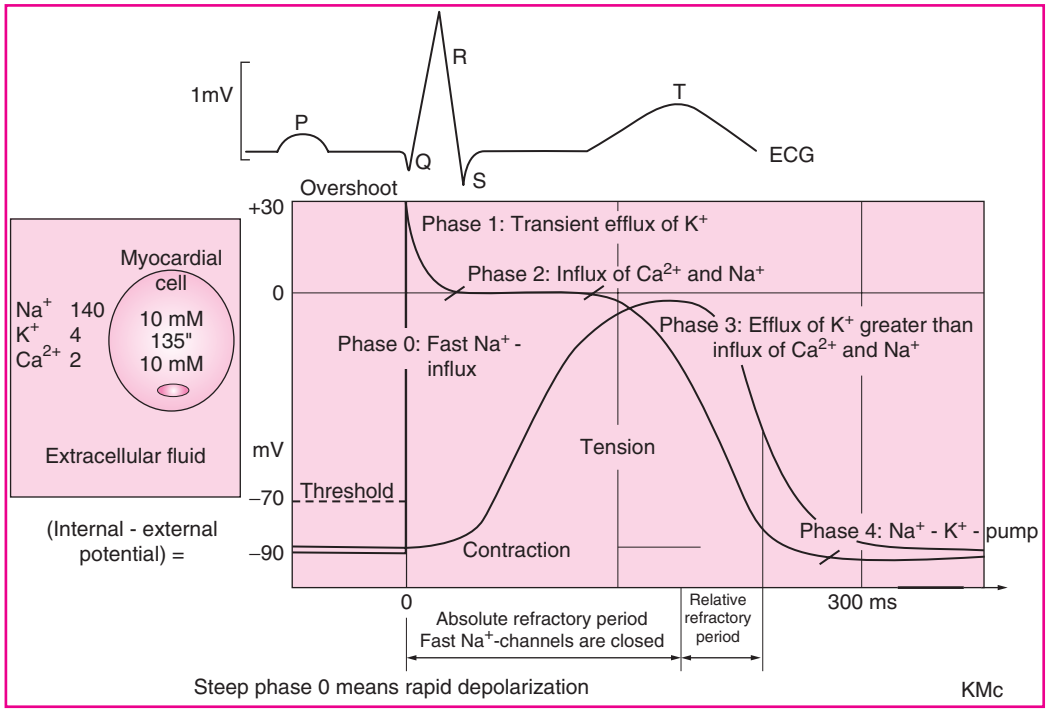

FIGURE 6–2. The ventricular action potential depicting the flow of specific ions responsible for each phase. The specific phases of the action potential that correspond to the absolute and relative refractory periods are portrayed, and the relationship between phases of the action potential and the ECG are shown. Ca, calcium; ECG, electrocardiogram; K, potassium; Na, sodium. (Reprinted with permission from Pauler P-E. *Textbook in Medical Physiology and Pathophysiology, Essentials and Clinical Problems*. Copenhagen: Copenhagen Medical Publishers; 2000.[2]) Accessed at http://www.mfi.ku.dk/ppauler/chapter11/chapter%2011.htm.

between the ventricular action potential and the ECG is depicted in Fig. 6–2.[2] The P wave on the ECG represents atrial depolarization (atrial depolarization is not depicted in the action potential shown in Fig. 6–2, which shows only the ventricular action potential, but not the atrial action potential). Phase 0 of the action potential corresponds to the QRS complex; therefore, the QRS complex on the ECG is a non-invasive representation of ventricular depolarization. The T wave on the ECG corresponds to phase 3 repolarization of the ventricles. The interval from the beginning of the Q wave to the end of the T wave, known as the QT interval, is used as a non-invasive marker of ventricular repolarization time. Atrial repolarization is not displayed on the ECG, because it occurs during ventricular depolarization and is obscured by the QRS complex.

Several intervals and durations are routinely measured on the ECG. The PR interval represents the time of conduction of impulses from the atria to the ventricles through the AV node; the normal PR interval in adults is 0.12 to 0.2 seconds. The QRS duration represents the time required for ventricular depolarization, which is normally 0.08 to 0.12 seconds in adults. The QT interval represents the time required for ventricular repolarization. The QT interval varies with heart rate—the faster the heart rate, the shorter the QT interval, and vice versa. Therefore, the QT interval is corrected for heart rate using Bazett's equation[3], which is:

$$QT_C = \frac{QT}{\sqrt{RR}}$$

where QTc is the QT interval corrected for rate, and RR is the interval from the onset of one QRS complex to the onset of the next QRS complex, measured in seconds. The normal QTc interval in adults is 0.36 to 0.44 seconds.

Refractory Periods

After an electrical impulse is initiated and conducted, there is a period of time during which cells and fibers cannot be depolarized again. This period of time is referred to as the absolute **refractory period** (Fig. 6–2),[2] and corresponds to phases 1, 2, and approximately half of phase 3 repolarization on the action potential. The absolute refractory period also corresponds to the period from the Q wave to approximately the first half of the T wave on the ECG (Fig. 6–2). During this period, if there is a premature stimulus for an electrical impulse, this impulse cannot be conducted, because the tissue is absolutely refractory.

However, there is a period of time following the absolute refractory period during which a premature electrical stimulus can be conducted, and is often conducted abnormally. This period of time is called the relative refractory period (Fig. 6–2).[2] The relative refractory period corresponds roughly to the latter half of phase 3 repolarization on the action potential and to the latter half of the T wave on the ECG. If a new (premature) electrical stimulus is initiated during the relative refractory period, it can be conducted abnormally, potentially in an arrhythmia.

Mechanisms of Cardiac Arrhythmias

❶ *In general, cardiac arrhythmias are caused by (1) abnormal impulse formation; (2) abnormal impulse conduction; or (3) both.*

Abnormal Impulse Initiation

Abnormal initiation of electrical impulses occurs as a result of abnormal automaticity. If the automaticity of the SA node increases, this results in an increased rate of generation of impulses and a rapid heart rate (sinus tachycardia). If other cardiac fibers become abnormally automatic, such that the rate of initiation of spontaneous impulses exceeds that of the SA node, other types of tachyarrhythmias may occur. Many cardiac fibers possess the capability for automaticity, including the atrial tissue, the AV node, the Purkinje fibers, and the ventricular tissue. In addition, fibers with the capability of initiating and conducting electrical impulses are present in the pulmonary veins. Abnormal atrial automaticity may result in premature atrial contractions or may precipitate atrial tachycardia or atrial fibrillation (AF); abnormal AV nodal automaticity may result in "junctional tachycardia" (the AV node is also sometimes referred to as the AV junction). Abnormal automaticity in the ventricles may result in ventricular premature depolarizations (VPDs) or may precipitate ventricular tachycardia (VT) or ventricular fibrillation (VF). In addition, abnormal automaticity originating from the pulmonary veins is a precipitant of AF.

Automaticity of cardiac fibers is controlled in part by activity of the sympathetic and parasympathetic nervous systems. Enhanced activity of the sympathetic nervous system may result in increased automaticity of the SA node or other automatic cardiac fibers. Enhanced activity of the parasympathetic nervous system tends to suppress automaticity; conversely, inhibition of activity of the parasympathetic nervous system increases automaticity. Other factors may lead to abnormal increases in automaticity of extra-SA nodal tissues, including hypoxia, atrial or ventricular stretch [as might occur following long-standing hypertension or after the development of heart failure (HF)], and electrolyte abnormalities such as hypokalemia or hypomagnesemia.

Abnormal Impulse Conduction

The mechanism of abnormal impulse conduction is traditionally referred to as "reentry." ❶ *Reentry is often initiated as a result of an abnormal premature electrical impulse (abnormal automaticity); therefore, in these situations, the mechanism of the arrhythmia is both abnormal impulse formation (automaticity) and abnormal impulse conduction (reentry).* In order for reentry to occur, three conditions must be present. There must be (1) at least two pathways down which an electrical impulse may

travel (which is the case in the majority of cardiac fibers); (2) a "unidirectional block" in one of the conduction pathways (this "unidirectional block" is sometimes a result of prolonged refractoriness in this pathway); and (3) slowing of the velocity of impulse conduction down the other conduction pathway.

The process of reentry is depicted in Fig. 6–3.[4] Under normal circumstances, when a premature impulse is initiated, it cannot be conducted in either direction down either pathway because the tissue is in its absolute refractory period from the previous beat. A premature impulse may be conducted down both pathways if it is only slightly premature and arrives after the tissue is no longer refractory. However, when refractoriness is prolonged down one of the pathways, a precisely timed premature beat may be conducted down one pathway, but cannot be conducted in either direction in the pathway with prolonged refractoriness because the tissue is still in its absolute refractory period (Fig. 6–3, panel 1a).[4] When the third condition for reentry is present, that is, when the velocity of impulse conduction in the other pathway is slowed, the impulse traveling forward down the other pathway still cannot be conducted. However, because the impulse in the other pathway is traveling so slowly, by the time it circles around and travels upward down the other pathway, that pathway is no longer in its absolute refractory period, and now the impulse may travel upward in that pathway. In other words, the electrical impulse "reenters" a previously stimulated pathway in the wrong direction. This results in circular movement of electrical impulses; as the impulse travels in this circular fashion, it excites each cell around it, and if the impulse is traveling at a rate faster than the intrinsic rate of the SA node, a tachycardia occurs in the tissue in question. Reentry may occur in numerous tissues, including the atria, the AV node, and the ventricles.

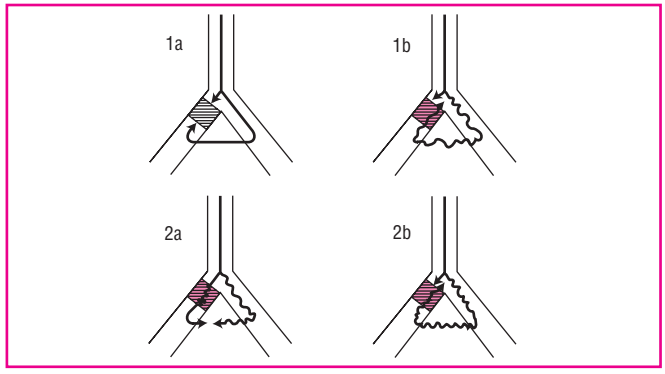

FIGURE 6–3. The process of initiation of reentry. (1a) Two pathways for impulse conduction, with bidirectional block in one pathway (shaded area), resulting in a non-viable reentrant loop. (1b) Two pathways for impulse conduction; slowing of conduction down one pathway, with no change in refractory period down the other pathway, resulting in unidirectional block. The retrograde impulse may reenter the area of unidirectional block, potentially resulting in a tachyarrhythmia. (2a) Two pathways for impulse conduction; lack of unidirectional block, therefore the potential reentrant pathway is non-viable. (2b) Two pathways for impulse conduction; refractory period is prolonged down one pathway, with no change in conduction down the other pathway, resulting in unidirectional block. The retrograde impulse may reenter the area of unidirectional block, potentially resulting in a tachyarrhythmia. (Reprinted with permission from Bauman JL, Dekker Schoen M. Arrhythmias. In: DiPiro JT, Talbert RL, Yee GC, et al. (eds.) *Pharmacotherapy. A Physiologic Approach*, 6th ed. New York: McGraw-Hill; 2005:324.[4])

Prolonged refractoriness and/or slowed impulse conduction velocity may be present in cardiac tissues for a variety of reasons. Myocardial ischemia may alter ventricular refractory periods or impulse conduction velocity, facilitating ventricular reentry. In patients with past myocardial infarction, the infarcted myocardium is dead and cannot conduct impulses. However, there is typically a border zone of tissue which is damaged, and in which refractory periods and conduction velocity are often deranged, facilitating ventricular reentry. In patients with left atrial or LV hypertrophy as a result of long-standing hypertension, refractory periods and conduction velocity are often perturbed. In patients with HF due to LV dysfunction, ventricular refractoriness and conduction velocity are often altered due to LV hypertrophy, collagen deposition, and other anatomic and structural changes.

Vaughan-Williams Classification of Anti-arrhythmic Drugs

The Vaughan-Williams classification of antiarrhythmic drugs, first described in 1970[5] and subsequently further expanded,[6,7] is presented in Table 6–1. This classification is based on the effects of specific drugs on ventricular conduction velocity, repolarization/refractoriness and automaticity. Class I drugs, which are the sodium channel blocking agents, primarily inhibit ventricular automaticity and slow conduction velocity. However, due to differences in the potency of the drugs to slow conduction velocity, the class I drugs are subdivided into class IA, IB, and IC. The class IC drugs have the greatest potency for slowing ventricular conduction, the class IA drugs have intermediate potency, and the class IB drugs have the lowest potency, with minimal effects on conduction velocity. Class II drugs are the adrenergic β-receptor inhibitors (β-blockers), class III drugs are those that inhibit ventricular repolarization or prolong refractoriness, and class IV drugs are the calcium channel blockers (CCBs), diltiazem and verapamil.

The Vaughan-Williams classification of antiarrhythmic drugs has been criticized for a number of reasons. The classification is based on the effects of drugs on normal, rather than diseased, myocardium. In addition, many of the drugs may be placed into more than one class. For example, the class IA drugs prolong repolarization/refractoriness, either via the parent drug[8,9] or an active metabolite,[10] and therefore also may be placed in class III. Sotalol is also a β-blocker, and therefore fits into class II. Amiodarone inhibits sodium and potassium channels, is a non-competitive inhibitor of β-receptors, and inhibits calcium

TABLE 6–1. Vaughan-Williams Classification of Anti-arrhythmic Agents*

Class	Drug	Conduction Velocity	Repolarization/ Refractoriness	Automaticity
IA	Quinidine Procainamide Disopyramide	↓	↑	↓
IB	Lidocaine Mexiletine Tocainide	0/↓	↓/0	↓
IC	Flecainide Moricizine Propafenone	↓↓	0	↓
II	β-blockers:[a] Acebutolol Atenolol Betaxolol Bisoprolol Carteolol Carvedilol[b] Esmolol Labetalol[b] Metoprolol Nadolol Penbutolol Pindolol Propranolol Timolol	0	0	0
III	Amiodarone[c] Dofetilide Ibutilide Sotalol	0	↑	0
IV	Calcium channel blockers:[a] Diltiazem Verapamil	0	0	0

↑, increase/prolong; ↓, decrease; 0, no effect; 0/↓, does not change or may decrease: ↓/0, decreases or does not change.
*Adenosine and digoxin are agents used for the management of arrhythmias that do not fit into the Vaughan Williams classification.
[a]Slows conduction, prolongs refractory period, and reduces automaticity in SA node and AV node tissue, but not in the ventricles.
[b]Combined α and β-blocker.
[c]Amiodarone slows conduction velocity and inhibits automaticity.

channels, and therefore may be placed into any of the four classes. For this reason, drugs within each class cannot be considered "interchangeable." Nonetheless, despite attempts to develop mechanism-based classifications that better distinguish the actions of antiarrhythmic drugs,[11] the Vaughan-Williams classification continues to be widely used because of its simplicity and the fact that it is relatively easy to remember and understand.

CARDIAC ARRHYTHMIAS

In general, cardiac arrhythmias are classified into two broad categories: supraventricular (those occurring above the ventricles) and ventricular (those occurring in the ventricles). The names of specific arrhythmias are generally composed of two words; the first word indicates the location of the electrophysiologic abnormality resulting in the arrhythmia (sinus, AV node, atrial, or ventricular), and the second word describes the arrhythmia in terms of whether it is abnormally slow (bradycardia) or fast (tachycardia), or the type of arrhythmia (block, fibrillation, or flutter).

SUPRAVENTRICULAR ARRHYTHMIAS

Sinus Bradycardia

Sinus bradycardia is an arrhythmia that originates in the SA node, defined by a sinus rate less than 60 beats per minute (bpm).[12]

Epidemiology and Etiology

Many individuals, particularly those who partake in regular vigorous exercise, have heart rates less than 60 bpm. For those individuals, sinus bradycardia is normal and healthy, and does not require evaluation or treatment. However, some individuals develop symptomatic sinus node dysfunction. In the absence of correctable underlying causes, idiopathic sinus node dysfunction is referred to as "sick sinus syndrome,[12]" and occurs with greater frequency with advancing age. The prevalence of sick sinus syndrome is approximately 1 in 600 individuals over the age of 65 years.[12]

Sick sinus syndrome leading to sinus bradycardia may be caused by degenerative changes in the sinus node that occur with advancing age. ❷ *However, there are other possible etiologies of sinus bradycardia, including drugs (Table 6–2).*[13]

TABLE 6–2. Etiologies of Sinus Bradycardia[12,13]

Idiopathic ("sick sinus syndrome")
Myocardial ischemia
Carotid-sinus hypersensitivity
Neurocardiac syncope
Electrolyte abnormalities: hypokalemia or hyperkalemia
Hypothyroidism
Hypothermia
Amyloidosis
Sarcoidosis
Systemic lupus erythematosus
Scleroderma
Sleep apnea
Drugs:

Amiodarone	Flecainide
β-Blockers	Fluoxetine
Cisplatin	Isradipine
Citalopram	Nitroglycerin
Clonidine	Propafenone
Cocaine	Sotalol
Digoxin	Thalidomide
Diltiazem	Verapamil
Donepezil	

Clinical Presentation and Diagnosis: Sinus Bradycardia

Symptoms

- Many patients are asymptomatic, particularly those with normal resting heart rates less than 60 bpm as a result of physical fitness due to regular vigorous exercise.
- Susceptible patients may develop symptoms, depending on the degree of heart rate lowering.
- Symptoms of bradyarrhythmias include dizziness, fatigue, lightheadedness, syncope, chest pain (in patients with underlying myocardial ischemia), and shortness of breath and other symptoms of heart failure (in patients with underlying left ventricular dysfunction).

Diagnosis

- Cannot be made on the basis of symptoms alone, as the symptoms of all bradyarrhythmias are similar.
- History of present illness, presenting symptoms, and 12-lead ECG that reveals sinus bradycardia.
- Assess possible correctable etiologies, including myocardial ischemia, serum potassium concentration (for hyperkalemia), and thyroid function tests (for hypothyroidism).
- Determine whether the patient is taking any drugs known to cause sinus bradycardia. If the patient is currently taking digoxin, determine the serum digoxin concentration and ascertain whether it is supratherapeutic (greater than 2 ng/mL [2.56 nmol/L]).

Pathophysiology

Sick sinus syndrome leading to sinus bradycardia occurs as a result of fibrotic tissue in the SA node, which replaces normal SA node tissue.[12]

Treatment

Desired Outcomes

The desired outcomes for treatment are to restore normal heart rate and alleviate patient symptoms.

Pharmacologic Therapy

Treatment of sinus bradycardia is only necessary in patients who become symptomatic. ❷ *If the patient is taking any medication(s) that may cause sinus bradycardia, the drug(s) should be discontinued whenever possible.* If the patient remains in sinus bradycardia after discontinuation of the drug(s) and after five half-lives of the drug(s) have elapsed, then the drugs(s) can usually be excluded as the etiology of the arrhythmia. In certain circumstances, however, discontinuation of the medication(s) may be undesirable, even if it may be the cause of symptomatic sinus bradycardia. For example, if the patient has a history of myocardial infarction or HF, discontinuation of a β-blocker is undesirable, because β-blockers have been shown to reduce mortality and prolong life in patients with those diseases, and the benefits of therapy with β-blockers outweigh the risks associated with sinus bradycardia. In these patients, a permanent pacemaker may be implanted in order to allow the patient to maintain therapy with β-blockers.

Acute treatment of the symptomatic patient consists primarily of administration of the anticholinergic drug atropine, which may be given in doses of 0.5 mg intravenously (IV) every 3 to 5 minutes. The maximum recommended total dose of atropine is 3 mg;[14] however, this total dose should not be administered to patients with sinus bradycardia, but rather should be reserved for patients with cardiac arrest due to asystole, as complete vagal inhibition at this dose can increase myocardial oxygen demand and precipitate ischemia or tachyarrhythmias in patients with underlying coronary artery disease (CAD). Therefore, for management of sinus bradycardia, the maximum atropine dose should be approximately 2 mg. In patients with hemodynamically unstable or severely symptomatic sinus bradycardia that is unresponsive to atropine and in whom temporary or **transvenous pacing** is not available or is ineffective, epinephrine (2 to 10 mcg/minute, titrate to response) and/or dopamine (2 to 10 mcg/kg/minute) may be administered.[14] Both drugs stimulate adrenergic α- and β-receptors.

In patients with sinus bradycardia due to underlying correctable disorders (such as electrolyte abnormalities or hypothyroidism), management consists of correcting those disorders.

Nonpharmacologic Therapy

Long-term management of patients with sick sinus syndrome requires implantation of a permanent pacemaker.[12]

Outcome Evaluation

- Monitor the patient for heart rate and alleviation of symptoms.
- Monitor for adverse effects of medications, such as atropine (dry mouth, mydriasis, urinary retention, and tachycardia).

AV Nodal Blockade

AV nodal blockade occurs when conduction of electrical impulses through the AV node is impaired to varying degrees. AV nodal blockade is classified into three categories. First-degree AV block is defined simply as prolongation of the PR interval to greater than 0.2 seconds. During first-degree AV block, all impulses initiated by the SA node that have resulted in atrial depolarization are conducted through the AV node; the abnormality is simply that the impulses are conducted more slowly than normal through the AV node, resulting in prolongation of the PR interval.[15] Second-degree AV block is further distinguished into two types: Mobitz type I (also known as Wenckebach) and Mobitz type II. In both types of second-degree AV block, some of the impulses initiated by the SA node are not conducted through the AV node. This often occurs in a regular pattern; for example, every third or fourth impulse

generated by the SA node may not be conducted. During third-degree AV block, which is also referred to as "complete heart block," none of the impulses generated by the SA node are conducted through the AV node. This results in "AV dissociation," during which the atria continue to depolarize normally as a result of normal impulses initiated by the SA node; however, the ventricles initiate their own depolarizations, because no SA node–generated impulses are conducted to the ventricles. Therefore, on the ECG, there is no relationship between the P waves and the QRS complexes.

Epidemiology and Etiology

The incidence of AV nodal blockade is unknown. AV nodal blockade may be caused by degenerative changes in the AV node. ❷ *In addition, there are many other possible etiologies of AV nodal blockade, including drugs (Table 6–3).*[13]

Pathophysiology

First-degree AV nodal blockade occurs due to inhibition of conduction within the upper portion of the node.[15] Mobitz type I second-degree AV nodal blockade occurs as a result of inhibition of conduction further down within the node.[12,15] Mobitz type II second-degree AV nodal blockade is caused by inhibition of conduction within or below the level of the bundle of His.[12,15] Third-degree AV nodal blockade may be a result of inhibition of conduction either within the AV node or within the bundle of His or the His-Purkinje system.[12,15] AV block may occur as a result of age-related AV node degeneration.

Clinical Presentation and Diagnosis: AV Nodal Blockade

Symptoms

- First-degree AV nodal blockade is rarely symptomatic, because it rarely results in bradycardia.
- Second-degree AV nodal blockade may cause bradycardia, as not all impulses generated by the SA node are conducted through the AV node to the ventricles.
- In third-degree AV nodal blockade, or complete heart block, the heart rate is usually 30 to 40 bpm, resulting in symptoms.
- Symptoms of bradyarrhythmias such as second- or third-degree AV block consist of dizziness, fatigue, lightheadedness, syncope, chest pain (in patients with underlying myocardial ischemia), and shortness of breath and other symptoms of heart failure (in patients with underlying left ventricular dysfunction).

Diagnosis

- Made on the basis of patient presentation, including history of present illness and presenting symptoms, as well as a 12-lead ECG that reveals AV nodal blockade.
- Assess potentially correctable etiologies, including myocardial ischemia, serum potassium concentration (for hyperkalemia), and thyroid function tests (for hypothyroidism)
- Determine whether the patient is taking any drugs known to cause AV block.
- If the patient is currently taking digoxin, determine the serum digoxin concentration and ascertain whether it is supratherapeutic (greater than 2 ng/mL [2.56 nmol/L]).

Adenosine	Hydroxychloroquine
β-Blockers	Phenylpropanolamine
Amiodarone	Propafenone
Carbamazepine	Propofol
Chloroquine	Sotalol
Digoxin	Thioridazine
Diltiazem	Tricyclic antidepressants
Gatifloxacin	Verapamil

Treatment

Desired Outcomes

The desired outcomes for treatment are to restore normal sinus rhythm and alleviate patient symptoms.

Pharmacologic Therapy

Treatment of first-degree AV nodal blockade is rarely necessary, because symptoms rarely occur. However, the ECGs of patients with first-degree AV nodal blockade should be monitored to assess the possibility of progression of first-degree AV nodal blockade to second- or third-degree block. Second- or third-degree AV nodal blockade requires treatment, because bradycardia usually results in symptoms. If the patient is taking any medication(s) that may cause AV nodal blockade, the drug(s) should be discontinued whenever possible. If the patient's rhythm still exhibits AV nodal blockade after discontinuing the medication(s) and after five half-lives of the drug(s) have elapsed, then the drug(s) can usually be excluded as the etiology of the arrhythmia. However, in certain circumstances, discontinuation of a medication that is

inducing AV nodal blockade may be undesirable. For example, if the patient has a history of myocardial infarction or HF, discontinuation of a β-blocker is undesirable because β-blockers have been shown to reduce mortality and prolong life in patients with those diseases, and the benefits of therapy with β-blockers outweighs the risks associated with AV nodal blockade. In these patients, a permanent pacemaker may be implanted in order to allow the patient to maintain therapy with β-blockers.

Acute treatment of patients with second- or third-degree AV nodal blockade consists primarily of administration of atropine, which may be administered in the same doses as recommended for management of sinus bradycardia. In patients with hemodynamically unstable or severely symptomatic AV nodal blockade that is unresponsive to atropine and in whom temporary or transvenous pacing is not available or is ineffective, epinephrine (2 to 10 mcg/minute, titrate to response) and/or dopamine (2 to 10 mcg/kg/minute) may be administered.[14]

In patients with second- or third-degree AV block due to underlying correctable disorders (such as electrolyte abnormalities or hypothyroidism), management consists of correcting those disorders.

Nonpharmacologic Therapy

Long-term management of patients with AV nodal blockade due to idiopathic degeneration of the AV node requires implantation of a permanent pacemaker.[12]

Outcome Evaluation

- Monitor the patient for termination of AV nodal blockade and restoration of normal sinus rhythm, heart rate, and alleviation of symptoms.
- If atropine is administered, monitor the patient for adverse effects including dry mouth, mydriasis, urinary retention, and tachycardia.

Atrial Fibrillation

Atrial fibrillation (AF) is the most common arrhythmia encountered in clinical practice. It is important for clinicians to understand AF, because it is associated with substantial morbidity and mortality and because many strategies for drug therapy are available. Drugs used to treat AF often have a narrow therapeutic index and a broad adverse effect profile.

Epidemiology and Etiology

Approximately 2.3 million Americans have AF. The prevalence of AF increases with advancing age; roughly 9% of patients between the ages of 80 and 89 years have AF.[16] Similarly, the incidence of AF increases with age, and it occurs more commonly in men than women.[16]

Etiologies of AF are presented in Table 6–4. The common feature of the majority of etiologies of AF is the development of left atrial hypertrophy. Hypertension may be the most important risk factor for development of AF. However, AF occurs commonly in patients with CAD. In addition, HF is increasingly recognized as a cause of AF; approximately 25% to 30% of patients with New York Heart Association (NYHA) class III heart failure have AF,[17] and the arrhythmia is present in as many as 50% of patients with NYHA class IV heart failure.[18]

TABLE 6–4. Etiologies of Atrial Fibrillation

Hypertension	
Coronary artery disease	
Heart failure	
Diabetes	
Hyperthyroidism	
Rheumatic heart disease	
Diseases of the heart valves:	
Mitral stenosis or regurgitation	
Mitral valve prolapse	
Chronic obstructive pulmonary disease	
Pulmonary embolism	
Idiopathic ("lone" atrial fibrillation)	
Thoracic surgery:	
Coronary artery bypass graft surgery	
Pulmonary resection	
Thoracoabdominal esophagectomy	
Drugs:[13]	
Adenosine	Milrinone
Albuterol	Theophylline
Alcohol	
Ipratropium bromide	

Drug-induced AF is relatively uncommon, and the list of drugs that may induce AF is relatively small.[13] However, acute ingestion of large amounts of alcohol may cause AF; this phenomenon has been referred to as the "holiday heart" syndrome.[19]

Pathophysiology

❶ *Atrial fibrillation may be caused by both abnormal impulse formation and abnormal impulse conduction.* Traditionally, AF was believed to be initiated by premature impulses initiated in the atria. However, it is now understood that in many patients AF is triggered by electrical impulses generated within the pulmonary veins.[20] These impulses initiate the process of reentry within the atria, and AF is believed to be sustained by multiple reentrant wavelets operating simultaneously within the atria.[21] Some believe that, at least in some patients, the increased automaticity in the pulmonary veins may be the sole mechanism of AF and that the multiple reentrant wavelet hypothesis may be incorrect.[21] However, the concept of multiple simultaneous reentrant wavelets remains the predominant hypothesis regarding the mechanism of AF.

Atrial fibrillation leads to electrical remodeling of the atria. Episodes of AF that are of longer duration and episodes that occur with increasing frequency result in progressive shortening of atrial refractory periods, further potentiating the reentrant circuits in the atria.[22] Therefore, it is often said that "atrial

Clinical Presentation and Diagnosis: Atrial Fibrillation

Symptoms

- Approximately 20% to 30% of patients with AF remain asymptomatic.
- Symptoms typical of tachyarrhythmias include palpitations, dizziness, lightheadedness, shortness of breath, chest pain (if underlying CAD is present), near-syncope, and syncope. Patients commonly complain of palpitations; often the complaint is "I can feel my heart beating fast" or "It feels like my heart is going to beat out of my chest."
- Other symptoms are dependent on the degree to which cardiac output is diminished, which is in turn dependent on the heart rate and the degree to which **stroke volume** is reduced by the rapidly beating heart.
- In some patients, the first symptom of AF is stroke.

Diagnosis

- Because the symptoms of all tachyarrhythmias are dependent on heart rate and are therefore essentially the same, the diagnosis depends on the presence of AF on the ECG.
- Atrial fibrillation is characterized on ECG by an absence of P waves, an undulating baseline that represents roughly 350 to 600 attempted atrial depolarizations per minute, and an irregularly irregular rhythm, meaning that the intervals between the R waves are irregular and that there is no pattern to the irregularity.

fibrillation begets atrial fibrillation," that is, AF causes atrial electrophysiologic alterations that promote further AF.[21,22]

The AV node is incapable of conducting 350 to 600 impulses per minute; however, it may conduct 100 to 200 impulses per minute, resulting in ventricular rates ranging from 100 to 200 bpm.

Atrial fibrillation is classified as **paroxysmal,** persistent, or permanent (Fig. 6–4).[23] Patients with paroxysmal AF have episodes that start suddenly and spontaneously, last minutes to hours, or rarely as long as 7 days, and terminate suddenly and spontaneously. Some patients with paroxysmal AF have episodes that do not terminate spontaneously but require intervention, and this is known as persistent AF. Approximately one-third of patients with AF progress to the point of permanent AF; these patients are subsequently never in normal sinus rhythm, but rather are always in AF.

Atrial fibrillation is associated with substantial morbidity and mortality. Atrial fibrillation is associated with a risk of ischemic stroke of approximately 5% per year.[23] The risk of stroke is increased two- to seven-fold in patients with AF compared to patients without this arrhythmia.[23] Atrial fibrillation is the cause of roughly one of every six strokes.[21] During AF, atrial contraction is absent. Therefore, due to the fact that atrial contraction is responsible for approximately 30% of left ventricular filling, this blood that is not ejected from the left atrium to the left ventricle pools in the atrium, particularly in the left atrial appendage. Blood pooling facilitates the formation of a thrombus, which subsequently may travel through the mitral valve into the left ventricle and may be ejected during ventricular contraction. The thrombus then may travel through a carotid artery into the brain, resulting in an ischemic stroke.

Patient Encounter, Part 1

DA is a 58-year-old male who presents to the emergency department (ED) complaining that his "heart is beating fast," which started when he was taking out the garbage. He also complains of feeling lightheaded and short of breath. His pulse is irregularly irregular, with a rate of 135 bpm.

- What information is suggestive of atrial fibrillation?
- What additional information do you need in order to develop a treatment plan?

Patient Encounter, Part 2: Medical History, Physical Exam and Diagnostic Tests

PMH

Hypertension × 15 years
Coronary artery disease × 10 years
Myocardial infarction 1998
Heart failure × 3 years

Meds

Aspirin 81 mg once daily
Metoprolol 50 mg twice daily
Enalapril 5 mg twice daily
Furosemide 40 mg daily

PE

Height 5'10" (178 cm), wt. 80 kg (176 lb), BP 110/70 mm Hg, pulse 135 bpm, RR 20/minute; remainder of physical exam non-contributory

Labs

All within normal limits

Chest x-ray: Mild pulmonary edema

Echo: Moderately reduced left ventricular function, left ventricular ejection fraction 35%

ECG: Atrial fibrillation

- What is your assessment of DA's condition?
- What are your treatment goals?
- What pharmacologic or nonpharmacologic alternatives are available for each treatment goal?

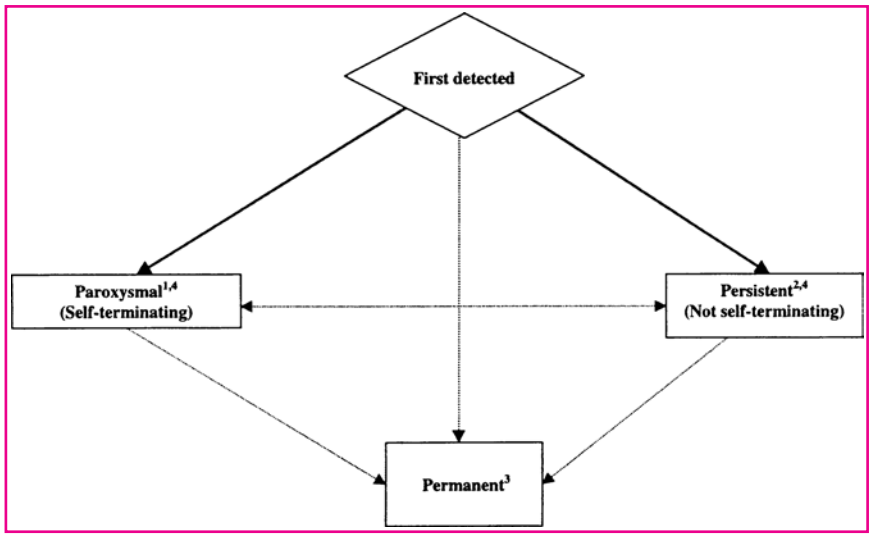

FIGURE 6–4. Classification of atrial fibrillation. [1]Episodes that generally last less than or equal to 7 days (most less than 24 hours). [2]Episodes that usually last greater than 7 days. [3]Cardioversion failed or not attempted. [4]Either paroxysmal or persistent atrial fibrillation may be recurrent. (Reprinted with permission from Fuster V, Rydén LE, Asinger RW, et al. ACC/AHA/ESC guidelines for the management of patients with atrial fibrillation: a report of the American College of Cardiology, American Heart Association Task Force on Practice Guidelines and the European Society of Cardiology Committee for Practice Guidelines and Policy Conferences (Committee to Develop Guidelines for the Management of Patients with Atrial Fibrillation). J Am Coll Cardiol 2001; 38:1266i–lxx.[23])

Atrial fibrillation leads to the development of HF, as a result of tachycardia-induced cardiomyopathy.[25] Atrial fibrillation increases the risk of mortality approximately two-fold compared to that in patients without AF;[23] the causes of death are likely stroke or HF.

Treatment

Desired Outcomes

❸ *The goals of therapy of AF are: (1) ventricular rate control; (2) termination of AF and restoration of sinus rhythm (commonly referred to as "cardioversion" or "conversion to sinus rhythm"); (3) maintenance of sinus rhythm, or reduction in the frequency of episodes of paroxysmal AF; and (4) prevention of stroke.*

Hemodynamically Unstable AF

For patients who present with an episode of AF that is hemodynamically unstable, emergent conversion to sinus rhythm is necessary using **direct current cardioversion** (DCC). Hemodynamic instability may be defined as the presence of any one of the following:[14] (1) patient has altered mental status, (2) hypotension (systolic blood pressure less than 90 mm Hg) or other signs of shock, (3) ventricular rate greater than 150 bpm, and/or (4) patient is experiencing squeezing, crushing chest pain suggestive of myocardial ischemia.

Direct current cardioversion is the process of administering a synchronized electrical shock to the chest. The purpose of DCC is to simultaneously depolarize all of the myocardial cells, resulting in interruption and termination of the multiple reentrant circuits and restoration of normal sinus rhythm. The initial energy level of the shock is 100 joules (J); if the DCC attempt is unsuccessful, successive cardioversion attempts may be made at 200, 300, and 360 J.[14] Delivery of the shock is synchronized to the ECG by the cardioverter machine, such that the electrical charge is not delivered during the latter portion of the T wave (i.e., the relative refractory period), to avoid delivering an electrical impulse that may be conducted abnormally, which may result in a life-threatening ventricular arrhythmia.

The remainder of this section will be devoted to management of hemodynamically stable AF.

Pharmacologic Therapy

Ventricular Rate Control is achieved by inhibiting the proportion of electrical impulses conducted from the atria to the ventricles through the AV node. Therefore, drugs that are effective for ventricular rate control are those that inhibit AV nodal impulse conduction: β-blockers, diltiazem, verapamil, and digoxin (Tables 6–5 and 6–6). Amiodarone also inhibits AV nodal conduction, but is not a preferred drug for ventricular rate control in AF due to its unfavorable adverse-effect profile (Table 6–6).

In patients who present with their first detected episode of AF, or for those who present with an episode of persistent AF, ventricular rate control is usually initially achieved using intravenous drugs. A decision algorithm for selecting a specific drug for acute ventricular rate control is presented in Fig. 6–5. In general, IV diltiazem is a preferred drug for ventricular rate control in patients with normal LV function, as ventricular rate control can often be achieved within several minutes. In patients with HF due to LV dysfunction, digoxin may be preferred because diltiazem is associated with negative inotropic effects and may exacerbate HF.[26] However, in patients with HF who are substantially symptomatic and in whom it is undesirable to wait 4 to 6 hours for the effects of digoxin to occur, IV diltiazem may be used for up to 24 hours without inducing HF exacerbation in most patients.

A decision strategy for long-term rate control in patients with paroxysmal or permanent AF is presented in Fig. 6–6. In general, while digoxin is effective for ventricular rate control in

TABLE 6–5. Drugs for Ventricular Rate Control in Atrial Fibrillation

Drug	Mechanism of Action	Loading Dose	Daily Dose	Drug Interactions
β-Blockers[a]	Inhibit AV nodal conduction by slowing AV nodal conduction and prolonging AV nodal refractoriness	Esmolol: 500 mcg/kg IV over 1 minute Propranolol: 0.15 mg/kg IV Metoprolol: 2.5–5 mg IV × 2–3 doses	Esmolol: 50–200 mcg/kg/minute continuous infusion Propranolol: 80–240 mg/day Metoprolol: 50–200 mg/day	
Diltiazem	Inhibits AV nodal conduction by slowing AV nodal conduction and prolonging AV nodal refractoriness	1. 0.25 mg/kg IV load over 2 minutes 2. If necessary, 0.35 mg/kg IV over 2 minutes after first dose	Continuous infusion of 5–15 mg/hour Oral: 120–360 mg/day	Inhibits elimination of cyclosporine
Verapamil	Inhibits AV nodal conduction by slowing AV nodal conduction and prolonging AV nodal refractoriness	1. 5–10 mg IV over 2–3 minutes 2. If necessary, an additional dose of 5–10 mg may be administered 30 minutes later	120–360 mg/day	Inhibits digoxin elimination
Digoxin	Inhibits AV nodal conduction by: 1. Vagal stimulation 2. Directly slowing AV nodal conduction and prolonging AV nodal refractoriness	0.25 mg every 2 hours up to 1.5 mg	0.125–0.25 mg PO once daily	Amiodarone, verapamil, quinidine inhibit digoxin elimination

AV, atrioventricular; IV, intravenous; PO, orally.
[a]While oral β-blockers are important agents for mortality reduction in patients with heart failure, intravenous β-blockers should be avoided, due to the potential for heart failure exacerbation.

patients at rest, digoxin is less effective than CCBs or β-blockers for ventricular rate control in patients undergoing physical activity, including activities of daily living. This is likely because activation of the sympathetic nervous system during exercise and activity overwhelms the stimulating effect of digoxin on the parasympathetic nervous system. Therefore, in patients with normal LV function, CCBs or β-blockers are preferred for long-term ventricular rate control. Diltiazem may be preferable to verapamil in older patients due to a lower incidence of constipation. However, in patients with HF, oral diltiazem and verapamil are contraindicated as a result of their negative inotropic activity and propensity to exacerbate HF. Therefore, the options in this population are β-blockers or digoxin. The majority of patients with HF receive therapy with oral β-blockers for the goal of achieving mortality reduction. In patients with HF that develop rapid AF while receiving therapy with β-blockers, digoxin should be administered for purposes of ventricular rate control. Fortunately, studies have found the combination of digoxin and β-blockers to be effective for ventricular rate control, likely as a result of suppression of the inhibitory effects of the sympathetic nervous system on the efficacy of digoxin.

Conversion to Sinus Rhythm Termination of AF in hemodynamically stable patients may be performed using antiarrhythmic drug therapy or elective DCC. Drugs that may be used for conversion to sinus rhythm are presented in Table 6–7; these agents slow atrial conduction velocity and/or prolong refractoriness, facilitating interruption of reentrant circuits and restoration of sinus rhythm. DCC is generally more effective than drug therapy for conversion of AF to sinus rhythm. However, patients who undergo elective DCC must be sedated and/or anesthetized to avoid the discomfort associated with delivery of 100 to 360 J of electricity to the chest. Therefore, it is important that patients scheduled to undergo elective DCC do not eat within approximately 8 to 12 hours of the procedure to avoid aspiration of stomach contents during the period of sedation/anesthesia. This often factors into the decision as to whether to employ elective DCC or drug therapy for conversion of AF to sinus rhythm. If a patient presents with AF requiring conversion to sinus rhythm, and the patient has eaten a meal that day, then pharmacologic methods must be used for cardioversion on that day, or DCC must be postponed to the following day to allow for a period of fasting prior to the procedure.

A decision strategy for conversion of AF to sinus rhythm is presented in Fig. 6–7. The cardioversion decision strategy depends greatly on the duration of AF. If the AF episode began within 48 hours, conversion to sinus rhythm is safe and may be attempted with elective DCC or specific drug therapy (Fig. 6–7). However, if the duration of the AF episode is longer than 48 hours or if there is uncertainty regarding the duration of the episode, two strategies for conversion may be considered. Because data indicate that a thrombus may form in the left

TABLE 6–6. Adverse Effects of Drugs Used to Treat Arrhythmias

Drug	Adverse Effects
Adenosine	Chest pain, flushing, shortness of breath, sinus bradycardia/AV block
Amiodarone	IV: Hypotension, sinus bradycardia Oral: Blue-grey skin discoloration, photosensitivity, corneal microdeposits, pulmonary fibrosis, hepatotoxicity, sinus bradycardia, hypo- or hyperthyroidism, AV block
Atropine	Tachycardia, urinary retention, blurred vision, dry mouth, mydriasis
Digoxin	Nausea, vomiting, anorexia, green-yellow halos around objects, ventricular arrhythmias
Diltiazem	Hypotension, sinus bradycardia, heart failure exacerbation, AV block
Dofetilide	Torsades de pointes
Esmolol	Hypotension, sinus bradycardia, AV block, heart failure exacerbation
Flecainide	Dizziness, blurred vision, heart failure exacerbation
Ibutilide	Torsades de pointes
Lidocaine	Dizziness, confusion, seizures (if dose too high)
Metoprolol	Hypotension, sinus bradycardia, AV block, fatigue, heart failure exacerbation[a]
Procainamide	Hypotension, torsades de pointes
Propafenone	Dizziness, blurred vision
Propranolol	Hypotension, bradycardia, AV block, heart failure exacerbation[a]
Sotalol	Sinus bradycardia, AV block, fatigue, torsades de pointes
Verapamil	Hypotension, heart failure exacerbation, bradycardia, AV block, constipation (oral)

AV, atrioventricular; IV, intravenous.
[a]Associated with intravenous administration, inappropriately high oral doses at initiation of therapy, or overly aggressive and rapid dose titration.

atrium during AF episodes of 48 hours or longer, conversion should be deferred unless it is known that an atrial thrombus is not present. In the past, common practice in patients with AF of greater than 48 hours' duration was to anticoagulate patients with warfarin, maintaining a therapeutic International Normalized Ratio (INR) for 3 weeks, after which cardioversion may be performed. Patients were subsequently anticoagulated for 4 weeks following the restoration of sinus rhythm. Today, rather than send patients with ongoing AF home for 3 weeks of anticoagulation, it is becoming standard practice at many institutions to perform a transesophageal echocardiogram (TEE) to determine whether an atrial thrombus is present; if such a thrombus is not present, DCC or pharmacologic cardioversion may be performed within 24 hours. If this strategy is selected, patients should undergo anticoagulation with intravenous unfractionated heparin, with the dose targeted to a partial thromboplastin time (PTT) of 60 seconds (range 50 to 70 seconds), or warfarin therapy (target INR 2.5; range 2 to 3) for several days prior to the TEE and cardioversion procedure. If no thrombus is present during TEE and cardioversion is successful, patients should undergo anticoagulation with warfarin (target INR 2.5; range 2 to 3) for at least 4 weeks. If a thrombus is observed during TEE, then cardioversion should be postponed and anticoagulation should be continued indefinitely. Another TEE should be performed prior to a subsequent cardioversion attempt.[27]

Conversion of AF to sinus rhythm is usually performed in patients with the first detected episode of AF or in patients with an episode of persistent AF. In patients with permanent AF, conversion to sinus rhythm is usually not attempted because cardioversion is unlikely to be successful, and in those

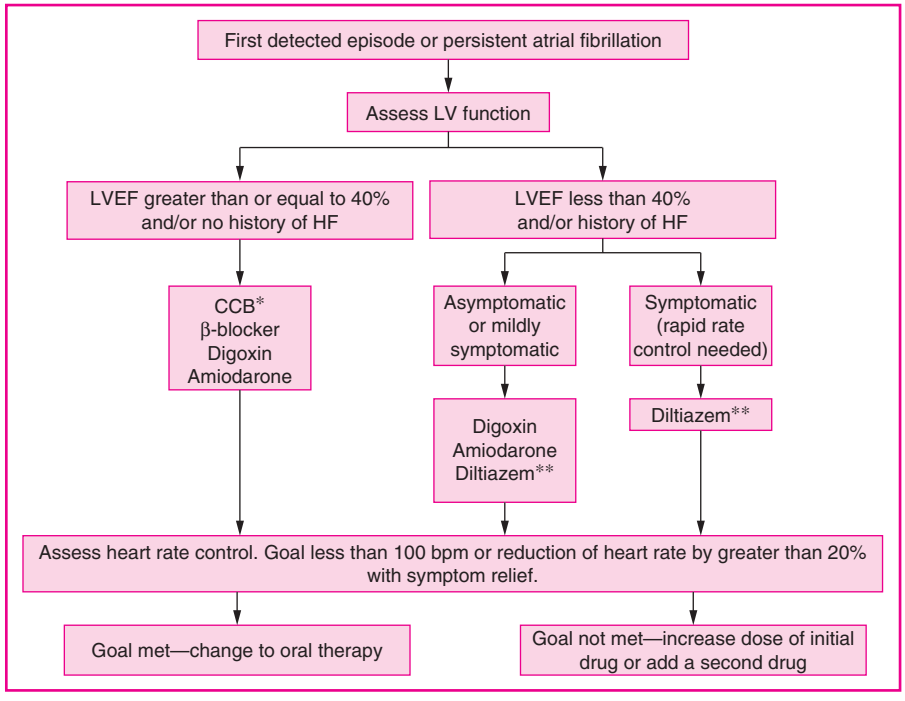

FIGURE 6–5. Decision algorithm for ventricular rate control using intravenous drug therapy for patients presenting with the first detected episode or an episode of persistent atrial fibrillation that is hemodynamically stable.
*Diltiazem is generally preferred over verapamil because of a lower risk of severe hypotension.
**Intravenous diltiazem can be used cautiously for up to 24 hours in patients with non-decompensated heart failure.
bpm, beats per minute; CCB, calcium channel blocker (diltiazem or verapamil); HF, heart failure; LV, left ventricular; LVEF, left ventricular ejection fraction.

patients in whom sinus rhythm is restored successfully, AF usually recurs shortly thereafter.

Maintenance of Sinus Rhythm/Reduction in the Frequency of Episodes of Paroxysmal AF In many patients, permanent maintenance of sinus rhythm following cardioversion is an unrealistic goal. Many, if not most, patients experience recurrence of AF after cardioversion. Therefore, a more realistic goal for many patients is not permanent maintenance of sinus rhythm, but rather reduction in the frequency of episodes of paroxysmal AF.

In recent years, numerous studies have been performed to determine whether drug therapy for maintenance of sinus rhythm is preferred to drug therapy for ventricular rate control.[28–31] In these studies, patients have been assigned randomly to receive therapy either with drugs for rate control or with drugs for rhythm control (Table 6–8). These studies have found

TABLE 6–7. Drugs for Conversion of Atrial Fibrillation to Normal Sinus Rhythm

Treatment	Loading Dose	Continuous Infusion Rate	Drug Interactions
Amiodarone	5–7 mg/kg IV over 30–60 minutes	700–1200 mg over 24 hours	Inhibits elimination of digoxin and warfarin
Dofetilide	See below[a]; patients must be hospitalized for 3 days during initiation of therapy	—	Cimetidine, hydrochlorothiazide, ketoconazole, medroxyprogesterone, promethazine, trimethoprim, verapamil (all inhibit dofetilide elimination)
Ibutilide	1 mg IV over 10 minutes, followed by a second 1 mg IV dose if necessary	—	—
Propafenone	600 mg single oral dose	—	—
Flecainide	200–300 mg single oral dose	—	—
Procainamide	12–17 mg/kg, no faster than 20 mg/minute	1–4 mg/minute	Cimetidine, ranitidine, and trimethoprim inhibit procainamide elimination

IV, intravenously.

[a]Dofetilide dosing:

Calculated Creatinine Clearance	Dofetilide Dose
Greater than 60 mL/minute	500 mcg twice daily
40–60 mL/minute	250 mcg twice daily
20–40 mL/minute	125 mcg twice daily
Less than 20mL/minute	Contraindicated

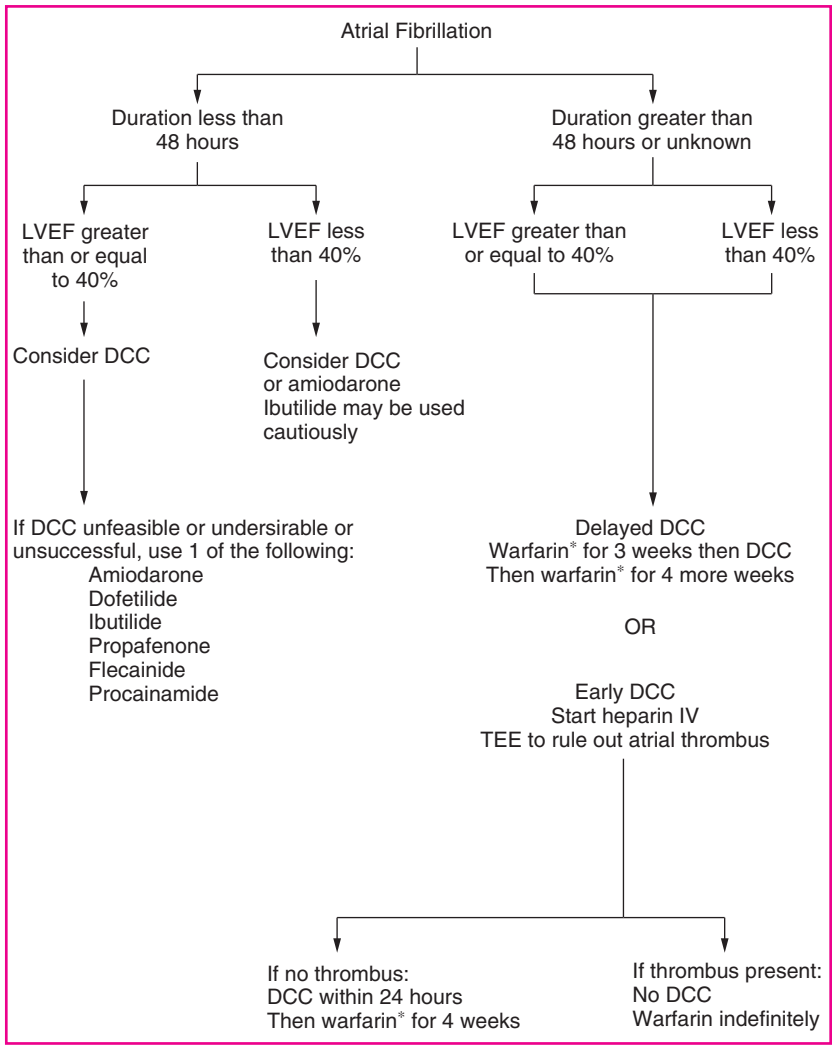

FIGURE 6–7. Decision algorithm for conversion of atrial fibrillation to normal sinus rhythm. DCC, direct current cardioversion; IV, intravenously; LVEF, left ventricular ejection fraction; TEE, transesophageal echocardiogram.
*Target International Normalized Ratio = 2.5 (range 2 to 3).
(Algorithm adapted with permission from Tisdale JE, Moser LR. Tachyarrhythmias. In: Mueller BA, Bertch KE, Dunsworth TS, et al. (eds.) *Pharmacotherapy Self-Assessment Program*, 4th ed. Kansas City: American College of Clinical Pharmacy; 2001: 217–267.)[50]

no significant differences in mortality in patients who received rhythm control therapy versus those who received rate control therapy.[28–31] However, patients assigned to the rhythm control strategy were more likely to be hospitalized[28,30,31] and were more likely to experience adverse effects associated with drug therapy.[28,29] ❹ *Therefore, drug therapy for the purpose of maintaining sinus rhythm or reducing the frequency of episodes of AF should be initiated only in those patients with episodes of paroxysmal AF who continue to experience symptoms despite maximum tolerated doses of drugs for ventricular rate control.* A decision strategy for maintenance therapy of sinus rhythm is presented in Fig. 6–8. Drug therapy for maintenance of sinus rhythm and/or reduction in the frequency of episodes of paroxysmal AF should not be initiated in patients with underlying correctable causes of AF, such as hyperthyroidism; rather, the underlying cause of the arrhythmia should be corrected.

TABLE 6–8. Drugs for Maintenance of Sinus Rhythm/ Reduction in the Frequency of Episodes of Atrial Fibrillation

Drug	Dose
Amiodarone	100–400 mg PO once daily
Dofetilide	As described in Table 6–7
Sotalol	80–160 mg PO twice daily
Propafenone	150–300 mg PO three times daily
Flecainide	100–150 mg PO twice daily
Procainamide	50 mg/kg/day, divided 4–6 × daily

PO, orally.

Stroke Prevention All patients with paroxysmal, persistent, or permanent AF should receive therapy for stroke prevention, unless compelling contraindications exist. A decision strategy for stroke prevention in AF is presented in Fig. 6–9.[27] ❺ *In general, most patients require therapy with warfarin; in some patients with no additional risk factors for stroke, aspirin may be acceptable.* For some patients, serious consideration of the benefits of warfarin versus the risks of bleeding associated with warfarin therapy is warranted. The potential bleeding risks associated with warfarin may outweigh the benefits in

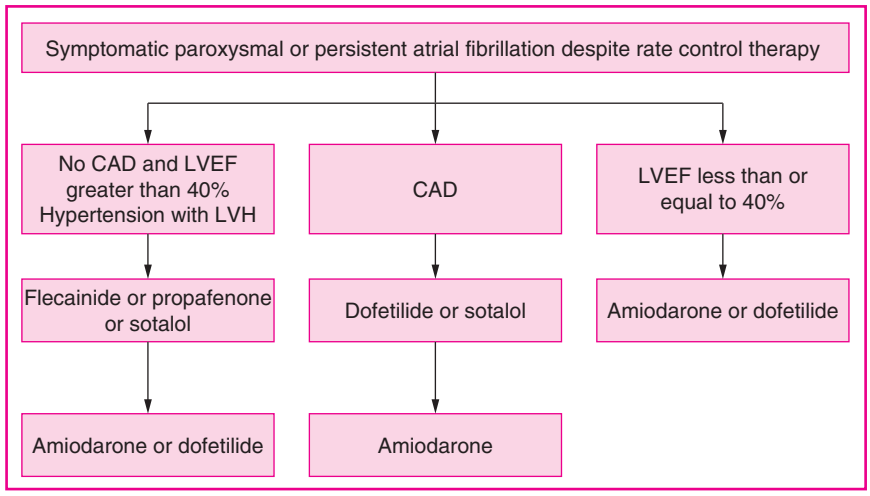

FIGURE 6–8. Decision algorithm for maintenance of sinus rhythm/reduction in the frequency of episodes of atrial fibrillation. CAD, coronary artery disease; LVEF, left ventricular ejection fraction; LVH, left ventricular hypertrophy. (Algorithm adapted with permission from Tisdale JE, Moser LR. Tachyarrhythmias. In: Mueller BA, Bertch KE, Dunsworth TS, et al. (eds.) *Pharmacotherapy Self-Assessment Program*, 4th ed. Kansas City: American College of Clinical Pharmacy; 2001: 217–267.)[50]

patients with a pretreatment INR of greater than 2.0, alcoholism, anticipated poor compliance, a history of falls, or current bleeding diathesis. In these situations, patients are at risk of severe bleeding associated with warfarin, including intracerebral bleeding, which may be associated with consequences as serious as those associated with a thrombotic stroke.

Outcome Evaluation

- Monitor the patient to determine whether the goal of ventricular rate control is met: heart rate less than 100 bpm or decrease in heart rate of 20% from the pretreatment value.
- Monitor ECG to assess continued presence of AF and to determine whether conversion to sinus rhythm has occurred.
- Monitor INR approximately monthly to make sure it is therapeutic (target 2.5; range 2 to 3).
- Monitor patients for adverse effects of specific drug therapy (Table 6–6). Monitor patients receiving warfarin for signs and symptoms of bruising or bleeding.

Patient Encounter, Part 3: Creating a Care Plan

Based on the information presented, create a care plan for DA's acute AF episode, and for long-term management of his AF.

Your plan should include: (1) a statement of the drug-related needs and/or problems, (2) the goals of therapy, (3) a patient-specific detailed therapeutic plan, and (4) a plan for follow-up to determine whether the goals have been achieved and adverse effects avoided.

Paroxysmal Supraventricular Tachycardia

Paroxysmal supraventricular tachycardia (PSVT) is a term that refers to a number of arrhythmias that occur above the ventricles and that require atrial or AV nodal tissue for initiation and maintenance.[32] The most common of these arrhythmias is

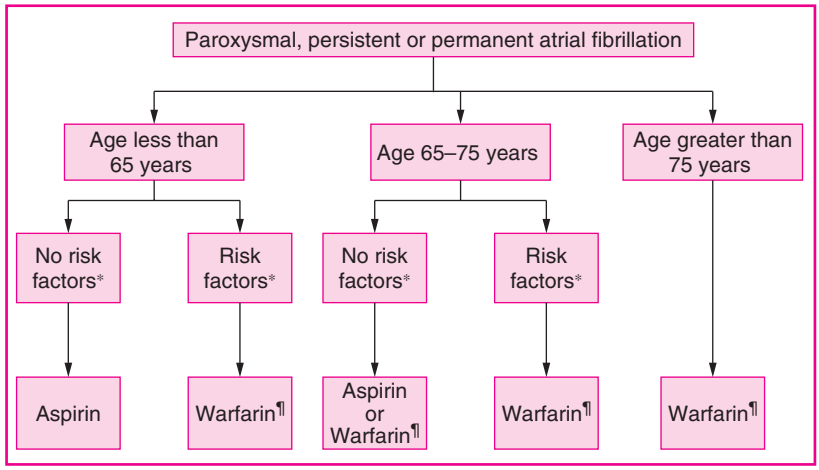

FIGURE 6–9. Decision algorithm for stroke prevention in atrial fibrillation.[27]
*Risk factors for stroke: prior transient ischemic attack or stroke; hypertension; heart failure; rheumatic heart valve disease; prosthetic heart valve.
¶Target International Normalized Ratio = 2.5 (range 2 to 3).
(Algorithm adapted with permission from Tisdale JE, Moser LR. Tachyarrhythmias. In: Mueller BA, Bertch KE, Dunsworth TS, et al. (eds.) *Pharmacotherapy Self-Assessment Program*, 4th ed. Kansas City: American College of Clinical Pharmacy; 2001: 217–267.)[50]

known as atrioventricular reciprocating tachycardia, in which the arrhythmia is caused by a reentrant circuit that involves the AV node or tissue adjacent to the AV node. Other types of PSVT include the relatively uncommon Wolff-Parkinson-White syndrome, which is caused by reentry through an accessory extra-AV nodal pathway. For the purposes of this section, the term PSVT will refer to AV nodal reentrant tachycardia.

Epidemiology and Etiology

While PSVT can be associated with myocardial ischemia or infarction, it often occurs in relatively young individuals with no history of cardiac disease. The overall incidence of PSVT is unknown.

Pathophysiology

❶ *Paroxysmal supraventricular tachycardia is caused by reentry that includes the AV node as a part of the reentrant circuit. Typically, electrical impulses travel forward (antegrade) down the AV node and then travel back up the AV node (retrograde) in a repetitive circuit. In some patients, the retrograde conduction pathway of the reentrant circuit may exist in extra-AV nodal tissue adjacent to the AV node. One of these pathways usually conducts impulses rapidly, while the other usually conducts impulses slowly.* Most commonly, during PSVT the impulse conducts antegrade through the slow pathway and retrograde through the faster pathway; in approximately 10% of patients, the reentrant circuit is reversed.[32]

Clinical Presentation and Diagnosis: PSVT

- May occur at any age, but most commonly during the fourth and fifth decades of life.[32]
- Occurs more commonly in females than in males; approximately two-thirds of patients that experience PSVT are women.[32]

Symptoms

- Symptoms typical of tachyarrhythmias include palpitations, dizziness, lightheadedness, shortness of breath, chest pain (if underlying CAD is present), near-syncope, and syncope. Patients commonly complain of palpitations; often the complaint is "I can feel my heart beating fast" or "It feels like my heart is going to beat out of my chest."
- Other symptoms are dependent on the degree to which cardiac output is diminished, which is in turn dependent on the heart rate and the degree to which stroke volume is reduced by the rapidly beating heart.

Diagnosis

- Because the symptoms of all tachyarrhythmias are dependent on heart rate and are therefore essentially the same, diagnosis depends on the presence of PSVT on the ECG, characterized by narrow QRS complexes (usually less than 0.12 seconds). P waves may or may not be visible, depending on the heart rate.
- PSVT is a regular rhythm and occurs at rates ranging from 100 to 250 bpm.

Treatment

Desired Outcomes

The desired outcomes for treatment are to terminate the arrhythmia, restore sinus rhythm, and prevent recurrence. Drug therapy is employed to terminate the arrhythmia and restore sinus rhythm; nonpharmacologic measures are employed to prevent recurrence.

Termination of PSVT

Hemodynamically unstable PSVT should be treated with immediate synchronized DCC, using an initial energy level of 50 J; if the DCC attempt is unsuccessful, successive cardioversion attempts may be made at 100, 200, 300, and 360 J.[14]

The primary method of termination of hemodynamically stable PSVT is inhibition of impulse conduction and prolongation of the refractory period within the AV node. Since PSVT is propagated via a reentrant circuit involving the AV node, inhibition of conduction within the AV node interrupts and terminates the reentrant circuit.

Prior to initiation of drug therapy for termination of hemodynamically stable PSVT, some simple nonpharmacologic methods known as **vagal maneuvers** may be attempted.[33] Vagal maneuvers stimulate the activity of the parasympathetic nervous system, which inhibits AV nodal conduction, facilitating termination of the arrhythmia. Perhaps the simplest vagal maneuver is cough, which stimulates the vagus nerve. Instructing the patient to cough two or three times may successfully terminate the PSVT. Another vagal maneuver that may be attempted is carotid sinus massage; one of the carotid sinuses, located in the neck in the vicinity of the carotid arteries, may be gently massaged, stimulating vagal activity.[33] Carotid sinus massage should not be performed in patients with a history of stroke or transient ischemic attack, or in those in whom carotid bruits may be heard on auscultation. The **Valsalva maneuver,** during which patients bear down against a closed glottis, may also be attempted.[33]

If vagal maneuvers are unsuccessful, intravenous drug therapy should be initiated.[32] Drugs that may be used for termination of hemodynamically stable PSVT are presented in Table 6–9. A decision strategy for pharmacologic termination of hemodynamically stable PSVT is presented in Fig. 6–10.[33] ❻ *Adenosine is the drug of choice for pharmacologic termination of PSVT and is successful in 90% to 95% of patients.* The drug is associated with adverse effects (Table 6–6) including flushing, sinus bradycardia or AV nodal blockade, and bronchospasm in susceptible patients. In addition, adenosine may cause chest pain that mimics the discomfort of myocardial ischemia, but which is not actually associated with ischemia. The half-life of adenosine is approximately 10 seconds, due to deamination in the blood; therefore, in the vast majority of patients, adverse effects are of short duration.

TABLE 6–9. Drugs for Termination of Paroxysmal Supraventricular Tachycardia

Drug	Mechanism	Dose	Drug Interactions
Adenosine	Direct AV nodal inhibition	6 mg IV rapid bolus If no response in 1–2 minutes, 12 mg IV rapid bolus If no response in 1–2 minutes, 12 mg IV rapid bolus	Theophylline inhibits response to adenosine Dipyridamole accentuates response to adenosine
Verapamil	Direct AV nodal inhibition	1. 5–10 mg IV over 2–3 minutes 2. If necessary, an additional dose of 5-10 mg may be administered 30 minutes later	Inhibits digoxin elimination
Diltiazem	Direct AV nodal inhibition	1. 0.25 mg/kg IV load over 2 minutes 2. If necessary, 0.35 mg/kg IV over 2 minutes after first dose	Inhibits elimination of cyclosporine
Digoxin	1. Vagal stimulation 2. Direct AV nodal inhibition	0.25 mg IV every 2 hours, up to 1.5 mg	Amiodarone and verapamil (inhibit digoxin elimination)
β-Blockers	Direct AV nodal inhibition	Esmolol: 500 mcg/kg IV, over 1 minute then 50–200 mcg/kg/minute continuous infusion Propranolol: 0.15 mg/kg IV Metoprolol: 2.5–5 mg IV × 2–3 doses	
Amiodarone	Direct AV nodal inhibition	5–7 mg/kg IV over 30–60 minutes then 700–1200 mg IV infusion over 24 hours	Inhibits elimination of digoxin and warfarin

AV, atrioventricular; IV, intravenous

If adenosine therapy is unsuccessful for termination of PSVT, subsequent choices of therapy depend on whether the patient has HF and/or a depressed left ventricular ejection fraction (LVEF).

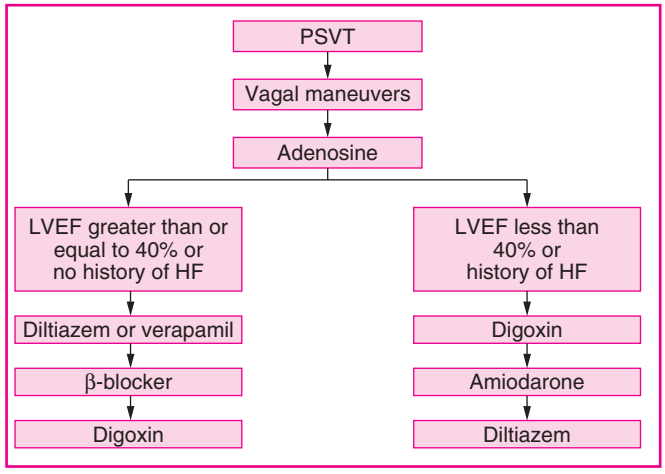

FIGURE 6–10. Decision algorithm for termination of paroxysmal supraventricular tachycardia. HF, heart failure; LVEF, left ventricular ejection fraction; PSVT, paroxysmal supraventricular tachycardia. (Algorithm adapted with permission from Tisdale JE, Moser LR. Tachyarrhythmias. In: Mueller BA, Bertch KE, Dunsworth TS, et al. (eds.) *Pharmacotherapy Self-Assessment Program*, 4th ed. Kansas City: American College of Clinical Pharmacy; 2001: 217–267.)[50]

Nonpharmacologic Therapy: Prevention of Recurrence

In the past, prevention of recurrence of PSVT was attempted using long-term oral therapy with drugs such as verapamil or digoxin. Unfortunately, oral therapy with these drugs was associated with relatively limited success. Currently, the treatment of choice for long-term prevention of recurrence of PSVT is **radiofrequency catheter ablation**. During this procedure, a catheter is introduced transvenously and directed to the right atrium under fluoroscopic guidance. The catheter is directed to the AV node, and radiofrequency energy is delivered to ablate, or destroy, one of the pathways of the reentrant circuit. This procedure usually achieves a complete cure of PSVT and is associated with a relatively low risk of complications, and therefore obviates the need for long-term antiarrhythmic drug therapy in this population.

Outcome Evaluation

- Monitor patients for termination of PSVT and restoration of normal sinus rhythm.
- Monitor patients for adverse effects of adenosine or any other anti-arrhythmic agents administered (Table 6–6).

VENTRICULAR ARRHYTHMIAS

Ventricular Premature Depolarizations

Ventricular premature depolarizations (VPDs) are ectopic electrical impulses originating in ventricular tissue, resulting

in wide, misshapen, abnormal QRS complexes. Ventricular premature depolarizations are also commonly known by other terms, including premature ventricular contractions (PVCs), ventricular premature beats (VPBs), and ventricular premature contractions (VPCs).

Epidemiology, Etiology, and Pathophysiology

Ventricular premature depolarizations occur with variable frequency, depending on underlying comorbid conditions. The prevalence of complex or frequent VPDs is approximately 33% and 12% in men with and without CAD, respectively;[34] in women, the prevalence of complex or frequent VPDs is 26% and 12% in those with and without CAD, respectively.[35] Ventricular premature depolarizations occur more commonly in patients with ischemic heart disease, a history of myocardial infarction, and HF due to LV dysfunction. They may also occur as a result of hypoxia, anemia, and following cardiac surgery.

❶ *Ventricular premature depolarizations occur as a result of abnormal ventricular automaticity, as a result of enhanced activity of the sympathetic nervous system and altered electrophysiologic characteristics of the heart during myocardial ischemia and following myocardial infarction.*

In patients with underlying CAD or a history of myocardial infarction, the presence of complex or frequent VPDs is associated with an increased risk of mortality due to sudden cardiac death.[36]

Treatment

Desired Outcomes

The desired outcomes for treatment are to alleviate patient symptoms.

Clinical Presentation and Diagnosis: Ventricular Premature Depolarizations

- VPDs are usually categorized as simple or complex: simple VPDs are those that occur as infrequent, isolated single abnormal beats; complex VPDs are those that occur more frequently and/or in specific patterns.
- Two consecutive VPDs are referred to as a couplet.[35] The term bigeminy refers to VPDs occurring with every other beat; trigeminy means VPDs occurring with every third beat; quadrigeminy means VPDs occurring every fourth beat.[35] VPDs occurring at a rate of more than 10 per hour or 6 or more per minute are defined as frequent.[35]

Symptoms

- The majority of patients who experience simple or complex VPDs are asymptomatic. Occasionally, patients with complex or frequent VPDs may experience symptoms of palpitations, lightheadedness, fatigue, near-syncope or syncope.

Pharmacologic Therapy

❼ *Asymptomatic VPDs should not be treated with antiarrhythmic drug therapy.* Based on the knowledge that complex or frequent VPDs increase the risk of sudden cardiac death in patients with a history of myocardial infarction, the Cardiac Arrhythmia Suppression Trials (CAST I and II)[37,38] tested the hypothesis that suppression of asymptomatic VPDs with the drugs flecainide, encainide, or moricizine in patients with a relatively recent history of myocardial infarction would lead to a reduction in the incidence of sudden cardiac death. However, the results of the trial showed that not only did these antiarrhythmic agents not reduce the risk of sudden cardiac death, patients who received therapy with encainide or flecainide experienced a significant *increase* in the risk of death compared to those that received placebo.[37] During the continuation of the study with moricizine, a trend was found toward an increase in the incidence of death in the patients who received this antiarrhythmic drug as well.[38] A subsequent meta-analysis of studies of other Vaughan-Williams class I drugs, including quinidine, procainamide, and disopyramide, found that the patients with complex VPDs who received these drugs following myocardial infarction were also at increased risk of death.[39] Therefore, all available evidence shows that patients with complex VPDs following myocardial infarction do not benefit from therapy with antiarrhythmic agents and that many of these drugs increase the risk of death. ❼ *Therefore, asymptomatic VPDs should not be treated.*

Patients with symptomatic VPDs should be treated with β-blockers, as the majority of patients with symptomatic VPDs have underlying CAD. β-Blockers have been shown to reduce mortality in this population and have been shown to be effective for VPD suppression.[40]

Outcome Evaluation

- Monitor patients for relief of symptoms.
- Monitor for adverse effects of β-blockers—heart rate, blood pressure, fatigue, masking of symptoms of hypoglycemia and/or glucose intolerance (in patients with diabetes), wheezing or shortness of breath (in patients with asthma or chronic obstructive pulmonary disease), etc.

Ventricular Tachycardia

Ventricular tachycardia is a series of three or more consecutive VPDs at a rate of greater than 100 bpm. Ventricular tachycardia is defined as non-sustained if it lasts less than 30 seconds and terminates spontaneously; sustained VT lasts greater than 30 seconds and does not terminate spontaneously, but rather requires therapeutic intervention for termination.

Epidemiology, Etiology, and Pathophysiology

Etiologies of VT are presented in Table 6–10. The incidence of VT is variable, depending on underlying comorbidities. Up to 20% of patients who experience acute myocardial infarction

TABLE 6–10. Etiologies of Ventricular Tachycardia and Ventricular Fibrillation

Coronary artery disease
Myocardial infarction
Heart failure

Propafenone
Sotalol
Terbutaline
Theophylline
Thioridazine
Trazodone
Tricyclic antidepressants

experience ventricular arrhythmias.[41] Approximately 2% to 4% of patients with myocardial infarction develop VT during the period of hospitalization.[41] Non-sustained VT occurs in 34% to 79% of patients with HF.[42] Other etiologies of VT include electrolyte abnormalities such as hypokalemia, hypoxia, and some drugs (Table 6–10).

❶ *Ventricular tachycardia is usually initiated by a precisely timed VPD, occurring during the relative refractory period, which provokes reentry within ventricular tissue.*

Sustained VT requires immediate intervention, because if untreated, the rhythm may cause sudden cardiac death via hemodynamic instability and the absence of a pulse (pulseless VT) or via degeneration of VT into VF.

Treatment

Desired Outcomes

The desired outcomes for treatment are to terminate the arrhythmia and restore sinus rhythm, and to prevent sudden cardiac death.

Pharmacologic Therapy

Termination of VT Hemodynamically unstable VT should be terminated immediately using synchronized DCC beginning with 100 J and increasing subsequent shocks to 200, 300, and 360 J.[14] In the event that VT is present but the patient has no pulse (and therefore no blood pressure), asynchronous defibrillation should be performed, starting with 200 J and increasing to 300 and 360 J.[14]

Drugs used for the termination of hemodynamically stable VT are presented in Table 6–11. Intravenous drug administration is required. A decision algorithm for management of hemodynamically stable VT is presented in Fig. 6–11. Amiodarone is considered the preferred first-line antiarrhythmic agent for management of VT, regardless of the patient's underlying LV function.[14] In patients with normal LV function who do not respond to amiodarone, IV procainamide may be administered;[14] data suggest superior efficacy of procainamide compared with that of lidocaine.[43] However, in patients with HF due to LV dysfunction, procainamide should be avoided, due to

Clinical Presentation and Diagnosis: Ventricular Tachycardia

Symptoms

- As with other tachyarrhythmias, symptoms associated with VT are dependent primarily on heart rate and include palpitations, dizziness, lightheadedness, shortness of breath, chest pain (if underlying CAD is present), near-syncope, and syncope.
- Patients with non-sustained VT may be asymptomatic, if the duration of the arrhythmia is sufficiently short. However, if the rate is sufficiently rapid, patients with non-sustained VT may experience symptoms.
- Patients with sustained VT are usually symptomatic, provided that the rate is fast enough to provoke symptoms. Patients with rapid sustained VT may be hemodynamically unstable.
- In some patients, sustained VT results in the absence of a pulse, resulting in the syndrome of sudden cardiac death.

Diagnosis

- Diagnosis of VT requires ECG confirmation of the arrhythmia.
- Ventricular tachycardia is characterized by wide, misshapen QRS complexes, with the rate varying from 100 to 250 bpm.
- In the majority of patients with VT, the shape and appearance of the QRS complexes are consistent and similar, and is referred to as monomorphic VT. However, some patients experience polymorphic VT, in which the shape and appearance of the QRS complexes vary.

TABLE 6–11. Drugs for Termination of Ventricular Tachycardia

Drug	Loading Dose	Maintenance Dose
Procainamide	12–17 mg/kg IV, no faster than 20 mg/minute	1–4 mg/minute continuous infusion
Lidocaine	0.5–0.75 mg/kg IV bolus Repeat every 5–10 minutes to a total of 3 mg/kg	1–4 mg/minute continuous infusion
Amiodarone	150 mg IV over 10 minutes	1 mg/minute continuous infusion for 6 hours, 0.5 mg/minute for 18 hours

IV, intravenously.

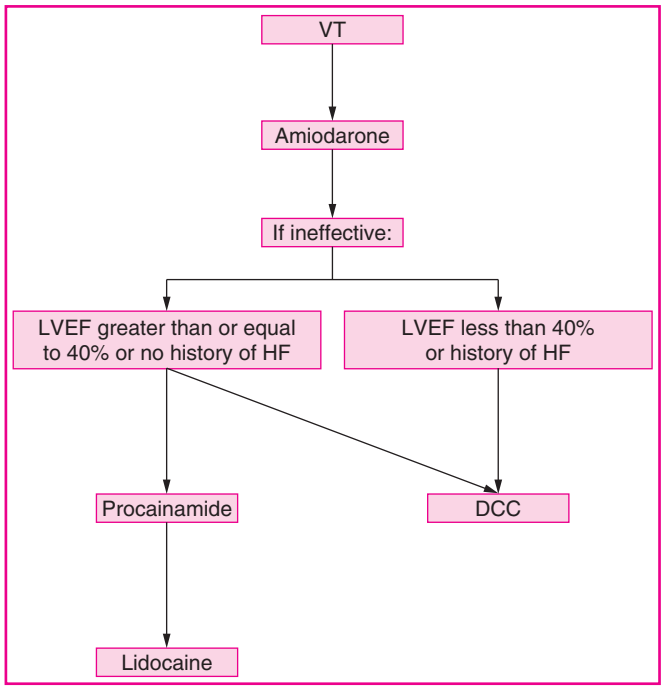

FIGURE 6–11. Decision algorithm for termination of hemodynamically stable ventricular tachycardia.

(Algorithm adapted with permission from Tisdale JE, Moser LR. Tachyarrhythmias. In: Mueller BA, Bertch KE, Dunsworth TS, et al. (eds.) *Pharmacotherapy Self-Assessment Program*, 4th ed. Kansas City: American College of Clinical Pharmacy; 2001:217–267.)[50]

an increased risk of hypotension and drug-induced torsades de pointes and due to negative inotropic activity.[14]

Nonpharmacologic Therapy: Prevention of Sudden Cardiac Death

❸ *In patients who have experienced VT and are at risk for sudden cardiac death, implantation of an* ***implantable cardioverter-defibrillator*** *(ICD) is the treatment of choice.*[44] An ICD is a device that provides internal electrical cardioversion of VT or defibrillation of VF; the ICD does not prevent the patient from developing the arrhythmia, but it reduces the risk that the patient will die of sudden cardiac death as a result of the arrhythmia. Whereas in the past ICD implantation required a thoracotomy, these devices now may be implanted transvenously, similarly to pacemakers, markedly reducing the complication rate.

ICDs have been found to be significantly more effective than antiarrhythmic agents such as amiodarone or sotalol for reducing the risk of sudden cardiac death;[45,46] therefore, ICDs are preferred therapy.[44] However, many patients with ICDs receive concurrent antiarrhythmic drug therapy to reduce the frequency with which patients experience the discomfort of shocks and to prolong battery life of the devices. Combined pharmacotherapy with amiodarone and a β-blocker is more effective than monotherapy with sotalol or β-blockers for reduction in the frequency of ICD shocks.[47]

Outcome Evaluation

- Monitor patients for termination of VT and restoration of normal sinus rhythm.
- Monitor patients for adverse effects of antiarrhythmic drugs administered (Table 6–6).

Ventricular Fibrillation

Ventricular fibrillation is irregular, disorganized, chaotic electrical activity in the ventricles resulting in absence of ventricular depolarizations, and, consequently, lack of pulse, cardiac output, and blood pressure.

Epidemiology and Etiology

Approximately 400,000 people die of sudden cardiac death annually in the United States. While some of these deaths occur as a result of asystole, the majority occur as a result of primary VF or VT that degenerates into VF. Etiologies of VF are presented in Table 6–10 and are similar to those of VT.

Treatment

Desired Outcomes

The desired outcomes for treatment are to: (1) terminate VF, (2) achieve return of spontaneous circulation, and (3) achieve patient survival to hospital admission (in those with out-of-hospital cardiac arrest) and to hospital discharge.

Pharmacologic and Nonpharmacologic Therapy

Ventricular fibrillation is by definition hemodynamically unstable, due to the absence of pulse and blood pressure. Initial management includes provision of basic life support, including calling for help and initiation of cardiopulmonary resuscitation (CPR).[48] Oxygen should be administered as soon

Clinical Presentation and Diagnosis: Ventricular Fibrillation

Symptoms

- VF results in immediate loss of pulse and blood pressure. Patients who are in the standing position at the onset of VF suddenly immediately collapse to the ground.

Diagnosis

- The absence of a pulse does not guarantee VF, as the pulse may also be absent in patients with asystole, VT, or pulseless electrical activity.
- Confirmation of the diagnosis with an ECG is necessary in order to determine appropriate treatment. ECG reveals no organized, recognizable QRS complexes. If treatment is not initiated within a few minutes, death will occur, or at best, resuscitation of the patient with permanent anoxic brain injury.

as it is available. Most importantly, defibrillation should be performed as soon as possible. It is critically important to understand that the only means of successfully terminating VF and restoring sinus rhythm is electrical defibrillation. Defibrillation should be attempted using 200 J, after which CPR should be resumed immediately while the defibrillator charges; if the first shock was unsuccessful, subsequent defibrillation shocks should be 360 J.[48]

If VF persists following one or two defibrillation shocks, drug therapy may be administered. ❾ *The purpose of drug administration for treatment of VF is to facilitate successful defibrillation. Drug therapy alone will not result in termination of VF. Drugs that are used for facilitation of defibrillation in patients with VF are listed in Table 6–12.* Drug administration should occur during CPR, before or after delivery of a defibrillation shock. The vasopressor agents epinephrine or vasopressin are administered initially, because it has been shown that a critical factor in successful defibrillation is maintenance of coronary perfusion pressure, which is achieved via the vasoconstricting effects of these drugs. A decision algorithm for the treatment of VF is presented in Fig. 6–12. Epinephrine and vasopressin are equally effective for facilitation of defibrillation leading to survival to hospital admission in patients with out-of-hospital cardiac arrest due to VF. Amiodarone is more effective than lidocaine for facilitation of defibrillation leading to survival to hospital admission in patients with VF,[49] which is the reason that amiodarone administration is recommended earlier than lidocaine administration in the decision algorithm.[48] Note that the amiodarone doses recommended for administration during a resuscitation attempt for VF (Table 6–12) are different than those recommended for administration for termination of VT (Table 6–11).

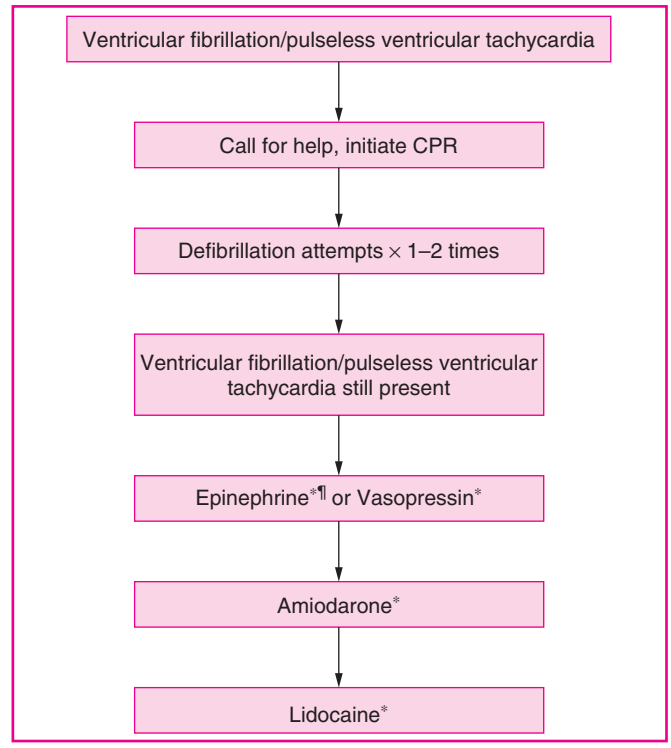

FIGURE 6–12. Decision algorithm for resuscitation of ventricular fibrillation or pulseless ventricular tachycardia.
CPR, cardiopulmonary resuscitation.
*A defibrillation attempt should be made after every dose of drug.
¶If epinephrine is selected, the drug should continue to be administered every 3 to 5 minutes throughout the remainder of the resuscitation attempt.

Outcome Evaluation

- Monitor the patient for return of pulse and blood pressure, and for termination of VF and restoration of normal sinus rhythm.
- After successful resuscitation, monitor the patient for adverse effects of drugs administered (Table 6–6).

TABLE 6–12. Drugs for Facilitation of Defibrillation in Patients with Ventricular Fibrillation

Drug	Dose
Epinephrine	1 mg IV every 3–5 minutes
Vasopressin	40 units IV single dose
Amiodarone	300 mg IV diluted in 20–30 mL D_5W One subsequent dose of 150 mg IV may be administered
Lidocaine	1–1.5 mg/kg IV bolus Follow with additional IV boluses of 0.5–0.75 mg/kg up to total of 3 mg/kg

IV, intravenous.

Torsades de Pointes

Torsades de pointes is a specific polymorphic VT that is associated with prolongation of the QT interval in the sinus beats that precede the arrhythmia.[13]

Epidemiology and Etiology

The incidence of torsades de pointes in the population at large is unknown. The incidence of torsades de pointes associated with specific drugs ranges from less than 1% to as high as 8% to 10%, depending on dose and plasma concentration of the drug and the presence of other risk factors for the arrhythmia.

Torsades de pointes may be inherited or acquired. Patients with specific genetic mutations may have the inherited long QT syndrome, in which the QT interval is prolonged, and these patients are at risk for torsades de pointes. Acquired torsades de pointes may be caused by numerous drugs (Table 6–13); the list of drugs that are known to cause torsades de pointes continues to expand.

TABLE 6–13. Drugs That Have Been Reported to Cause Torsades de Pointes[13]

Amiodarone	Ibutilide
Amitriptyline	Indapamide
Arsenic	Levofloxacin
Bepridil	Levomethadyl
Chloroquine	Loratadine
Chlorpromazine	Methadone
Ciprofloxacin	Metoclopramide
Clarithromycin	Pentamidine
Disopyramide	Pimozide
Dofetilide	Procainamide
Doxepin	Propafenone
Droperidol	Quinidine
Erythromycin	Sertraline
Famotidine	Sotalol
Flecainide	Tacrolimus
Fluconazole	Thioridazine
Fluoxetine	Trazodone
Gatifloxacin	Trimethoprim-sulfamethoxazole
Haloperidol	

Pathophysiology

Torsades de pointes is caused by circumstances, often drugs, that lead to prolongation in the repolarization phase of the ventricular action potential (Fig. 6–2) manifested on the ECG by prolongation of the QT interval. Prolongation of ventricular repolarization occurs via inhibition of efflux of potassium through potassium channels; therefore, drugs that inhibit conductance through potassium channels may cause QT interval prolongation and torsades de pointes. ❶ *Prolongation of ventricular repolarization likely promotes the development of early ventricular afterdepolarizations during the relative refractory period, which may provoke reentry leading to torsades de pointes.*

❿ *Drug-induced torsades de pointes rarely occurs in patients without specific risk factors for the arrhythmia (Table 6–14).* In most cases, administration of a drug known to cause torsades de pointes is unlikely to cause the arrhythmia; however, the likelihood of the arrhythmia increases markedly in patients with concomitant risk factors.

The onset of torsades de pointes associated with oral drug therapy is somewhat variable and in some cases may be delayed; often, a patient can be taking a drug known to cause torsades de pointes for months or longer without problem, until another risk factor for the arrhythmia becomes present, which then may trigger the arrhythmia.

In some patients, torsades de pointes may be of short duration and may terminate spontaneously. However, torsades de pointes may not terminate on its own, and if left untreated, may degenerate into VF and result in sudden cardiac death.[13] Several drugs, including terfenadine, astemizole, and cisapride have been withdrawn from the United States market as a result of causing deaths due to torsades de pointes.

TABLE 6–14. Risk Factors for Drug-Induced Torsades de Pointes[13]

QTc interval greater than 500 milliseconds
Increase in QTc interval by more than 60 milliseconds compared with the pretreatment value
Female gender
Heart failure
Electrolyte abnormalities: hypokalemia and hypomagnesemia
Bradycardia
Elevated plasma concentrations of QT interval-prolonging drugs due to drug interactions or absence of dose adjustment for organ dysfunction
Rapid intravenous infusion of torsades-inducing drugs
Concomitant administration of more than one agent known to cause QT interval prolongation/torsades de pointes
Possible genetic predisposition
Previous history of drug-induced torsades de pointes

QTc, corrected QT interval

Clinical Presentation and Diagnosis: Torsades de pointes

Symptoms

- As with other tachyarrhythmias, symptoms associated with torsades de pointes are dependent primarily on heart rate and include palpitations, dizziness, lightheadedness, shortness of breath, chest pain (if underlying CAD is present), near-syncope, and syncope.
- Torsades de pointes may be hemodynamically unstable if the rate is sufficiently rapid.
- Like sustained monomorphic VT, torsades de pointes may result in the absence of a pulse, or may rapidly degenerate into VF, resulting in the syndrome of sudden cardiac death.

Diagnosis

- Diagnosis of torsades de pointes requires examination of the arrhythmia on ECG.
- Torsades de pointes, or "twisting of the points," appears on ECG as apparent twisting of the wide QRS complexes around the isoelectric baseline.
- The arrhythmia is associated with heart rates from 150 to 300 bpm.
- Characteristic feature: a "long-short" initiating sequence, which occurs as a result of a ventricular premature beat followed by a compensatory pause, which is followed by the first beat of the torsades de pointes.
- Episodes of torsades de pointes may self-terminate, with frequent recurrence.

Prevention and Treatment

Desired Outcomes

The desired outcomes for treatment include the: (1) prevention of torsades de pointes, (2) termination of torsades de pointes, (3) prevention of recurrence, and (4) prevention of sudden cardiac death.

Pharmacologic and Nonpharmacologic Therapy

⑩ *In patients with risk factors for torsades de pointes, drugs with the potential to cause QT interval prolongation and torsades de pointes should be avoided or used with extreme caution, and diligent QT interval monitoring should be performed.*

Management of drug-induced torsades de pointes includes discontinuation of the potentially causative agent. Patients with hemodynamically unstable torsades de pointes should undergo immediate synchronized DCC. In patients with hemodynamically stable torsades de pointes, electrolyte abnormalities such as hypokalemia and hypomagnesemia should be corrected. Hemodynamically stable torsades de pointes is often treated with intravenous magnesium, irrespective of whether the patient is hypomagnesemic; magnesium has been shown to terminate torsades de pointes in normomagnesemic patients. Intravenous magnesium may be administered in doses of 1 to 2 g, diluted in 50 to 100 mL D_5W, administered over 5 to 10 minutes; doses may be repeated to a total of 12 g.

Alternatively, a continuous magnesium infusion may be initiated after the first bolus, at a rate of 0.5 to 1 g/hour. Alternative treatments include: transvenous insertion of a temporary pacemaker for overdrive pacing, which shortens the QT interval and may terminate torsades de pointes; intravenous isoproterenol 2 to 10 mcg/minute, to increase the heart rate and shorten the QT interval; intravenous lidocaine, which may shorten the duration of ventricular repolarization; or intravenous phenytoin, which may also shorten the duration of ventricular repolarization, administered at a dose of 10 to 15 mg/kg infused at a rate of 25 to 50 mg/minute.

Outcome Evaluation

- Monitor vital signs (heart rate and blood pressure).
- Monitor the ECG to determine the QTc interval (maintain less than 450 milliseconds) and for the presence of torsades de pointes.
- Monitor serum potassium and magnesium concentrations.
- Monitor for symptoms of tachycardia.

Patient Care and Monitoring

1. Perform a thorough medication history to determine whether the patient is receiving any prescription or non-prescription drugs that may cause or contribute to the development of an arrhythmia.
2. Evaluate the patient for the presence of drug-induced diseases, drug allergies, and drug interactions.
3. Determine and monitor the patient's serum electrolyte concentrations to determine the presence or absence of hypokalemia, hyperkalemia, hypomagnesemia, or hypermagnesemia.
4. Consider the patient's heart rate, blood pressure, and symptoms to determine whether he or she is hemodynamically stable or unstable.
5. Monitor the patient's 12-lead ECG or single rhythm strips to determine if an arrhythmia is present and to identify the specific arrhythmia, and evaluate and monitor the patient's symptoms.
6. Develop drug therapy treatment plans for management of the specific arrhythmia that the patient is experiencing: sinus bradycardia, AV nodal blockade, AF, PSVT, VPDs, VT (including torsades de pointes), or VF.
7. Develop specific drug therapy monitoring plans for the treatment plan implemented. Monitoring includes assessment of symptoms, ECG, adverse effects of drugs, and potential drug interactions.
8. In those receiving warfarin for AF, determine whether the patient's INR is therapeutic.
9. Provide information regarding safe and effective warfarin therapy:
   - Notify appropriate clinicians in the event of severe bruising, blood in urine or stool, or frequent nosebleeds;
   - Avoid radical changes in diet;
   - Avoid alcohol;
   - Do not take non-prescription medications or herbal/alternative/complementary medicines without notifying your physician, pharmacist, and/or health care team members.
10. Stress the importance of adherence to the therapeutic regimen.
11. Provide patient education regarding disease state and drug therapy.

7 Venous Thromboembolism

Stuart T. Haines and Edith A. Nutescu

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Identify risk factors and signs and symptoms of deep vein thrombosis and pulmonary embolism.
2. Describe the processes of hemostasis and thrombosis, including the role of the vascular endothelium, platelets, coagulation cascade, and thrombolytic proteins.
3. Determine a patient's relative risk (low, moderate, high, or very high) of developing venous thrombosis.
4. State at least two potential advantages of the low-molecular-weight heparins and fondaparinux over unfractionated heparin.
5. Formulate an appropriate prevention strategy for a patient at risk for deep vein thrombosis.
6. Identify factors that place a patient at high risk of bleeding while receiving antithrombotic drugs.
7. Select and interpret laboratory test(s) to monitor antithrombotic drugs.
8. Identify and analyze warfarin drug-drug and drug-food interactions.
9. Manage a patient with an elevated International Normalized Ratio (INR) with or without bleeding.
10. Formulate an appropriate treatment plan for a patient who develops a deep vein thrombosis or pulmonary embolism, and develop a comprehensive education plan for a patient who is receiving an antithrombotic drug.

Key Concepts

❶ Antithrombotic therapies require meticulous and systematic monitoring, as well as ongoing patient education. Well-organized anticoagulation management services improve the quality of patient care and reduce the overall cost.

❷ The risk of venous thromboembolism (VTE) is related to several easily identifiable factors including age, prior history of VTE, major surgery (particularly orthopedic procedures of the lower extremities), trauma, malignancy, pregnancy, estrogen use, and hypercoagulable states. These risks are additive.

❸ The diagnosis of VTE must be confirmed by an objective test.

❹ At the time of hospital admission, all patients should be evaluated for their risk of VTE, and strategies to prevent VTE appropriate for each patient's level of risk should be routinely employed. Prophylaxis should be continued throughout the period of risk.

❺ In the absence of contraindications, the treatment of VTE should initially include a rapid-acting anticoagulant (e.g., unfractionated heparin, low-molecular-weight heparin, or fondaparinux) overlapped with warfarin for at least 5 days and until the patient's INR is greater than 2. Anticoagulation therapy should be continued for a minimum of 3 months. However, the duration of anticoagulation therapy should be based on the patient's risk of VTE recurrence and major bleeding.

❻ Bleeding is the most common adverse effect associated with antithrombotic drugs. A patient's risk of major hemorrhage is related to the intensity and stability of therapy, age, concurrent drug use, history of gastrointestinal bleeding, risk of falls or trauma, and recent surgery.

❼ Most patients with an uncomplicated deep vein thrombosis (DVT) can be managed safely at home.
❽ Warfarin is prone to numerous clinically important drug-drug and drug-food interactions.

Venous thromboembolism (VTE) is one of the most common cardiovascular disorders in the United States. VTE is manifested as **deep vein thrombosis** (DVT) and **pulmonary embolism** (PE) resulting from **thrombus** formation in the venous circulation (Fig. 7–1).[1] It is often provoked by prolonged immobility and vascular injury and is most frequently seen in patients who have been hospitalized for a serious medical illness, trauma, or major surgery. VTE can also occur with little or no provocation in patients who have an underlying hypercoagulable disorder.

While VTE may initially cause few or no symptoms, the first overt manifestation of the disease may be sudden death.[2] Death from PE can occur within minutes, before effective treatment can be given. In addition to the symptoms produced by the acute event, the long-term sequelae of VTE such as the post-thrombotic syndrome (PTS; a complication of VTE occurring due to damage to the vein caused by a blood clot) and recurrent thromboembolic events cause long-term pain and suffering.

The treatment of VTE is fraught with substantial risks.[3] ❶ *Antithrombotic drugs require precise dosing and meticulous monitoring, as well as ongoing patient education.*[4,5] *Well organized anticoagulation management services improve the quality of patient care and reduce the overall cost.* A systematic approach to drug therapy management substantially reduces these risks, but bleeding remains a common and serious complication.[6] Therefore, preventing VTE is paramount to improving outcomes. When VTE is suspected, a rapid and accurate diagnosis is critical to making appropriate treatment decisions. The optimal use of antithrombotic drugs requires not only an in-depth knowledge of their pharmacology and pharmacokinetic properties, but also a comprehensive approach to patient management.[7]

EPIDEMIOLOGY AND ETIOLOGY

The true incidence of VTE in the general population is unknown because many patients, perhaps more than 50%, have no overt symptoms or go undiagnosed.[8] An estimated

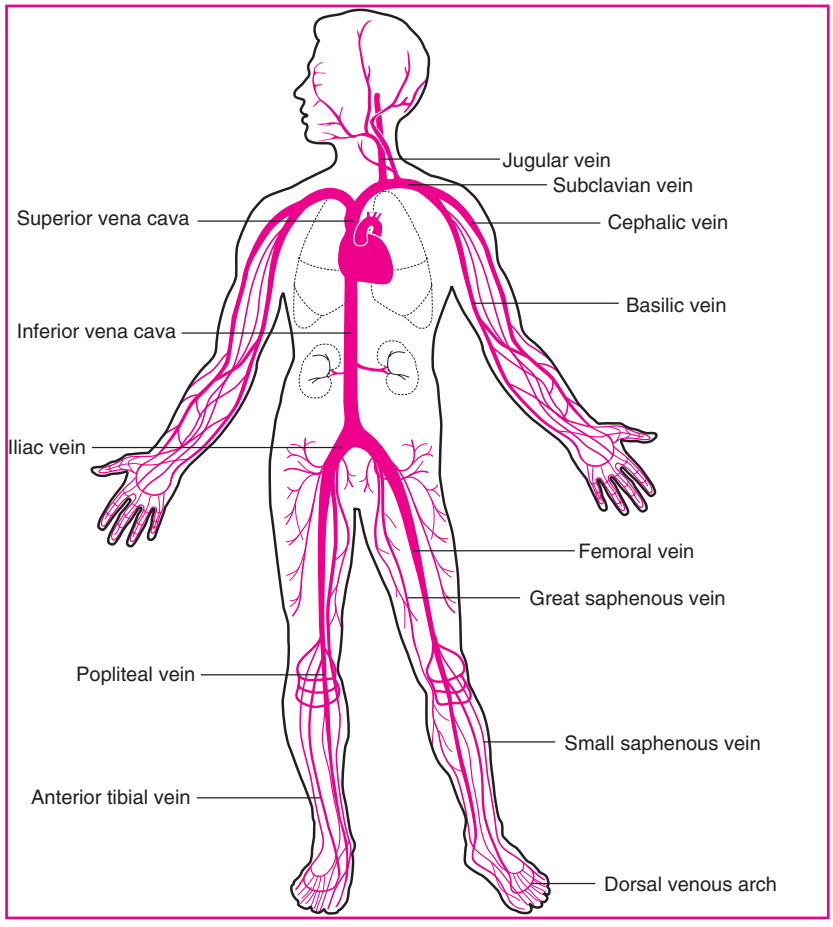

FIGURE 7–1. Venous circulation. (Reproduced from Haines ST, Zeolla M, Witt DM. Venous thromboembolism. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 374, with permission.)

2 million people in the United States develop VTE each year; 600,000 are hospitalized and 60,000 die. The estimated annual direct medical costs of managing the disease are well over $1 billion. The best available data indicate the age-adjusted incidence of symptomatic VTE in Caucasians is 117 per 100,000 per year.[9] The incidence of VTE nearly doubles in each decade of life over the age of 50 and is slightly higher in men. The age-adjusted incidence of PE has declined slightly in recent years, presumably because of heightened awareness of VTE, effective prevention strategies, early diagnosis, and prompt treatment. However, as the population ages, the total number of cases of DVT and PE continues to rise.

❷ *The risk of VTE is related to several easily identifiable factors including age, prior history of VTE, major surgery (particularly orthopedic procedures of the lower extremities), trauma, malignancy, pregnancy, estrogen use, and hypercoagulable state (Table 7–1).*[2] *These risk factors are additive and can be easily identified in clinical practice. A prior history of venous* ***thrombosis*** *is perhaps the strongest risk factor for recurrent VTE, presumably because of the destruction of venous valves and obstruction of blood flow caused by the initial event.* Rapid blood flow has an inhibitory effect on thrombus formation, but a slow rate of flow reduces the clearance of activated clotting factors in the zone of injury and slows the influx of regulatory substances. Stasis tips the delicate balance of procoagulation and anticoagulation in favor of **thrombogenesis**. The rate of blood flow in the venous circulation, particularly in the deep veins of the lower extremities, is relatively slow. Valves in the deep veins of the legs, as well as contraction of the calf and thigh muscles, facilitate the flow of blood back to the heart and lungs. Damage to the venous valves and periods of prolonged immobility result in venous stasis. Vessel obstruction, either from a thrombus or external compression, promotes clot propagation. Numerous medical conditions and surgical procedures are associated with reduced venous blood flow and increase the risk of VTE (Table 7–1). Greater than normal blood viscosity, seen in myeloproliferative disorders like polycythemia vera, for example, may also contribute to slowed blood flow and thrombus formation.

TABLE 7–1. Risk Factors for Venous Thromboembolism

Risk Factor	Example
Age	Risk doubles with each decade after age 50
Prior history of VTE	Strongest known risk factor for DVT and PE
Venous stasis	Major medical illness (e.g., congestive heart failure) Major surgery (e.g., general anesthesia for greater than 30 minutes) Paralysis (e.g., due to stroke or spinal cord injury) Polycythemia vera Obesity Varicose veins
Vascular inujury	Major orthopedic surgery (e.g., knee and hip replacement) Trauma (esp. fractures of the pelvis, hip, or leg) Indwelling venous catheters
Hypercoagulable states	Malignancy, diagnosed or occult Activated protein C resistance/factor V Leiden Prothrombin (20210A) gene mutation Protein C deficiency Protein S deficiency Antithrombin deficiency Factor VIII excess (greater than 90th percentile) Factor XI excess (greater than 90th percentile) Antiphospholipid antibodies Dysfibrinogenemia PAI-l excess Pregnancy/postpartum
Drug therapy	Estrogen-containing oral contraceptive pills Estrogen replacement therapy SERMs HIT

DVT, deep vein thrombosis; HIT, heparin-induced thrombocytopenia; PAI-l, plasminogen activator inhibitor; PE, pulmonary embolism; SERM, selective estrogen receptor modulator; VTE, venous thromboembolism.

A growing list of hereditary deficiencies, gene mutations, and acquired diseases have been linked to hypercoagulability (Table 7–1).[10] Activated protein C resistance is the most common genetic disorder of hypercoagulability, found in nearly 5% of individuals of northern European descent and in as many as 40% of those who suffer an idiopathic DVT. Although these patients have normal plasma concentrations of protein C, they have a mutation on factor V that renders it resistant to degradation by activated protein C. This mutation is known as factor V Leiden, named after the city of Leiden, Holland, where the defect was initially reported. The prothrombin 20210A mutation is also a relatively common defect, occurring in as many as 3% of healthy individuals of southern European descent and 16% of those with an idiopathic DVT. Although less common, inherited deficiencies of the natural **anticoagulants** protein C, protein S, and antithrombin place patients at a high lifetime risk for VTE. Conversely, high concentrations of factors VIII, IX, and XI also increase the risk of VTE. Some patients have multiple genetic defects.

Acquired disorders of hypercoagulability include malignancy, antiphospholipid antibodies, estrogen use, and pregnancy.[2] The strong link between cancer and thrombosis has been recognized since the late 1800s.[11] Tumor cells secrete a number of procoagulant substances that activate the clotting cascade. Furthermore, patients with cancer often have suppressed levels of protein C, protein S, and antithrombin. Antiphospholipid antibodies, commonly found in patients with autoimmune disorders such as systemic lupus erythematosus and inflammatory bowel disease, can cause venous and arterial thrombosis.[12] The antiphospholipid antibody syndrome is associated with repeated pregnancy loss. The precise mechanism by which these antibodies provoke thrombosis is unclear, but they activate the coagulation cascade and platelets, as well as inhibit the anticoagulant

activity of proteins C and S. Estrogen-containing contraceptives, estrogen replacement therapy, and many of the selective estrogen receptor modulators (SERMs) increase the risk of venous thrombosis.[2,13] While the mechanisms are not clearly understood, estrogens increase serum **clotting factor** concentrations and induce activated protein C resistance. Increased serum estrogen concentrations may explain, in part, the increased risk of VTE during pregnancy and the postpartum period.[14]

PATHOPHYSIOLOGY

The arrest of bleeding following vascular injury, or hemostasis, is essential to life.[15] Within the vascular system, blood remains in a fluid state, transporting oxygen, nutrients, plasma proteins, and waste. With vascular injury, a dynamic interplay between **thrombogenic** (activating) and antithrombotic (inhibiting) forces result in the local formation of a hemostatic plug that seals the vessel wall and prevents further blood loss (Figs. 7–2, 7–3, and 7–4). A disruption of this delicate system of checks and balances may lead to inappropriate clot formation within the blood vessel that can obstruct blood flow or embolize to a distant vascular bed.

Under normal circumstances, the endothelial cells that line the inside of blood vessels maintain blood flow by producing a number of substances that inhibit platelet adherence, prevent the activation of the coagulation cascade, and facilitate **fibrinolysis**.[15,16] Vascular injury exposes the subendothelium (Fig. 7–3). Platelets readily adhere to the subendothelium, using glycoprotein Ib receptors found on their surfaces and facilitated by von Willebrand factor. This causes platelets to become activated, releasing a number of procoagulant substances that stimulate circulating platelets to expose glycoprotein IIb-IIIa receptors and allow platelets to adhere to one another, resulting in platelet aggregation. The damaged vascular tissue releases tissue factor which activates the extrinsic pathway of the coagulation cascade (Fig. 7–4).

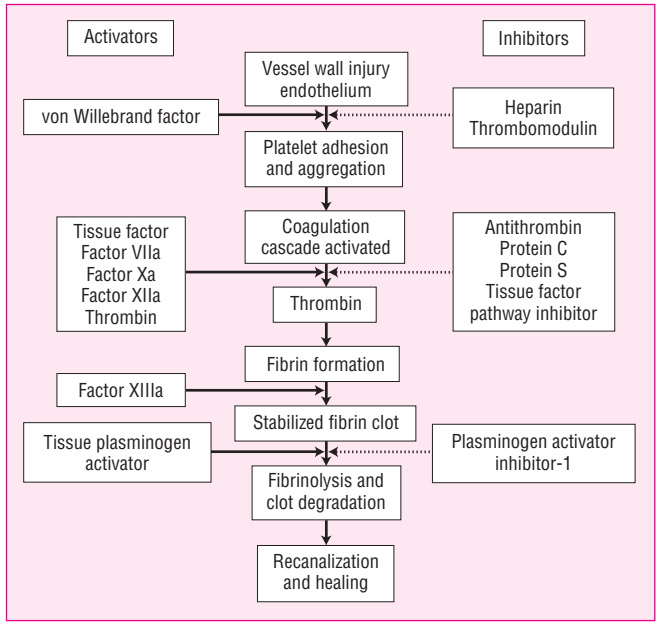

FIGURE 7–2. Hemostasis and thrombosis. (Reproduced from Haines ST, Zeolla M, Witt DM. Venous thromboembolism. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 376, with permission.)

The **clotting cascade** is a stepwise series of enzymatic reactions that result in the formation of a fibrin mesh.[15,16] Clotting factors circulate in the blood in inactive forms. Once a precursor is activated by specific stimuli, it activates the next precursor in the sequence. The final steps in the cascade are the conversion of **prothrombin** to **thrombin** and fibrinogen to **fibrin**. Thrombin plays a key role in the coagulation cascade; it is responsible not only for the production of fibrin, but also for the conversion of factors V and VIII, creating a positive feedback loop that greatly accelerates the entire cascade. Thrombin also enhances platelet aggregation. Traditionally, the coagulation cascade has been divided into three distinct parts: the intrinsic, the extrinsic, and the common pathways (Fig. 7–4). This artificial division is misleading because there are numerous interactions between the three pathways.

A number of tempering mechanisms control coagulation (Fig. 7–2).[15,16] Without effective self-regulation, the coagulation cascade would proceed unabated until all the clotting factors and platelets are consumed. The intact endothelium adjacent to the damaged tissue actively secretes several antithrombotic substances including heparan sulfate, thrombomodulin, protein C, and protein S. Activated protein C inhibits factor Va and VIIIa activity. Antithrombin and heparin cofactor II (HCII) are circulating proteins that inhibit thrombin and factor Xa. Heparan sulfate exponentially accelerates antithrombin and HCII activity. Tissue factor pathway inhibitor (TFPI) inhibits the extrinsic coagulation pathway. When these self-regulatory mechanisms are intact, the formation of the fibrin clot is limited to the zone of tissue injury. However, disruptions in the system often result in inappropriate clot formation.

The fibrinolytic protein plasmin degrades the fibrin mesh into soluble end products collectively known as fibrin split products or fibrin degradation products.[15,16] The fibrinolytic system is also under the control of a series of stimulatory and inhibitory substances. Tissue plasminogen activator (t-PA) and urokinase plasminogen activator (u-PA) convert plasminogen to plasmin. Plasminogen activator inhibitor-1 (PAI-1) inhibits the plasminogen activators and α_2-antiplasmin inhibits plasmin activity. Aberrations in the fibrinolytic system have also been linked to hypercoagulability.

CLINICAL PRESENTATION AND DIAGNOSIS

Although a thrombus can form in any part of the venous circulation, the majority begin in the lower extremities. Once formed, a venous thrombus may behave in several ways including: (1) remain asymptomatic, (2) spontaneously lyse, (3) obstruct the venous circulation, (4) propagate into more proximal veins, (5) embolize, and/or (6) slowly incorporate into the endothelial layer of the vessel.[15] The majority of patients with VTE never develop symptoms.[2] However, even those who initially experience no symptoms may suffer long-term consequences, such as the postthrombotic syndrome and recurrent VTE. ❸ *The symptoms of DVT or PE are nonspecific, and it is extremely difficult to distinguish VTE from other disorders.*[17] *Therefore, objective tests are required to confirm or exclude the diagnosis.* Patients with deep vein thrombosis often present with unilateral leg pain and swelling. Similarly, the postthrombotic syndrome, a long-term complication of DVT caused by damage to the venous valves, produces chronic lower extremity swelling, pain, tenderness, skin discoloration, and ulceration. The D-dimer test, a quantitative measure of fibrin breakdown in the serum, is a marker of acute thrombotic activity and may help to distinguish between an acute DVT and the post-thrombotic syndrome. Symptomatic PE often produces shortness of breath, tachypnea, and tachycardia. **Hemoptysis**, while distressing, occurs in less than one-third of patients. The physical exam may reveal diminished breath sounds, crackles, wheezes, or a pleural friction rub during auscultation of the lungs. Cardiovascular collapse, characterized by cyanosis, shock, and oliguria, is an ominous sign.[18]

Given that VTE can be debilitating or fatal, it is important to treat it quickly and aggressively.[8] On the other hand, because major bleeding induced by antithrombotic drugs can be equally harmful, it is important to avoid treatment when the diagnosis is not reasonably certain. Assessment of the patient's status should focus on the search for risk factors in the patient's medical history

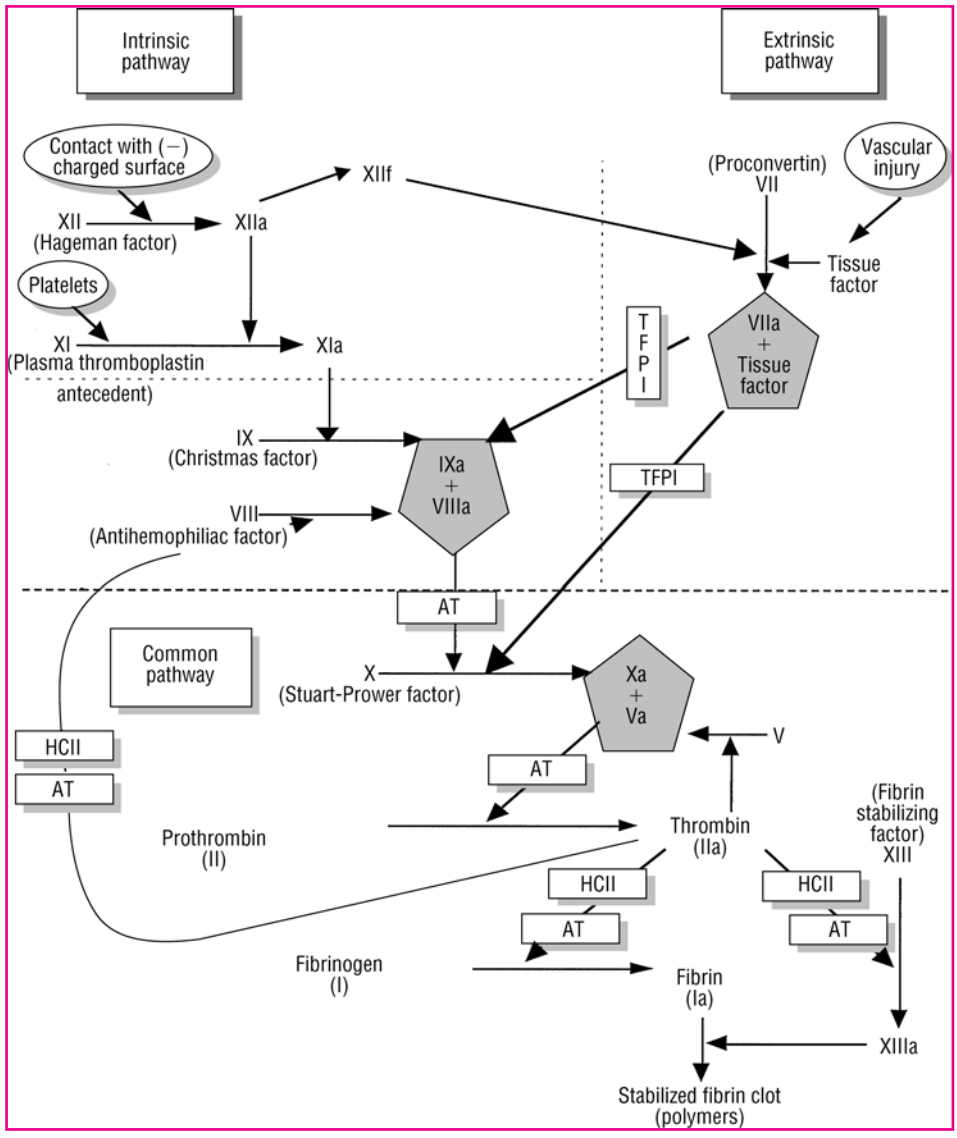

FIGURE 7–4. Coagulation cascade. AT, antithrombin; HCII, heparin cofactor II; TFPI, tissue factor pathway inhibitor. (Reproduced from Haines ST, Zeolla M, Witt DM. Venous thromboembolism. (Table 7–1).[17] Venous thrombosis is uncommon in the absence of risk factors, and the effects of these risks are additive. Conversely, even in the absence of symptoms, VTE should be strongly suspected in those with multiple risk factors.

Because radiographic contrast studies are the most accurate and reliable methods for the diagnosis of VTE, they are considered the gold standards in clinical trials.[17] Contrast venography allows visualization of the entire venous system in the lower extremities and abdomen. Pulmonary angiography allows the visualization of the pulmonary arteries. The diagnosis of VTE can be made if there is a persistent intraluminal filling defect observed on multiple x-ray films. Contrast studies are expensive, invasive procedures that are technically difficult to perform and evaluate. Severely ill patients often are unable to tolerate the procedure, and many develop hypotension and cardiac arrhythmias. Furthermore, the contrast medium is irritating to vessel walls and toxic to the kidneys. For these reasons, non-invasive tests, such as ultrasonography, computed tomography (CT) scans, and the ventilation/perfusion (V/Q) scan are frequently used in clinical practice for the initial evaluation of patients with suspected VTE.

PREVENTION OF VENOUS THROMBOEMBOLISM

Given that VTE is often clinically silent and potentially fatal, prevention strategies have the greatest potential to improve patient outcomes.[2] To rely on the early diagnosis and treatment of VTE is unacceptable because many patients will die before treatment can be initiated. Furthermore, even clinically silent disease is associated with long-term morbidity from the postthrombotic syndrome and predisposes the patient to future thromboembolic events. Despite an immense body of literature that overwhelmingly supports the widespread use of

Clinical Presentation and Diagnosis of Deep Vein Thrombosis

General

Venous thromboembolism most commonly develops in patients with identifiable risk factors (Table 7–1) during or following a hospitalization. Many, perhaps the majority of patients, have asymptomatic disease. Patients may die suddenly of pulmonary embolism.

Symptoms

- The patient may complain of leg swelling, pain, or warmth. Symptoms are non-specific and objective testing must be performed to establish the diagnosis.

Signs

- The patient's superficial veins may be dilated and a "palpable cord" may be felt in the affected leg.
- The patient may experience pain in back of the knee in the affected leg when the examiner dorsiflexes the foot while the knee is slightly bent.

Laboratory Tests

- Serum concentrations of D-dimer, a by-product of thrombin generation, is usually elevated. The patient may have an elevated erythrocyte sedimentation rate (ESR) and white blood cell (WBC) count.

Diagnostic Tests

- Duplex ultrasonography is the most commonly used test to diagnosis DVT. It is a non-invasive test that can measure the rate and direction of blood flow and visualize clot formation in proximal veins of the legs. It cannot reliably detect small blood clots in distal veins. Coupled with a careful clinical assessment, it can rule in or out (include or exclude) the diagnosis in the majority of cases.
- Venography (also known as phlebography) is the gold standard for the diagnosis of DVT. However, it is an invasive test that involves injection of radiopaque contrast dye into a foot vein. It is expensive and can cause anaphylaxis and nephrotoxicity.

Clinical Presentation and Diagnosis of Pulmonary Embolism

General

Pulmonary embolism most commonly develops in patients with risk factors for VTE (Table 7–2) during or following a hospitalization. While many patients will have symptoms of DVT prior to developing a PE, many do not. Patients may die suddenly before effective treatment can be initiated.

Symptoms

- The patient may complain of cough, chest pain, chest tightness, shortness of breath, or palpitations.
- The patient may spit or cough up blood (hemoptysis).
- The patient may complain of dizziness or lightheadedness.
- Symptoms may be confused for a myocardial infarction and objective testing must be performed to establish the diagnosis.

Signs

- The patient may have tachypnea (increased respiratory rate) and tachycardia (increased heart rate).
- The patient may appear diaphoretic (sweaty).
- The patient's neck veins may be distended.
- The examiner may hear diminished breath sounds, crackles, wheezes, or pleural friction rub during auscultation of the lungs.
- In massive PE, the patient may appear cyanotic and may become hypotensive. In such cases, oxygen saturation by pulse oximetry or arterial blood gas will likely indicate that the patient is hypoxic.
- In the worst cases, the patient may go into circulatory shock and die within minutes.

Laboratory Tests

- Serum concentrations of D-dimer, a by-product of thrombin generation, is usually elevated. The patient may have an elevated ESR and WBC count.

Diagnostic tests

- V/Q scan and CT scans are the most commonly used tests to diagnose PE. A V/Q scan measures the distribution of blood and air flow in the lungs. When there is a large mismatch between blood and air flow in one area of the lung, there is a high probability that the patient has a PE. Spiral CT scans can detect emboli in the pulmonary arteries.
- Pulmonary angiography is the gold standard for the diagnosis of PE. However, it is an invasive test that involves injection of radiopaque contrast dye into the pulmonary artery. The test is expensive and associated with a significant risk of mortality.

pharmacologic and nonpharmacologic strategies to prevent VTE, prophylaxis is underutilized in most hospitals. Even when prophylaxis is given, many patients receive prophylaxis that is less than optimal. Educational programs and computerized clinical decision support systems have been shown to improve the appropriate use of VTE prevention methods.[2]

The goal of an effective VTE prophylaxis program is to identify all patients at risk, determine each patient's level of risk, and select and implement regimens that provide sufficient protection for the level of risk. ❹ *At the time of hospital admission, all patients should be evaluated for their risk of VTE, and strategies to prevent VTE appropriate for each patient's level of risk should be routinely employed. Prophylaxis should be continued throughout the period of risk.* The risk classification criteria and recommended prophylaxis strategies published by the American College of Chest Physicians (ACCP) Conference on Antithrombotic Therapy are widely used in North America (Table 7–2).[2] Several pharmacologic and nonpharmacologic methods are effective for preventing VTE, and these can be used alone or in combination. Nonpharmacologic methods improve venous blood flow by

TABLE 7–2. Risk Classification and Consensus Guidelines for VTE Prevention[2]

Level of Risk	Calf Vein Thrombosis (%)	Symptomatic PE (%)	Fatal PE (%)	Prevention Strategies
Low				
Minor surgery, age less than 40 years, and no clinical risk factors	2	0.2	0.002	Ambulation
Moderate				
Major or minor surgery, age 40–60 years, and no clinical risk factors Major surgery, age less than 40 years, and no clinical risk factors Minor surgery, with clinical risk factor(s) Acutely ill (e.g., myocardial infarction, ischemic stroke, heart failure exacerbation), and no clinical risk factors	10–20	1–2	0.1–0.4	UFH 5000 units SC every 12 hours Dalteparin 2500 units SC every 24 hours Enoxaparin 40 mg SC every 24 hours Tinzaparin 3500 units SC every 24 hours IPC Graduated compression stockings
High				
Major surgery, age greater than 60 years, and no clinical risk factors Major surgery, age 40–60 years, with clinical risk factor(s) Acutely ill (e.g., myocardial infarction, ischemic stroke, heart failure exacerbation), with clinical risk factor(s)	20–40	2–4	0.4–1	UFH 5000 units SC every 8 hours Dalteparin 5000 units SC every 24 hours Enoxaparin 40 mg SC every 24 hours Fondaparinux 2.5 mg SC every 24 hours Tinzaparin 75 units/kg SC every 24 hours IPC
Highest				
Major lower extremity orthopedic surgery Hip fracture Multiple trauma Major surgery, age greater than 40 years, and prior history of VTE Major surgery, age greater than 40 years, and malignancy Major surgery, age greater than 40 years, and hypercoagulable state Spinal cord injury or stroke with limb paralysis	40–80	4–10	0.2–5	Adjusted dose UFH SC every 8 hours (aPTT greater than 36 seconds) Dalteparin 5000 units SC every 24 hours Desirudin 15 mg SC every 12 hours Enoxaparin 30 mg SC every 12 hours Fondaparinux 2.5 mg SC every 24 hours Tinzaparin 75 units/kg SC every 24 hours Warfarin (target INR = 2–3) IPC with UFH 5000 units SC every 8 hours

aPTT, activated partial thromboplastin time; INR, International Normalized Ratio; IPC, intermittent pneumatic compression; PE, pulmonary embolism; SC, subcutaneous; UFH, unfractionated heparin; VTE, venous thromboembolism.

mechanical means, while drug therapy prevents thrombus formation by inhibiting the coagulation cascade.

Nonpharmacologic Therapy

Ambulation as soon as possible following surgery lowers the incidence of VTE in low-risk patients.[2] Walking increases venous blood flow and promotes the flow of natural antithrombotic factors into the lower extremities. Graduated compression stockings (GCS) reduce the incidence of VTE by approximately 60% following general surgery, neurosurgery, and stroke. Compared with anticoagulant drugs, graduated compression stockings are relatively inexpensive and safe. They are a good choice in low- to moderate-risk patients when pharmacologic interventions are contraindicated. When combined with pharmacologic interventions, graduated compression stockings have an additive effect. However, some patients are unable to wear compression stockings because of the size or shape of their legs.

Similar to graduated compression stockings, intermittent pneumatic compression (IPC) devices increase the velocity of blood flow in the lower extremities.[2] These devices sequentially inflate a series of cuffs wrapped around the patient's legs from the ankles to the thighs and then deflate in 1- to 2-minute cycles. IPC has been shown to reduce the risk of VTE by more than 60% following general surgery, neurosurgery, and orthopedic surgery. Although IPC is well tolerated and safe to use in patients who have contraindications to pharmacologic therapies, it does have a few drawbacks: it is more expensive than the use of graduated compression stockings, it is a relatively cumbersome technique, and some patients may have difficulty sleeping while using it. Continuous passive motion devices, electrical calf muscle stimulation, and plantar compression system devices are also used in some institutions,

but they have not been shown to be as effective as other mechanical methods.

Inferior vena cava (IVC) filters, also known as Greenfield filters, provide short-term protection against pulmonary embolism in very-high-risk patients by preventing the **embolization** of a thrombus formed in the lower extremities into the pulmonary circulation.[2] Insertion of a filter into the IVC is a minimally invasive procedure. Despite the widespread use of IVC filters, there are very limited data regarding their effectiveness and long-term safety. The evidence suggests that IVC filters, particularly in the absence of effective antithrombotic therapy, increase the long-term risk of recurrent DVT. In the only randomized clinical trial examining the short- and long-term effectiveness of the filters in patients with a documented proximal DVT, treatment with IVC filters reduced the risk of pulmonary embolism by more than 75% during the first 12 days following insertion.[19] However, this benefit was not sustained during 2 years of follow-up and the long-term risk of recurrent deep vein thrombosis was nearly two-fold higher in those who received a filter. Although IVC filters can reduce the short-term risk of PE in patients at highest risk, they should be reserved for patients in whom other prophylactic strategies cannot be used. To further reduce the long-term risk of VTE in association with IVC filters, pharmacologic prophylaxis is necessary and warfarin therapy should begin as soon as the patient is able to tolerate it.

Pharmacologic Therapy

Numerous randomized clinical trials have extensively evaluated pharmacologic strategies for VTE prophylaxis.[2] Appropriately selected drug therapies can dramatically reduce the incidence of VTE following hip replacement, knee replacement, general surgery, myocardial infarction, and ischemic stroke (Table 7–2). The choice of medication and dose to use for VTE prevention must be based on the patient's level of risk for thrombosis and bleeding complications, as well as the cost and availability of an adequate drug therapy monitoring system.

The ACCP Conference on Antithrombotic Therapy recommended against the use of aspirin as the primary method of VTE prophylaxis.[2] Antiplatelet drugs clearly reduce the risk of coronary artery and cerebrovascular events in patients with arterial disease, but aspirin produces a very modest reduction in VTE following orthopedic surgeries of the lower extremities. The relative contribution of venous stasis in the pathogenesis of venous thrombosis compared with that of platelets in arterial thrombosis likely explains the reason for this difference.

The most extensively studied drugs for the prevention of VTE are unfractionated heparin (UFH), the low-molecular-weight heparins (LMWHs; dalteparin, enoxaparin, and tinzaparin), fondaparinux, and warfarin.[2] The LMWHs and fondaparinux provide superior protection against VTE when compared to low-dose unfractionated heparin after hip and knee replacement surgery and in other very-high-risk populations. Even so, unfractionated heparin remains a highly effective, cost-conscious choice for many patient populations, provided that it is given in the appropriate dose (Table 7–2). Low-dose UFH (5000 units every 8 or 12 hours) given subcutaneously (SC) has been shown to reduce the risk of VTE by 55% to 70% both in patients undergoing a wide range of general surgical procedures and following a myocardial infarction or stroke. For the prevention of VTE following hip and knee replacement surgery, the effectiveness of low-dose UFH is considerably lower. Adjusted-dose UFH therapy provided subcutaneously, which requires dose adjustments to maintain the activated partial thromboplastin time (aPTT) at the high end of the normal range, may be used in the highest-risk patient populations. However, adjusted-dose UFH has been studied in only a few, relatively small clinical trials and requires frequent laboratory monitoring. The LMWHs and fondaparinux appear to provide a high degree of protection against VTE in most high-risk populations. The appropriate prophylactic dose for each LMWH product is indication-specific (Table 7–2). There is no evidence that one LMWH is superior to another for the prevention of VTE. Fondaparinux was significantly more effective than enoxaparin in several clinical trials that enrolled patients undergoing high-risk orthopedic procedures, but has not been shown to reduce the incidence of symptomatic pulmonary embolism or mortality.[20] To provide optimal protection, some experts believe that the LMWHs should be initiated prior to surgery.[2]

Warfarin is another commonly used option for the prevention of VTE following orthopedic surgeries of the lower extremities.[2] Warfarin appears to be as effective as the LMWHs for the prevention of symptomatic VTE events in the highest-risk populations. When used to prevent VTE, the dose of warfarin must be adjusted to maintain an **International Normalized Ratio** (INR) between 2 and 3. Oral administration and low drug cost give warfarin some advantages over the LMWHs and fondaparinux. However, warfarin does not achieve its full antithrombotic effect for several days, requires frequent monitoring and periodic dosage adjustments, and carries a substantial risk of major bleeding. Warfarin should only be used when a systematic patient monitoring system is available.

The optimal duration for VTE prophylaxis following surgery is not well established.[2] Prophylaxis should be given throughout the period of risk. For general surgical procedures and medical conditions, once the patient is able to ambulate regularly and other risk factors are no longer present, prophylaxis can be discontinued. The risk of VTE in the first month following hospital discharge among patients who have undergone total hip replacement or hip fracture repair is very high. Therefore, extended prophylaxis for 21 to 35 days following hospital discharge with an LMWH, fondaparinux, or warfarin is recommended.

Patient Encounter 1, Part 1

KK is a 69-year-old obese female who fell on her way to church and fractured her right hip. She is hospitalized and will undergo surgery to repair her fractured right hip.

PMH
Hypertension × 12 years; dyslipidemia × 10 years; obesity × 20 years; degenerative joint disease × 5 years; recurrent urinary tract infections

FH
Non-significant

SH
Smoke one-half pack per day for 25 years; occasional alcohol use
The patient has Medicare, but due to her fixed income, has difficulty paying for medications, leading to occasional periods of non-compliance.

Current Meds
Metoprolol 100 mg by mouth twice daily
Hydrochlorothiazide 25 mg by mouth daily
Vytorin 10/40 (ezetimibe 10 mg/simvastatin 40 mg) by mouth daily
Salsalate 750 mg by mouth twice daily
Trimethoprim-sulfamethoxazole SS tablets by mouth twice daily for 7 days (last treatment was 1 month ago)
Shark cartilage 3 tablets by mouth daily
Enteric-coated aspirin 81 mg by mouth daily
Ginseng 2 tablets by mouth daily

Allergies
No known drug allergies

PE
VS: blood pressure 145/90 mm Hg; heart rate, 72; respiratory rate, 16; temperature , 37.4ºC (99.3°F); weight 280 lb (127.3 kg); body mass index (BMI) 40 kg/m^2

Labs
Within normal limits; estimated glomerular filtration rate = 74 mL/minute

- Which risk factor(s) predispose KK to VTE?
- What is KK's estimated risk for developing VTE?
- Given KK's presentation and history, create an appropriate VTE prophylaxis plan including the pharmacologic agent, dose, route and frequency of administration, duration of therapy, monitoring parameters, and patient education.

TREATMENT OF VENOUS THROMBOEMBOLISM

Desired Therapeutic Outcomes

The goal of VTE treatment is to prevent short- and long-term complications of the disease. In the short-term (i.e., the first few days to 6 months), the aim of therapy is to prevent propagation or local extension of the clot, embolization, and death. In the long-term (i.e., more than 6 months after the first event), the aim of therapy is to prevent complications, such as the postthrombotic syndrome, pulmonary hypertension, and recurrent VTE.[8, 21]

General Treatment Principles

Anticoagulant drugs are considered the mainstay of therapy for patients with VTE, and the therapeutic strategies for DVT and PE are essentially identical.[8, 22] ❺ *In the absence of contraindications, the treatment of VTE should initially include a rapid-acting anticoagulant (e.g., unfractionated heparin, low-molecular-weight heparin, or fondaparinux) overlapped with warfarin for at least 5 days and until the patient's International Normalized Ratio (INR) is greater than 2. Anticoagulation therapy should be continued for a minimum of 3 months. However, the duration of anticoagulation therapy should be based on the patient's risk of VTE recurrence and major bleeding.* The treatment of VTE can be divided into acute, subacute, and chronic phases (Fig. 7–5).[23,24] The acute treatment phase of VTE is typically accomplished by administering a fast-acting parenteral anticoagulant (Table 7–3). The subacute and chronic phase treatments of VTE are usually accomplished using oral anticoagulant agents, such as warfarin.[8,24] In certain populations, such as patients with cancer and women who are pregnant, the LMWHs are the preferred agents during subacute and chronic treatment phases.[8] In the last decade, several novel anticoagulants, such as direct thrombin inhibitors and factor Xa inhibitors have emerged as potential alternatives for the acute, subacute, and chronic phases of treatment. As data from clinical trials using these new agents in VTE treatment continue to emerge, their role in clinical practice will be better understood.[8,21]

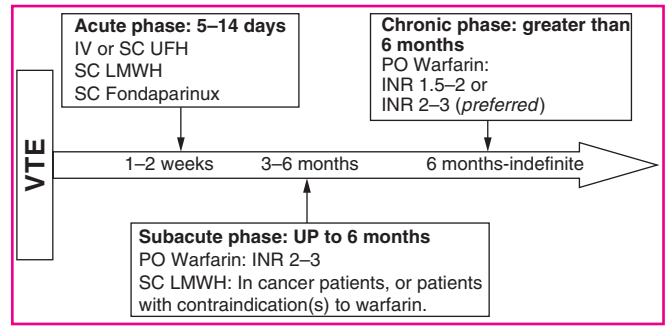

FIGURE 7–5. Treatment approach for patients with VTE. INR, International Normalized Ratio; IV, intravenous; LMWH, low-molecular-weight heparin; PO, oral; SC, subcutaneous; UFH, unfractionated heparin; VTE, venous thromboembolism. (Adapted from Nutescu EA. Emerging options in the treatment of venous thromboembolism. Am J Health Syst Pharm 2004;61(Suppl 7):S16, with permission.)

TABLE 7–3. Pharmacologic Options for the Initial Treatment of Acute VTE[21,24,34]

Unfractionated Heparin

IV administration:[a] use weight-based dosing nomogram (Table 7–5)
or
SC administration: 17,500 units given every 12 hours (an initial 5000 unit IV bolus dose is recommended to obtain rapid anticoagulation)
Adjust subsequent doses to attain a goal aPTT based on the institution-specific therapeutic range

Low-Molecular-Weight Heparins

Dalteparin:[b] 200 units/kg SC once daily **or** 100 units/kg SC twice daily
Enoxaparin: 1.5 mg/kg SC once daily **or** 1 mg/kg SC twice daily; if CrCl is less than 30 mL/minute: 1 mg/kg SC once daily
Tinzaparin: 175 units/kg SC once daily

Factor Xa Inhibitor

Fondaparinux:
For body weight less than 50 kg (110 lb) use 5 mg SC once daily
For body weight 50–100 kg (110–220 lb) use 7.5 mg SC once daily
For body weight greater than 100 kg (220 lb) use 10 mg SC once daily

[a]IV administration preferred due to improved dosing precision.
[b]Not FDA approved for treatment of VTE.
aPTT, activated partial thromboplastin time; CrCl, creatinine clearance; FDA, Food and Drug Administration; IV, intravenous; SC, subcutaneous; VTE, venous thromboembolism.

TABLE 7–4. Thrombolysis for the Treatment of VTE

- Thrombolytic therapy should be reserved for patients who present with shock, hypotension, right ventricular strain, or massive DVT with limb gangrene
- Diagnosis must be objectively confirmed before initiating thrombolytic therapy
- Thrombolytic therapy is most effective when administered as soon as possible after PE diagnosis, but benefit may extend up to 14 days after symptom onset
- Approved PE thrombolytic regimens:
  - Streptokinase 250,000 units intravenously over 30 minutes followed by 100,000 units/hour for 24 hours[a]
  - Urokinase 4400 units/kg intravenously over 10 minutes followed by 4400 units/kg/hour for 12–24 hours[a]
  - Alteplase 100 mg intravenously over 2 hours
- Factors that increase the risk of bleeding must be evaluated before thrombolytic therapy is initiated (i.e., recent surgery, trauma or internal bleeding, uncontrolled hypertension, recent stroke, or intracranial hemorrhage)
- Baseline labs should include CBC and blood typing in case transfusion is needed
- Unfractionated heparin should not be used during thrombolytic therapy. Neither the aPTT nor any other anticoagulation parameter should be monitored during the thrombolytic infusion
- aPTT should be measured following the completion of thrombolytic therapy:
  - If aPTT less than 2.5 times the control value, unfractionated heparin infusion should be started and adjusted to maintain aPTT in therapeutic range
  - If aPTT greater than 2.5 times the control value, remeasure every 2–4 hours and start unfractionated heparin infusion when aPTT is less than 2.5
- Avoid phlebotomy, arterial puncture, and other invasive procedures during thrombolytic therapy to minimize the risk of bleeding

[a]2-Hour infusions of streptokinase and urokinase are as effective and safe as alteplase. aPTT, activated partial thromboplastin time; CBC, complete cell blood count; DVT, deep vein thrombosis; PE, pulmonary embolism; VTE, venous thromboembolism.

Treatment Options

Pharmacologic Therapy

Thrombolytics

The role of **thrombolysis** in the treatment of VTE is controversial. **Thrombolytic** agents are proteolytic enzymes that have the ability to dissolve, or lyse, the fibrin clot. Thrombolytics are administered systemically or directly into the thrombus using a catheter-directed infusion.[8] Compared to anticoagulants, thrombolytics restore venous patency more quickly; however, the bleeding risk associated with their use is significantly higher.[25] In patients with DVT, thrombolytics decrease short-term pain and swelling and prevent destruction of the venous valves. It is not clear if thrombolytics decrease the incidence and severity of postthrombotic syndrome. Clinical trials have failed to show any long-term benefits from the routine use of thrombolytics; therefore, their use in the majority of patients is not recommended.[8,25] In a select group of high-risk patients with massive iliofemoral DVT who are at risk of limb gangrene, thrombolysis may be considered[8] (Table 7–4).

In patients with acute PE, the use of thrombolytics provides short-term benefits such as restoring pulmonary artery patency and hemodynamic stability.[8,26] A recent meta-analysis of nine small randomized clinical trials showed a slightly lower risk of death or recurrent PE in patients treated with thrombolytics when compared to those treated with heparin alone. However, this small benefit was offset by a higher risk of major bleeding.[27] Tissue plasminogen activator (t-PA), streptokinase, and urokinase have all been studied and are Food and Drug Administration (FDA) approved in the treatment of PE. All three agents have comparable thrombolytic capacity but t-PA has the potential advantage of a shorter infusion time. Reteplase is not currently FDA-approved for the treatment of PE, but it has also been studied. Reteplase is administered as two 10 unit IV boluses given 30 minutes apart.[8,28] Given the relative lack of data to support their routine use, thrombolytics should be reserved for select high risk circumstances (Table 7–4). Candidates for thrombolytic therapy are patients with acute massive **embolism** who are hemodynamically unstable [systolic blood pressure (SBP) less than 90 mm Hg] and at low risk for bleeding.[8] The use of thrombolytics in hemodynamically stable patients with right ventricular dysfunction is controversial but some experts support their use.

Unfractionated Heparin

Unfractionated heparin has traditionally been the drug of choice for indications requiring a rapid anticoagulation, including the acute treatment of VTE. Commercially available UFH preparations are isolated from porcine intestinal mucosa or bovine lung. Unfractionated heparin is composed of a heterogeneous mixture of glycosaminoglycans with variable length, molecular weight, and pharmacologic properties. Unlike thrombolytics, UFH and other anticoagulants will not dissolve a formed clot but prevent its propagation and growth.[5,29] Heparin exerts its anticoagulant effect by augmenting the natural anticoagulant antithrombin (AT). A specific pentasaccharide sequence on the heparin molecule binds to AT and causes a conformational change that greatly accelerates its activity (Fig. 7–6). This complex inhibits thrombin (factor IIa), as well as factors Xa, IXa, XIa, and XIIa. Thrombin and factor Xa are most sensitive to this inhibition and are inactivated in an equal 1:1 ratio. In order to inactivate thrombin, the UFH molecule needs to form a ternary complex by binding to both AT and thrombin. Only UFH molecules that are at least 18 saccharide units long are able to form this bridge between AT and thrombin. In contrast, inhibition of factor Xa does not require the formation of a ternary complex. Unfractionated heparin molecules as short as five saccharide units can catalyze the inactivation of factor Xa. Due to its nonspecific binding to cellular proteins, UFH has several limitations, including poor bioavailability when given subcutaneously and significant intra- and interpatient variability in anticoagulant response.[5,22]

Unfractionated heparin can be administered via the intravenous (IV) or subcutaneous (SC) route. When rapid anticoagulation is required, unfractionated heparin should be administered intravenously and an initial bolus dose should be given. For the treatment of VTE, UFH is generally given as a continuous IV infusion. Intermittent IV bolus dosing is associated with a higher risk of bleeding and is therefore not recommended. When given SC, the bioavailability of UFH ranges from 30% to 70%, depending on the dose given. Therefore, higher doses of unfractionated heparin must be given if the SC route of administration is used. Onset of anticoagulation is delayed by 1 to 2 hours after the SC injection. Due to the risk of hematomas and erratic absorption, intramuscular (IM) administration is not recommended. The half-life of UFH is dose dependent and ranges from 30 to 90 minutes, but may be significantly longer, up to 150 minutes, with high doses. Unfractionated heparin is eliminated by two mechanisms: (1) enzymatic degradation via a saturable zero-order process, and (2) renally via a first-order process. Lower UFH doses are primarily cleared via enzymatic processes, while higher doses are primarily renally eliminated. Clearance

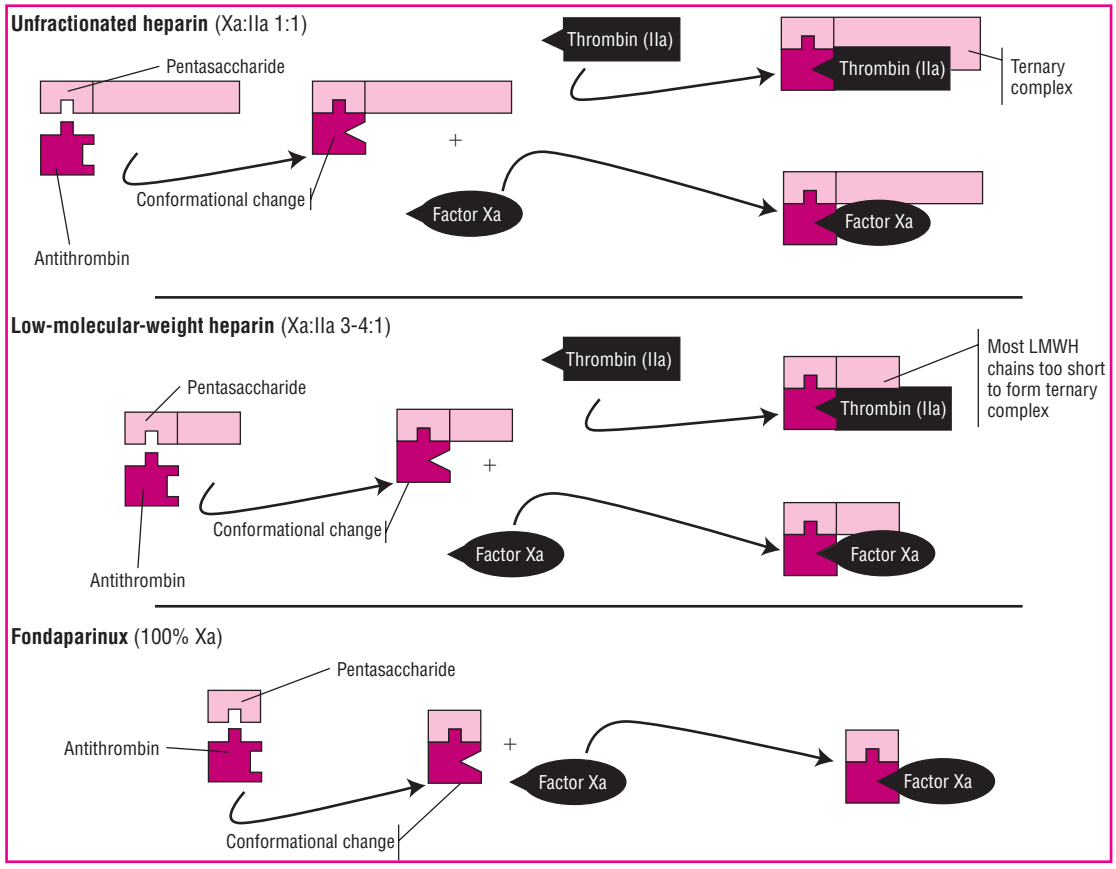

FIGURE 7–6. Mechanism of action of unfractionated heparin, low-molecular-weight heparin (LMWH), and fondaparinux. (Reproduced from Haines ST, Zeolla M, Witt DM. Venous thromboembolism. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 381, with permission.)

of UFH can be impaired in patients with renal and hepatic dysfunction. Patients with active thrombosis may require higher UFH doses due to a more rapid elimination or variations in the plasma concentrations of heparin-binding proteins. Antithrombin deficiency and elevated factor VIII levels that are common in pregnant patients have also been linked to higher UFH dose requirements. The requirement of these higher UFH doses is termed "heparin resistance."[5,15]

The dose of UFH required to achieve a therapeutic anticoagulant response is correlated to the patient's weight. Traditional dosing regimens consist of a 5000 unit bolus dose followed by an infusion administered at 1000 to 1200 units/hour.[5] However, weight-based dosing regimens are more likely to exceed the therapeutic threshold in the first 24 hours after initiating treatment.[30] Achieving a therapeutic aPTT in the first 24 hours after initiating unfractionated heparin is critical because this has been shown to lower the risk of recurrent VTE.[5,30] For non-obese patients, the actual body weight should be used to calculate the initial UFH dose (Table 7–5). For obese patients, using the actual body weight to calculate the initial dose is controversial. Some experts recommend using an adjusted body weight instead. The infusion rate is then adjusted based on laboratory monitoring of the patient's response. Unfractionated heparin can also be administered via the SC route; however, IV infusion is preferred by most clinicians because it can be dosed more precisely. If the SC route is selected, an initial 5000 unit IV bolus should be given followed by 17,500 units given SC every 12 hours. Subsequent doses of SC unfractionated heparin need to be adjusted based on the patient's response.[5,8]

TABLE 7–5. Weight-Based[a] Dosing for UFH Administered by Continuous Intravenous Infusion for Venous Thromboembolism

Initial Loading Dose	Initial Infusion Rate
80–100 units/kg (maximum = 10,000 units)	17–20 units/kg/hour (maximum = 2300 units/hour)
	Maintenance Infusion Rate
aPTT (seconds)	**Dose Adjustment**
Less than 37 (or less than 12 seconds below institution-specific therapeutic range)	80 units/kg bolus then increase infusion by 4 units/kg/hour
37–47 (or 1–12 seconds below institution-specific therapeutic range)	40 units/kg bolus then increase infusion by 2 units/kg/hour
48–71 (within institution-specific therapeutic range)	No change
72–93 (or 1–22 seconds above institution-specific therapeutic range)	Decrease infusion by 2 units/kg/hour
Greater than 93 (or greater than 22 seconds above institution-specific therapeutic range)	Hold infusion for 1 hour then decrease by 3 units/kg/hour

[a]Use actual body weight for all calculations. Adjusted body weight (ABW) may be used for obese patients (greater than 130% of IBW). ABW = IBW + (actual body weight − IBW) × 0.7.
aPTT, activated partial thromboplastin time; IBW, ideal body weight; UFH, unfractionated heparin.

❶ *Due to significant variability in interpatient response and changes in patient response over time, unfractionated heparin requires close monitoring and periodic dose adjustment.* The response to unfractionated heparin can be monitored using a variety of laboratory tests including the aPTT, the whole blood clotting time, activated clotting time (ACT), anti–factor Xa activity, and the plasma heparin concentration.[5,31] Although it has several limitations, the aPTT is the most widely used test in clinical practice to monitor UFH. Traditionally, therapeutic aPTT range is defined as 1.5 to 2.5 times the control aPTT value. However, due to variations in the reagents and instruments used to measure the aPTT in different laboratories, each institution should establish a therapeutic range for UFH. The institution-specific therapy range should correlate with a plasma heparin concentration of 0.2 to 0.4 units/mL by protamine titration or 0.3 to 0.7 units/mL by an amidolytic anti–factor Xa assay.[5,31] An aPTT should be obtained at baseline, 6 hours after initiating the heparin infusion, and 6 hours after each dose change, as this is the time required to reach steady state. The UFH dose is then adjusted based on the aPTT measurement and the institutional-specific therapeutic range. (Table 7–5) In patients with "heparin resistance," anti–factor Xa concentrations may be a more accurate method of monitoring the patient's response.[5,31]

Side effects associated with UFH include bleeding, thrombocytopenia, hypersensitivity reactions, and with prolonged use, alopecia, hyperkalemia, and osteoporosis.[22,29] ❻ *Bleeding is the most common adverse effect associated with antithrombotic drugs, including UFH therapy. A patient's risk of major hemorrhage is related to the intensity and stability of therapy, age, concurrent drug use, history of gastrointestinal bleeding, risk of falls or trauma, and recent surgery.* Several risk factors can increase the risk of unfractionated heparin–induced bleeding (Table 7–6). The risk of bleeding is related to the intensity of anticoagulation.

TABLE 7–6. Risk Factors for Major Bleeding While Taking Anticoagulation Therapy

Anticoagulation intensity (e.g., INR greater than 5, aPTT greater than 120 seconds)
Initiation of therapy (first few days and weeks)
Unstable anticoagulation response
Age greater than 65 years
Concurrent antiplatelet drug use
Concurrent non-steroidal anti-inflammatory drug or aspirin use
History of gastrointestinal bleeding
Recent surgery or trauma
High risk for fall/trauma
Heavy alcohol use
Renal failure
Cerebrovascular disease
Malignancy

aPTT, activated partial thromboplastin time; INR, International Normalized Ratio.

Higher aPTT values are associated with an increased risk of bleeding. The risk of major bleeding is 1% to 5% during the first few days of treatment. [3] In addition to the aPTT, hemoglobin, hematocrit, and blood pressure should also be monitored. Concurrent use of UFH with other antithrombotic agents, such as thrombolytics and antiplatelet agents, also increases the risk of bleeding. Patients receiving UFH therapy should be closely monitored for signs and symptoms of bleeding, including epistaxis, hemoptysis, hematuria, bright red blood per rectum, tarry stools, severe headache, and joint pain. If major bleeding occurs, UFH should be stopped immediately and the source of bleeding treated.[3,5] If necessary, use protamine sulfate to reverse the effects of UFH. The usual dose is 1 mg protamine sulfate per 100 units of UFH, up to a maximum of 50 mg, given as a slow IV infusion over 10 minutes. The effects of UFH are neutralized in 5 minutes, and the effects of protamine persist for 2 hours. If the bleeding is not controlled or the anticoagulant effect rebounds, repeated doses of protamine may be administered.[5]

Heparin-induced thrombocytopenia (HIT) is a very serious adverse effect associated with UFH use. Platelet counts should be monitored every 2 to 3 days during the course of UFH therapy.[5] HIT should be suspected if the platelet count drops by more than 50% from baseline or to below 120,000. In patients with contraindications to anticoagulation therapy, UFH should not be administered (Table 7–7).

Unfractionated heparin is an FDA pregnancy category C drug and may be used to treat VTE during pregnancy. Unfractionated heparin should be used with caution in the peripartum period due to the risk of maternal hemorrhage. Unfractionated heparin is not secreted into the breast milk and is safe for use by women who wish to breastfeed.[14] For the treatment of VTE in children, the UFH dose is 50 units/kg bolus followed by an infusion of 20,000 units/m^2/24 hours. Alternatively, a loading dose of 75 units/kg followed by an infusion of 28 units/kg/hour if less than 12 months old and 20 units/kg/hour if greater than 1 year old may be considered.[32]

Low-Molecular-Weight Heparins

The LMWHs are smaller heparin fragments obtained by chemical or enzymatic depolymerization of UFH. Low-molecular-weight heparins are heterogeneous mixtures of glycosaminoglycans and each product has slightly different molecular weight distributions and pharmacologic properties.[5] Compared with unfractionated heparin, LMWHs have improved pharmacodynamic and pharmacokinetic properties. They exhibit less binding to plasma and cellular proteins, resulting in a more predictable anticoagulant response. Consequently, routine monitoring of anticoagulation activity and dose adjustments are not required in the majority of patients. Low-molecular-weight heparins have longer plasma half-lives, allowing once- or twice-daily administration, improved subcutaneous bioavailability, and dose-independent renal clearance. In addition, LMWHs have a more favorable side-effect profile than UFH. They are also associated with a lower incidence of HIT and osteopenia. Three LMWHs are currently available in the United States: dalteparin, enoxaparin, and tinzaparin.[5,29]

Like UFH, LMWHs prevent the propagation and growth of formed thrombi. The anticoagulant effect is mediated through a specific pentasaccharide sequence that binds to AT. The primary difference in the pharmacologic activity of UFH and LMWH is their relative inhibition of thrombin (factor IIa) and factor Xa. Smaller heparin fragments cannot bind AT and thrombin simultaneously (Fig. 7–6). Due to their smaller chain length, LMWHs have relatively greater activity against factor Xa and inhibit thrombin to a lesser degree. The anti–factor Xa:IIa activity ratio for the LMWHs range from 2:1 to 4:1. The SC bioavailability of the LMWHs is greater

TABLE 7–7. Contraindications to Anticoagulation Therapy

General
Active bleeding
Hemophilia or other hemorrhagic tendencies
Severe liver disease with elevated baseline PT
Severe thrombocytopenia (platelet count less than 20,000)
Malignant hypertension
Inability to meticulously supervise and monitor treatment
Product-Specific Contraindications
UFH
Hypersensitivity to unfractionated heparin
History of HIT
LMWHs
Hypersensitivity to low-molecular-weight heparin, unfractionated heparin, pork products, methylparaben, or propylparaben
History of HIT or suspected HIT
Fondaparinux
Hypersensitivity to fondaparinux
Severe renal insufficiency (creatinine clearance less than 30 mL/minute)
Body weight less than 50 kg (110 lb)
Bacterial endocarditis
Thrombocytopenia with a positive in vitro test for antiplatelet antibodies in the presence of fondaparinux
Lepirudin
Hypersensitivity to hirudins
Argatroban
Hypersensitivity to argatroban
Warfarin
Hypersensitivity to warfarin
Pregnancy
History of warfarin-induced skin necrosis
Inability to obtain follow-up PT/INR measurements
Inappropriate medication use or lifestyle behaviors

HIT, heparin-induced thrombocytopenia; INR, International Normalized Ratio; LMWHs, low-molecular-weight heparins; PT, prothrombin time; UFH, unfractionated heparin.

than 90%. The peak anticoagulant effect of the LMWHs is reached 3 to 5 hours after a SC dose. The elimination half-life is 3 to 6 hours and is agent-specific. In patients with renal impairment, the half-life of LMWHs is prolonged.[5,21,29]

The dose of LMWHs for the treatment of VTE is determined based on the patient's weight and administered subcutaneously once or twice daily (Table 7–3). Once-daily dosing of enoxaparin appears to be as effective as twice-daily dosing; however, some data suggest that twice-daily dosing may be more effective in patients who are obese or have cancer.[8,21] The dose of enoxaparin is expressed in milligrams, whereas the doses of dalteparin and tinzaparin are expressed in units of anti–factor Xa activity. Due to their predictable anticoagulant effect, routine monitoring is not necessary in the majority of patients.[5] Low-molecular-weight heparins have been evaluated in a large number of randomized trials and have been shown to be at least as safe and effective as UFH for the treatment of VTE.[8,21] Indeed, the rate of mortality was lower in patients treated with a LMWH in clinical trials. This mortality benefit was primarily seen in patients with cancer.[33]

Prior to initiating treatment with a LMWH, baseline laboratory tests should include PT (**prothrombin time**)/INR, aPTT, complete blood cell count (CBC), and serum creatinine. Monitor the CBC every 3 to 4 days during the first 2 weeks of therapy, and every 2 to 4 weeks with extended use.[5] Use LMWHs cautiously in patients with renal impairment. Specific dosing recommendations for patients with a creatinine clearance (CrCl) less than 30 mL/minute are currently available for enoxaparin but lacking for other agents of the class (Table 7–3). Current guidelines recommend the use of UFH over LMWH in patients with severe renal dysfunction (CrCl less than 30 mL/minute).[8]

❼ *Most patients with an uncomplicated DVT can be managed safely at home.* LMWHs can be easily administered in the outpatient setting, thus enabling the treatment of VTE at home. Several large clinical trials have demonstrated the efficacy and safety of LMWHs used for outpatient treatment of DVT.[8,34,35] Acceptance of this treatment approach has increased tremendously over the last several years among clinicians. Patients who can be treated safely at home are stable and have normal vital signs, have low bleeding risk, and have no other comorbid conditions requiring hospitalization.[34,35] Although the treatment of patients with PE in the outpatient setting is controversial, patients with submassive PE who are hemodynamically stable can be safely treated in the outpatient setting as well.[36] Patients considered for outpatient therapy need to be reliable or have adequate caregiver support and must be able to strictly adhere to the prescribed treatment regimen and recommended follow-up visits. Close patient follow-up is critical to the success of any outpatient DVT treatment program.[35] Home DVT treatment results in cost savings and improved patient satisfaction and quality of life.[8]

Laboratory methods of measuring a patient's response to LMWH may be warranted in certain situations.[5] Although controversial, measurement of anti–factor Xa activity has been the most widely used method in clinical practice and is recommended by the College of American Pathologists.[37] Monitoring of anti–factor Xa activity may be considered in adult patients who are morbidly obese (weight greater than 150 kg [330 lb] or BMI greater than 50 kg/m^2), weigh less than 50 kg (110 lb), or have significant renal impairment (CrCl less than 30 mL/minute). Laboratory monitoring may also be useful in children and pregnant women. When monitoring anti–factor Xa activity, the sample should be obtained approximately 4 hours after the SC dose is administered, when peak concentration is anticipated. The therapeutic range for anti–factor Xa activity has not been clearly defined, and there is a limited correlation between anti–factor Xa activity and safety or efficacy. For the treatment of VTE, an acceptable anti–factor Xa activity range is 0.6 to 1 unit/mL with twice-daily dosing. In patients treated with once-daily LMWH regimens, a target level between 1 and 2 units/mL is recommended by some experts.[8,37]

Similar to UFH, bleeding is the major complication associated with LMWHs. The frequency of major bleeding appears to be numerically lower with LMWHs than with UFH.[33] The incidence of major bleeding reported in clinical trials is less than 3%.[8] Minor bleeding, especially bruising at the injection site, occurs frequently. Protamine sulfate will partially reverse the anticoagulant effects of the LMWHs and should be administered in the event of major bleeding. Due to its limited binding to LMWH chains, protamine only neutralizes 60% of their antithrombotic activity. If the LMWH was administered within the previous 8 hours, give 1 mg protamine sulfate per 1 mg of enoxaparin or 100 anti–factor Xa units of dalteparin or tinzaparin. If the bleeding is not controlled, give 0.5 mg of protamine sulfate for every anti–factor Xa 100 units of LMWH. Give smaller protamine doses if more than 8 hours have lapsed since the last LMWH dose.[5]

The incidence of HIT is lower with LMWHs than with UFH. However, LMWHs cross-react with heparin antibodies in vitro and should not be given as an alternative anticoagulant in patients with a diagnosis or history of HIT.[5] Monitor platelet counts every few days during the first 2 weeks and periodically thereafter.[5]

Low-molecular-weight heparins are an excellent alternative to UFH for the treatment of VTE in pregnant women.[34] The LMWHs do not cross the placenta, and they are FDA pregnancy category B. Because the pharmacokinetics of LMWHs may change during pregnancy, monitor anti–factor Xa activity every 3 to 4 weeks to make dose adjustments.[34] Low-molecular-weight heparins have also been used to treat

VTE in pediatric patients. Children less than 1 year old require higher doses (e.g., enoxaparin 1.5 mg/kg SC every 12 hours). Monitor anti–factor Xa activity to guide dosing in children.[32]

Factor Xa Inhibitors

Fondaparinux, the first agent in this class, is an indirect inhibitor of factor Xa, and exerts its anticoagulant activity by accelerating AT. Fondaparinux contains the specific 5-saccharide sequence found in unfractionated heparin that is responsible for its pharmacologic activity. Due to its small size, fondaparinux exerts inhibitory activity specifically against factor Xa and has no effect on thrombin (factor IIa)[38] (Fig. 7–6). Fondaparinux is currently the only agent of the class that is commercially available in the United States. Idraparinux and razaxaban are anti–factor Xa inhibitors currently undergoing Phase III clinical trials. Fondaparinux and idraparinux are administered SC; razaxaban is administered orally. After SC administration, fondaparinux is completely absorbed, and peak plasma concentrations are reached within 2 to 3 hours.[38]

As synthetic drugs (unlike UFH and the LMWHs), factor Xa inhibitors cannot transmit animal pathogens, are consistent from batch-to-batch, and are available in an unlimited supply. Other favorable attributes of the anti–factor Xa inhibitors include a predictable and linear dose-response relationship, rapid onset of activity, and long half-life.[29] Factor Xa inhibitors do not require routine coagulation monitoring or dose adjustments. Fondaparinux has a half-life of 17 to 21 hours, permitting once-daily administration, but the anticoagulant effects of fondaparinux will persist for 2 to 4 days after stopping the drug. In patients with renal impairment, the anticoagulant effect persists even longer. Idraparinux has a significantly longer duration of activity and is being developed for once-weekly injection. Neither fondaparinux nor idraparinux are metabolized in the liver and therefore have few drug interactions. However, concurrent use with other antithrombotic agents will increase the risk of bleeding. Unlike the heparins, factor Xa inhibitors do not affect platelet function and do not react with the heparin platelet factor-4 (PF-4) antibodies seen in patients with HIT. Some centers use fondaparinux in patients with a history of HIT who require anticoagulation therapy.[29,38,39]

Fondaparinux has been used for the treatment of DVT and PE in two large Phase III trials and is approved by the FDA for these indications. Fondaparinux is as safe and effective as IV UFH for the treatment of PE and SC LMWH for DVT treatment.[36,40] The recommended dose for fondaparinux in the treatment of VTE is based on the patient's weight (Table 7–3). Fondaparinux is renally eliminated and accumulation can occur in patients with renal dysfunction. Due to the lack of specific dosing guidelines, fondaparinux is contraindicated in patients with severe renal impairment (CrCl less than 30 mL/minute). Baseline renal function should be measured and monitored closely during the course of therapy. Monitoring anti–factor Xa activity to guide fondaparinux dosing is not recommended.[29,38,39]

As with other anticoagulants, the major side effect associated with fondaparinux is bleeding. Fondaparinux should be used with caution in elderly patients because their risk of bleeding is higher. Patients receiving fondaparinux should be carefully monitored for signs and symptoms of bleeding. A CBC should be obtained at baseline and monitored periodically to detect the possibility of occult bleeding. In the event of major bleeding, fresh frozen plasma and factor concentrates should be given. In the case of a life-threatening bleed, recombinant factor VIIa may be considered, but this is a very costly option and it can also increase the risk of thrombosis. Fondaparinux is not reversed by protamine.[29,38,39]

Fondaparinux is pregnancy category B, but there are very limited data regarding its use during pregnancy. Use in pediatric patients has not been studied.[29,38,39]

Direct Thrombin Inhibitors (DTIs)

Given that thrombin is the central mediator of coagulation and amplifies its own production, it is a natural target for pharmacologic intervention. Direct thrombin inhibitors (DTIs) bind thrombin and prevent interactions with its substrates (Fig. 7–7). Several injectable DTIs are approved for use in the United States including lepirudin, bivalirudin, argatroban, and desirudin. Several oral DTIs are currently in

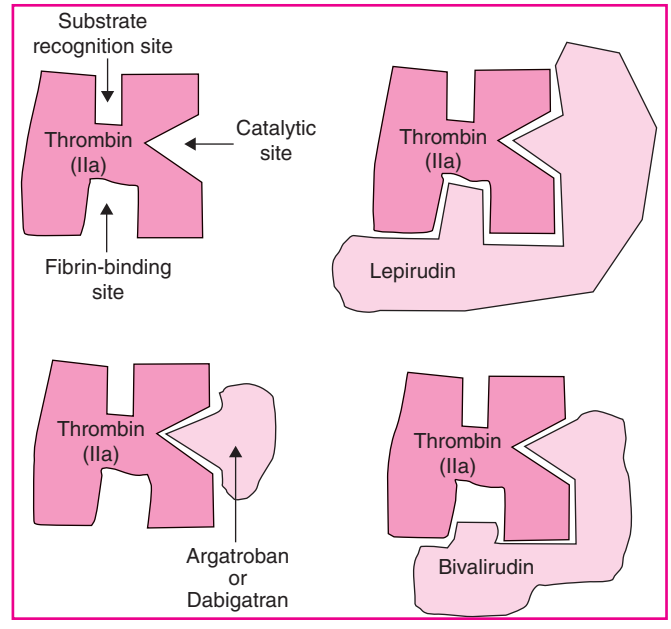

FIGURE 7–7. Mechanism of action of direct thrombin inhibitors. (Reproduced from Haines ST, Zeolla M, Witt DM. Venous thromboembolism. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 387, with permission.)

development. These agents differ in terms of their chemical structure, molecular weight, and binding to the thrombin molecule. Potential advantages of DTIs include a targeted specificity for thrombin, the ability to inactivate clot-bound thrombin, and an absence of platelet interactions that can lead to HIT. Unlike heparins, DTIs do not require antithrombin as a co-factor and do not bind to plasma proteins. Therefore they produce a more predictable anticoagulant effect. DTIs are considered the drugs of choice for the treatment of VTE in patients with a diagnosis or history of HIT.[29,38,41]

The prototype of this class is hirudin, which was originally isolated from the salivary glands of the medicinal leech, *Hirudo medicinalis*. Hirudin itself is not commercially available, but recombinant technology has permitted production of hirudin derivatives, namely lepirudin and desirudin.[29,38,41] Lepirudin has a short half-life of approximately 40 minutes after IV administration and 120 minutes when given SC. Elimination of lepirudin is primarily renal; therefore, doses must be adjusted based on the patient's renal function. The dose should be monitored and adjusted to achieve an aPTT ratio of 1.5 to 2.5 times the baseline measurement. Lepirudin is currently approved for use in patients with HIT and related thrombosis. Up to 40% of patients treated with lepirudin will develop antibodies to the drug.[29,38,41]

Bivalirudin, a smaller-molecular-weight DTI, is given by IV infusion. Bivalirudin has a shorter elimination half-life (~25 minutes) than lepirudin and is only partially eliminated renally. Unlike lepirudin, bivalirudin is a reversible inhibitor of thrombin and provides transient antithrombotic activity. Patients with moderate or severe renal impairment (CrCl less than 60 mL/minute) may require dose adjustment because clearance of bivalirudin is reduced by approximately 20% in these patients. Bivalirudin is approved for use in patients with unstable angina undergoing percutaneous transluminal coronary angioplasty. The activated clotting time is used to monitor the anticoagulant effect of bivalirudin during percutaneous coronary intervention (PCI).[29,38,41]

Desirudin is a SC administered DTI approved for VTE prevention after hip replacement surgery but is not yet commercially available in the United States. Desirudin has an elimination half-life of 2 to 3 hours and is typically dosed every 12 hours. It is primarily eliminated through the kidneys, so dose reduction is needed in patients with renal impairment. The aPTT should be used to measure desirudin's anticoagulant activity.[29,38,41]

Argatroban is a small synthetic molecule that binds reversibly to the active site of thrombin (Fig. 7–7). Argatroban is IV administered and has a 40 to 50 minute elimination half-life. The aPTT must be monitored to assess its anticoagulant activity. Argatroban is hepatically metabolized; therefore, dose reductions and careful monitoring are recommended in patients with hepatic dysfunction. Renal impairment has no influence on the elimination half-life or dosing of argatroban. Argatroban is approved for prevention and treatment of thrombosis in patients with HIT and in patients with HIT undergoing PCI.[29,38,41]

Small-molecule direct thrombin inhibitors have been structurally modified for oral administration. Approximately 10 oral DTIs are in development. There was considerable excitement about ximelagatran, the first oral DTI to complete several large Phase III clinical trials.[29,38,41] Ximelagatran was given in fixed doses without laboratory monitoring for VTE prophylaxis and acute and long-term VTE treatment. While these studies showed that ximelagatran was as effective as standard treatment regimens, the FDA denied its approval due to concerns regarding liver toxicity. Dabigatran is another promising oral DTI that is currently undergoing Phase III clinical trials for the treatment of VTE.

Contraindications to the use of DTIs and risk factors for bleeding are similar to those of other antithrombotic agents (Tables 7–6 and 7–7). Bleeding is the most common side effect reported with the use of DTIs. Concurrent use of DTIs with thrombolytics significantly increases bleeding complications. Currently, there are no known antidotes to reverse the effects of the DTIs. Fresh frozen plasma, factor concentrates, or recombinant factor VIIa should be given in the event of a major bleed. DTIs can increase the PT/INR and can interfere with the accuracy of monitoring and dosing of warfarin therapy. Data on the use of DTIs in pregnancy and pediatric patients are very limited.[29,38,41]

Warfarin

Warfarin has been the primary oral anticoagulant used in the United States for the past 60 years. Warfarin is the anticoagulant of choice when long-term or extended anticoagulation is required. Warfarin is FDA-approved for the prevention and treatment of VTE, as well as the prevention of thromboembolic complications in patients with myocardial infarction, atrial fibrillation, and heart valve replacement. While very effective, warfarin has a narrow therapeutic index, requiring frequent dose adjustments and careful patient monitoring.[15,29]

Warfarin exerts its anticoagulant effect by inhibiting the production of the vitamin K–dependent coagulation factors II (prothrombin), VII, IX, and X, as well as the anticoagulant proteins C and S (Fig. 7–8). Warfarin has no effect on circulating coagulation factors that have been previously formed, and its full antithrombotic activity is delayed for 7 to 15 days. This delay is related to half-lives of the clotting factors: 60 to 100 hours for factor II (prothrombin), 6 to 8 hours for factor VII, 20 to 30 hours for factor IX, and 24 to 40 hours for factor X. Proteins C and S, the natural anticoagulants, are inhibited more rapidly due to their shorter half-lives, 8 to 10 hours and 40 to 60 hours, respectively. Reductions in the concentration of natural anticoagulants before the clotting factors are depleted can lead to a paradoxical **hypercoagulable state** during the first few days of warfarin therapy. It is for this reason that patients with acute thrombosis should receive a fast-acting anticoagulant

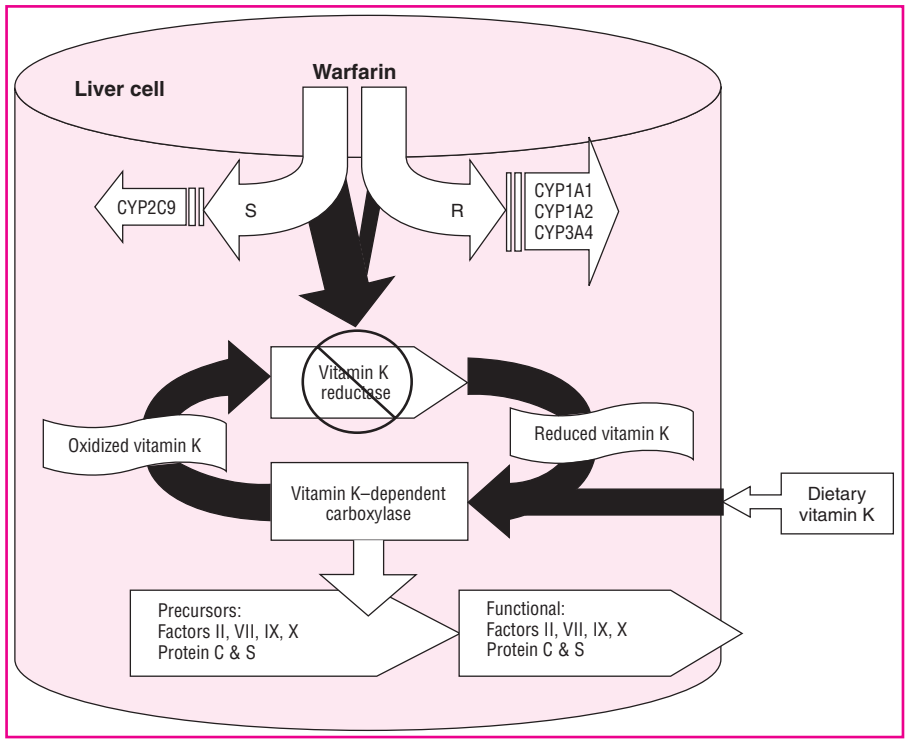

FIGURE 7–8. Pharmacologic activity and metabolism of warfarin. CYP, cytochrome P-450 isoenzyme**.** (Reproduced from Haines ST, Zeolla M, Witt DM. Venous thromboembolism. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 389, with permission.)

(heparin, LMWH, or fondaparinux) while transitioning to warfarin therapy.[4,29,34]

Warfarin is a racemic mixture of two isomers, the S and the R forms. The S-isomer is two to five times more potent than the R-isomer. Both isomers are extensively bound to albumin. The two isomers are metabolized in the liver via several isoenzymes including cytochrome P-450 (CYP)1A2, 2C9, 2C19, 2C18, and 3A4 (Fig. 7–8). Hepatic metabolism of warfarin varies greatly among patients, leading to very large interpatient differences in dose requirements and genetic variations in these isoenzymes; specifically, polymorphisms in the CYP2C9*2, CYP2C9*3, and the VKORC1 haplotypes result in a significantly lower warfarin dose requirement to achieve a therapeutic response.[4,42]

Warfarin does not follow linear kinetics. Small dose adjustments can lead to large changes in anticoagulant response. The dose of warfarin is determined by each patient's individual response to therapy and the desired intensity of anticoagulation. In addition to hepatic metabolism, warfarin dose requirements are influenced by diet, drug-drug interactions, and health status. Therefore, the dose of warfarin must be determined by frequent clinical and laboratory monitoring.[4,22,34] While there are conflicting data regarding the optimal warfarin induction regimen, most patients can start with 5 mg daily and subsequent doses are determined based on INR response (Fig. 7–9). When initiating therapy, it is difficult to predict the precise warfarin maintenance dose that a patient will require. Patients who are younger (less than 55 years of age) and otherwise healthy can safely use higher warfarin "initiation" doses (e.g., 7.5 or 10 mg). A more conservative "initiation" dose (e.g., 5 mg or less) should be given to elderly patients (greater than 75 years of age); patients with heart failure, liver disease, or poor nutritional status; and patients who are taking interacting medications or are at high risk of bleeding.[4,21] Loading doses of warfarin (e.g., 15 to 20 mg) are not recommended. These large doses can lead to the false impression that a therapeutic INR has been achieved in 2 to 3 days and also increases the risk of bleeding.[4] Before initiating therapy, screen the patient for any contraindications to anticoagulation therapy and risk factors for major bleeding (Tables 7–6 and 7–7). In addition, conduct a thorough medication history including the use of prescription and over-the-counter drugs, and any herbal supplements to detect interactions that may affect warfarin dosing requirements. In patients with acute VTE, a rapid-acting anticoagulant (UFH, LMWH, or fondaparinux) should be overlapped with warfarin for a minimum of 5 days and until the INR is greater than 2 and stable. This is important because the full antithrombotic effect will not be reached until 5 to 7 days or even longer after initiating warfarin therapy.[4,8] The typical maintenance dose of warfarin for most patients will be between 25 and 55 mg per week, although some patients require higher or lower doses. Adjustments in the maintenance warfarin dose should be determined on the total weekly dose and by reducing or increasing the weekly dose by 5% to 25%. When adjusting the maintenance dose, wait at least 7 days to ensure that a steady state has been attained on the new dose before checking the INR again. Checking the INR too soon can lead to inappropriate dose adjustments and unstable anticoagulation status.[4]

❶ *Warfarin requires frequent laboratory monitoring to ensure optimal outcomes and minimize complications.* The prothrombin

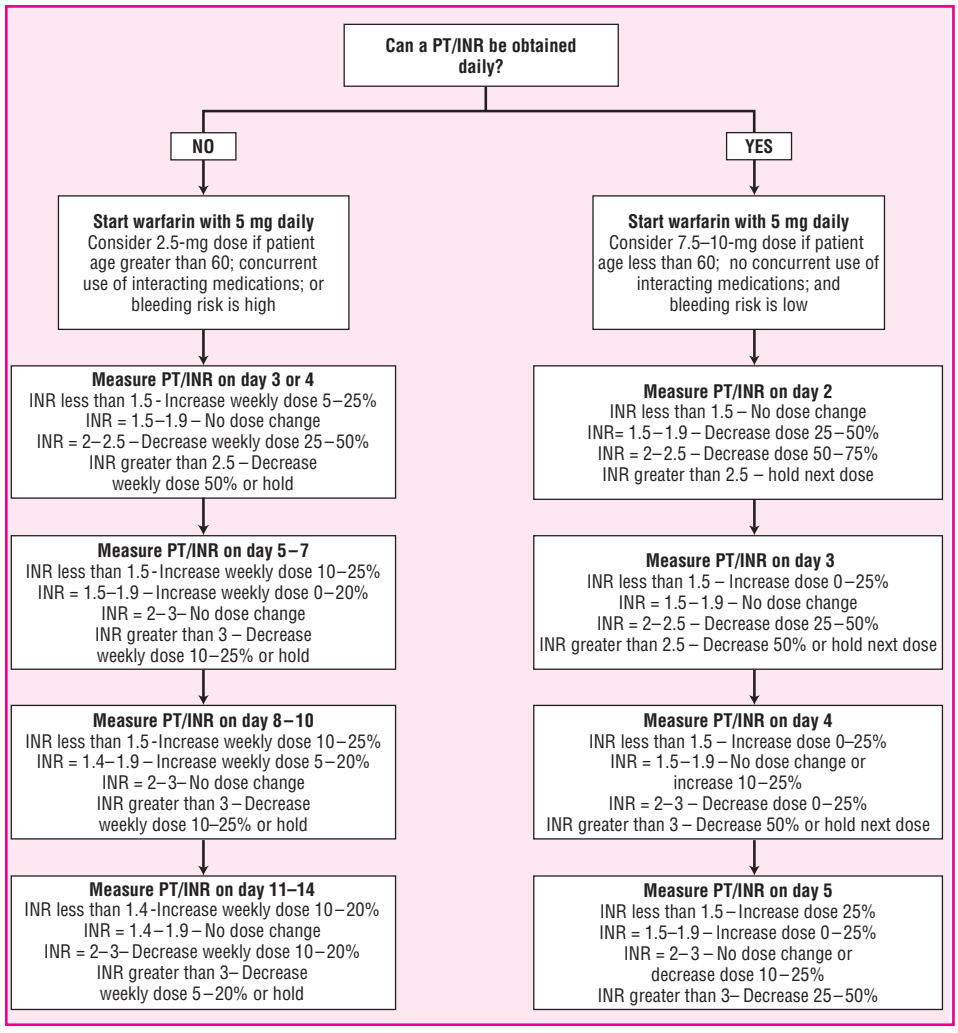

FIGURE 7–9. Initiation of warfarin therapy. INR, International Normalized Ratio; PT, prothrombin time. (Reproduced from Haines ST, Zeolla M, Witt DM. Venous thromboembolism. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 391, with permission.)

time is the most frequently used test to monitor warfarin's anticoagulant effect. The PT measures the biological activity of factors II, VII, and X. Due to wide variation in reagent sensitivity, different **thromboplastins** will result in different PT results, potentially leading to inappropriate dosing decisions.[4,22] In order to standardize result reporting, the World Health Organization (WHO) developed a reference thromboplastin and recommended the INR to monitor warfarin therapy. The INR corrects for the differences in thromboplastin reagents and uses the following formula: $INR = (PT^{Patient}/PT^{Control})_{ISI}$. The International Sensitivity Index (ISI) is a measure of the thromboplastin's responsiveness compared to the WHO reference.[4] The goal or target INR for each patient is based on the indication for warfarin therapy. For the treatment and prevention of VTE, the INR target is 2.5 with an acceptable range of 2 to 3. In certain high-risk patients (e.g., mechanical heart valves), a higher target INR of 3 with a range of 2.5 to 3.5 is recommended.[4] Before initiating warfarin therapy, a baseline PT/INR and CBC should be obtained. After initiating warfarin therapy, the INR should be monitored at least every 2 to 3 days during the first week of therapy. Once a stable response to therapy is achieved, INR monitoring is performed less frequently, weekly for the first 1 to 2 weeks, then every 2 weeks, and monthly thereafter.[4] At each encounter, carefully question the patient regarding any factors that may influence the INR result. These factors include adherence to therapy, the use of interacting medications, consumption of vitamin K–rich foods, alcohol use, and general health status. Patients should also be questioned about symptoms related to bleeding and thromboembolic events. Warfarin dose adjustments should take into account not only the INR result, but also patient-related factors that influence the result. Structured anticoagulation therapy management services (anticoagulation clinics) have been demonstrated to improve the efficacy and safety of warfarin therapy when compared to "usual" medical care. Some patients engage in self-testing and self-management by using a point of care PT/INR device approved for home use. Highly motivated and well-trained patients are good candidates for self-testing or self-management.[4,7,22,34]

❻ *Similar to other anticoagulants, warfarin's primary side effect is bleeding.* Warfarin can "unmask" an existing lesion. The incidence of warfarin-related bleeding appears to be highest during the first few weeks of therapy. The annual incidence of major bleeding ranges from 1% to 10% depending on the quality of warfarin therapy management. Bleeding in the gastrointestinal tract is most common. Intracranial hemorrhage (ICH) is one of the most serious complications, as it often causes severe disability and death. The intensity of anticoagulation therapy is related to bleeding risk. Higher INRs result in higher bleeding risk, and the risk of ICH increases when the INR exceeds 4.[3,4] Instability and wide fluctuations in the INR are also associated with higher bleeding risk. In cases of warfarin overdose or over-anticoagulation, vitamin K may be used to reverse warfarin's effect (Fig. 7–10).[4] Vitamin K can be given by the IV or oral route; the SC route is no longer recommended. When given SC, vitamin K is erratically absorbed and frequently ineffective. The IV route is reserved for cases of severe warfarin overdose (e.g., INR greater than 20) or major bleeding. Anaphylactoid reactions have been reported with rapid IV administration, therefore slow infusion is recommended. An oral dose of vitamin K will reduce the INR within 24 hours. If the INR is still elevated after 24 hours, another dose of oral vitamin K can be given. The dose of vitamin K should be based on the INR elevation. A dose of 1 to 2.5 mg is sufficient when the INR is between 5 and 9, but 5 mg may be

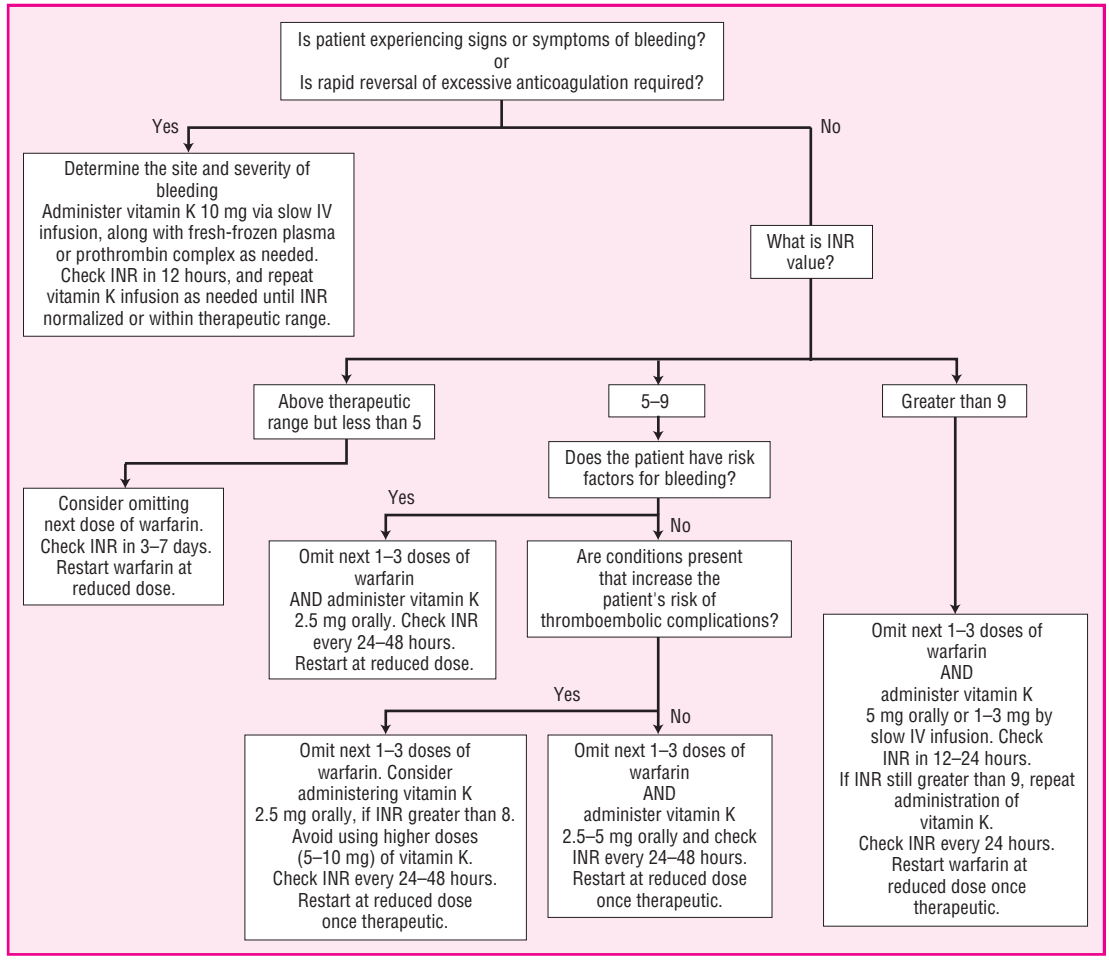

FIGURE 7–10. Management of an elevated INR in patients taking warfarin. Dose reductions should be made by determining the weekly warfarin dose and reducing the weekly dose by 10% to 25% based on the degree of INR elevation. Conditions that increase the risk of thromboembolic complications include history of hypercoagulability disorders (e.g., protein C or S deficiency, presence of antiphospholipid antibodies, antithrombin deficiency, or activated protein C resistance), arterial or venous thrombosis within the previous month, thromboembolism associated with malignancy, mechanical mitral valve in conjunction with atrial fibrillation, previous stroke, poor ventricular function, or co-existing mechanical aortic valve. INR, International Normalized Ratio; IV, intravenous. (Reproduced from Haines ST, Zeolla M, Witt DM. Venous thromboembolism. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 394, with permission.)

required for INRs greater than 9. Higher doses (e.g., 10 mg) can lead to prolonged warfarin resistance. In cases of life-threatening bleeding, fresh frozen plasma or clotting factor concentrates should be administered, in addition to IV vitamin K. In cases in whom the INR is less than 9 and there is no active bleeding or imminent risk of bleeding, simply withholding warfarin until the INR decreases to within therapeutic range and reducing the weekly dose with more frequent monitoring is appropriate.[4]

Non-hemorrhagic side effects related to warfarin are rare but can be severe when they occur. Warfarin-induced skin necrosis presents as an eggplant-colored skin lesion or a maculopapular rash that can progress to necrotic gangrene. It usually manifests in fatty areas such as the abdomen, buttocks, and breasts. The incidence is less than 0.1%, and it generally appears during the first week of therapy. Patients with protein C or S deficiency or those who receive large loading doses of warfarin are at greatest risk. The mechanism is thought to be due to imbalances between procoagulant and anticoagulant proteins early in the course of warfarin therapy. Warfarin-induced purple toe syndrome is another rare side effect; patients present with a purplish discoloration of their toes. If these side effects are suspected, warfarin therapy should be discontinued immediately and an alternative anticoagulant given. There is a theoretical risk that warfarin may cause accelerated bone loss with long-term use, but to date there is no evidence to support this concern. Warfarin is teratogenic and is FDA pregnancy category X. It should be avoided during pregnancy, and women of child-bearing potential should be instructed to use an effective form of contraception. Unfractionated heparin and LMWH are the agents of choice for the treatment of VTE during pregnancy.[4,22]

❽ *Warfarin is prone to numerous clinically significant drug-drug and drug-food interactions (Tables 7–8, 7–9, and 7–10)* Patients on warfarin should be questioned at every encounter to assess for any potential interactions with foods, drugs, herbal products, and nutritional supplements. When an interacting drug is initiated or discontinued, more frequent monitoring should be instituted. In addition, the dose of warfarin can be modified (increased or decreased) in anticipation of the expected impact on the INR.[4,43] Warfarin-related drug interactions can generally be divided into two major categories: pharmacokinetic and pharmacodynamic. Pharmacokinetic interactions are most commonly due to changes in hepatic metabolism or binding to plasma proteins. Drugs that affect the CYP2C9, CYP3A4, and CYP1A2 have the greatest impact on warfarin metabolism. Interactions that impact the metabolism of the S-isomer result in greater changes in the INR than interactions affecting the R-isomer. Pharmacodynamic drug interactions enhance or diminish the anticoagulant effect of warfarin, increasing the risk of bleeding or clotting, but may not alter the INR.[4,43] There are increasing reports regarding dietary supplements, nutraceuticals, and vitamins that can interact with warfarin.[44] Patients on warfarin may experience changes in the INR due to fluctuating intake of dietary vitamin K. Patients should be instructed to maintain a consistent diet and avoid large fluctuations in vitamin K intake rather than strictly avoiding vitamin K–rich foods.[45]

TABLE 7–8. Clinically Significant Warfarin Drug Interactions

Increase Anticoagulation Effect (↑ INR)	Decrease Anticoagulation Effect (↓ INR)	Increase Bleeding Risk
Acetaminophen	Amobarbital	Argatroban
Alcohol binge	Butabarbital	Aspirin
Allopurinol	Carbamazepine	Clopidogrel
Amiodarone	Cholestyramine	Danaparoid
Cephalosporins (with MTP side chain)	Dicloxacillin	Dipyridamole

Thrombectomy

Most cases of VTE can be successfully treated with anticoagulation. In some cases, removal of the occluding thrombus by surgical intervention may be warranted. Surgical thrombectomy can be considered in patients with massive iliofemoral DVT when there is a risk of limb gangrene due to venous occlusion. The procedure can be complicated by recurrence of thrombus formation. In patients who present with massive PE, pulmonary embolectomy can be performed in emergency cases when conservative measures have failed. Patients who are hemodynamically unstable and have a contraindication to thrombolysis are candidates for pulmonary embolectomy. Administer heparin by IV infusion to achieve a therapeutic aPTT during the operation and postoperatively. Thereafter, give warfarin for the usual recommended duration.[8,21]

TABLE 7–10. Vitamin K Content of Select Foods[a]

Very High (greater than 200 mcg)	High (100–200 mcg)	Medium (50–100 mcg)	Low (less than 50 mcg)
Brussels sprouts	Basil	Apple, green	Apple, red
Chickpea	Broccoli	Asparagus	Avocado

[a]Approximate amount of vitamin K per 100-g (3.5-oz) serving.

Patient Encounter 1, Part 2

KK has been hospitalized for right hip fracture repair. Two weeks after her discharge from the hospital, she presents to the emergency department with complaints of swelling, redness, and pain in her right lower extremity. KK states her symptoms started 3 days ago and have gotten progressively worse. During your interview, the patient states that she was sent home with a prescription for fondaparinux 2.5 mg SC daily. A duplex ultrasound shows a proximal DVT in her right lower extremity. All of her other laboratory values are within normal limits.

- Which of KK's symptoms are consistent with an acute DVT?
- Design an appropriate treatment plan for KK. Your plan should include acute and chronic therapy—specify the drug(s), dose(s), route, frequency of administration, and duration of each therapy, as well monitoring parameters, patient education, and follow-up plan.
- Assuming KK continues to take the prescription and over-the-counter medications listed in her medication history obtained during her hospitalization, should any of these medications be discontinued or changed? If changed, what alternative therapy would you recommend?
- Is KK a candidate for outpatient treatment of her DVT?

Vena Cava Interruption

Inferior vena cava (IVC) interruption is indicated in patients with PE who have a contraindication to anticoagulation therapy and in patients who have recurrent VTE while taking anticoagulation therapy.[8,46] IVC interruption is accomplished by inserting a filter through the internal jugular vein or femoral vein and advancing it into the IVC using ultrasound or fluoroscopic guidance. IVC filters reduce the short-term risk of PE, but this benefit is not sustained in the long term. The incidence of DVT at 1 year after IVC filter insertion is higher when compared to patients without filters. Survival after a PE is no different in patients with filters versus patients without filters.[19] Therefore, anticoagulation therapy should be resumed as soon as possible after filter insertion and continued as long as the filter is in place due to the high risk of DVT.[8,46] Temporary or removable filters are currently under study, and these may replace the permanent filters now used in practice.[8,46]

Compression Stockings

Postthrombotic syndrome occurs in 20% to 50% of patients within 8 years after a DVT. Wearing graduated compression stockings (GCS) after a DVT reduces the risk of PTS by as much as 50%. Current guidelines recommend the use of GCS with an ankle pressure of 30 to 40 mm Hg for 2 years after a DVT. To be effective, GCS must fit properly. Traditionally, strict bed rest has been recommended after a DVT, but this approach has now been refuted and patients should be encouraged to ambulate as tolerated.[8,34]

Patient Encounter 2, Part 1

BA is a 38-year-old female who presents to the emergency department complaining of chest pain, shortness of breath, and lightheadedness. The patient states that her symptoms started with some mild left calf pain approximately 5 days ago. She started feeling short of breath and experiencing chest pain last evening. She could not sleep and her shortness of breath has gotten progressively worse in the last several hours. BA was hospitalized because she was suspected to have a pulmonary embolism.

PMH
Obesity × 12 years; asthma

FH
Mother died of a stroke; paternal grandmother had clots in her legs

SH
The patient is a school teacher

Current meds
Albuterol (salbutamol) metered-dose inhaler as needed
Ortho-Tri-Cyclen Lo by mouth daily
Echinacea 1 to 2 tablets by mouth daily as needed
Multivitamin 1 tablet by mouth daily

Allergies
Shellfish, no known drug allergies

PE
VS: blood pressure 104/64 mm Hg; heart rate 102; respiratory rate 20; temperature 38ºC (100.4°F); weight 211 lb (96 kg); height 65 inches (165 cm)

Labs
Within normal limits; estimated glomerular filtration rate (GFR) 101 mL/minute

Procedures/Tests
Electrocardiograph: normal sinus rhythm
Chest x-ray: slightly enlarged heart
Ventilation/perfusion (V/Q) scan: high probability of PE

- What signs and symptoms are consistent with the diagnosis of PE in BA's case? What are the most likely etiologies for pulmonary embolism in this case?
- What are appropriate initial and chronic treatment options for BA?
- If unfractionated heparin is chosen as the initial anticoagulation treatment option, what is the goal aPTT?
- What is BA's goal INR for warfarin therapy?
- How long should BA remain on anticoagulation therapy?
- Given the list of medications BA took prior to hospitalization, should any of these medications be discontinued or changed? If changed, what alternative therapy would you recommend?

APPROACH TO TREATING PATIENTS WITH VENOUS THROMBOEMBOLISM

❺ *Once the diagnosis of VTE has been confirmed with an objective test, promptly start anticoagulation therapy in full therapeutic doses. If there is high clinical suspicion of VTE, anticoagulation therapy can be initiated while waiting for the results of diagnostic tests.[8] Initiate therapy with a quick-acting anticoagulant such as UFH (given IV), an LMWH (given SC), or fondaparinux (given SC) (Figs. 7–5 and 7–11). In patients with adequate renal function, the LMWHs are preferred over UFH.[8] Recent evidence also supports the use of SC fondaparinux as an alternative option to UFH or LMWH for the initial treatment of VTE.[8,21] For the long-term treatment phase, warfarin is the preferred approach except for patients with cancer, in whom an LMWH is recommended. Initiate warfarin on the first day of therapy after the first dose of UFH, LMWH, or fondaparinux is given. Overlap the injectable agent with warfarin therapy for a minimum of 5 days. Warfarin should be dosed to achieve a goal INR range of 2 to 3. Once the INR is stable and above 2, the injectable anticoagulant should be discontinued. Anticoagulation therapy is continued for a minimum of 3 months but should be given longer depending on the underlying etiology of the VTE and the patient's risk factors (Table 7–11).[8,21,34] Use a thrombolytic only if the patient has a massive iliofemoral DVT and is at risk of limb gangrene. In patients with PE, use a thrombolytic if the patient is hemodynamically unstable (i.e., SBP less than 90 mm Hg). If there is a contraindication to anticoagulation therapy or the patient has failed therapy with an anticoagulant, a vena cava filter should*

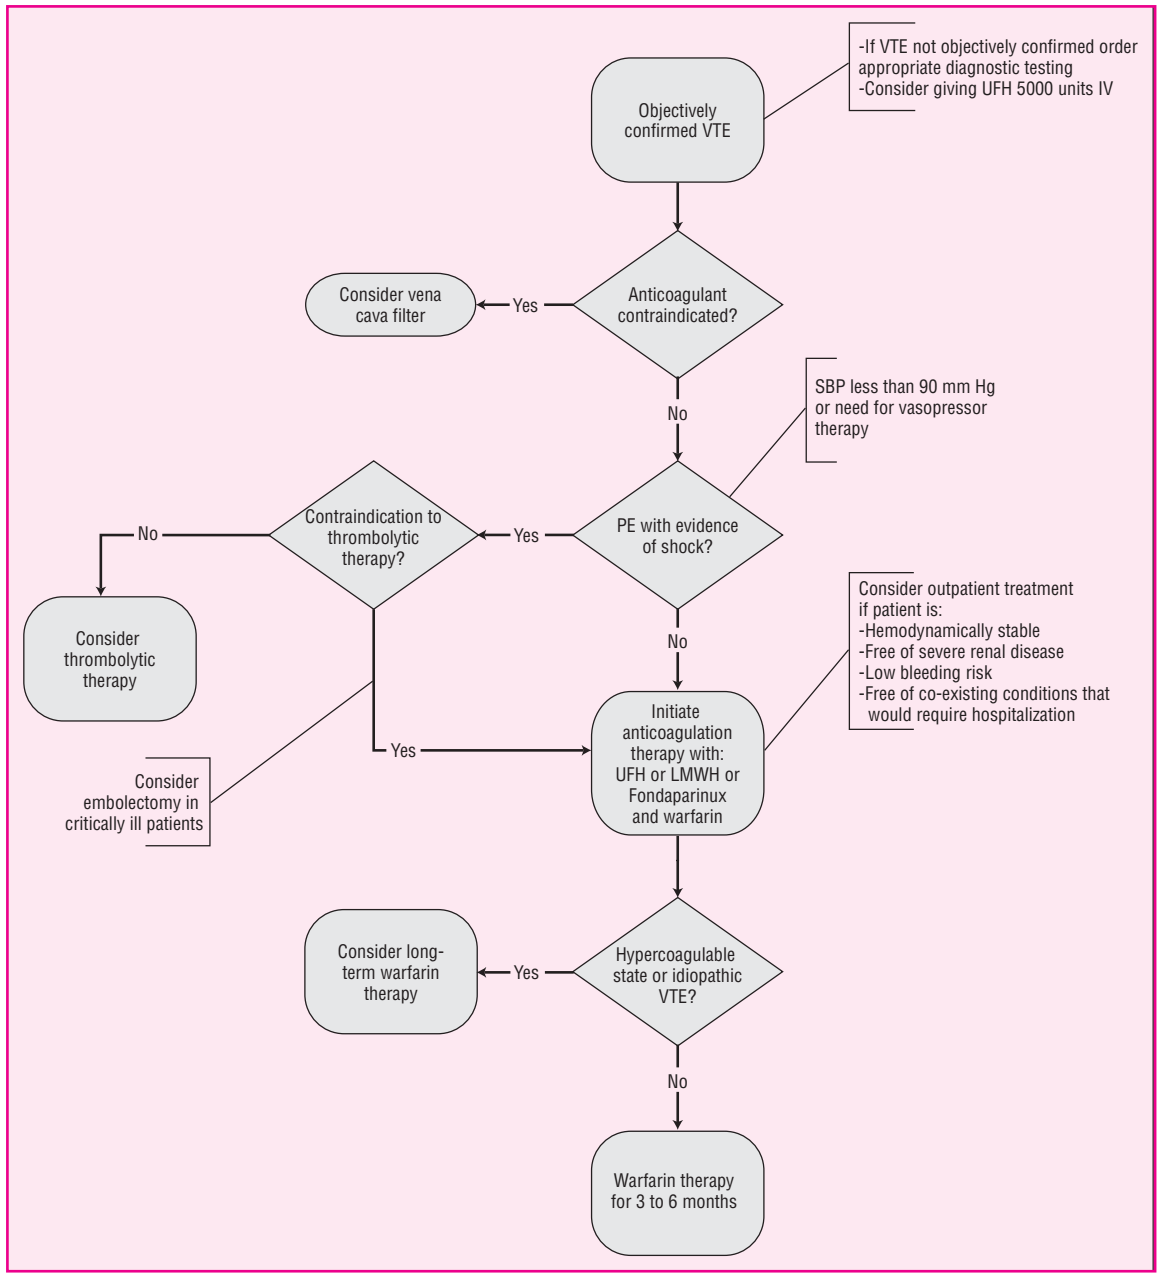

FIGURE 7–11. Treatment of venous thromboembolism. LMWH, low-molecular-weight heparin; PE, pulmonary embolism; SBP, systolic blood pressure; UFH, unfractionated heparin; VTE, venous thromboembolism. New York: McGraw-Hill; 2005: 398, with permission.)

be inserted. Encourage early ambulation as tolerated by the patient during the initial treatment phase.[8,21]

OUTCOME EVALUATION

- Achieve optimal outcomes by (1) preventing the occurrence of VTE in patients who are at risk, (2) administering effective treatments in a timely manner to patients who develop VTE, (3) preventing treatment-related complications, and (4) reducing the likelihood of long-term complications including recurrent events.
- Given that VTE is often clinically silent and potentially fatal, strategies to increase the widespread use of prophylaxis have the greatest potential to improve patient outcomes.
- Relying on the early diagnosis and treatment of VTE is unacceptable because many patients will die before treatment can be initiated.

- Effective VTE prophylaxis programs screen and identify all patients at risk, determine each patient's level of risk, and select and implement regimens that provide sufficient protection for the level of risk.
- Periodically evaluate patients who receive prophylaxis during the course of treatment for signs and symptoms of VTE, such as swelling, pain, warmth, and redness of lower extremities, and for DVT, as well as chest pain, shortness of breath, palpitations, and hemoptysis.
- Providing effective treatment in a timely manner is the primary goal for patients who develop VTE. Treat DVT and PE quickly and aggressively with effective doses of anticoagulant drugs.
- The short-term aim of therapy is to prevent propagation or local extension of the clot, embolization, and death.
- Regularly monitor patients for the development of new symptoms or worsening of existing symptoms.
- Anticoagulant drugs require precise dosing and meticulous monitoring. Closely monitor patients receiving anticoagulant therapy for signs and symptoms of bleeding, including epistaxis, hemoptysis, hematuria, bright red blood per rectum, tarry stools, severe headache, and joint pain. If major bleeding occurs, stop therapy immediately and treat the source of bleeding. In addition, closely monitor patients for potential drug-drug and drug-food interactions and adherence with the prescribed regimen.
- The long-term (i.e., more than 3 months after the first event) goals of therapy are to prevent complications such as the postthrombotic syndrome, pulmonary hypertension, and recurrent VTE.
- Encourage all patients who have had DVT to wear graduated compression stockings.
- Continue warfarin therapy for an appropriate duration based on the presence of ongoing risk factors.

Patient Encounter 2, Part 2

BA is a 38-year-old female with acute PE discharged home on warfarin therapy. She was referred to a local area antithrombosis center for monitoring of her oral anticoagulation therapy and has been maintained on warfarin 6 mg daily for the last 3 months. The patient presents today for a routine visit for anticoagulation monitoring and her INR is 8.3. She reports that 6 days ago she was started on metronidazole 500 mg by mouth twice daily, which was prescribed by her primary care physician for a vaginal infection. In addition, the primary care physician told the patient that her thyroid gland was enlarged and ordered some lab tests to determine if she has a thyroid problem. The patient has not heard what the results are. She also reports that her intake of vitamin K–rich foods (spinach, broccoli, and cabbage) has increased significantly over the last month because she is trying to lose weight. BA has no other complaints today and denies any signs or symptoms of bleeding.

- What is the most likely explanation for elevated INR in BA's case?
- Should BA be given vitamin K? If yes, discuss the dose, route of administration, and an appropriate patient monitoring plan.
- How will you manage BA's warfarin therapy? Outline a plan including specific dose changes, timing of monitoring, and patient education.

TABLE 7–11. Duration of Anticoagulation Therapy for the Treatment of VTE

Patient Characteristics	Drug	Duration of Therapy (Months)	Comments
First episode of VTE secondary to a transient (reversible) risk factor	Warfarin	3	Recommendation applies to both proximal and calf vein thrombosis
First episode of VTE and cancer	Low-molecular-weight heparin	6	Low-molecular-weight heparin is recommended over warfarin
First episode of idiopathic VTE with or without a documented hypercoagulable abnormality	Warfarin	12	Continue warfarin therapy after 12 months if patient is at low risk for bleeding
First episode of VTE with documented antiphospholipid antibodies or two or more hypercoagulable abnormalities	Warfarin	24+	Continue warfarin therapy after 24 months if patient is at low risk for bleeding
Second episode of VTE	Warfarin	24+	Continue warfarin therapy after 24 months if patient is at low risk for bleeding

VTE, venous thromboembolism.

Patient Care and Monitoring

Day 1

1. It is critical to first confirm diagnosis of VTE
- Clinical assessment: look for risk factors for VTE
- If DVT symptoms are present, obtain a venous ultrasound
- If PE is suspected, obtain a V/Q or computed tomography scan
- D-dimer: this test may be a helpful adjunct to either a venous ultrasound or V/Q scan

2. Obtain baseline laboratory tests. These tests must be obtained prior to initiating anticoagulation therapy:
- Prothrombin time (PT) and calculated International Normalized Ratio (INR)
- Activated partial thromboplastin time (aPTT)
- Serum creatinine
- Complete blood cell count (CBC) with platelets

3. Medications:
- Screen the patient's pharmacy profile for potential drug-drug interactions with anticoagulation therapy
- Initiate unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH) or fondaparinux by injection (see Table 7–3 for dosing guidelines)
- Start warfarin sodium orally every evening (see Fig. 7–9 for dosing guidelines)
- Start pain medication if necessary (avoid non-steroidal anti-inflammatory drugs)

4. Patient Education:
- Educate the patient regarding the purpose of therapy and importance of proper monitoring of anticoagulant drugs. Assist the patient to determine an appropriate provider for long-term monitoring of anticoagulation therapy.
- If LMWH or fondaparinux is selected, teach the patient how to self-administer (if the patient or a family member is unwilling or unable to self-administer, visiting nurse services should be arranged). Initial injection should be administered in the medical office or hospital.
- Inform patient about the effects of vitamin K–rich foods on warfarin therapy. Moderate intake (less than 500 to 1000 mcg) of vitamin K is acceptable. Provide patient with written material regarding vitamin K content of foods.
- Inform the patient about the potential drug-drug interactions with warfarin, including over-the-counter medications and dietary supplements (Tables 7–8, 7–9, and 7–10). Instruct the patient to call the health care practitioner responsible for monitoring warfarin therapy before starting any new medications or dietary supplements.
- Instruct the patient regarding nonpharmacologic strategies including elevation of the affected extremity and anti-embolic exercises such as flexion/extension of the ankle (for lower extremity VTE) or hand squeezing/relaxation (for upper extremity VTE).

5. Next steps:
- If the patient is to be treated at home, dispense to the patient a 5- to 7-day supply of prefilled LMWH or fondaparinux syringes in patient-specific dose.
- If the patient is to be treated with UFH, measure aPTT (or anti–factor Xa activity) 6 hours after initiating the IV infusion. Adjust dose if necessary (Table 7–5) and measure aPTT (or anti–factor Xa activity) every 6 hours after each dose change until therapeutic. Measure aPTT (or anti–factor Xa activity) daily thereafter.
- Arrange for follow-up and long-term anticoagulation therapy management. Communicate with the patient's primary care physician and/or refer to a local antithrombosis service, if available. If the patient is to be treated primarily in the hospital, these arrangements can be made 1 to 2 days prior to hospital discharge.

6. Document all activities in medical record.

Day 2

1. If the patient is being treated with UFH, remeasure aPTT (or anti–factor Xa activity), and adjust dose if necessary. If patient is being treated with LMWH or fondaparinux, continue therapy.
2. Interview the patient to determine if there is worsening or new symptoms related to VTE. Ask the patient about overt bruising or bleeding, particularly at the injection site, as well as changes in stool or urine color.
3. Advise the patient to limit physical activity if pain persists and to elevate the extremity; increase activity as tolerated.
4. Document activities in medical record.

Days 3 to 5

1. Measure PT/INR every 1 to 2 days.
2. Interview the patient to determine if there is worsening or new symptoms related to VTE. Inquire about and evaluate patient adherence to therapy. Ask the patient about overt bruising or bleeding, particularly at the injection site, as well as changes in stool or urine color. Advise the patient to limit physical activity if pain persists and to elevate the extremity; increase activity as tolerated. Reinforce previous patient education regarding vitamin K intake and potential drug-drug interactions with warfarin.
3. Hold or adjust warfarin dose as necessary. If the patient is being treated with UFH, measure aPTT daily (or anti–factor Xa activity), and adjust dose if necessary. If the patient is being treated with an LMWH or fondaparinux, continue therapy.
4. Document activities in medical record.

Days 6 to 8

1. Measure PT/INR every 2 to 3 days. Obtain CBC or platelet count.
2. Interview the patient to determine if there is worsening or new symptoms related to VTE. Inquire about and evaluate patient adherence to therapy. Ask the patient about overt bruising or bleeding, particularly at the injection site, as well as changes in stool or urine color. Advise the patient to limit physical activity if pain persists and to elevate the extremity; increase activity as tolerated. Reinforce previous patient education regarding vitamin K intake and potential drug-drug interactions with warfarin.

(*Continued*)

3. Hold or adjust warfarin dose as necessary. Discontinue UFH, LMWH, or fondaparinux if INR is greater than 2 on two consecutive occasions. If the patient requires continued treatment with UFH, measure aPTT, and adjust dose if necessary.
4. If the patient is treated with UFH or LMWH and platelet count has dropped by more than 50% from baseline or is less than $120 \times 10^3/\mu L$, evaluate the patient for heparin-induced thrombocytopenia (HIT).
5. Document activities in medical record.

Days 9 to 14

1. Measure PT/INR every 3 to 5 days.
2. Interview the patient to determine if there is worsening or new symptoms related to VTE. Inquire about and evaluate patient adherence to therapy. Ask the patient about overt bruising or bleeding, particularly at the injection site, as well as changes in stool or urine color. Advise the patient to elevate the extremity and increase activity as tolerated. Reinforce previous patient education regarding vitamin K intake and potential drug-drug interactions with warfarin.
3. Hold or adjust warfarin dose as necessary. Discontinue UFH, LMWH, or fondaparinux if INR is greater than 2 on two consecutive occasions. If the patient requires continued treatment with UFH, re-measure aPTT, and adjust dose if necessary.
4. Obtain CBC or platelet count. If the patient is treated with UFH or LMWH and platelet count has dropped by more than 50% from baseline or is less than $120 \times 10^3/\mu L$, evaluate the patient for HIT.
5. Document activities in medical record.

Days 15 to 90

1. Measure PT/INR every 1 to 4 weeks based on the stability of the INR and patient's health status.
2. Interview the patient to determine if there is worsening or new symptoms related to VTE. Inquire about and evaluate patient adherence to therapy. Ask the patient about overt bruising or bleeding as well as changes in stool or urine color. Encourage the patient to increase activity as tolerated. Reinforce previous patient education regarding vitamin K intake and potential drug-drug interactions with warfarin.
3. Adjust warfarin dose as necessary. Consider restarting LMWH or fondaparinux if INR drops below 1.5.
4. Document activities in medical record.

Three Months and Beyond

1. Measure PT/INR every 1 to 4 weeks based on the stability of the INR and patient's health status.
2. Interview the patient to determine if there is worsening or new symptoms related to VTE. Inquire about and evaluate patient adherence to therapy. Ask the patient about overt bruising or bleeding as well as changes in stool or urine color. Reinforce previous patient education regarding vitamin K intake and potential drug-drug interactions with warfarin.
3. Re-evaluate the risks and benefits of continuing warfarin therapy.
4. Document activities in medical record.

8 Stroke

Susan R. Winkler

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Understand the types of cerebrovascular disease including transient ischemic attack, cerebral infarction, and cerebral hemorrhage.
2. Understand the pathophysiology of cerebral ischemia and cerebral hemorrhage.
3. Identify the modifiable and non-modifiable risk factors associated with ischemic stroke and hemorrhagic stroke.
4. Identify risk factors for ischemic stroke in a patient and provide the appropriate patient education.
5. Discuss the various treatment options for acute ischemic stroke and hemorrhagic stroke.
6. Determine whether thrombolytic therapy is indicated in a patient with acute ischemic stroke.
7. Develop an appropriate patient-specific therapeutic plan for acute ischemic stroke.
8. Develop an appropriate therapeutic plan for outpatient management of a patient with ischemic stroke, including an appropriate agent to prevent stroke recurrence.

Key Concepts

❶ Strokes can either be ischemic (88%) or hemorrhagic (12%).

❷ Ischemic stroke is the abrupt development of a focal neurologic deficit that occurs due to inadequate blood supply to an area of the brain. Most often, this is due to a thrombotic or embolic arterial occlusion leading to cerebral infarction.

❸ Hemorrhagic stroke is a result of bleeding into the brain and other spaces within the central nervous system and includes subarachnoid hemorrhage, intracerebral hemorrhage, and subdural hematomas.

❹ There are two main classifications of cerebral ischemic events: transient ischemic attacks and cerebral infarction.

❺ A major goal in the long-term treatment of ischemic stroke involves the prevention of a recurrent stroke through the reduction and modification of risk factors.

❻ All patients should have a brain computed tomography scan or magnetic resonance imaging scan to differentiate an ischemic stroke from a hemorrhagic stroke, as the treatment will differ accordingly and thrombolytic (fibrinolytic) therapy must be avoided until a hemorrhagic stroke is ruled out.

❼ In carefully selected patients, alteplase is effective in limiting the infarct size and protecting brain tissue from ischemia and cell death by restoring blood flow. Treatment must be given within 3 hours of the onset of symptoms and offers no benefit if given beyond this time period.

❽ Early aspirin therapy is recommended in most patients with acute ischemic stroke within the first 24 to 48 hours after stroke onset and should be continued for at least 2 weeks.

❾ Aspirin is typically considered to be the first-line secondary prevention agent for ischemic stroke and decreases the risk of subsequent stroke by approximately 25% in both men and women with previous transient ischemic attacks or stroke.

❿ There is no proven treatment for intracerebral hemorrhage. Management is based on neurointensive care treatment and prevention of complications. Oral nimodipine is recommended in subarachnoid hemorrhage to prevent delayed cerebral ischemia.

EPIDEMIOLOGY AND ETIOLOGY

Cerebrovascular disease (CVD), or stroke, is the third leading cause of death in the United States and the second most common cause of death worldwide. Over 700,000 strokes occur in the United States each year. ❶ *Strokes can either be ischemic (88% of all strokes) or hemorrhagic (12% of all strokes).* Figure 8–1 provides a classification of stroke by mechanism. New strokes account for 500,000 of this total, while recurrent strokes account for the remaining 200,000 strokes each year. Stroke is the leading cause of long-term disability in adults, with 90% of survivors having residual deficits. Moderate to severe disability is seen in 70% of survivors. The American Heart Association estimates that there are 4.7 million survivors of stroke in the United States. The societal impact and economic burden is great, with costs exceeding $57 billion per year in the United States. Stroke mortality has declined due to improved recognition and treatment of risk factors; however, risk factor management is still inadequate today. Stroke incidence increases with age, especially after age 55, resulting in an increased stroke incidence due to aging of the population.[1]

❷ *Ischemic stroke is the abrupt development of a focal neurologic deficit that occurs due to inadequate blood supply to an area of the brain. Most often, this is due to a thrombotic or embolic arterial occlusion leading to cerebral infarction.* A thrombotic occlusion occurs when a **thrombus** forms inside an artery in the brain. An embolism refers to a clot originating outside of the brain in which a piece of the clot breaks loose and is carried to the brain.

❸ *Hemorrhagic stroke is a result of bleeding into the brain and other spaces within the central nervous system and includes subarachnoid hemorrhage, intracerebral hemorrhage, and subdural hematomas.* Subarachnoid hemorrhage (SAH) results from sudden bleeding into the space between the inner layer and middle layer of the **meninges**, most often due to trauma or rupture of a cerebral aneurysm or arteriovenous malformation (AVM). Intracerebral hemorrhage (ICH) is bleeding directly into the brain parenchyma, often as a result of chronic, uncontrolled hypertension. Subdural hematomas result from bleeding under the dura which covers the brain and most often occur as a result of head trauma.

PATHOPHYSIOLOGY

Classification of Cerebral Ischemic Events

❹ *There are two main classifications of ischemic events,* ***transient ischemic attack*** *(TIA) and cerebral infarction.* A TIA is a temporary reduction in perfusion to a focal region of the brain causing a short-lived disturbance of function. TIAs have a rapid onset (5 minutes) and short duration (2 to 15 minutes, up to 24 hours). The symptoms vary depending on the area of the brain affected; however, no deficit remains after the attack. A TIA may be the only warning of an impending stroke, with the greatest risk occurring in the first several weeks. Cerebral infarction is similar to a TIA; however, symptoms last longer than 24 hours, and in 90% of patients residual deficits remain after the event.

Classification of Hemorrhagic Events

A sudden severe headache, nausea and vomiting, and **photophobia** may be the first signs and symptoms of hemorrhagic stroke. Neck pain and **nuchal rigidity** may also be experienced at the time of the hemorrhage. Patients may complain that the headache is "the worst headache of my life," especially if the cause is an SAH. It is important to note that a diagnosis of the type of stroke cannot be made solely on signs and

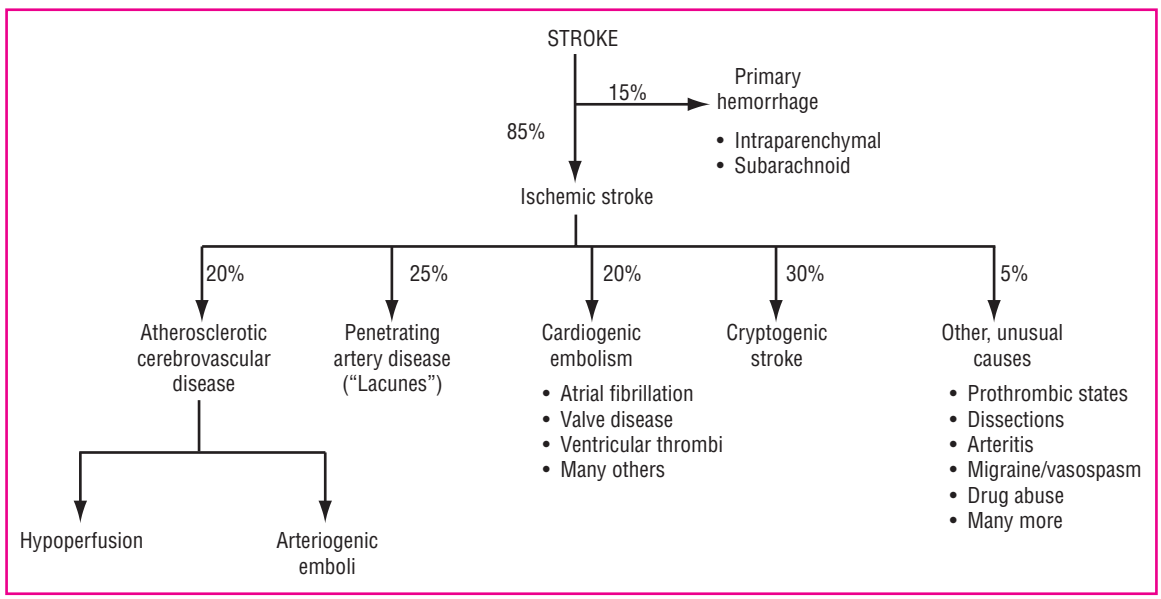

FIGURE 8–1. Classification of stroke. (Adapted from Fagan SC, Hess DC. Stroke. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 416, with permission.)

TABLE 8–1. Signs and Symptoms of Stroke

Sudden weakness, numbness, or paralysis of the face, arm, or leg (especially on one side of the body)
Loss of speech or trouble talking or understanding language
Sudden loss of vision
Sudden severe headache
Unexplained dizziness or loss of balance or coordination

symptoms, as many of these overlap between the types of stroke. Table 8–1 identifies the signs and symptoms of stroke.

Pathophysiology of Ischemic Stroke

There are three major pathophysiologic mechanisms underlying the occurrence of ischemic stroke including large-vessel disease, small-vessel disease, and embolism. In ischemic stroke, there is an interruption of the blood supply to an area of the brain either due to thrombus formation or an embolism. Loss of cerebral blood flow results in a failure of energy production in the affected brain cells. This lack of blood flow results in tissue hypoperfusion, tissue hypoxia, and cell death. Lipid deposits in the vessel wall cause turbulent blood flow and lead to vessel injury, exposing vessel collagen to blood. This vessel injury initiates the platelet aggregation process due to the exposed subendothelium. Platelets release adenosine diphosphate (ADP), which causes platelet aggregation and consolidation of the platelet plug. Thromboxane A_2 is released, contributing to platelet aggregation and vasoconstriction. The vessel injury also activates the coagulation cascade, which leads to thrombin production. Thrombin converts fibrinogen to fibrin, leading to clot formation as fibrin molecules, platelets, and blood cells aggregate. Figures 8–2 and 8–3 depict these processes.

Once the initial event occurs, secondary events occur at the cellular level that contribute to cell death. Regardless of the specific initiating event, the cellular processes that follow may be similar. Excitatory amino acids such as glutamate accumulate within the cells, causing intracellular calcium accumulation. Inflammation occurs and oxygen free radicals are formed ending in the common pathway of cell death.

Often, there is a core of ischemia containing unsalvageable brain cells. Surrounding this core is an area often termed the ischemic penumbra. In this area, cells are still salvageable; however, this is a time-sensitive endeavor, as without restoration of adequate perfusion, cell death continues throughout a larger area of the brain. This process ultimately leads to neurologic deficits. No agents have been shown to be effective at providing neuroprotection at this time.

Pathophysiology of Hemorrhagic Stroke

The pathophysiology of hemorrhagic stroke is not as well studied as that of ischemic stroke; however, it is a more complex process than previously thought. Much of the process is related to the presence of blood in the brain tissue and/or surrounding

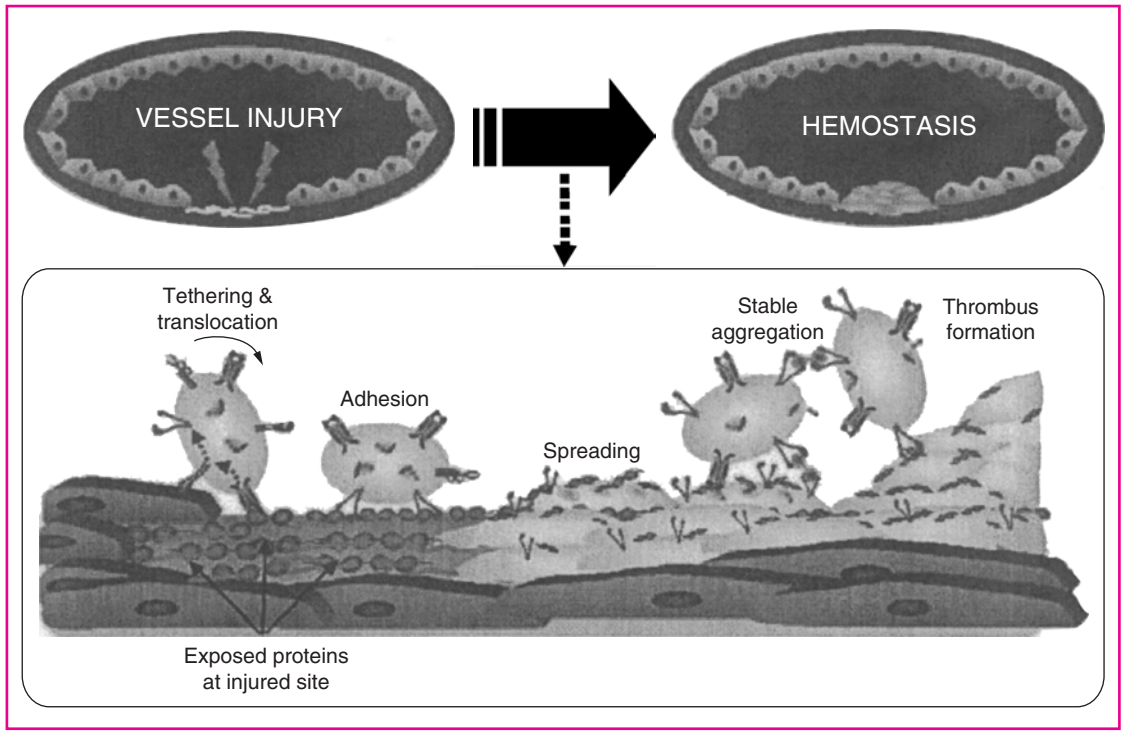

FIGURE 8–2. Platelet aggregation. This figure shows the process of platelet aggregation. Vessel injury occurs resulting in adhesion of the platelets to the vessel wall. This leads to continued adhesion and aggregation of platelets resulting in thrombus formation.

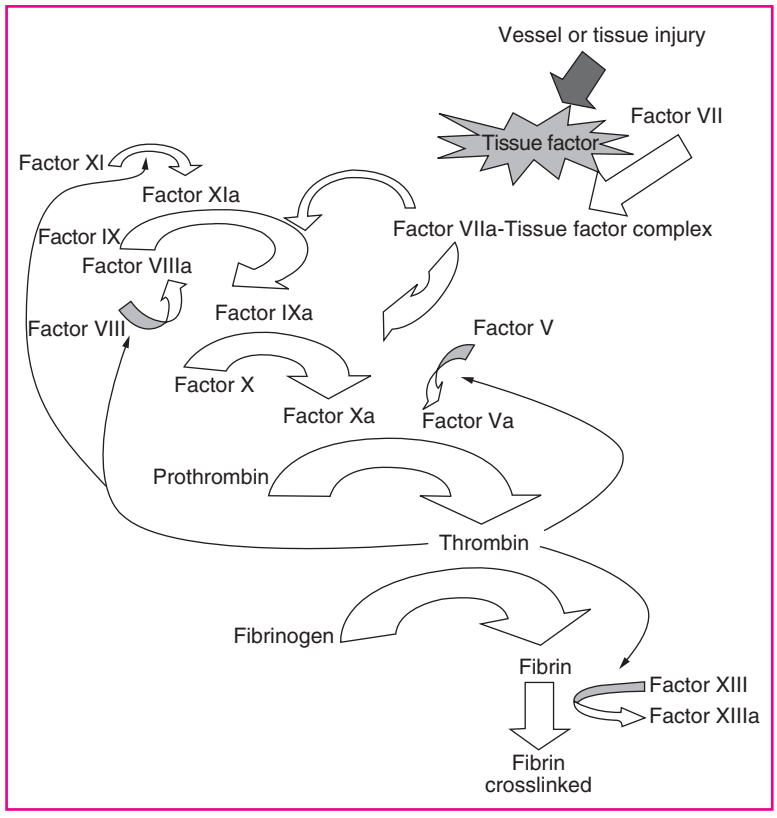

FIGURE 8–3. The physiologic clotting cascade. Clot formation beginning with vessel or tissue injury. Tissue injury starts the complex process involving clotting factors and resulting in cross-linked fibrin. This is a schematic of the factors and steps involved in the process.

spaces resulting in compression. It is now known that the hematoma that forms may continue to grow and enlarge after the initial bleed and that early growth of the hematoma is associated with a poor outcome. Brain tissue swelling and injury is a result of inflammation caused by thrombin and other blood products. This can lead to increased intracranial pressure and **herniation**.[2,3]

Risk Factors

Assessment of risk factors for ischemic stroke as well as for hemorrhagic stroke is an important component of the diagnosis and treatment of patients. ❺ *A major goal in the long-term treatment of ischemic stroke involves the prevention of a recurrent stroke through the reduction and modification of risk factors.* The major focus of primary prevention (prevention of the first stroke) is also reduction and modification of risk factors. Risk factors for ischemic stroke can be divided into modifiable and non-modifiable factors. Every patient should have risk factors assessed and treated, if possible, as management of risk factors can decrease the occurrence and/or recurrence of stroke.[4]

Non-modifiable risk factors include age, gender, race/ethnicity, and heredity. Ischemic stroke risk is increased in those greater than 55 years of age, in men, and in African-Americans, Hispanics, and Asian-Pacific Islanders. It is also increased in those with a family history of stroke. Modifiable risk factors include a number of treatable disease states and lifestyle factors that can greatly influence overall stroke risk. Hypertension is one of the major risk factors for both ischemic and hemorrhagic stroke. For ICH specifically, uncontrolled hypertension is thought to be the cause of hemorrhage in 60% to 70% of patients.[5] Other risk factors for hemorrhagic stroke include trauma, cigarette smoking, cocaine use, heavy alcohol use, and cerebral aneurysm and AVM rupture. Tables 8–2 and 8–3 provide a listing of risk factors in ischemic stroke.

DESIRED TREATMENT OUTCOMES

The short-term goals of treatment for acute ischemic stroke include reducing secondary brain damage by re-establishing and maintaining adequate perfusion to marginally ischemic areas of the brain and to protect these areas from the effects of ischemia (i.e., neuroprotection). The long-term goals of treatment include prevention of a recurrent stroke through reduction and modification of risk factors and by use of appropriate treatments.

TABLE 8–2. Non-modifiable Risk Factors for Ischemic Stroke

Age (greater than 55 years of age)
Gender (males greater than females)
Race (African-American, Hispanic, or Asian-Pacific Islander)
Ethnicity
Heredity

Clinical Presentation and Diagnosis

General

- The patient may not be able to reliably report the history owing to cognitive or language deficits. A reliable history may have to come from a family member or another witness.

Symptoms

- The patient may complain of weakness on one side of the body, inability to speak, loss of vision, **vertigo**, or falling. Stroke patients may complain of headache; however, with hemorrhagic stroke, the headache can be severe.

Signs

- Patients usually have multiple signs of neurologic dysfunction, and the specific deficits are determined by the area of the brain involved.
- **Hemiparesis** or **monoparesis** occur commonly, as does a **hemisensory deficit**.
- Patients with vertigo and double vision are likely to have posterior circulation involvement.
- **Aphasia** is seen commonly in patients with anterior circulation strokes.
- Patients may also suffer from **dysarthria**, visual field defects, and altered levels of consciousness.

Laboratory Tests

- There are no specific laboratory tests for stroke.
- Tests for hypercoagulable states, such as protein C deficiency and antiphospholipid antibody, should be done only when the cause of stroke cannot be determined based on the presence of well-known risk factors for stroke.

Other Diagnostic Tests

- A computed tomography (CT) scan of the head will reveal an area of hyperintensity (white) identifying that a hemorrhage has occurred. The CT scan will either be normal or hypointense (dark) in an area where an infarction has occurred. The CT scan may take 24 hours (rarely longer) to reveal the area of infarction.
- Magnetic resonance imaging (MRI) of the head will reveal areas of ischemia earlier and with better resolution than a CT scan. Some types of imaging can reveal an evolving infarct within minutes.
- Carotid Doppler studies will determine whether the patient has a high degree of stenosis in the carotid arteries supplying blood to the brain (extracranial disease).
- The electrocardiogram will determine whether the patient has atrial fibrillation, which is a major risk factor for stroke.
- A transthoracic echocardiogram will identify whether there are heart valve abnormalities or problems with wall motion resulting in emboli to the brain.

Patient Encounter, Part 1

GR is a 68-year-old African-American male who presents to the emergency department with dizziness and loss of speech that began 1 hour ago. His past medical history is significant for hypertension, diabetes mellitus, hypercholesterolemia, and benign prostatic hypertrophy (BPH). Social history is significant for smoking 1 pack per day for the last 38 years. Current medications include metoprolol 50 mg twice daily, insulin NPH 20 units twice daily, and simvastatin 20 mg daily.

- What signs and symptoms does GR have that are suggestive of stroke?
- What non-modifiable and modifiable risk factors does GR have for acute ischemic stroke?

The short-term goals for the treatment of hemorrhagic stroke include rapid neurointensive care treatment to maintain adequate oxygenation, breathing, and circulation. Management of increased intracranial pressure and blood pressure (BP) are important in the acute setting. Long-term management includes prevention of complications and prevention of a recurrent bleed and delayed cerebral ischemia.

Prevention of long-term disability and death related to the stroke are important regardless of the type of stroke.

TABLE 8–3. Modifiable Risk Factors for Ischemic Stroke

Hypertension (single most important risk factor)
Cardiac disease
Atrial fibrillation (most important and treatable cardiac cause of stroke)
Mitral stenosis
Mitral annular calcification
Left atrial enlargement
Structural abnormalities such as atrial-septal aneurysm
Myocardial infarction
Transient ischemic attacks or prior stroke (major independent risk factor)
Diabetes (independent risk factor)
Hypercholesterolemia
Lifestyle factors
Cigarette smoking
Excessive alcohol use
Physical inactivity
Obesity
Diet
Cocaine and intravenous drug use
Low socioeconomic status
Increased hematocrit
Sickle cell disease
Elevated homocysteine level (still under study, but may be related to stroke risk)
Migraine (risk not clear)
Asymptomatic carotid stenosis
Oral contraceptives (with estrogen content greater than 50 mcg)

GENERAL APPROACH TO TREATMENT

❻ *All patients should have a brain computed tomography (CT) scan or magnetic resonance imaging (MRI) scan to differentiate an ischemic stroke from a hemorrhagic stroke, as the treatment will differ accordingly and thrombolytic (fibrinolytic) therapy must be avoided until a hemorrhagic stroke is ruled out (in other words, until it is determined that it is not a hemorrhagic stroke).* A CT scan is the most important diagnostic test in patients with acute stroke. For those with an ischemic stroke, an evaluation should be done to determine the appropriateness of reperfusion therapy. In hemorrhagic stroke, a surgical evaluation should be completed to assess the need for surgical clipping of an aneurysm or other procedure to control the bleed and prevent re-bleeding and other complications. Figure 8–4 provides an algorithm for the initial management of the acute stroke patient.

TREATMENT OF ACUTE ISCHEMIC STROKE

Acute stroke is considered to be an acute medical emergency. Identification of the time and manner of stroke onset is an important determinant in treatment. The time the patient was last without symptoms is used as the time of stroke onset. Since patients typically do not experience pain, determining the onset time can be difficult. It is also important to document risk factors and previous functional status of the patient to assess current disability due to the stroke.

Supportive Measures

Acute complications of stroke include cerebral edema, increased intracranial pressure, seizures, and **hemorrhagic conversion**. In the acute setting, several supportive interventions and treatments to prevent acute complications should be initiated.

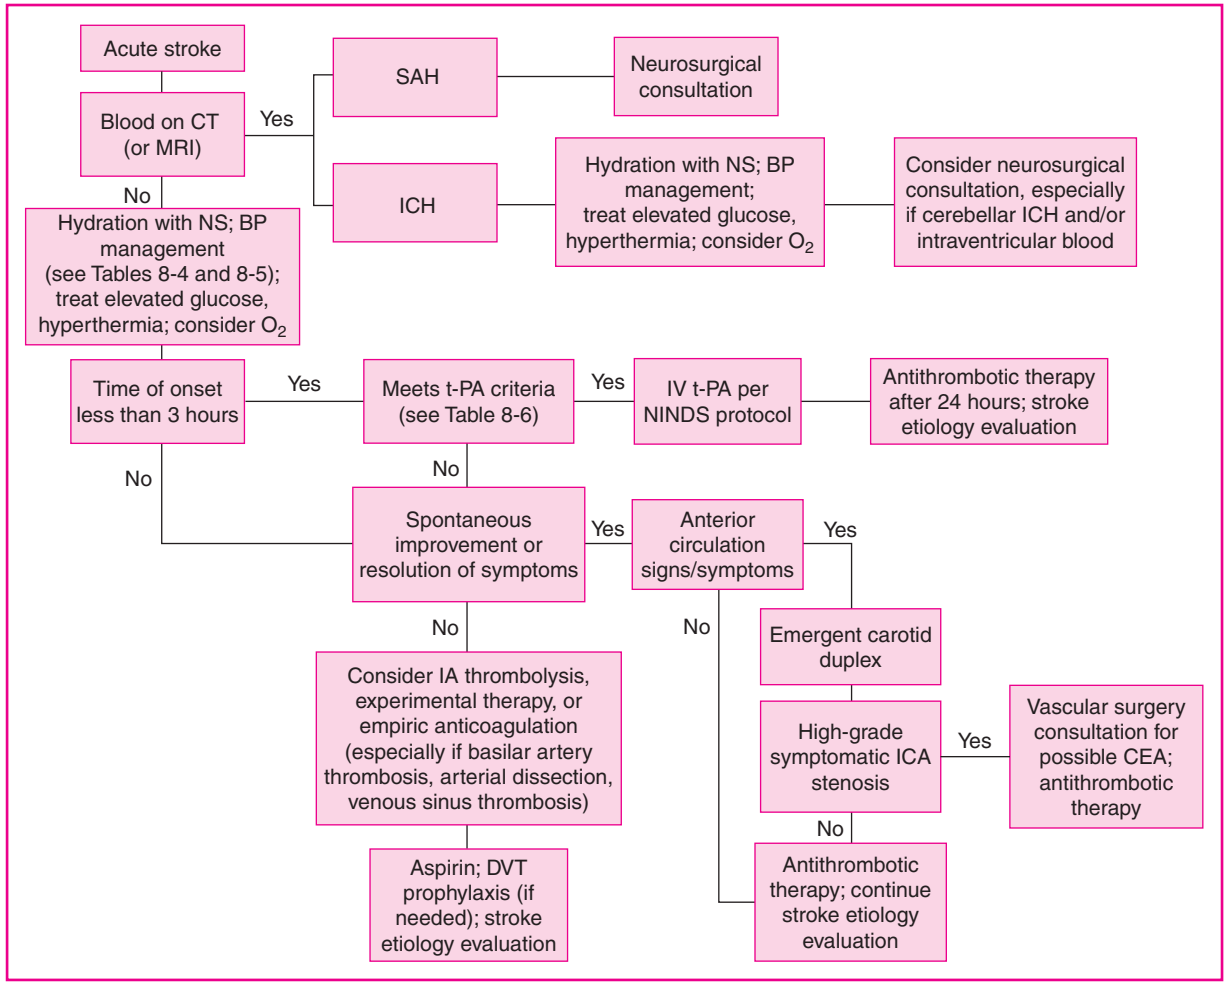

FIGURE 8–4. Acute stroke treatment algorithm. BP, blood pressure; CEA, carotid endarterectomy; CT, computed tomography; DVT, deep vein thrombosis; IA, intra-arterial; ICA, internal carotid artery; ICH, intracerebral hemorrhage; IV, intravenous; MRI, magnetic resonance imaging; NINDS, National Institute of Neurological Disorders and Stroke; NS, normal saline; SAH, subarachnoid hemorrhage; t-PA, tissue plasminogen activator.

Tissue oxygenation should be maintained acutely. Measure the oxygen saturation using pulse oximetry and supplement the patient with oxygen if necessary. The oxygen saturation should be maintained at 95% or greater.[6] Volume status and electrolytes should be corrected. If required, the blood glucose should be corrected, as both hyperglycemia and hypoglycemia may worsen brain ischemia. When hypoglycemia is present, bolus with 50% dextrose immediately. A blood glucose that is severely elevated should be lowered cautiously to less than 300 mg/dL (16.7 mmol/L) using subcutaneous insulin. If the patient is febrile, treat with acetaminophen, as fever is associated with brain ischemia and increased morbidity and mortality after stroke. Alternately, cooling devices can be used.[7] Intravenous (IV) and subcutaneous heparin will significantly decrease the risk of developing deep vein thrombosis (DVT) post-stroke. Heparin 5000 units subcutaneously every 12 hours should be given for DVT prophylaxis in patients who are not candidates for intravenous alteplase. In patients receiving IV alteplase, the administration of subcutaneous heparin should be delayed 24 hours to avoid bleeding complications.

In the setting of acute ischemic stroke, many patients will have an elevated BP in the first 24 to 48 hours.[8] Blood pressure should be optimized; however, hypertension should generally not be treated initially in acute stroke patients, as this may cause decreased blood flow in ischemic areas, potentially increasing the infarction size. The cautious use of antihypertensive medications may be necessary in patients who are otherwise candidates for thrombolytic therapy, including those with severely elevated blood pressure (systolic BP greater than 220 mm Hg or diastolic BP greater than 120 mm Hg), and those with other medical disorders requiring immediate lowering of BP. Tables 8–4 and 8–5 provide recommendations on blood pressure management in those eligible and those not eligible for alteplase. In those not eligible for alteplase, when blood pressure is lowered, aim for a 10% to 15% reduction. Avoid using sublingual calcium channel blockers, as these may lower BP too rapidly. Blood pressure should be checked three times with each reading taken 5 minutes apart.

TABLE 8–4. Blood Pressure Recommendations for Ischemic Stroke (Not Eligible for Alteplase)

Systolic BP less than 220 mm Hg or diastolic BP less than 120 mm Hg	Observe unless other end-organ involvement
Systolic BP greater than 220 mm Hg or diastolic BP 121–140 mm Hg	Labetalol 10–20 mg IV over 1–2 minutes (may repeat or double every 10 minutes); nicardipine infusion 3–5 mg/hour titrated to response
Diastolic BP greater than 140 mm Hg	Nitroprusside 0.25–0.3 mcg/kg/minute titrated to response

BP, blood pressure; IV, intravenous.

TABLE 8–5. Recommendations for Ischemic Stroke (Eligible for Alteplase)

Before treatment, if systolic BP is greater than 185 mm Hg or diastolic BP is greater than 110 mm Hg	Labetalol 10–20 mg IV over 1–2 minutes (may repeat or double every 10 minutes)
During and after treatment, if diastolic BP is greater than 140 mm Hg	Nitroprusside 0.25–0.3 mcg/kg/minute titrated to response
If systolic BP is greater than 230 mm Hg or diastolic BP is 121–140 mm Hg	Labetalol or nicardipine infusion 3–5 mg/hour titrated to response
If systolic BP is 180–230 mm Hg or diastolic BP is 105–120 mm Hg	Labetalol 10–20 mg IV over 1–2 minutes (may repeat or double every 10 minutes)

BP, blood pressure; IV, intravenous.

Nonpharmacologic Therapy

Carotid Endarterectomy and Middle Cerebral Artery Embolectomy

It is unknown whether carotid **endarterectomy** is of value when performed emergently after stroke, meaning within the first 24 hours after symptoms begin.[9] It appears that patients with mild to moderate neurologic deficits, **crescendo** TIAs or stroke-in-evolution can be operated on safely within the first few hours after the onset of symptoms. Patients with more severe neurologic deficits should only be considered for carotid endarterectomy when the procedure can be performed within the first few hours after the onset of symptoms. It is not indicated for patients with permanent deficits from a moderate to severe completed stroke.

Middle cerebral artery embolectomy remains controversial in the acute treatment of stroke. Patients who may benefit from this procedure are those who have good collateral circulation and can be operated on within the first few hours after the onset of symptoms.

Due to the lack of proven efficacy of any of these procedures when performed emergently in acute ischemic stroke, they are not routinely recommended except within a research environment.

Thrombolytic Therapy

Systemic Thrombolytic Therapy

Alteplase

Alteplase (rt-PA; Activase) is an IV thrombolytic (fibrinolytic) that was approved for acute stroke treatment in 1996 based on the results of the National Institute of Neurological Disorders and Stroke (NINDS) rt-PA Stroke Trial.[10] The current American Stroke Association guidelines include alteplase as the only Food and Drug Administration (FDA) approved acute treatment for ischemic stroke and strongly encourage early diagnosis and treatment of appropriate patients.[11]

Based on several assessment scales, patients treated with alteplase were 30% more likely to have minimal or no disability at 3 months compared with patients given placebo. Alteplase treatment resulted in an 11% to 13% absolute increase in patients with excellent outcomes at 3 months and a benefit was seen regardless of patient age, stroke sub-type, stroke severity, or prior use of aspirin.[12] Intracerebral hemorrhage within 36 hours after stroke onset occurred in 6.4% of those given alteplase versus 0.6% in those given placebo (*p* less than 0.001). There was no significant difference in mortality between the two groups at 3 months. ❼ *In carefully selected patients, alteplase is effective in limiting the infarct size and protecting brain tissue from ischemia and cell death by restoring blood flow. Treatment must be given within 3 hours of the onset of symptoms and offers no benefit if given beyond this time period.* A dose of 0.9 mg/kg (maximum 90 mg) is recommended; the first 10% is given as an IV bolus and the remainder is infused over 1 hour. Table 8–6 details the inclusion and exclusion criteria for the administration of alteplase in acute ischemic stroke.

TABLE 8–6. Inclusion and Exclusion Criteria for Alteplase Use in Acute Ischemic Stroke

Inclusion Criteria
- 18 years of age or older
- Clinical diagnosis of ischemic stroke causing a measurable neurologic deficit
- Time of symptom onset well established to be less than 180 minutes before treatment would begin

Exclusion Criteria
- Evidence of intracranial hemorrhage on CT scan of the brain prior to treatment
- Only minor or rapidly improving stroke symptoms
- Clinical presentation suggestive of subarachnoid hemorrhage even with a normal head CT
- Active internal bleeding
- Known bleeding diathesis, including but not limited to (1) platelet count less than $100 \times 10^3/mm^3$ ($100 \times 10^9/L$); (2) heparin within 48 hours with an elevated aPTT; or (3) current oral anticoagulant use (e.g., warfarin) or recent use with an elevated PT (greater than 15 seconds) or INR (greater than 1.7)
- Intracranial surgery, serious head trauma, or previous stroke within 3 months
- Suspected aortic dissection associated with stroke
- Suspected subacute bacterial endocarditis or vasculitis
- History of gastrointestinal or urinary tract hemorrhage within 21 days
- Major surgery or serious trauma within 14 days
- Recent arterial puncture at a non-compressible site
- Lumbar puncture within 7 days
- History of intracranial hemorrhage
- Known arteriovenous malformation or aneurysm
- Witnessed seizure at the same time as the onset of stroke symptoms occurred
- Recent acute myocardial infarction
- SBP greater than 185 mm Hg or DBP greater than 110 mm Hg at the time of treatment, or patient requires aggressive treatment to reduce blood pressure to within these limits

aPTT, activated partial thromboplastin time; CT, computed tomography; DBP, diastolic blood pressure; INR, International Normalized Ratio; PT, prothrombin time; SBP, systolic blood pressure.

Studies following the NINDS trial protocol have supported alteplase use in acute ischemic stroke and have shown similar rates for both response and intracerebral hemorrhage occurrence. Studies that have varied from this protocol and administered alteplase beyond the 3-hour window have failed to show a benefit to treatment. When the clinical trials are pooled, study results show that the sooner alteplase is given after acute stroke, the greater the benefit seen in neurologic outcome.[13] Current guidelines recommend against using alteplase beyond 3 hours after stroke onset, as beyond this time the risk outweighs the benefit.[12]

Antiplatelet agents, anticoagulants, and invasive procedures such as the insertion of a central line or the placement of a nasogastric tube should be avoided for 24 hours after the infusion of alteplase to prevent bleeding complications. Bladder catheterization should also be avoided for 30 minutes post-infusion.

Efficacy is measured by the elimination of existing neurologic deficits and the long-term improvement in neurologic status and functioning based on neurologic examinations and other outcome measures. Neurologic examinations should be completed every 15 minutes during the infusion of alteplase, every 30 minutes for the first 6 hours after the infusion, and then every 4 hours up to 24 hours after alteplase administration. In the NINDS trial, neurologic function was assessed 24 hours after the administration of alteplase using the National Institutes of Health Stroke Scale (NIHSS). This scale quantifies neurologic deficits in patients who have had a stroke and is easy to perform. At 3 months, four outcome measures were used including the Barthel Index, modified Rankin scale, Glasgow outcome scale, and the NIHSS. The Barthel Index is a measure of the ability to perform activities of daily living, the modified Rankin scale is a simplified overall assessment of functioning, and the Glasgow outcome scale is a global assessment of functioning.

The major adverse effects of thrombolytic therapy are bleeding, including intracerebral hemorrhage and serious systemic bleeding. Mental status changes and a severe headache may indicate an intracerebral hemorrhage. Signs of bleeding include easy bruising; hematemesis; guaiac-positive stools; black, tarry stools; hematoma formation; hematuria; bleeding gums; and nosebleeds.

Streptokinase

Streptokinase is not indicated for use in acute ischemic stroke treatment. Three large randomized controlled trials evaluating streptokinase were stopped early due to a high incidence of hemorrhage in the streptokinase-treated patients.[14–16] At the present time, there is no indication for the use of streptokinase or thrombolytics other than alteplase in the acute treatment of ischemic stroke.

Intra-arterial Thrombolytics

Intra-arterial thrombolytics may improve outcomes in selected patients with acute ischemic stroke due to large-vessel occlusion. Patients in the Prolyse in Acute Cerebral Thromboembolism II (PROACT II) trial were given 9 mg prourokinase (r-pro UK)

plus heparin or heparin alone within 6 hours of symptom onset.[17] In those patients receiving prourokinase plus heparin, 40% had slight or no disability at 90 days. In the heparin-only group, 25% had slight or no disability at 90 days. No difference in mortality was found between the groups, although the incidence of intracranial hemorrhage was greater in the r-pro UK plus heparin group versus heparin alone. Note in particular, the drug used in this trial is not FDA-approved and is not currently available for clinical use. Intra-arterial thrombolytics are typically avoided except at major stroke centers where there is more experience with this route of administration. Alteplase is the only product currently available; therefore, when intra-arterial thombolytics are given, alteplase must be used. Due to the limitations of intra-arterial thrombolysis, current guidelines recommend that treatment with IV alteplase in eligible patients not be delayed by waiting for intra-arterial thrombolytics.

Heparin

Intravenous heparin has been commonly used in acute stroke therapy; however, no adequately designed trials have been done to establish its efficacy and safety. Current acute ischemic stroke treatment guidelines do not recommend routine, urgent anticoagulation with heparin or low-molecular-weight heparins (LMWHs) due to the lack of a proven benefit in improving neurologic function and the risk of intracranial bleeding.[11,18] Heparin may prevent early recurrent stroke in patients with large-vessel atherothrombosis or those thought to be at high risk of recurrent stroke (i.e., cardioembolic stroke); however, more study is required.

The major complications of heparin include evolution of the ischemic stroke into a hemorrhagic stroke, bleeding, and thrombocytopenia. The occurrence of severe headache and mental status changes may indicate an intracerebral hemorrhage. Signs of bleeding include easy bruising; hematemesis; guaiac-positive stools; black, tarry stools; hematoma formation; hematuria; bleeding gums; and nosebleeds. The hemoglobin, hematocrit, and platelet count should be obtained at least every 3 days to detect bleeding and thrombocytopenia.

Low-Molecular-Weight Heparins and Heparinoids

Low-molecular-weight heparins and heparinoids are not recommended in the treatment of acute ischemic stroke.[11] A meta-analysis was performed using data from 10 randomized controlled trials.[19] A non-significant decrease in combined death and disability and a non-significant increase in case fatality and hemorrhage were seen. A reduction in venous thromboembolic events was observed in acute stroke patients; however, there was also an increase in extracranial bleeding.

Aspirin

Aspirin in acute ischemic stroke has been studied in two large, randomized trials, the International Stroke Trial and the Chinese Acute Stroke Trial.[20,21] Patients who received aspirin within 24 to 48 hours of the onset of acute stroke symptoms were less likely to suffer early recurrent stroke, death, and disability. **8** *Early aspirin therapy is recommended in most patients with acute ischemic stroke within the first 24 to 48 hours after stroke onset and should be continued for at least 2 weeks.* The administration of anticoagulants and antiplatelet agents should be delayed for 24 hours in those patients receiving alteplase.

Ancrod

Ancrod is an investigational agent that acts to decrease plasma fibrinogen levels. It may be beneficial in patients with acute ischemic stroke when administered within 3 hours of symptom onset. In a randomized, parallel-group, double-blind, placebo-controlled trial, an improved functional status was observed in more patients receiving ancrod (42.2%) than in patients receiving placebo (34.4%; $p = 0.04$).[22] No difference in mortality was seen between the groups; however, there was a non-significant increase in symptomatic intracranial hemorrhages in the ancrod group (5.2% versus 2.0%; $p = 0.06$). Patients received ancrod or placebo as a 72-hour continuous infusion, followed by 1-hour infusions at 96 and 120 hours. Prior to the completion of this trial, previous trials showed a trend toward an improved outcome, although the number of patients studied was small and a 6-hour treatment window was used. Based upon available clinical trials, ancrod appears to have a potential benefit. However, it is not recommended for clinical use because its efficacy and safety have not been definitively established.[11]

PREVENTION OF ACUTE ISCHEMIC STROKE

Primary Prevention

Aspirin

Randomized trials have been completed assessing the role of antiplatelet therapy with aspirin for primary stroke prevention. The use of aspirin in patients with no history of stroke or ischemic heart disease reduced the incidence of non-fatal myocardial infarction (MI) but not of stroke. A meta-analysis of eight trials found that the risk of stroke was slightly increased with aspirin use, especially hemorrhagic stroke. Major bleeding risk was also increased with aspirin use.[4] Aspirin is beneficial in the primary prevention of MI, but not for primary stroke prevention.

Statin Therapy

Hyperlipidemia has not clearly been established as a risk factor for stroke, although it is a modifiable risk factor for coronary heart disease. Recent studies show that statin use may reduce the incidence of a first stroke in high-risk patients (e.g., hypertension, coronary heart disease, or diabetes) including patients with normal lipid levels. A recent meta-analysis showed a 25% risk reduction for fatal and non-fatal strokes with statin use.[4] Patients with a history of MI, elevated lipid levels, diabetes, and

Patient Encounter, Part 2

In the emergency department an IV line is placed, a physical and neurologic exam is completed, and GR is moved to the stroke unit. The CT scan is negative for hemorrhagic stroke.

- Identify your treatment goals for GR.
- What acute management would be appropriate for GR at this point?

other risk factors may benefit from treatment with a lipid-lowering agent; however, even patients with normal lipid levels may benefit from treatment.

Blood Pressure Management

Lowering blood pressure in patients who are hypertensive has been shown to reduce the relative risk of stroke, both ischemic and hemorrhagic, by 35% to 45%.[23] Also, the more blood pressure is lowered, the greater the reduction in stroke risk.[24] All patients should have their blood pressure monitored and controlled appropriately based on current guidelines for blood pressure management. However, no one agent has been clearly shown to be more beneficial than any other for preventing stroke.

Secondary Prevention

Nonpharmacologic Therapy

Carotid Endarterectomy

The benefit of carotid endarterectomy for prevention of recurrent stroke has been studied previously in major trials.[25,26] A recent meta-analysis has been completed that has combined these clinical trials to evaluate 6,092 patients.[27] Carotid endarterectomy has been shown to be beneficial for preventing **ipsilateral** stroke in patients with symptomatic carotid artery **stenosis** of 70% or greater and is recommended in these patients. In patients with symptomatic stenosis of 50% to 69%, a moderate reduction in risk is seen in clinical trials. In all patients with stenosis of 50% to 69% and a recent stroke, carotid endarterectomy is appropriate. In other patients, surgical risk factors and surgeon skill should be considered prior to surgery. The patient should have, at a minimum, a life expectancy of 5 years, and the surgical risk of stroke and/or death should be less than 6%. Carotid endarterectomy is not beneficial for symptomatic carotid stenosis less than 50% and should not be considered in these patients.

There are data to suggest that patients with asymptomatic carotid artery stenosis of 60% or more benefit from carotid endarterectomy if it is performed by a qualified surgeon with low complication rates (less than 3%). At this time, there is considerable controversy over how this information can be applied to clinical practice. A current review recommends considering carotid endarterectomy in patients with carotid artery stenosis of 60% to 99% who are between 40 and 75 years of age if there is a 5-year life expectancy and the operative risks are low.[28]

Carotid Angioplasty

Carotid angioplasty with or without **stenting** is typically restricted to patients who are refractory to medical therapy and are not surgical candidates. Clinical trials are currently ongoing to further define the role of carotid angioplasty in both symptomatic and asymptomatic patients.

Pharmacologic Therapy

Aspirin

In a recent meta-analysis including 144,051 patients with previous MI, acute MI, previous TIA or stroke, and acute stroke, as well as others at high risk, aspirin was found to decrease the risk of recurrent stroke by approximately 25%.[29] ❾ *Aspirin is typically considered to be the first-line secondary prevention agent for ischemic stroke and decreases the risk of subsequent stroke by approximately 25% in both men and women with previous transient ischemic attacks or stroke.* A wide range of doses have been used (30 to 1500 mg per day); however, enteric-coated aspirin 325 mg orally once daily is the most widely used and recommended regimen. The FDA has approved doses of 50 to 325 mg for secondary ischemic stroke prevention. In those who fail aspirin therapy, increasing the daily dose of aspirin or switching to either clopidogrel or the combination of extended-release dipyridamole plus aspirin are options. Clopidogrel is a reasonable alternative if aspirin is not tolerated, and it may be considered as first-line therapy in patients with peripheral arterial disease. Adverse effects of aspirin include gastrointestinal intolerance, gastrointestinal bleeding, and hypersensitivity reactions.

Warfarin

Warfarin has not been adequately studied in non-cardioembolic stroke, but it is often recommended in patients after antiplatelet agents fail. One small retrospective study suggests that warfarin is better than aspirin.[30] More recent clinical trials have not found oral anticoagulation in those patients without atrial fibrillation or carotid stenosis to be better than antiplatelet therapy. In the majority of patients without atrial fibrillation, antiplatelet therapy is recommended over warfarin. In patients with atrial fibrillation, long-term anticoagulation with warfarin is recommended and is effective in both primary and secondary prevention of stroke.[12] The goal International Normalized Ratio (INR) for this indication is 2 to 3.

Ticlopidine

Ticlopidine is slightly more beneficial in stroke prevention than aspirin in both men and women.[31,32] The usual recommended dosage is 250 mg orally twice daily. Ticlopidine is costly, and side effects include bone marrow suppression, rash, diarrhea, and an increased cholesterol level. Neutropenia is seen in approximately 2% of patients. **Thrombotic thrombocytopenic**

purpura (TTP) occurs in 1 of every 2000 to 4000 patients treated with ticlopidine. For these reasons, monitoring of the complete blood cell count (CBC) is required every 2 weeks for the first 3 months of therapy. Ticlopidine is an alternative in patients who cannot tolerate or who have failed aspirin therapy; however, because of the costly laboratory monitoring required and the adverse effect profile, many clinicians choose an alternative agent such as clopidogrel or aspirin/extended-release dipyridamole.

Clopidogrel

Clopidogrel is slightly more effective than aspirin with a relative-risk reduction of 7.3% more than that provided by aspirin.[33] The usual dose is 75 mg orally taken on a daily basis. Clopidogrel has a significantly lower incidence of diarrhea and neutropenia than ticlopidine, and laboratory monitoring is typically not required. There are 11 case reports of TTP occurring secondary to clopidogrel, with the majority occurring within the first 2 weeks of therapy. Currently, clopidogrel is favored over ticlopidine; however, clinicians need to be aware that there is a potential for the development of TTP. Clopidogrel may be preferred as monotherapy; in the MATCH trial, low-dose aspirin plus clopidogrel combination therapy compared to clopidogrel alone did not show a significant benefit.[34] This trial found that the addition of aspirin increased the risk of major bleeding. However, there is no difference in the bleeding risk between aspirin and clopidogrel as monotherapy, and the cost of clopidogrel is significantly higher than the cost of aspirin.

Extended-Release (ER) Dipyridamole plus Immediate-Release (IR) Aspirin

Combination therapy with extended-release dipyridamole plus immediate-release aspirin was more effective than either treatment alone in the European Stroke Prevention Study 2 (ESPS2).[35] In this study, patients received either placebo, aspirin 25 mg twice daily, ER dipyridamole 200 mg twice daily, or a combination of both agents. The individual agents produced risk reductions of 18.1% with aspirin and 16.3% with ER dipyridamole, whereas the combination produced a 37% risk reduction. Headache and diarrhea were common adverse effects of dipyridamole, while bleeding was more common in the treatment groups receiving aspirin. This is the first study showing that combination antiplatelet therapy has additive effects over each agent alone. The currently available formulation is a combination product containing 25 mg aspirin and 200 mg ER dipyridamole. This agent is not an option for patients who are intolerant to aspirin; however, it may be useful in patients who have failed clopidogrel or aspirin monotherapy. Further trials are underway to compare this combination to each individual component at full doses. Trials comparing this combination to other antiplatelet agents are also necessary.

Recommendations

The most recent CHEST guidelines continue to recommend aspirin therapy for the secondary prevention of stroke.[12] The guidelines also make the recommendation that due to a slight benefit in the absolute risk reduction in ischemic stroke with clopidogrel and the combination of aspirin/ER dipyridamole, these agents may be preferred if cost is factored out.

Patient Encounter, Part 3

GR is ready for discharge after spending 5 days in the hospital.

- What would be an appropriate discharge plan for GR at this time?
- What specific medications would you recommend upon discharge?

Blood Pressure Management

Hypertension is an important risk factor for stroke; however, it had been unclear if lowering BP reduced the incidence of secondary ischemic stroke. In the PROGRESS trial, it was shown that blood pressure reduction using the angiotensin-converting enzyme inhibitor (ACE-I) perindopril alone resulted in a 28% reduction in recurrent stroke compared to placebo. With the addition of the diuretic indapamide to perindopril, a 43% reduction in stroke recurrence was seen.[36] This reduction in stroke incidence occurred even in patients who were not hypertensive. In patients with a previous history of stroke or TIA, the Joint National Committee on the Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) recommends a diuretic and an ACE-I.[37] Table 8–7 provides drug and dosing recommendations for the treatment of ischemic stroke.

TABLE 8–7. Recommendations for Pharmacotherapy of Ischemic Stroke

	Primary Agents	Alternatives
Acute Treatment	t-PA 0.9 mg/kg IV (maximum 90 mg) over 1 hour in selected patients within 3 hours of onset Aspirin 160–325 mg daily started within 48 hours of onset	t-PA (various doses) intra-arterially up to 6 hours after onset in selected patients
Secondary Prevention	Aspirin 50–325 mg daily Clopidogrel 75 mg daily Aspirin 25 mg + extended-release dipyridamole 200 mg twice daily	Ticlopidine 250 mg twice daily
Cardioembolic	Warfarin (INR 2–3)	
All	ACE-I + diuretic or ARB; blood pressure lowering: Peridopril 2–8 mg daily Indapamide 1.25–5 mg daily; Statin therapy	

ACE-I, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; INR, International Normalized Ratio; IV, intravenous; t-PA, tissue plasminogen activator.

TREATMENT OF ACUTE HEMORRHAGIC STROKE

Supportive Measures

Acute hemorrhagic stroke is considered to be an acute medical emergency. Initially, patients experiencing a hemorrhagic stroke should be transported to a neurointensive care unit. ⓫ *There is no proven treatment for intracerebral hemorrhage. Management is based on neurointensive care treatment and prevention of complications.* Treatment should be provided to manage the needs of the critically ill patient including management of increased intracranial pressure, seizures, infections, and prevention of re-bleeding and delayed cerebral ischemia. In those with severely depressed consciousness, rapid endotracheal intubation and mechanical ventilation may be necessary. Blood pressure is often elevated after hemorrhagic stroke and appropriate management is important to prevent re-bleeding and expansion of the hematoma.[8] Blood pressure can be controlled with IV boluses of labetalol 10 to 80 mg every 10 minutes up to a maximum of 300 mg or with IV infusions of labetalol (0.5 to 2 mg/minute) or nicardipine (5 to 15 mg/hour). Deep vein thrombosis prophylaxis with intermittent compression stockings should be implemented early after admission. In those patients with SAH, once the aneurysm has been treated, heparin may be instituted.[2,3]

Nonpharmacologic Therapy

Patients with hemorrhagic stroke are evaluated for surgical treatment of SAH and ICH. In SAH, either clipping of the aneurysm or coil embolization is recommended within 72 hours after the initial event to prevent re-bleeding. Coil embolization, also called coiling, is a minimally invasive procedure in which a platinum coil is threaded into the aneurysm. The flexible coil fills up the space to block blood flow into the aneurysm thereby preventing re-bleeding. Surgical removal of the blood in patients with ICH is controversial, as one large randomized trial did not show a benefit to removal compared with those treated conservatively according to the current guidelines.[38,39]

Calcium Antagonists

⓬ *Oral nimodipine is recommended in subarachnoid hemorrhage to prevent delayed cerebral ischemia.* Delayed cerebral ischemia occurs 4 to 14 days after the initial aneurysm rupture and is a common cause of neurologic deficits and death. A meta-analysis of 12 studies was conducted and concluded that oral nimodipine 60 mg every 4 hours for 21 days following aneurysmal SAH reduced the risk of a poor outcome and delayed cerebral ischemia.[40]

Hemostatic Therapy

Recombinant factor VIIa has been shown to have a benefit in the treatment of ICH. The Recombinant Activated Factor VII Intracerebral Hemorrhage Trial compared three different doses and placebo. Doses were 40, 80, or 160 mcg/kg or placebo given as an IV infusion over 1 to 2 minutes within 4 hours after the onset of symptoms. Hematoma growth was decreased at 24 hours, mortality was decreased at 90 days, and overall functioning was increased at 90 days. Further studies are ongoing to evaluate the role of recombinant factor VIIa in ICH treatment.[41]

OUTCOME EVALUATION

- Stroke outcomes are measured based on the neurologic status and functioning of the patient after the acute event. The National Institutes of Health Stroke Scale (NIHSS) is a measure of daily functioning and is used to assess patient status following a stroke.
- Early rehabilitation can reduce functional impairment after a stroke. Recent stroke rehabilitation guidelines have been endorsed by the American Heart Association and the American Stroke Association. These guidelines recommend that patients receive care in a multidisciplinary setting or stroke unit, receive early assessment using the NIHSS, and recommend that rehabilitation is started as soon as possible after the stroke. Other recommendations include screening for **dysphagia** and aggressive secondary stroke prevention treatments.[42]
- Table 8–8 provides monitoring guidelines for the acute stroke patient.

Patient Care and Monitoring

1. Assess the patient's signs and symptoms including the time of onset of symptoms and the time of arrival in the emergency department.
2. Perform thorough neurological and physical examinations evaluating for a potential cause of the stroke.
3. Perform a CT scan to rule out a hemorrhagic stroke prior to administering any treatment.
4. Evaluate the inclusion and exclusion criteria for thrombolytic therapy to determine if it is appropriate for the patient.
5. Transfer the patient to a stroke center if available and develop a plan for the acute management of the patient.
6. Determine the patient's risk factors for stroke.
7. Develop a plan for the long-term management of risk factors in order to prevent a recurrent stroke.
8. Educate the patient on appropriate lifestyle modifications that will reduce stroke risk.
9. Educate the patient on their medication regimen and stress the importance of compliance.

TABLE 8–8. Monitoring the Stroke Patient

Treatment	Parameter(s)	Monitoring Frequency	Comments
Ischemic Stroke			
t-PA	BP, neurologic function, bleeding	Every 15 minutes × 1 hour, every 0.5 hour × 6 hours, every 1 hour × 17 hours; then every shift	
Aspirin	Bleeding	Daily	
Clopidogrel	Bleeding	Daily	
ASA/extended-release dipyridamole	Headache, bleeding	Daily	
Warfarin	Bleeding, INR, Hb/Hct	INR daily × 3 days; weekly until stable; then monthly	
Hemorrhagic Stroke			
	BP, neurologic function, ICP	Every 2 hours in ICU	May require treatments to lower BP to less than 180 mm Hg systolic
Nimodipine for SAH	BP, neurologic function, fluid status	Every 2 hours in ICU	

ASA, aspirin; BP, blood pressure; Hb, hemoglobin; Hct, hematocrit; ICP, intracranial pressure; ICU, intensive care unit; INR, International Normalized Ratio; SAH, subarachnoid hemorrhage; t-PA, tissue plasminogen activator.

ABBREVIATIONS

ACE-I: angiotensin-converting enzyme inhibitor
ADP: adenosine diphosphate
aPTT: activated partial thromboplastin time
ARB: angiotensin receptor blocker
ASA: aspirin
AVM: arteriovenous malformation
BP: blood pressure
BPH: benign prostatic hypertrophy
CBC: complete blood count
CEA: carotid endarterectomy
CT: computed tomography
CVD: cerebrovascular disease
DBP: diastolic blood pressure
DVT: deep vein thrombosis
ER: extended-release

9 HYPERLIPIDEMIA

Matthew K. Ito

LEARNING OBJECTIVES

UPON COMPLETION OF THE CHAPTER, THE READER WILL BE ABLE TO:

1. Identify the major components within each lipoprotein and their role in lipoprotein metabolism and the development of atherosclerosis.
2. Identify the common types of lipid disorders.
3. Determine a patient's coronary heart disease risk and corresponding treatment goals according to the National Cholesterol Education Program Adult Treatment Panel III guidelines.
4. Recommend appropriate therapeutic lifestyle changes (TLC) and pharmacotherapy interventions for patients with dyslipidemia.
5. Describe the components of a monitoring plan to assess effectiveness and adverse effects of pharmacotherapy for dyslipidemias.
6. Educate patients about the disease state, appropriate TLC, and drug therapy required for effective treatment.

KEY CONCEPTS

❶ The risk of atherosclerosis is directly related to increasing levels of serum cholesterol.

❷ The National Cholesterol Education Program Adult Treatment Panel III guidelines have set the "optimal" level for low-density lipoprotein (LDL) cholesterol for all adults as less than 100 mg/dL (2.59 mmol/L).

❸ All adults greater than 20 years of age should be screened at least every 5 years using a fasting blood sample.

❹ The benefits of lowering LDL cholesterol to as low as 70 mg/dL (1.81 mmol/L) have been demonstrated in clinical trials; however, the lowest level at which to treat LDL cholesterol has not yet been determined.

❺ An adequate trial of therapeutic lifestyle changes should be employed in all patients, but pharmacotherapy should be instituted concurrently in higher-risk patients.

❻ Typically, statins are the medications of choice to treat high LDL cholesterol because of their ability to substantially reduce LDL cholesterol, ability to reduce morbidity and mortality from atherosclerotic disease, convenient once-daily dosing, and low risk of side effects.

❼ Patients with metabolic syndrome have an additional lipid parameter that needs to be assessed, namely non-high-density lipoprotein (non-HDL) cholesterol (total cholesterol minus HDL cholesterol). The target for non-HDL cholesterol is less than the patient's LDL cholesterol target plus 30 mg/dL (0.78 mmol/L).

❽ After assessment and control of LDL cholesterol, patients with serum triglycerides of 200 to 499 mg/dL (2.26 to 5.64 mmol/L) should be assessed for atherogenic dyslipidemia (low HDL cholesterol and increased small-dense LDL particles) and metabolic syndrome.

❾ Combination drug therapy is an effective means to achieve greater reductions in LDL cholesterol (statin + ezetimibe or bile acid resin, bile acid resin + ezetimibe, or three-drug combinations) as well as raising HDL cholesterol and lowering serum triglycerides (statin + niacin or fibrate).

❿ Reducing LDL cholesterol while substantially raising HDL cholesterol (statin + niacin) appears to reduce the risk of atherosclerotic disease progression to a greater degree than statin monotherapy.

❶ *The risk of **atherosclerosis** is directly related to increasing levels of serum cholesterol.* Hypercholesterolemia (elevation in serum cholesterol) and other abnormalities in serum lipids play a major role in plaque formation leading to coronary heart disease (CHD) as well as other forms of atherosclerosis, such as **carotid** and peripheral artery disease (atherosclerosis of the peripheral arteries). This predictive relationship has been demonstrated from large epidemiologic,[1] animal, and genetic studies. Coronary heart disease is the leading cause of death in both men and women in the United States and most industrialized nations. It is also the chief cause of premature, permanent disability in the United States workforce. Annually, approximately 700,000 Americans will suffer a new heart attack and 500,000 will have a recurrent event. The average age of a first heart attack is 66 years for American men and 70 years for women. The direct and indirect cost of CHD to the United States economy is almost $140 billion.[2] Clinical trials have consistently demonstrated that lowering serum cholesterol reduces atherosclerotic progression and mortality from CHD.

The development of CHD is a lifelong process. Except in rare cases of severely elevated serum cholesterol levels, years of poor dietary habits, sedentary lifestyle, and life-habit risk factors (e.g., smoking and obesity) contribute to the development of atherosclerosis.[3] Unfortunately, many individuals at risk for CHD do not receive lipid-lowering therapy or are not optimally treated. This chapter will help identify individuals at risk, assess treatment goals based on the level of CHD risk, and implement optimal treatment strategies and monitoring plans.

PATHOPHYSIOLOGY

Lipid and Lipoprotein Metabolism

Cholesterol is an essential substance manufactured by most cells in the body. Cholesterol is used to maintain cell wall integrity and for the biosynthesis of **bile acids** and steroid hormones.[4] Other major lipids in our body are triglycerides and phospholipids. Since cholesterol is a relatively water-insoluble molecule, it is unable to circulate through the blood alone. Cholesterol along with triglycerides and phospholipids are packaged in a large carrier-protein called a lipoprotein (Fig. 9–1). Lipoproteins are water soluble, which allows transportation of the major lipids in the blood. These lipoproteins are spherical and vary in size (~1,000 to 6 nm) and density (less than 0.94 to 1.21 g/mL)[4] (Table 9–1). The amount of cholesterol and triglycerides vary by lipoprotein size. The major lipoproteins in descending size and ascending density are chylomicrons, very low-density lipoprotein (VLDL), intermediate-density lipoprotein (IDL), low-density lipoprotein (LDL), and high-density lipoprotein (HDL). When clinical laboratories measure and report serum total cholesterol, what they are measuring and reporting are total cholesterol molecules in all the major lipoproteins. The estimated value of LDL cholesterol is found using the following equation:

$$\text{LDL cholesterol} = \text{total cholesterol} - (\text{HDL cholesterol} + \text{triglycerides}/5)$$

If serum triglycerides are greater than 400 mg/dL (4.52 mmol/L), this formula becomes inaccurate and LDL cholesterol must be directly measured.[3]

Each lipoprotein has various proteins called apolipoproteins embedded on the surface (Fig. 9-1). These apolipoproteins serve four main purposes, they: (1) are required for assembly and secretion of lipoproteins (such as apolipoproteins B-48 and B-100); (2) serve as major structural components of lipoproteins; (3) act as ligands (apolipoprotein B-100 and apolipoprotein E) for binding to receptors on cell surfaces (LDL receptors); and (4) can be co-factors (such as apolipoprotein C-II) for activation of enzymes (such as lipoprotein lipase [LPL]) involved in the breakdown of triglycerides from chylomicrons and VLDL. Apolipoproteins A-I and A-II are major structural proteins on

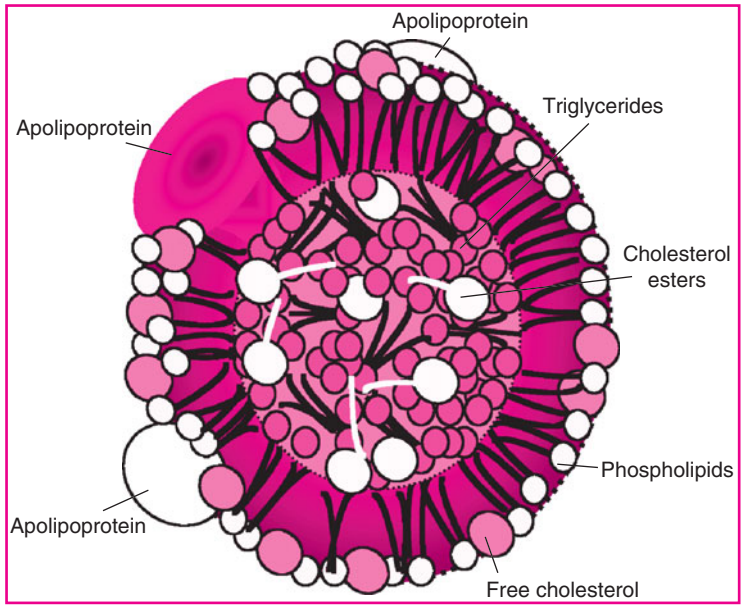

FIGURE 9–1. Lipoprotein structure. Lipoproteins are a diverse group of particles with varying size and density. They contain variable amounts of core cholesterol esters and triglycerides, and have varying numbers and types of surface apolipoproteins. The apolipoproteins function to direct the processing and removal of individual lipoprotein particles. (Reprinted from LipoScience, Inc. with permission.)

TABLE 9–1. Physical Characteristics of Lipoproteins

Lipoprotein	Density Range (g/mL)	Size (nm)	Composition (%)		
			Cholesterol	Triglycerides	Apolipoprotein
Chylomicrons	Less than 0.95	100–1000	3–7	85–95	A-I, A-II, A-IV, B-48, C-I, C-II, E
VLDL	Less than 1.006	40–50	20–30	50–65	B-100, C-I, C-II, C-III, E
IDL	1.006–1.019	25–30	40	20	B-100, E
LDL	1.019–1.063	20–25	51–58	4–8	B-100
HDL	1.063–1.21	6–10	18–25	2–7	A-I, A-II, C-I, C-II, C-III, E

HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; VLDL, very low-density lipoprotein.

the surface of HDL. Apolipoprotein A-I interacts with adenosine triphosphate (ATP) binding cassette A1 to traffic cholesterol from extra-hepatic tissue (such as the arterial wall) to immature or **nascent** HDL.[4]

Cholesterol from the diet as well as from bile enters the small intestine, where it is emulsified by bile salts into **micelles** (Fig. 9–2). These micelles interact with the duodenal and jejunal enterocyte surfaces, and cholesterol is transported from the micelles into these cells by the Niemann-Pick C1 Like 1 (NPC1L1) transporter.[5] Some cholesterol and most plant sterols, which are structurally similar to cholesterol, are exported back from the enterocyte into the intestinal lumen by the ATP-binding cassette (ABC) G5/G8 transporter. Cholesterol within enterocytes is esterified and packaged into chylomicrons along with triglycerides, phospholipids, and apolipoprotein B-48 as well as apolipoproteins C and E, which are then released into the **lymphatic** circulation. In the circulation, chylomicrons are converted to chylomicron remnants (through loss of triglycerides by the interaction of apolipoprotein C-II and LPL). During this process, chylomicrons also interact with HDL particles (Fig. 9–3) and exchange triglyceride and cholesterol content, and HDL particles acquire apolipoproteins A and C. Chylomicron remnant particles are then taken up by LDL-related protein (LRP).[4]

In the liver, cholesterol and triglycerides are incorporated into VLDL along with phospholipids and apolipoprotein B-100 (Fig. 9–4). Very low-density lipoprotein particles are released into the circulation where they acquire apolipoprotein E and apolipoprotein C-II from HDL. Very-low density lipoprotein loses its triglyceride content through the interaction with LPL to form VLDL remnant and IDL. Intermediate-density lipoprotein can be cleared from the circulation by hepatic LDL receptors or further converted to LDL (by further depletion of triglycerides) through the action of hepatic lipases (HL). Approximately 50% of IDL is converted to LDL. Low-density lipoprotein particles are cleared from the circulation primarily by hepatic LDL receptors by interaction with apolipoprotein B-100. They can also be taken up by extra-hepatic tissues or enter the arterial wall, contributing to atherogenesis.[4,6]

Cholesterol is transported from the arterial wall or other extra-hepatic tissues back to the liver by HDL (Fig. 9–3). Apolipoprotein A-I (derived from the intestine and liver) on nascent HDL interacts with ABCA1 transporter on extra-hepatic tissue. Cholesterol in nascent HDL is esterified by lecithin-cholesterol acyltransferase (LCAT) resulting in mature HDL. The esterified cholesterol can be transferred as noted above to apolipoprotein B-containing particles in exchange for triglycerides. Triglyceride-rich HDL is hydrolyzed by HL, generating fatty acids and nascent HDL particles, or the mature HDL can bind to the scavenger receptors (SR-BI) on hepatocytes and transfer their cholesterol ester content.[4]

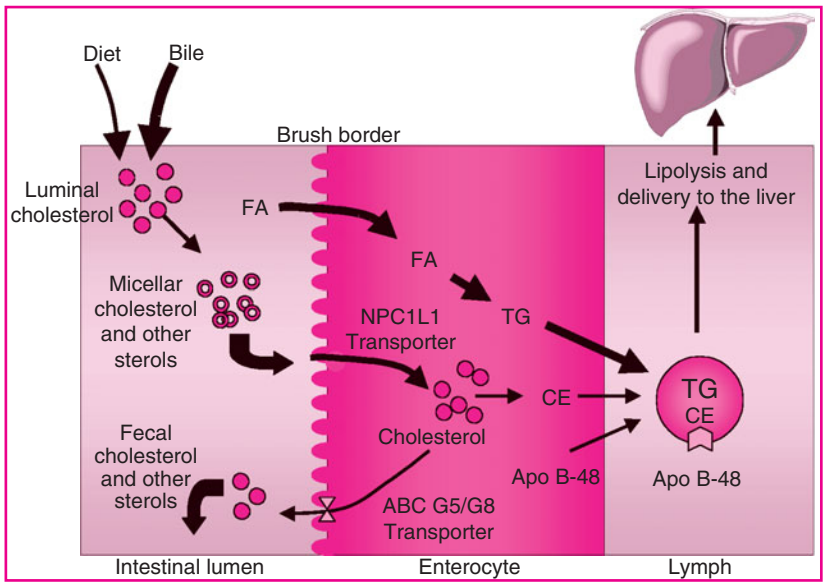

FIGURE 9–2. Intestinal cholesterol absorption and transport. Cholesterol from food and bile enter the gut lumen and are emulsified by bile acids into micelles. Micelles binding to the intestinal enterocytes, and cholesterol and other sterols are transported from the micelles into the enterocytes by a sterol transporter. Triglycerides synthesized by absorbed fatty acids along with cholesterol and apolipoprotein B-48 are incorporated into chylomicrons. Chylomicrons are released into the lymphatic circulation and are converted to chylomicron remnants (through loss of triglyceride), and then taken up by the hepatic LDL receptor-related protein (LRP). ABC G5/G8, ATP-binding cassette G5/G8; Apo, apolipoprotein; CE, cholesterol ester; FA, fatty acid; NPC1L1, Niemann-Pick C1 Like 1; TG, triglyceride.

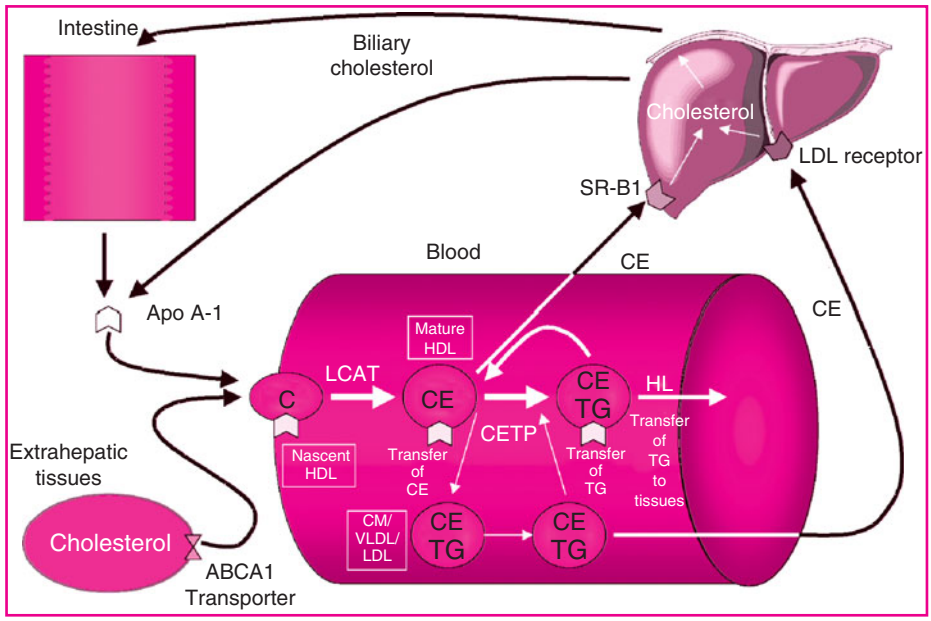

FIGURE 9–3. Reverse cholesterol transport. Cholesterol is transported from the arterial wall or other extra-hepatic tissues back to the liver by HDL. Esterified cholesterol from HDL can be transferred to apolipoprotein B-containing particles in exchange for triglycerides. Cholesterol esters transferred from HDL to VLDL and LDL are taken up by hepatic LDL receptors or delivered back to extra-hepatic tissue. ABCA1, ATP-binding cassette A1; Apo, apolipoprotein; C, cholesterol; CE, cholesterol ester; CETP, cholesterol ester transfer protein; CM, chylomicrons; HDL, high-density lipoprotein; HL, hepatic lipase; LCAT, lecithin cholesterol acyltransferase; LDL, low-density lipoprotein; SR-BI, scavenger receptors; TG, triglyceride; VLDL, very low-density lipoprotein.

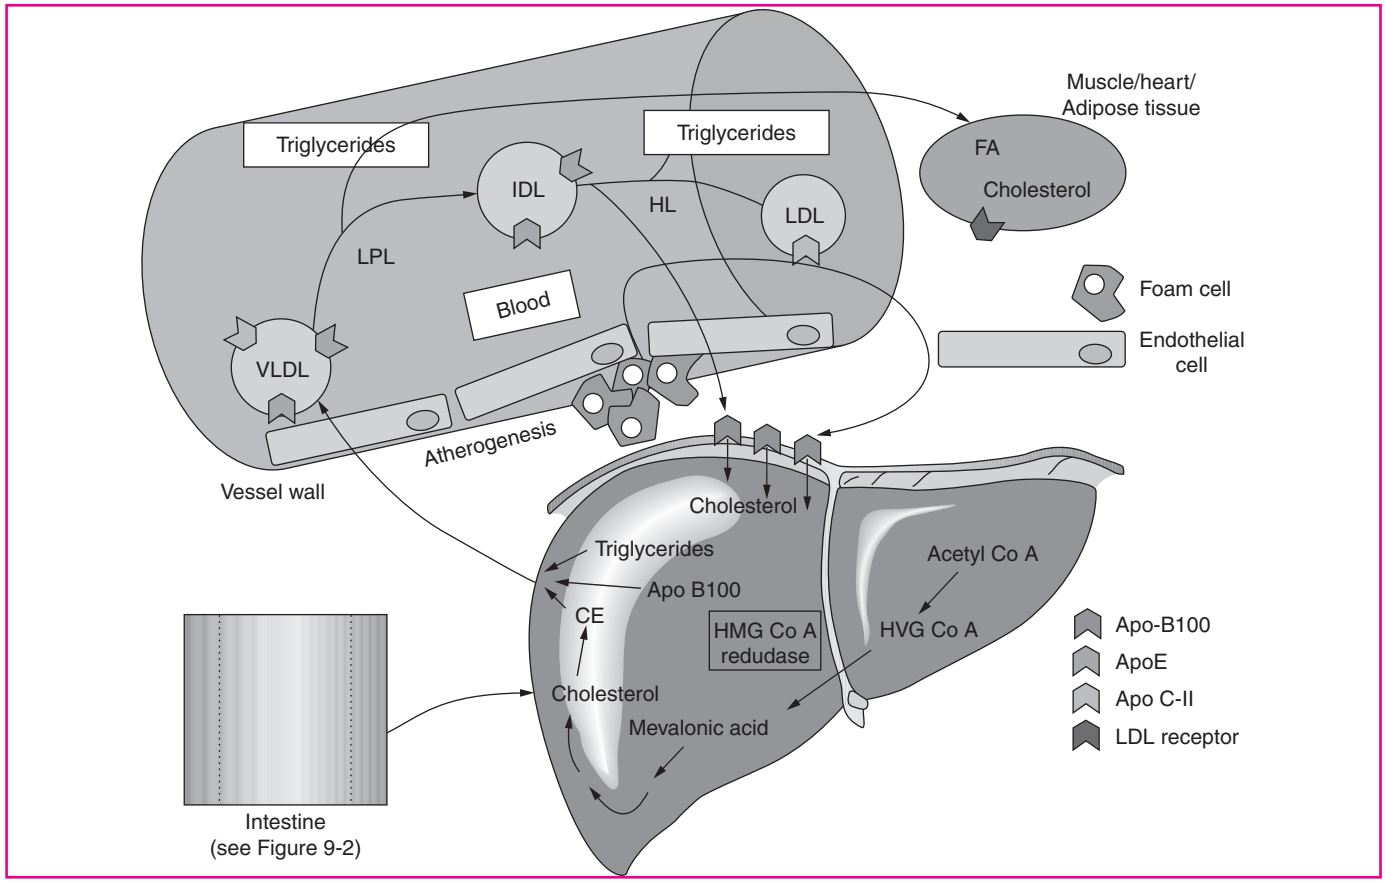

FIGURE 9–4. Endogenous lipoprotein metabolism. In liver cells, cholesterol and triglycerides are packaged into VLDL particles and exported into blood where VLDL is converted to IDL. Intermediate-density lipoprotein can be either cleared by hepatic LDL receptors or further metabolized to LDL. LDL can be cleared by hepatic LDL receptors or can enter the arterial wall, contributing to atherosclerosis. Acetyl CoA, acetyl coenzyme A; Apo, apolipoprotein; C, cholesterol; CE, cholesterol ester; FA, fatty acid; HL, hepatic lipase; HMG CoA, 3-hydroxy-3-methyglutaryl coenzyme A; IDL, intermediate-density lipoprotein; LCAT, lecithin-cholesterol acyltransferase; LDL, low-density lipoprotein; LPL, lipoprotein lipase; VLDL, very low-density lipoprotein.

A variety of genetic mutations occur in the above steps during lipoprotein synthesis and metabolism that cause lipid disorders. The major genetic disorders and their effect on serum lipids are presented in Table 9–2.[4] Disorders that increase serum cholesterol are generally those that affect the number or affinity of LDL receptors (also known as apolipoprotein B-E receptors) known as familial hypercholesterolemia, or the ability of apolipoprotein B-100 to bind to the receptor known as familial defective apolipoprotein B-100. These patients commonly present with **corneal arcus** of the eye and **xanthomas** of extensor tendons of the hand and Achilles tendon. Elevations in triglycerides are generally associated with overproduction of VLDL, mutations in apolipoprotein E, or lack of LPL. Patients with extremely elevated serum triglycerides can develop **pancreatitis** and **tuberoeruptive xanthomas**. Most individuals have mild to moderate elevations in cholesterol caused by a polygenic disorder. Polygenic hypercholesterolemia is not as well understood as the single-gene disorders discussed above. Polygenic hypercholesterolemia is thought to be caused by various, more subtle genetic defects as well as environmental factors such as diet and lack of physical activity.[3]

Pathophysiology of Coronary Artery Disease

The most widely accepted theory of the process of atherosclerosis is that it is a low-grade inflammatory response due to injury of the vascular endothelium.[6] The process begins when lipoproteins migrate between the **endothelial cells** into the arterial wall (Fig. 9–5). The initial lesion, known as a fatty streak, appears to form after accumulation of lipoproteins within the **intima**. After entering the intima, lipoproteins are then structurally modified by oxidation. Oxidized lipoproteins as well as other cytotoxic agents promote endothelial dysfunction by disturbing the production of vasoactive molecules such as nitric oxide that maintain vasomotor tone. Small, denser LDL particles migrate into the arterial wall more readily and are particularly susceptible to oxidation. The oxidized particles cause an increased expression of cell-adhesion molecules on vascular endothelial cells leading to recruitment of **monocytes** into the intima. The monocytes differentiate into **macrophages** and express scavenger receptors allowing enhanced uptake of apolipoprotein B-containing lipoproteins. The macrophages continue to accumulate lipoproteins and ultimately develop into lipid-laden **foam cells**. Accumulation of foam cells leads to formation of a lipid-rich core, which marks the transition to a more complicated atherosclerotic plaque. Vascular wall remodeling leading to outward growth of the wall occurs to accommodate this lipid-rich core. Thus, the vascular lumen is relatively well preserved and generally the lesion would not be detected using traditional coronary angiographic techniques. Initially, smooth muscle cells migrate and proliferate from the **media** to the intima forming a protective fibrous cap which separates the potentially thrombogenic lipid core from circulating blood. As the plaque matures, inflammatory cells secrete **matrix metalloproteinases** that degrade collagen and fibrin produced by smooth muscle cells that lead to a weakened fibrous cap. Ischemic events result when the fibrous cap of these unstable plaques rupture and produce an occlusive **thrombus**. In contrast, repeated wound healing secondary to less significant plaque disruption that causes no symptoms might produce a more stable plaque as a consequence of smooth muscle cell, collagen, and fibrin accumulation and a resolution of the lipid core.[6] These more stable plaques usually cause luminal encroachment (detected by traditional coronary angiographic techniques) and may produce **angina pectoris**. Unstable lesions usually outnumber the more stable plaques, thus accounting for a majority of **acute coronary syndromes**. Evidence demonstrates that aggressive lipid lowering does stabilize these vulnerable lesions and restores endothelial function.[3,6,7]

TABLE 9–2. Selected Characteristics of Primary Dyslipidemias

Disorder	Estimated Frequency	Metabolic Defect	Main Lipid Parameter
Familial hypercholesterolemia			
Homozygous	1/1 million	LDL-receptor negative	LDL-C greater than 500 mg/dL (12.95 mmol/L)
Heterozygous	1/500	Reduction in LDL receptors	LDL-C 250–500 mg/dL (6.48–12.95 mmol/L)
Familial defective apo B-100	1/1000	Single nucleotide mutation	LDL-C 250–500 mg/L (6.48–12.95 mmol/L)
Polygenic hypercholesterolemia	Common	Metabolic and environmental	LDL-C 160–250 mg/dL (4.14–6.48 mmol/L)
Familial combined dyslipidemia	1/200–300	Overproduction of VLDL and/or LDL	LDL-C 250–350 mg/dL (6.48–9.07 mmol/L) TG 200–800 mg/dL (2.26–9.04 mmol/L)
Familial hyperapobetalipoproteinemia	5%	Increase apo B production	Apo B greater than 125 mg/dL
Familial dysbetalipoproteinemia	0.5%	Apo E2/2 phenotype	LDL-C 300–600 mg/dL (7.77–15.54 mmol/L) TG 400–800 mg/dL (4.52–9.04 mmol/L)
Familial hypertriglyceridemia			
Type IV	1/300	Unknown	TG 200–500 mg/dL (2.26–5.65 mmol/L)
Type V	1/205,000	Unknown	TG greater than 1000 mg/dL (11.3 mmol/L)
Hypoalphalipoproteinemia	3–5%	Defect in HDL catabolism	HDL-C less than 35 mg/dL (0.91 mmol/L)

Apo, apolipoprotein; C, cholesterol; HDL, high-density lipoprotein; LDL, low-density lipoprotein; TG, triglyceride; VLDL, very low-density lipoprotein.

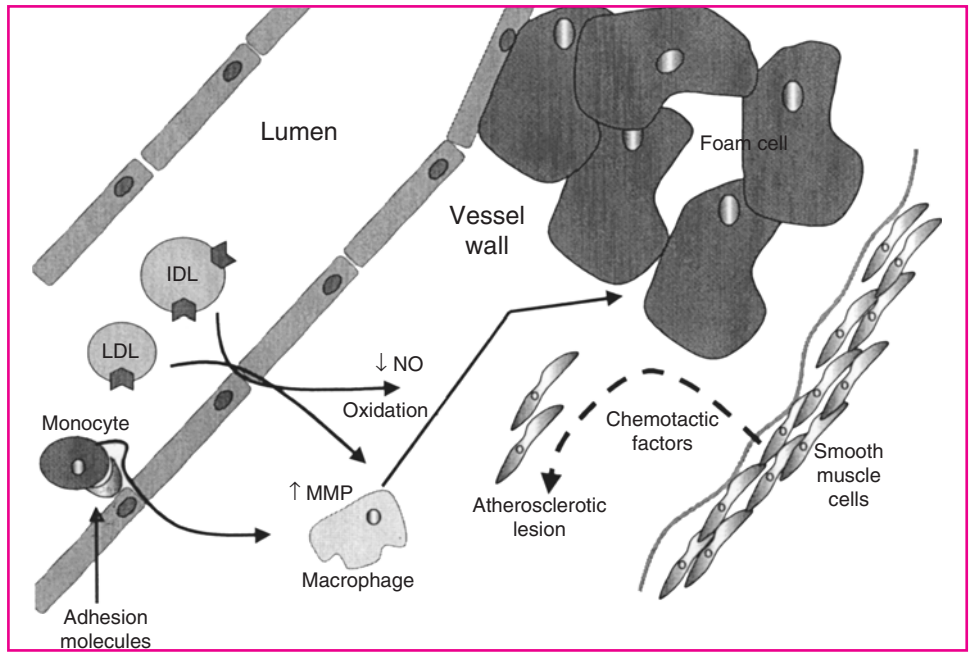

FIGURE 9–5. The process of atherogenesis. Atherosclerosis is initiated by the migration of LDL and remnant lipoprotein particles into the vessel wall. These particles undergo oxidation and are taken up by macrophages in an unregulated fashion. The oxidized particles participate to induce endothelial cell dysfunction leading to a reduced ability of the endothelium to dilate the artery and cause a prothrombotic state. The unregulated uptake of cholesterol by macrophages leads to foam cell formation and the development of a blood clot–favoring fatty lipid core. The enlarging lipid core eventually causes an encroachment of the vessel lumen. Early in the process, smooth muscle cells are activated and recruited from the media to the intima, helping to produce a collagen matrix that covers the growing clot protecting it from circulating blood. Later, macrophages produce and secrete matrix metalloproteinases which degrade the collagen matrix, leading to unstable plaque which may cause a myocardial infarction. IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; MMP, matrix metalloproteinases; NO, nitric oxide.

TREATMENT

In the United States, prevention and treatment of CHD is based primarily on guidelines issued in 2001 by the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III [ATP III]).[3] Low-density lipoprotein cholesterol is the primary diagnostic and therapeutic target. ❷ *The NCEP ATP III guidelines have set the "optimal" level for LDL cholesterol for all adults as less than 100 mg/dL (2.59 mmol/L).* The NCEP panel issued an update in 2004 to the ATP III guidelines based on more recent clinical trial evidence.[8] The update outlines additional treatment options for certain patient populations, mainly those who are at very high risk of recurrent CHD events. These treatment options emphasize the benefits of diet, exercise, and weight control and the use of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (or statins) as first-line drugs. If statins or other drugs used to treat hyperlipidemia are prescribed, doses that reduce LDL cholesterol by at least 30% to 40% should be recommended.[8]

Most recently, the American Heart Association and American College of Cardiology issued guidelines for secondary prevention in patients with established CHD or other atherosclerotic vascular disease based on the results of two additional trials published after the 2004 NCEP update.[9] These guidelines suggest it is reasonable to set an LDL cholesterol goal of less than 70 mg/dL (1.81 mmol/L) in all patients with CHD or other forms of atherosclerotic vascular disease. If it is not possible to attain LDL cholesterol less than 70 mg/dL (1.81 mmol/L) due to a high baseline LDL cholesterol, it is generally possible to achieve an LDL cholesterol reduction of greater than 50% with more intensive LDL lowering therapy, including combination drug therapy.

Guidelines for Treatment

Step 1: Patient Assessment

Determine lipoprotein profile after fasting for 9 to 12 hours. ❸ *The NCEP guidelines recommend that all adults greater than 20 years of age should be screened at least every 5 years using a fasting blood sample to obtain a lipid profile (total cholesterol, LDL cholesterol, HDL cholesterol, and triglycerides).* A fasting lipid profile is preferred so an accurate assessment of LDL cholesterol can be performed. Fasting permits the clearance of triglycerides

Clinical Presentation and Diagnosis

Lipid Panel

- Patients presenting with a total cholesterol level exceeding 200 mg/dL (5.18 mmol/L) or LDL cholesterol exceeding 100 mg/dL (2.59 mmol/L) should be evaluated for high cholesterol.
- Patients with serum triglycerides from 150–500 mg/dL (1.70–5.65 mmol/L) and serum HDL cholesterol less than 40 mg/dL (1.04 mmol/L) may have metabolic syndrome and need to be evaluated.

Physical Findings

- Patients with genetic disorders that cause a marked increase in serum LDL cholesterol (greater than 250 mg/dL [6.48 mmol/L]) may present with corneal arcus of the eye and xanthomas of extensor tendons of the hand and Achilles tendon.
- Patients with extremely elevated serum triglycerides (greater than 1,000 mg/dL [11.3 mmol/L]) can develop pancreatitis and tuberoeruptive xanthomas.

Indications for Lipid Panel

- All adults greater than 20 years of age should be screened at least every 5 years using a fasting blood sample to obtain a lipid profile (total cholesterol, LDL cholesterol, HDL cholesterol, and triglycerides). A fasting lipid profile is preferred so an accurate assessment of LDL cholesterol can be performed, and fasting will allow the clearance of triglycerides carried by chylomicrons from the circulation, allowing VLDL cholesterol to be determined.
- Children between 2 and 20 years old should be screened for high cholesterol if their parents have premature CHD or if one of their parents has a total cholesterol greater than 240 mg/dL (6.22 mmol/L). Early screening will help to identify children at highest risk of developing CHD in whom early education and dietary intervention is warranted.

Indications for Other Tests

- Conditions that may produce lipid abnormalities (such as those listed in Table 9–3) should be screened for using appropriate tests. If present, these conditions should be properly addressed.

carried by chylomicrons from the circulation thus allowing VLDL cholesterol to be determined. Children between 2 and 20 years old should be screened for high cholesterol if their parents have premature CHD or if one of their parents has a total cholesterol greater than 240 mg/dL (6.22 mmol/L).[3] Early screening will help to identify children at highest risk of developing CHD, in whom early education and dietary intervention is warranted.

Step 2: Rule Out Secondary Causes of Dyslipidemia

Certain drugs and diseases can cause abnormalities in serum lipids and should be evaluated (Table 9–3). Every effort should be made to correct or control underlying diseases such as hypothyroidism and diabetes. Concurrent medications known to induce lipid abnormalities should be evaluated for discontinuation prior to instituting long-term lipid-lowering therapy.[3]

Step 3: Identify the Presence of Clinical Atherosclerotic Disease That Confers High Risk for CHD Events

Individuals with established CHD, other clinical atherosclerotic disease (CAD), or diabetes have a greater than 20% risk over a 10-year period of developing CHD.[3] The ATP III guidelines set the target LDL cholesterol level at less than 100 mg/dL (2.59 mmol/L) for high-risk patients who have a history of one or more of the following:

- Myocardial infarction (MI)
- Unstable angina
- Chronic stable angina
- Coronary interventions (coronary bypass, percutaneous transluminal coronary angioplasty, or stents)
- Peripheral arterial disease (claudication or ankle-brachial index less than 0.9)
- Symptomatic carotid artery disease (stroke or transient ischemic attack)
- Diabetes (types 1 and 2)
- Multiple risk factors with a Framingham calculated risk (Fig. 9–6) greater than 20%

FIGURE 9–6. Framingham point scale for estimating 10-Year CHD risk. The Framingham score is used to determine a patient's CHD risk category when they are found to have two or more CHD risk factors (Table 9–4). This system assigns points to the following risk factors: age, total cholesterol level, smoking status, HDL cholesterol level, and systolic blood pressure. The point total corresponds to the 10-year risk (%) of a CHD event (non-fatal myocardial infarction and coronary death), which serves as a basis for deciding how intensively to treat hypercholesterolemia and other risk factors. To calculate risk factor using the Framingham Point Scale, go to the following website: http://www.nhlbi.nih.gov/guidelines/cholesterol/index.htm. The Système International units for the corresponding conventional units in the Framingham Point Scale illustration include: (1) total cholesterol (160 mg/dL = 4.14 mmol/L; 160 to 199 mg/dL = 4.14 to 5.15 mmol/L; 200 to 239 mg/dL = 5.18 to 6.19 mmol/L; 240 to 279 mg/dL = 6.22 to 7.23 mmol/L; 280 mg/dL = 7.25 mmol/L) and (2) HDL (60 mg/dL = 1.55 mmol/L; 50 to 59 mg/dL = 1.3 to 1.53 mmol/L; 40 to 49 mg/dL = 1.04 to 1.27 mmol/L; 40 mg/dL = 1.04 mmol/L). BP, blood pressure; CHD, coronary heart disease; HDL, high-density lipoprotein. (From http://www.nhlbi.nih.gov/guidelines/cholesterol/index.htm.)

Patient Encounter 1

MN is a 48-year-old man with a history of hypertension and smoking who presents to the clinic for evaluation of his cholesterol. He denies having chest pain or history of myocardial infarction, stroke, or peripheral artery disease. He has no siblings and both parents are alive with no history of CHD. MN says that he smokes about 1 pack of cigarettes per day. He does not exercise on a regular basis. He has been fasting for approximately 11 hours.

- Can MN be evaluated today for his cholesterol?
- Does he have risk factors for CHD?
- What additional information do you need to know for the evaluation of MN?

❹ *The benefits of lowering LDL cholesterol to as low as 70 mg/dL (1.81 mmol/L) have been demonstrated in clinical trials; however, the lowest level at which to treat LDL cholesterol has not yet been determined.* Thus, in patients considered very high risk and those conferring a CHD risk much greater than 20%, an LDL cholesterol goal of less than 70 mg/dL (1.81 mmol/L) is a therapeutic option.[7] These individuals are those with established CAD plus: multiple major risk factors (especially diabetes), severe and poorly controlled risk factors (especially continued cigarette smoking), multiple risk factors of metabolic syndrome, and acute coronary syndromes.

Step 4: Determine the Presence of Major Risk Factors

In individuals who do not have established CHD or CHD risk equivalent, the next step is to count major risk factors for CHD as presented in Table 9–4. These risk factors are considered independent predictors of CHD. High-density lipoprotein cholesterol of greater than or equal to 60 mg/dL (1.55 mmol/L) is considered a negative risk factor and means 1 risk factor can be subtracted from the total count.[3]

TABLE 9–4. Risk Factors for Coronary Heart Disease

Risk Factor	Definition
Age (years)	Male greater than or equal to 45; female greater than or equal to 55
Family history of premature CHD events	Male first-degree relative at less than 55 years Female first-degree relative at less than 65 years
Hypertension	SBP greater than or equal to 140 mm Hg DBP greater than or equal to 90 mm Hg
HDL cholesterol	Less than 40 mg/dL (1.04 mmol/L)
Cigarette smoking	Within the past month

HDL cholesterol greater than or equal to 60 mg/dL (1.55 mmol/L) is considered a negative risk factor; thus, subtract 1 risk factor from the total from above.
CHD, coronary heart disease; DBP, diastolic blood pressure; HDL, high-density lipoprotein; SBP, systolic blood pressure.

TABLE 9–5. CHD Risk Factors and Needed Risk Factors for Framingham Score Calculation

Risk Profile	10-Year Risk for CHD	Need for Framingham Calculation
Less than or equal to 1 risk factor	Less than 10%	No
Greater than or equal to 2 risk factors	0–10% 10–20%	Yes Yes
CAD or CAD risk-equivalent	Greater than 20%	No
Very-high risk	Much greater than 20%	No

CAD, clinical atherosclerotic disease; CHD, coronary heart disease.

Step 5: If Two or More Risk Factors are Present Without CHD or CHD Risk Equivalent, Assess 10-Year CHD Risk

Listed in Table 9–5 are the risk groups that require risk calculations using the Framingham scoring system.[3] Since individuals with two or more risk factors may carry a risk equivalent to individuals with established CHD, and therefore should be treated with the same intensity, a scoring system developed from the Framingham Coronary Heart Disease Study is used to estimate this 10-year risk (Fig. 9–6). This system assigns points to the following risk factors: age, total cholesterol level, smoking status, HDL cholesterol level, and systolic blood pressure. The score is used to determine a patient's risk category and the intensity of treatment to lower their LDL cholesterol. To calculate a Framingham score, visit the following website: http://www.nhlbi.nih.gov/guidelines/cholesterol/ index.htm.

Step 6: Determine Treatment Goals and Therapy

Treatment goals for LDL cholesterol and thresholds for the institution of therapeutic lifestyle changes (TLC) and pharmacotherapy is the next step (Table 9–6).

Step 7: Initiate Therapeutic Lifestyle Changes If LDL Is Above Goal

Therapeutic lifestyle changes should be the first approach tried in all patients (Table 9–7).[3] ❺ *An adequate trial of TLC should be employed in all patients, but pharmacotherapy should be instituted concurrently in higher-risk patients.* This includes dietary restrictions of cholesterol and saturated fats as well as regular exercise and weight reduction. In addition, therapeutic options to enhance LDL cholesterol lowering such as consumption of plant stanols/sterols (which competitively inhibit incorporation of cholesterol into micelles) and dietary fiber should be encouraged. These therapeutic options collectively may reduce LDL cholesterol by 20% to 25%.

Step 8: Consider Adding Drug Therapy If LDL Is Above Threshold Level

Patients unable or unlikely to achieve their LDL cholesterol goals following a reasonable trial of TLC (typically 12 weeks for patients without CHD and sooner for those at high risk or

TABLE 9–6. National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III [ATP III]) Treatment Goals for LDL Cholesterol and Thresholds for Starting Therapeutic Lifestyle Changes and Pharmacotherapy

Risk Category	LDL cholesterol Goal	Initiate Therapeutic Lifestyle Changes (TLC)	Consider Drug Therapy
High Risk CHD or CHD risk equivalents (10-year risk greater than 20%)	Less than 100 mg/dL (2.59 mmol/L)	Greater than or equal to 100 mg/dL (2.59 mmol/L)	Greater than or equal to 100 mg/dL (2.59 mmol/L)
Very-High Risk	Optional goal of less than 70 mg/dL[a] (1.81 mmol/L)		
Moderately-High Risk Greater than or equal to 2 risk factors (10-year risk 10%–20%)	Less than 130 mg/dL (3.37 mmol/L) (Optional goal of less than 100 mg/dL[a] [2.59 mmol/L])	Greater than or equal to 130 mg/dL (3.37 mmol/L)	Greater than or equal to 130 mg/dL (3.37 mmol/L) (consider drug options if LDL cholesterol 100–129 mg/dL [2.59–3.34 mmol/L)
Moderate Risk Greater than or equal to 2 risk factors (10-year risk less than 10%)	Less than 130 mg/dL (3.37 mmol/L)	Greater than or equal to 130 mg/dL (3.37 mmol/L)	Greater than 160 mg/dL (4.14 mmol/L)
Low Risk	Less than 160 mg/dL (4.14 mmol/L)	Greater than or equal to 160 mg/dL (4.14 mmol/L)	Greater than or equal to 190 mg/dL (4.91 mmol/L) (consider drug options if LDL cholesterol 160–189 mg/dL [4.14–4.89 mmol/L])

[a]Optional goals indicated in the NCEP ATP III 2004 update of the guidelines.
CHD, coronary heart disease; LDL, low-density lipoprotein.

with LDL cholesterol greater than 190 mg/dL [4.92 mmol/L] at baseline) are candidates for drug therapy (Table 9–6). ❻ *Typically, statins are the medications of choice to treat high LDL cholesterol because of their ability to substantially reduce LDL cholesterol, ability to reduce morbidity and mortality from atherosclerotic disease, convenient once-daily dosing, and low risk of side effects.*

TABLE 9–7. Essential Components of Therapeutic Lifestyle Changes (TLC)

Component	Recommendation
LDL-raising nutrients	Total fat range should be 25–35% for most cases
Saturated fats	Less than 7% of total calories and reduce intake of trans fatty acids
Dietary cholesterol	Less than 200 mg/day
Therapeutic options for LDL lowering	
Plant stanols/sterols	2 g per day
Increased viscous (soluble) fiber	10–25 g per day
Total calories	Adjust caloric intake to maintain desirable body weight and prevent weight gain
Physical activity	Include enough moderate exercise to expend at least 200 kcal per day

LDL, low-density lipoprotein.

Step 9: Identify Patients with the Metabolic Syndrome

The diagnosis of metabolic syndrome is made when three or more of the following risk factors are present:[3,10]

- Waist circumference greater than 40 inches (101.6 cm) in men (greater than 35 inches in Asian males), or 35 inches (88.9 cm) in women (greater than 31 inches in Asian females)
- Triglycerides greater than or equal to 150 mg/dL (1.70 mmol/L) or on drug treatment for elevated triglycerides
- HDL cholesterol less than 40 mg/dL (1.04 mmol/L) in men or 50 mg/dL (1.3 mmol/L) in women or on drug treatment for reduced HDL cholesterol
- Blood pressure greater than or equal to 130/85 mm Hg or on drug treatment for hypertension
- Fasting blood glucose greater than or equal to 100 mg/dL (5.55 mmol/L) or on drug treatment for elevated glucose

Patients with metabolic syndrome are twice as likely to develop type 2 diabetes and four times more likely to develop CHD.[3,11] These individuals are usually insulin resistant, obese, have hypertension, are in a **prothrombotic state**, and have atherogenic dyslipidemia characterized by low HDL cholesterol and elevated triglycerides, and an increased proportion of their LDL particles are small and dense.[3]

NCEP ATP III identified metabolic syndrome as an important target for further reducing CHD risk. Treatment of metabolic syndrome starts with increased physical activity, weight reduction (which also enhances LDL cholesterol lowering and

insulin sensitivity), and moderation of ethanol use and carbohydrate intake, which effectively reduce many of the associated risk factors. Each of the risk factors should be addressed independently as appropriate, including treatment of hypertension and use of aspirin in CHD patients to reduce the prothrombotic state. ❼ *Patients with metabolic syndrome have an additional lipid parameter that needs to be assessed, namely non-HDL cholesterol (total cholesterol minus HDL cholesterol).*[3] *The target for non-HDL cholesterol is less than the patient's LDL cholesterol target plus 30 mg/dL (0.78 mmol/L).* ❽ *After assessment and control of LDL cholesterol, patients with serum triglycerides between 200 and 499 mg/dL (2.26 and 5.64 mmol/L) should be assessed for atherogenic dyslipidemia (low HDL cholesterol, increased small-dense LDL particles) and metabolic syndrome.* Non-HDL cholesterol estimates the cholesterol carried by all apolipoprotein B-containing lipoprotein particles. Thus, non-HDL cholesterol represents the sum of LDL cholesterol, VLDL cholesterol, and other remnant particles. The non-HDL cholesterol goal is 30 mg/dL (0.78 mmol/L) higher than the LDL cholesterol goal. This is based on the premise that a VLDL cholesterol level less than or equal to 30 mg/dL (0.78 mmol/L) is normal. For example, the LDL cholesterol goal is less than 100 mg/dL (2.59 mmol/L) and the non-HDL cholesterol goal is less than 130 mg/dL (3.37 mmol/L) for a diabetic patient without a history of CHD. Two treatment approaches can be considered for achieving the non-HDL cholesterol goal: titrating existing LDL-lowering therapy or adding niacin or a fibrate to the LDL-lowering therapy.[3]

Step 10: Treatment of Elevated Triglycerides

Patients with serum triglycerides exceeding 500 mg/dL (5.65 mmol/L) are at increased risk of pancreatitis.[3] Reducing triglycerides in these individuals becomes the primary target for intervention. Reduction in ethanol and carbohydrates should be considered and secondary causes (Table 9–3) should be assessed. When pharmacotherapy is instituted, the intensity of therapy should be to reduce triglycerides to less than 150 mg/dL (1.70 mmol/L). Once triglycerides are less than 500 mg/dL (5.65 mmol/L), the primary focus of intervention should once again be on LDL cholesterol. Niacin, fibrates, and fish oils are the most effective agents in patients with hypertriglyceridemia.[3]

Emerging and Life-Habit Risk Factors

In addition to the five major risks, the ATP III guidelines recognize other factors that contribute to CHD risk. These are classified as life-habit risk factors and emerging risk factors. Life-habit risk factors, consisting of obesity, physical inactivity, and an atherogenic diet, require direct intervention. For example, emerging risk factors are lipoprotein(a), homocysteine, prothrombotic/proinflammatory factors, and C-reactive protein (CRP). C-reactive protein is a marker of low-level inflammation and appears to help in predicting CHD risk beyond LDL cholesterol and major CHD risk factors.[11] In some patients, emerging risk factors may be used to guide the intensity of risk-reduction therapy. Deciding when to consider emerging risk factors requires the use of clinical judgment.

Patient Encounter 1, Part 2: Medical History, Physical Exam, and Diagnostic Tests

PMH
Hypertension for 9 years; history of gout

FH
Father and mother both alive with no history of CHD or diabetes.

SH
Works as a computer programmer and sits at his desk most of the day; does not exercise on a regular basis; drinks alcohol (2 to 3 beers) mainly on the weekends while watching sports on TV

Meds
Aspirin 80 mg once daily
Verapamil SR 180 mg once daily

ROS
No chest pain, shortness of breath, or dizziness

PE

VS: BP 142/86 mm Hg, pulse 71 beats per minute, respiratory rate 16 beats per minute, temperature 37°C (98.6°F), waist circumference 38 inches (96.52 cm)
CV: RRR, normal S_1, S_2; no murmurs, rubs, or gallops
Abd: Soft, non-tender, non-distended; positive for bowel sounds, no hepatosplenomegaly or abdominal aortic aneurysm
Exts: Ankle-brachial index 1.1
Neck: No carotid and basilar bruits

Labs
Total cholesterol 256 mg/dL (6.63 mmol/L), triglycerides 235 mg/dL (2.66 mmol/L), HDL cholesterol 27 mg/dL (0.70 mmol/L), glucose 115 mg/dL (6.38 mmol/L), all other labs within normal limits

- Given this additional information, what is your assessment of MN's CHD risk?
- Identify your treatment goals for MN.
- What diagnostic parameters does MN have for the metabolic syndrome?
- What nonpharmacologic and pharmacologic alternatives are available for MN?
- Develop a care plan for MN.

Pharmacotherapy

Statins (HMG-CoA Reductase Inhibitors)

Statins are very effective LDL-lowering medications and are proven to reduce the risk of CHD, stroke, and death. Thus, NCEP ATP III considers statins the preferred LDL-lowering medications. Data concerning the efficacy and safety of the statins now go back nearly 25 years. Statins are effective in reducing MIs, strokes, revascularization procedures, cardiovascular deaths, and in some cases, total mortality. This effectiveness has been demonstrated in both genders, the elderly, patients with diabetes and hypertension, those with and without preexisting CHD, and following an acute coronary syndrome.[12–22] Statins inhibit conversion of HMG-CoA to L-mevalonic acid and subsequently cholesterol. Statins lower LDL cholesterol levels by approximately 25% to 62% (Table 9–8). A substantial reduction in LDL cholesterol occurs at the usual starting dose and each doubling of the daily dose only produces an additional 6% average reduction (known as the "rule of 6"). This is important when considering dose escalation versus adding on an additional LDL-lowering drug. Statins are moderately effective at reducing triglycerides and modestly raise HDL cholesterol (Table 9–8). By inhibiting the synthesis of L-mevalonic acid, statins in turn inhibit other important by-products in the cholesterol biosynthetic pathway that affect intracellular transport, membrane trafficking, and gene transcription.[23] This may explain some of the cholesterol-independent benefits (so-called "pleiotropic" effects) of statins such as reducing lipoprotein oxidation, enhancing endothelial synthesis of nitric oxide, and inhibiting **thrombosis**. These pleiotropic effects are thought to contribute to the rapid/earlier benefits of statins on CHD risk while the decrease in serum lipids accounts for the slower late benefit.

Statins are well tolerated with less than 4% of patients in clinical trials discontinuing therapy due to adverse side effects (Table 9–9). Elevations in liver function tests (LFTs) and **myopathy**, including **rhabdomyolysis**, are important adverse effects associated with the statins. Liver toxicity, defined as LFT elevations greater than three times the upper limit of normal, is reported in less than 2% of patients; however, the incidence is higher at higher doses and the progression to liver failure is thought to be exceedingly rare. Liver function tests should be obtained at baseline and 6 to 12 weeks after starting therapy or any dose escalation. Annual monitoring of LFTs is usually sufficient. Myopathy, defined as muscle symptoms with creatine kinase (CK; or creatine phosphokinase [CPK]) 10 times the upper limit of normal, is reported to range from 0% to less than 0.5% for the currently marketed statins at Food and Drug Administration (FDA)-approved doses. Rhabdomyolysis, defined as muscle symptoms with marked

TABLE 9–8. Effects of Lipid-Lowering Drugs on Serum Lipids at FDA-Approved Doses

Lipid-Lowering Drug	LDL Cholesterol	HDL Cholesterol	Triglycerides	Total Cholesterol
Statins				
Atorvastatin	–26% to –60%	+5% to +13%	–17% to –53%	–25% to –45%

TABLE 9–9. Formulation, Dosing, and Common Adverse Effects of Lipid-Lowering Drugs

Lipid-Lowering Drug	Dosage Forms	Usual Adult Maintenance Dose Range	Adverse Effects
Statins			
Atorvastatin	10, 20, 40, 80 mg tablets	10 to 80 mg once daily (at any time of day)	Most frequent side effects are constipation, abdominal pain, diarrhea, dyspepsia, and nausea. Statins should be discontinued promptly if serum transaminase levels (liver function tests) rise to 3 times upper limit of normal, or if patient develops signs or symptoms of myopathy. Approximate equivalent doses of HMG-CoA reductase inhibitors are: atorvastatin 10 mg, fluvastatin 80 mg, lovastatin 40 mg, pravastatin 40 mg, simvastatin 20 mg, and rosuvastatin 5 mg.
Fluvastatin	20, 40 mg capsules; 80 mg extended-release tablets	20–40 mg/day as a single dose (evening) or 40 mg twice daily; 80 mg once daily (evening)	
Lovastatin	10, 20, 40 mg tablets	10 to 80 mg/day as a single dose (with evening meal) or divided twice daily with food	
Lovastatin ER	20, 30, 60 mg tablets	20 to 60 mg/day as a single dose	
Pravastatin	10, 20, 40, 80 mg tablets	10 to 80 mg/day as a single dose at bedtime	
Rosuvastatin	5, 10, 20, 40 mg tablets	5–40 mg/day (at any time of day). 40 mg reserved for those who don't achieve LDL cholesterol goal on 20 mg	
Simvastatin	5, 10, 20, 40, 80 mg tablets	5–80 mg/day as a single dose in the evening, or divided	
Bile Acid Sequestrants			
Cholestyramine	4 g packets	4–24 g/day in two or more divided doses	Main side effects are nausea, constipation, bloating, and flatulence, although these may be less with colesevelam. Increasing fluid and dietary fiber intake may relieve constipation and bloating. Impair absorption of fat-soluble vitamins.
Colesevelam	625 mg tablets	3750–4375 mg/day as a single dose or divided twice daily, with meals	
Colestipol	5 g packets	5–30 g/day as a single dose or divided	
	1 g tablets	2–16 g/day as a single dose or divided	
Cholesterol Absorption Inhibitors			
Ezetimibe	10 mg tablet	10 mg once daily	The overall incidence of adverse events reported with ezetimibe alone was similar to that reported with placebo and generally similar between ezetimibe with a statin and statin alone. The frequency of increased transaminases was slightly higher in patients receiving ezetimibe plus a statin compared with those receiving statin monotherapy (1.3% versus 0.4%).
Nicotinic Acid			
Niacin ER	500, 750, 1000 mg extended-release tablets	1000–2000 mg once daily at bedtime	Side effects include flushing, itching, gastric distress, headache, hepatotoxicity, hyperglycemia, and hyperuricemia.
Niacin	50 to 750 mg tabs or caps, immediate-release	1–5 g/day in three or more divided doses	
	250 to 750 mg sustained-release	1–2 g/day (never exceed 2 g/day due to increased risk of hepatotoxicity)	
Fibric Acid Derivatives			
Fenofibrate	54, 160 mg tablets	54–160 mg/day	Most common side effects are nausea, diarrhea, abdominal pain, and rash. Increased risk of rhabdomyolysis when given with a statin. Fibric acids are associated with gallstones, myositis, and hepatitis.
Gemfibrozil	600 mg tablets	1200 mg/day in two doses, 30 minutes before meals	

(*Continued*)

TABLE 9–9. Formulation, Dosing, and Common Adverse Effects of Lipid-Lowering Drugs (*Continued*)

Lipid-Lowering Drug	Dosage Forms	Usual Adult Maintenance Dose Range	Adverse Effects
Combination Products			
Niacin ER and lovastatin	500 mg/20 mg, 750 mg/20 mg, 1000 mg/20 mg tablets	500 mg/20 mg to 2000 mg/40 mg daily, at bedtime	See entries on prior page for each drug (niacin ER and lovastatin)
Ezetimibe and simvastatin	10 mg/10 mg, 10 mg/20 mg, 10 mg/40 mg, 10 mg/80 mg	The dosage range is 10/10 mg/day through 10/80 mg/day. The recommended usual starting dose is 10/20 mg/day. Initiation of therapy with 10/10 mg/day may be considered for patients requiring less aggressive LDL cholesterol reductions.	See entries on prior page for each drug (ezetimibe and simvastatin)

ER, extended release; HMG-CoA, 3-hydroxy-3-methyglutaryl coenzyme A; LDL, low-density lipoprotein.

elevation in CK 10 times the upper limit of normal with creatinine elevation usually associated with **myoglobinuria** and brown urine, is very rare.[24] The concern of statin-associated myopathy has increased since the voluntary removal of cerivastatin from the world market in 2001 because the reported rate of fatal rhabdomyolysis was 16 to 80 times higher than the rate for any other statins, and many of these cases were reported in patients treated with concomitant gemfibrozil.[25] The American College of Cardiology/American Heart Association/National Heart, Lung and Blood Institute published a clinical advisory with a focus on myopathy.[24] Listed below are the risks associated with statin-induced myopathy published in this report:

- Small body frame and frailty
- Multisystem disease (e.g., chronic renal insufficiency, especially due to diabetes)
- Multiple medications
- Perioperative periods
- Specific concomitant medications or consumptions (check specific statin package insert for warnings): fibrates (especially gemfibrozil, but other fibrates too), nicotinic acid (rarely), cyclosporine, azole antifungals such as itraconazole and ketoconazole, macrolide antibiotics such as erythromycin and clarithromycin, protease inhibitors used to treat Acquired Immune Deficiency Syndrome, nefazodone (antidepressant), verapamil, amiodarone, large quantities of grapefruit juice (usually more than 1 quart per day), and alcohol abuse (independently predisposes to myopathy)

Baseline CK should be obtained in all patients prior to starting statin therapy. Follow-up CK should only be obtained in patients complaining of muscle pain, weakness, tenderness, or brown urine. Routine monitoring of CK is of little value in the absence of clinical signs or symptoms. Patient assessment for symptoms of myopathy should be done 6 to 12 weeks after starting therapy and at each visit. More frequent monitoring should be done in higher-risk individuals such as those identified above.

With the exception of pravastatin which is mainly metabolized by isomerization in the gut to a relatively inactive metabolite, the other statins undergo biotransformation by the cytochrome P-450 system. Therefore, drugs known to inhibit statin metabolism should be used cautiously. The time until maximum effect on lipids for statins is generally 4 to 6 weeks.

Cholesterol Absorption Inhibitors

Ezetimibe is the first drug in a new class of agents referred to as cholesterol absorption inhibitors. Ezetimibe blocks biliary and dietary cholesterol as well as phytosterol (plant sterol)

Patient Encounter 2

LC is a 51-year-old female with a history of CHD (stent placement in the left anterior descending coronary artery 3 years prior) and type 2 diabetes who is referred to you for follow-up of her cholesterol. She is taking simvastatin 20 mg once daily in the evening for her cholesterol, and metformin 2000 mg once daily in the evening and pioglitizone 15 mg once daily for diabetes. Her diabetes is well controlled. Her laboratory test results are within normal limits, except for her fasting lipid profile: total cholesterol 215 mg/dL (5.57 mmol/L), triglycerides 135 mg/dL (1.53 mmol/L), HDL cholesterol 51 mg/dL (1.32 mmol/L), and LDL cholesterol 137 mg/dL (3.55 mmol/L).

- What is your assessment of LC's cholesterol results?
- Identify treatment goals for LC.
- Assess LC's risk for statin-induced side effects.
- Design a treatment plan for LC.

absorption by interacting with the NPC1L1 transporter located in the brush border membrane of enterocytes[5] (Fig. 9–2). Ezetimibe inhibits 54% of all intestinal cholesterol absorption on average. By reducing the cholesterol content within chylomicrons delivered to the liver, ezetimibe reduces liver cholesterol stores, inducing an up-regulation of LDL receptors resulting in a decrease in serum cholesterol. As a result, ezetimibe also induces a compensatory increase in cholesterol biosynthesis. Since statins inhibit cholesterol biosynthesis, the compensatory increase in cholesterol biosynthesis by ezetimibe can be blocked by combining ezetimibe with a statin.

Ezetimibe reduces LDL cholesterol by an average of 18% (Table 9–8). However, larger reductions can be seen in some individuals, presumably due to higher absorption of cholesterol. These individuals appear to have a blunted response to statin therapy. Ezetimibe lowers triglycerides by 7% to 9% and modestly increases HDL cholesterol.

Once absorbed, ezetimibe undergoes extensive glucuronidation in the intestinal wall to the active metabolite (ezetimibe glucuronide). Ezetimibe and the active metabolite are enterohepatically recirculated back to the site of action, which limits systemic exposure and may explain the low incidence of adverse effects (Table 9–9). Ezetimibe alone or with a statin is contraindicated in patients with active liver disease or unexplained persistent elevations in LFTs. Currently, clinical trials designed to determine ezetimibe's effects on CHD morbidity and mortality have not been completed. The time until maximum effect on lipids for ezetemibe is generally 2 weeks.

Bile Acid Sequestrants

Cholestyramine, colestipol, and colesevelam are the bile acid-binding resins or sequestrants (BAS) currently available in the United States. Resins are highly charged molecules that bind to bile acids (which are produced from cholesterol) in the gut. The resin-bile acid complex is then excreted in the feces. The loss of bile causes a compensatory conversion of hepatic cholesterol to bile, reducing hepatocellular stores of cholesterol resulting in an up-regulation of LDL receptors to replenish hepatocellular stores which then result in a decrease in serum cholesterol. Resins have been shown to reduce CHD events in patients without CHD.[26]

Resins are moderately effective in lowering LDL cholesterol but do not lower triglycerides (Table 9–8). Moreover, in patients with elevated triglycerides, the use of a resin may worsen the condition. This may be due to a compensatory increase in HMG-CoA reductase activity and results in an increase in assembly and secretion of VLDL. The increase in HMG-CoA reductase activity can be blocked with a statin, resulting in enhanced reductions in serum lipids (see section on combination therapy). Resins reduce LDL cholesterol from 15% to 30%, with a modest increase in HDL cholesterol (3% to 5%) (Table 9–8). Resins are most often used as adjuncts to statins in patients who require additional lowering of LDL cholesterol. Since these drugs are not absorbed, adverse effects are limited to the gastrointestinal tract (Table 9–9). About 20% of patients taking cholestyramine or colestipol report constipation and symptoms such as flatulence and bloating. A large number of patients stop therapy because of this. Resins should be started at the lowest dose and escalated slowly over weeks to months as tolerated until the desired response is obtained. Patients should be instructed to prepare the powder formulations in 6 to 8 ounces (approximately 180–240 mL) of noncarbonated fluids, usually juice (enhances palatability) or water. Fluid intake should be increased to minimize constipation. Colesevelam is better tolerated with fewer gastrointestinal side effects, although it is more expensive. All resins have the potential to prevent the absorption of other drugs such as digoxin, warfarin, thyroxine, thiazides, β-blockers, fat-soluble vitamins, and folic acid. Potential drug interactions can be avoided by taking a resin either 1 hour before or 4 hours after these other agents. Colesevelam appears less likely than the older agents to reduce drug absorption, and the manufacturer does not state that colesevelam has to be dosed hours apart from other medications.[27] The time until maximum effect on lipids for resins is generally 2 to 4 weeks.

Niacin

Niacin (vitamin B_3) has broad applications in the treatment of lipid disorders when used at higher doses than those used as a nutritional supplement. Niacin inhibits fatty acid release from adipose tissue and inhibits fatty acid and triglyceride production in liver cells. This results in an increased intracellular degradation of apolipoprotein B, and in turn, a reduction in the number of VLDL particles secreted (Fig. 9–4). The lower VLDL levels and the lower triglyceride content in these particles leads to an overall reduction in LDL cholesterol as well as a decrease in the number of small, dense LDL particles. Niacin also reduces the uptake of HDL-apolipoprotein A1 particles and increases uptake of cholesterol esters by the liver, thus improving the efficiency of reverse cholesterol transport between HDL particles and vascular tissue (Fig. 9–4). Niacin is indicated for patients with elevated triglycerides, low HDL cholesterol, and elevated LDL cholesterol.[3]

Several different niacin formulations are available: niacin immediate-release (IR), niacin sustained-release (SR), and niacin extended-release (ER).[28,29] These formulations differ in terms of dissolution and absorption rates, metabolism, efficacy, and side effects. Limitations of niacin IR and SR are flushing and **hepatotoxicity**, respectively. These differences appear related to the dissolution and absorption rates of niacin formulations and its subsequent metabolism. Niacin IR is available by prescription (Niacor®) as well as a dietary supplement which is not regulated by the FDA.[28] Currently, there are no FDA-approved niacin SR products, thus, all SR products are available only as dietary supplements.

Niacin IR is usually completely absorbed within 1 to 2 hours; thus, it quickly saturates a high-affinity, low-capacity metabolic pathway, and the majority of the drug is metabolized by a

second low-affinity, high-capacity system with metabolites associated with flushing.[30] Conversely, absorption of niacin SR may exceed 12 hours. Because niacin SR is absorbed over 12 or more hours, the high-affinity pathway metabolizes the majority of the drug, resulting in the production of metabolites associated with hepatotoxicity. Niacin ER was developed as a once-daily formulation to be taken at bedtime, with the goal of reducing the incidence of flushing without increasing the risk of hepatotoxicity. Niacin ER (Niaspan®) is the only long-acting niacin product approved by the FDA for dyslipidemia. Niacin ER has an absorption rate of 8 to 12 hours, intermediate to niacin IR and SR, and therefore balances metabolism more evenly over the high-affinity, low-capacity pathway and the low-affinity, high-capacity pathway. Furthermore, taking niacin ER at bedtime can minimize the impact of flushing.

Niacin use is limited by cutaneous reactions such as flushing and pruritus of the face and body. The use of aspirin or a non-steroidal anti-inflammatory drug 30 minutes prior to taking niacin can help alleviate these reactions, as they are mediated by an increase in prostaglandin D_2.[3] In addition, taking niacin with food and avoiding hot liquids at the time niacin is taken is helpful in minimizing flushing and pruritus.

In general, niacin reduces LDL cholesterol from 5% to 25%, reduces triglycerides by 20% to 50%, and increases HDL cholesterol by 15% to 35% (Table 9–8). Niacin has been shown to reduce CHD events and total mortality[31] as well as the progression of atherosclerosis when combined with a statin.[31]

Niacin can raise uric acid levels, and in diabetics can raise blood glucose levels. However, several clinical trials have shown that niacin can be used safely and effectively in patients with diabetes.[33] Due to the high cardiovascular risk of patients with diabetes, the benefits of improving the lipid profile appear to outweigh any adjustment in diabetic medication(s) that is needed.[33]

Niacin should be instituted at the lowest dose and gradually titrated to a maximum dose of 2 grams daily for ER and SR products and no more than 5 grams daily for IR products. FDA-approved niacin products are preferred because of product consistency. Moreover, niacin products labeled as "no flush" don't contain nicotinic acid and therefore have no therapeutic role in the treatment of lipid disorders.[28] The time until maximum effect on lipids for niacins is generally 3 to 5 weeks.

Fibrates

The predominant effects of fibrates are a decrease in triglyceride levels by 20% to 50% and an increase in HDL cholesterol levels by 9% to 30% (Table 9–8). The effect on LDL cholesterol is less predictable. In patients with high triglycerides, however, LDL cholesterol may increase. Fibrates increase the size and reduce the density of LDL particles much like niacin. Fibrates are the most effective triglyceride-lowering drugs and are used primarily in patients with elevated triglycerides and low HDL cholesterol.

Fibrates work by reducing apolipoproteins B, C-III (an inhibitor of LPL), and E, and increasing apolipoproteins A-I and A-II through activation of peroxisome proliferator-activated receptors-alpha (PPAR-α), a nuclear receptor involved in cellular function. The changes in these apolipoproteins result in a reduction in triglyceride-rich lipoproteins (VLDL and IDL) and an increase in HDL.

Clinical trials of fibrate therapy in patients with elevated cholesterol and no history of CHD demonstrated a reduction in CHD incidence, although less than the reduction attained with statin therapy.[35] In addition, a large study of men with CHD, low HDL cholesterol, low LDL cholesterol, and elevated triglycerides demonstrated a 24% reduction in the risk of death from CHD, non-fatal MI, and stroke with gemfibrozil.[36] Fibrates may be appropriate in the prevention of CHD events for patients with established CHD, low HDL cholesterol, and triglycerides below 200 mg/dL (2.26 mmol/L). However, LDL-lowering therapy should be the primary target if LDL cholesterol is elevated. Evidence of a reduction in CHD risk among patients with established CHD has not been demonstrated with fenofibrate.

The fibric acid derivatives are generally well tolerated. The most common adverse effects include dyspepsia, abdominal pain, diarrhea, flatulence, rash, muscle pain, and fatigue (Table 9–9). Myopathy and rhabdomyolysis can occur, and the risk appears to increase with renal insufficiency or concurrent statin therapy. If a fibrate is used with a statin, fenofibrate is preferred because it appears to inhibit the glucuronidation of the statin hydroxy and moiety less than gemfibrozil, allowing greater renal clearance of the statins.[24,37] A CK level should be checked before therapy is started and if symptoms occur. Liver dysfunction has been reported, and LFTs should be monitored. Fibrates increase cholesterol in the bile and have caused gallbladder and bile duct disorders, such as **cholelithiasis** and **cholecystitis**. Unlike niacin, these agents do not increase glucose or uric acid levels. Fibrates are contraindicated in patients with gallbladder disease, liver dysfunction, or severe kidney dysfunction. The risk of bleeding is increased in patients taking both a fibrate and warfarin. The time until maximum effect on lipids is generally 2 weeks for fenofibrate and 3 to 4 weeks for gemfibrozil.

Fish Oils

Omega-3 fatty acids (eicosapentaenoic acid and docosahexaenoic acid), the predominant fatty acids in the oil of cold-water fish, lower triglycerides by as much as 35% when taken in large amounts. Fish oil supplements may be useful for patients with high triglycerides despite diet, alcohol restriction, and fibrate therapy. This effect may be modulated thru PPAR-α and a reduction in apolipoprotein B-100 secretion. Omega-3 fatty acids reduce platelet aggregation and have

anti-arrhythmic properties, and therefore their use has been associated with a reduction in MI and sudden cardiac death, respectively.[38]

Omega-3 fatty acids are usually started at 1 gram daily, and the FDA recommends not exceeding 4 grams daily for the treatment of elevated triglycerides. Use of high-quality omega-3 fatty acids free of contaminants such as mercury and organic pollutants should be encouraged when using these agents. Common side effects associated with omega-3 fatty acids are diarrhea and excess bleeding. Patients taking anticoagulant or antiplatelet agents should be monitored more closely when consuming these products because excessive amounts of omega-3 fatty acids (for example, greater than 3 grams daily) may lead to bleeding and may increase the risk of hemorrhagic stroke.

Combination Therapy

A large proportion of the United States population won't achieve their NCEP cholesterol targets for a variety of reasons.[39] These include inadequate patient adherence, adverse events, inadequate starting doses, lack of dose escalation, and lower treatment targets.[28,40] Moreover, patients with concomitant elevations in triglycerides and/or low levels of HDL cholesterol may need combination drug therapy to normalize their lipid profile. ❾ *Combination drug therapy is an effective means to achieve greater reductions in LDL cholesterol (statin + ezetimibe or bile acid resin, bile acid resin + ezetimibe, or three-drug combinations) as well as raising HDL cholesterol and lowering serum triglycerides (statin + niacin or fibrate).*

Combination Therapy for Elevated LDL Cholesterol

For patients who don't achieve their LDL or non-HDL cholesterol goals with statin monotherapy and lifestyle modifications including those unable to tolerate high doses due to adverse effects, combination therapy may be appropriate. Resins or ezetimibe combine effectively with statins to augment LDL cholesterol reduction. When added to a statin, ezetimibe can reduce LDL cholesterol levels by an additional 18% to 21% or up to 65% total reduction with maximum doses of the more potent statins. Ezetimibe and simvastatin are available as a combination tablet (Vytorin®) and indicated as adjunctive therapy to diet for the reduction of elevated total cholesterol, LDL cholesterol, apolipoprotein B, triglycerides, and non-HDL cholesterol, and to increase HDL cholesterol. The usual starting dose is 10 mg/20 mg, and the maximum dose is 10 mg/80 mg (Table 9–9). Adverse events are similar to those of each product taken separately; however, the percentage of patients with LFT elevations greater than 3 times normal is slightly higher than with a statin alone, and there appears to be a slightly higher risk of myopathy and rhabdomyolysis when statins and ezetimibe are combined. The time until maximum effect on lipids for this combination is generally 2 to 6 weeks.

A statin combined with a resin results in similar reductions in LDL cholesterol as those seen with ezetimibe. However, the magnitude of triglyceride reduction is less with a resin compared to ezetimibe, and this should be considered in patients with higher baseline triglyceride levels. In addition, gastrointestinal adverse events and potential drug interactions limit the utility of this combination.

Ezetimibe and a resin can also be combined. A study which assessed the effects of adding ezetimibe to ongoing resin therapy showed an additional 19% reduction in LDL cholesterol and an additional 14% reduction in triglycerides. This combination was well tolerated.[41]

Some patients, in particular those with genetic forms of hypercholesterolemia (Table 9–2), will require three or more drugs to manage their disorder. Regimens using a statin, resin, and niacin were found to reduce LDL cholesterol up to 75%.[42] These early studies were conducted with lovastatin, so larger reductions would be expected with the more potent statins available today.

Combination Therapy for Elevated Cholesterol and Triglyceridemia with or without Low HDL Cholesterol

Fibrates are the most effective triglyceride-lowering agents and also raise HDL cholesterol levels. Combination therapy with a fibrate, particularly gemfibrozil, and a statin has been found to increase the risk for myopathy. Of the 31 rhabdomyolysis deaths reported with cerivastatin use, 12 involved concomitant gemfibrozil.[25] Therefore, more frequent monitoring, thorough patient education, and consideration of factors that increase the risk as reviewed previously should be considered.

❿ *Reducing LDL cholesterol while substantially raising HDL cholesterol (statin + niacin) appears to reduce the risk of atherosclerotic disease progression to a greater degree than statin monotherapy.* Combining niacin with a statin augments the LDL cholesterol–lowering potential of niacin while enhancing both the HDL cholesterol–raising effects and triglyceride–lowering effects of the statin. A statin combined with niacin appears to offer greater benefits for reducing atherosclerosis progression compared to a statin alone.[32] A formulation combining ER niacin and lovastatin (Advicor™) is available and is indicated for treatment of primary hypercholesterolemia and mixed dyslipidemia in patients treated with lovastatin who require further triglyceride lowering or HDL cholesterol raising and may benefit from having niacin added to their regimen. The combination is also indicated for patients treated with niacin who require further LDL cholesterol lowering and may benefit from having lovastatin added to their regimen. The time until maximum effect on lipids for this combination is generally 3 to 6 weeks.

Niacin can be combined with a fibrate in patients with high elevations in serum triglycerides. The combination may increase the risk of myopathy compared to either agent alone.

Compared with monotherapy, combination therapy is relatively unstudied in terms of the effects on CHD event reduction and may reduce patient compliance through increased side effects and increased costs. When used appropriately and with proper precautions, however, they are effective in normalizing lipid abnormalities, particularly in patients who cannot tolerate adequate doses of statin therapy for more severe forms of dyslipidemia.

Investigational Agents

There are numerous investigational drugs in development for the treatment of lipid disorders and prevention of atherosclerosis. Many of these will likely be used in combination with currently available lipid-modulating drugs. The most promising are the cholesterol ester transfer protein (CETP) inhibitors, which have the potential to significantly raise HDL cholesterol.[43] Other agents in development include newer statins; bile acid transport inhibitors; phytostanol analogues; acyl coenzyme A: cholesterol acyltransferase (ACAT) inhibitors; squalene synthase inhibitors; and newer PPAR-α, -γ, and -δ agonists, as well as dual PPAR-α/γ agonists. In addition, weekly infusions of genetically engineered HDL (Apolipoprotein A1 Milano) in patients with atherosclerosis has been shown to cause significant reduction in atheroma volume compared to placebo after just 5 weeks of therapy.[44]

These novel therapies will provide opportunities for developing different combination strategies to further reduce the risk of CHD even after adequate treatment with existing agents. Well-designed studies using non-invasive imaging technology and long-term follow-up periods are needed to ensure that there is a favorable risk:benefit ratio.

OUTCOME EVALUATION

- The successful outcome in cholesterol management is to reduce cholesterol and triglycerides below the NCEP ATP III goals in an effort to alter the natural course of atherosclerosis and decrease future cardiovascular events.
- ❺ *Employ an adequate trial of TLC in all patients, but institute pharmacotherapy concurrently in higher-risk patients.*
- When indicated, initiate drug therapy at a dose that will reduce LDL cholesterol in the range of 30% to 40%.
- ❻ *Typically, statins are the medications of choice to treat high LDL cholesterol because of their ability to substantially reduce LDL cholesterol, ability to reduce morbidity and mortality from atherosclerotic disease, convenient once-daily dosing, and low risk of side effects.*
- Employ an individualized patient monitoring plan in an effort to minimize side effects and maintain treatment adherence and lipid goals.

Patient Care and Monitoring

1. Assess the patient for the presence of CHD or other atherosclerosis disorders.
2. Assess major risk factors for CHD.
3. For patients without CHD or CHD risk equivalent, but two or more major CHD risk factors, perform Framingham risk assessment.
4. Obtain fasting cholesterol profile and assess any abnormal lipid levels.
5. Obtain a thorough history of prescription, nonprescription, and natural drug product use. Determine what treatments for cholesterol the patient has used in the past (if any). Assess if the patient is taking any medications that may contribute to his or her abnormal lipid levels.
6. Assess concomitant diseases that may contribute to the patient's abnormal lipid levels.
7. Assess risk factors for metabolic syndrome.
8. Determine the treatment goal for LDL cholesterol based on the patient's CHD risk and non-HDL cholesterol goal if patient meets criteria for metabolic syndrome.
9. Educate all patients on therapeutic lifestyle changes (TLC) and the importance of regular physical activity.
10. For patients exceeding their LDL cholesterol goal, initiate TLC. Consider starting concurrent pharmacotherapy in patients in the high-risk or moderately-high-risk categories. Pharmacotherapy should be initiated at a dose to reduce LDL cholesterol by 30% to 40% at a minimum.
11. Therapeutic lifestyle changes should be continued and intensified (consider adding plant sterols/stanols and increase fiber) after 6 weeks if not below LDL cholesterol target. For those patients above their LDL cholesterol target after adequate trial of TLC (12 to 18 weeks), pharmacotherapy should be strongly considered.
12. Institute appropriate pharmacotherapy based on lipid abnormality. Obtain appropriate baseline labs to monitor for adverse drug effects. Assess potential disease and drug interactions that may affect choice or intensity of pharmacotherapy.
13. Monitor response, safety, and adherence after a minimum of 4 to 6 weeks. Titrate therapy or add a second drug as needed.
14. Once the LDL cholesterol goal is achieved, assess non-HDL cholesterol in those with metabolic syndrome and intensify LDL-lowering therapy further or consider adding niacin or fibrate.
15. Provide patient education in regard to CHD, hyperlipidemia, therapeutic lifestyle modifications, drug therapy, and therapy adherence.

10 Hypovolemic Shock

Bradley A. Boucher and G. Christopher Wood

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. List the most common etiologies of decreased intravascular volume in hypovolemic shock patients.
2. Describe the major hemodynamic and metabolic abnormalities that occur in patients with hypovolemic shock.
3. Describe the clinical presentation, including signs, symptoms, and laboratory test measurements, for the typical hypovolemic shock patient.
4. Prepare a treatment plan with clearly defined outcome criteria for a hypovolemic shock patient that includes both fluid management and other pharmacologic therapy.
5. Compare and contrast the relative advantages and disadvantages of crystalloids, colloids, and blood products in the treatment of hypovolemic shock.
6. Formulate a stepwise monitoring strategy for a hypovolemic shock patient.

Key Concepts

❶ Hypovolemic shock occurs as a consequence of inadequate intravascular volume to meet the oxygen and metabolic needs of the body.

❷ Protracted tissue hypoxia sets in motion a downward spiral of events secondary to organ dysfunction and eventual failure if untreated.

❸ The overarching goals in treating hypovolemic shock are to restore effective circulating blood volume, as well as managing its underlying cause, thereby reversing organ dysfunction and returning to homeostasis.

❹ Three major therapeutic options are available to clinicians for restoring circulating blood volume: crystalloids (electrolyte-based solutions), colloids (large-molecular-weight solutions), and blood products.

❺ In the absence of ongoing blood loss, administration of 2000 to 4000 mL of isotonic crystalloid will normally re-establish baseline vital signs in adult hypovolemic shock patients.

❻ The volume of colloid administered is primarily confined to the intravascular space, in contrast to isotonic crystalloid solutions that distribute throughout the extracellular fluid space.

❼ Blood products are indicated in adult hypovolemic shock patients who have sustained blood loss from hemorrhage exceeding 1500 mL.

❽ Vasopressors may be warranted as a temporary measure in patients with profound hypotension or evidence of organ dysfunction in the early stages of shock.

❾ Major treatment goals in hypovolemic shock following fluid resuscitation are as follows: arterial systolic blood pressure greater than 90 mm Hg within 1 hour, organ dysfunction reversal, and normalization of laboratory measurements as rapidly as possible (less than 24 hours).

The principal function of the circulatory system is to supply oxygen and vital metabolic substrates to cells throughout the body, as well as removal of metabolic waste products. **Circulatory shock** is a life-threatening condition whereby this principal function is compromised. When circulatory shock is caused by a severe loss of blood volume or body water it is called **hypovolemic shock,** the focus of this chapter. Regardless of etiology, the most distinctive manifestations of hypovolemic shock are **arterial hypotension** and **metabolic acidosis.** Metabolic acidosis is a consequence of an accumulation of lactic acid resulting from tissue hypoxia and anaerobic

metabolism. If the decrease in arterial blood pressure is severe and protracted, such hypotension will inevitably lead to severe hypoperfusion and organ dysfunction. Rapid and effective restoration of circulatory homeostasis through the use of blood products, fluids, and/or pharmacologic agents is imperative to prevent complications of untreated shock and ultimately death.

ETIOLOGY AND EPIDEMIOLOGY

Practitioners must have a good understanding of cardiovascular physiology to diagnose, treat, and monitor circulatory problems in critically ill patients. Eugene Braunwald, a renowned cardiologist, described the interrelationships between the major hemodynamic variables (Fig. 10–1).[1] These variables include: arterial blood pressure, **cardiac output** (CO), **systemic vascular resistance** (SVR), heart rate (HR), **stroke volume** (SV), left ventricular size, **afterload, myocardial contractility,** and **preload.** While an oversimplification, Fig. 10–1 is beneficial in conceptualizing where the major abnormalities occur in patients with circulatory shock as well as predicting the body's compensatory responses.

Shock can be effectively categorized by etiology into four major types: hypovolemic, obstructive, cardiogenic, and distributive (Table 10–1).[2] As noted, all patients with shock have profound decreases in arterial blood pressure. Understanding the primary cause of the circulatory abnormality in these respective shock states is invaluable to their management. Hypovolemic shock is caused by a loss of intravascular volume. Obstructive shock is caused by an obstruction that directly compromises inflow or outflow of blood from the heart. Cardiogenic shock is caused by diminished myocardial contractility resulting in decreased CO. Lastly, distributive shock is caused by a major decrease in SVR. In all shock types, one would expect a compensatory increase in HR to bolster the fallen arterial blood pressure. The exception is relative bradycardia seen in **spinal shock** resulting from spinal cord injury. Differentiating between the underlying abnormality and the

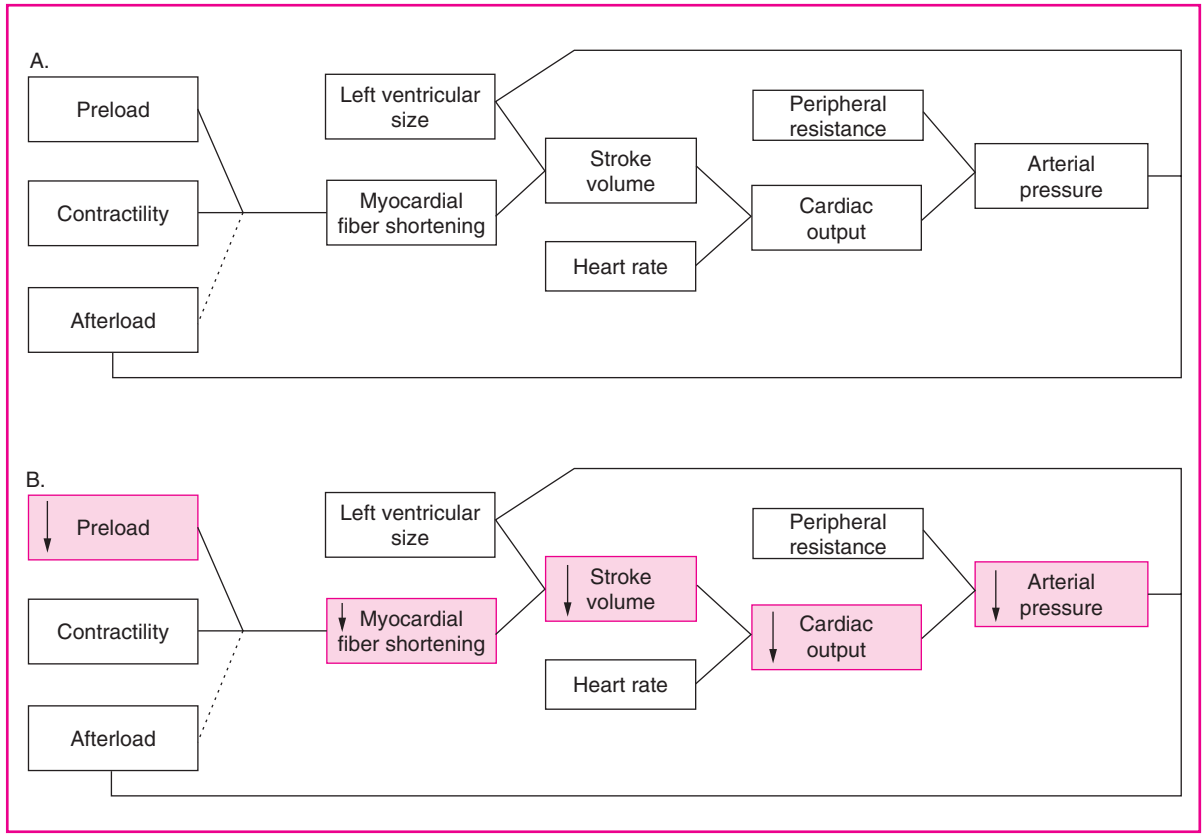

FIGURE 10–1. Hemodynamic relationships between key cardiovascular parameters (panel *A*). Solid lines represent a direct relationship; the broken line represents an inverse relationship. In panel *B*, the perturbations typically observed in hypovolemic shock are highlighted in blue with arrows depicting the likely direction of the pertubation. (Reprinted from Braunwald E. Regulation of the circulation. I. N Engl J Med 1974;290:1129, with permission.)

TABLE 10–1. Major Shock Classifications and Etiologies[2,49]

I. Hypovolemic

associated compensatory response is also essential in terms of treatment and monitoring. Hypovolemic shock is considered to be essentially a profound deficit in preload. Preload is defined as the volume in the left ventricle at the end of diastole. Decreased preload results in subsequent decreases in SV, CO, and eventually, **mean arterial pressure** (MAP). As such, restoration of preload becomes an overriding goal in the management of hypovolemic shock.

The prognosis of shock patients depends on several variables including severity, duration, underlying etiology, preexisting organ dysfunction, and reversibility.[2] Data are not readily available as to the incidence of hypovolemic shock, although mortality rates have been reported as high as 30% to 40% in trauma patients.[3]

PATHOPHYSIOLOGY

The total amount of water in a typical 70 kg (154 lb) adult is approximately 42 liters (Fig. 10–2).[4] About 28 of the 42 liters are inside the cells of the body (intracellular fluid) while the remaining 14 liters are in the extracellular fluid space (fluid outside of cells: interstitial fluid and plasma). Circulating blood volume for a normal adult is roughly 5 liters (70 mL/kg) and is comprised of 2 liters of red blood cell fluid (intracellular) and 3 liters of plasma (extracellular).❶ *By definition, hypovolemic shock occurs as a consequence of inadequate intravascular volume to meet the oxygen and metabolic needs of the body.* Diminished intravascular volume can result from severe external or internal bleeding, profound fluid losses from gastrointestinal sources such as diarrhea or vomiting, or urinary losses such as diuretic use, diabetic ketoacidosis, or diabetes insipidus (Table 10–1).[2] Other sources of intravascular fluid loss can occur through damaged skin, as

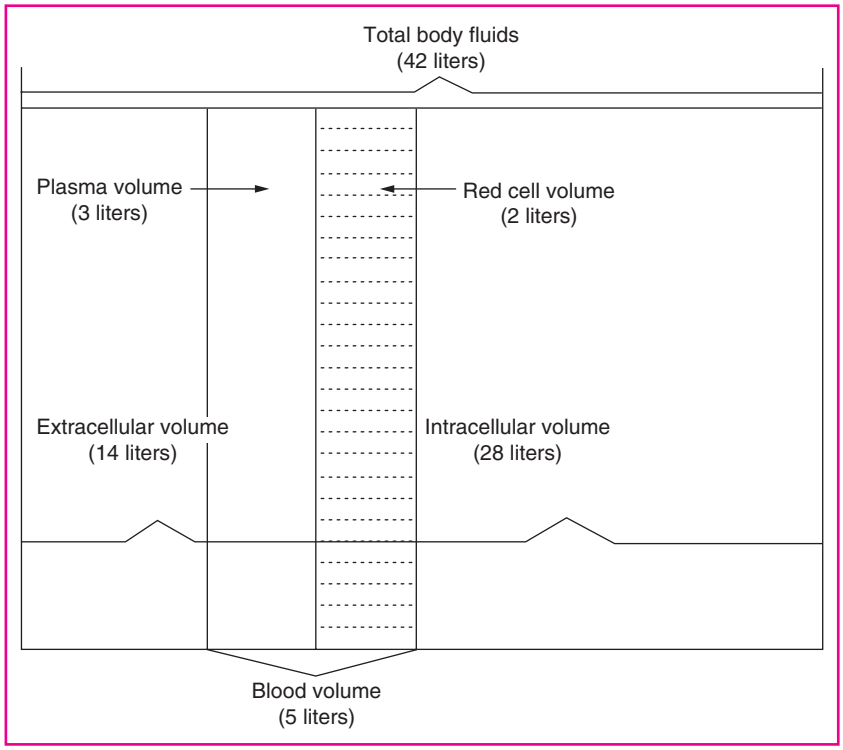

FIGURE 10–2. Distribution of body fluids showing the extracellular fluid volume, intracellular body fluid volume, and total body fluids in a 70 kg adult. Extracellular volume (ECV) comprises 14 liters of total body fluid (42 liters). Plasma volume makes up approximately 3 liters of the 14 liters of ECV. Intracellular volume accounts for the remaining 28 liters of total body fluids with roughly 2 liters being located within the red blood cells. Blood volume (approximately 5 liters) is also depicted and is made up of primarily red blood cells and plasma. (Reprinted from Guyton AC, Hall JE. *Textbook of Medical Physiology*. 8th ed. Philadelphia: Saunders, 1991: 275, with permission.)

seen with burns, or via "**capillary leak**" into the interstitial space or peritoneal cavity, as seen with edema or ascites. This latter phenomenon is often referred to as "third spacing" since fluid accumulates in the interstitial space disproportionately to the intracellular and extracellular fluid spaces. Regional ischemia may also develop as blood flow is naturally shunted from organs such as the gastrointestinal tract or the kidneys to more immediately vital organs such as the heart and brain.

Hypovolemic shock symptoms begin to occur with decreases in intravascular volume in excess of 750 mL or 15% of the circulating blood volume (20 mL/kg in pediatric patients).[5] As previously outlined, decreases in preload or left ventricular end-diastolic volumes result in decreases in SV. Initially, CO may be partially maintained by compensatory tachycardia. Similarly, reflex increases in SVR and myocardial contractility may attenuate arterial hypotension. This neurohumoral response to hypovolemia is mediated by the sympathetic nervous system in an attempt to preserve perfusion to vital organs such as the heart and brain (Fig. 10–3). Two major endpoints of this response are to conserve water to maximize intravascular volume and to improve tissue perfusion by increasing blood pressure and CO (oxygen delivery). The body attempts to maximize its fluid status by decreasing water and sodium excretion through release of antidiuretic hormone, aldosterone, and cortisol. Blood pressure is maintained by peripheral vasoconstriction mediated by catecholamine release and the renin-angiotensin system. Cardiac output is augmented by catecholamine release and fluid retention.[6] However, when intravascular volume losses exceed 1500 mL, the compensatory mechanisms are inadequate, typically resulting in a fall in CO and arterial blood pressure, while acute losses greater than 2000 mL are life-threatening (35 mL/kg in pediatric patients).[6] The decrease in CO results in a diminished delivery of oxygen to tissues within the body. Oxygen delivery can be further compromised by inadequate blood hemoglobin levels due to hemorrhage and/or diminished hemoglobin saturation due to impaired ventilation. Decreased delivery of oxygen and other vital nutrients results in diminished production of the energy substrate, adenosine triphosphate (ATP). Lactic acid is then produced as a by-product of anaerobic metabolism within tissues throughout the body.[7] Hyperglycemia produced during the stress response from cortisol release is also a contributing factor in the development of **lactic acidosis**. Lactic acidosis indicates that inadequate tissue perfusion has occurred.[7] Intracellularly, organelles such as endoplasmic reticulum and mitochondria begin to swell. Eventually, lysosomal rupture that releases degradative enzymes into the cell and abnormal calcium deposition contribute to cellular damage. Reactive oxygen species may also have a role in facilitating cellular damage, especially when organs are reperfused with blood and fluids after the initial hemorrhage.[2] The degree to which irreparable cellular damage has occurred will largely determine the reversibility of the shock event.

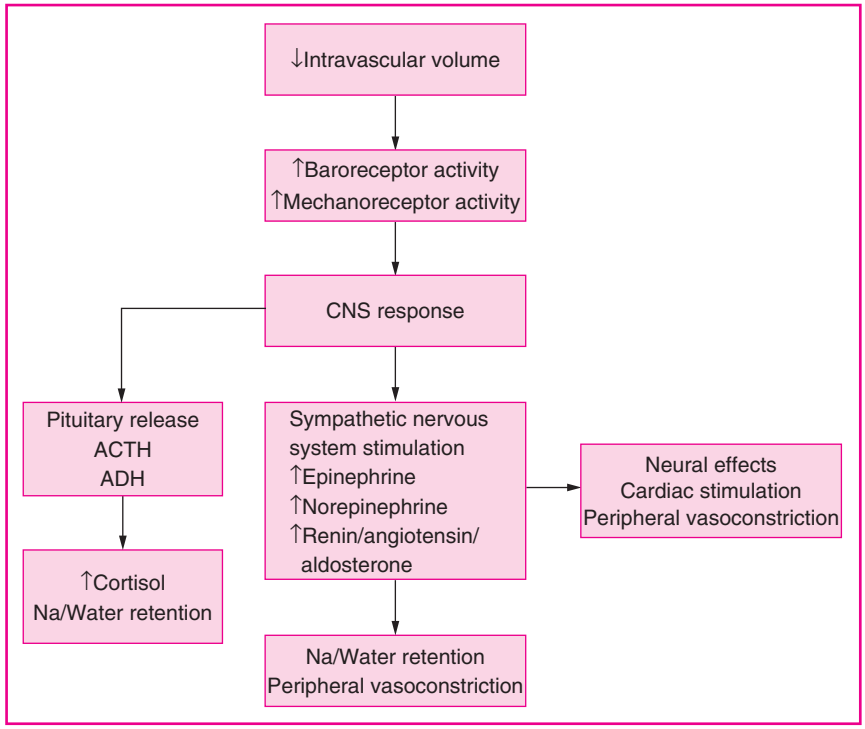

FIGURE 10–3. Expected neurohumoral response to hypovolemia. ACTH, adrenocorticotropic hormone; ADH, antidiuretic hormone; CNS, central nervous system; Na, sodium. (Reprinted from Jimenez EJ. Shock. ❷ *Protracted tissue hypoxia sets in motion a downward spiral of events secondary to organ dysfunction and eventual failure if untreated.*[5] Table 10–2 describes the effects of shock on the body's major organs. Relative failure of more than one organ, regardless of etiology, is referred to as the **multiple organ dysfunction syndrome** (MODS). Involvement of the heart is particularly devastating considering the central role it plays in oxygen delivery and the potential for myocardial dysfunction to perpetuate the shock state. Preexisting organ dysfunction can also exacerbate the effects of hypovolemic shock and its complications. For example, acute or chronic heart failure can lead to pulmonary edema, further aggravating gas exchange in the lungs and, ultimately, tissue hypoxia. MODS develops in approximately 20% of trauma patients who require fluid resuscitation. Only about one-third of early-onset MODS is quickly reversible (within 48 hours) with proper fluid resuscitation. Thus, it is imperative that hypovolemic shock be treated quickly to avoid MODS.[8]

Clinical Presentation and Diagnosis

General

Patients will be in acute distress although symptoms and signs will vary depending on the severity of the hypovolemia and whether the etiology is hemorrhagic versus non-hemorrhagic.

Symptoms

- Thirst
- Weakness
- Lightheadedness

Signs

- Hypotension, arterial SBP (systolic blood pressure) less than 90 mm Hg or fall in SBP greater than 40 mm Hg
- Tachycardia
- Tachypnea
- Hypothermia
- **Oliguria**
- Dark, yellow-colored urine
- Skin color: pale to ashen; may be cyanotic in severe cases
- Skin temperature: cool to cold
- Mental status: confusion to coma
- **Pulmonary artery catheter** measurements: decreased CO, decreased SV, increased SVR, low PAOP (pulmonary artery occlusion pressure)

Laboratory Tests

- Hypernatremia
- Elevated serum creatinine
- Elevated blood urea nitrogen
- Decreased hemoglobin/hematocrit (hemorrhagic hypovolemic shock)
- Hyperglycemia
- Increased serum lactate
- Decreased arterial pH

TABLE 10–2. Shock Manifestations on Major Organs

Heart	
	• Myocardial ischemia
	• Dysrhythmias
Brain	
	• Restlessness, confusion, obtundation
	• Global cerebral ischemia
Liver	
	• Release of liver enzymes
	• Biliary stasis
Lungs	
	• Pulmonary edema
	• Acute respiratory distress syndrome (ARDS)
Kidneys	
	• Oliguria
	• Decreased glomerular filtration
	• Acute renal failure
Gastrointestinal tract	
	• Stress-related mucosal disease
	• Bacterial translocation

TREATMENT

Desired Outcomes

❸ *The overarching goals in treating hypovolemic shock are to restore effective circulating blood volume, as well as manage its underlying cause. In achieving this goal, the downward spiral of events that can perpetuate severe or protracted hypovolemic shock is interrupted.*[2] *This is accomplished through the delivery of adequate oxygen and metabolic substrates such as glucose and electrolytes to the tissues throughout the body that will optimally bring about a restoration of organ function and return to homeostasis.* Evidence of the latter is a return to the patient's baseline **vital signs,** relative normalization of laboratory test results, and alleviation of the other signs and symptoms of hypovolemic shock previously discussed.[9] Concurrent supportive therapy is also warranted to avoid exacerbation of organ dysfunction associated with the hypovolemic shock event.

General Approach to Therapy

Securing an adequate airway and ventilation is imperative in hypovolemic shock patients consistent with the "ABCs" (airway, breathing, and circulation) of life support. Any compromise in ventilation will only accentuate the tissue hypoxia occurring secondary to inadequate perfusion. Thus, tracheal intubation and mechanical ventilation may be needed (Fig. 10–4). Intravenous access is also essential for administration of intravenous fluids and medications. Intravenous access can be accomplished through the placement of peripheral intravenous lines or catheterization with central venous lines if rapid or large volumes of resuscitative fluids are indicated. While primarily facilitating fluid administration, the intravenous lines provide access for blood samples for obtaining

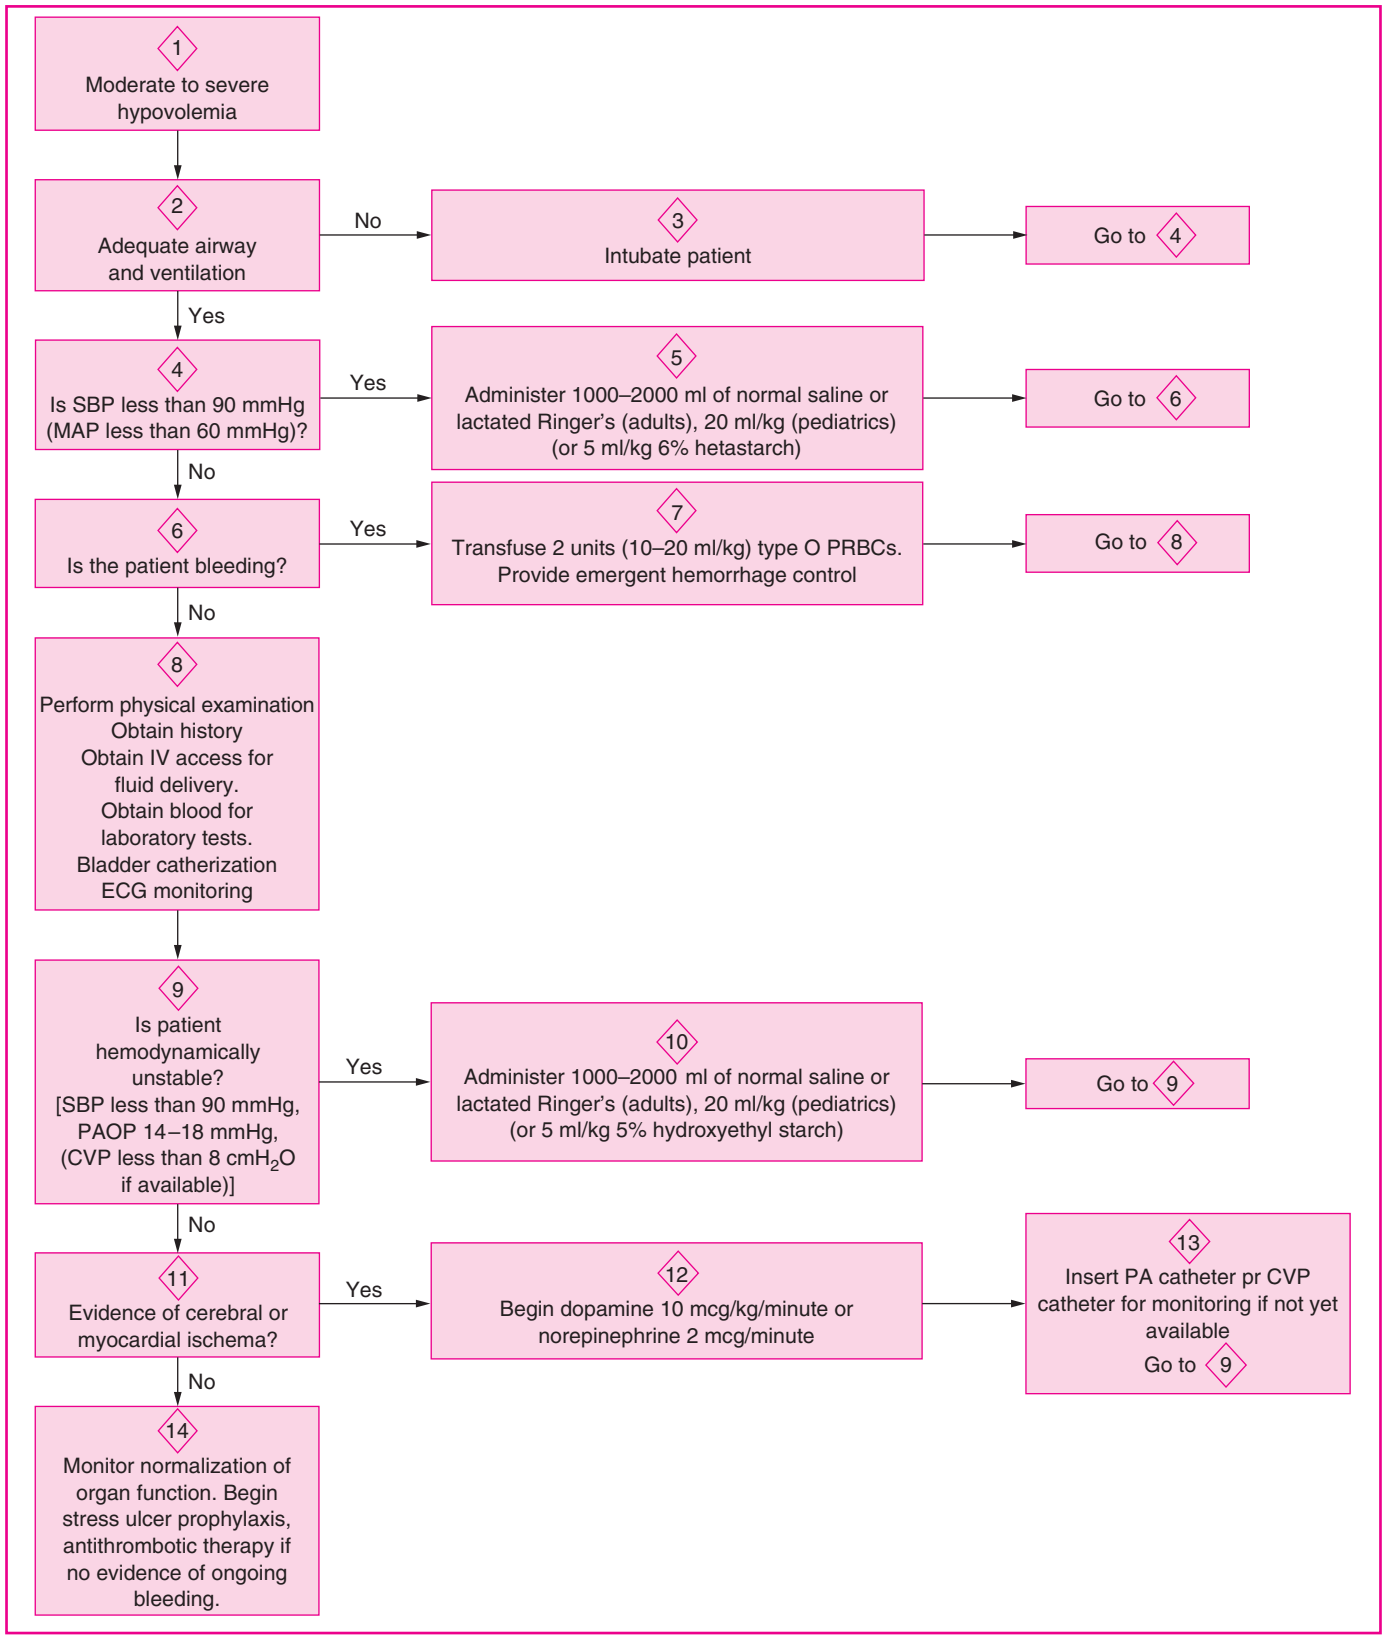

FIGURE 10–4. Treatment algorithm for the management of moderate to severe hypovolemia. BP, blood pressure; CVP, central venous pressure; ECG, electrocardiogram; MAP, mean arterial pressure; PA, pulmonary artery; PAOP, pulmonary artery occlusion pressure; PRBCs, packed red blood cells; SBP, systolic blood pressure.

appropriate laboratory tests. Placement of an arterial catheter is advantageous to allow for accurate and continual monitoring of blood pressure, as well as arterial blood gas (ABG) sampling. A bladder catheter should be inserted for ongoing monitoring of urine output. Baseline laboratory tests that should be done immediately include: complete blood cell counts with differentials, platelet count, serum chemistry profile, liver enzymes, prothrombin and partial thromboplastin times, and serum lactate. A urinalysis and an ABG should also be obtained and ongoing electrocardiogram (ECG) monitoring should be performed. In addition to restoring circulating blood volume, it is necessary to prevent further losses from the vascular space. This is especially true with hemorrhagic hypovolemic shock where identifying the bleeding site and achievement of hemostasis are critical in the successful resuscitation of the patient. This frequently involves surgical treatment of hemorrhages. Similarly, other types of shock may also require interventions that treat the underlying cause of hypovolemia, such as epinephrine to treat anaphylactic shock.

Upon stabilization, placement of a pulmonary artery (PA) catheter may be indicated based on the need for more extensive cardiovascular monitoring than is available from noninvasive measurements such as vital signs, cardiac rhythm, and urine output.[9,10] Key measured parameters that can be obtained from a PA catheter are the pulmonary artery occlusion pressure, which is a measure of preload, and CO. From these values and simultaneous measurement of HR and blood pressure (BP), one can calculate the left ventricular SV and SVR.[10] Placement of a PA catheter should be reserved for patients at high risk of death due to the severity of shock or preexisting medical conditions such as heart failure.[11] Use of PA catheters in broad populations of critically ill patients is somewhat controversial because clinical trials have not shown consistent benefits with their use.[12–14] However, critically ill patients with a high severity of illness may have improved outcomes from PA catheter placement. It is not clear why this was seen, but it could be that more severely ill patients have less physiologic reserve and less "room for error" and benefit from the therapeutic decisions that come from detailed PA catheter data.[15] The goal of resuscitating patients to supra-normal hemodynamic values (e.g., cardiac index [CI] greater than 4.5 L/minute per square meter) has also been controversial, but does not appear to be beneficial for most patients.[16] An alternative to the PA catheter is placement of a central venous catheter that typically resides in the superior vena cava to monitor central venous pressure (CVP). While central venous catheters are less expensive and more readily placed, they are not particularly accurate in monitoring effective fluid resuscitation.

Patient Encounter, Part 1

TJ is a 21-year-old male who is admitted to the emergency department (ED) after being stabbed in the leg during an assault. The paramedics report a large amount of blood loss at the scene from a probable blood vessel injury. The acute bleeding has been partially stabilized with pressure but the patient has just lost consciousness. The initial diagnosis by the ED team is hypovolemic shock. A physical exam is being performed and blood samples are being sent to the laboratory.

- What type of hypovolemic shock does TJ have?
- What signs and symptoms of hypovolemic shock would you expect to see in TJ?
- What laboratory abnormalities might be expected in TJ?

Fluid Therapy

❹ *Three major therapeutic options are available to clinicians for restoring circulating blood volume: blood products,* ***crystalloids*** *(electrolyte-based solutions), and colloids (large-molecular-weight solutions).* Blood products are used only in instances involving hemorrhage (or severe preexisting anemia), thus leaving crystalloids and colloids as the mainstay of therapy in all types of hypovolemic shock, along with adjunctive **vasopressor** support. The aggressiveness of fluid resuscitation (rate and volume) will be dictated by the severity of the hypovolemic shock and the underlying cause. Warming of all fluids to 37°C (98.6°F) prior to administration is an important consideration to prevent hypothermia, since hypothermia will have a negative impact on the success of the resuscitation effort.[17]

Crystalloids

Conventional, "balanced" crystalloids are fluids with (1) electrolyte composition that approximates plasma, such as lactated Ringer's (LR), or (2) a total calculated osmolality similar to that of plasma (280 to 295 mOsm/kg), such as 0.9% sodium chloride (also known as normal saline [NS] or 0.9% NaCl) (Table 10–3).[18] Thus, conventional crystalloids will distribute in normal proportions throughout the extracellular fluid space upon administration. In other words, expansion of the intravascular space will only increase by roughly 200 to 250 mL for every liter of isotonic crystalloid fluid administered.[18] Hypertonic crystalloid solutions such as 3% NaCl or 7.5% NaCl have osmolalities substantially higher than plasma. The effect observed with these fluids is a relatively larger volume expansion of the intravascular space. By comparison to conventional crystalloids, administration of 1 liter of 3% sodium chloride will result in an intravascular space increase of 1000 mL.[18] This increase is a result of the fluid administered as well as osmotic drawing of intracellular fluid into the intravascular and interstitial spaces. This occurs because the hypertonic saline increases the osmolality of the intravascular and interstitial fluid compared to the intracellular fluid. Hypertonic saline also has the potential for decreasing the inflammatory response.[19] Despite these theoretical advantages, data are lacking demonstrating

TABLE 10–3. Composition of Common Resuscitation Fluids[18]

Fluid	Na mEq/L[a]	Cl mEq/L[a]	K mEq/L[a]	Mg mEq/L[b]	Ca mEq/L[b]	Lactate mEq/L[a]	Other	pH	Osmolality mOsm/kg[c]
0.9 NaCl	154	154						5.0	308
3% NaCl	513	513						5.0	1027
7.5% NaCl	1283	1283						5.0	2567
Lactated Ringer's	130	109	4		3	28			
Hextend	143	124	3	0.9	5	28	Hetastarch 6 g/dL	5.9	307
Hetastarch	154	154					Hetastarch 6 g/dL	5.5	310
Pentastarch	154	154					Pentastarch 10 g/dL	5.0	326
5% Albumin	130–160	130–160					Albumin 5 g/dL (50 g/dL)	6.9	
25% Albumin	130–160	130–160					Albumin 25 g/dL (250 g/L)	6.9	
5% Plasma protein fraction (PPF)	130–160	130–160	0.25				Plasma Proteins 5 g/dL (50 g/L) (88% albumin)	7.0	
Dextran 40	154	154					Dextran 10 g/dL (avg. molecular weight 40 kDa)		
Dextran 70	154	154					Dextran 6 gm/dL (avg. molecular weight 70 kDa)	5.5	308
Dextran 75	154	154					Dextran 6 gm/dL (avg. molecular weight 75 kDa)	5.5	308

[a]For these values, mEq/L = mmol/L; e.g., 154 mEq/L Na = 154 mmol/L.
[b]For these values, mEq/L × 0.5 = mmol/L; e.g., 0.9 mEq/L Mg = 0.45 mmol/L Mg.
[c]For this value, mOsm/kg = mmol/kg; e.g., 308 mOsm/kg = 308 mmol/kg.

superiority of hypertonic crystalloid solutions compared with isotonic solutions.[20] Crystalloids are generally advocated as the initial resuscitation fluid in hypovolemic shock because of their availability, low cost, and equivalent outcomes compared with colloids.[9] A reasonable initial volume of an isotonic crystalloid (0.9% NaCl or LR) in adult patients is 1000 to 2000 mL administered over the first hour of therapy. Ongoing external or internal bleeding will require more aggressive fluid resuscitation. ❺ *In the absence of ongoing blood loss, administration of 2000 to 4000 mL of isotonic crystalloid will normally re-establish baseline vital signs in adult hypovolemic shock patients.*[2] Selected populations, such as burn patients, may require more aggressive fluid resuscitation, while other patient subsets such as those with cardiogenic shock or heart failure may warrant less aggressive fluid administration to avoid over-resuscitation.[21] In hemorrhagic shock patients, approximately three to four times the shed blood volume of isotonic crystalloids is needed for effective resuscitation.[21,22]

Side effects from crystalloids primarily involve fluid overload and electrolyte disturbances of sodium, potassium, and chloride.[23] Dilution of coagulation factors can also occur resulting in a dilutional coagulopathy.[24] Two clinically significant reasons LR is different from NS is that LR contains potassium and has a lower sodium content (130 versus 154 mEq/L or mmol/L). Thus, LR has a greater potential than NS to cause hyponatremia and/or hyperkalemia. Alternatively, NS can cause hypernatremia and hypokalemia. While LR does contain lactate, it does not result in increases in serum lactate when used for fluid replacement.[25] This is likely because the exogenous lactate is used as a metabolic substrate. Overall, there is no clear cut advantage when comparing NS and LR. Clinician preference and the patient's serum electrolyte concentrations will usually guide selection.

Colloids

Understanding the effects of colloid administration on circulating blood volume necessitates a review of those physiologic forces that determine fluid movement between capillaries and the interstitial space throughout the circulation (Fig. 10–5).[4] Relative hydrostatic pressure between the capillary lumen and the interstitial space is one of the major determinants of net fluid flow into or out of the circulation. The other major determinant is the relative colloid osmotic pressure between the two spaces. Administration of exogenous colloids results in an increase in the intravascular colloid osmotic pressure. In the case of isosomotic colloids (5% albumin, 6% hetastarch, and dextran products), initial expansion of the intravascular space is essentially that of the volume of colloid administered. In the case of hyperoncotic solutions such as 25% albumin, fluid is pulled from the interstitial space into the vasculature

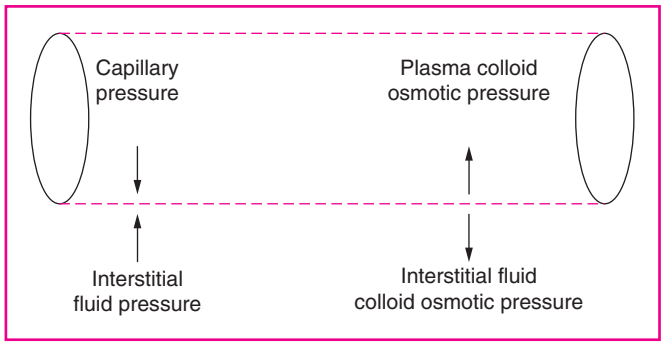

FIGURE 10–5. Operative forces at the capillary membrane tending to move fluid either outward or inward through the capillary membrane. In hypovolemic shock, one therapeutic strategy is the administration of colloids that can sustain and/or draw fluid from the interstitial space by increasing the plasma colloid osmotic pressure. (Reprinted from Guyton AC, Hall JE. *Textbook of Medical Physiology*. 8th ed. Philadelphia: Saunders, 1991: 174, with permission.)

resulting in an increase in the intravascular volume that is much greater than the original volume of the 25% albumin that was administered. While theoretically attractive, hyperoncotic solutions should not be used for hypovolemic shock since the expansion of the intravascular space is at the expense of depletion of the interstitial space. The effects of colloids on intravascular volume are a consequence of their relatively large molecular size (greater than 30 kilodaltons [kDa]), limiting their passage across the capillary membrane in large amounts except under conditions in which capillary permeability may be increased such as during a "capillary leak." Examples of the latter, situations in which colloids may be less effective as intravascular volume expanders, include any condition involving the systemic inflammatory response syndrome (SIRS) such as trauma, sepsis, and pancreatitis.[2] Nonetheless, under circumstances in which capillary permeability is normal, colloids can be thought of as "sponges" drawing fluid into the intravascular space from the interstitial space. ❻ *Thus, the volume of colloid administered remains primarily confined to the intravascular space, in contrast to isotonic crystalloid solutions that distribute throughout the extracellular fluid space.* Eventually, the exogenous colloids will migrate to the interstitial space diminishing the expansion in intravascular volume. Exogenous colloids available in the United States include 5% albumin, 25% albumin, 5% plasma protein fraction (PPF), 6% hetastarch, 10% pentastarch, 10% dextran 40, 6% dextran 70, and 6% dextran 75 (Table 10–3). The first three products are derived from pooled human plasma. Hetastarch and pentastarch are semisynthetic hydroxyethyl starches derived from amylopectin. The dextran products are semisynthetic glucose polymers that vary in terms of the average molecular weight of the polymers. Superiority of one colloid solution over another has not been clearly established.[26]

For years within the critical care literature a controversy known as the "colloid versus crystalloid debate" raged over the relative merits of the two types of resuscitation fluids. At the center of the debate was what the goal of fluid resuscitation in shock should be: immediate expansion of the intravascular space with colloids versus expansion of the entire extracellular fluid space with crystalloids. A meta-analysis showed no difference in outcomes between crystalloids and albumin.[27] However, the balance was tipped in favor of those advocating crystalloids after a meta-analysis performed by the Cochrane group revealed a relative increase in mortality in all shock patients receiving albumin versus crystalloids.[28] This increased risk was not statistically significant when only comparing studies of hypovolemic shock patients.[28] A more recent randomized controlled study involving 6997 critically ill patients [Saline versus Albumin Fluid Evaluation (SAFE) Study] challenged the overall Cochrane findings by demonstrating no difference in mortality between patients receiving saline versus albumin.[28,29] Largely in response to the SAFE trial, the Food and Drug Administration (FDA) issued a revised notice to health care providers in May 2005 declaring albumin safe for use in most critically ill patients. Burn, traumatic brain injury, and septic shock patients were excluded from the SAFE trial; however, based on previous data there does not appear to be a clear-cut overall advantage for either crystalloids or colloids in these patient groups.[30] Thus, while the debate is not fully resolved, most clinicians today prefer using crystalloids based on their availability and inexpensive cost compared with colloids.[21,31]

Generally, the major adverse effects associated with colloids are fluid overload, dilutional coagulopathy, and anaphylactoid/anaphylactic reactions.[24,32] Although derived from pooled human plasma, there is no risk of disease transmission from commercially available albumin or PPF products since they are heated and sterilized by ultrafiltration prior to distribution.[24] Because of direct effects on the coagulation system with the hydroxyethyl starch and dextran products, they should be used cautiously in hemorrhagic shock patients. This is another reason why crystalloids may be preferred in hemorrhagic shock. Furthermore, hetastarch can result in an increase in amylase not associated with pancreatitis. As such, the adverse-effect profiles of the various fluid types should also be considered when selecting a resuscitation fluid.

Blood Products

❼ *Blood products are indicated in hypovolemic shock patients who have sustained blood losses from hemorrhage exceeding 1500 mL (30 to 35 mL/kg).* This, in fact, is the only setting in which freshly procured whole blood is administered. In virtually all other settings, blood products are given as the individual components of whole blood units, such as packed red blood cells (PRBCs), fresh frozen plasma (FFP), platelets, cryoprecipitate, and concentrated coagulation factors.[33,34] This includes ongoing resuscitation of hemorrhagic shock, when PRBCs can be transfused to increase oxygen-carrying

capacity in concert with crystalloid solutions to increase blood volume. In patients with documented coagulopathies, FFP for global replacement of lost or diluted clotting factors, or platelets for patients with severe thrombocytopenia (less than 20,000 cells/m^3 [$20 \times 10^3/\mu L$ or $20 \times 10^9/L$]) should be administered.[34] Type O blood or "universal donor blood" is given in emergent cases of hemorrhagic shock. Thereafter, blood that has been typed and cross-matched with the recipient's blood is given. The traditional threshold for PRBC transfusion in hypovolemic shock has been a serum hemoglobin of less than 10 g/dL (100 g/L or 6.2 mmol/L) and hematocrit less than 30%.[35] However, a more restrictive transfusion threshold of 7 g/dL (70 g/L or 4.34 mmol/L) appears to be safe for critically ill patients after they have received appropriate fluid resuscitation and have no signs of ongoing bleeding. Traditional risks from allogenic blood product administration include hemolytic and non-hemolytic transfusion reactions and transmission of blood-borne infections in contaminated blood. However, recent large studies have also shown that transfusions are associated with higher mortality, possibly because of adverse immune and inflammatory effects.[36,37] Based on limitations of homologous blood donations, intraoperative salvage techniques can be employed in patients with massive hemorrhage in an effort to conserve blood.[5,38]

Due to blood shortages and associated risks with transfusions, there are ongoing research efforts concerning the development of red blood cell substitutes as a possible therapy alternative. Products that have reached clinical trials include perfluorocarbon emulsions and hemoglobin-based oxygen carriers (HBOCs).[39,40] These blood products have several advantages over PRBCs including greater availability (because donors aren't needed), increased shelf-life, absence of infectious risks, and no need for cross-matching. As such, red blood cell substitutes have the potential to serve as temporizing measures in hypovolemic shock patients until conventional red blood cell transfusions can be administered or in instances in which availability of donated PRBCs is extremely limited. Nonetheless, lack of adequate efficacy data and additional side effects associated with each of the respective red blood cell substitutes have precluded their approval in the United States at present.

Research also continues into the use of recombinant activated factor VII (rFVIIa) as an adjunctive agent to treat uncontrolled hemorrhage. Initial experiences with rFVIIa show that it can decrease transfusions, though large studies have not been performed.[41] Ultimately, pharmacoeconomic analyses of rFVIIa will be needed because of the very high acquisition costs of the drug.

Pharmacologic Therapy

Vasopressor Therapy

Vasopressor is the term used to describe any pharmacologic agent that can induce arterial vasoconstriction through stimulation of the α_1-adrenergic receptors. 8 *While replenishment of intravascular volume is undoubtedly the cornerstone of hypovolemic shock therapy, use of vasopressors may be warranted as a temporary measure in patients with profound hypotension or evidence of organ dysfunction in the early stages of shock.*[2,9,42] Often vasopressors are used concurrently with fluid administration. Table 10–4 is a list of those vasopressors used in the management of hypovolemic shock. Dopamine or norepinephrine may be preferred over epinephrine because epinephrine has an increased potential for causing cardiac arrhythmias and impaired abdominal organ (splanchnic) circulation.[43] In cases involving concurrent heart failure, an inotropic agent such as dobutamine may be needed, in addition to the use of a vasopressor. Patients with spinal shock may require some level of vasopressor and/or inotropic support even after adequate fluid resuscitation.

Vasopressors are almost exclusively administered as continuous infusions because of their very short half-lives and the need for close titration of their dose-related effects. Starting doses should be at the lower end of the dosing range followed by rapid titration upward if needed to maintain adequate blood pressure. Monitoring of end-organ function such as adequate urine output can also be used to monitor therapy. Once blood pressure is restored, vasopressors should be weaned and discontinued as soon as possible to avoid any untoward events. The most significant systemic adverse events associated with vasopressors are excessive vasoconstriction resulting in decreased organ perfusion and potential to induce arrhythmias (Table 10–4). Central venous catheters should be used to minimize the risk of local tissue necrosis that can occur with extravasation of peripheral intravenous catheters.[42]

Treatment of Lactic Acidosis

Lactic acidosis, which typically accompanies hypovolemic shock as a consequence of tissue hypoxia, is best treated by reversal of the underlying cause. Administration of alkalizing agents such as sodium bicarbonate has not been demonstrated to have any

TABLE 10–4. Vasopressor Drugs

Drug	Usual IV Dose	Adrenergic Effects			Potential to Cause Arrhythmias
		α_1	β_1	Dopaminergic	
Dopamine	10–20 mcg/kg per minute[a]	+++	++	+++	+++
Norepinephrine	0.5–80 mcg/minute	+++	++	0	++
Epinephrine	1–200 mcg/minute	++	+++	0	+++
Phenylephrine	0.5–9 mcg/kg per minute	+++	0	0	0

IV, intravenous.
[a]Note: Lower dosages of dopamine may not produce desired α_1-adrenergic (vasopressor) effects.

beneficial effects[44] and may actually worsen intracellular acidosis.[45] Nonetheless, administration of sodium bicarbonate, 100 to 150 mEq intravenously, can be considered when the pH is below 7.1.[2] An alternative to sodium bicarbonate is the proton acceptor tromethamine (i.e., tris-hydroxymethyl aminomethane, or THAM). THAM has the advantage over sodium bicarbonate in buffering lactic acidosis without increasing sodium concentrations or fostering the production of additional carbon dioxide.[46,47] This could be particularly advantageous in hypovolemic shock patients with respiratory failure who may have a difficult time clearing carbon dioxide from their lungs. However, there are no large studies evaluating THAM for treating metabolic acidosis. If used, the initial dose of THAM can be determined by the following equation: amount (in milliliters) of 0.3 mol/L THAM = lean body weight (kg) × base deficit (mmol/L).[47] THAM should not be used in patients with renal failure.

Patient Encounter, Part 2: Physical Exam, Diagnostic Tests, and Initial Treatment

PMH
Non-contributory

Meds
None

SH
Occasional alcohol use (per family)

FH
Non-contributory

PE
Ht 5′10″ (178 cm), Wt 85 kg (187 lb)

VS: BP 80/40 mm Hg, pulse 130/minute, respiratory rate 22 beats per minute, temperature 35°C (95°F), urine output: none since catheterization 10 minutes ago.
Neurologic: Recent loss of consciousness, had been conscious but confused during transport to the ED, pupils equal and reactive
Pulmonary: Normal breath sounds, undergoing tracheal intubation for mechanical ventilation
CV: ECG shows sinus tachycardia, otherwise normal
Abd: Within normal limits
Exts: Stab wound to left thigh with some ongoing bleeding

- What are the first nonpharmacologic steps in treating TJ?
- Identify treatment goals for TJ in the next 24 hours.
- What initial pharmacologic/fluid therapy is required at this time?

Supportive Care Measures

Since gastrointestinal ischemia is a common complication of hypovolemic shock, prevention of stress-related mucosal disease should be instituted as soon as the patient is stabilized. The most common agents used for stress ulcer prophylaxis are the histamine$_2$-receptor antagonists and proton pump inhibitors. Prevention of thromboembolic events is another secondary consideration in hypovolemic shock patients. This can be accomplished with the use of external devices such as sequential compression devices and/or antithrombotic therapy such as the low-molecular-weight heparin products or unfractionated heparin. Patients with adrenal insufficiency due to preexisting disease, glucocorticoid use, or critical illness may have refractory hypotension despite resuscitation. Such patients should receive appropriate glucocorticoid replacement therapy.

OUTCOME EVALUATION

❾ *Successful treatment of hypovolemic shock is measured by the restoration of blood pressure to baseline values and reversal of associated organ dysfunction. The likelihood of a successful fluid resuscitation will be directly related to the expediency of treatment. Therapy goals include:*

- *Arterial systolic blood pressure greater than 90 mm Hg (MAP greater than 60 mm Hg) within 1 hour;*
- *Organ dysfunction reversal evident by increased urine output to greater than 0.5 mL/kg per hour (1.0 mL/kg per hour in pediatrics), return of mental status to baseline, and normalization of skin color and temperature over the first 24 hours;*
- *Heart rate should begin to decrease reciprocally to increases in the intravascular volume within minutes to hours;*
- *Normalization of laboratory measurements expected within hours to days following fluid resuscitation. Specifically, normalization of base deficit and serum lactate is recommended within 24 hours to potentially decrease mortality;[48] and*
- *Achievement of PAOP to a goal pressure of 14 to 18 mm Hg occurs (alternatively CVP 8 to 15 mm Hg).*

Patient Encounter, Part 3: Care Plan/Ongoing Therapy

One hour after the initial fluid bolus and transfusion TJ's vital signs are:
BP 85/50 mm Hg, HR 120 beats per minute, RR 20/minute, urine output: 5 mL in the past hour. Pertinent new labs: pH 7.2, lactate 3.8 mg/dL (0.422 mmol/L). The bleeding has stopped.

- What is your assessment of TJ's condition compared to 1 hour ago?
- What therapy is required at this time?
- Describe monitoring over the next 24 hours for TJ.

Patient Care and Monitoring

1. Does the patient have an adequate airway and ventilation (hemoglobin saturation greater than 92%)? If not, trained emergency personnel should consider performing tracheal intubation with initiation of mechanical ventilation.
2. Is there a detectable blood pressure? If yes, obtain history, perform physical examination, obtain blood for baseline laboratory tests, and monitor ECG. If not, begin isotonic crystalloid fluid resuscitation immediately (see step 4 below).
3. Monitor the following serial laboratories for comparison to baseline values every 6 hours in the first 24 hours and daily thereafter until normalized: sodium, serum creatinine, blood urea nitrogen, serum lactate, glucose, bilirubin, hemoglobin, hematocrit, platelets, prothrombin time, partial thromboplastin time, arterial blood gases, and pH.
4. Is the systolic blood pressure less than 90 mm Hg (MAP less than 60 mm Hg)? If yes, start aggressive fluid therapy beginning with 1000 to 2000 mL lactated Ringer's over 1 hour in adults (20 mL/kg in pediatrics). Monitor blood pressure at least every 15 minutes (or continuously via an arterial catheter).
5. Is the patient bleeding? If yes, transfuse 5 to 10 mL/kg PRBCs (note: 1 unit PRBCs will provide approximately 3% increase in hematocrit or 1 g/dL [10 g/L or 0.62 mmol/L] increase in hemoglobin). Do not allow hemoglobin concentrations to fall below 7 g/dL (70 g/L or 4.34 mmol/L) (hematocrit 20%). Conventional goal hemoglobin concentration is 10 g/dL (100 g/L or 6.2 mmol/L) (alternatively hematocrit greater than or equal to 30%). Provide emergent control of ongoing hemorrhaging.
6. Is there evidence of cerebral or myocardial ischemia? If yes, begin vasopressor therapy of dopamine 10 mcg/kg per minute or norepineprhine 2 mcg/minute. Titrate dosage every 5 minutes as needed. Wean and discontinue vasopressor as soon as the goal arterial blood pressure has been achieved.
7. Has the goal arterial blood pressure been achieved? If not, give additional fluid therapy hourly blending crystalloids and isooncotic colloids based on inadequate blood pressure response.
8. Is the patient hemodynamically stable? If not, admit to the intensive care unit for ongoing treatment and monitoring. A PA catheter (or CVP catheter) should be inserted by trained medical personnel. Monitor PAOP to a goal pressure of 14 to 18 mm Hg and minimum cardiac index of 2.2 L/minute per square meter (alternatively CVP 8 to 15 cm H_2O).
9. Is the arterial pH less than 7.1? If yes, consider administration of sodium bicarbonate 100 to 150 mEq intravenously as slow infusion. Alternatively, consider use of tromethamine intravenously.
10. Monitor normalization of organ function to baseline state including mental status, urine output to greater than 0.5 mL/kg per hour (1 mL/kg per hour in pediatric patients), normal skin color and temperature, and normalization of base deficit and/or lactate. Begin supportive care measures including stress ulcer prophylaxis and antithrombotic therapy if there is no evidence of ongoing bleeding.
11. Has the underlying cause of the hypovolemic shock been addressed to prevent its recurrence? If not, treat as necessary.
12. Is there any evidence of adverse events from the resuscitation therapies employed such as fluid overload, electrolyte disturbances, transfusion reactions, and/or alterations in coagulation? If yes, manage the particular adverse event accordingly.

ED: emergency department
FDA: Food and Drug Administration
FFP: fresh frozen plasma
HBOC: hemoglobin-based oxygen carrier
HCO_3: bicarbonate
Hct: hematocrit
Hgb: hemoglobin
HR: heart rate
IV: intravenous
K: potassium
kDa: kilodalton
LR: lactated Ringer's
MAP: mean arterial pressure
Mg: magnesium
MODS: multiple organ dysfunction syndrome
Na: sodium

NaCl: sodium chloride
NS: normal saline
PA: pulmonary artery
Pa_{O_2}: partial pressure of arterial oxygen
PAOP: pulmonary artery occlusion pressure
P_{CO_2}: partial pressure of carbon dioxide
PPF: plasma protein fraction
PRBCs: packed red blood cells
rFVIIa: recombinant activated factor VII
RR: respiratory rate
SAFE: Saline versus Albumin Fluid Evaluation Study
SBP: systolic blood pressure
SCr: serum creatinine
SIRS: systemic inflammatory response syndrome
SV: stroke volume
SVR: systemic vascular resistance
THAM: tris-hydroxymethyl aminomethane (tromethamine)

11 Asthma

W. Greg Leader

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiology of asthma.
2. Identify the goals of asthma management.
3. Classify asthma severity based on asthma symptoms.
4. Recommend environmental control strategies for patients with identified allergies.
5. Educate patients on the use of inhaled drug delivery devices, peak flow monitors, and asthma education plans.
6. Develop a therapeutic plan for patients with chronic asthma that maximizes patient response while minimizing adverse drug events and other drug-related problems.
7. Evaluate current asthma therapy and make changes when necessary.
8. Develop a therapeutic plan for treating patients with acute asthma.

Key Concepts

❶ Asthma is a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role.
❷ Therapy for chronic asthma is directed at suppressing the underlying inflammatory response and normalizing pulmonary function.
❸ Classification of asthma severity is based on daytime and nighttime symptoms, physical activity, lung function, variability in peak expiratory flow (PEF), and use of reliever medications.
❹ Direct airway administration of asthma medications through inhalation is the most efficient route and minimizes systemic adverse effects.
❺ Inhaled short-acting β_2-agonists are the most effective agents for reversing acute airway obstruction caused by bronchoconstriction.
❻ In persistent asthma, inhaled corticosteroids provide the most comprehensive control of the inflammatory process.
❼ Intensity of pharmacologic therapy is based on the severity of the disease.
❽ Adding a long-acting inhaled β_2-agonist to low-dose inhaled corticosteroids is equally or more effective than doubling the inhaled corticosteroid dose or adding other long-term control medications and decreases the potential for adverse effects.
❾ Excessive use of inhaled short-acting β_2-agonists is an indicator of inadequately controlled asthma.

❶ "*Asthma is a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role*, in particular, mast cells, eosinophils, T lymphocytes, macrophages, neutrophils, and epithelial cells. In susceptible individuals, this inflammation causes recurrent episodes of **wheezing**, breathlessness, chest tightness, and coughing, particularly at night or in the early morning. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible spontaneously or with treatment. The inflammation also causes an associated increase in existing airway hyperresponsiveness to a variety of stimuli."[1] Additionally, it is now recognized that airway remodeling may occur, resulting in a fixed or irreversible airway defect.[2,3]

Asthma is a diverse disease that presents in a heterogeneous manner. Severity of chronic disease ranges from mild with intermittent symptoms to severe and disabling if left untreated. Despite variances in the underlying severity of chronic asthma, all asthmatics are at risk of severe acute disease when exposed to the appropriate trigger or if inadequately treated. The National Asthma Education and Prevention Program (NAEPP) Expert Panel Report 2[1] and its subsequent update[2] provide guidelines for the diagnosis and management of asthma. These guidelines emphasize the importance of treating underlying

airway inflammation as a means of controlling persistent asthma and preventing acute exacerbations of the disease.

EPIDEMIOLOGY AND ETIOLOGY

Asthma is the most common chronic disease of childhood, and it causes significant morbidity and mortality in both adults and children. Approximately 20 million people in the United States carried the diagnosis of asthma in 2002, with Puerto Ricans, non-Hispanic blacks, and Native Americans having a significantly higher prevalence than non-Hispanic whites.[4] Approximately 12 million workdays and 15 million schooldays are missed yearly due to asthma. In 2002, there were 1.9 million emergency department visits and 484,000 hospitalizations for asthma. Children younger than 4 years of age have the highest rate of emergency department visits and hospitalizations. There were approximately 4600 asthma-related deaths in 2002, but the annual mortality rate appears to be decreasing.[4]

Asthma is also a significant economic burden in the United States, costing $12.7 billion in 1998 with direct medical expenditures accounting for 58% of the cost or approximately $7.4 billion.[5] Hospital and emergency department care accounted for 45.1% of the direct medical expenditures, with prescription drugs and physician office visits accounting for 43.3% and 11.6%, respectively. Costs appear to increase with disease severity, and it has been suggested that fewer than 20% of asthma patients account for more than 80% of direct medical expenditures.[5]

Asthma results from a complex interaction of genetic and environmental factors; however, the underlying cause is not well understood. There appears to be an inheritable component, as the presence of asthma in a parent is a strong risk factor for the development of asthma in a child. This risk increases when a family history of **atopy** is also present.[1,3] Approximately 50% of asthma can be attributed to atopy, and atopic asthma is more common in children than adults.[3] Furthermore, atopy in childhood asthma is the strongest prognostic factor for continued asthma as an adult.[1,3]

Genetic factors cannot explain the recent rapid rise in asthma prevalence. Asthma appears to require both genetic predisposition and environmental exposure. Many patients with occupational asthma develop the disease late in life upon exposure to specific allergens in the workplace. Environmental influences in utero or in infancy may contribute to the development of asthma. Maternal smoking during pregnancy or exposure to secondhand smoke after birth increases the risk of childhood asthma.[3] Adult-onset asthma is not uncommon and may be related to atopy, nasal polyps, aspirin sensitivity, occupational exposure, or a recurrence of childhood asthma.

PATHOPHYSIOLOGY

Asthma is characterized by inflammation, airway hyperresponsiveness (AHR), and airway obstruction. Inhaled antigens induce a type 2 T-helper CD4+ (T_H2) response. Antigens are taken up by antigen-presenting cells,[6] and presentation of antigens to T lymphocytes causes activation of the T_H2 type response, leading to B-cell production of antigen-specific immunoglobulin E (IgE) and proinflammatory cytokines and chemokines that recruit and activate eosinophils, neutrophils, and alveolar macrophages.[6,7] Further exposure to the antigen results in cross-linking of cell-bound IgE in mast cells and basophils, causing the release or generation of inflammatory mediators such as histamine, cysteinyl leukotrienes (C_4, D_4, and E_4), and prostaglandins. Activation and degranulation of mast cells and basophils results in an early phase response that involves an acute bronchoconstriction that usually lasts approximately 1 hour after allergen exposure.[6] This early phase response can be blocked by pretreatment with an inhaled β_2-agonist or cromolyn.

In the late phase response, activated airway cells release inflammatory cytokines and chemokines, recruiting inflammatory cells into the lungs. The late phase response occurs 4 to 6 hours after the initial allergen challenge and results in a less intense bronchoconstriction as well as increased airway hyperresponsiveness and airway inflammation.[6]

Airway Inflammation and Hyperresponsiveness

T_H2 lymphocytes are one of the primary factors initiating and perpetuating the inflammatory response.[7] In addition, proinflammatory mediators such as the leukotrienes generated during mast cell degranulation can increase vascular permeability, leading to airway edema and increased mucus production.[8] Eosinophilic infiltration of the airways is a hallmark of asthma, and activated eosinophils can cause bronchoconstriction and AHR.[9]

Airway hyperresponsiveness is defined as the exaggerated ability of the airways to narrow in response to a variety of stimuli. Although AHR exists in patients without asthma, it is a characteristic feature of asthma and appears to be directly related to airway inflammation and the severity of asthma.[1,3] Treatment of airway inflammation with inhaled corticosteroids attenuates AHR in asthma but does not eliminate it.[1] Clinically, AHR manifests as increased variability of airway function. Although not commonly used to diagnose asthma, AHR can be evaluated clinically using a methacholine or histamine bronchoprovocation test.

Airway Obstruction

Airway obstruction manifests itself as symptoms such as chest tightness, cough, and wheezing. Airway obstruction can be caused by multiple factors including airway smooth muscle constriction, airway edema, mucus hypersecretion, and airway remodeling. Airway smooth muscle tone is maintained by an interaction between sympathetic, parasympathetic, and nonadrenergic mechanisms. Acute bronchoconstriction usually

results from preformed or generated mediators such as histamine and cysteinyl leukotrienes released during mast cell and basophil degranulation that act directly on the airways.[3] Inflammatory mediators such as histamine, leukotrienes, and bradykinin increase microvascular permeability leading to mucosal edema, which causes the airway to become more rigid and limits airflow.[10] These changes exaggerate the consequences of acute bronchoconstriction. In asthmatics, there is an increased number and volume of mucous glands with increased mucus secretion.[11] Extensive mucus plugging has been demonstrated in patients who have died from acute asthma and is likely a cause of persistent airway obstruction in severe acute attacks.

Although airway obstruction in asthma has generally been considered reversible, some asthmatics have an irreversible or fixed obstruction. The process that produces the structural airway changes leading to this fixed obstruction has been termed airway remodeling and is characterized by airway epithelial damage, subepithelial fibrosis, airway smooth muscle hypertrophy and hyperplasia, increased mucus production, and increased vascularity of the airways.[3,11] Airway remodeling may be caused by repetitive injury to the airways, by an abnormal injury-repair cycle of dysfunctional epithelial cells, or in response to the chronic inflammatory process. Structural airway changes can be demonstrated early in asthma, may be present in newly diagnosed asthmatics, and has been seen prior to the onset of asthma.[11]

CLINICAL PRESENTATION AND DIAGNOSIS

Factors Affecting Asthma Severity

Major factors that may contribute to the severity of asthma include allergens typically associated with atopy; chemical exposures in occupational environments; and exposure to tobacco smoke, irritants, and indoor and outdoor pollution. Other factors include concurrent disease states or medications that may worsen asthma severity.

Up to 80% of asthmatics have symptoms of rhinitis, and inflammation of the upper airways may increase AHR.[1,3] Treatment of rhinitis with intranasal corticosteroids may improve asthma symptoms and is recommended for asthma patients with rhinitis.

Acute and chronic sinusitis can also aggravate asthma, and antibiotic therapy of sinusitis may improve asthma symptoms.[3] Nasal polyps are associated with aspirin-sensitive asthma, and adult patients with nasal polyps should be counseled against using non-steroidal anti-inflammatory medications.[1,3]

Gastroesophageal reflux has been associated with increased asthma symptoms, especially nighttime symptoms.

Non-selective β-blockers, including those in ophthalmic preparations, may cause asthma symptoms, and these agents should be avoided in asthmatics unless the benefits of therapy outweigh the risks.[1] In asthmatic patients requiring β-blocker therapy, a β_1-selective agent should be chosen. Because selectivity is dose related, the lowest effective dose should be used. β-Blockers may inhibit β-agonist reversal of bronchospasm, and a larger dose of β-agonist or the use of an anticholinergic agent may be necessary to reverse bronchospasm.

Clinical Presentation of Chronic Asthma

General

Asthma severity ranges from normal pulmonary function and symptoms only with acute exacerbations to significantly decreased pulmonary function with continuous symptoms.

Symptoms

- Symptoms may include **dyspnea**, cough, wheezing, and chest tightness. These symptoms may be continual, episodic, seasonal, or occur in association with known triggers.
- Symptoms may occur more often at night, early in the morning, or with exercise.
- Patients with mild intermittent asthma may be symptom-free and have normal pulmonary function between exacerbations.

Signs

- Patients may have end-expiratory wheezing and dry cough.

Laboratory Tests

- Increased serum concentrations of IgE or eosinophils may help confirm the diagnosis of asthma but are not diagnostic for asthma.

Other Diagnostic Tests

- **Spirometry**, an objective measure of pulmonary function, can be used to assist in confirming the diagnosis of asthma. The primary pulmonary function tests used to assist in the diagnosis of asthma are the forced expiratory volume in 1 second (FEV_1), forced vital capacity (FVC), and **peak expiratory flow** (PEF). Values used to support a diagnosis of asthma include:

- Decreased FEV_1/FVC (less than 80%, but may be normal between exacerbations) demonstrates airway obstruction.
- A greater than or equal to 12% (at least 200 mL) improvement in FEV_1 after an inhaled bronchodilator demonstrates a reversible obstruction. A 2- to 3-week course of oral corticosteroids may be necessary to demonstrate reversibility in airway obstruction.
- A greater than or equal to 15% decrease in FEV_1 after an exercise test is diagnostic for exercise-induced asthma.

Assessment of diurnal variation of PEF may be useful in patients who have asthma symptoms and normal spirometry. When spirometry is equivocal, a 20% or greater decrease in FEV_1 after the administration of methacholine is diagnostic for asthma. A negative bronchoprovocation test with methacholine may help rule out asthma.

A positive allergen test may help guide nonpharmacologic therapy but is not diagnostic for asthma.

Clinical Presentation of Acute Asthma

General

Acute asthma can present rapidly (within 3 to 6 hours) but more commonly, deterioration occurs over several hours, days, or even weeks. Typically there is gradual deterioration over several days followed by a more rapid deterioration over 2 to 3 days. Acute asthma can be a life-threatening event, and severity does not correspond to severity of the chronic disease.

Symptoms

- The patient usually presents with complaints of dyspnea, cough, shortness of breath, and chest tightness.
- Because of their inability to breathe, patients are generally anxious and may be agitated. In severe acute asthma, patients may be unable to communicate in complete sentences.
- Mental status changes may indicate impending respiratory failure.

Signs

- The patient usually has **tachypnea** and may have tachycardia.
- Wheezing may vary from end-expiratory wheezing in mild exacerbations to wheezing throughout inspiration and expiration in severe exacerbations.
- Bradycardia and absence of wheezing may indicate impending respiratory failure.
- Patients may also present with hyperinflation, use of accessory muscles to breathe, **pulsus paradoxus**, diaphoresis, and **cyanosis**.

Laboratory Tests

- Arterial blood gases for evaluating partial arterial pressure of carbon dioxide (P_{CO_2}) should be considered for patients in severe distress, suspected hypoventilation, or when PEF or FEV_1 is less than or equal to 30% after initial treatment.
- A complete blood count with differential should be obtained in patients with fever or purulent sputum.
- Serum electrolytes should be obtained, because frequent β_2-agonist administration may decrease serum potassium, magnesium, and phosphate.

Other Diagnostic Tests

- Patients may present with PEF rates greater than 80% and oxygen saturation greater than 95% in mild exacerbations to PEF rates less than 50%, oxygen saturations less than 91%, partial arterial oxygen pressures (Pa_{O_2}) less than 50 mm Hg (less than 6.65 kPa), and P_{CO_2} greater than 42 mm Hg (greater than 5.59 kPa) in a severe exacerbation.
- A chest x-ray should be performed when pneumonia is suspected.

The ingestion of sulfites can also worsen asthma. These agents are often found in processed potatoes, shrimp, dried foods, beer, and wines. Patients sensitive to sulfites should be warned not to ingest these products, as they have been known to cause severe exacerbations, particularly in severe asthmatics.

Patient Encounter, Part 1

RB is a 13-year-old African-American female who presents with complaints of shortness of breath when she exercises. She has joined the cross-country team, and she is having trouble keeping up with the other girls on the team because she gets extremely short of breath 5 or 10 minutes into her run; her chest begins to feel tight, and she coughs. The symptoms usually go away 30 minutes to an hour after she stops running. She also wakes up at night approximately once a week because she is having trouble catching her breath.

- What information is suggestive of asthma?
- How would you classify this patient's asthma severity?
- What additional information do you need to know before creating a treatment plan for this patient?

There is little evidence for other food allergies as a routine cause of worsening asthma symptoms.[1,3]

Viral infections are the most common cause of increased asthma symptoms and asthma exacerbations.

TREATMENT OF ASTHMA

Desired Outcomes

Chronic Asthma

❷ *Therapy for chronic asthma is directed at suppressing the underlying inflammatory response and normalizing pulmonary function*. The goals of treatment for chronic asthma are to: (1) prevent chronic and troublesome symptoms; (2) maintain normal or near normal pulmonary function; (3) maintain normal activity levels, including exercise and other physical activities; (4) prevent recurrent exacerbations of asthma and minimize the need for emergency department visits or hospitalizations; (5) provide optimal pharmacotherapy with minimal or no adverse effects; and (6) meet patients' and families' expectations of and satisfaction with asthma care.[1]

Because of the varying presentation of asthma, treatment guidelines for asthma therapy should serve as a guide for therapy with the therapeutic plan individualized for each patient to achieve these goals.

Acute Severe Asthma

Worsening or acute asthma can be a life-threatening situation, and appropriate outcomes require rapid assessment and appropriate intensification of therapy. Mortality associated with asthma exacerbations is usually related to an inappropriate assessment of the severity of the exacerbation resulting in insufficient treatment or referral for medical care.[12] The goals

of therapy are to: (1) correct significant **hypoxemia**; (2) rapidly reverse airflow obstruction; and (3) reduce the likelihood of recurrent severe airflow obstruction.[1]

Because of the significance of the event, patients may be more open to education about asthma after resolution of the exacerbation. Health care professionals should use this opportunity to provide information to help prevent future episodes, including recognition of early indicators of an exacerbation and a process to appropriately intensify pharmacotherapy during the early stages of future exacerbations, including an individualized written asthma action plan.

General Approach to Treatment

❸ In chronic asthma, *classification of asthma severity is based on daytime and nighttime symptoms, physical activity, lung function (PEF or FEV_1), PEF variability, and reliever medication use.* Because lung function is difficult to measure in preschool children (children 5 years of age or younger), it cannot be used to classify disease severity in this age group. Chronic asthma is classified as mild intermittent asthma, or mild, moderate or severe persistent asthma (Table 11–1).

Treatment of asthma involves avoidance of triggers known to precipitate or worsen asthma and the use of long-term control and quick relief medications. Long-term control medications include inhaled corticosteroids, inhaled long-acting β_2-adrenergic agonists, oral theophylline, and oral leukotriene modifying agents. In patients with severe asthma, systemic corticosteroids may be used as a long-term control medication. Quick relief medications include short-acting β_2-agonists, anticholinergics, and systemic corticosteroids. A stepwise approach to therapy is recommended to achieve the treatment goals[2] (Table 11–1).

In acute severe asthma, the severity of an exacerbation is not dependent upon the classification of the patient's chronic asthma, as even patients with mild intermittent asthma can have life-threatening acute exacerbations. Treatment of acute or worsening asthma primarily involves pharmacologic treatment. Early and aggressive treatment is necessary for quick resolution.[1,3] Important elements of an early treatment plan include: (1) a written action plan; (2) recognition of early indicators of an acute exacerbation, including asthma symptoms as well as worsening PEF or FEV_1; (3) appropriate intensification of pharmacotherapy, which may include a short course of oral corticosteroids; and (4) removal of triggers or irritants that may be contributing to the acute exacerbation.

Treatment of severe acute asthma includes the use of oxygen for the rapid reversal of hypoxemia, a short-acting β_2-agonist to reverse airway constriction, and a systemic corticosteroid to attenuate the inflammatory response.[1] Close monitoring of objective measures such as FEV_1 or PEF is important to quantify the response to therapy. Because recovery from exacerbations is often gradual, intensified therapy should be continued for several days.

Nonpharmacologic Therapy

Patients should play an active role in their therapy. The development of a health care provider–patient partnership is vital to the success of any treatment plan. Goals for asthma treatment should be shared with the patient and family, and the patient and health care provider should jointly agree on the patient's personal treatment goals.

Nonpharmacologic therapy should be incorporated into each step of therapy. Patient education should occur early in the disease process, include all members of the health care team, and be tailored to meet individual patient needs.[1] Patients should be taught basic facts about asthma, including the difference between the asthmatic and normal lung, what happens to the lung during an asthma attack, how medications work, environmental control measures, and self-management of asthma, including skills for self-monitoring of pulmonary function, symptoms of asthma deterioration, and when and how to take rescue actions.

Patients must understand the role of long-term control and quick relief medications in their asthma treatment plan. The importance of understanding asthma as a chronic disease and the need for daily treatment with long-term control medications should be stressed. Additionally, the importance of proper use of medication delivery devices should be continually reinforced. Basic education should be provided over several visits with the health care provider.

Risk Factor Avoidance

Patients who smoke should be strongly encouraged to quit; cigarette smoking decreases the efficacy of inhaled corticosteroids and can trigger an acute asthmatic response.[3] All patients should also avoid secondhand smoke. Parents of children with asthma should be instructed not to smoke in the home and not to allow others to smoke in the home. Patients should also avoid outdoor activities when air quality is poor and avoid exposure to other irritants such as hairspray, paint, exhaust fumes, and smoke from any fire.

Patients sensitive to specific allergens should be educated on ways to avoid them. Environmental controls to reduce the allergen load in the patient's home may reduce asthma symptoms, school absences because of asthma, and unscheduled clinic and emergency visits for asthma.[13] Patients allergic to warm-blooded pets should remove them from the home if possible or at least keep them out of the bedroom. However, allergens may remain in the home for months after the pet is removed.[1]

Patients allergic to cockroach antigens should ensure that food and garbage are not left exposed and cockroach populations are controlled. For patients with house dust mite allergies, essential measures to reduce the allergen load include encasing the mattress and pillow in allergen-impermeable covers and washing the patient's bed sheets and covers in hot water [130°F (54°C)] weekly. Dust mite exposure may also be minimized by removing carpets from the bedroom, removing

TABLE 11–1. Classification of Severity and Stepwise Approach For Managing Asthma

Severity Classification (Prior to Treatment)	Clinical Features Before Treatment or Adequate Control[a,b,c]	Medication Required to Maintain Long-Term Control: Adults and Children Older Than 5 Years of Age	Medication Required to Maintain Long-Term Control: Children 5 Years of Age and Younger
Step 4: Severe persistent	**Daytime Symptoms** • Continual symptoms • Limited physical activity **Nighttime Symptoms** • Frequent **Exacerbations** • Frequent **Lung Function** • FEV_1 or PEF less than or equal to 60% predicted; PEF variability greater than 30%	**Preferred Treatment** • High-dose inhaled corticosteroids *AND* • Long-acting inhaled β_2-agonists *AND* if needed • Corticosteroid tablets or syrup long term (2 mg/kg per day; generally do not exceed 60 mg/day); make repeated attempts to reduce systemic corticosteroids and maintain control with high-dose inhaled corticosteroids	**Preferred Treatment** • High-dose inhaled corticosteroids *AND* • Long-acting inhaled β_2-agonists *AND* if needed • Corticosteroid tablets or syrup long term (2 mg/kg per day; generally do not exceed 60 mg/day); make repeated attempts to reduce systemic corticosteroids and maintain control with high-dose inhaled corticosteroids
Step 3: Moderate persistent	**Daytime Symptoms** • Daily symptoms • Daily use of inhaled short-acting β_2-adrenergic agonists **Nighttime Symptoms** • Greater than 1 time per week **Exacerbations** • Affect activity; occur greater than or equal to 2 times per week; exacerbations may last days **Lung Function** • FEV_1 or PEF greater than 60% but less than 80% predicted; PEF variability greater than 30%	**Preferred Treatment** • Low- to medium-dose inhaled corticosteroids and long-acting inhaled β_2-agonists **Alternate Treatment** • Increase inhaled corticosteroid dose into the medium-dose range *OR* • Low- to medium-dose inhaled corticosteroids and either leukotriene modifier or theophylline If needed (particularly in patients with recurring severe exacerbation): **Preferred Treatment** • Increase inhaled corticosteroids within medium-dose range and add long-acting β_2 agonist **Alternative Treatment** • Increase inhaled corticosteroids within medium-dose range and add either leukotriene modifier or theophylline	**Preferred Treatment** • Low-dose inhaled corticosteroids and long-acting inhaled β_2-agonists *OR* • Medium-dose inhaled corticosteroids **Alternate Treatment** • Low-dose inhaled corticosteroids and either leukotriene receptor antagonist or theophylline If needed (particularly in patients with recurring severe exacerbations): **Preferred Treatment** • Medium-dose inhaled corticosteroids and long-acting β_2-agonists **Alternative Treatment** • Medium-dose inhaled corticosteroids and either a leukotriene receptor antagonist or theophylline
Step 2: Mild persistent	**Daytime Symptoms** • Symptoms greater than 2 times per week but less than 1 time per day **Nighttime Symptoms** • Greater than 2 times per month **Exacerbations** • May affect activity **Lung Function** • FEV_1 or PEF greater than or equal to 80%; PEF variability 20–30%	**Preferred Treatment** • Low-dose inhaled corticosteroids **Alternative Treatment** • Cromolyn, leukotriene modifiers, nedocromil *OR* sustained-release theophylline adjusted to a serum concentration of 5–15 mcg/mL (28–83 µmol/L)	**Preferred Treatment** • Low-dose inhaled corticosteroids (with nebulizer or MDI with holding chamber with or without facemask or DPI) **Alternative Treatment** • Cromolyn (nebulizer is preferred or MDI with holding chamber) *OR* leukotriene receptor antagonists

Step 1: Mild intermittent	**Daytime Symptoms** • Symptoms less than or equal to 2 times per week • Asymptomatic or normal PEF between exacerbations **Nighttime Symptoms** • Less than or equal to 2 times per month **Exacerbations** • Brief (from a few hours to a few days); intensity may vary **Lung Function** • FEV_1 or PEF greater than or equal to 80% PEF variability less than 20%	• No daily medications needed • Severe exacerbations may occur, separated by long periods of normal lung function; a course of systemic corticosteroids is recommended	• No daily medications needed
Quick Relief for All Patients[c]		• Short-acting bronchodilator: 2–4 puffs short-acting inhaled β_2-agonist as needed for symptoms • Intensity of treatment depends on severity of exacerbation: up to 3 treatments at 20-minute intervals or a single nebulizer treatment as needed; a course of systemic corticosteroids may be needed • Use of short-acting β_2-agonist greater than 2 times a week in intermittent asthma (daily or increasing use in persistent asthma) may indicate the need to initiate or increase long-term-control therapy	• Bronchodilators as needed for symptoms; intensity of treatment depends on the severity of the exacerbation • **Preferred Treatment** Short-acting inhaled β_2-agonist by nebulizer or facemask and spacer/holding chamber • **Alternative Treatment** Oral β_2-agonist • With viral respiratory infection: • Bronchodilator every 4–6 hours up to 24 hour (longer with physician consult); in general, repeat no more than once every 6 weeks • Consider systemic corticosteroid if exacerbation is severe or patient has a history of previous severe exacerbations • Use of short-acting β_2-agonist greater than 2 times a week in intermittent asthma (daily or increasing use in persistent asthma) may indicate the need to initiate or increase long-term-control therapy

Notes:

- The stepwise approach is intended to assist, not replace, the clinical decision making required to meet individual patient needs.
- There are very few studies on asthma therapy for infants.
- Gain control as quickly as possible (a short course of systemic corticosteroids may be required.); then step down to the least medication necessary to maintain control.
- Minimize use of short-acting inhaled β_2-agonists. Overreliance on short-acting inhaled β_2-agonists (e.g., use of short-acting inhaled β_2-agonists every day, increasing use or lack of expected effect, or use of approximately one canister a month even if not using it every day) indicates inadequate control of asthma therapy and the need to initiate or intensify long-term control therapy.
- Provide education on self-management or parent education on asthma management and controlling environmental factors that make asthma worse (e.g., allergens and irritants).
- Consultation with an asthma specialist is recommended for patients with moderate or severe persistent asthma. Consider consultation for patients with mild, persistent asthma.

[a]The presence of one of the features of severity is sufficient to place a patient in that category. An individual should be assigned the most severe grade to which any feature occurs. The characteristics noted in this table are general and may overlap because asthma is highly variable. Furthermore, an individual's classification may change over time.
[b]Accurate assessment of FEV_1 or PEF may not be possible in children less than 5 years of age.
[c]Patients at any level can have mild, moderate, or severe exacerbations. Some patients with intermittent asthma experience severe and life-threatening exacerbations separated by long periods of normal lung function and no symptoms.
FEV_1, forced expiratory volume in 1 second; PEF, peak expiratory flow; MDI, metered-dose inhaler; DPI, dry powder inhaler.

carpets laid over concrete slabs, and avoiding sleeping or lying on upholstered furniture. Reducing indoor humidity to less than 50% helps control dust mite populations and decreases exposure to indoor mold. Patients allergic to outdoor allergens should stay indoors during times of peak allergen levels.

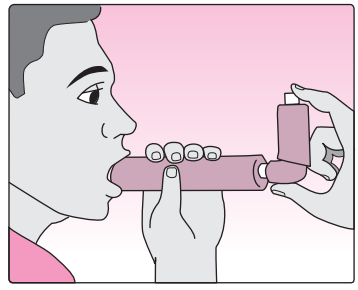
Asthma patients should receive the influenza vaccine every year.[1] Although the pneumococcal vaccine may decrease the risk of invasive pneumococcal disease in asthmatics, current guidelines do not include the routine administration of this vaccine to asthma patients.[1,14]

Drug Delivery Devices

❹ *Direct airway administration of asthma medications through inhalation is most efficient and minimizes systemic adverse effects.* Poor inhaler technique can result in increased oropharyngeal deposition of the drug with decreased efficacy and increased adverse effects. Figure 11–1 provides steps for the appropriate use of inhaled delivery devices. Inhaled asthma medications are available in metered-dose inhalers (MDIs), dry powder inhalers (DPIs), and nebulized solutions.

Patients switched from an MDI to a DPI should be counseled that the DPI requires a rapid and forceful inhalation as compared to the slow inhalation used for an MDI. Patients using a DPI should also be counseled not to exhale into the device, as it will cause a loss of dose or decreased drug delivery. Because delivery technique with inhalers deteriorates over time, the health care provider should take every opportunity to reinforce appropriate inhaler technique.

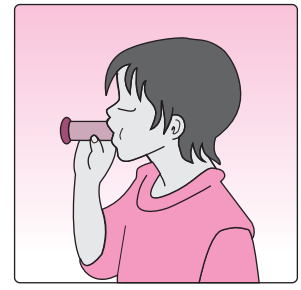
Patients should also be educated to keep track of inhaler use. Many DPIs have a built-in counter or device to notify the patient of how many doses are remaining (e.g., Diskus® and Twisthaler®) or that the inhaler is approaching empty (e.g., Turbuhaler®).



Steps for Using Your Inhaler

Please demonstrate your inhaler technique at every visit.

1. Remove the cap and hold inhaler upright.
2. Shake the inhaler.
3. Tilt your head back slightly and breathe out slowly.
4. Position the inhaler in one of the following ways (A or B is optimal, but C is acceptable for those who have difficulty with A or B. C is required for breath-activated inhalers):



A Open mouth with inhaler 1 to 2 inches away.

B Use spacer/holding chamber (that is recommended especially for young children and for people using corticosteroids).

C In the mouth. Do not use for corticosteroids.

D NOTE: Inhaled dry powder capsules require a different inhalation technique. To use a dry powder inhaler, it is important to close the mouth tightly around the mouthpiece of the inhaler and to inhale rapidly.

5. Press down on the inhaler to release medication as you start to breathe in slowly.
6. Breathe in slowly (3 to 5 seconds).
7. Hold your breath for 10 seconds to allow the medicine to reach deeply into your lungs.
8. Repeat puff as directed. Waiting 1 minute between puffs may permit second puff to penetrate your lungs better.
9. Spacers/holding chambers are useful for all patients. They are particularly recommended for young children and older adults and for use with corticosteroids.

Avoid common inhaler mistakes. Follow these inhaler tips:

- Breathe out *before* pressing your inhaler.
- Inhale *slowly*.
- Breathe in through your mouth, not your nose.
- Press down on your inhaler at the *start* of inhalation (or within the first second of inhalation).
- Keep inhaling as you press down on inhaler.
- Press your inhaler only *once* while you are inhaling (one breath for each puff).
- Make sure you breathe in evenly and deeply.

NOTE: Other inhalers are becoming available in addition to those illustrated above. Different types of inhalers require different techniques.

FIGURE 11–1. Steps for using your inhaler. (From Kelly HW, Sorkness CA. Asthma. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 515, with permission.)

Spacers or holding chambers decrease the need for coordination of actuation of MDI devices with inhalation, decrease oropharyngeal deposition of drug, and increase pulmonary drug delivery.[15,16] These devices are equipped with a mouthpiece or a facemask allowing the use of an MDI in children less than 5 years of age. Patients using a spacer or holding chamber should be counseled to place only one puff of the drug into the chamber at a time, because actuating the MDI more than once into the chamber before inhalation decreases drug delivery.[15] Additionally, patients should be instructed not to delay inhalation after actuation of the MDI, as a 10- to 20-second delay in inhalation may also significantly decrease drug delivery. Taking multiple breaths after a single actuation is appropriate and does not decrease drug efficacy.[15]

Although nebulizers have often been used for drug delivery in children, their use is expensive and time consuming. Nebulizers may atomize drug using compressed air or oxygen (jet nebulizers) or by high-frequency vibration (ultrasonic nebulizers). Ultrasonic nebulizers should not be used for drugs in suspension, as they are ineffective in delivering the suspended particles.[16]

Asthma Self-Management

Asthma self-management plans give patients the freedom to adjust therapy based on personal assessment of disease severity and a pre-agreed upon action plan. Furthermore, because most asthma exacerbations occur at home or in the community, these plans allow for the rapid initiation of patient-specific therapy. Asthma self-management plans reduce morbidity and the need for medical services.[17] For self-management plans to be effective, patients should be given a written action plan that is part of a global educational program.[3]

Patients should be educated to assess asthma severity by evaluating key asthma symptoms and monitoring PEF. Early signs of asthma deterioration include increasing nocturnal symptoms, increasing use of short-acting inhaled β_2-agonists, or symptoms that do not respond to increased use of short-acting inhaled β_2-agonists. Patients with moderate to severe persistent asthma should monitor PEF every day.[1] Measurement of PEF may be particularly important for the patient who is a poor judge of symptoms or whose perceptions of decreased airflow do not correlate with objective measures of airflow.[3]

Measurement of PEF is highly dependent upon patient effort and technique; therefore, the health care provider should educate the patient on the proper technique for measuring PEF and review this technique on a regular basis. To use the peak flow meter properly, the patient should be instructed to move the indicator to the bottom of the numerical scale; stand up; take a deep breath completely filling their lungs; place the mouthpiece in the mouth being careful to close their lips around it and not to obstruct the hole with their tongue; and blow out as hard and fast as they can in a single blow.[1] This effort should be repeated three times, with the highest value of the three recorded in the patient's PEF diary. The NAEPP recommends PEF be measured daily in the morning on waking, prior to taking a bronchodilator.[1]

Because PEF values in patients do not always correlate well with predicted PEF values, daily PEF values should be compared to the patient's personal best PEF. Personal best PEF should be established over a 2- to 3-week period when the patient is receiving optimal treatment.[1,3] During this time, the patient should measure PEF at least twice a day, in the morning and early afternoon, and before and after a dose of bronchodilator if the patient is taking one. At each time period, the patient should record the best of three attempts. The highest PEF recorded during this 2- to 3-week period is the patient's personal best. If the patient's personal best is less than 80% of predicted values or if peak flow variability is greater than 20%, more aggressive therapy (including a short course of oral corticosteroids) may be required to adequately assess the patient's personal best.[3]

Subsequent evaluation of PEF is done in relation to its variability from the patient's best. Consistent PEF measurements less than 80% of personal best indicate the need for intensifying therapy and a PEF measurement less than 50% indicates a severe exacerbation. The NAEPP recommends that these zones be associated with a "traffic light" system to assist the patient in their use.[1] PEF measurements in the range of 80% to 100% of personal best are in the green zone and indicate that current therapy is acceptable. A PEF in the range of 50% to 79% of personal best is in the yellow zone and indicates caution. PEF measurements in the yellow zone may indicate an impending exacerbation and based on his or her self-management plan, the patient should increase the use of relief medication, intensify inhaled corticosteroid therapy, or begin a short course of oral corticosteroids. A PEF less than 50% is in the red zone and signals a medical alert. Patients should use their short-acting β_2-agonist immediately and consult their asthma action plan.

Pharmacologic Therapy

Beta$_2$-Adrenergic Agonists

β_2-Agonists relax airway smooth muscle by directly stimulating β_2-adrenergic receptors.[18] They also increase mucociliary clearance and stabilize mast cell membranes. Inhalation, oral, and injectable dosage forms are available, and the inhalation dosage forms are most commonly used. Oral β_2-agonists should not be used in acute asthma because of a delayed onset of action compared to the inhaled route.[1] Inhaled β_2-agonists are classified as either short- or long-acting based on their duration of action.

Short-Acting Inhaled Beta$_2$-Agonists

❺ *Inhaled short-acting β_2-agonists are the most effective agents for reversing acute airway obstruction caused by bronchoconstriction* and are the drugs of choice for treating acute severe asthma and symptoms of chronic asthma.[1] Short-acting inhaled β_2-agonists have an onset of action of less than 5 minutes and a duration of action of 4 to 6 hours. β_2-Agonists have

significantly better bronchodilating activity in acute asthma than theophylline or anticholinergic agents.

Adverse effects of the inhaled β_2-agonists include tachycardia, tremor, and hypokalemia, which are usually not problematic. Because of increased adverse effects, oral β_2-agonists should be avoided in patients who are able to use inhaled medications.

Albuterol (also known as salbutamol outside the United States), the most commonly used inhaled short-acting β_2-agonist, is a racemic mixture (50:50) of albuterol enantiomers. The R-enantiomer is the active component whereas the S-enantiomer is inactive or may be associated with unwanted effects. Levalbuterol, the pure R-enantiomer of albuterol, is available as a solution for nebulization and as an MDI dosage form. Comparative studies show similar efficacy and safety between levalbuterol and albuterol, but the acquisition cost of levalbuterol is substantially higher.

Other commonly used short-acting inhaled β_2-agonists include pirbuterol and terbutaline. Non-selective β_2-agonists such as metaproterenol are no longer commonly used due to the potential for increased adverse effects. Although not equivalent on a milligram basis, the inhaled short-acting β_2-agonists are equally potent when given in equivalent doses. Doses for use as quick relief drugs in chronic asthma are provided in Table 11–2. Usual rescue doses may be doubled for mild exacerbations. Because of previous β-agonist use by the patient and the underlying inflammatory process in acute severe asthma, the dose-response curve for β_2-agonists is shifted to the right, and the duration of action is decreased; therefore, larger doses of short-acting inhaled β_2-agonists may need to be administered more often.[18]

Inhaled short-acting β_2-agonists may be administered through a nebulizer or an MDI. Compared to nebulization, administration through an MDI with a spacer is quicker and at least as effective with fewer adverse effects. In infants and young children, short-acting β_2-agonists administered by MDI should be administered through a spacer with a facemask, and in older children and adults through a spacer with a mouthpiece. In the case of crying infants and patients unwilling to use an MDI with a spacer, short-acting β_2-agonists may be administered via nebulization connected to oxygen. Infants should receive nebulization via a facemask that fits over the nose and mouth. Continuous nebulization is as effective as intermittent nebulization with fewer adverse effects.[19]

In patients hospitalized because of asthma, patient-initiated (on-demand) therapy may result in decreased nebulized doses, decreased adverse effects, and shorter hospital stays than therapy given regularly at 4-hour intervals.[20] In patients admitted to the intensive care unit and placed on mechanical ventilation, β_2-agonists can be delivered via an MDI or nebulization through the ventilatory circuit.

Long-Acting Inhaled Beta$_2$-Agonists

Salmeterol and formoterol are long-acting inhaled β_2-agonists that provide up to 12 hours of bronchodilation after a single dose. Both agents are approved for the chronic prevention of asthma symptoms. Salmeterol is a partial agonist with an onset of action of approximately 30 minutes. Because of this delayed onset of action, patients should be cautioned not to use salmeterol as a quick relief medication. Formoterol is a full agonist that has an onset of action similar to that of albuterol, but it is not currently indicated for the treatment of acute bronchospasm.

Inhaled long-acting β_2-agonists are indicated for add-on therapy for asthma not controlled on low to medium doses of inhaled corticosteroids. Adding a long-acting inhaled β_2-agonist is at least as effective as doubling the dose of an inhaled corticosteroid with respect to improving lung function and symptom scores and decreasing nocturnal symptoms, reliever medication use, and asthma exacerbations.[2] Addition of a long-acting inhaled β_2-agonist to inhaled corticosteroid therapy also reduces the amount of inhaled corticosteroids necessary for asthma control.[2,21] Combined therapy with a long-acting inhaled β_2-agonist and an inhaled corticosteroid is also superior to the combination of a leukotriene modifier or theophylline with an inhaled corticosteroid.[2,22–24]

Although both formoterol and salmeterol are effective as add-on therapy for moderate persistent asthma, neither agent should be used as monotherapy for chronic asthma. Patients treated with salmeterol alone are at greater risk of worsening asthma than those treated with inhaled corticosteroids.[25,26]

Salmeterol is also available in a fixed ratio combination product containing fluticasone, and a new drug application has been filed for a fixed combination product containing budesonide and formoterol. Combination products have the potential advantage of increasing patient adherence due to the decreased number of inhalers and inhalations; however, these products offer less flexibility with respect to dosage adjustments when necessary.

Corticosteroids

Corticosteroids are the most potent anti-inflammatory agents available for the treatment of asthma. The efficacy of corticosteroids is due to their ability to affect multiple inflammatory pathways, resulting in the suppression of inflammatory cell activation and function, prevention of microvascular leakage, decreased mucus production, and upregulation of β_2-adrenergic receptors.[10,18] Clinically, corticosteroids decrease airway inflammation, decrease AHR, decrease mucus production and secretion, and improve the response to β_2-agonists.[18] Corticosteroids for the treatment of asthma are available in inhaled, oral, and injectable dosage forms.

Inhaled Corticosteroids

❻ *In persistent asthma, inhaled corticosteroids provide the most comprehensive control of the inflammatory process* and are the cornerstone of therapy.[2] Inhaled corticosteroids are more effective than cromolyn, leukotriene modifiers, nedocromil, and theophylline in reducing markers of inflammation and AHR, improving lung function, and preventing emergency department visits and hospitalizations due to asthma exacerbations.[2,25] The primary

TABLE 11–2. Usual Dosages for Selected Quick-Relief Medications

Medication	Dosage Form	Adult Dose	Child Dose[a]
Short-Acting Inhaled β_2-Agonists			
Albuterol	MDI: 90 mcg/puff 200 puffs	2 puffs 5 minutes before exercise 2 puffs 3–4 times a day as needed	1–2 puffs 5 minutes before exercise 2 puffs 3–4 times a day as needed
Albuterol HFA	MDI: 90 mcg/puff 200 puffs		
Levalbuterol HFA	MDI: 45 mcg/puff 200 puffs	2 puffs every 4–6 hours (1 puff every 4 hours may be sufficient in some patients)	2 puffs every 4–6 hours (1 puff every 4 hours may be sufficient in some patients)
Albuterol nebulizer solution	5 mg/mL (5%) 2.5 mg/3 mL 1.25 mg/3 mL 0.63 mg/3 mL	1.25–5 mg in 3 mL of saline every 4–8 hours	0.05 mg/kg (minimum of 1.25 mg, maximum of 2.5 mg) in 3 mL of saline every 4–6 hours
Levalbuterol (R-albuterol) nebulizer solution	0.31 mg/3 mL 0.63 mg/3 mL 1.25 mg/3 mL	0.63–2.5 mg every 4–8 hours	0.025 mg/kg (minimum of 0.63 mg; maximum of 1.25 mg every 4–8 hours
Anticholinergics			
Ipratropium	MDI CFC: 18 mcg/puff, 200 puffs MDI HFA: 17 mcg/puff, 200 puffs	2–3 puffs every 6 hours	1–2 puffs every 6 hours
	Nebulizer solution: 0.25 mg/mL (0.25%)	0.25 mg every 6 hours	0.25–0.5 mg every 6 hours
Ipratropium with albuterol	MDI: 18 mcg/puff of ipratropium bromide and 90 mcg/puff of albuterol	2–3 puffs every 6 hours	1–2 puffs every 8 hours
	Nebulizer solution: 0.5 mg/3 mL ipratropium bromide and 2.5 mg/3 mL albuterol	3 mL every 4–6 hours	1.5–3 mL every 4–8 hours
Systemic Corticosteroids			
Methylprednisolone Prednisolone	2-, 4-, 8-, 16-, 32-mg tablets 5-mg tablets 5 mg/5 mL 15 mg/5 mL	Short course "burst" to achieve control; 40–60 mg/day as single or two divided doses for 3–10 days	Short-course "burst" to achieve control; 1–2 mg/kg per day, maximum of 60 mg/day for 3–10 days
Prednisone	1-, 2.5-, 5-, 10-, 20-, 50-mg tablets 5 mg/mL 5 mg/5 mL		
Methylprednisolone acetate	Repository injection: 40 mg/mL 80 mg/mL	240 mg intramuscularly once	7.5 mg/kg intramuscularly once

[a]Children less than or equal to 12 years of age.
CFC, chlorofluorocarbon propellant; HFA, hydrofluoroalkane propellant; MDI, metered-dose inhaler.

advantage of the use of inhaled corticosteroids compared to systemic corticosteroids is the targeted delivery of drug to the lungs, which decreases the risk of systemic adverse effects.

Inhaled corticosteroids are not equivalent on a milligram basis; however, equivalent doses have been approximated (Table 11–3). Low to moderate doses have been shown to be safe and effective in all age groups. Although some effect is seen from inhaled corticosteroids within 12 hours, 2 weeks of therapy is necessary to see significant clinical effects, and longer treatment periods may be necessary to see the full effect of these agents on airway inflammation and remodeling.

Inhaled corticosteroids appear to have a flat dose-response curve, with a two-fold increase in dose having a limited additional effect on asthma control.[3,27] Although a four-fold increase in inhaled corticosteroid dose has been shown to improve asthma control, this significantly increases the risk of systemic adverse effects.[2,28] These agents are generally effective when given twice daily and may be effective when given once daily for mild asthma; however, dosing four times a day may be required to achieve asthma control in patients with severe asthma.[3]

Local adverse effects of inhaled corticosteroids include oral candidiasis and **dysphonia**. The incidence of local adverse

TABLE 11–3. Estimated Comparative Dosages for Inhaled Corticosteroids

Medication	Age[a]	Low Daily Dose	Medium Daily Dose	High Daily Dose
Beclomethasone	Adult	80–240 mcg	240–480 mcg	Greater than 480 mcg
MDI (HFA): 40–80 mcg/puff	Child	80–160 mcg	160–320 mcg	Greater than 320 mcg
Budesonide	Adult	200–600 mcg	600–1200 mcg	Greater than 1200 mcg
DPI: 200 mcg/inhalation	Child	200–400 mcg	400–800 mcg	Greater than 800 mcg
Budesonide solution for inhalation 250 mcg or 500 mcg/2 mL	Child	0.5 mg	1 mg	2 mg
Flunisolide	Adult	500–1000 mcg	1000–2000 mcg	Greater than 2000 mcg
MDI (CFC): 250 mcg/puff	Child	500–750 mcg	1000–1250 mcg	Greater than 1250 mcg
Fluticasone	Adult	88–264 mcg	264–660 mcg	Greater than 660 mcg
MDI: 44, 110, or 220 mcg/puff	Child	88–176 mcg	176–440 mcg	Greater than 440 mcg
Mometasone furoate	Adult	200–400 mcg	400–800 mcg	Greater than 800 mcg
DPI: 200 mcg/inhalation	Child	—	—	—
Triamcinolone acetonide MDI	Adult	400–1000 mcg	1000–2000 mcg	Greater than 2000 mcg
(CFC): 100 mcg/puff	Child	400–800 mcg	800–1200 mcg	Greater than 1200 mcg

effects can be reduced by using a spacer or holding chamber and by having the patient rinse their mouth with water and expectorate after using the inhaled corticosteroids. Systemic absorption occurs via the pulmonary and oral routes. Although only a fraction of the drug is delivered to the lungs, 100% of the drug reaching the lungs is absorbed systemically.[1,3] For most delivery devices, the majority of the drug is deposited in the oropharyngeal cavity and swallowed. Systemic exposure to swallowed drug is primarily determined by the degree of first-pass metabolism of the agent. Because spacers and holding chambers decrease oral deposition and increase pulmonary delivery, these devices may increase the systemic effects of inhaled corticosteroids.[15,16] Additionally, changes in drug delivery devices [e.g., from a CFC to a hydrofluoroalkane (HFA) propellant or from an MDI to a DPI] may also alter pulmonary drug deposition with a resulting change in efficacy or systemic adverse effects.[3]

Systemic adverse effects are dose-dependent and are rare at low to medium doses; however, high-dose inhaled corticosteroids have been associated with adrenal suppression, decreased bone mineral density, skin thinning, and easy bruising.[3,29] Growth suppression in children may occur even with low-dose inhaled corticosteroids; however, suppression appears to occur primarily in the first year of treatment and may be due to delayed growth with the potential of future catch-up growth.[30]

Because all inhaled corticosteroids are equally effective if given in equipotent doses, product selection should be individualized based on the available dosage form, delivery device, and patient preference. In infants, administration may require the use of a nebulizer or spacer/holding chamber with a facemask. Caregivers should use a soft, damp cloth to wipe the face of infants receiving an inhaled corticosteroid via a facemask to prevent topical candidiasis.[18]

Systemic Corticosteroids

Systemic corticosteroids are effective as both long-term control and rescue medications; however, due to the potential for serious adverse effects, systemic corticosteroids should only be used for long-term control of asthma in patients who have failed other therapies. Serious adverse effects include hypothalamic-pituitary-adrenal suppression, growth retardation, osteoporosis, aseptic necrosis of the bone, psychiatric disturbances, sodium and water retention, hyperkalemia, hyperglycemia, immunosuppression, impaired wound healing, glaucoma, posterior subcapsular cataracts, skin thinning and easy bruising, central redistribution of fat, and moon facies.

If it is necessary to use systemic corticosteroids for long-term control therapy, once-daily or every-other-day therapy should be used and repeated attempts should be made to decrease the dose or discontinue the drug. Withdrawal of chronic therapy may precipitate adrenal failure or unmask underlying inflammatory disorders such as **Churg-Strauss syndrome**.

Systemic corticosteroids are the cornerstone of the treatment of worsening asthma not responding to bronchodilators and acute severe asthma. For patients with worsening asthma not responding to bronchodilators, a short course or "burst" of systemic corticosteroids is effective for gaining control and preventing progression.[1,3] The short course should be continued until the PEF reaches 80% of personal best or symptoms resolve. Three to ten days of therapy are usually sufficient, but longer therapy may be required.[1]

In acute severe asthma, systemic corticosteroids should be given to all patients who do not respond to initial bronchodilator therapy and all patients with moderate to severe exacerbations. Corticosteroids attenuate the inflammatory

response and increase the response to β_2-agonists. They speed recovery from the exacerbation, decrease hospital admissions, and reduce relapse rates. Their onset of effects is delayed, and a clinical response may not be seen for 4 to 12 hours.[18] For this reason, systemic corticosteroids should be started early in the course of acute exacerbations or worsening asthma.

There is no evidence that intravenous corticosteroid administration is more effective than oral administration, and the oral route is preferred in acute severe asthma.[3] There are also few data to guide selection of initial corticosteroid doses. Recommended doses for acute severe asthma are shown in Table 11–5, page 227; however, recent data indicate that

TABLE 11–4. Usual Doses for Long-Term Control Medications

Medication	Dosage Form	Adult Dose	Child Dose[a]
Inhaled Corticosteroids			
See Table 11–3			
Systemic Corticosteroids			
Methylprednisolone	2-, 4-, 8-, 16-, 32-mg tablets	7.5–60 mg daily in a single dose in the morning or every other day as needed for control	0.25–2 mg/kg daily in a single dose in the morning or every other day as needed for control
Prednisolone	5-mg tablets 5 mg/5 mL 15 mg/5 mL		
Prednisone	1-, 2.5-, 5-, 10-, 20-, 50-mg tablets 5 mg/mL 5 mg/5 mL		
Long-Acting Inhaled β_2-Agonists			
Salmeterol	DPI 50 mcg/blister	1 blister every 12 hours	1 blister every 12 hours
Formoterol	DPI 12 mcg/single-use capsule	1 capsule every 12 hours	1 capsule every 12 hours
Cromolyn and Nedocromil			
Cromolyn	MDI 1 mg/puff Nebulizer: 20 mg/ampule	2–4 puffs 3–4 times a day 1 ampule 3–4 times a day	1–2 puffs 3–4 times a day 1 ampule 3–4 times a day
Nedocromil	MDI 1.75 mg/puff	2–4 puffs 2–4 times a day	1–2 puffs 2–4 times a day
Leukotriene Modifiers			
Montelukast	4 mg/pack granules 4- or 5-mg chewable tablet 10-mg tablet	10 mg at bedtime (greater than 14 years of age)	4 mg at bedtime (12 mo–5 years, granules; 2–5 years of age, chewable tablet) 5 mg at bedtime (6–14 years of age)
Zafirlukast	10- or 20-mg tablet	20 mg twice a day	10 mg twice a day (7–11 years of age)
Zileuton	300- or 600-mg tablet	600 mg four times a day	—
Methylxanthine			
Theophylline	Liquids, sustained-release tablets, capsules	Starting dose: 10 mg/kg per day up to 300 mg maximum; usual maximum dose is 800 mg/day	Starting dose: 10 mg/kg per day; usual maximum dose is: Less than 1 year of age: (0.2 × age in weeks) + 5 = dose in mg/kg per day Greater than or equal to 1 year of age: 16 mg/kg per day up to 300 mg maximum
Miscellaneous			
IgE monoclonal antibody	Lyophilized powder for reconstitution with sterile water: 150 mg/vial	Dosed every 2 or 4 weeks based on patient weight and baseline total IgE concentrations	—

[a]Children less than or equal to 12 years of age.
DPI, dry powder inhaler; MDI, metered-dose inhaler.
Adapted from National Institutes of Health, National Heart Lung and Blood Institute. National Asthma and Education Prevention Program. Expert Panel Report. methylprednisolone 60 to 80 mg/day (or equivalent) is adequate for hospitalized patients, and doses as low as 40 mg/day (or equivalent) are probably adequate.[3] No advantage has been shown for higher doses in acute severe asthma.[1,3]

Although the optimal duration of systemic corticosteroids is unknown, therapy should be continued until PEF is greater than or equal to 80% of predicted or personal best. According to the NAEPP, the usual regimen is to continue frequent multiple doses until the patient's FEV_1 or PEF improves to 50% of predicted and then decrease the frequency to twice daily. In general, the duration of therapy ranges from 3 days for mild exacerbations to 14 days for severe exacerbations. It is not necessary to taper the systemic steroid dose in patients receiving short bursts of systemic corticosteroid therapy, as the adrenal suppression that occurs is transient and rapidly reversible.[18]

Anticholinergics

Anticholinergic agents act by inhibiting the effects of acetylcholine on muscarinic receptors in the airways. They only protect against cholinergic-mediated bronchoconstriction and are not as effective as bronchodilators as are β_2-agonists in asthma.[18] Administration can be associated with bothersome adverse effects such as blurred vision, dry mouth, urinary retention, and constipation. However, the anticholinergic agents currently available for inhalation are quaternary amines that are not absorbed systemically and have limited adverse effects.

Ipratropium is the most commonly used anticholinergic for treating bronchoconstriction in asthma. It is available as an MDI and solution for nebulization. Ipratropium has an onset of action of approximately 30 minutes and a duration of action of 4 to 8 hours. Care should be taken not to spray the metered-dose inhaler into or allow the nebulized solution to get in the patient's eyes, as it can cause mydriasis and blurred vision.

The addition of ipratropium bromide to inhaled β_2-agonist therapy in acute severe asthma improves pulmonary function and decreases hospitalization rates in both adult and pediatric patients.[31] The benefit of combining ipratropium and albuterol appears to be greatest in moderate to severe exacerbations, and the combination should be considered first-line therapy in severe exacerbations.

Tiotropium is a long-acting inhaled anticholinergic available in a DPI; it has an onset of action of approximately 30 minutes and a duration of action longer than 24 hours.[32] Because pure asthmatics were excluded from clinical trials for tiotropium, a paucity of data exist concerning its use in asthma.

Leukotriene Modifiers

Leukotriene modifiers either inhibit 5-lipoxygenase (zileuton) or competitively antagonize the effects of leukotriene D_4 (montelukast and zafirlukast). These agents improve FEV_1 and decrease asthma symptoms, rescue drug use, and exacerbations due to asthma. Although these agents offer the convenience of oral therapy for asthma, they are significantly less effective than low doses of inhaled corticosteroids.[2,33]

Use of zileuton is uncommon due to the need for dosing four times a day, potential drug interactions, and the potential for hepatotoxicity with the resulting need for frequent monitoring of liver enzymes. In patients started on zileuton, serum alanine aminotransferase concentrations should be monitored before treatment begins, monthly for the first 3 months, every 2 to 3 months for the remainder of the first year, and then periodically thereafter for as long as the patient continues to receive the medication. Zileuton also inhibits the cytochrome P-450 (CYP) mixed function enzyme system and has been shown to decrease the clearance of theophylline, R-warfarin and propranolol.[34]

The leukotriene inhibitors zafirlukast and montelukast are generally well tolerated and dosed twice and once a day, respectively. Significant increases in hepatic enzymes have been reported in postmarketing studies for zafirlukast but not montelukast.[34] Zafirlukast also inhibits the CYP2C9 and CYP3A4 isoenzymes and may increase prothrombin times in patients receiving warfarin. The International Normalized Ratio should be monitored if warfarin and zafirlukast are used concomitantly. Erythromycin and theophylline may decrease zafirlukast concentrations, whereas aspirin may increase zafirlukast concentrations. It is not clear if these interactions are clinically important. Montelukast does not appear to inhibit the cytochrome P-450 enzymes, but drugs that induce CYP3A4 may decrease montelukast concentrations.

Both of these agents have been associated with rare reports of Churg-Strauss syndrome. This syndrome may result from the corticosteroid dose reduction, as it has also been reported when systemic corticosteroids have been reduced or withdrawn in conjunction with the initiation of high-potency inhaled corticosteroids.[35]

Cromolyn and Nedocromil

Cromolyn and nedocromil are inhaled anti-inflammatory agents that block both the early- and late-phase response. Both agents are considered alternative therapies to inhaled corticosteroids for the treatment of mild persistent asthma; however, both are less effective than low doses of inhaled corticosteroids.[2,30] The exact mechanism of action of these agents is not understood, but they appear to inhibit mast cell mediator release as well as modulate other inflammatory responses.[3]

Patients receiving these agents may notice improvement in 1 to 2 weeks, but maximal benefit may not be seen for 4 to 6 weeks. Cromolyn and nedocromil appear to be similar in efficacy to the leukotriene antagonists and theophylline for persistent asthma.[18] Both agents are well tolerated with adverse effects limited to cough and wheezing. Bad taste and headache have also been reported with nedocromil. One dose of cromolyn or nedocromil prior to exercise or allergen exposure will provide effective prophylaxis for 1 to 2 hours. Cromolyn and nedocromil are not as effective as albuterol for prophylaxis of exercise-induced asthma.

In addition to their decreased efficacy compared to corticosteroids, a primary drawback to the use of these agents is

the need to dose them four times a day until symptoms stabilize, after which the dosage frequency can be reduced to three times a day for cromolyn and twice a day for nedocromil.[18]

Methylxanthines

Theophylline is also considered an alternative to inhaled corticosteroids for the treatment of mild persistent asthma; however, limited efficacy compared to inhaled corticosteroids, a narrow therapeutic index with life-threatening toxicity, and multiple clinically important drug interactions have severely limited its use. Theophylline causes bronchodilation through inhibition of phosphodiesterase and antagonism of adenosine and appears to have anti-inflammatory and immunomodulatory properties as well.[36]

Target serum theophylline concentrations are 5 to 15 mg/L (28 to 83 µmol/L). Adverse effects generally are not problematic at serum concentrations below 15 mg/L (83 µmol/L), but the increased risk of adverse effects outweighs the increase in bronchodilation in most patients above 15 mg/L (83 µmol/L).[36] Headache, nausea, vomiting, and irritability may occur at serum concentrations less than 20 mg/L (110 µmol/L) but are rare when the dose is started low and increased slowly. More serious adverse effects, including cardiac arrhythmias, seizures, toxic encephalopathy, and death can occur at higher concentrations.[18] Arrhythmias and seizures may occur without nausea and vomiting, particularly in chronic toxicity.

Theophylline is primarily metabolized by CYP1A2 and CYP3A4 and is involved in a large number of disease and drug interactions. Theophylline exhibits non-linear pharmacokinetics in the therapeutic range; therefore, serum concentration changes due to dosage adjustments and drug interactions may not always be predictable.[18,36] Theophylline also exhibits interpatient variability in hepatic clearance, and therefore patients receiving theophylline should have their serum theophylline concentrations monitored.

Omalizumab

Omalizumab is a recombinant humanized monoclonal anti-IgE antibody that inhibits binding of IgE to receptors on mast cells and basophils, resulting in the inhibition of mediator release and attenuation of the early- and late-phase allergic response. It may be a treatment option for moderate to severe persistent asthmatics 12 years of age or older whose asthma is not controlled by inhaled corticosteroids and who have a positive skin test or in vitro reactivity to perennial allergens.[37] Omalizumab significantly decreases inhaled corticosteroid use, number and length of exacerbations, and increases asthma-related quality of life.[37]

Omalizumab is given as a subcutaneous injection, and the dose is based on the patient's weight and initial total IgE serum concentration. The dosage should not be adjusted based on subsequent total serum IgE measurements. Drug clearance appears to depend on patient weight, and dosage should be adjusted if there is a significant change in body weight. Doses greater than 150 mg should be administered as separate injections at multiple sites. The most common adverse effects are injection site reactions and include bruising, redness, pain, stinging, itching, and burning. Anaphylactic reactions are rare.

Treatment of Chronic Asthma

The intensity of pharmacologic therapy is based on the severity of the disease, and the least amount of medications necessary to meet the goals of asthma therapy should be used.[1,3] Stepwise therapy for the treatment of chronic asthma based on disease severity is shown in Table 11–1.

Mild Intermittent Asthma

In patients with mild intermittent asthma, long-term control medications are not necessary, and patients should use a short-acting inhaled β_2-agonist to prevent or treat symptoms.[2] This classification includes patients with exercise-induced asthma, seasonal asthma, or asthma symptoms associated with infrequent trigger exposure. Patients can pre-treat with two puffs of cromolyn or nedocromil prior to exposure to a known trigger. The treatment of choice for exercise-induced asthma is two inhalations of albuterol 5 minutes prior to exercise.[1] Cromolyn and nedocromil are less effective than albuterol for prophylaxis of exercise-induced asthma.

Persistent Asthma

Patients who use their short-acting inhaled β_2-agonist more than twice a week should be treated as mild persistent asthma, and consideration should be given to treating those with a history of severe exacerbations as having moderate persistent asthma.[2,3]

Patients with persistent asthma require daily long-term control therapy (Table 11–4). The NAEPP recommends that long-term control therapy be initiated one step above the severity classification to gain quick control, and once the asthma is controlled, therapy should be stepped down to the least amount of medication necessary to maintain control.[1] This may require high-dose inhaled corticosteroids or a short course of systemic corticosteroids. However, initiating treatment at a moderate dose of inhaled corticosteroids may be as effective as initiating therapy with a high-dose inhaled corticosteroid and may decrease the chances of overmedication.[3,38] Therapy should be evaluated on a regular basis, and a gradual step down in long-term control therapy should be initiated when possible.[1] Inhaled corticosteroids are the long-term control medication of choice at all levels of severity and in all age groups.[2] Cromolyn, leukotriene modifiers, nedocromil, and theophylline are non-preferred alternatives to inhaled corticosteroids.

Mild Persistent Asthma

In mild persistent asthma, daily use of a low-dose inhaled corticosteroid is the preferred treatment in all age groups. Cromolyn,

nedocromil, and leukotriene modifiers should be reserved for patients who cannot take inhaled corticosteroids.[2,25]

Moderate Persistent Asthma

❸ *The addition of a long-acting inhaled β_2-agonist to low-dose inhaled corticosteroids is the preferred treatment of moderate asthma in adults and school-age children.*[2] Although efficacy data in pre-school children are lacking, the combination is one of the preferred treatments for moderate persistent asthma in this age group as well. Medium-dose inhaled corticosteroids have also been shown to be effective in pre-school children and are also a preferred treatment in this age group.[2] In some patients with moderate persistent asthma, particularly those with risks for severe exacerbations, the combination of a medium-dose inhaled corticosteroid plus a long-acting inhaled β_2-agonist may be preferred for asthma control.[2]

Severe Persistent Asthma

Patients with severe persistent asthma should receive high-dose inhaled corticosteroids, a long-acting inhaled β_2-agonist, and if needed, systemic corticosteroids.[2] Because of the significant adverse effects seen with long-term therapy, efforts should be made to optimize other therapies in an attempt to discontinue or limit systemic corticosteroid therapy. The Global Initiative for Asthma guidelines suggest adding a leukotriene modifier or theophylline as an alternative to starting systemic corticosteroids.[3]

Leukotriene modifiers may permit dose reduction of inhaled corticosteroids in moderate and severe asthmatics, improve surrogate markers of inflammation in patients treated with inhaled corticosteroids plus a long acting β_2-agonist, and improve asthma control in patients not controlled on low to high doses of inhaled corticosteroids.[3,39] Thus, addition of a leukotriene modifier should be considered for patients not controlled by high-dose inhaled corticosteroids and an inhaled long-acting β_2-adrenergic agonist before starting systemic corticosteroids.[3] In patients in whom systemic corticosteroids are necessary for asthma control, the lowest effective dose should be used, and repeated attempts should be made to wean the patient from systemic corticosteroids or decrease the dose.

All patients with chronic asthma should be prescribed a short-acting inhaled β-agonist to treat symptoms; however, use of these agents should be minimized. ❾ *Excessive use of inhaled short-acting β_2-agonists is an indicator of inadequately controlled asthma*, and long-term control therapy should be intensified. Excessive use can be demonstrated by daily use of these agents, use of more than one canister a month, increasing use, or lack of expected effect.[2] Additionally, failure to have a rapid and sustained response to these agents in worsening asthma indicates the need for further medical attention and intensification of therapy.[3] Use of an inhaled short-acting β_2-agonist more than twice a week to treat symptoms is cause to consider stepping up long-term control therapy.[10]

Patient Encounter, Part 2: The Medical History, Physical Exam, and Diagnostic Tests

PMH
Allergic rhinitis for 6 years
Bronchitis 3 times in the last 6 years, last episode 6 months ago
Hospitalized with viral lower respiratory tract infections twice at ages 2 and 4

FH
Mother had asthma as a child, but "outgrew" it and has had no problems with it since she was 12 or 13 years old; both her mother and father have allergic rhinitis

SH
Only child who lives at home with her mother and father in a two-bedroom duplex built on a concrete slab; neither the patient nor her parents smoke or drink alcohol; they have no animals inside or outside the home

Meds
Fexofenadine SR 180 mg PO daily

ROS
Unremarkable except as described above

PE
General appearance: Small for her age but appears to be well nourished and healthy

VS: Blood pressure 112/68 mm Hg, pulse 78 beats per minute, respiratory rate 18/minute, temperature 37.0°C (98.7°F), Ht 4′6″ (137 cm), Wt 62 lb (28 kg)
Chest: CTA bilaterally, no wheezing
CV: RRR, S_1 and S_2 normal, no rubs, gallops, or murmurs
Exts: No clubbing, cyanosis, or edema

Labs
Normal except for an eosinophil count of 7% of the total white blood cell count

Pulmonary function tests
FEV_1: 1.6 L (90% predicted)
FVC: 1.75 L (92% predicted)
FEV_1/FVC: 0.914
Post-bronchodilator FEV_1: 1.73 L (8.1% increase)
FEV_1 after exercise 1.23 L (23.1% decrease)

- Given this additional information, what is your assessment of the patient's condition?
- Identify your treatment goals for this patient.
- What nonpharmacologic and pharmacologic alternatives are feasible for this patient?
- Outline a treatment plan for this patient that includes nonpharmacologic therapy, pharmacologic therapy, and a monitoring plan. Justify your therapeutic selections.

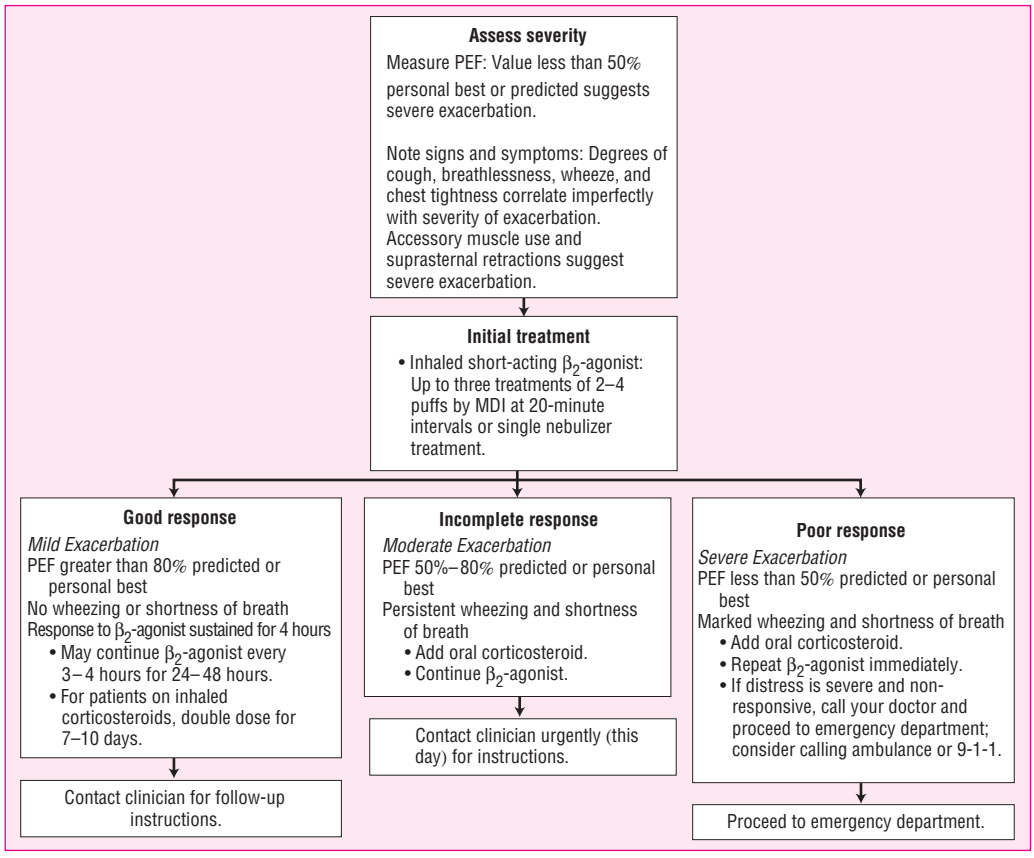

FIGURE 11–2. Home management of acute asthma exacerbation. Patients at risk for asthma-related death should receive immediate clinical attention after initial treatment. PEF, peak expiratory flow. (From Kelly HW, Sorkness CA. Asthma. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 516, with permission.)

Treatment of Acute Severe Asthma

The optimal treatment of acute severe asthma depends on the severity of the exacerbation (Figs. 11–2 and 11–3). The patient's condition usually deteriorates over several hours, days, or weeks; however, rapid deterioration can occur in some patients.[3] Gradual deterioration may indicate failure of long-term controller therapy. Patients with rapid deterioration usually respond well to bronchodilator therapy.[40] Severity at the time of the evaluation can be estimated by signs and symptoms, but patient response 30 minutes after inhalation of a bronchodilator is the best predictor of outcome.[12]

Starting therapy at home allows for rapid initiation and early assessment of response. Patients should follow their written action plan as symptoms intensify or lung function deteriorates. An algorithm for the initial treatment of an asthma exacerbation at home is shown in Fig. 11–2. Based on the initial response to β_2-agonist therapy, the severity of the exacerbation can be assessed, and treatment can be appropriately intensified.[1]

Patients with a good response to therapy should consider intensification of anti-inflammatory therapy.[1] Although guidelines recommend doubling the previous inhaled corticosteroid dose, this may not be necessary for mild exacerbations.[3,41,42] Treatment selection should be individualized based on what has worked for the patient previously.

Patients with mild exacerbations whose response to inhaled short-acting β_2-agonists lasts less than 1 hour and patients with incomplete responses should start a short course of oral prednisone. Corticosteroid therapy should continue until PEF is at least 80% of predicted or personal best.[40] Short-acting β_2-agonist therapy can be continued at two to four inhalations every 3 to 4 hours for several days until symptoms resolve. Continued reliance on short-acting β_2-adrenergic agonists for prolonged periods indicates a need to seek medical care.

Patients with incomplete responses should contact their health care provider immediately for instructions, while those with a poor response should proceed directly to the emergency department.[1] In the emergency department, baseline PEF measurements and oxygen saturation should be monitored. PEF should be monitored before and 15 to 20 minutes after bronchodilator administration. Treatment should be initiated as soon as lung function is assessed (Fig. 11–3). Dosages for emergency department and hospital use of quick relief medications are shown in Table 11–5.

Patients with an oxygen saturation less than 90% (less than 95% in children, pregnant women, and patients with co-existing heart disease) should receive oxygen with the dose adjusted to keep oxygen saturation above these levels.[3,12,40] **Hypoxemia** usually results from a ventilation/perfusion mismatch, and low oxygen levels (less than 30% of the fraction of inspired air) administered by nasal cannula or facemask are sufficient to reverse hypoxemia in most patients.

Infants and young children may present with dehydration due to increased respiratory losses and decreased intake.[1,3] Rehydration

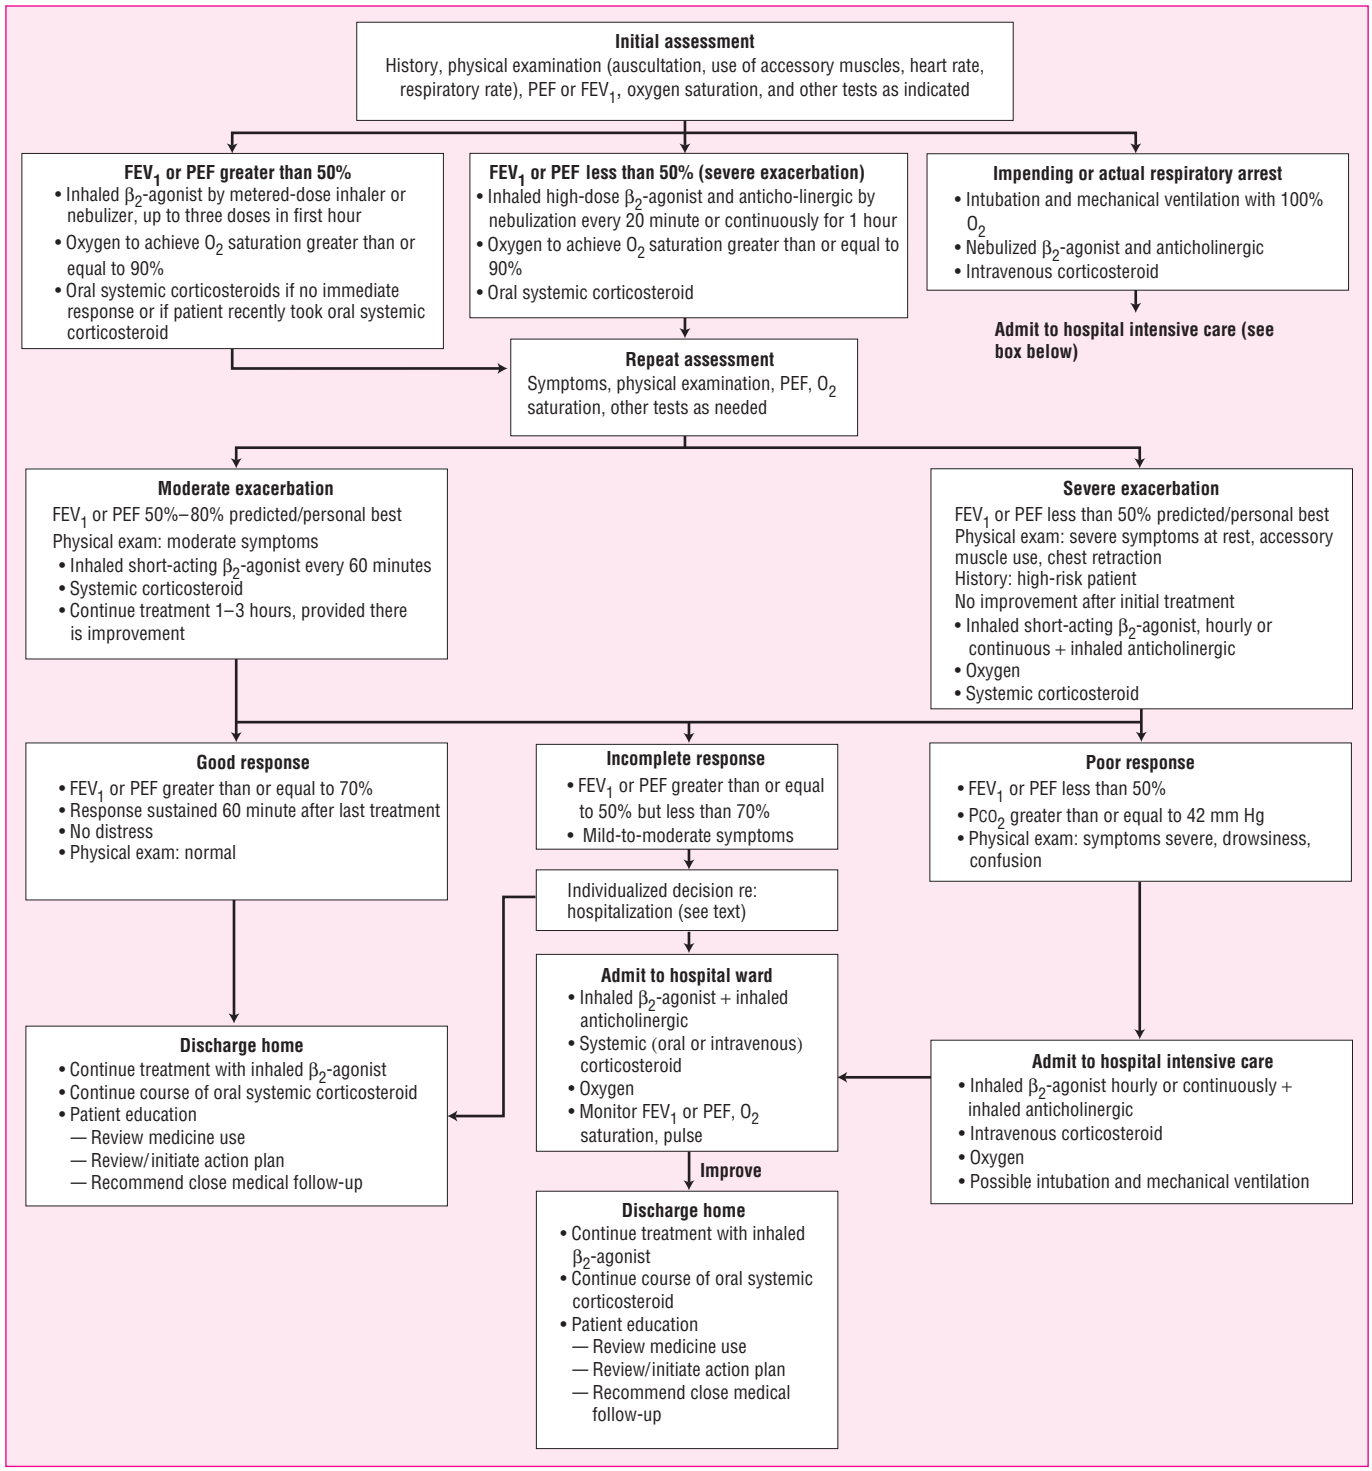

FIGURE 11–3. Emergency department and hospital-based management of asthma exacerbation. FEV_1, forced expiratory volume in 1 second; P_{CO_2}, partial arterial pressure of carbon dioxide; PEF, peak expiratory flow; O_2, oxygen. (From Kelly HW, Sorkness CA. Asthma. TABLE 11–5. Dosages of Selected Medications for Asthma Exacerbations in Emergency Medical Care or Hospital

Medication	Dosage Form	Adult Dose	Child Dose[a]
Short-Acting Inhaled β_2-Agonists			
Albuterol	Nebulizer solution: 5 mg/mL (5%) 2.5 mg/3 mL 1.25 mg/3 mL 0.63 mg/3 mL MDI: 90 mcg/puff	2.5–5 mg every 20 minutes for 3 doses, then 2.5–10 mg every 1–4 hours as needed, or 10–15 mg/hour continuously 4–8 puffs every 20 minutes up to 4 hours, then every 1–4 hours as needed	0.15 mg/kg (minimum dose 2.5 mg) every 20 minutes for 3 doses, then 0.15–0.3 mg/kg up to 10 mg every 1–4 hours as needed, or 0.5 mg/kg per hour by continuous nebulization 4–8 puffs every 20 minutes for 3 doses, then every 1–4 hours inhalation maneuver; use spacer/holding chamber
Levalbuterol	Nebulizer solution 0.31 mg/3 mL 0.63 mg/3 mL 1.25 mg/3 mL MDI: 45 mcg/puff	1.25–2.5 mg every 20 minutes for 3 doses, then 1.25–5 mg every 1–4 hours as needed or 5–7 mg/hour continuously See albuterol dose; thought to be twice as potent as albuterol on a mg basis	0.075 mg/kg (maximum dose 1.25 mg) every 20 minutes for 3 doses, then 0.075–0.15 mg/kg, up to 5 mg, every 1–4 hours as needed or 0.25 mg/hour by continuous nebulization See albuterol dose; thought to be twice as potent as albuterol on a mg basis
Anticholinergics			
Ipratropium bromide	Nebulizer solution 0.25 mg/mL MDI CFC: 18 mcg/puff MDI HFA: 17 mcg/puff	0.5 mg every 30 minutes for 3 doses then every 2–4 hours as needed 4–8 puffs as needed	0.25 mg every 20 minutes for 3 doses, then every 2–4 hours 4–8 puffs as needed
Ipratropium with albuterol	Nebulizer solution: 0.5 mg ipratropium bromide and 2.5 mg albuterol per 3-mL vial MDI: 18 mcg of ipratropium bromide and 90 mcg of albuterol per puff	3 mL every 30 minutes for 3 doses, then every 2–4 hours as needed 4–8 puffs as needed	1.5 mL every 20 minutes for 3 doses, then every 2–4 hours 4–8 puffs as needed
Systemic Corticosteroids			
Methylprednisolone	Tablets: 2, 4, 8, 16, 32 mg Injection: 40-mg, 125-mg, 500-mg, 1-g, and 2-g vials	120–180 mg/day in 3 or 4 divided doses for 48 hours, then 60–80 mg/day until PEF reaches 70% of predicted or personal best	1 mg/kg every 6 hours for 48 hours, then 1–2 mg/kg per day (maximum of 60 mg/day) in 2 divided doses until PEF 70% of predicted or personal best
Prednisolone	Tablets: 5 mg Oral liquid: 5 mg/5 mL, 15 mg/5 mL		
Prednisone	Tablets: 1, 2.5, 5, 10, 20, 50 mg Oral liquid: 5 mg/mL, 5 mg/5 mL		

[a]Children less than or equal to 12 years of age.
CFC, chlorofluorocarbon; HFA, hydrofluoroalkane; MDI, metered-dose inhaler; PEF, peak expiratory flow.
Adapted from: National Institutes of Health, National Heart Lung and Blood Institute. National Asthma and Education Prevention Program. Expert Panel Report. Guidelines for the Diagnosis and Management of Asthma. Update on Selected Topics 2002. http://www.nhlbi.nih.gov/guidelines/asthma/asthmafullrpt.pdf; accessed August 2005; used with permission.

therapy is appropriate and should be guided by an assessment of fluid status from urine output, urine specific gravity, mucous membrane moisture, and serum electrolytes.[1,18] Dehydration is not problematic in older children and adults; therefore, aggressive rehydration is not recommended.

After the initiation of treatment, the health care professional should conduct an initial history that includes: (1) the time of onset of symptoms; (2) severity of the symptoms, especially compared to previous exacerbations; (3) all current medications and time of last dose; and (4) identification of risk factors for fatal asthma. These risk factors include a past history of severe asthma, use of more than two canisters of a short-acting β_2-adrenergic agonists in a month, current use of systemic corticosteroids or recent withdrawal from corticosteroids, cardiopulmonary comorbidities, serious psychiatric or psychosocial problems, low socioeconomic status and

urban residence, illicit drug use, and sensitivity to the mold allergen *Alternaria*.[1]

A focused physical exam should be conducted that includes the general presentation (level of alertness, fluid status, presence of cyanosis, and use of accessory muscles), auscultation of the lungs, heart rate, and respiratory rate.

Routine antibiotic use is not warranted because the primary infectious agents associated with asthma exacerbations are viruses.[2,3] Antibiotics should be reserved for situations when bacterial infection is strongly suspected (e.g., fever and purulent sputum, pneumonia, and suspected sinusitis).

Theophylline is not recommended for treatment of acute asthma.[2] It provides no additional benefit when optimal inhaled bronchodilators are used and increases the risk of adverse events. Similarly, although magnesium has bronchodilator activity, it offers no significant benefits when optimal bronchodilator therapy is used.[12,40]

Heliox is a mixture of helium and oxygen that results in a lower density of inspired air, thereby improving oxygen delivery. Heliox does not appear to have any significant adverse effects, but it does limit oxygen flow to approximately 30% and therefore is not useful in patients needing higher concentrations of oxygen.[12,40]

Patients who do not respond adequately to intensive therapy in the emergency department within 3 to 4 hours should be admitted to the hospital. Patients responding to therapy in the emergency department with a sustained response to inhaled β_2-agonists (PEF greater than 60%) that lasts at least an hour can be discharged home.[1,12] It is important to ensure that the patient has an inhaled short-term β_2-agonist, is restarted on maintenance medications, and receives a 3- to 10-day course of oral corticosteroids. Prior to discharge, the health care provider should instruct the patient on what to do if asthma symptoms worsen, review medication use, and instruct the patient to schedule a follow-up visit with their health care provider in 3 to 5 days.[1]

Special Populations

Pregnancy

Approximately 4% to 8% of pregnant women are affected by asthma with roughly one-third of them experiencing worsening asthma during pregnancy.[43] Because inadequate control of asthma is a greater risk to the fetus than is the risk of asthma medication use, it is safer for pregnant women to have their asthma appropriately treated with medications than to risk worsening asthma.[43] Goals for asthma therapy in pregnancy are the same as those for the general population, and recent guidelines propose a stepwise approach to asthma therapy in pregnancy that is similar to the guidelines for the general population with respect to preferred therapies for each step.[43]

Because budesonide has the most safety data in humans, it is the preferred inhaled corticosteroid and is the only inhaled corticosteroid classified as pregnancy category B; however, there are no data indicating that other inhaled corticosteroids contribute to increased risk to the mother or fetus.[43] Because of the risk to the fetus, asthma exacerbations should be managed aggressively. Albuterol is the drug of choice for the treatment of asthma symptoms and exacerbations in pregnancy.[43]

Exercise-Induced Asthma

Exercise is one of the most common precipitants of asthma symptoms, and exercise-induced asthma is commonly seen in children and adolescents. Exercise may be a precipitant in up to 90% of the population with asthma and may be the first precipitant noticed in an asthma patient.[18] Shortness of breath, wheezing, or chest tightness usually occur during or shortly after vigorous exercise and resolve within 30 to 60 minutes.

Patients with exercise-induced asthma should warm-up prior to vigorous exercise and cover their mouth and nose with a scarf or mask during cold weather. Increased physical conditioning and gradually decreasing the intensity of exercise prior to stopping may also help prevent bronchospasm. Pre-treatment with albuterol 5 minutes prior to exercise is the treatment of choice and will protect against bronchospasm for 2 to 3 hours.[1] Pretreatment with cromolyn sodium or nedocromil is also effective in preventing bronchospasm, but it is not as effective as albuterol.[18] Pretreatment with salmeterol or formoterol can protect against bronchospasm for up to 12 hours; however, tolerance to the bronchoprotective effects occurs with repeated use and a more reasonable expectation for protection is for 6 to 9 hours. Pretreatment with a leukotriene modifier and regular treatment with inhaled corticosteroids also prevents bronchospasm associated with exercise. Consideration should be given to initiating long-term control therapy in mild intermittent asthmatics using multiple weekly doses of a bronchodilator to prevent asthma symptoms associated with exercise.[3]

Aspirin Sensitivity

Patients with aspirin-sensitive asthma are usually adults and often present with the triad of rhinitis, nasal polyps, and asthma. In this population, acute asthma may occur within minutes of ingesting aspirin or another non-steroidal anti-inflammatory agent. Although acetaminophen is thought to be safe in this population, doses larger than 1 gram may cause acute asthmatic reactions in some patients, and the incidence of asthma is significantly greater in frequent users of acetaminophen compared to non-users.[44,45] Patients with aspirin-sensitive asthma may be able to tolerate cyclooxygenase-2 inhibitors; however, given the potentially serious adverse events that could occur in aspirin-sensitive asthmatics, the first dose of a cyclooxygenase-2 inhibitor should be given under the observation of a health care provider with rescue drugs available.[44]

OUTCOME EVALUATION

Chronic Asthma

- Monitor symptoms such as wheezing, shortness of breath, chest tightness, cough, and nocturnal awakenings due to asthma symptoms. Daytime symptoms should occur no

more frequently than twice a week, and nocturnal symptoms should occur twice a month or less. Patients with more frequent symptoms should have their long-term control medications increased to the next step of therapy.

- Monitor and maintain PEF above 80% of personal best; PEF variability should be less than 20%. Patients with PEF rates consistently greater than 80% over several months should be evaluated for a step down in long-term control therapy. Patients with a PEF less than 80% of personal best should begin to monitor PEF twice daily and consult their asthma action plan. Patients with a PEF less than 50% of personal best should immediately use their short-acting inhaled β_2-agonist and consult their asthma action plan.
- Monitor patient activity levels. Inability of a patient to perform routine physical activities indicates inappropriate therapy, and long-term control medications should be increased according to the next step of therapy.
- Monitor frequency of patient exacerbations. Frequent exacerbations, unscheduled clinic visits, emergency department visits, and hospitalizations due to asthma may indicate a non-adherent patient or the need to step up long-term control medications.
- Monitor patient use of long-term control medications to ensure adherence to the medication plan. Patients not adhering to the long-term control medication regimen should be re-educated on the importance of these medications for asthma control.
- Monitor use of short-acting inhaled β_2-agonists. Use of these agents more than twice a week in intermittent asthma may indicate the need to initiate long-term control therapy. Use of more than one canister per a month indicates the need to step up long-term control therapy.
- Monitor for adverse events from medications, including candidiasis and dysphonia from inhaled corticosteroids.

Acute Severe Asthma

- Monitor PEF, which should increase to greater than 60% of personal best or predicted after the first three doses of an inhaled short-acting β_2-agonist.
- Monitor patients for hypoxemia. Oxygen saturation should be greater than 90% in adults and greater than 95% in children, pregnant women, and patients with co-existing cardiovascular disease.
- In patients with severe exacerbations, monitoring of P_{CO_2} should be considered. Patients with acute asthma usually have a respiratory alkalosis, and a normal or increased P_{CO_2} indicates the potential for respiratory failure.
- Monitor serum potassium in patients receiving high-dose or continuous nebulization of a short-acting β_2-agonist. Serum potassium concentrations should be obtained upon admission, and if hypokalemic, every 4 hours (after each 30 to 40 mEq or mmol of replacement) until the patient's potassium is stable. Potassium should be monitored every 3 to 6 months after discharge.

Patient Encounter, Part 3

Follow-Up

Six months later, RB's mother brings her back for a check-up. The patient has been using her albuterol inhaler 3 to 4 times a week to treat symptoms, and she is waking up about twice a month with shortness of breath. She has developed a sore mouth. White patches on the back of her tongue and the inside of her cheek are observed on examination.

Meds

Qvar™ 84 mcg/puff, 1 puff 4 times a day
Proventil HFA 2 puffs PRN for symptoms
Flonase 1 puff in each nostril daily

- What further information do you need before altering this patient's therapy?
- How would you counsel this patient to prevent further adverse reactions?
- Assuming that the patient is currently using her medications appropriately, how would you adjust this patient's medication?

Patient Care and Monitoring

Chronic Asthma

1. Obtain a thorough medical history focusing on disease states that may worsen the severity of asthma.
2. Ask the patient about the frequency and severity of symptoms, when symptoms occur, and whether or not the symptoms are associated with exposure to known allergens. Ask the patient about previous emergency department visits and hospitalizations due to asthma.
3. Use the patient's symptoms and pulmonary function tests to classify disease severity.
4. Explain the goals of therapy to the patient and ask if (s)he has any personal therapeutic goals.
5. Develop a patient education plan that fits the patient's needs. Educate about the differences between the asthmatic and normal lung and what happens to the lung during an asthma attack. Counsel the patient on how their medications work and differentiate between long-term control and quick relief medications.
6. Provide the patient with a specific allergen avoidance plan and counsel all patients to avoid secondhand tobacco smoke.
7. Demonstrate the appropriate use of drug delivery devices and peak flow meters; then have the patient perform these activities for you. If the task is performed incorrectly, demonstrate the skill again, emphasizing the incorrect step and have the patient re-demonstrate the skill.

(*Continued*)

Patient Care and Monitoring (*Continued*)

8. Prepare a patient-specific self-monitoring plan and review it with the patient. Educate the patient on the signs and symptoms of asthma deterioration and when and how to take rescue actions.
9. Assess the patient's adherence to long-term control therapy. If the patient is non-adherent, stress the importance of adherence to this therapy. Evaluate the complexity of the patient's treatment plan and simplify it as much as possible. Determine whether the patient would benefit from an inhaled corticosteroid/inhaled long-acting β_2-agonist combination product.
10. Assess the patient for adverse effects, particularly candidiasis and dysphonia associated with inhaled corticosteroids.
11. Evaluate therapy on a regular basis. Assess the patient's control of asthma by evaluating symptoms, PEF diary entries, and rescue medication use. Step long-term control therapy up or down based on these parameters. Before stepping up therapy, reassess the patient's inhaler technique to assure appropriate drug delivery.

Acute Severe Asthma

1. Assess the patient's PEF.
2. Assess whether or not the patient can use an MDI with a spacer or holding chamber. If the patient cannot use the device, determine whether someone can assist the patient with the inhaler device, or whether a nebulizer is necessary.
3. Initiate therapy with a short-acting β_2-agonist and 2 to 6 L/minute of oxygen if needed.
4. Perform a brief medical history to determine the time of symptom onset, symptom severity, symptom severity in relation to previous exacerbations, current medications, previous emergency department visits or hospitalizations due to asthma, previous history of respiratory failure, and psychiatric or psychological disorders.
5. Assess the patient's general appearance, use of accessory muscles, respiratory rate, heart rate, lung sounds, pulsus paradoxus, PEF, and oxygen saturation.
6. Reassess pulmonary function every 20 to 30 minutes. If there was not an immediate response to the inhaled short acting β_2-agonist, initiate systemic corticosteroid therapy. If the patient is not improving, add ipratropium to the patient's therapy and continue with a high-dose inhaled short-acting β_2-agonist.
7. Assess the patient for hospitalization or discharge home.
8. If the patient is discharged home, ensure that the patient has a short-acting β_2-agonist, review the appropriate technique for inhaler use with the patient, and ensure that the patient has a prescription for 3 to 10 days of oral corticosteroids.
9. Restart the patient on maintenance therapy. Instruct the patient on what to do if asthma should worsen and to follow-up with his/her health care provider in 3 to 5 days.

12 Chronic Obstructive Pulmonary Disease

Tara R. Whetsel and Nicole D. Verkleeren

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiology of chronic obstructive pulmonary disease (COPD).
2. Identify signs and symptoms of COPD.
3. List the treatment goals for a patient with COPD.
4. Design an appropriate COPD treatment regimen based on patient-specific data.
5. Develop a monitoring plan to assess effectiveness and adverse effects of pharmacotherapy for COPD.
6. Formulate an appropriate education plan for a patient with COPD.

Key Concepts

❶ Inflammation plays a key role in the pathophysiology of COPD, but it differs from that seen in asthma; therefore, the use of and response to anti-inflammatory medications are different.

❷ An integrated approach of health maintenance (e.g., smoking cessation), drug therapy, and supplemental therapy (e.g., oxygen and pulmonary rehabilitation) should be used in a stepwise manner.

❸ Smoking cessation is the only intervention known to slow the rate of decline in pulmonary function in patients with COPD.

❹ Bronchodilators are the mainstay of treatment for symptomatic COPD. They reduce symptoms and improve exercise tolerance and quality of life.

❺ In symptomatic patients with severe COPD and frequent exacerbations, regular treatment with inhaled corticosteroids decreases the number of exacerbations per year and improves health status; however, corticosteroids do not slow the long-term decline in pulmonary function.

❻ Antibiotics should be used in patients with COPD exacerbations who have either of the following characteristics: (1) at least two of three cardinal symptoms: increased dyspnea, sputum volume, or sputum purulence; or (2) a severe exacerbation requiring mechanical ventilation.

Chronic obstructive pulmonary disease (COPD) is a progressive disease characterized by airflow limitation that is not fully reversible. It is caused by exposure to noxious particles or gases, most commonly cigarette smoke. It is a major cause of morbidity and mortality and a leading cause of disability in the United States.

COPD includes chronic bronchitis and emphysema. Chronic bronchitis is defined clinically as a chronic productive cough for at least 3 months in each of two consecutive years in a patient in whom other causes have been excluded.[1] Emphysema is defined pathologically as the presence of permanent enlargement of the airspaces distal to the terminal bronchioles, accompanied by destruction of their walls without obvious fibrosis.[1] The major risk factor for both conditions is cigarette smoking, and many patients share characteristics of each condition. Therefore, new consensus guidelines have moved away from using these subsets and instead focus on chronic airflow limitation.

The Global Initiative for Chronic Obstructive Lung Disease (GOLD) is an expert panel of health professionals who have developed a consensus document with recommendations for the diagnosis and care of patients with COPD.[2] The online document is updated annually and is commonly referred to as the GOLD guidelines. The American Thoracic Society (ATS) and the European Respiratory Society (ERS) have jointly published standards for the diagnosis and treatment of patients with COPD.[1] The ATS/ERS guidelines provide more specific recommendations on oxygen therapy, pulmonary rehabilitation, and other treatment issues than the broader GOLD guidelines.

EPIDEMIOLOGY AND ETIOLOGY

In 2001, 12.1 million United States adults 25 years of age and older reported having COPD.[3] The true prevalence is larger; COPD is underdiagnosed because many patients have few or no symptoms in the early stages.

COPD is the fourth leading cause of death in the United States; in 2000, 119,000 adults died from the disease.[3] In 2002, COPD was estimated to cost the United States $32.1 billion, with direct medical costs accounting for $18 billion of the total.[3] Morbidity, mortality, and costs are all expected to increase over the next decade.

Exposures and host factors play a role in the development of COPD. Cigarette smoking is the leading cause of COPD and accounts for 80% to 90% of cases in developed countries.[4] Occupational exposure to dusts and chemicals (vapors, irritants, and fumes) also plays a role. Environmental air pollution has been implicated as an etiologic factor, but its exact role is unclear. Not all smokers develop clinically significant COPD, which suggests that genetic susceptibility plays a role. The best documented genetic factor is a rare hereditary deficiency of α_1-antitrypsin (AAT). Severe deficiency of this enzyme results in premature and accelerated development of emphysema. Asthma and airway hyperresponsiveness have been identified as risk factors, but how they influence the development of COPD is unknown. Failure to reach maximal lung function, due to recurrent infections or exposure to tobacco smoke during childhood, may also increase the risk of COPD.

PATHOPHYSIOLOGY

COPD is characterized by pathologic changes in the central airways, peripheral airways, lung **parenchyma**, and pulmonary vasculature. Chronic inflammation in the lung from repeated exposure to noxious particles and gases is primarily responsible for these changes.[2] An imbalance between **proteinases** and **antiproteinases** in the lung and oxidative stress are also thought to be important in the pathogenesis of COPD. These processes may be a result of ongoing inflammation or may arise from environmental (e.g., oxidants in cigarette smoke) or genetic (e.g., AAT deficiency) factors (Fig. 12–1).[2] In addition to these destructive processes, chronic inflammation and exposure to noxious particles and gases disrupts or impairs the normal protective and repair mechanisms.

Inflammation is present in the lungs of all smokers. It is unclear why only 15% to 20% of smokers develop COPD, but susceptible individuals appear to have an exaggerated inflammatory response.[5] ❶ *The inflammation of COPD differs from that seen in asthma, so the use of anti-inflammatory medications and the response to those medications are different.* The inflammation of asthma is mainly mediated through eosinophils and mast cells. In COPD the primary inflammatory cells include neutrophils, macrophages, and $CD8^+$ T lymphocytes.

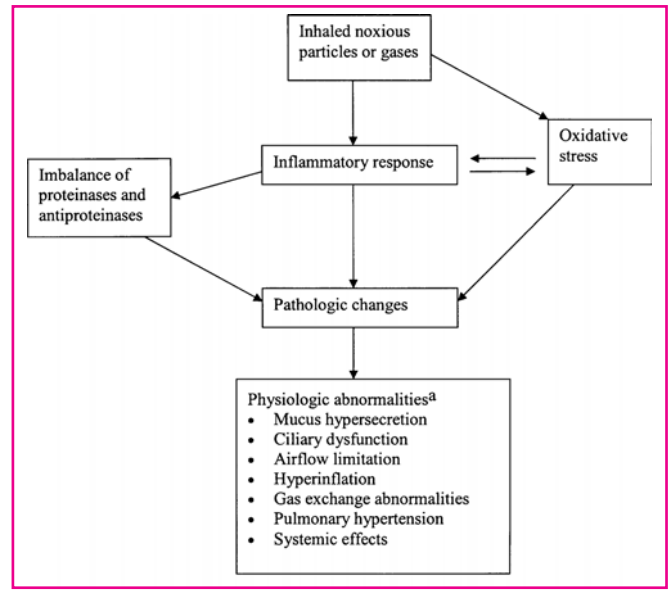

FIGURE 12–1. Pathophysiology of chronic obstructive pulmonary disease.
[a]The physiologic abnormalities usually develop in this order.

Eosinophils may be increased in some patients, particularly during exacerbations. Activated inflammatory cells release a variety of mediators, most notably leukotriene B_4, interleukin-8, and tumor necrosis factor-α (TNF-α). Various proteinases, such as elastase, cathepsin G, and proteinase-3, are secreted by activated neutrophils. These mediators and proteinases are capable of sustaining inflammation and damaging lung structures.

Proteinases and antiproteinases are part of the normal protective and repair mechanisms in the lungs. The imbalance of proteinase-antiproteinase activity in COPD is a result of either increased production or activity of destructive proteinases or inactivation or reduced production of protective antiproteinases. AAT (an antiproteinase) inhibits trypsin, elastase, and several other proteolytic enzymes. Deficiency of AAT results in unopposed proteinase activity, which promotes destruction of alveolar walls and lung parenchyma, leading to emphysema.

Markers of oxidative stress (e.g., hydrogen peroxide, nitric oxide, and isoprostane $F_2\alpha$-III) have been found in the epithelial fluid, breath, and urine of cigarette smokers and patients with COPD.[2] Increased oxidative stress contributes to COPD in a variety of ways. Oxidants (e.g., reactive oxygen species, superoxide, and nitric oxide) can react with and damage a variety of molecules leading to cell dysfunction and damage to the lung extracellular matrix. Oxidative stress promotes inflammation and contributes to the proteinase-antiproteinase imbalance by reducing antiproteinase activity. In addition, oxidants constrict airway smooth muscle, contributing to reversible airway narrowing.

In the central airways (the trachea, bronchi, and bronchioles greater than 2 to 4 mm in internal diameter), inflammatory cells and mediators stimulate mucus-secreting gland **hyperplasia**

and mucus hypersecretion. Mucus hypersecretion and ciliary dysfunction lead to chronic cough and sputum production. The major site of airflow obstruction is the peripheral airways (small bronchi and bronchioles with an internal diameter less than 2 mm). Three mechanisms are postulated to be involved in the narrowing of these small airways.[2] Airways may be blocked by inflammatory exudates and mucus hypersecretion. Loss of elasticity and destruction of alveolar attachments leads to loss of support and closure of small airways during expiration. Infiltration of inflammatory cells, increased smooth muscle tissue, and fibrosis cause thickening of airway walls. Of these mechanisms, the structural changes in the airway walls are the most important cause of fixed airflow obstruction.

As airflow obstruction worsens, the rate of lung emptying is slowed and the interval between inspirations does not allow expiration to the relaxation volume of the lungs. This leads to pulmonary hyperinflation, which initially only occurs during exercise, but later is also seen at rest. Hyperinflation contributes to the discomfort associated with airflow obstruction by flattening the diaphragm and placing it at a mechanical disadvantage.

In advanced COPD, airflow obstruction, damaged bronchioles and alveoli, and pulmonary vascular abnormalities lead to impaired gas exchange. This results in **hypoxemia** and eventually **hypercapnia**. Hypoxemia is initially present only during exercise but occurs at rest as the disease progresses. Inequality in the **ventilation/perfusion ratio (V_AQ)** is the major mechanism behind hypoxemia in COPD.

Pulmonary hypertension develops late in the course of COPD, usually after the development of severe hypoxemia. It is the most common cardiovascular complication of COPD and can result in **cor pulmonale**, or right-sided heart failure. Hypoxemia plays the primary role in the development of pulmonary hypertension by causing vasoconstriction of the pulmonary arteries and by promoting vessel wall remodeling. Destruction of the pulmonary capillary bed by emphysema further contributes by increasing the pressure required to perfuse the pulmonary vascular bed. Cor pulmonale is associated with venous stasis and thrombosis that may result in pulmonary embolism. Another important systemic effect is the progressive loss of skeletal muscle mass, which contributes to exercise limitations and declining health status.

DIAGNOSIS

A suspected diagnosis of COPD should be based on the patient's symptoms and/or history of exposure to risk factors. **Spirometry** is required to confirm the diagnosis. The presence of a postbronchodilator FEV_1/FVC ratio less than 70% [the ratio of FEV_1 to forced vital capacity (FVC)] confirms the presence of airflow limitation that is not fully reversible.[1,2] Spirometry results can further be used to classify COPD severity (Table 12–1). Full pulmonary function tests (PFTs) with lung volumes and diffusion capacity and arterial blood gases are not necessary to establish the diagnosis or severity of COPD.

Clinical Presentation of Chronic Obstructive Pulmonary Disease

General

- Patients with COPD are initially asymptomatic. The disease is usually not diagnosed until declining lung function leads to significant symptoms and prompts patients to seek medical care.

Symptoms

- The onset of symptoms is variable but often does not occur until the forced expiratory volume in one second (FEV_1) has fallen to approximately 50% of predicted.[2]
- Initial symptoms include chronic cough (duration greater than 3 months), which may be intermittent at first; chronic sputum production; and dyspnea on exertion.
- As COPD progresses, dyspnea at rest develops and the ability to perform activities of daily living declines.

Signs

- Observation of the patient may reveal use of accessory muscles of respiration (manifested as paradoxical movements of the chest and abdomen, in a "see-saw"–type motion), pursed-lips breathing, and hyperinflation of the chest with increased anterior-posterior diameter ("barrel chest").
- On auscultation of the lungs, patients may have distant breath sounds, wheezing, a prolonged expiratory phase of respiration, and **rhonchi**.
- In advanced COPD, signs of hypoxemia may include **cyanosis** and tachycardia.
- Signs of cor pulmonale include increased pulmonic component of the second heart sound, jugular venous distention (JVD), lower extremity edema, and hepatomegaly.

Laboratory Tests

- Hematocrit may be elevated and may exceed 55% (**polycythemia**).
- Arterial blood gases (ABGs) should be obtained in patients with an FEV_1 less than 40% predicted or signs or symptoms suggestive of cor pulmonale or respiratory failure.[2] COPD patients characteristically exhibit normal or increased arterial carbon dioxide tension ($PaCO_2$) and decreased arterial oxygen tension (PaO_2).
- An α_1-antitrypsin level should be obtained in younger patients (less than 45 years old) presenting with COPD signs and symptoms, especially if there is a strong family history of emphysema.

It is important to distinguish COPD from asthma because treatment and prognosis differ. Differentiating factors include age of onset, smoking history, triggers, occupational history, and degree of reversibility measured by pre- and postbronchodilator spirometry. In some patients a clear distinction between asthma and COPD is not possible. Management of these patients should be similar to that of asthma. **Bronchiectasis**, cystic fibrosis, **obliterative bronchiolitis**, congestive heart failure, and

TABLE 12–1. GOLD Classification of COPD Severity[a]

Stage	Category	FEV_1/FVC	FEV_1	Symptoms
0	At risk	Greater than or equal to 70%	Greater than or equal to 80% predicted	Chronic cough and sputum production
I	Mild	Less than 70%	Greater than or equal to 80% predicted	With or without chronic cough and sputum production
II	Moderate	Less than 70%	50%–79% predicted	With or without chronic cough and sputum production
III	Severe	Less than 70%	30%–49% predicted	With or without chronic cough and sputum production
IV	Very severe	Less than 70%	Less than 30% predicted or less than 50% predicted plus chronic respiratory failure[b]	

[a]Classification based on postbronchodilator FEV_1.
[b]Respiratory failure: Arterial partial pressure of oxygen (PaO_2) less than 60 mm Hg with or without arterial partial pressure of carbon dioxide ($Paco_2$) greater than 50 mm Hg while breathing air at sea level. FEV_1, forced expiratory volume in one second; FVC, forced vital capacity; GOLD, Global Initiative for Chronic Obstructive Lung Disease.

tuberculosis are other possible differential diagnoses that are usually easier to distinguish from COPD. Chest radiography or high-resolution computed tomography (CT) along with patient presentation help rule out these other lung diseases.

TREATMENT

Desired Outcomes

The goals of COPD management include: (1) smoking cessation; (2) reducing symptoms; (3) minimizing the rate of decline in lung function; (4) maintaining or improving quality of life; (5) preventing and treating exacerbations; and (6) limiting complications.

Patient Encounter, Part 1

A 49-year-old man with a past medical history of hypertension presents to the clinic complaining of shortness of breath that began about 3 to 4 years ago. His symptoms have gradually gotten worse since then. He is now unable to walk 100 yards without having to stop and rest. He also has a daily cough that is usually productive of yellowish sputum. He smokes about $1^1/_2$ packs of cigarettes a day and has done so for the past 30 years. He also drinks on average 6 to 7 beers a day. He does not have any significant occupational exposures to dust, gases, or fumes.

- What information is suggestive of COPD?
- What risk factors does he have for COPD?
- What additional information do you need to know before creating a treatment plan for this patient?

General Approach to Treatment

❷ *An integrated approach of health maintenance (e.g., smoking cessation), drug therapy, and supplemental therapy (e.g., oxygen and pulmonary rehabilitation) should be used in a stepwise manner.* Table 12–2 provides an overview of the management of stable COPD.

Nonpharmacologic Therapy

Smoking Cessation

❸ *Smoking cessation is the only intervention known to slow the rate of decline in pulmonary function in patients with COPD.*[6,7] Stopping smoking can also reduce cough and sputum production and decrease airway reactivity. Therefore, it is a critical part of any treatment plan for patients with COPD. Unfortunately, achieving and maintaining cessation is a major challenge. A clinical practice guideline from the United States Public Health Service recommends a specific action plan depending on the current smoking status and desire to quit (Fig. 12–2).[8] Brief interventions are effective and can increase cessation rates significantly. The five A's and the five R's can be used to guide brief interventions (Table 12–3).

All tobacco users should be assessed for their readiness to quit and appropriate strategies implemented. Those who are ready to quit should be treated with a combination of counseling on behavioral and cognitive strategies and pharmacotherapy (nicotine replacement therapy, sustained-release bupropion, or varenicline). In COPD patients, the likelihood of sustained abstinence is higher with nicotine replacement therapy than with sustained-release bupropion.[9]

TABLE 12–2. Treatment Algorithm for Stable Chronic Obstructive Pulmonary Disease

GOLD Stage	Recommended Therapy[2]
0: At Risk	Avoidance of risk factor(s), especially smoking cessation; influenza vaccination
	ADD
I: Mild	Short-acting inhaled bronchodilator when needed (e.g., ipratropium, albuterol, or combination inhaler)
	ADD
II: Moderate	Pulmonary rehabilitation Inhaled LABD on a scheduled basis (e.g., tiotropium,[a] salmeterol, or formoterol) ↓ Inadequate response to LABD? ↓ Yes Use alternative class or combine classes of inhaled LABD ↓ Inadequate response to LABD? ↓ Yes Add/substitute oral theophylline
	ADD
III: Severe	Inhaled corticosteroids if repeated exacerbations[b]
	ADD
IV: Very severe	Long-term oxygen if chronic respiratory failure Consider surgical treatment

[a]Albuterol should be used as rescue therapy for patients treated with tiotropium.
[b]Defined as three exacerbations in the past 3 years by GOLD and as at least one exacerbation requiring a course of oral corticosteroids or antibiotics within the last year by ATS/ERS. Other authorities define frequent exacerbations as at least two within the past year.
ATS, American Thoracic Society; ERS, European Respiratory Society; LABD, long-acting bronchodilator.

Pulmonary Rehabilitation

Pulmonary rehabilitation results in significant and clinically meaningful improvements in dyspnea, exercise capacity, health status, and health care utilization.[10] It should be considered for patients with COPD who have dyspnea or other respiratory symptoms, reduced exercise capacity, a restriction in activities because of their disease, or impaired health status.[1] A comprehensive pulmonary rehabilitation program should include exercise training, nutrition counseling, and education. It should cover a range of non-pulmonary problems including exercise deconditioning, relative social isolation, altered mood states (especially depression), muscle wasting, and weight loss.

Rehabilitation programs may be conducted in the inpatient, outpatient (most common), or home setting. The minimum length of an effective program is 2 months; the longer the program, the more sustained the results.[10] It is important for patients to continue with a home exercise program to maintain the benefits gained from the pulmonary rehabilitation program.

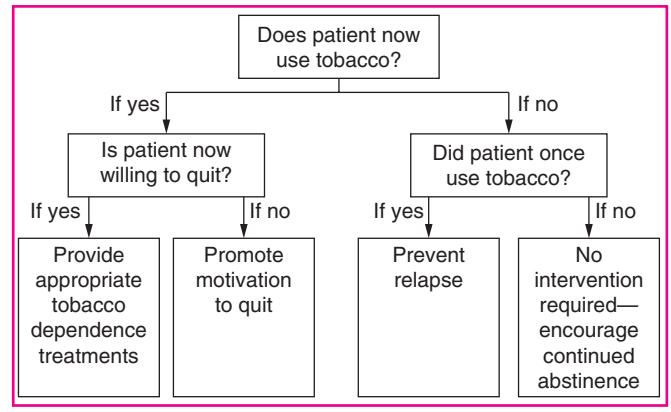

FIGURE 12–2. Algorithm for routine assessment of tobacco use status. (Reproduced from Treating Tobacco Use and Dependence—Clinician's Packet. A How-To Guide for Implementing the Public Health Service Clinical Practice Guideline, March 2003. United States Public Health Service. Available at: www.surgeongeneral.gov/tobacco/clinpack.html.)

Long-Term Oxygen Therapy

Long-term administration of oxygen (greater than 15 hours per day) to patients with chronic respiratory failure has been shown to reduce mortality and improve quality of life.[1,2] Oxygen therapy should be initiated in stable patients with very severe COPD (GOLD stage IV) who are optimized on

TABLE 12–3. Components of Brief Interventions for Tobacco Users

The 5 A's for Brief Intervention
- **A**sk: Identify and document tobacco use status for every patient at every visit.
- **A**dvise: Urge every tobacco user to quit.
- **A**ssess: Is the tobacco user willing to make a quit attempt at this time?
- **A**ssist: Use counseling and pharmacotherapy to help patients willing to make a quit attempt.
- **A**rrange: Schedule follow-up contact, preferably within the first week after the quit date.

The 5 R's to Motivate Smokers Unwilling to Quit at Present
- **R**elevance: Tailor advice and discussion to each smoker.
- **R**isks: Help the patient identify potential negative consequences of tobacco use.
- **R**ewards: Help the patient identify the potential benefits of quitting.
- **R**oadblocks: Help the patient identify barriers to quitting.
- **R**epetition: Repeat the motivational message at every visit.

drug therapy and meet one of the following criteria: (1) A resting Pa_{O_2} at or below 55 mm Hg (7.32 kPa) or oxygen saturation (Sa_{O_2}) at or below 88%; (2) Pa_{O_2} between 55 and 60 mm Hg (7.32 and 7.98 kPa) or Sa_{O_2} of 89% and evidence of pulmonary hypertension, peripheral edema suggesting congestive heart failure, or polycythemia.[1,2]

The dual-prong nasal cannula is the standard means of delivering continuous flow oxygen. The goal of therapy is to increase the baseline oxygen saturation to at least 90% and/or Pa_{O_2} to at least 60 mm Hg (7.98 kPa), allowing adequate oxygenation of vital organs. The flow rate, expressed as liters per minute (L/minute), must be increased during exercise and sleep and can be adjusted based on pulse oximetry. Hypoxemia also worsens during air travel; patients requiring oxygen should generally increase their flow rate by 2 L/minute during flight.[1]

Oxygen therapy should be continued indefinitely if it was initiated while the patient was in a stable state (rather than during an acute episode). Withdrawal of oxygen because of improved Pa_{O_2} in such a patient may be detrimental.

Surgery

Bullectomy, lung volume reduction surgery, and lung transplantation are surgical options for very severe COPD. These procedures may result in improved spirometry, lung volumes, exercise capacity, dyspnea, health-related quality of life, and possibly survival. Patient selection is critical because not all patients benefit. Refer to the ATS/ERS COPD standards for a detailed discussion of appropriate selection of surgical candidates.[1]

Pharmacologic Therapy of Stable COPD

The medications available for COPD are effective for reducing or relieving symptoms, improving exercise tolerance, reducing the number and severity of exacerbations, and improving quality of life. No medications presently available have been shown to slow the rate of decline in lung function.

Bronchodilators

❹ *Bronchodilators are the mainstay of treatment for symptomatic COPD. They reduce symptoms and improve exercise tolerance and quality of life.*[2] They can be used as needed for symptoms or on a scheduled basis to prevent or reduce symptoms. Bronchodilator drugs commonly used in COPD include β_2-agonists, anticholinergics, and theophylline. The choice depends on availability, individual response, and preferences. The inhaled route is preferred, but attention must be paid to proper inhaler technique training. Long-acting inhaled bronchodilators are more effective and convenient but more expensive than short-acting inhaled bronchodilators. Combination therapy improves efficacy and is preferred over increasing the dose of a single agent, especially since the dose-response relationship using FEV_1 as the outcome is relatively flat for single-agent therapy.

Beta$_2$-Agonists

β_2-Agonists cause airway smooth muscle relaxation by stimulating adenyl cyclase to increase the formation of cyclic adenosine monophosphate (cAMP). Other non-bronchodilator effects have been observed, such as improvement in mucociliary transport, but their significance is uncertain.[11] β_2-Agonists are available in inhalation, oral, and parenteral dosage forms; the inhalation route is preferred because of fewer adverse effects.

These drugs are also available in short-acting and long-acting formulations (Table 12–4). The short-acting β_2-agonists include albuterol, levalbuterol, pirbuterol, and terbutaline. They are used as "rescue" therapy for acute symptom relief. Most COPD patients need continuous bronchodilator therapy on a scheduled basis every day. For these patients, short-acting β_2-agonists are inconvenient because of the need for frequent dosing. In addition, short-acting β_2-agonists have been associated with a slight, but statistically significant, loss of effectiveness when used regularly for more than 3 months (tachyphylaxis).[12]

Long-acting β_2-agonists include salmeterol and formoterol. Salmeterol is a partial agonist with a slower onset of action than short-acting β_2-agonists. Formoterol is a more complete agonist and has an onset of action similar to that of albuterol. Full agonists (formoterol) produce greater response at full receptor capacity than partial agonists (salmeterol). Bronchodilator effects of salmeterol and formoterol last at least 12 hours, allowing for twice-daily dosing. Long-acting bronchodilators are superior to scheduled short-acting bronchodilators on important clinical outcomes, including frequency of exacerbations, degree of dyspnea, and health-related quality of life.[11] For symptomatic patients, these are preferred over short-acting agents for maintenance therapy. Patients should also have a short-acting β_2-agonist such as albuterol available for as-needed use ("rescue" medication).

Adverse effects of β_2-agonists are dose-related and include palpitations, tachycardia, and tremor. Sleep disturbance may also occur and appears to be worse with higher doses of inhaled long-acting β_2-agonists. Increasing doses beyond those clinically recommended is without benefit and could be associated with increased adverse effects.

Anticholinergics

Ipratropium and tiotropium are inhaled anticholinergic medications commonly used for COPD. They produce bronchodilation by competitively blocking muscarinic receptors in bronchial smooth muscle. They may also decrease mucus secretion, although this effect is variable. Tiotropium dissociates from receptors extremely slowly resulting in a half-life longer than 36 hours, allowing for once-daily dosing. Ipratropium has an elimination half-life of about 2 hours, necessitating dosing every 6 to 8 hours.

Tiotropium provides the most consistent improvements on the widest range of outcomes among all the bronchodilators. It has been shown to be superior to ipratropium and salmeterol in improving lung function and superior to ipratropium

TABLE 12–4. Maintenance Medications for COPD

	Medication	Onset	Peak	Duration	Usual dose
Short-Acting β_2-Agonists	**Albuterol**				
	Nebulization	5–15 minutes	0.5–2 hours	2–6 hours	2.5 mg every 6–8 hours (max: 30 mg/day)
	Inhalation	5–15 minutes	0.5–2 hours	2–6 hours	MDI (90 mcg/puff) 1–2 puffs every 4–6 hours (max: 1080 mcg/day)
	Oral	7–30 minutes	2–3 hours	4–6 hours ER: 8–12 hours	2–4 mg three to four times a day ER: 4–8 mg every 12 hours (max: 32 mg/day)
	Levalbuterol				
	Nebulization	10–20 minutes	1.5 hours	5–8 hours	0.63–1.25 mg three times a day, 6–8 hours apart (max: 3.75 mg/day)
	Inhalation	5–10 minutes	1–1.5 hours	3–6 hours	MDI (45 mcg/puff) 1–2 puffs every 4–6 hours (max: 540 mcg/day)
	Pirbuterol				
	Inhalation	5 minutes	0.5–1.5 hours	4–5 hours	MDI (200 mcg/puff) 1–2 puffs every 4–6 hours (max: 2400 mcg/day)
	Terbutaline				
	Oral	0.5–2 hours	1–3 hours	6–8 hours	2.5–5 mg three times a day, 6 hours apart (max: 15 mg/day)
Long-Acting β_2 Agonists	**Formoterol**				
	Inhalation	1–3 minutes	1–3 hours	12 hours	Powder (12 mcg/inhalation) 1 inhalation every 12 hours (max: 24 mcg/day)
	Salmeterol				
	Inhalation	10 minutes–2 hours	2–5 hours	12 hours	Powder (50 mcg/inhalation) 1 inhalation every 12 hours (max: 100 mcg/day)
Short-Acting Anticholinergic	**Ipratropium**				
	Nebulization	1–30 minutes	1.5–2 hours	4–6 hours	500 mcg every 6–8 hours (max: 2000 mcg/day)
	Inhalation	1–30 minutes	1.5–2 hours	4–6 hours	MDI (18 mcg/puff) 2 puffs four times a day (max: 216 mcg/day)
Long-Acting Anticholinergic	**Tiotropium**				
	Inhalation	30 minutes	1–4 hours	24 hours	Powder (18 mcg/inhalation) 1 inhalation every 24 hours (max: 18 mcg/day)
Methylxanthine	**Theophylline**				
	Oral	0.5–2 hours	Up to 24 hours, depending on formulation	6–24 hours	400–600 mg/day divided every 6–24 hours based on formulation Adjust dose to serum concentrations of 5–15 mcg/mL (28–83 µmol/L)
Inhaled Corticosteroids	**Beclomethasone**	1–7 days	1–4 weeks		MDI (40, 80 mcg/puff) 40–160 mcg twice a day (max: 640 mcg/day)
	Budesonide	1–7 days	1–2 weeks		Powder (200 mcg/inhalation) 1–2 inhalations twice a day (max: 1600 mcg/day)
	Fluticasone	1–7 days	1–2 weeks		MDI (44, 110, 220 mcg/puff) 88–440 mcg twice a day (max: 1760 mcg/day)
	Triamcinolone	1–7 days	1–2 weeks		MDI (100 mcg/puff) 2 puffs three to four times a day or 4 puffs twice a day (max: 1600 mcg/day)

MDI, metered-dose inhaler; ER, extended-release.

in relieving symptoms, reducing exacerbation frequency, and improving health status.[13,14] Because of its superior efficacy, tiotropium is considered first-line therapy for all COPD patients with persistent symptoms (e.g., dyspnea, need for rescue medication more than twice a week, and night waking). The largest drawback to widespread use of tiotropium is the high cost of therapy. Patients using tiotropium as maintenance therapy should be prescribed albuterol as their rescue therapy. The combination of ipratropium and tiotropium is not recommended because of the risks of excessive anticholinergic effects.

Inhaled anticholinergics are well tolerated with the most common adverse effect being dry mouth. Occasional metallic taste has also been reported with ipratropium. Other anticholinergic adverse effects include constipation, tachycardia, blurred vision, and precipitation of narrow-angle glaucoma symptoms. Urinary retention could be a problem, especially for those with concurrent bladder outlet obstruction.

Theophylline

Theophylline is a non-specific phosphodiesterase inhibitor that increases intracellular cAMP within airway smooth muscle resulting in bronchodilation. It has a modest bronchodilator effect in patients with COPD, and its use is limited due to a narrow therapeutic index, multiple drug interactions, and adverse effects. Theophylline should be reserved for patients who cannot use inhaled medications or who remain symptomatic despite appropriate use of inhaled bronchodilators.

Theophylline's bronchodilatory effects are dependent upon achieving adequate serum concentrations, and therapeutic drug monitoring is needed to optimize therapy because of wide interpatient variability. If theophylline is used, serum concentrations in the range of 5 to 15 mcg/mL (28 to 83 μmol/L) provide adequate clinical response with a greater margin of safety than the traditionally recommended range of 10 to 20 mcg/mL (55 to 110 μmol/L). The most common adverse effects include heartburn, restlessness, insomnia, irritability, tachycardia, and tremor. Dose-related adverse effects include nausea and vomiting, seizures, and arrhythmias.

Tobacco smoke contains chemicals that induce the cytochrome P-450 isoenzymes 1A1, 1A2, and 2E1. Theophylline is metabolized by 1A2 and 2E1, and therefore smoking leads to increased clearance and subsequently decreased plasma levels of the drug.[15] Because most patients with COPD are current or past smokers, it is important to assess current tobacco use and adjust the theophylline dose as required based on altered plasma theophylline levels if tobacco use changes.

Combinations of Bronchodilators

Patients with COPD often need maintenance treatment with two or three bronchodilators. Combining albuterol plus ipratropium, a long-acting β_2-agonist plus theophylline, or a long-acting β_2-agonist plus tiotropium produces a greater change in spirometry than either drug alone.[1,2,16,17] Administering a long-acting β_2-agonist plus ipratropium leads to fewer exacerbations than either drug alone.[18] A combination of all three bronchodilator classes (β_2-agonist, anticholinergic, and theophylline) can be used if the response to a two-drug combination is inadequate. However, this approach has not been evaluated adequately in clinical trials.

Corticosteroids

❺ *In symptomatic patients with severe COPD (FEV_1 less than 50% predicted) and frequent exacerbations, regular treatment with inhaled corticosteroids decreases the number of exacerbations per year and improves health status; however, corticosteroids do not slow the long-term decline in pulmonary function.*[2,19–23] A combination inhaler device is recommended when using a long-acting β_2-agonist with an inhaled corticosteroid [e.g., Advair (fluticasone/salmeterol)]. Patients should be reassessed 6 to 8 weeks after initiating inhaled corticosteroids to determine whether there has been a positive response. A positive response is indicated by an increase in FEV_1 of 15% or more, improvement in symptoms, and/or improvement in 6-minute walking distance.[24] Treatment should be discontinued if no substantial clinical or physiologic improvement is seen.[1,24]

Upon discontinuation of inhaled corticosteroids some patients may experience deterioration in lung function and an increase in dyspnea and mild exacerbations; it is reasonable to reinstitute the medication in these patients.[25] Completion of ongoing clinical trials assessing mortality should help to clarify the role of corticosteroid treatment of COPD.

The most common adverse effects from inhaled corticosteroids include oropharyngeal candidiasis and hoarse voice. These can be minimized by rinsing the mouth after use and by using a spacer device with metered-dose inhalers. Increased bruising and decreased bone density have also been reported; the clinical importance of these effects remains uncertain.[1,2,19]

Long-term use of oral corticosteroids should be avoided due to an unfavorable risk/benefit ratio. The steroid myopathy that can result from long-term use of oral corticosteroids weakens muscles, further decreasing the respiratory drive in patients with advanced disease.

Immunizations

Serious illness and death in COPD patients can be reduced by about 50% with annual influenza vaccination. The optimal time for vaccination is usually from early October through mid-November. All patients with COPD should also receive a one-time vaccination with the pneumococcal polysaccharide vaccine, even though sufficient data supporting its use in COPD patients are lacking.[1,2] Patients over 65 years of age should be revaccinated if it has been more than 5 years since initial vaccination and they were less than 65 years of age at the time.

$Alpha_1$-Antitrypsin Augmentation Therapy

The American Thoracic Society and the European Respiratory Society have published standards for the diagnosis and management of individuals with AAT deficiency.[26] They recommend intravenous augmentation therapy for individuals with AAT

deficiency and moderate airflow obstruction (FEV_1 35% to 60% predicted). In these patients, augmentation therapy appears to reduce overall mortality and slow the decline in FEV_1, although large randomized controlled trials have not been conducted. Augmentation therapy consists of weekly transfusions of pooled human AAT with the goal of maintaining adequate plasma levels of the enzyme. The benefits of augmentation therapy are unclear in patients with severe (FEV_1 less than 35% predicted) or mild (FEV_1 greater than 60% predicted) airflow obstruction. Augmentation therapy is not recommended for individuals with AAT deficiency who do not demonstrate lung disease.

Other Pharmacologic Therapies

Leukotriene modifiers (e.g., zafirlukast and montelukast) have not been adequately evaluated in COPD patients and are not recommended for routine use. Small, short-term studies showed improvement in pulmonary function, dyspnea, and quality of life when leukotriene modifiers were added on to inhaled bronchodilator therapy.[27,28] Additional long-term studies are needed to clarify their role.

Nedocromil, a mast cell stabilizer, has not been adequately tested in COPD patients and is not included in the GOLD recommendations.

N-acetylcysteine has antioxidant and mucolytic activity, which makes it a promising agent for COPD treatment, but clinical trials have produced conflicting results. One of the largest trials found N-acetylcysteine to be ineffective at reducing the decline in lung function and preventing exacerbations.[29] Routine use cannot be recommended at this time.

Prophylactic, continuous use of antibiotics has no effect on the frequency of exacerbations; antibiotics should only be used for treating infectious exacerbations. Antitussives are contraindicated because cough has an important protective role. Opioids may be effective for dyspnea in advanced disease but may have serious adverse effects; they may be used to manage symptoms in terminal patients.

Pharmacologic Therapy of COPD Exacerbations

An exacerbation is a sustained worsening of the patient's symptoms from his or her usual stable state that is beyond normal day-to-day variations. It is acute in onset and sufficient to warrant a change in management. Commonly reported symptoms are worsening of dyspnea, increased sputum production, and change in sputum color. The most common causes of an exacerbation are respiratory infection and air pollution, but the cause cannot be identified in about one-third of severe exacerbations.[2]

Treatment depends on the symptoms and severity of the exacerbation. Mild exacerbations can often be treated at home with an increase in bronchodilator therapy with or without oral corticosteroids (Fig. 12–3). Antibiotics are indicated only if there are clinical signs of airway infection (e.g., increased volume and change in color of sputum and/or fever). Moderate to severe exacerbations require management in the emergency department or hospital. Management should consist of controlled oxygen therapy, bronchodilators, oral or intravenous corticosteroids, antibiotics if indicated, and consideration of mechanical ventilation (non-invasive or invasive).

Patient Encounter, Part 2: The Medical History, Physical Exam, and Diagnostic Tests

PMH
Hypertension for 6 years, currently controlled

SH
Patient works as an accountant; married with two children

FH
Father with emphysema and lung cancer. There is no family history of type 2 diabetes or heart disease

Meds
Lisinopril 40 mg PO once daily
Hydrochlorothiazide 25 mg PO once daily

ROS
(–) skin rash; (–) nasal congestion, drainage; (–) chest pain, paroxysmal nocturnal dyspnea, orthopnea; (+) shortness of breath, cough, intermittent wheezing; (–) hemoptysis; (–) heartburn, reflux symptoms, N/V/D, change in appetite, change in bowel habits; (–) joint pain or swelling; (–) pedal edema

PE
VS: blood pressure 134/82 mm Hg, pulse 80 beats per minute, respiratory rate 20/minute, temperature 35.8°C, Wt 132 lb (60 kg), Ht 64 in. (163 cm), body mass index 22.7 kg/m^2
HEENT: EOMI; mucosal membranes are moist; no evidence of JVD; no palpably enlarged cervical lymph nodes
Lungs: Barrel-shaped chest; hyperresonant percussion noted bilaterally; lung sounds are fairly distant, no rhonchi or crackles.
CV: RRR, normal S_1, S_2; no murmur, gallop, or rub
Abd: Soft, non-tender, no hepatosplenomegaly
Exts: No cyanosis, edema, or finger clubbing; evidence of onychomycosis on all fingernails

PFTs

	Prebronchodilator		Postbronchodilator	
	Actual	% Predicted	Actual	% Predicted
FVC (L)	4.4	107%	4.0	97%
FEV_1 (L)	1.68	50%	1.59	47%
FEV_1/FVC (%)			39%	

Chest x-ray: Hyperlucency and hyperinflation of the lungs suggestive of emphysematous change

- Given this additional information, what is your assessment of the patient's condition?
- This patient's COPD can be classified as what stage?
- What are the treatment goals for this patient?
- What nonpharmacologic and pharmacologic alternatives are feasible for this patient?
- Develop a treatment plan for this patient.

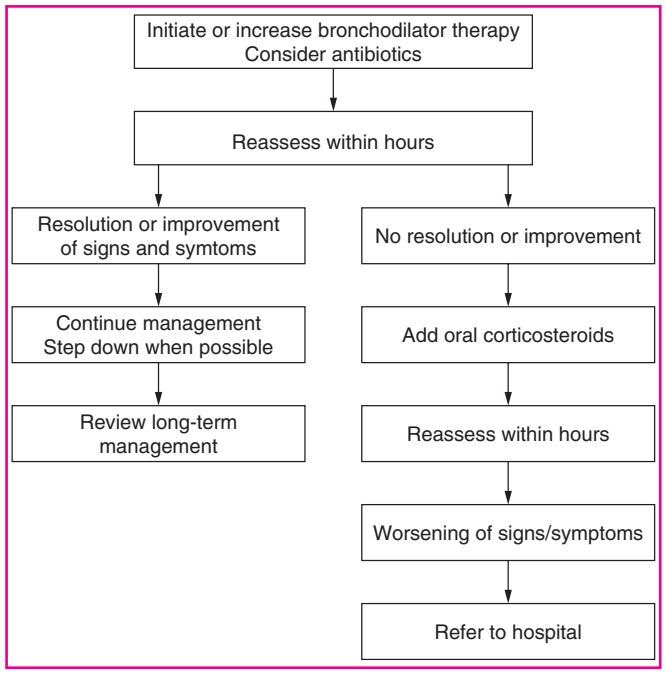

FIGURE 12–3. Algorithm for the management of an exacerbation of COPD at home. (Reproduced from GOLD Science Committee. Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease. Updated 2005. Available at: www.goldcopd.com. Used with permission.)

Bronchodilators

Albuterol is the preferred bronchodilator for treatment of acute exacerbations because of its rapid onset of action. Ipratropium can be added to allow for lower doses of albuterol, thus reducing dose-dependent adverse effects such as tachycardia and tremor. Delivery can be through metered-dose inhaler (MDI) and spacer or nebulizer. The nebulizer route is preferred in patients with severe dyspnea and/or cough that would limit delivery of medication through an MDI with spacer. If response is inadequate, theophylline can be considered; however, clinical evidence supporting its use is lacking.

Oral Corticosteroids

Systemic corticosteroids shorten the recovery time, help to restore lung function more quickly, and may reduce the risk of early relapse.[30] The GOLD guidelines recommend that corticosteroids be considered in addition to bronchodilators in all hospitalized patients and in outpatients with baseline FEV_1 less than 50% predicted.[2] Other authorities recommend corticosteroids for all patients experiencing a COPD exacerbation.[1] Oral prednisone 30 to 40 mg/day for 10 to 14 days is recommended. Prolonged treatment does not result in greater efficacy and increases the risk of adverse effects. If inhaled corticosteroids are part of the patient's usual treatment regimen, they should be continued during systemic therapy.

Antibiotics

The role of bacterial infections in COPD exacerbations is controversial, and there are limited data on the efficacy of antibiotics in treating COPD exacerbations. Recent studies suggest that bacteria cause 40% to 50% of acute exacerbations.[31]

❻ *Antibiotics should be used in patients with COPD exacerbations who have either of the following characteristics: (1) at least two of three cardinal symptoms: increased dyspnea, sputum volume, or sputum purulence; or (2) a severe exacerbation requiring mechanical ventilation.*[2]

The predominant bacterial organisms in patients with mild exacerbations are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. In patients with more severe underlying COPD, other bacteria, such as enteric gram-negative bacilli (*Escherichia coli, Klebsiella pneumoniae,* and *Enterobacter cloacae*) and *Pseudomonas aeruginosa* may be more common. Selection of empiric antibiotic therapy should be based on the most likely organism(s) thought to be responsible for the infection and on local resistance patterns. A risk stratification approach has been advocated to help guide antibiotic selection.[1,2,31] This approach is based on risk factors found to be predictive of treatment failure or early relapse. Patients at risk for poor outcome are candidates for more aggressive initial antibiotic treatment. Table 12–5 provides recommended antibiotic treatment based on this risk stratification approach.[2,31] Antibiotic treatment for most patients should be maintained for 3 to 10 days, until the patient has been afebrile for 3 consecutive days. Exacerbations due to certain infecting organisms (*P. aeruginosa, E. cloacae,* and methicillin-resistant *Staphylococcus aureus*), while not common, require more lengthy courses of therapy (21 to 42 days) when they occur. If there is worsening clinical status or inadequate clinical response in 48 to 72 hours, re-evaluate the patient, consider sputum Gram's stain and culture if not already obtained, and adjust antimicrobial therapy. If Gram's stain and culture results are available, narrow the antibiotic therapy according to cultured organism(s) and sensitivities. If no cultures have been obtained, or cultures remain negative, consider additional antibiotics and/or change to antibiotics with a broader spectrum of activity.

Oxygen

The goal of oxygen therapy is to maintain PaO_2 above 60 mm Hg (8 kPa) or SaO_2 above 90% in order to prevent tissue hypoxia and preserve cellular oxygenation.[1] Increasing the PaO_2 much further confers little added benefit and may increase the risk of CO_2 retention, which may lead to respiratory acidosis. An arterial blood gas should be obtained after 1 to 2 hours to assess for hypercapnia.

In advanced COPD, caution should be used since overly aggressive administration of oxygen to patients with chronic hypercapnia may result in respiratory depression and respiratory failure. In these patients, mild hypoxemia, rather than carbon dioxide accumulation, triggers their drive to breathe.

TABLE 12–5. Recommended Antibiotic Therapy in Acute Exacerbations of COPD

Patient Characteristics	Likely Pathogens	Recommended Antibiotics[a,b]
Uncomplicated exacerbation Not requiring hospitalization Less than 3 exacerbations per year No comorbid illness FEV_1 greater than 50% predicted No recent antibiotic therapy	*Streptococcus pneumoniae, Haemophilus influenzae, Moraxella catarrhalis*	*Oral:* Macrolide (azithromycin, clarithromycin) Second- or third-generation cephalosporin (cefuroxime, cefpodoxime, cefdinir, cefprozil) Doxycycline Ketolide (telithromycin) β-Lactam/β-lactamase inhibitor (amoxicillin-clavulanate) *Intravenous:* Not recommended
Complicated exacerbation FEV_1 less than 50% predicted Comorbid cardiac disease Greater than or equal to 3 exacerbations per year Antibiotic therapy in the previous 3 months	Above organisms plus: drug-resistant pneumococci, β-lactamase-producing *H. influenzae* and *M. catarrhalis, Escherichia coli, Proteus* spp., *Enterobacter* spp., *Klebsiella pneumoniae*	*Oral:* β-Lactam/β-lactamase inhibitor (amoxicillin-clavulanate) Fluoroquinolone with enhanced pneumococcal activity (levofloxacin, gemifloxacin, moxifloxacin) *Intravenous:* β-lactam/β-lactamase inhibitor (ampicillin-sulbactam) Second- or third-generation cephalosporin (cefuroxime, ceftriaxone) Fluoroquinolone with enhanced pneumococcal activity (levofloxacin, moxifloxacin)
Complicated exacerbation with risk factors for P. aeruginosa Recent hospitalization Greater than or equal to 4 courses of antibiotics in the last year Very severe COPD (GOLD stage IV) Previous isolation of *P. aeruginosa*	Above organisms plus: *P. aeruginosa*	*Oral*[c]: Antipseudomonal fluoroquinolone (ciprofloxacin, high-dose levofloxacin) *Intravenous:* Antipseudomonal β-lactamase resistant penicillin (piperacillin-tazobactam) Third- or fourth-generation cephalosporin with antipseudomonal activity (ceftazidime, cefepime) Antipseudomonal fluoroquinolone (ciprofloxacin, high-dose levofloxacin)

[a]Antibiotics indicated if patient has at least two of three cardinal symptoms: increased dyspnea, sputum volume, or sputum purulence; or a severe exacerbation requiring mechanical ventilation.
[b]Trimethoprim-sulfamethoxazole, amoxicillin, first-generation cephalosporins, and erythromycin are not recommended due to susceptibility and resistance patterns of the likely infectious organisms.
[c]Double coverage (e.g., use of two antipseudomonal antibiotics) should be considered for likely pseudomonal infection. Additional antipseudomonal antibiotic choices to add for double coverage include aminoglycosides, imipenem, meropenem, and aztreonam.
COPD, chronic obstructive pulmonary disease; FEV_1, forced expiratory volume in one second.

Assisted Ventilation

Mechanical ventilation can be administered as follows: (1) invasive (conventional) mechanical ventilation through an endotracheal tube; (2) non-invasive mechanical ventilation using either negative (e.g., iron lung—not recommended) or positive pressure devices. Non-invasive positive pressure ventilation (NPPV) is preferred whenever possible. NPPV improves signs and symptoms, decreases the length of hospital stay, and most importantly, reduces mortality.[32] Appropriate patients to consider for NPPV include those with the following characteristics: (1) moderate to severe dyspnea with use of accessory muscles and paradoxical abdominal motion; (2) moderate to severe acidosis (pH between 7.25 and 7.35) and hypercapnia ($PaCO_2$ between 45 and 60 mm Hg [6–8 kPa]); and (3) respiratory rate between 25 and 35 breaths per minute.[2] Invasive mechanical ventilation should be used in patients with more severe symptoms and in those failing NPPV.

OUTCOME EVALUATION

- Monitor the patient for improvement in symptoms (dyspnea, cough, sputum production, and fatigue).
- Changes in FEV_1 should not be the main outcome assessed. FEV_1 changes are weakly related to symptoms, exacerbations, and health-related quality of life (outcomes that are important to patients).
- The Medical Research Council (MRC) dyspnea scale can be used to monitor physical limitation due to breathlessness

(Table 12–6). The scale is simple to administer and correlates well with scores of health status.[33]

- The BODE Index is a validated predictor of mortality and is a better predictor than FEV_1 alone.[34] It is a composite score derived from body mass index or BMI (**B**), FEV_1 or degree of airflow obstruction (**O**), modified Medical Research Council (MMRC) dyspnea scale (**D**), and 6-minute walking distance (**E**, exercise capacity). All of these variables predict important outcomes such as health-related quality of life, the rate of exacerbations, and the risk of death. The composite score is based on a 10-point scale in which higher scores indicate a higher risk of death (Table 12–7). The BODE Index can be used clinically to monitor disease progression. Its usefulness in measuring outcomes of drug therapy, pulmonary rehabilitation, and the degree of health care resource utilization needs further study.
- Assess quality of life using the St. George's Respiratory Questionnaire, which has been validated and is specific for COPD patients.[35]
- Monitor theophylline levels with goal serum concentrations in the range of 5 to 15 mcg/mL (28 to 83 µmol/L). Trough levels should be obtained 1 to 2 weeks after initiation of treatment and after any dosage adjustment. Routine levels are not necessary unless toxicity is suspected or disease has worsened.

TABLE 12–6. Medical Research Council (MRC) Dyspnea Scale

Grade	Modified Grade[a]	Statement about Perceived Breathlessness[b]
1	0	"I only get breathless with strenuous activity."
2	1	"I get short of breath when hurrying on the level or up a slight hill."
3	2	"I walk slower than people of the same age on the level because of breathlessness or I have to stop for breath after a mile or so on the level at my own pace."
4	3	"I stop for breath after walking 100 yards or after a few minutes on the level."
5	4	"I am too breathless to leave the house or I get breathless while dressing."

[a]The modified grade is used in the BODE index.
[b]The last statement to which the patient answers "yes" is their grade.

Patient Care and Monitoring

1. Assess the patient's symptoms and history of exposure to risk factors. For new patients obtain a detailed medical history including:
   - Past medical history, especially history of respiratory conditions
   - Immunization status (pneumococcal and influenza)
   - Family history of COPD or other chronic respiratory disease
   - History of exacerbations or previous hospitalizations for respiratory disorders
   - Impact of disease on the patient's life, including limitation of activity, missed work, and feelings of depression or anxiety
2. Obtain spirometry measurements to assess airflow limitation and aid in severity classification and treatment decisions. Measure arterial blood gases if FEV_1 is less than 40% predicted or if the patient has clinical signs suggestive of respiratory failure or right heart failure.
3. Obtain a thorough history of prescription, non-prescription, and dietary supplement use. Assess inhaler technique and adherence to the medication regimen. Ask the patient about effectiveness of medications at controlling symptoms and adverse effects.
4. Ask current tobacco users about daily quantity, past quit attempts, and current readiness to quit.
5. Design a therapeutic plan including lifestyle modifications (e.g., smoking cessation) and optimal drug therapy. Consider need for pulmonary rehabilitation, oxygen therapy, and/or surgery.
6. Provide patient education about the disease state and therapeutic plan:
   - What COPD is and the natural course of the disease
   - Smoking cessation counseling
   - Role of regular exercise and healthy eating
   - How and when to take medications; importance of adherence to the medication plan; adverse effects and how to minimize them
   - Signs and symptoms of an exacerbation and what to do if one occurs
   - Advanced directives and end-of-life issues for patients with more severe disease
7. Determine the follow-up period based on patient status and needs (typically 3 to 6 months).
8. Follow-up visits should include:
   - Assessment of tobacco use and/or quit attempts
   - Assessment of change in symptoms. Obtain spirometry if there is a substantial increase in symptoms or a complication
   - Review of drug therapy (dosages, adherence, inhaler technique, effectiveness, adverse effects, and drug interactions)
   - Evaluation of exacerbation frequency, severity, and likely causes
9. Perform spirometry at least annually to assess disease progression.
10. Provide annual influenza vaccination.
11. Assess inhaler technique at every visit. Have the patient demonstrate proper use of each device using a placebo inhaler or personal inhaler. Proper use of these devices is critical for therapeutic success.

TABLE 12–7. The BODE Index

	Points on BODE Index[a]			
Variable	**0**	**1**	**2**	**3**
FEV_1 (% of predicted)	Greater than or equal to 65	50–64	36–49	Less than or equal to 35
Distance walked in 6 minute (meters)	Greater than or equal to 350	250–349	150–249	Less than or equal to 149
MMRC dyspnea scale	0–1	2	3	4
Body mass index (kg/m^2)	Greater than 21	Less than or equal to 21		

[a]The cutoff values for the assignment of points are shown for each variable.
FEV_1, forced expiratory volume in one second; MMRC, modified Medical Research Council. From Celli BR, Cote CG, Marin JM, et al. 13 Cystic Fibrosis

Kimberly J. Novak

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiology of cystic fibrosis (CF) and its multi–organ system involvement.
2. Describe the common clinical presentation and diagnosis of CF.
3. Consider long-term treatment goals with respect to clinical course and prognosis of CF.
4. Identify nonpharmacologic therapies for CF management.
5. Recommend appropriate pharmacologic therapies for chronic CF management.
6. Design appropriate antibiotic regimens for acute pulmonary exacerbations of CF.
7. Employ pharmacokinetic principles when calculating drug doses in CF patients.
8. Formulate monitoring plans for acute and chronic CF pharmacologic therapies.

Key Concepts

❶ In CF, the cystic fibrosis transmembrane regulator (CFTR) chloride channel is dysfunctional and usually results in decreased chloride secretion and increased sodium absorption, leading to altered viscosity of fluid excreted by the exocrine glands and mucosal obstruction.

❷ Pulmonary disease is characterized by thick mucus secretions, impaired mucus clearance, chronic airway infection and colonization, obstruction, and an exaggerated neutrophil-dominated inflammatory response.

❸ Maximizing nutritional status through pancreatic enzyme replacement and vitamin and nutritional supplements is necessary for normal growth and development and for maintaining long-term lung function.

❹ Airway clearance therapy is a necessary routine for all CF patients to clear secretions and control infection. It is typically performed once or twice daily for maintenance care and three or four times per day for acute exacerbations.

❺ Antibiotic therapy is indicated in three distinct situations over the course of CF: (1) early eradication and delay of colonization; (2) suppression of bacterial growth once colonization occurs; and (3) reduction of bacterial load in acute overgrowth.

❻ Antibiotic selection is based on periodic culture and sensitivity data, typically covering all organisms identified over the preceding year. If no culture data are available, empiric antibiotics should cover the most likely organisms for the patient's age group.

❼ Antibiotic regimens in severe CF exacerbations include an intravenous antipseudomonal β-lactam plus an aminoglycoside.

❽ CF patients have a larger volume of distribution and enhanced total body clearance of many antibiotics, which often results in the need for higher doses to attain target levels.

❾ Titration of pancreatic enzyme doses is based on control of steatorrhea, stool output, and abdominal symptoms.

❿ Because CF-related diabetes (CFRD) results from insulin insufficiency, exogenous insulin replacement is required.

Cystic fibrosis (CF) is an inherited multi–organ system disorder affecting children and an ever-growing adult population. It is the most common life-threatening genetic disease among Caucasians and the major cause of severe chronic lung disease and pancreatic insufficiency in children. The disease generally manifests as mucosal obstruction of exocrine glands caused by defective ion transport within epithelial cells. Due to the array of affected organ systems and complicated medical therapies, appropriate CF treatment necessitates multidisciplinary team collaboration.

EPIDEMIOLOGY AND ETIOLOGY

In the United States, CF most commonly occurs in the Caucasian population, ranging from 1 in 1900 to 3700 individuals. CF is less common in Hispanics (1 in 9000), African-Americans

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

(1 in 15,000), and Asian Americans (1 in 32,000).[1] CF is inherited as an autosomal recessive trait, and approximately 1 in 25 Caucasians are **heterozygous** carriers. For example, offspring of a carrier couple (each parent being heterozygous) have a one in four chance of having the disease (**homozygous**), a one in two chance of being a carrier (heterozygous), and a one in four chance of receiving no trait. The gene mutation is found on the long arm of chromosome 7 and encodes for the cystic fibrosis transmembrane regulator (CFTR) protein, which functions as a chloride channel to transport water and electrolytes. Over 1000 mutations have been described in the CF gene; however, the ΔF508 mutation is the most common and is present in 70% to 90% of CF patients in the United States.[2]

PATHOPHYSIOLOGY

CF is a disease of exocrine gland epithelial cells where CFTR is largely expressed. Normally, these cells transport chloride through CFTR chloride channels with sodium and water accompanying this flux across the cell membrane (Fig. 13–1). CFTR is regulated by protein kinases in response to varying levels of the intracellular second messenger cyclic-3′, 5′-adenosine monophosphate (cAMP). CFTR also downregulates the epithelial sodium channel, regulates calcium-activated chloride and potassium channels, and may function in exocytosis and formation of plasma membrane molecular complexes and proteins important in inflammatory responses.[2] ❶ *In CF, the CFTR chloride channel is dysfunctional and usually results in decreased chloride secretion and increased sodium absorption, leading to altered viscosity of fluid excreted by the exocrine glands and mucosal obstruction.*

Pulmonary System

Chronic lung disease is a hallmark of CF, leading to death in 90% of patients.[3] ❷ *Pulmonary disease is characterized by thick mucus secretions, impaired mucus clearance, chronic airway infection and colonization, obstruction, and an exaggerated neutrophil-dominated inflammatory response.*[4] Over time, chronic obstruction and inflammation lead to air trapping, **atelectasis**, mucus plugging, **bronchiectasis**, cystic lesions, pulmonary hypertension, and eventual respiratory failure. In the United States CF population, pulmonary function declines at an average yearly rate of 2%, as measured by forced expiratory volume in 1 second (FEV_1). The rate in an individual patient may be higher or lower depending on severity of CFTR dysfunction and comorbidities. Patients may show a slow steady decline over time, or they may have stable lung function for several years and then experience periods of sharp decline.[1] In the upper airways, sinusitis and nasal polyps are also common, and microbial colonization is similar to that of the lungs.

Bacterial pathogens are often acquired in an age-dependent sequence, and prevalence is tracked in the Cystic Fibrosis Foundation Patient Registry. Early infection is most often caused by *Staphylococcus aureus* and non-typeable *Haemophilus influenzae* (and thus is not prevented by childhood *H. influenzae* type b immunization). *Pseudomonas aeruginosa* infection also occurs early in life and is the most significant CF pathogen among all age groups. *P. aeruginosa* expresses extracellular toxins that perpetuate lung inflammation. Mucoid strains of *P. aeruginosa* produce an alginate biofilm layer that interferes with antibiotic penetration. Other organisms identified later in the disease course include *Stenotrophomonas maltophilia*, *Alcaligenes xylosoxidans*, *Burkholderia cepacia*, fungi including *Candida* and *Aspergillus* species, and non-tuberculous mycobacteria.[1] Other organisms may also present chronically or intermittently. Similarly, cultured organisms may represent an initial infection, chronic colonization, or microbial overgrowth in an acute exacerbation.

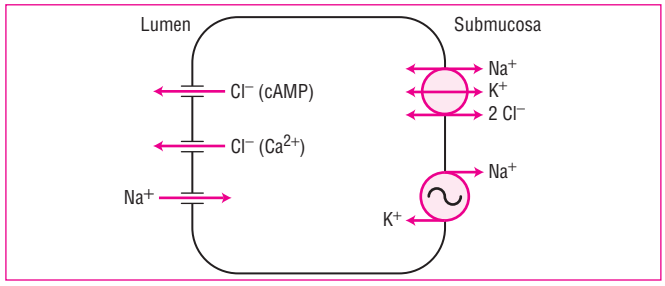

FIGURE 13–1. Electrolyte transport in the airway epithelial cell. Ca, calcium; cAMP, cyclic-3′, 5′-adenosine monophosphate; Cl, chloride; Na, sodium; K potassium. (From Milavetz G, Smith JJ. Cystic fibrosis. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 592, with permission.)

Gastrointestinal System

Gastrointestinal involvement may present initially as small bowel obstruction shortly after birth (known as meconium ileus) due to abnormally thick **meconium** that cannot be passed. Older CF patients may develop distal intestinal obstruction syndrome (DIOS), formerly called meconium ileus equivalent, which occurs due to fecal impaction in the terminal ileum and cecum.

Maldigestion due to pancreatic enzyme insufficiency is present in about 85% to 90% of CF patients.[5] Thick pancreatic secretions and cellular debris obstruct the pancreatic ducts and lead to fibrosis. Volume and concentration of pancreatic enzymes and bicarbonate are reduced, leading to maldigestion of fat and protein. Subsequently, absorption of fat-soluble vitamins (A, D, E, and K) is often impaired. Maldigestion is characterized by abdominal distention, numerous large foul-smelling loose stools (**steatorrhea**), flatulence, and malnourishment and hunger despite voracious intake. Maldigestion is progressive and may develop later in a previously pancreatic sufficient patient.

Other complications may include gastroesophageal reflux, dysmotility, **intussusception**, **volvulus**, **atresia**, **rectal prolapse**, and complications related to corrective surgery for meconium ileus.[6]

Hepatobiliary disease occurs due to bile duct obstruction from abnormal bile composition and flow. Hepatomegaly, splenomegaly, and cholecystitis may be present. Hepatic **steatosis** may also be present due to effects of malnutrition. The progression from cholestasis (impaired bile flow) to portal fibrosis and to focal and multilobar cirrhosis, esophageal varices, and portal hypertension takes several years. Many patients are compensated and asymptomatic but may be susceptible to acute decompensation in the event of extrinsic hepatic insult from viruses, medications, or other factors.[7]

Endocrine System

CF-related diabetes shares characteristics of both type 1 and type 2 diabetes mellitus but is categorized separately. The primary cause of CFRD is insulin deficiency resulting from both reduced functional pancreatic islet cells and increased islet **amyloid** deposition. Insulin secretion is delayed in response to glucose challenge, and absolute insulin secretion over time is reduced. Some insulin resistance may also be present in CFRD; however, sensitivity may be increased in CF patients without diabetes.[8]

Postprandial hyperglycemia is common, but because some basal insulin secretion is maintained, fasting hyperglycemia is less severe and ketosis is rare.[5] Diet, acute and chronic infection, and corticosteroid use lead to fluctuations in glucose tolerance over time.[8] CFRD is associated with greater nutritional failure, increased pulmonary disease, and earlier death. The average age of onset is 18 to 21 years; but underdiagnosis is thought to be common.

Reproductive System

CF patients often experience delayed puberty. In females, menarche occurs 18 months later than average, and menstrual irregularity is common. Females also have reduced fertility due to increased viscosity of cervical mucus. Due to increasing life expectancy, pregnancy is becoming more common; however, outcomes depend on pre-partum nutritional and pulmonary status.

Almost all males with CF are **azoospermic** due to congenital absence of the vas deferens with resultant obstruction; however, conception still occurs occasionally. Conception can also occur through application of assisted reproductive technologies.[9]

Musculoskeletal System

Several factors contribute to development of bone disease in CF: (1) malabsorption of vitamins D and K and calcium; (2) poor nutrition and decreased body mass; (3) physical inactivity; (4) corticosteroid therapy; and (5) delayed puberty. Chronic pulmonary infection, through release of inflammatory cytokines, can cause increased bone resorption and decreased formation. **Osteopenia**, osteoporosis, pathologic fractures, and **kyphosis** can then occur.[10]

Episodic or chronic arthritis and hypertrophic pulmonary osteoarthropathy may also occur due to immune complex formation in response to chronic inflammation.[11] Digital **clubbing** is commonly observed and is a marker for hypoxia.

Hematologic System

Anemia may be present in some patients due to impaired erythropoietin regulation, nutritional factors (vitamin E and iron malabsorption), or chronic inflammation. With chronic pulmonary disease, increased cytokine production can lead to shortened red blood cell survival, reduced erythropoietin response, and impaired mobilization of iron stores.

Additionally, with chronic hypoxia, normal hemoglobin and hematocrit values may represent relative anemia.[12] Increased red blood cell production is a physiologic response to hypoxia; however, this response may be blunted in CF and may result in symptoms of anemia despite normal lab values. Abnormal bleeding may also be observed as a result of vitamin K malabsorption or antibiotic-associated depletion of gastrointestinal flora and vitamin K synthesis.

Miscellaneous Systems

Abnormally high concentrations of sodium and chloride are found in sweat due to impaired reabsorption within the sweat duct from loss of CFTR channels. Patients are usually asymptomatic (other than a characteristic salty taste to the skin).[2] In rare instances such as hot weather or excessive sweating during physical activity, patients may become dehydrated and experience symptoms of hyponatremia (nausea, headache, lethargy, and confusion). Similar CFTR defects are also seen in the salivary glands, manifested by increased saliva viscosity and impaired salivary function.

CLINICAL PRESENTATION AND DIAGNOSIS

Diagnosis

Diagnosis of CF is based on two separate elevated sweat chloride concentrations of greater than or equal to 60 mEq/L (or mmol/L) obtained through pilocarpine **iontophoresis** (referred to as the "sweat test"). Genetic testing (CFTR mutation analysis) may be performed to confirm the diagnosis, screen in utero, or detect carrier status. More than 70% of diagnoses are made by 12 months of age and almost all are made by age 12.

Clinical Presentation of Cystic Fibrosis

General

- CF is usually diagnosed in neonates or during early childhood. Some patients may present much later in life due to less severe symptoms or misdiagnosis.

Symptoms

- Pulmonary symptoms may include chronic cough, sputum production, and decreased exercise tolerance.
- Patients with intestinal obstruction may complain of abdominal pain, abdominal distention, and/or decreased bowel movements.
- Maldigestion may be manifested by the presence of numerous large foul-smelling loose stools (steatorrhea) and flatulence.
- Patients with vitamin A deficiency may report visual disturbances, night blindness, and dry skin.
- Acute infection may be marked by increased cough, changes in sputum (darker and thicker), dyspnea, and fever.

Signs

- Signs of obstructive airway disease include tachypnea, dyspnea, **cyanosis**, wheezes, crackles, sternal retractions, digital clubbing, and barrel chest.
- Infants and children with maldigestion may have evidence of failure to thrive (below age-based normals in both height and weight), and adults may be near or below their ideal body weight despite apparent adequate caloric intake.
- Salty taste to the skin may be noticed.
- Biliary cirrhosis may be asymptomatic or evidenced by hepatomegaly, splenomegaly, or prolonged bleeding.
- Recurrent pancreatitis (usually in pancreatic-sufficient patients) may present with episodes of epigastric abdominal pain, persistent vomiting, and fever.

Laboratory Tests

- Maldigestion results in decreased serum levels of the fat-soluble vitamins A, D, E, and K.
- Decreased vitamin K levels may result in elevated prothrombin time (PT) and International Normalized Ratio (INR).
- There may be glucose intolerance, as indicated by blood glucose between 140 and 199 mg/dL (7.77 to 11.04 mmol/L) 2 hours after an oral glucose tolerance test.
- Patients may have CFRD, as indicated by blood glucose greater than or equal to 200 mg/dL (greater than or equal to 11.1 mmol/L) 2 hours after an oral glucose tolerance test.
- Some patients have CFRD with fasting hyperglycemia (fasting blood glucose greater than or equal to 126 mg/dL (greater than or equal to 6.99 mmol/L) regardless of the post–glucose challenge level).
- Serum aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, γ-glutamyl transferase, and bilirubin may be elevated in patients with hepatobiliary disease.
- White blood cell count with an associated increase in polymorphonuclear (PMN) leukocytes and bands may occur in acute pulmonary infection; however, infection may occur without these laboratory abnormalities.

Other Tests

- Pulmonary function tests (PFTs) indicate decreased forced expiratory volume in 1 second (FEV_1), decreased forced vital capacity (FVC), and increased residual volume. Values are typically worse during acute pulmonary exacerbations.
- Chest x-ray or chest computed tomography scan may reveal infiltrates, atelectasis, bronchiectasis, and mucus plugging.
- Intestinal obstruction may be manifested as meconium ileus, distal intestinal obstruction syndrome, or intussusception on abdominal x-ray or computed tomography scan. Rectal prolapse may be noted on physical exam.
- In recurrent pneumonia or sinusitis, *P. aeruginosa*, *S. aureus*, *S. maltophilia*, and other CF-related organisms may be isolated in sputum, throat, or sinus cultures.

Clinical Course and Prognosis

Life expectancy has greatly increased from a predicted survival of 16 years in 1970 to more than 40 years for patients born in the 1990s.[5] The average age of patients in the Cystic Fibrosis Foundation Registry is now more than 16 years, and many are living far into adulthood. More than 40% of CF patients in the 2004 Registry annual report are over 18 years old, and the oldest is age 74.[13]

The clinical course varies greatly among patients because of the multiple genetic mutations and heterogeneous profile of the ΔF508 mutation. Some patients develop severe lung disease early in childhood and reach end-stage lung disease by their teens, whereas others maintain near-normal lung function into adulthood. Newly-diagnosed adults tend to present with chronic respiratory symptoms but usually have milder lung disease, less frequent *Pseudomonas* infection, and less severe pancreatic insufficiency.[5] Life expectancy and quality of life are expected to continue to increase with aggressive treatment strategies, lung transplantation when appropriate, and new therapies being investigated.

TREATMENT

Desired Outcomes

Therapeutic outcomes in CF care relate to both chronic and acute treatment goals. With chronic management, the primary goals are to delay disease progression and optimize quality of life. ❸ *Maximizing nutritional status through pancreatic enzyme replacement and vitamin and nutritional supplements is necessary for normal growth and development and for maintaining long-term lung function.* Reduction of airway

Patient Encounter, Part 1

Jessica is an 18-month-old female who is brought to her pediatrician because of difficulty gaining weight. Her mother states that Jessica has had four to five loose stools daily "ever since I can remember." She was previously diagnosed with reflux and milk allergy. Oral ranitidine and elimination of cow's milk–based dairy products have not helped. Jessica is plotted on the growth chart at less than the third percentile for both height and weight. Mom also reports that she has been treated in the emergency department for pneumonia twice since birth. Mom is concerned since her mother's older sister died from some strange "wasting illness" when she was a young child.

- What other information would you like to gather?
- How would you pursue making the diagnosis of CF?

inflammation and infection and aggressive preventive therapies minimize acute pulmonary exacerbations and delay pulmonary decline. In pulmonary exacerbations, therapy is directed toward reducing acute airway inflammation and obstruction. This is accomplished through more aggressive air clearance regimens and antibiotic therapy with a goal of returning lung function to pre-exacerbation levels or greater.

General Approach to Treatment

The intensity of the daily chronic maintenance regimen varies based on patient age, baseline lung function, other organ system involvement, and social factors such as time available for therapy and patient-selected care choices. Generally, with more severe lung disease and multi–organ system involvement, therapies become more complicated and time intensive. Additionally, therapy is intensified when pulmonary symptoms are increased with acute exacerbations or even mild viral upper respiratory illness such as the common cold. The approach to treatment is best described by the organ system affected.

Nonpharmacologic Therapy

Airway Clearance Therapy

❹ *Airway clearance therapy is a necessary routine for all CF patients to clear secretions and control infection, even at diagnosis prior to becoming symptomatic.* Waiting until development of a first pneumonia or until daily symptoms are present delays benefits and may contribute to a faster pulmonary decline.

The traditional form of chest physiotherapy (CPT) is known as percussion and postural drainage. Areas of the patient's chest, sides, and back are rapidly "clapped" by hand in different patient positions, followed by cough or forced expiration to mobilize secretions. Patients may also be taught autogenic drainage, which consists of deep breathing exercises followed by forced cough.

Several devices are also available to promote airway clearance. Flutter valve devices employ oscillating positive expiratory pressure (OPEP) to cause vibratory air flow obstruction and an internal percussive effect to mobilize secretions. Intrapulmonary percussive ventilation (IPV) provides continuous oscillating pressures during inhalation and exhalation. Finally, the most commonly used technique is high-frequency chest compression (HFCC) with an inflatable vest that provides external oscillation. Vest therapy is often preferred by patients because they can independently perform the therapy even from an early age.[5,14]

If performed appropriately, airway clearance techniques provide similar clearance results, so choice should be based on patient preference and compliance. Airway clearance therapy is typically performed once or twice daily for maintenance care and is increased to three or four times per day for acute exacerbations. Inhaled medications are usually given with the therapies and will be discussed in a later section.

Nutrition

Most CF patients have an increased caloric need due to increased energy expenditure through increased work of breathing and increased basal metabolism. Prevention of malnutrition requires early nutritional intervention. In patients with mild lung disease and well-controlled absorption, required caloric intake is approximately 100% to 120% of the recommended daily allowance (RDA) for age.[15] As lung disease progresses, caloric requirements increase.

Nutrition in malnourished patients consists of baseline required calories plus additional calories for weight gain. Even with aggressive diet and oral supplements, the caloric requirement may not be achieved. Placement of a **gastrostomy** or **jejunostomy** tube to allow for nighttime bolus or continuous formula feeds in addition to daytime meals may be required to meet caloric goals.[5] Patients with continued malabsorption on appropriate pancreatic enzyme supplementation or diabetes are especially challenging due to their unique caloric needs. Collaboration with a dietician specially trained in CF nutrition is essential.

Pharmacologic Therapy

Pulmonary System

Treating Obstruction and Inflammation

Airway clearance therapy is usually accompanied by bronchodilator treatment [albuterol (also known as salbutamol outside the United States) by nebulizer or metered-dose inhaler] to stimulate mucociliary clearance and prevent bronchospasm associated with other inhaled agents. A mucolytic agent may be administered to reduce sputum viscosity and enhance clearance.

Dornase alfa (Pulmozyme®) is a recombinant human (rh) DNase that selectively cleaves extracellular deoxyribonucleic acid (DNA). This DNA is released during neutrophil degradation and contributes to the high viscosity of CF sputum. Nebulization of dornase alfa 2.5 mg once or twice daily improves daily pulmonary symptoms and function, reduces pulmonary exacerbations, and improves quality of life.[16] N-acetylcysteine and hypertonic saline are other mucolytic agents that are occasionally used; however, they are not preferred agents due to a greater incidence of bronchospasm and unpleasant odor and taste.[5]

Many patients with CF also have a reactive airways component or concurrent asthma and benefit from long-acting β_2-agonists.[5] Patients with recurrent wheezing or dyspnea who have demonstrated improvement with albuterol should be considered for maintenance therapy, as should patients with bronchodilator-responsive pulmonary function tests. Inhaled corticosteroids may also attenuate reactive airways and reduce airway inflammation in some patients. While many patients appear to respond clinically to these agents, clear benefit in CF has not been established.[1,17] Drug delivery to the site of inflammation is limited by the severity of lung disease, which may prevent maximal efficacy in CF. CF patients who are on inhaled corticosteroids and/or long-acting β_2-agonists should be advised to administer these medications after airway clearance therapies to optimize drug delivery. Montelukast, antihistamines, and/or intranasal steroids are sometimes used for CF patients with a reactive airways or allergic rhinitis component to their disease.

Several systemic therapies aim at reducing airway inflammation. Long-term oral corticosteroids, namely prednisone and prednisolone, have been shown to reduce airway inflammation and improve lung function; however, beneficial effects diminish upon discontinuation. Concern for long-term adverse effects including diabetes, osteoporosis, cataracts, cushingoid effects, growth suppression, and infection limits their use as maintenance therapy.[17] In clinical practice, systemic steroids may be added for short courses in acute exacerbations or for longer treatment of the allergic response to *Aspergillus* colonization (allergic bronchopulmonary aspergillosis or ABPA); however, dose and duration of therapy should be minimized.[1,18]

High-dose ibuprofen to achieve peak concentrations of 50 to 100 mcg/mL (243 to 485 μmol/L) has been shown to slow progression of disease. At high doses, ibuprofen inhibits the lipoxygenase pathway, reducing neutrophil migration and function as well as release of lysosomal enzymes. At the lower concentrations achieved with analgesic dosing, neutrophil migration increases, potentially increasing inflammation.[19,20] The greatest benefit with high-dose ibuprofen is in children 5 to 13 years of age with mild lung disease (FEV_1 greater than 60%). A dose of 20 to 30 mg/kg given twice daily is usually needed to attain these levels, but serum concentration monitoring is necessary due to interpatient variability.[19] Due to the need for therapeutic drug monitoring and concerns regarding long-term safety and tolerability, only a few CF centers currently prescribe high-dose ibuprofen.[1,17]

Azithromycin is a macrolide antibiotic commonly used in CF as an anti-inflammatory agent. The exact mechanism for this activity is unclear, but azithromycin has been shown to improve overall lung function. Proposed mechanisms include interference with *Pseudomonas* alginate biofilm production, bactericidal activity during stationary *Pseudomonas* growth, neutrophil inhibition, interleukin-8 reduction, and reduction in sputum viscosity.[22,23] Due to its long tissue half-life, azithromycin is typically dosed 3 days per week (Monday, Wednesday, and Friday), with a dose of 500 mg for patients weighing at least 40 kg and 250 mg for patients weighing 25 to 39 kg. Alternatively, patients may take 500 mg or 250 mg either every day or only Monday through Friday, based on the same weight parameters. To minimize the risk of selecting for macrolide-resistant non-tuberculous mycobacteria, patients should have a screening acid-fast bacillus sputum culture obtained prior to starting therapy and then every 6 months. Confirmed mycobacterial colonization is usually a contraindication to chronic azithromycin therapy.[17]

Antibiotic Therapy

❺ *Antibiotic therapy is used in three distinct clinical settings within the course of CF. First, in early lung disease, the primary goals are to detect infection early and institute appropriate antibiotic therapy to eradicate infection and delay colonization. Second, once colonization is present, chronic maintenance antibiotics are used to suppress bacterial growth. Third, in acute exacerbations, intensive antibiotics are administered in an attempt to drastically reduce bacterial load and return lung function to pre-exacerbation levels or greater.*[1] ❻ *Antibiotic selection is based on periodic culture and sensitivity data, typically covering all organisms identified over the preceding year. If no culture data are available, empiric antibiotics should cover the most likely organisms for the patient's age group.* Due to altered pharmacokinetics and microorganism resistance, care must be taken to ensure that optimal doses are prescribed (Table 13–1).

Severity of pulmonary symptoms also guides selection of antibiotic regimens for treatment of acute exacerbations. If symptoms are recent in onset and/or mild in severity (e.g., slight increase in cough and sputum production without fever), patients may be treated with oral and inhaled antibiotics for 14 to 21 days on an outpatient basis. Outpatient fluoroquinolone use is common among CF patients infected with *P. aeruginosa*, even in children. Despite concerns regarding cartilage and tendon toxicity in animal studies, clinical practice has not shown an increased risk in children.[23]

To prevent development of resistance and promote synergy, inhaled tobramycin or colistin is usually added to an oral fluoroquinolone for *P. aeruginosa* coverage.[1,3] Methicillin-sensitive *S. aureus* (MSSA) may be treated with oral amoxicillin-clavulanic acid, dicloxacillin, first- or second-generation cephalosporins, trimethoprim-sulfamethoxazole, or clindamycin, depending on sensitivity. Likewise, methicillin-resistant *S. aureus* (MRSA) may be treated with oral trimethoprim-sulfamethoxazole, clindamycin, minocycline, or linezolid. *H. influenzae* often produces

TABLE 13–1. Antibiotic Dosing in Cystic Fibrosis[a]

Antibiotic	Pediatric Dose (mg/kg per day)	Adult Maximum Daily Dose	Interval (Hours)
Intravenous			
Tobramycin, gentamicin[b]	10	None	8–12
Amikacin[b]	30	None	8–12
Ceftazidime	150	6 g	8
Cefepime	150	6 g	8
Piperacillin-tazobactam	400	16 g	6
Ticarcillin-clavulanate	400	12 g	6
Meropenem	120	6 g	8
Aztreonam	200	8 g	6
Ciprofloxacin	30	1.2 g	8–12
Levofloxacin	—	750 mg	24
Nafcillin	200	12	4–6
Vancomycin[b]	40–60	None	8–12
Linezolid	20–30	1.2 g	8–12
Colistin	5–8	480 mg	8
Chloramphenicol[b]	60–80	4 g	6
Oral			
Amoxicillin ± clavulanic acid	45–90	4 g	12
Dicloxacillin	100	2 g	6
Cephalexin	50–100	4 g	6–8
Cefuroxime	30	1 g	12
Trimethoprim-sulfamethoxazole[c]	10–20	640 mg	6–12
Clindamycin	30	1.8 g	6–8
Ciprofloxacin	40	2 g	12
Levofloxacin	—	750 mg	24
Minocycline[d]	4	200 mg	12
Linezolid	20–30	1.2 g	8–12
Inhaled			
Tobramycin	160–600 mg/day	600 mg	12
Colistin	75–150 mg/day	300 mg	12

[a]All doses assume normal renal and hepatic function. Consult a specialized drug reference for dosage adjustment if function is impaired.
[b]Empiric starting doses only. Adjust dose per therapeutic drug monitoring.
[c]Dose based on trimethoprim component.
[d]Children greater than 8 years of age.

β-lactamases but can usually be treated with amoxicillin-clavulanic acid, a cephalosporin, or trimethoprim-sulfamethoxazole. Oral trimethoprim-sulfamethoxazole or minocycline may be used to treat *S. maltophilia*.

For more severe infections or patients failing outpatient therapy, intravenous (IV) antibiotic therapy is started and continued for 2 to 3 weeks. Most patients are admitted to the hospital for initiation of IV antibiotics; however, depending on the availability of home health services, patients may be discharged to finish their course or even receive their entire course at home. ❼ *Typical regimens for severe infections include an antipseudomonal β-lactam plus an aminoglycoside for added synergy and delay of resistance development.*[1,3] Cephalosporins tend to be better tolerated and offer the benefit of administration every 8 hours. Extended-spectrum penicillins have been associated with a higher incidence of allergy. Aztreonam offers the added benefit of little cross-reactivity in penicillin- or cephalosporin-allergic patients; however, it has no gram-positive coverage. Meropenem should be reserved for organisms resistant to all other antibiotics to minimize development of resistance in the carbapenem drug class, as it is the last line of defense against extended-spectrum β-lactamase (ESBL)-producing organisms.

Intravenous tobramycin is generally the first-line aminoglycoside. Isolates are usually resistant to gentamicin, and amikacin is reserved for tobramycin-resistant strains. Pharmacokinetic goals are listed in Table 13–2. In general, higher peak serum concentrations are targeted in CF. As a result, lower serum trough levels are desirable to reduce toxicity.

Some centers use once-daily aminoglycoside dosing to achieve higher peaks and minimize troughs. Since aminoglycosides exhibit concentration-dependent killing, once-daily dosing may optimize this effect; however, time below the minimum inhibitory concentration (MIC) is prolonged with once-daily administration, possibly leading to loss of synergy for a substantial portion of the dosing interval. With once-daily administration, tobramycin is typically dosed at 10 to 15 mg/kg per day and amikacin at 35 mg/kg per day. Long-term studies are needed to examine the efficacy and resistance patterns associated with once-daily aminoglycosides in the CF population.[1,3]

TABLE 13–2. Pharmacokinetic Goals in Cystic Fibrosis

	Traditional Units of Measurement		SI Units of Measurement	
Antibiotic	Goal Peak[a] (mcg/mL)	Goal Trough[b] (mcg/mL)	Goal Peak[a] (μmol/L)	Goal Trough[b] (μmol/L)
Tobramycin, gentamicin	10–12	Less than 1.5	21.4–25.7	Less than 3.2
Amikacin	30–40	Less than 5.0	35.1–46.8	Less than 5.85
Vancomycin	—[c]	10–15	—[c]	7–10.35

[a]Peaks calculated 30 minutes after end of infusion for aminoglycosides. Higher peaks may be targeted with corresponding lower trough concentrations for aminoglycosides.
[b]Troughs calculated immediately prior to the time the dose is due.
[c]Not routinely measured.

Routine use of once-daily aminoglycosides in CF is not recommended and should be limited to adults and older teens, in whom the time below the MIC can be minimized. Due to a shorter half-life, once-daily aminoglycoside dosing does not appear to be optimal for use in younger children.

Most other serious gram-negative infections are also treated with combination therapy. *S. maltophilia* is highly resistant and is most often treated with trimethoprim-sulfamethoxazole or ticarcillin-clavulanate. *A. xylosoxidans* and *B. cepacia* are also highly resistant and may have minimal therapeutic options. In some cases, fluoroquinolones may be substituted for aminoglycosides based on sensitivity data or if renal dysfunction is present. Due to excellent bioavailability, oral fluoroquinolones, trimethoprim-sulfamethoxazole, minocycline, and linezolid should be used whenever possible. Due to toxicity risk, colistin and chloramphenicol are reserved for life-threatening, highly resistant infections. Additional combinations of two or three drugs may be used for highly-resistant organisms based on synergy studies that test susceptibility of different antibiotic combinations.

Inpatient treatment of methicillin-resistant *S. aureus* can consist of IV vancomycin or oral agents as described above, depending on the severity of infection and concomitant organisms. IV vancomycin may also be converted to oral step-down therapy upon discharge.

Chronic maintenance antibiotic therapy may be used in patients with *Pseudomonas* colonization in an attempt to prevent bacterial overgrowth. Some centers advocate regular scheduled CF "clean-outs" with IV or oral antibiotics regardless of symptoms.[5] However, long-term systemic antibiotics are not recommended due to emergence of resistant isolates.[1] Chronic or rotating inhaled antibiotic maintenance therapy has become a more common practice for preventing, treating, and suppressing *P. aeruginosa* colonization.

Inhaled tobramycin (TOBI®) is typically administered to patients 6 years of age and older in alternating 28-day cycles of 300 mg nebulized twice daily, followed by a 28-day washout or "off" period to minimize development of resistance. Long-term intermittent administration improves pulmonary function, decreases microbial burden, and reduces the need for hospitalization for IV therapy.[24,25] Due to minimal systemic absorption, pharmacokinetic monitoring is not necessary with normal renal function. Lower doses of nebulized tobramycin solution for injection have been used in younger children, and studies are underway using 300 mg twice daily in children under age 6.

Nebulized colistin using the IV formulation may be an option in patients with tobramycin-resistant strains or intolerance to inhaled tobramycin. Due to an increased risk of bronchoconstriction after colistin inhalation, patients should pre-treat with albuterol and administer the first doses under medical observation.[1,5]

Inhaled antibiotics are typically stopped during an acute exacerbation requiring IV therapy. Drug delivery is reduced with increased sputum production, and concomitant use of IV aminoglycosides may increase risk of toxicity.

Pharmacokinetic Considerations

CF patients have larger volumes of distribution of many antibiotics due to an increased ratio of lean body mass to total body mass and lower fat stores. CF patients also have an enhanced total body clearance, although the exact mechanism has not been determined. Increased renal clearance, increased glomerular filtration rate, decreased protein binding, increased tubular secretion, decreased tubular reabsorption, extrarenal elimination, and increased metabolism have all been proposed as possible reasons for the increased clearance.

As a result of these pharmacokinetic changes, higher doses of aminoglycosides are needed to achieve target serum levels and promote adequate tissue penetration. Higher doses of β-lactam antibiotics are also needed to achieve and sustain levels above the MIC. Trimethoprim-sulfamethoxazole displays enhanced renal clearance and hepatic metabolism in the CF population. Fluoroquinolones and vancomycin have fewer pharmacokinetic deviations in the CF population; however, higher doses are typically needed to attain inhibitory serum and tissue concentrations against CF pathogens.[26]

Although most CF patients have shorter half-lives and larger volumes of distribution than non-CF patients, some patients exhibit decreased clearance. Possible causes include concomitant use of nephrotoxic medications, presence of diabetic nephropathy, history of transplantation (with immunosuppressant use and/or procedural hypoxic injury), and age-related decline in renal function in older adult patients. Additionally, CF patients are repeatedly exposed to multiple courses of IV aminoglycosides, which can result in decreased renal function. Evaluation of previous pharmacokinetic parameters and trends, along with incorporation of new health information, is key to providing appropriate dosage recommendations.

Gastrointestinal System

Pancreatic enzyme replacement is the mainstay of gastrointestinal therapy. Most enzyme products are formulated as capsules containing enteric-coated microspheres or microtablets to avoid inactivation of enzymes in the acidic stomach; instead, they dissolve in the more alkaline environment of the duodenum. Capsules may be opened and the microbeads swallowed with food, as long as they are not chewed. A powder form is available for patients unable to swallow the capsules or microbeads, but bioavailability is poor. While products may contain similar enzyme ratios, they are not bioequivalent and cannot be substituted. Generic enzyme products generally display poor dissolution and should not be used.[5] Table 13–3 lists commonly used enzyme replacement products.

Pancreatic enzyme doses are initiated at 500 to 1000 units/kg per meal of lipase component with half-doses given with snacks. Infants are typically started at 1500 to 2500 units of

TABLE 13–3. Common Pancreatic Enzyme Replacement Products

Trade Name[a]	Lipase (Units)	Amylase (Units)	Protease (Units)
Enteric-Coated			
Creon® 5	5,000	16,600	18,750
Creon® 10	10,000	33,200	37,500

[a]The number after a trade name refers to the number of thousands of units of lipase contained per dosage form.

lipase per 120 mL of formula or breast milk. Capsules may be opened and beads divided to obtain appropriate doses. Enzymes should be taken at the beginning or divided throughout the meal and must be given with any fat-containing snack. They should not be mixed with alkaline or hot foods, as enzymes may be denatured.

❾ *Titration of pancreatic enzyme doses is based on control of steatorrhea, stool output, and abdominal symptoms.* Doses up to 2500 units/kg per meal may be needed. Higher doses should be used with caution due to the risk of fibrosing colonopathy.[5,6] Patients who respond poorly to maximal doses of one product may benefit from changing to another product.[6] Patients may also benefit from addition of a histamine H_2-receptor antagonist or proton pump inhibitor to boost effective enzyme dose if duodenal pH is not alkaline enough to neutralize residual gastric acid. Antacid therapy is also often used to treat concomitant gastroesophageal reflux, which is common in the CF population.[5,6]

Fat-soluble vitamin supplementation is usually required in pancreatic insufficiency. Specially-formulated products for CF patients (ADEKs® and Vitamax®) are usually sufficient to attain normal serum vitamin levels at a dose of 1 tablet daily for younger children and 2 tablets daily for teenagers and adults. Additional supplementation may be needed in uncontrolled malabsorption or for replacement of severe vitamin deficiency.[5,15] Appetite stimulants such as cyproheptadine may be an option for promoting nutrition and weight gain, but efficacy has not been established.

Ursodiol may slow progression of liver disease. It improves bile flow and may displace toxic bile acids that accumulate in a cholestatic liver, stimulate bicarbonate secretion into the bile, offer a cytoprotective effect, and reduce elevated liver tests. Ursodiol is typically dosed at 15 to 20 mg/kg per day in two divided doses and may be rounded to the nearest tablet size.[5,7]

Treatment of distal intestinal obstruction syndrome (DIOS) consists of oral or nasogastric administration of polyethylene glycol electrolyte (PEG) solutions. Enemas may also be used to facilitate stool clearance. IV fluids are often required to correct dehydration due to vomiting or decreased oral intake. Re-evaluation of enzyme compliance and dosing is essential to prevent further episodes. Patients with recurrent symptoms may require daily PEG administration (Miralax®).[5] Severe presentations of DIOS or initial meconium ileus may require surgical resection.

Endocrine System

Patients with mild CFRD may be managed with dietary modification if their nutritional status will allow carbohydrate control. However, most patients present with poor nutrition and weight loss and require more aggressive treatment. ❿ *Because CFRD results from insulin insufficiency, exogenous insulin replacement is required in most cases.* Many patients can be successfully managed by meal coverage with short- or rapid-acting insulin (regular, lispro, or aspart) dosed by carbohydrate counting. Patients with fasting hyperglycemia or patients receiving nighttime tube feedings typically also require longer-acting basal insulin. Regular home glucose monitoring is essential to appropriate therapy. Little information is available regarding use of oral antidiabetic agents in CFRD, and routine use is not recommended.[5,8]

Musculoskeletal System

CF patients with low bone mineral density and low serum vitamin D levels may improve bone health through supplemental vitamin D analogs beyond those found in standard CF vitamins. The optimal dose and analog have not been determined. For ergocalciferol, a minimum of 400 IU and 800 IU

Patient Encounter, Part 2

Laboratory testing confirms the diagnosis of CF, and Jessica has been referred to her regional CF center for treatment. Additional stool studies indicate the presence of severe fat maldigestion. The pulmonologist indicates that she would like to start Jessica (weight 8.2 kg) on pancreatic enzyme replacement therapy.

- What formulation and dose would you recommend?
- How would you administer the enzymes?
- How would you titrate the dose?

should be taken daily by infants and patients over 1 year of age, respectively. Total weekly doses of 12,000 IU for children less than 5 years of age and 50,000 IU for patients 5 years of age and older may be required to achieve target vitamin D concentrations. Supplemental calcium should be provided if 1300 to 1500 mg of elemental calcium intake cannot be achieved through diet.

Antiresorptive agents (oral or IV bisphosphonates) may be used to treat adult CF patients with osteoporosis. Remaining upright for 30 minutes may be difficult in patients needing to perform airway clearance therapy, so once-weekly dosing should be considered. A high incidence of gastroesophageal reflux and presence of cirrhosis-associated esophageal varices may also complicate therapy and increase the risk of erosive esophagitis. IV pamidronate, dosed at 30 mg every 3 months, has increased bone mineral density in adult CF patients. Studies using IV bisphosphonates in children with CF are underway.

Androgen replacement in male CF patients with documented hypogonadism may also benefit bone health but should be decided on an individual basis.[10,27]

Short courses of non-steroidal anti-inflammatory drugs (NSAIDs) can be used to treat CF-related arthritis and hypertrophic pulmonary osteoarthropathy.[5] The impact on neutrophil recruitment in the lung with long-term NSAID therapy at lower analgesic doses is unknown.

Future Direction of Therapy

Significant strides have been made in past decades with development of new therapies that have led to the ever-lengthening CF life-span. Since the discovery of the CF gene and the CFTR protein defect, research has focused on gene therapy as a way to restore normal CFTR function through DNA transfer.

Pharmacologic approaches are being investigated to correct dysfunctional CFTR by suppressing premature stop codons in the CFTR gene and to activate alternative chloride channels, effectively bypassing dysfunctional CFTR. Additional research is being conducted with anti-inflammatory therapies, anti-pseudomonal vaccines, and development of exogenous cationic antimicrobial peptides to mimic those found naturally in the lung.[1] Development of more effective systemic and inhaled antibiotic agents continues to be a major focus as well.

OUTCOME EVALUATION

Pulmonary System

- Monitor for changes in pulmonary symptoms such as cough, sputum production, respiratory rate, and oxygen saturation. Symptoms of an acute exacerbation should improve with antibiotics and aggressive airway clearance therapy. Pulmonary function tests should be markedly increased after 1 week and trend back to pre-exacerbation levels after 2 weeks of therapy. If improvement lags, 3 weeks of therapy may be needed.
- Obtain serum drug levels for aminoglycosides and/or vancomycin and perform pharmacokinetic analysis. Adjust the dose, if needed, according to the parameters in Table 13–2. Obtain follow-up trough levels at weekly intervals or sooner if renal function is unstable. Follow serum creatinine levels if renal function is unstable. Hearing tests may be scheduled yearly or per patient preference.

Gastrointestinal System

- Monitor short- and long-term nutritional status through evaluation of height, weight, and body mass index. Ideally, parameters should be near the normals for non-CF patients.
- Evaluate the patient's stool patterns. Steatorrhea indicates suboptimal enzyme replacement or non-compliance. Infants should have two to three well-formed stools daily, while older children and adults may have one or two stools.
- Monitor efficacy of vitamin supplementation through yearly serum vitamin levels. Obtain levels more frequently if an identified deficiency is being treated.

Endocrine System

- Monitor blood glucose several times daily in patients with CFRD or those taking systemic corticosteroids. Follow glycosylated hemoglobin levels on an outpatient basis to assess long-term glucose control. Levels may be falsely low in CF due to a shorter red blood cell half-life.

Patient Encounter, Part 3

At Jessica's follow-up appointment 1 month later, her weight is up to 8.8 kg. Her mother reports that she seems to have caught a cold and has been coughing quite a bit of late and has not been eating as well as usual. In clinic, the following vitals are noted: respiratory rate 40/minute, temperature 38.3°C (101°F), and oxygen saturation 92%. The throat culture from her previous visit was positive for *S. aureus* (sensitive to cefazolin, nafcillin, trimethoprim-sulfamethoxazole, clindamycin, vancomycin, and linezolid; resistant to erythromycin) and *P. aeruginosa* (sensitive to ceftazidime, cefepime, piperacillin, aztreonam, meropenem, ciprofloxacin, tobramycin, and amikacin; resistant to gentamicin).

- What antibiotic(s) and dose(s) would you recommend for outpatient therapy?
- What antibiotic(s) and dose(s) would you recommend for inpatient therapy?
- Develop a monitoring plan to assess antibiotic response.

Patient Care and Monitoring

1. Perform a thorough history of prescription, nonprescription, and alternative medications. Assess adherence to the prescribed regimen, including timing of inhaled medications with respect to airway clearance therapies and timing of enzymes and insulin with regard to meals. Is the patient taking any medications not prescribed by the CF center team?
2. Is the patient on all appropriate maintenance medications? Are medications at the appropriate doses for weight and/or age? If the patient is admitted, are maintenance medications ordered?
3. Evaluate the medication regimen for drug interactions, adverse reactions, and allergies.
4. Assess pulmonary symptoms. Review the incidence and quality of cough, dyspnea, respiratory rate, sputum production, and fever. Are the patient's PFTs decreased? Is there an oxygen requirement?
5. Review culture and sensitivity history over the last 1 to 2 years. What antibiotics were used in the past, and did the patient appear to respond better to a particular regimen? Is the patient currently on antibiotics, and if so, are the symptoms improving? Recommend an appropriate antibiotic regimen based on culture and sensitivity data.
6. Review the pharmacokinetic history. Are there any possible changes in clearance since the last antibiotic course? Will the patient be discharged home on IV antibiotics? Can the IV regimen be simplified or made more convenient for home administration? Recommend appropriate doses based on the patient's clearance and an appropriate but convenient schedule.
7. Perform pharmacokinetic adjustments as necessary. Recommend a monitoring plan for the antibiotic course. Are any other laboratory tests necessary? Are signs of toxicity present?
8. Assess nutritional status. Is the patient gaining or maintaining weight according to age? Are any oral supplements or tube feedings being used?
9. Assess gastrointestinal symptoms. What is the quantity and quality of bowel movements? Does the patient have bloating, flatulence, or abdominal pain?
10. Assess quality-of-life measures such as physical, psychological, and social well-being.
11. Understand that CF therapy is complicated, and recommend regimens to ease the care burden if possible.
12. Educate the patient and family, stressing the importance of adherence to the regimen.

14 Gastroesophageal Reflux Disease

Dianne B. Williams and Marie A. Chisholm-Burns

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Explain the underlying causes of gastroesophageal reflux disease (GERD).
2. Differentiate between typical, atypical, and complicated symptoms of GERD.
3. Determine which diagnostic test should be recommended based on the patient's clinical presentation.
4. Identify the desired therapeutic outcomes for patients with GERD.
5. Recommend appropriate lifestyle modifications and pharmacotherapy interventions for patients with GERD.
6. Discuss other nonpharmacologic interventions that may be appropriate for patients with GERD.
7. Formulate a monitoring plan to assess the effectiveness and safety of pharmacotherapy for GERD.
8. Educate patients on appropriate lifestyle modifications and drug therapy issues including compliance, adverse effects, and drug interactions.

Key Concepts

❶ GERD can be divided into three distinct categories: erosive esophagitis, non-erosive reflux disease, and Barrett's esophagus.
❷ Patients with GERD may display symptoms described as (1) typical, (2) atypical, or (3) complicated.
❸ Patients presenting with uncomplicated, typical symptoms of reflux (heartburn and regurgitation) do not usually require invasive esophageal evaluation.
❹ The goals of treatment of GERD are to alleviate symptoms, decrease the frequency of recurrent disease, promote healing of mucosal injury, and prevent complications.
❺ Treatment for GERD involves one or more of the following modalities: (1) lifestyle changes and patient-directed therapy; (2) pharmacologic intervention primarily with acid-suppressing agents; (3) anti-reflux surgery, or (4) endoscopic therapies.
❻ Acid-suppressing therapy is the mainstay of GERD treatment and should be considered for anyone not responding to lifestyle changes and patient-directed therapy after 2 weeks.
❼ Anti-reflux surgery or endoscopic therapies offer an alternative treatment for refractory GERD or when pharmacologic management is undesirable.
❽ Many patients with GERD experience relapse if medication is withdrawn, and long-term maintenance treatment is required in such patients.
❾ Patient medication profiles should be reviewed for drugs that may aggravate GERD.

Gastroesophageal reflux disease (GERD) refers to symptoms or mucosal damage that result from abnormal reflux of gastric contents into the esophagus.[1] ❶ *GERD can be divided into three distinct categories: (1) erosive* ***esophagitis****, (2) non-erosive reflux disease, and (3) Barrett's esophagus.*[2] Erosive esophagitis occurs when the esophagus is repeatedly exposed to refluxed material for prolonged periods (Fig. 14–1). The inflammation that occurs progresses to erosions of the squamous epithelium. Non-erosive reflux disease, also referred to as "symptomatic" GERD or **endoscopy**-negative reflux disease, is associated with severe reflux symptoms with normal endoscopic findings. Barrett's esophagus is a complication of GERD characterized

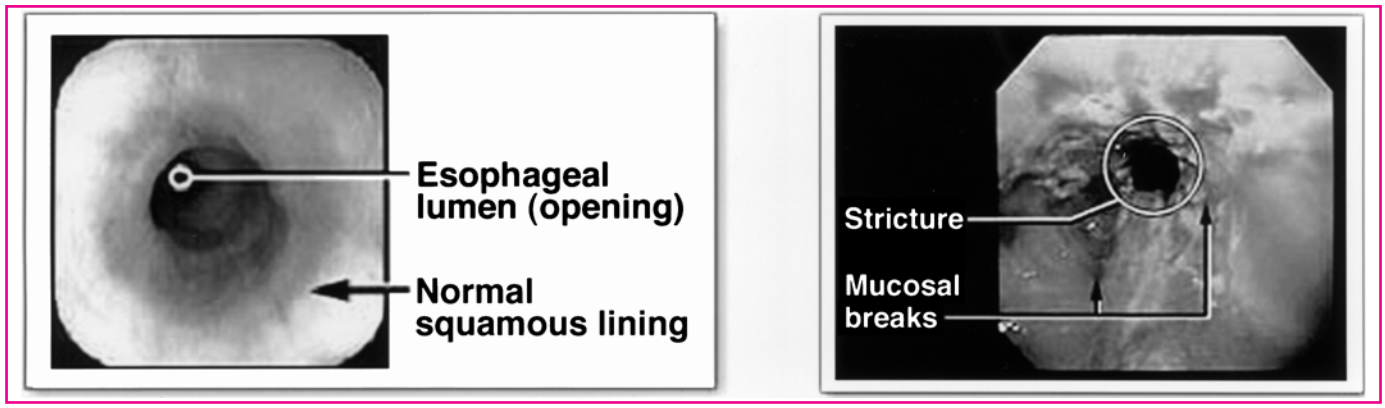

FIGURE 14–1. Endoscopic images of the esophagus. *Left:* Image taken during an endoscopy of the esophagus revealing normal smooth squamous cell lining. *Right:* Narrowed esophageal lumen (stricture) due to chronic GERD with inflammation and scarring. The surrounding esophageal lining has ulcerations and erosions from chronic acid injury. (From Barrett's esophagus website: http://www.barrettsinfo.com.; reprinted with permission.)

by replacement of the normal squamous epithelial lining of the esophagus by specialized columnar-type epithelium. Barrett's esophagus is more likely to occur in patients with a long history (years) of symptomatic reflux and may be a risk factor for developing adenocarcinoma of the esophagus.

EPIDEMIOLOGY AND ETIOLOGY

GERD is prevalent in patients of all ages. Although mortality associated with GERD is rare, symptoms can significantly decrease quality of life. The true prevalence and incidence of GERD are unknown because: (1) many patients do not seek medical treatment; (2) symptoms do not always correlate well with disease severity; and (3) there is no gold standard for diagnosing the disease. The prevalence of erosive esophagitis increases in adults older than 40 years of age. However, non-erosive reflux disease may begin approximately a decade sooner. There does not appear to be a major difference in incidence between men and women except for its association with pregnancy and possibly the non-erosive reflux disease seen in females. Although gender does not play a major role in the development of GERD, it is an important factor in the development of Barrett's esophagus, which occurs more frequently in males.

PATHOPHYSIOLOGY

The retrograde movement of acid or other noxious substances from the stomach into the esophagus is a major factor in the development of GERD.[3] Commonly, gastroesophageal reflux is associated with defective lower esophageal sphincter pressure or function. Problems with other normal mucosal defense mechanisms such as anatomic factors, esophageal clearance, mucosal resistance, gastric emptying, epidermal growth factor, and salivary buffering may also contribute to the development of GERD. Aggressive factors that may promote esophageal damage upon reflux into the esophagus include gastric acid, pepsin, bile acids, and pancreatic enzymes. Therapeutic regimens for GERD are designed to maximize normal mucosal defense mechanisms and attenuate the aggressive factors.

Lower Esophageal Sphincter Pressure

The lower esophageal sphincter is a manometrically-defined zone of the distal esophagus with an elevated basal resting pressure. The sphincter is normally in a tonic, contracted state, preventing the reflux of gastric material from the stomach. It relaxes on swallowing to permit the free passage of food into the stomach.

Mechanisms by which defective lower esophageal sphincter pressure may cause gastroesophageal reflux are three-fold. First, and probably most important, reflux may occur after spontaneous transient lower esophageal sphincter relaxations that are not associated with swallowing.[4] Esophageal distention, vomiting, belching, and retching can cause relaxation of the lower esophageal sphincter. These transient relaxations, which are normal postprandially, may play an important role in intermittent non-erosive reflux.[5] Transient decreases in sphincter pressure are responsible for approximately 65% of the reflux episodes in patients with GERD.

Second, reflux may occur after transient increases in intra-abdominal pressure (stress reflux).[3] An increase in intra-abdominal pressure such as that occurring during straining, bending over, coughing, eating, or a Valsalva maneuver may overcome a weak lower esophageal sphincter, and thus may lead to reflux.

Third, the lower esophageal sphincter may be atonic, thus permitting free reflux. Although transient relaxations are more likely to occur when there is normal lower esophageal sphincter pressure, the latter two mechanisms are more likely

TABLE 14–1. Foods and Medications that may Worsen GERD Symptoms

Decreased Lower Esophageal Sphincter Pressure	
Foods	
Fatty meal	Garlic
Carminatives (peppermint, spearmint)	Onions
Chocolate	Chili peppers
Coffee, cola, tea	
Medications	
Anticholinergics	Isoproterenol
Barbiturates	Narcotics (meperidine, morphine)
Benzodiazepines (e.g., diazepam)	Nicotine (smoking)
Caffeine	Nitrates
Dihydropyridine calcium channel blockers	Phentolamine
Dopamine	Progesterone
Estrogen	Theophylline
Ethanol	
Direct Irritants to the Esophageal Mucosa	
Foods	
Spicy foods	Tomato juice
Orange juice	Coffee
Medications	
Alendronate	Quinidine
Aspirin	Potassium chloride
Iron	
Non-steroidal anti-inflammatory drugs

when the lower esophageal sphincter pressure is decreased by such factors as fatty foods, gastric distention, smoking, or medications.[3] Certain foods and medications may worsen esophageal reflux by decreasing lower esophageal sphincter pressure or by irritating the esophageal mucosa (Table 14–1).[6]

Anatomic Factors

Disruption of the normal anatomic barriers by a hiatal hernia was once thought to be a primary etiology of gastroesophageal reflux and esophagitis. It is now believed that lower esophageal sphincter pressure is a more important factor related to symptoms in patients with hiatal hernia. Although anatomic factors are considered significant by some clinicians, the diagnosis of hiatal hernia is generally considered a separate entity with which reflux may or may not simultaneously occur.

Esophageal Clearance

Many patients with GERD produce normal amounts of acid, but the acid produced spends too much time in contact with the esophageal mucosa. The contact time is dependent on the rate at which the esophagus clears the noxious material, as well as the frequency of reflux. The esophagus is cleared by primary peristalsis in response to swallowing, or by secondary peristalsis in response to esophageal distention and gravitational effects.

Swallowing contributes to esophageal clearance by increasing salivary flow. Saliva contains bicarbonate that buffers the residual gastric material on the surface of the esophagus. The production of saliva decreases with increasing age, making it more difficult to maintain a neutral intra-esophageal pH. Therefore, esophageal damage due to reflux occurs more often in the elderly and patients with **Sjögren's syndrome** or **xerostomia**. Swallowing is also decreased during sleep, which contributes to nocturnal GERD in some patients.

Mucosal Resistance

The esophageal mucosa and submucosa consist of mucus-secreting glands that contain bicarbonate. Bicarbonate moving from the blood to the lumen can neutralize acidic refluxate in the esophagus. When the mucosa is repeatedly exposed to the refluxate in GERD, or if there is a defect in the normal mucosal defenses, hydrogen ions diffuse into the mucosa, leading to the cellular acidification and necrosis that ultimately cause esophagitis.[3]

Gastric Emptying

Gastric volume is related to the amount of material ingested, rate of gastric secretion, rate of gastric emptying, and amount and frequency of duodenal reflux into the stomach. Delayed gastric emptying can lead to increased gastric volume and contribute to reflux. An increase in gastric volume may increase both the frequency of reflux and the amount of gastric fluid available to be refluxed. Factors that increase gastric volume and/or decrease gastric emptying, such as smoking and high-fat meals, are often associated with gastroesophageal reflux. This partially explains the prevalence of postprandial gastroesophageal reflux.

Composition of Refluxate

The composition, pH, and volume of the refluxate are aggressive factors associated with gastroesophageal reflux. Duodenogastric reflux esophagitis or "alkaline esophagitis" refers to esophagitis induced by the reflux of bilious and pancreatic fluid. Although bile acids have both a direct irritant effect on the esophageal mucosa and an indirect effect of increasing hydrogen ion permeability of the mucosa, symptoms are more often related to acid reflux than to bile reflux. The percentage of time that esophageal pH is below 4 is greater for patients with severe disease than for those with mild disease.

The pathophysiology of GERD is a complex process. It is difficult to determine which occurs first: gastroesophageal reflux leading to defective peristalsis with delayed clearing, or an incompetent lower esophageal sphincter pressure leading

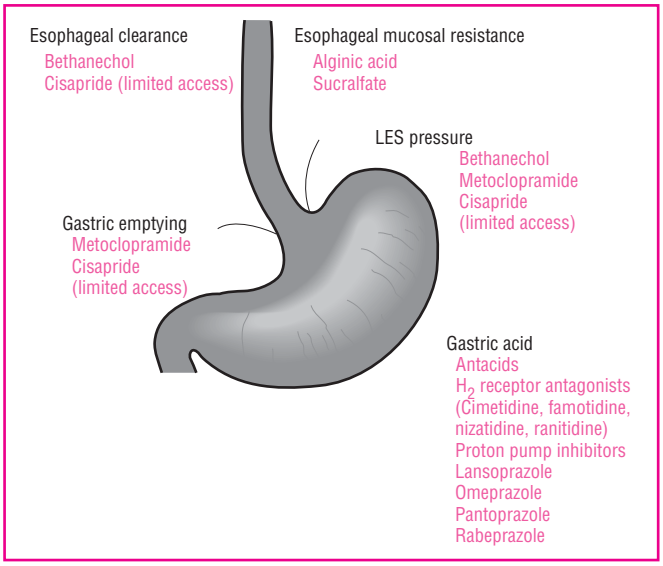

FIGURE 14–2. Therapeutic interventions in the management of gastroesophageal reflux disease. Pharmacologic interventions are targeted at improving defense mechanisms or decreasing aggressive factors. LES, lower esophageal sphincter. (Adapted from Williams DB, Schade RR. Gastroesophageal reflux disease. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 617, with permission.)

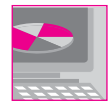
to gastroesophageal reflux. Understanding factors associated with the development of GERD is essential to providing effective treatment (Fig. 14–2).



CLINICAL PRESENTATION AND DIAGNOSIS

❷ *Patients with GERD may display symptoms described as (1) typical, (2) atypical, or (3) complicated (see Clinical Presentation Box).*[7]

Complications of GERD

The severity of symptoms of gastroesophageal reflux does not always correlate with the degree of esophagitis, but it does correlate with the duration of reflux. Patients who are not adequately treated for GERD can develop complications from long-term acid exposure. Long-term, recurrent reflux symptoms that are not adequately treated may lead to Barrett's esophagus and may be an independent risk factor for esophageal adenocarcinoma.[8] Esophageal strictures (Fig. 14–1) may be present in patients presenting with dysphagia.

The use of non-steroidal anti-inflammatory drugs or aspirin is an additional risk factor that may contribute to the development or worsening of esophageal strictures. These complicated symptoms must be distinguished from other esophageal disorders such as esophageal diverticulum, achalasia, obstruction, esophageal spasm, esophageal infections, scleroderma, and malignancy.

Clinical Presentation of GERD

Typical Symptoms

- Heartburn is the hallmark symptom of GERD and is generally described as a substernal sensation of warmth or burning rising up from the abdomen that may radiate to the neck. It may be waxing and waning in character.
- Regurgitation is also very common.
- Symptoms may be worse after a fatty meal, when bending over, or when lying in a recumbent position.[1]
- Other symptoms include water brash (hypersalivation) and belching.

Atypical Symptoms

- Atypical symptoms include non-allergic asthma, chronic cough, hoarseness, pharyngitis, chest pain, and dental erosions.
- In some cases, these extra-esophageal symptoms may be the only ones present, making it more difficult to recognize GERD as the cause, especially when endoscopic studies are normal.
- It is important to distinguish GERD symptoms from those of other diseases, especially when chest pain or pulmonary symptoms are present.

Complicated Symptoms

- These include continual pain, dysphagia (difficulty swallowing), odynophagia (painful swallowing), bleeding, unexplained weight loss, and choking.
- These symptoms may be indicative of complications of GERD such as Barrett's esophagus, esophageal strictures, or esophageal cancer.

Diagnosis of GERD

The most useful tool in the diagnosis of GERD is the clinical history, including both the presenting symptoms and associated risk factors. ❸ *Patients presenting with uncomplicated,*

Patient Encounter, Part 1

A 42-year-old man with a history of diabetes and hypertension presents complaining of "heartburn." He reports a burning sensation in his upper chest and some regurgitation of sour-tasting material into his throat. The symptoms began about 1 month ago, occur about twice a week, and are associated with heavy meals and lying down after eating. He says that he smokes about one pack of cigarettes per day and drinks coffee and alcohol-containing beverages on most days.

- What information is suggestive of GERD?
- Does he have any factors contributing to GERD?
- What additional information do you need before creating a treatment plan for this patient?

typical symptoms of reflux (heartburn and regurgitation) do not usually require invasive esophageal evaluation. These patients generally benefit from a trial of lifestyle modifications and empiric acid-suppressing therapy.[1] A clinical diagnosis of GERD can be assumed in patients who respond to appropriate therapy.

More specific diagnostic tests may be warranted in patients not responding to empiric (prescription) therapy, those with complicated or "alarm" symptoms (e.g., weight loss or dysphagia), or those with long-standing symptoms who are at risk for Barrett's esophagus.

More definitive diagnostic tests include endoscopy (via endoscope or Pillcam™ ESO capsule), 24-hour ambulatory pH monitoring, diagnostic proton pump inhibitor (PPI) administration, or esophageal manometry.

Upper gastrointestinal endoscopy is the preferred diagnostic test for assessing the mucosa for esophagitis and Barrett's esophagus.[1] It enables visualization and biopsy of the esophageal mucosa. Endoscopy should be considered upon initial presentation in any patient who presents with complicated symptoms and those at risk for Barrett's esophagus.[1]

The Pillcam™ ESO allows for visualization of the esophagus via a camera-containing capsule that is swallowed by the patient. Sensors are placed on the chest and are connected to a data collector that downloads images of the esophagus. The entire procedure takes less than 15 minutes and can be done in the physician's office. The camera-containing capsule is eliminated in the stool.

24-Hour ambulatory pH monitoring may be the only way to objectively prove that symptoms are reflux-related in patients with atypical symptoms or non-erosive reflux disease. Ambulatory pH monitoring may also be useful in patients whose symptoms are not improving on adequate doses of acid-suppressing therapy.

The empiric use of a standard-dose (or double-dose) PPI as a therapeutic trial may be used in diagnosing GERD. This approach is less expensive, more convenient, and more readily available than ambulatory pH monitoring. Problems with this diagnostic approach include lack of a standardized dosing regimen and duration of the diagnostic trial.

Esophageal manometry involves placing a multi-lumen tube into the stomach. Pressures are measured as the tube is pulled back across the lower esophageal sphincter, esophagus, and pharynx. Manometry may be useful in determining which surgical procedure is best for a given patient. A newer tubeless pH monitoring system does not require full manometry.

Barium radiography involves the ingestion of barium followed by x-rays of the esophagus. It is more cost effective than endoscopy but is no longer recommended for routine diagnosis of GERD. Barium radiography lacks the sensitivity and specificity needed to determine the presence of mucosal injury, especially in less severe cases, and it cannot distinguish between Barrett's esophagus and esophagitis.

TREATMENT

Desired Outcomes

❹ *The goals of treatment of GERD are to alleviate symptoms, decrease the frequency of recurrent disease, promote healing of mucosal injury, and prevent complications.*

General Approach to Treatment

❺ *Treatment for GERD involves one of the following modalities: (1) lifestyle changes and patient-directed therapy; (2) pharmacologic intervention primarily with acid-suppressing agents; (3) anti-reflux surgery, or (4) endoscopic therapies.* The first therapeutic option used depends upon the patient's condition (i.e., frequency of symptoms, degree of esophagitis, and presence of complications; Table 14–2).

❻ *Acid-suppressing therapy is the mainstay of GERD treatment and should be considered for anyone not responding to lifestyle changes and patient-directed therapy after 2 weeks.* PPIs provide the greatest relief of symptoms and highest rates of healing, especially in patients with erosive disease or moderate to severe symptoms.

Maintenance therapy is generally necessary to control symptoms and to prevent complications. GERD that is refractory to adequate acid suppression is rare. In these cases, the diagnosis should be confirmed through further diagnostic tests before long-term, high-dose therapy or anti-reflux surgery or endoscopic therapies are considered.[1]

Nonpharmacologic Therapy

Nonpharmacologic treatment of GERD includes lifestyle modifications, anti-reflux surgery, or endoscopic therapies.

Lifestyle Modifications

Although most patients do not respond to lifestyle changes alone, the importance of maintaining these lifestyle changes throughout the course of GERD therapy should be stressed to patients on a routine basis. The most common lifestyle changes that a patient should be educated about include: (1) losing weight; (2) elevating the head of the bed; (3) eating smaller meals and avoiding meals 3 hours before sleeping; (4) avoiding foods or medications that exacerbate GERD; (5) smoking cessation; and (6) avoiding alcohol.

A meal high in fat decreases lower esophageal sphincter pressure for 2 hours or more postprandially. In contrast, a high-protein, low-fat meal elevates lower esophageal sphincter pressure. Elevating the head of the bed about 6 to 10 inches with an under-mattress foam wedge (not just elevating the head with pillows) decreases nocturnal esophageal acid contact time and should be recommended.[3]

Patient medications and food histories should be evaluated to identify potential factors that may exacerbate GERD symptoms

TABLE 14–2. Therapeutic Approach to GERD

Patient Presentation	Recommended Treatment Regimen	Comments
Intermittent, mild heartburn	A. Lifestyle modifications **PLUS** B. Antacids • Magnesium/aluminum hydroxide 30 mL after meals and at bedtime as needed • Antacid/alginic acid (Gaviscon) 2 tablets or 15 mL after meals and at bedtime **AND/OR** C. Patient-directed therapy • Over-the-counter H_2RAs (each taken up to twice daily) - Cimetidine 200 mg - Famotidine 10 mg - Nizatidine 75 mg - Ranitidine 75 mg **OR** • Over-the-counter PPI (taken once daily) - Omeprazole 20 mg	• Start lifestyle changes initially and continue throughout the treatment course. • If symptoms are unrelieved with lifestyle changes and over-the-counter medications after 2 weeks, begin therapy with a standard dose acid-suppressing agent.
Symptomatic GERD	A. Lifestyle modifications **PLUS** B. Standard dose acid-suppressing therapy • H_2RAs (taken twice daily) for 6–12 weeks - Cimetidine 400 mg - Famotidine 20 mg - Nizatidine 150 mg - Ranitidine 150 mg **OR** • PPIs (taken once daily) for 4–8 weeks - Esomeprazole 20 mg - Lansoprazole 15–30 mg - Omeprazole 20 mg - Pantoprazole 40 mg - Rabeprazole 20 mg	• For typical symptoms, treat empirically with standard doses of acid-suppressing therapy. • Mild GERD can usually be treated effectively with H_2RAs. Patients with moderate to severe symptoms should receive a PPI as initial therapy. If symptoms are relieved, treat recurrences on an as-needed basis. • If symptoms recur frequently, consider maintenance therapy with the lowest effective dose. • Most patients require standard doses for maintenance therapy.
Healing of erosive esophagitis or treatment of moderate to severe symptoms or complications	A. Lifestyle modifications **PLUS** B. PPIs (taken once-twice daily) for 4–16 weeks - Esomeprazole 20–40 mg - Lansoprazole 30 mg - Omeprazole 20 mg - Rabeprazole 20 mg - Pantoprazole 40 mg	• For atypical symptoms, give a trial of a PPI or H_2RA. • If symptoms are relieved, consider maintenance therapy. • PPIs are the most effective maintenance therapy in patients with atypical symptoms, complicated symptoms, or erosive disease. • Patients not responding to acid-suppressing therapy, including those with persistent atypical symptoms, may be candidates for anti-reflux surgery or endoscopic therapies.

H_2RA, histamine$_2$-receptor antagonist; PPI, proton pump inhibitor.
Adapted from Williams DB, Schade RR. Gastroesophageal reflux disease. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 618, with permission.

(Table 14–1).[6,9,10] Patients should be closely monitored for symptoms when medications known to worsen GERD are started.

Anti-Reflux Surgery and Endoscopic Therapies

❼ *Anti-reflux surgery or endoscopic therapies offer alternative treatments for refractory GERD or when pharmacologic management is undesirable.*

Anti-Reflux Surgery

Surgical intervention is a viable alternative for selected patients with well-documented GERD.[1] The goal of surgery is to re-establish the anti-reflux barrier, to position the lower esophageal sphincter within the abdomen where it is under positive (intra-abdominal) pressure, and to close any associated hiatal defect.[11] It should be considered in patients who (1) fail to respond to pharmacologic treatment; (2) opt for

surgery despite successful treatment because of lifestyle considerations including age, time, or expense of medications; (3) have complications of GERD (Barrett's esophagus or strictures); or (4) have atypical symptoms and reflux documented on 24-hour ambulatory pH monitoring.[11]

Endoscopic Therapies[12]

Three endoscopic approaches to the management of GERD are available. They include: (1) application of radiofrequency energy to the lower esophageal sphincter area; (2) endoscopic suturing to produce a **plication**; and (3) endoscopic injection of a biopolymer at the gastroesophageal junction.[1] More studies and experience are needed to determine their exact role in the management of GERD.

Pharmacologic Therapy

Antacids and Antacid–Alginic Acid Products

Antacids are an appropriate component of treating mild GERD, as they are clearly effective for immediate, symptomatic relief. They are often used concurrently with other acid-suppressing therapies. Patients who require frequent use of antacids for chronic symptoms should be treated with prescription acid-suppressing therapy.

An antacid product combined with alginic acid (Gaviscon) is not a potent neutralizing agent but forms a highly viscous solution that floats on the surface of the gastric contents. This viscous solution serves as a protective barrier for the esophagus against reflux of gastric contents. It also reduces the frequency of the reflux episodes.[13]

Dosage recommendations for antacids vary and range from hourly dosing to administration on an as-needed basis. In general, antacids have a short duration of action, which requires frequent administration throughout the day to provide continuous acid neutralization.

Antacids also have clinically significant drug interactions with tetracycline, ferrous sulfate, isoniazid, quinidine, sulfonylureas, and quinolone antibiotics. Antacid-drug interactions are influenced by antacid composition, dose, dosage schedule, and formulation.

H_2-Receptor Antagonists

The histamine$_2$-receptor antagonists (H_2RAs) cimetidine, famotidine, nizatidine, and ranitidine decrease acid secretion by inhibiting the histamine$_2$-receptors in gastric parietal cells. When given in divided doses, they are effective for patients with mild to moderate GERD.[1] Standard doses provide symptomatic improvement in about 60% of patients after 12 weeks of therapy.[1] Healing rates per endoscopy tend to be lower (50%).[1] Response to the H_2RAs is dependent on (1) the severity of disease, (2) the dosage regimen used, and (3) the duration of therapy.

For symptomatic relief of mild GERD, low-dose, nonprescription H_2RAs may be beneficial. For patients not responding to patient-directed therapy with over-the-counter agents after 2 weeks, standard-dose acid-suppressing therapy is warranted. Although higher doses of H_2RAs may provide greater symptomatic and endoscopic healing rates, limited information exists regarding the safety of these regimens and they can be less effective and more costly than once-daily PPIs.

Because all H_2RAs have similar efficacy, selection of the specific agent should be based on factors such as differences in dosage regimen, safety profile, and cost. In general, H_2RAs are well tolerated. Patients should be monitored for adverse effects and potential drug interactions. Cimetidine may inhibit the metabolism of certain medications such as theophylline, warfarin, phenytoin, nifedipine, or propranolol. An alternate H_2RA should be selected if the patient is taking any of these medications.

Proton Pump Inhibitors

The PPIs esomeprazole, lansoprazole, omeprazole, pantoprazole, and rabeprazole block gastric acid secretion by inhibiting gastric H^+/K^+-adenosine triphosphatase in gastric parietal cells.[14] This produces a profound, long-lasting antisecretory effect capable of maintaining the gastric pH above 4, even during acid surges seen postprandially.[3,5]

The PPIs are superior to H_2RAs in patients with moderate to severe GERD. This includes not only patients with erosive esophagitis or complicated symptoms (Barrett's esophagus or strictures), but also those with non-erosive reflux disease who have moderate to severe symptoms. Symptomatic relief is seen in approximately 83% of patients and healing rates at 8 weeks as judged by endoscopy are 78%.[1]

Whether PPIs can reverse Barrett's esophagus remains a topic for debate. The use of high-dose omeprazole (40 mg twice daily) caused partial regression of Barrett's esophagitis, but no change was noted in patients receiving ranitidine 150 mg twice daily.[14] Others propose that islands of normal squamous cells that appear in patients with Barrett's esophagus after high-dose PPIs may be covering gastric mucosa and may mask the development of cancerous changes in the mucosa.[15] It is unknown whether regression of Barrett's esophagus reduces the risk of adenocarcinoma, but aggressive therapy to suppress acid reflux early in the disease may help prevent Barrett's esophagus.

Comparable daily doses of PPIs are omeprazole 20 mg = esomeprazole 20 mg = lansoprazole 30 mg = rabeprazole 20 mg = pantoprazole 40 mg. The PPIs degrade in acidic environments and are therefore formulated in delayed-release capsules or tablets.[16] Lansoprazole, esomeprazole, and omeprazole contain enteric-coated (pH-sensitive) granules in a capsule form. For patients unable to swallow the capsule or in pediatric patients, the contents of the capsule can be mixed in applesauce or placed in orange juice. If a patient has a nasogastric tube, the contents of an omeprazole capsule can be

mixed in 8.4% sodium bicarbonate solution. Esomeprazole can be mixed with water. Lansoprazole is contained in a packet for oral suspension and a delayed-release orally disintegrating tablet. While lansoprazole dosage forms are beneficial for those who cannot swallow the capsule, such as elderly or pediatric patients, they should not be placed into nasogastric tubes due to potential clogging. Patients taking pantoprazole or rabeprazole should be instructed not to crush, chew, or split the delayed-release tablets.

Pantoprazole, lansoprazole, and esomeprazole are available in intravenous formulations, which offer an alternative route for patients unable to take oral medications. The intravenous product is not more effective than the oral forms and is significantly more expensive.

Patients should be instructed to take their PPI in the morning, 15 to 30 minutes before breakfast to maximize efficacy, because these agents inhibit only actively secreting proton pumps.[5,17] While usually given prior to breakfast, patients with nighttime symptoms may benefit from taking their PPI prior to the evening meal.[1] If a second dose is needed, it should be administered before the evening meal and not at bedtime.[1] Regardless of the time of day, PPIs should be given prior to a meal to gain the most benefit.

The PPIs are generally well tolerated, and the choice of a particular agent is often based on cost. All PPIs can decrease the absorption of drugs (such as ketoconazole or itraconazole) that require an acidic environment to be absorbed. All PPIs are metabolized by the cytochrome P-450 system to some extent, specifically by the CYP2C19 and CYP3A4 enzymes. However, no interactions with lansoprazole, pantoprazole, or rabeprazole have been seen with CYP2C19 substrates such as diazepam, warfarin, or phenytoin.[18] Esomeprazole does not appear to interact with warfarin or phenytoin. Pantoprazole is metabolized by a cytosolic sulfotransferase and is therefore less likely to have significant drug interactions than other PPIs.[17]

While generally not of major concern, omeprazole may inhibit the metabolism of warfarin, diazepam, and phenytoin; lansoprazole may decrease theophylline concentrations. Drug interactions with omeprazole are of particular concern in patients who are considered "slow metabolizers," as are approximately 3% of the Caucasian population. Unfortunately, it is unclear which patients have the polymorphic gene variation that makes them slow metabolizers.[17] The metabolism of esomeprazole may also be altered in patients with this polymorphic gene variation. Patients on potentially interacting drugs should be monitored for development of drug-related problems.

Prolonged hypergastrinemia leading to the development of colonic polyps and potentially adenocarcinoma in rats was a concern that has proven to be unfounded with long-term use in humans.[19] The FDA has stated that there is insufficient evidence linking PPI use to atrophic gastritis, intestinal metaplasia, or gastric cancer.[20]

Prokinetic Agents

The prokinetic agents include cisapride, metoclopramide, and bethanechol. The inferior efficacy and side-effect profiles of metoclopramide and bethanechol limit their use in the treatment of GERD. Metoclopramide may cause tardive dyskinesia, especially with long-term use. In contrast, cisapride has comparable efficacy to H_2RAs in patients with mild esophagitis. Unfortunately, cisapride is no longer available for routine use because of life-threatening arrhythmias that may occur when given with certain medications and other disease states.

Mucosal Protectants

Sucralfate, a non-absorbable aluminum salt of sucrose octasulfate, has very limited value in the treatment of GERD and is not routinely recommended.

Combination Therapy

Two agents of different therapeutic classes should not be routinely used together unless a patient has esophagitis with known motor dysfunction occurring concurrently. In this case, an acid-suppressive agent and a prokinetic agent may be appropriate. Only modest improvements have been shown when a prokinetic agent is combined with a standard dose of an H_2RA. Therefore, patients not responding to standard H_2RA doses should have the dose increased, or they should be switched to a PPI instead of adding a prokinetic agent.

Monotherapy with a PPI is not only more effective in patients not responding to an H_2RA or prokinetic agent alone, but it also improves compliance with once-daily dosing and is ultimately more cost-effective.

Maintenance Therapy

❽ *Many patients with GERD relapse if medication is withdrawn, and long-term maintenance treatment is required in such patients.*[1] Candidates for maintenance therapy include patients whose symptoms return once therapy is discontinued or decreased, patients with complications such as Barrett's esophagus or strictures, and perhaps patients with atypical symptoms.

The goal of maintenance therapy is to improve quality of life by controlling symptoms and preventing complications. These goals cannot generally be achieved by decreasing the dose or switching to a less potent acid-suppressing agent. Most patients require standard doses to prevent relapses.[21] Patients should be counseled on the importance of complying with lifestyle changes and long-term maintenance therapy to prevent recurrence or worsening of disease.

The H_2RAs may be effective maintenance therapy for patients with mild disease.[5] The PPIs are first choice for maintenance treatment of moderate to severe GERD.[22] Preliminary data suggest that "on demand" maintenance therapy may be effective for some patients.[1] With on-demand therapy, patients takes their PPIs only when symptoms occur. However,

patients with more severe disease and/or complications should be maintained on standard daily doses of PPIs for maximum benefit.

Long-term use of higher PPI doses is not indicated unless the patient has complicated symptoms, has erosive esophagitis per endoscopy, or has had further diagnostic evaluation to determine degree and frequency of acid exposure. Anti-reflux surgery and endoscopic therapies may be viable alternatives to long-term drug use for maintenance therapy in selected patients.

Patient Encounter, Part 2: The Medical History, Physical Exam, and Diagnostic Tests

PMH
Type 2 diabetes mellitus since age 36; it is often not well controlled because of poor patient compliance
Hypertension x 3 years, currently controlled
History of hepatitis B

FH
Father died of MI at the age of 68 years; mother is still alive with history of colon cancer and diabetes

SH
Works as a laborer in a warehouse; drinks alcohol most days but denies any alcohol-related problems

Meds
Metformin 1000 mg orally twice daily
Hydrochlorothiazide 25 mg orally once daily
Nifedipine XL 60 mg orally once daily
Regular insulin 4 units SC 3 times daily with meals
Insulin glargine 20 units SC at bedtime

ROS
(+) Heartburn, regurgitation; (–) chest pain, nausea, vomiting, diarrhea, weight loss, change in appetite, shortness of breath or cough, difficulty or painful swallowing

PE
VS: Blood pressure 134/84 mm Hg, pulse 82 beats per minute, respiratory rate 16/minutes, temperature 37°C (98.6°F)
CV: RRR, normal S_1, S_2; no murmurs, rubs, or gallops
Abdomen: Soft, non-tender, non-distended; (+) bowel sounds, (–) hepatosplenomegaly, heme (–) stool
Endoscopy: Diffuse erythema and several isolated erosions in the distal esophagus; no evidence of ulceration, obstruction, or stricture

- Given this additional information, what findings are consistent with a diagnosis of GERD?
- Could any of the medications listed aggravate GERD symptoms in this patient?
- Identify your treatment goals for this patient.
- What nonpharmacologic and pharmacologic options are possible for this patient?

Special Population Considerations

Patients with Atypical GERD Symptoms

Patients presenting with atypical symptoms may require higher doses and longer treatment courses than patients with typical symptoms. These patients are best diagnosed with ambulatory pH testing or an empiric trial with a PPI.[23] These tests can confirm reflux in patients who have persistent symptoms without evidence of mucosal damage by endoscopy.[1] In patients presenting with non-cardiac chest pain, a short course (1 to 8 weeks) of omeprazole 20 mg twice daily has been advocated.[23]

In patients with asthma, anti-reflux medications may improve asthma symptoms and even decrease asthma medication use but cause little or no improvement in lung function.[24] A trial of 3 months has been advocated using twice-daily proton pump inhibitor therapy for asthma symptoms thought to be associated with GERD. Omeprazole doses as high as 60 mg daily have been used.[23] In patients with chronic cough, 24-hour ambulatory pH testing is the preferred approach for evaluation of GERD when available because many patients do not have erosive disease by endoscopy.[25] Maintenance therapy is generally indicated in patients who respond to the therapeutic trial or have evidence of reflux. Anti-reflux surgery or endoscopic therapies may be indicated in selected patients not responding to medical management.

Patients with Endoscopy-Negative Reflux Disease

Although endoscopy is the best diagnostic tool to evaluate the integrity of the esophageal mucosa, it cannot prove that the patient's symptoms are caused by GERD. Patients with typical symptoms and increased acid exposure may have no evidence of esophageal damage. Many patients with persistent, severe symptoms but normal endoscopy require therapy similar to those with positive endoscopic findings.

Patients presenting with normal esophageal mucosa on endoscopy may undergo 24-hour ambulatory pH testing or a therapeutic trial with a PPI to further confirm the diagnosis of GERD.

Pediatric Patients with GERD

Gastroesophageal reflux occurs in approximately 18% of infants. As in adults, transient lower esophageal sphincter relaxations appear to be the most common cause of GERD.[26] This is due to developmental immaturity of the lower esophageal sphincter.[27] Other causes include impaired luminal clearance of gastric acid, neurologic impairment, and type of infant formula.

Most infants have physiologic reflux with no clinical consequence.[26] Complications, although rare, include distal esophagitis, **failure to thrive**, esophageal strictures, and Barrett's esophagus.[27]

Uncomplicated GERD usually resolves by 12 to 18 months of life and responds to supportive therapy, including dietary

adjustments such as smaller meals, more frequent feedings, or thickened infant formula. Postural management (e.g., positioning the infant in an upright position, especially after meals), and reassurance for the parents may also be helpful.[27] Medical therapy may be indicated if there is no improvement.

The combination of a prokinetic agent and acid-suppressing drug is used commonly in pediatric patients with GERD.[27] Monotherapy with an H_2RA is also used frequently; ranitidine 2 to 4 mg/kg/day is effective in neonates and pediatric patients.

Use of PPIs is becoming more common in pediatrics. Lansoprazole is FDA-approved for treating symptomatic and erosive GERD in patients 1 through 11 years of age. The recommended dose is 15 mg once daily for children weighing less than or equal to 30 kg and 30 mg once daily for those weighing greater than 30 kg. Although omeprazole is not FDA-approved for use in children, evidence supports its effectiveness in children with GERD. A common dose for esophagitis is omeprazole 1 mg/kg/day (given once or twice daily).[28] Although no major adverse events have been noted in children receiving PPIs for up to 7 years, the safety of prolonged use in children is unknown.[28] There are no data evaluating the use of esomeprazole, pantoprazole, or rabeprazole in treating GERD in children.

Elderly Patients with GERD

Older individuals have decreased host defense mechanisms such as slowed gastric emptying and decreased saliva production. They may present with atypical symptoms such as chest pain, asthma, hoarseness, coughing, wheezing, or poor dentition. These patients often do not seek medical attention because they believe their symptoms are part of the normal aging process.

A PPI may be warranted in patients older than 60 years of age.[29] Proton pump inhibitors are the most useful option because they have superior efficacy and are dosed once daily. Elderly patients may be sensitive to the central nervous system effects of metoclopramide and H_2RAs.

Patient Encounter, Part 3: Creating a Care Plan

Based on the information presented, create a care plan for this patient's GERD. Your plan should include: (1) a statement of the drug-related needs and/or problems; (2) the goals of therapy; (3) a patient-specific detailed therapeutic plan; and (4) a plan for follow-up to determine whether the goals have been achieved and adverse effects avoided.

OUTCOME EVALUATION

- Monitor for symptom relief and the presence of complicated symptoms, such as difficulty swallowing, painful swallowing, or unexplained weight loss.
- Record the frequency and severity of symptoms by interviewing the patient after 6 to 8 weeks of acid-suppressing therapy. Continued symptoms may indicate the need for long-term maintenance therapy.
- Monitor for adverse drug reactions, drug-drug interactions, and compliance with the therapeutic regimen initially and any time there is a change in symptoms or medications.
- Educate patients about symptoms that suggest the presence of complications requiring immediate medical attention, such as dysphagia or odynophagia.
- Refer patients who present with atypical symptoms such as cough, non-allergic asthma, or chest pain to their physician for further diagnostic evaluation.

Patient Care and Monitoring

1. Assess patient symptoms to determine if further diagnostic evaluation is necessary. Does the patient have any GERD-related complications such as difficulty swallowing, painful swallowing, or unexplained weight loss?
2. ❾ *Perform a thorough medication history (nonprescription, prescription, and natural drug products), food, and patient history to determine exacerbating factors.*
3. Determine what treatments have been helpful in the past.
4. Instruct the patient to avoid foods that aggravate GERD symptoms.
5. Educate the patient on lifestyle modifications to improve symptoms.
6. Review the results of diagnostic tests.
7. Recommend appropriate therapy and develop a plan to assess effectiveness.
8. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.
9. Stress the importance of compliance with the therapeutic regimen.
10. Determine if long-term maintenance treatment is necessary.
11. Assess improvement in quality-of-life measures such as physical, psychological, and social functioning and well-being.
12. Provide patient education on disease, lifestyle modifications, and drug therapy:
    - What causes GERD and what are things to avoid?
    - What are possible complications of GERD?
    - When should medications be taken?
    - What potential adverse effects may occur?
    - Which drugs may interact with their therapy?
    - What warning signs should be reported to the physician?

ABBREVIATIONS

GERD: gastroesophageal reflux disease
H_2RA: histamine$_2$-receptor antagonist
LES: lower esophageal sphincter
PPI: proton pump inhibitor

15 Peptic Ulcer Disease

Jeffrey J. Fong and John W. Devlin

Learning Objectives

Upon completion of the chapter the reader will be able to:

1. Recognize differences between ulcers induced by *Helicobacter pylori* (HP) and non-steroidal anti-inflammatory drugs (NSAIDs) in terms of risk factors, pathogenesis, signs and symptoms, clinical course, and prognosis.
2. Identify desired therapeutic outcomes for patients with HP-associated ulcers and NSAID-induced ulcers.
3. Identify factors that guide selection of an HP eradication regimen and improve compliance with these regimens.
4. Determine the appropriate management for a patient taking a non-selective NSAID who is at high risk for ulcer-related gastrointestinal complications or who develops an ulcer.
5. Devise an algorithm for evaluation and treatment of a patient with signs and symptoms suggestive of an HP-associated or NSAID-induced ulcer.
6. Given patient-specific information and the prescribed drug treatment regimen, formulate a monitoring plan for a patient who is receiving drug therapy to either eradicate HP or to treat an active NSAID-induced ulcer or gastrointestinal complication.

Key Concepts

❶ Patients with peptic ulcer disease should avoid exposure to factors known to worsen the disease, exacerbate symptoms, or lead to ulcer recurrence [e.g., non-steroidal anti-inflammatory drug (NSAID) use or cigarette smoking].

❷ Reliance on conventional antiulcer drug therapy as an alternative to *Helicobacter pylori* (HP) eradication is discouraged because it is associated with a higher incidence of ulcer recurrence and side effects.

❸ Eradication therapy with a proton pump inhibitor–based three-drug regimen should be considered for all patients who test positive for HP and have an active ulcer or a documented history of either an ulcer or ulcer-related complication. Different antibiotics should be used if a second course of HP eradication therapy is required.

❹ In patients at risk for NSAID-induced ulcers, proton pump inhibitors (PPIs) at standard doses reduce the risk of both gastric and duodenal ulcers as effectively as misoprostol and are generally better tolerated.

❺ Selective cyclooxygenase-2 (COX-2) inhibitors have not been shown to be any more effective than the combination of a PPI and a non-selective NSAID in reducing the incidence of ulcers, and questions regarding their long-term cardiovascular safety remain.

❻ Low-dose maintenance therapy with a proton pump inhibitor or histamine$_2$-receptor antagonist is only indicated for patients who fail HP eradication, have HP-negative ulcers, or develop severe complications related to their ulcer disease.

Peptic ulcer disease (PUD) refers to an ulcer that forms on the muscular mucosa in the wall of the gastrointestinal tract. These **ulcerations** are usually located in the duodenum or stomach but can be found elsewhere in the gastrointestinal tract. Peptic ulcer disease is common and may adversely affect quality of life unless properly diagnosed and treated. The high prevalence and relapse rate associated with PUD pose a substantial economic burden. Peptic ulcers are most commonly caused by one of three etiologies: (1) HP infection, (2) use of NSAIDs; or (3) stress-related mucosal damage (SRMD). A number of pathophysiologic variables can be used to distinguish these three common types of peptic ulcer (Table 15–1). This chapter will focus on strategies to optimize pharmacotherapy for patients with PUD related to HP or NSAID therapy.

TABLE 15–1. Characteristics of Common Causes of Peptic Ulcer Disease

	H. pylori	NSAID	SRMD
Onset	Chronic	Chronic	Acute
Primary location of damage	Duodenum	Stomach	Stomach
Presence of symptoms	Frequent	Rare	Rare
Primary mechanism for ulceration	Infection resulting in inflammatory state	Loss of defense mechanisms	Loss of defense mechanisms
Depth of ulcers	Superficial	Deep	Superficial
Dependence on acid for mucosal damage	Greater	Lesser	Lesser
Characterization of GI bleeding	Minor	Major	Major
Responsive to acid-suppressive therapy	No	Yes	Yes

GI, gastrointestinal; *H. pylori, Helicobacter pylori*; NSAID, non-steroidal anti-inflammatory drug; SRMD, stress-related mucosal damage.

Stress-related mucosal damage occurs most frequently in critically ill patients and is thought to be caused by factors such as compromised mesenteric perfusion rather than HP or NSAIDs. Its onset is usually acute, and in a small proportion of patients may progress to deep ulceration and hemorrhage.

Less common causes of peptic ulceration include Zollinger-Ellison syndrome (ZES), cancer chemotherapy, radiation, and vascular insufficiency. ZES is caused by a gastrin-producing tumor called a gastrinoma and results in gastric acid hypersecretion. High-dose oral proton pump inhibitor (PPI) therapy is the initial treatment of choice for ZES; intermittent intravenous PPI therapy may be required for any patient in whom oral therapy is contraindicated.[1]

EPIDEMIOLOGY AND ETIOLOGY

Approximately, 25 million Americans are affected by PUD, with the lifetime prevalence estimated to be 12% in men and 10% in women.[2] Annual direct and indirect costs associated with PUD in the United States are estimated to be more than $9 billion. Despite the widespread use of conventional anti-ulcer therapy that effectively reduces gastric acid secretion, ulcers frequently recur, with 1-year recurrence rates (after ulcer initial healing) estimated to range from 60% to 100%.[1]

Helicobacter pylori infection and NSAID use account for most cases of PUD. The relatively high incidence of PUD in the elderly may be due to higher NSAID use. Although hospitalizations related to PUD have decreased over the past two decades, the incidence of PUD-related complications such as bleeding and perforation remain unchanged.

In general, ulcers related to HP infection more commonly affect the duodenum whereas ulcers related to NSAIDs more frequently affect the stomach. However, ulcers may be found in either location from either cause. Gastric ulcers (GUs) tend to occur much later in life than duodenal ulcers (DUs), with the peak incidence of GU occurring in patients over 60 years of age. Malignancy is more commonly found with GU than DU.

Helicobacter pylori

Since its discovery nearly 25 years ago, the role of HP in PUD has been increasingly recognized, and it is now one of the most common causes of PUD.[3] While HP causes **gastritis** in all infected patients, only a small proportion of patients actually develop PUD.

Helicobacter pylori normally resides in the human stomach and is transmitted via the fecal-oral route or through ingestion of fecal-contaminated water or food. Infection with HP is more common in developing countries because of crowded conditions and the presence of contaminated food and water. HP colonization does not necessarily reflect an active infection since the organism can attach itself to the gastric epithelium

Patient Encounter 1

PUD Secondary to *Helicobacter pylori*

A 51-year-old woman presents to the emergency department complaining of abdominal pain for the past 3 days and dark tarry stools over the past 2 days. She states that she has never had these symptoms before and that she has been feeling weak and tired for the past 2 weeks. She denies having bright red blood in her stools or vomiting. She does not take any prescription medications and only takes extra-strength acetaminophen for occasional headaches.

PMH

Hypertension × 10 years

FH

Mother died of a stroke at age 81, father died of pneumonia at age 71

SH

Denies alcohol, tobacco, or illicit drug use

Allergies: No known drug allergies

Meds

Acetaminophen extra-strength 2 tablets every 6 hours as needed for occasional headache

- Which signs and symptoms are suggestive of PUD?
- What are this patient's risk factors for PUD?
- What additional information do you need to know before creating a treatment plan for this patient?

without invading cells. Cellular invasion by HP is necessary for an active infection, which is usually asymptomatic and leads to chronic active gastritis.

Non-steroidal Anti-Inflammatory Drugs

NSAIDs are one of the most widely used classes of medications in the United States, particularly in the elderly.[4] More than 20,000 deaths occur in the United States per year as a direct result of adverse events related to NSAID use. Chronic NSAID ingestion leads to symptoms of nausea and dyspepsia in nearly half of patients. Peptic ulceration occurs in up to 30% of patients who use NSAIDs chronically, with gastrointestinal bleeding or perforation occurring in 1.5% of patients who develop an ulcer. NSAID-related peptic ulcers usually occur in the stomach; duodenal ulcers are much less common.

Risk factors for NSAID-induced peptic ulcers and complications are presented in Table 15–2. Several important principles should be considered when estimating the risk for developing PUD in a patient taking an NSAID (1) risk factors are generally additive; (2) some risk factors (e.g., corticosteroid therapy) are not by themselves a risk factor for ulceration but increase PUD risk substantially when combined with NSAID therapy; and (3) many of the risk factors postulated to increase PUD risk in a patient taking an NSAID (e.g., rheumatoid arthritis, tobacco smoking, alcohol consumption) remain unproven and thus should not generally be considered independent risk factors for NSAID-induced ulceration.[5]

TABLE 15–2. Established Risk Factors for Ulcers and Gastrointestinal Complications Related to NSAID Use

Age over 60
Concomitant anticoagulant use
Preexisting coagulopathy (elevated INR or thrombocytopenia)
Concomitant corticosteroid therapy
Previous peptic ulcer disease or upper gastrointestinal bleeding
Cardiovascular disease and other comorbid conditions
Multiple NSAID use (e.g., low-dose aspirin in conjunction with another NSAID)
Duration of NSAID use (greater than 1 month)
High-dose NSAID use
NSAID-related dyspepsia

INR, International Normalized Ratio; NSAID, non-steroidal anti-inflammatory drug.

Patient Encounter 2

PUD Secondary to NSAID use

A 65-year-old man with a history of osteoarthritis and chronic obstructive pulmonary disease (COPD) comes to your clinic complaining of burning abdominal pain. The pain has worsened over the past 2 weeks; it is worse at night and after meals.

PMH

Osteoarthritis for 5 years, started diclofenac within the past 2 months
COPD for 15 years

FH

Non-contributory

SH

Tobacco 1 pack per day × 40 years; drinks 2 beers/day

Meds

Ipratropium metered dose inhaler (MDI) 2 puffs every 6 hours
Albuterol MDI 2 puffs every 4 hours as needed
Prednisone 10 mg daily
Diclofenac 75 mg two times a day
Aspirin 81 mg daily

- Which signs and symptoms are suggestive of PUD?
- What are this patient's risk factors for PUD?
- What additional information do you need to know before creating a treatment plan for this patient?

Other Causative Factors

Cigarette smoking is associated with a higher prevalence of ulcers and may also impair healing of ulcers that develop.[6] The exact mechanism(s) for the detrimental effects of smoking on the gastric mucosa are unclear but may involve increased pepsin secretion, duodenogastric reflux of bile salts, elevated levels of free radicals, and reduced bicarbonate and **prostaglandin** production.[7,8] It is unknown whether nicotine or one of the many other ingredients found in cigarettes is responsible for these deleterious effects.

Until the discovery of HP, psychological stress was considered one of the primary causes of PUD. Although psychosocial factors such as life stress, baseline personality patterns, and depression may influence PUD prevalence, a clear causal relationship has not been demonstrated.

Dietary factors such as coffee, tea, cola, beer, and a highly-spiced diet may cause dyspepsia, but they have not been shown to independently increase PUD risk. Although caffeine increases gastric acid secretion and alcohol ingestion causes acute gastritis, there is inconclusive evidence to confirm that either of these substances are independent risk factors for peptic ulcers.

PATHOPHYSIOLOGY

Ulcer formation is the net result of a lack of homeostasis between factors within the gastrointestinal tract responsible for the breakdown of food (e.g., gastric acid and pepsin) and factors that promote epithelial defense and repair (e.g., bicarbonate, mucus secretion, and prostaglandins).

Gastric Acid and Pepsin

Hydrochloric acid and pepsin are the primary substances that cause gastric mucosal damage in PUD. Three different stimuli

(i.e., histamine, acetylcholine, and gastrin) are responsible for acid secretion through their interactions with the histaminic, cholinergic, and gastrin receptors on the surface of parietal cells. Gastric acid output occurs in two stages: (1) basal acid output (BAO), which reflects the baseline output of acid during the fasting state; and (2) maximal acid output (MAO), which occurs in response to meals. Basal acid secretion follows a **circadian** cycle in which it is highest at night and lowest in the morning and is modulated by the effects of acetylcholine and histamine acting on the parietal cell.

Food can cause maximal gastric acid secretion in two ways. In the cephalic phase of acid secretion, the vagus nerve stimulates acid secretion in response to the sight, smell, or taste of food. In both the gastric and intestinal phases of acid secretion, the physical distention caused by food in the gastric fundus and small intestine induces gastrin secretion resulting in acid production. After stimulation by histamine, acetylcholine, and gastrin, acid is secreted by the H^+-K^+-ATPase (proton) pump, located on the luminal side of parietal cells. Acid secretion in PUD is usually normal or slightly elevated. NSAID ingestion usually does not affect acid secretion, whereas HP infection usually leads to a slight increase in acid output. This is in contrast to ZES, in which acid secretion is substantially elevated.

Pepsinogen released during food digestion is converted to pepsin in the presence of an acidic environment and plays a key role in the initiation of protein digestion, **proteolysis** of collagen, and as a signal for the release of other digestive enzymes such as gastrin and cholecystokinin. The proteolytic activity of pepsin appears to influence ulcer formation.

Mucosal Defense and Repair

Several defense and repair mechanisms are responsible for preventing mucosal damage and subsequent ulcer formation. Mucus gel, through its buffering action, is the primary source of defense for the gastric epithelial surface against gastric acid. It allows an acidic environment to be maintained in the lumen but a near neutral pH to be maintained on the epithelial lining. On the epithelial lining, a number of protective mechanisms are responsible for the repair of damaged cells, production of defense mechanisms, and the promotion of epithelial growth.

Prostaglandins, one of the most important epithelial growth factors, inhibit gastric acid secretion and have numerous mucosal protective effects, the most important of which include the stimulation of both mucus and phospholipid production, promotion of bicarbonate secretion, and increased mucosal cell turnover. Damage to the mucosal defense system is the primary method by which HP or NSAIDs cause peptic ulcers.

Helicobacter pylori

Helicobacter pylori is a gram-negative microaerophilic rod that has a number of adaptive functions allowing it to live within the acidic environment of the stomach. It is an S-shaped bacterium with multiple flagella that initially inhabits the gastric antrum but migrates to the more proximal sections of the stomach over time. The motility provided by the flagella allows it to penetrate the mucous gel barrier, thus permitting a direct interaction with epithelial cells—the site where acute infection occurs. HP is able to survive in the acidic conditions of the stomach because of its ability to induce a transient **hypochlorhydria** via production of urease, an enzyme that hydrolyzes urea into carbon dioxide and ammonia.

A number of host and pathogenic factors contribute to the ability of HP to cause gastroduodenal mucosal injury including: (1) direct mucosal damage; (2) alterations to host inflammatory responses; and (3) hypergastrinemia leading to a state of elevated acid secretion. Bacterial-surface adhesion components facilitate binding of HP to epithelial cells, and vacuolating cytotoxin (vac A) facilitates the binding of HP to the cell membrane, thus enabling the HP organism better access to nutrients. The cag pathogenicity island (*cag*-PAI) leads to the release of cytokines thus leading to a chronic inflammatory state in HP-infected patients.[3] The complex interplay between bacterial virulence factors and an enhanced inflammatory response results in a chronic HP infection that elevates acid production and reduces various protective factors.

Non-steroidal Anti-Inflammatory Drugs

Non-selective NSAIDs [those that inhibit both cyclooxygenase-1 and -2 (COX-1 and COX-2)] cause gastric mucosal damage by two primary mechanisms: (1) a direct toxic interaction; and (2) systemic pharmacologic actions.

Direct irritation of the mucosal lining by NSAIDs occurs because NSAIDs are weak acids. Topical irritation is therefore most pronounced with more acidic NSAIDs such as aspirin. While the direct irritant effects of NSAIDs play a contributory role in the development of NSAID-induced gastritis, this mechanism generally plays a minor role in the evolution of NSAID-induced PUD.

The systemic effects of NSAIDs are the primary cause of PUD. Cyclooxygenase (COX) is the rate-limiting enzyme in the prostaglandin synthesis pathway (Fig. 15–1). Inhibition of prostaglandin production is the primary therapeutic effect of NSAIDs. COX is responsible for the conversion of arachidonic acid to prostaglandins (PGs) such as PGG_2 and PGH_2. There are two forms of the COX enzyme, cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2). COX-1 is routinely found in body tissues that produce prostaglandins for normal physiologic maintenance. In contrast, COX-2 is an inducible enzyme that is expressed during states in which cytokines and inflammatory mediators are elevated (e.g., fever and pain). Inhibition of the COX-1 isoenzyme decreases production of endogenous prostaglandins, particularly PGE_1, PGE_2, and PGI_2. Administration of NSAIDs parenterally (e.g., ketorolac) or rectally (e.g., indomethacin) is associated with an incidence of PUD that is similar to that with oral NSAIDs.

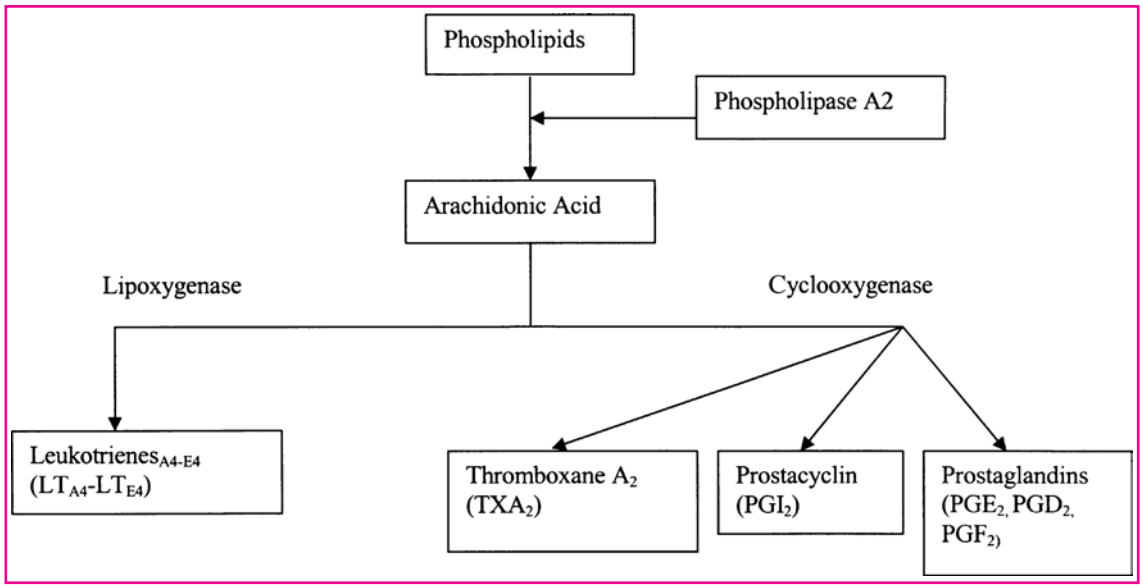

FIGURE 15–1. The arachidonic acid pathway.

Prostaglandins, through their effects on mucous cell secretion, basal bicarbonate secretion, and mucosal growth, are important factors in gastric healing and protection. Inhibition of prostaglandin production by NSAIDs compromises these important protective mechanisms. Finally, the antiplatelet effects of NSAIDs may worsen bleeding complications associated with PUD.

COMPLICATIONS

Hemorrhage is the most common complication of PUD and may occur when an ulcer erodes the wall of a gastric or duodenal artery. Bleeding occurs in approximately 15% of PUD patients and is more frequently seen in patients greater than 60 years of age, particularly those who ingest NSAIDs. Up to 20% of patients who develop a PUD-related hemorrhage do not have prior symptoms.

Gastric outlet obstruction occurs in approximately 2% of patients with PUD and is usually caused by ulcer-related inflammation or scar formation near the peripyloric region. Signs and symptoms of outlet obstruction include early satiety after meals, nausea, vomiting, abdominal pain, and weight loss. Ulcer healing with conventional acid-suppressive therapy is the primary treatment, but if this is unsuccessful then an endoscopic procedure (e.g., balloon dilation) is required.

CLINICAL PRESENTATION AND DIAGNOSIS

Diagnosis

Diagnostic tests for the presence of HP can be either endoscopic or non-endoscopic. Endoscopic diagnosis requires the extraction of gastric tissue samples that are subsequently tested for HP.[9] Although endoscopy is the gold standard for detecting HP infections, it may be associated with rare but severe complications and greater expense than non-endoscopic diagnostic methods. Endoscopy is therefore usually reserved for patients greater than 50 years of age who have anemia, gastrointestinal bleeding, or unexplained weight loss.

Non-endoscopic testing methods include the urea breath test, serologic testing, and the stool antigen assay. Compared to endoscopic procedures, these tests are more comfortable, less expensive, and do not require a special procedure. The urea breath test is usually the first-line test to detect active

Presentation of Peptic Ulcer Disease

Symptoms

- Mild epigastric pain that may be described as burning, gnawing, or aching in character.
- Abdominal pain may be described as burning or a feeling of discomfort.
- Some patients report nocturnal pain.
- The severity of pain often fluctuates.
- The intensity of pain can vary widely (e.g., from dull to sharp).
- Pain often occurs 1 to 3 hours after meals.
- Patients may also complain of heartburn, belching, bloating, nausea, or vomiting.

Signs

- Weight loss may be associated with nausea and vomiting.
- Complications such as bleeding, perforation, or obstruction may occur.
- Alarm signs and symptoms include: bleeding, anemia, tarry stools or "coffee-grounds" emesis, and weight loss.

Patient Encounter 1, Part 2: Physical Examination, Laboratory Tests, and Diagnostic Procedures

PE
VS: blood pressure 135/90 mm Hg, pulse 89 beats per minute, respiratory rate 14/minutes, temperature 37.5°C

HP infection because it has a sensitivity and specificity greater than 95% and a short turnaround time (2 days). Concomitant acid-suppressive or antibiotic therapy may give false-negatives with this test.

Office-based serologic testing provides a quick assessment (within 15 minutes) of an exposure to HP, but patients can remain seropositive for up to 1 year after eradication, making the clinical utility of this test limited. Stool antigen assays can be useful for the initial diagnosis or to confirm HP eradication, and unlike the urea breath test, are less affected by concomitant medication use.[9]

Radiologic and/or endoscopic procedures are usually required to objectively document the presence of ulcers. Barium studies have a high sensitivity and are considered first-line tests to radiographically document an ulcer. However, the cost and complexity of all of these tests has led to the promotion of an early empiric treatment strategy for patients at low risk for PUD-related sequelae (e.g., malignancy). An empiric treatment strategy is appropriate for patients less than 50 years of age who have mild or intermittent epigastric symptoms and no evidence of PUD-related systemic symptoms or complications.

TREATMENT

The treatment selected for PUD depends on the following factors: (1) the etiology of the ulcer; (2) whether the ulcer is new or recurrent; and (3) the presence of any ulcer-related complications. Figure 15–2 contains an algorithm for the evaluation and treatment of a patient with signs and symptoms suggestive of an *H. pylori*–associated or NSAID-induced ulcer.

Desired Outcomes

The goals of PUD therapy are to: (1) resolve symptoms; (2) reduce acid secretion; (3) promote epithelial healing; (4) prevent ulcer-related complications; and (5) prevent ulcer recurrence. For HP-related PUD, eradication of HP is an additional outcome.

Nonpharmacologic Therapy

❶ *Patients with PUD should avoid exposure to factors known to worsen the disease, exacerbate symptoms, or lead to ulcer recurrence.* Patients should be advised to reduce psychological

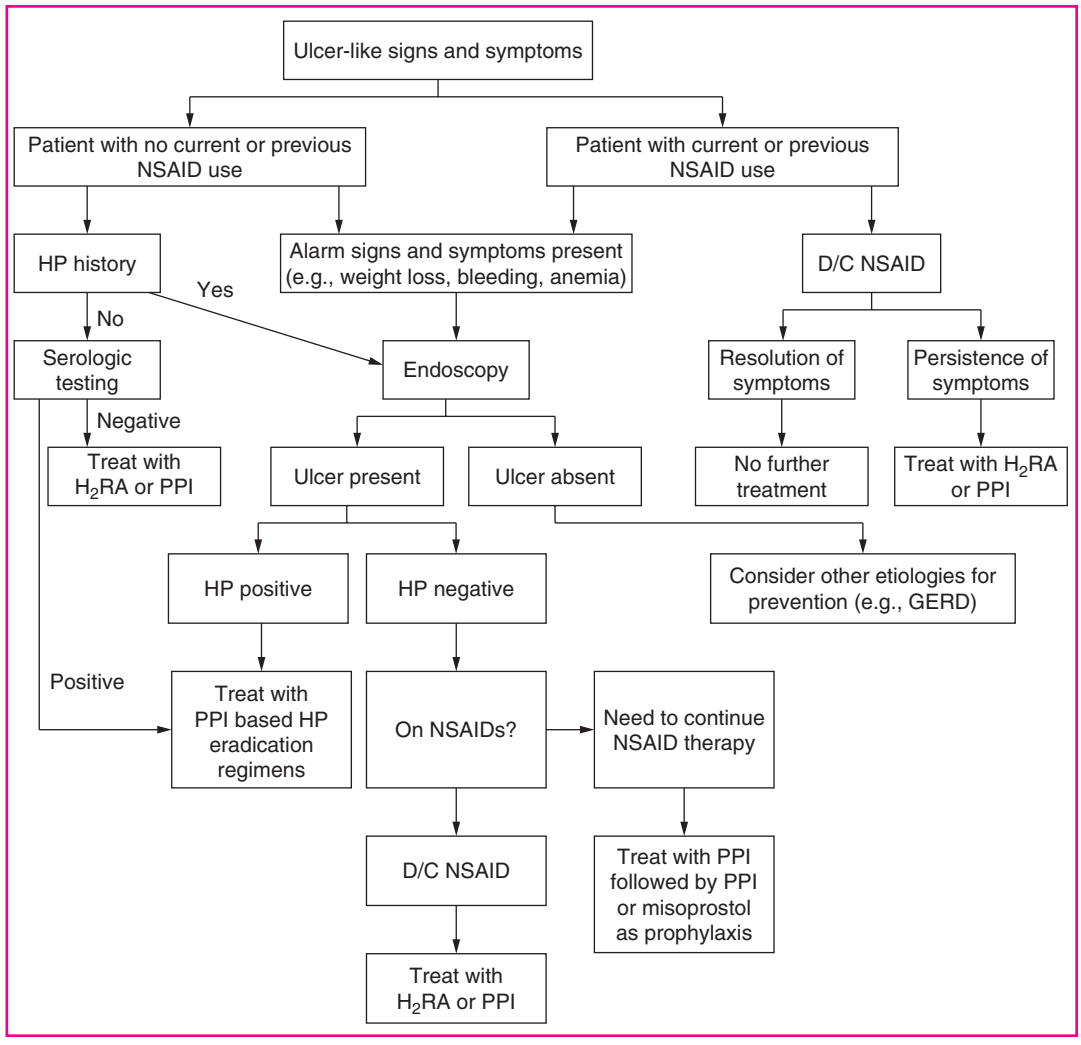

FIGURE 15–2. Approach to the patient presenting with ulcer-like symptoms. New York: McGraw-Hill; 2005: 637, with permission.)

stress and avoid cigarette smoking, alcohol consumption, foods or beverages that exacerbate ulcer symptoms, and NSAID or aspirin use.[10,11]

The high success rates of medical therapies have reduced the number of surgical procedures performed and relegated surgery primarily to elective situations. For this reason, surgical interventions are generally reserved for complicated or refractory PUD. Some surgical procedures include: (1) **vagotomy** and **pyloroplasty**; (2) highly-selective vagotomy; or (3) vagotomy combined with **antrectomy**. Vagotomy is the central component of most procedures because of its targeted effects on blocking further acid secretion. These procedures are associated with a high success rate. Complications are rare but can include dumping syndrome, bile reflux, diarrhea, malabsorption and gastric atony.[12]

Pharmacologic Therapy

Treatment of *Helicobacter pylori*–Associated Ulcers

The primary goal of HP therapy is to completely eradicate the organism using an effective antibiotic-containing regimen. ❷ *Reliance on conventional acid-suppressive drug therapy alone as an alternative to HP eradication is discouraged because it is associated with a higher incidence of ulcer recurrence and side effects*. Reinfection rates are generally low after the initial course of therapy as long as the patient has received a regimen with proven efficacy and is compliant with it. The HP regimen that is chosen should have a per-protocol cure rate of greater than or equal to 90% or a cure rate based on intention-to-treat analysis of greater than or equal to 80%.[9] In addition to proven efficacy, the optimal treatment regimen should cause minimal adverse events, have low risk for the development of bacterial resistance, and be cost effective.[9]

Helicobacter pylori treatment regimens are presented in Table 15–3. ❸ *Eradication therapy with a PPI-based three-drug regimen should be considered for all patients who test positive for HP and have an active ulcer or a documented history of either an ulcer or ulcer-related complication. Different antibiotics should be used if a second course of HP eradication therapy is required.*

The first-line regimen should contain a PPI plus clarithromycin and either amoxicillin or metronidazole. The combination of two antimicrobials and a PPI leads to cure rates greater than 80% (by intention-to-treat basis) and reduces the

TABLE 15–3. Drug Regimens to Eradicate *Helicobacter pylori*[a]

Treatment Regimen	Cure Rates[b]
Two Drugs	
Amoxicillin 1 g three times a day + omeprazole 20 mg twice a day	Poor
Clarithromycin 500 mg three times a day + omeprazole 40 mg every day	Poor
Clarithromycin 500 mg three times a day + RBC 400 mg twice a day	Fair
Three Drugs	
Clarithromycin 500 mg twice a day + metronidazole 500 mg twice a day + omeprazole 20 mg twice a day	Good–excellent
Clarithromycin 500 mg twice a day + amoxicillin 1 g twice a day + lansoprazole 30 mg twice a day	Good–excellent
Clarithromycin 500 mg twice a day + metronidazole 500 mg twice a day + RBC 400 mg twice a day	Good
Amoxicillin 1 g twice a day + clarithromycin 500 mg twice a day + RBC 400 mg twice a day	Good
Four Drugs	
BSS 525 mg four times a day + metronidazole 250 mg four times a day + tetracycline 500 mg four times a day + H_2RA (conventional ulcer-healing dose)[c]	Good–excellent
BSS 525 mg four times a day + metronidazole 250 mg four times a day + amoxicillin 500 mg four times a day + H_2RA (conventional ulcer-healing doses)[c]	Good
BSS 525 mg four times a day + metronidazole + amoxicillin + PPI[d]	Good
Rescue Therapy[e]	
BSS 525 mg four times a day + metronidazole 500 mg four times a day + tetracycline 500 mg four times a day + omeprazole 20 mg twice a day[d]	Good–excellent
Furazolidone 200 mg twice a day + amoxicillin 1 g twice a day + omeprazole 20 mg twice a day[f]	Good
Amoxicillin 1 g twice a day + rifabutin 300 mg every day + pantoprazole 40 mg twice a day[g]	Good–excellent

[a]These regimens based on efficacy for a 14-day treatment duration unless otherwise noted.
[b]Cure rates based on intention-to-treat analysis from references 3, 12, 14, and 35, where: poor = less than 70% eradication, fair = 70–80%, good = 80–90%, and excellent = greater than 90%.
[c]H_2RA therapy should be continued for an additional 2 weeks.
[d]Duration of therapy is 7–10 days.
[e]Data based on refractory treatment data.
[f]Given for 7 days.
[g]Given for 10 days.

risk of selecting out resistant organisms.[13] Monotherapy with a single antibiotic or antiulcer agent is not recommended due to high failure rates. In the United States, two-drug regimens consisting of a PPI and an antibiotic are also not recommended.

The duration of therapy is controversial and varies by continent. Europeans routinely treat patients for 7 days whereas Americans usually rely on a 14-day regimen. While this seven additional days of therapy improves the absolute cure rate by approximately 9%,[14] longer courses decrease compliance and increase drug cost.

Bismuth-based four-drug regimens have clinical cure rates similar to three-drug, PPI-based regimens. Bismuth-based regimens usually include tetracycline, metronidazole, and an antisecretory agent (e.g., PPI or histamine$_2$-receptor antagonist [H_2RA]). Bismuth salts promote ulcer healing through antibacterial and mucosal protective effects. Bismuth subsalicylate is the only bismuth product available in the United States. While cheaper than most other regimens, drawbacks of bismuth-based regimens include the frequency of administration (four times a day), risk for salicylate toxicity in patients with renal impairment, and propensity for bothersome side effects (e.g., stool and tongue discoloration, constipation, nausea, and vomiting).

Patients may remain infected with HP after the initial course of therapy because of reinfection, non-compliance with the initial regimen, or antimicrobial resistance. Factors associated with decreased compliance include use of a large number of medications, a need for frequent drug administration or a long treatment duration, and the use of drugs that may cause intolerable side effects. Potential adverse drug events include taste disturbances (clarithromycin and metronidazole), nausea, vomiting, abdominal pain, and diarrhea. Superinfections with oral thrush or vaginal candidiasis can occur.

Preexisting antimicrobial resistance is an increasing cause of treatment failure and is estimated to account for up to 70% of all treatment failures. Geography is the most important factor in HP resistance. Metronidazole-resistant strains are more prevalent in Asia (85%) than North America (30%).[15] Primary resistance to amoxicillin and tetracycline remains low in both the United States and Europe. Clarithromycin resistance rates are estimated to be approximately 10% in the United States. Another confounding factor when evaluating potential antibiotic resistance is that culture and sensitivity studies are not routinely performed with HP infection.

Initiation of a second HP treatment regimen after failure of the initial treatment regimen is usually associated with a lower success rate. Reasons for failure are often the same as those reported with failure of the initial regimen: patient non-compliance and/or

antimicrobial resistance. In these situations, quadruple therapy is generally required, and metronidazole or clarithromycin should be replaced by another antibiotic if either one of these agents was used in the initial regimen. If both clarithromycin and metronidazole were used as initial therapy, a regimen consisting of furazolidone 100 mg four times a day with tetracycline, bismuth, and a PPI can be used. Another second-line regimen consisting of a PPI, amoxicillin 1 g twice daily and rifabutin 300 mg once daily for 10 days resulted in eradication rates greater than 80%.[16,17]

Treatment of NSAID-Induced Ulcers

Treatment and dosing recommendations to heal peptic ulcers or provide maintenance therapy are shown in Table 15–4. Choice of regimen in a patient with PUD related to NSAID use depends on whether NSAID use is to be continued. NSAIDs should be discontinued if possible and replaced with alternatives (such as acetaminophen) although this may not be desirable or feasible in some patients. For patients discontinuing NSAID therapy, PPIs, H_2RAs, or sucralfate are all effective for ulcer healing. PPI therapy heals NSAID ulcers faster than H_2RAs.[16,17] For patients continuing NSAID therapy, PPIs are preferred over H_2RAs or sucralfate.[18–21] If the decision is made to continue NSAID therapy, adjunctive strategies may be required to promote ulcer healing and prevent future recurrences.

Prevention of NSAID-Induced Ulcers

Prophylactic regimens against PUD are often required in patients who require long-term NSAID or aspirin therapy for osteoarthritis, rheumatoid arthritis, or cardioprotection. Misoprostol, H_2RAs, PPIs, and COX-2 selective inhibitors have been evaluated in controlled trials to reduce the risk of NSAID-induced PUD. ❹ *In patients at risk for NSAID-induced ulcers, PPIs at standard doses reduce the risk of both gastric and duodenal ulcers as effectively as misoprostol and are generally better tolerated.*

Although acute gastrointestinal bleeding is the most serious adverse outcome of NSAID therapy and is ultimately what clinicians are trying to prevent with prophylactic therapy, few studies have compared PUD prophylaxis strategies using this outcome measure. Acute gastrointestinal bleeding is not usually evaluated in studies because of the low frequency with which bleeding occurs in NSAID users, the small size of most prophylaxis studies, and their short duration. Instead, studies usually rely on secondary outcome variables to evaluate efficacy such as the incidence of ulcers during screening endoscopy or the incidence of patient-reported ulcer symptoms. Correlation between these secondary outcomes and PUD-related bleeding events is poor and thus, clinicians must be cautious when extrapolating the results of these studies to patient care.

Misoprostol

Misoprostol is a synthetic prostaglandin E_1 analog that exogenously replaces prostaglandin stores. The minimum effective dose shown to inhibit acid secretion and promote mucosal defense is 400 mcg/day. Misoprostol use is limited by a high frequency of bothersome gastrointestinal effects such as abdominal pain, flatulence, and diarrhea. In placebo-controlled studies diarrhea occurred with twice the frequency in the

TABLE 15–4. Oral Drug Regimens to Heal Peptic Ulcers or Maintain Ulcer Healing

Drug	Duodenal Ulcer or Gastric Ulcer Healing (mg/day)	Maintenance of DU or GU Healing (mg/day)
Mucosal Protectant		
Sucralfate	1 g four times daily 2 g twice daily	1 g four times daily 1–2 g twice daily
H_2-Receptor Antagonists		
Cimetidine	300 mg four times daily 400 mg twice daily 800 mg at bedtime	400–800 mg daily
Famotidine	20 mg twice daily 40 mg at bedtime	20–40 mg daily
Nizatidine	150 mg twice daily 300 mg at bedtime	150–300 mg daily
Ranitidine	150 mg twice daily 300 mg at bedtime	150–300 mg daily
Proton Pump Inhibitors		
Esomeprazole	20–40 mg daily	20–40 mg daily
Lansoprazole	15–30 mg daily	15–30 mg daily
Omeprazole	20–40 mg daily	20–40 mg daily
Pantoprazole	40 mg daily	40 mg daily
Rabeprazole	20 mg daily	20 mg daily

DU, duodenal ulcer; GU, gastric ulcer.

misoprostol-treated groups and led to drug discontinuation in a substantial number of patients.

In two large multicenter, placebo-controlled trials, misoprostol 200 mcg orally four times daily was effective in reducing the incidence of both GU and DU in patients taking NSAIDs.[22,23] Misoprostol is superior to H_2RAs in preventing NSAID-associated ulcers. One large randomized study found a significantly lower incidence of GU in patients receiving misoprostol 200 mcg four times daily compared to those receiving ranitidine 150 mg orally twice daily (1% versus 6%; *p* less than 0.01). However, the incidence of GI side effects such as diarrhea was substantially higher in the misoprostol-treated group.[24]

H_2-Receptor Antagonists

Refer to Chapter 14 on gastroesophageal reflux disease for more information on the H_2RAs. When given in standard doses, H_2RAs are not effective in preventing NSAID-related ulceration, but they do reduce symptoms and are generally well tolerated.[11] One randomized study demonstrated that high-dose therapy may be effective for preventing NSAID complications. When famotidine 20 mg twice daily, famotidine 40 mg twice daily, and placebo were compared in patients taking NSAIDs who required GI prophylaxis, the incidence of GU was significantly lower in patients taking 40 mg twice daily than in those taking either 20 mg twice daily or placebo.[25] The incidence of duodenal ulceration was similar between both famotidine groups and was significantly reduced with H_2RA therapy. In summary, although standard-dose H_2RA therapy reduces the risk of NSAID-related duodenal ulcers, higher doses are needed to reduce the risk of gastric ulcers.

Proton Pump Inhibitors

Refer to Chapter 14 on gastroesophageal reflux disease for more information on the PPIs. The PPI omeprazole is superior to both ranitidine and misoprostol for preventing recurrence of NSAID-associated PUD. In one study, omeprazole 20 mg daily was compared to misoprostol 200 mcg twice daily for NSAID-associated PUD prevention. At 6 months, the omeprazole-treated group had significantly fewer ulcers than those taking misoprostol. Furthermore, more patients discontinued ulcer prophylaxis in the misoprostol group due to adverse events.[26]

Another study randomized patients requiring NSAID prophylaxis to either omeprazole 20 mg daily or ranitidine 150 mg twice daily.[19] At 6 months, more patients who received omeprazole (72%) than ranitidine (59%) were in ulcer-free remission ($p = 0.004$). Omeprazole was also more efficacious in preventing GU recurrence than ranitidine (5.2% versus 16.3%; p less than 0.01). Adverse drug events were similar in the two groups.

In patients who experience a PUD-related bleeding event while taking aspirin but who require continued aspirin therapy, the addition of a PPI reduces the incidence of recurrent GI bleeding.[27]

COX-2 Selective Inhibitors

With the availability of NSAIDs with COX-2 selectivity, clinicians postulated that these agents would avoid the need to add an additional prophylactic agent to therapy in patients with PUD risk factors. ❺ *However, selective COX-2 inhibitors have not been shown to be any more effective than the combination of a PPI and a non-selective NSAID in reducing the incidence of ulcers, and questions remain regarding their long-term cardiovascular safety.*

Two large trials, the Vioxx Gastrointestinal Outcomes Research (VIGOR) study and the Celecoxib Long-term Arthritis Safety Study (CLASS), compared selective COX-2 inhibitors and traditional, non-selective NSAID therapy in terms of their ability to prevent clinical PUD (i.e., symptomatic ulcers and ulcer complications). VIGOR (9-month median follow-up) demonstrated that rofecoxib (50 mg daily) therapy was significantly more efficacious than naproxen.[28] The CLASS study (6-month median follow-up) found that high-dose celecoxib (400 mg twice daily) was superior to non-selective NSAID therapy (either ibuprofen 800 mg three times daily or diclofenac 75 mg twice daily).[29]

A number of methodologic factors may account in part for the lower incidence of clinical PUD observed with COX-2 therapy in these studies, including the short duration of clinical follow-up and the high doses of both celecoxib and rofecoxib used.[30] An important difference between these two studies is that patients taking low-dose aspirin were excluded from VIGOR but not from CLASS. In CLASS, patients in the celecoxib group who were taking low-dose aspirin had the same incidence of clinical PUD as those receiving a traditional NSAID therapy. This is an important issue, as many patients with arthritis also have coronary artery disease and are prescribed low-dose aspirin therapy because of its cardioprotective effects.[31] Low-dose aspirin is associated with PUD bleeding itself, and its use with a COX-2 inhibitor appears to largely negate the gastrointestinal-sparing effects of these agents.

Selective COX-2 inhibitors are not superior to PPIs in preventing NSAID-related PUD. One randomized, placebo-controlled trial that included 267 patients at high risk for ulceration (arthritic patients with a previously healed bleeding ulcer) compared celecoxib 200 mg twice daily to the combination of diclofenac 75 mg twice daily plus omeprazole 20 mg daily.[32] After 6 months, the risk for recurrent bleeding was found to be similar between groups (celecoxib, 4.9% and diclofenac/omeprazole, 6.4%); the authors concluded that neither of these therapies can completely prevent recurrent ulcer complications.

Longer-term studies evaluating the cardiovascular risks associated with the use of COX-2 inhibitors have found a higher incidence of cardiovascular mortality with the use of these agents compared to traditional NSAIDs.[29,33,34] This prompted the withdrawal of both rofecoxib and valdecoxib from the market and the inclusion of a black box warning in

the celecoxib package insert.[34–36] Given the cardiovascular risk of the COX-2 inhibitors, it has been suggested that an older non-selective NSAID and a PPI can be used as an alternative to COX-2 therapy in patients at high risk for NSAID-related PUD.[5,37]

Sucralfate

Sucralfate is a negatively-charged, non-absorbable agent that forms a complex by binding with positively-charged proteins in exudates, forming a viscous, paste-like, adhesive substance. This forms a coating that protects the ulcerated area of the gastric mucosa against gastric acid, pepsin, and bile salts. Limitations of sucralfate include the need for multiple daily dosing, large tablet size, and interaction with a number of other medications. Adverse effects include constipation, nausea, metallic taste, and the possibility for aluminum toxicity in patients with renal failure. While sucralfate may be used for the treatment of an NSAID-related ulcer when NSAID therapy is being stopped, it is not recommended for use as prophylaxis against NSAID-induced ulcers.

Conventional Treatment of Active Duodenal and Gastric Ulcers and Long-Term Maintenance of Ulcer Healing

Conventional therapy prior to the advent of HP eradication therapy consisted of standard doses of sucralfate or an H_2RA for 6 to 8 weeks. A PPI provides equivalent efficacy with a treatment duration of only 4 weeks. Long-term antiulcer therapy is ineffective for treating HP infections.

❻ *Low-dose maintenance therapy with a PPI or H_2RA is only indicated for patients who fail HP eradication, have HP-negative ulcers, or develop severe complications related to ulcer disease.* Drug regimens and doses are presented in Table 15–4.

Treatment of Refractory Ulcers

The presence of refractory ulcers [ulcers that persist beyond 8 weeks (DU) or 12 weeks (GU)] requires thorough assessment, including evaluation of medication compliance. The patient should be questioned regarding recent NSAID ingestion. Tolerance has been reported with as few as 4 weeks of H_2RA therapy, and thus a change to PPI therapy should be considered in this situation.[38] Other assessments that may be considered include an ulcer biopsy to exclude malignancy, HP testing (if not done initially), a serum gastrin measurement to exclude ZES, and gastric acid studies. In one study, increasing the starting dose of PPI therapy healed 90% of refractory ulcers after 8 weeks.[39]

OUTCOME EVALUATION

- Obtain a baseline complete blood cell count (CBC). Recheck the CBC if the patient exhibits alarm signs or symptoms.
- Obtain a baseline serum creatinine measurement. Calculate the estimated creatinine clearance and adjust the dose of H_2RAs and sucralfate according to package insert recommendations.
- Obtain a history of symptoms from the patient. Monitor for improvements in pain symptoms (e.g., epigastric or abdominal pain) daily.
- Monitor the patient for the development of any alarm signs and symptoms.
- Recommend a follow-up visit if signs and symptoms worsen at any time or do not improve within the defined treatment period.
- Assess for potential drug interactions whenever there is a change in the patient's medications, particularly for patients taking cimetidine, omeprazole, or sucralfate.
- Educate the patient on the importance of adhering to the HP-eradication regimen.
- Monitor the patient for complications related to antibiotic therapy (e.g., diarrhea or oral thrush) during and after completion of HP eradication therapy.
- Recommend follow-up care if the patient's signs and symptoms do not improve after completion of HP-eradication therapy.

Patient Care and Monitoring

General Recommendations: HP-Associated and NSAID-Induced Ulcers

1. Assess the severity of signs and symptoms. Identify the presence of any alarm signs and symptoms.
2. Educate the patient on monitoring for alarm signs and symptoms.
3. Obtain a history of prescription medication, over-the-counter medication, and dietary supplement use.
4. Encourage lifestyle modifications such as reducing tobacco use and ethanol ingestion and decreasing psychological stress.
5. Determine the appropriate duration of therapy for acid-suppressive therapy.
6. Define the current impact of PUD on the patient's quality of life and the improvement in these outcomes sought with drug therapy.
7. Evaluate current drug therapy for potential adverse drug reactions and drug interactions.

Helicobacter pylori–Associated Ulcers

1. Recommend an appropriate drug regimen that will eradicate the organism.
2. Identify the patient's drug allergies and avoid drug classes a patient is allergic to.
3. Avoid regimens with tetracycline in children.

(Continued)

4. Educate patients on specific adverse drug effects, particularly with metronidazole (avoidance of alcohol) and bismuth (change in stool color).
5. Assess the potential for drug interactions, particularly in patients taking regimens containing metronidazole, clarithromycin, and/or cimetidine.
6. Recommend different antibiotics if this treatment regimen is a result of failure of a prior HP regimen.
7. Educate the patient on the importance of adherence to eradication therapy.

NSAID-Associated Ulcers

1. Assess for risk factors for NSAID ulcers and recommend an appropriate strategy to reduce ulcer risk.
2. Monitor for signs and symptoms of complications associated with NSAID-related ulceration.
3. Recommend an appropriate treatment regimen to achieve the desired outcomes.
4. Assess and counsel patients on potential adverse drug events and drug interactions.
5. Inform patients who are receiving prophylactic therapy on the importance of its use, potential adverse drug events, and the possible alarm symptoms associated with PUD.

16 Inflammatory Bowel Disease

Brian A. Hemstreet

Learning Objectives

Upon completion of the chapter the reader will be able to:

1. Characterize the pathophysiologic mechanisms underlying inflammatory bowel disease (IBD).
2. Recognize the signs and symptoms of IBD, including major differences between ulcerative colitis and Crohn's disease.
3. Identify appropriate therapeutic outcomes for patients with IBD.
4. Describe pharmacologic treatment options for patients with acute or chronic symptoms of ulcerative colitis and Crohn's disease.
5. Create a patient-specific drug treatment plan based on symptoms, severity, and location of ulcerative colitis or Crohn's disease.
6. Recommend appropriate monitoring parameters and patient education for selected drug regimens for treating symptoms of IBD.

Key Concepts

❶ Inflammatory bowel disease includes both ulcerative colitis and Crohn's disease and is associated with inflammation of various areas of the gastrointestinal tract.

❷ Differentiation of ulcerative colitis and Crohn's disease is based on signs and symptoms as well as characteristic endoscopic findings including the extent, pattern, and depth of inflammation.

❸ Patients may manifest extraintestinal symptoms of IBD, such as arthritis, primary sclerosing cholangitis, erythema nodosum, and pyoderma gangrenosum, among others.

❹ Major treatment goals for patients with IBD include alleviation of signs and symptoms and suppression of inflammation during acute episodes and maintenance of remission thereafter.

❺ When designing a drug regimen for treatment of IBD, several factors should be considered, including the patient's symptoms, medical history, current medication use, drug allergies, and location and severity of disease.

❻ Antidiarrheal medications that reduce GI motility, such as loperamide, diphenoxylate/atropine, or codeine should be avoided in patients with active IBD due to the risk of precipitating acute colonic dilation (toxic megacolon).

❼ Treatment of acute episodes of ulcerative colitis is dictated by the severity and extent of disease, and first-line therapy of mild to moderate disease involves oral or topical aminosalicylate derivatives.

❽ Maintenance of remission of ulcerative colitis may be achieved with oral or topical aminosalicylates. Immunosuppressants such as azathioprine or 6-mercaptopurine can be used for unresponsive patients or those who develop corticosteroid dependency.

❾ Treatment of active mild to moderate Crohn's disease involves use of oral or topical aminosalicylate derivatives, whereas moderate to severe disease may require systemic corticosteroid therapy.

❿ Maintenance of remission of Crohn's disease may be achieved with oral or topical aminosalicylate derivatives, immunosuppressants (such as azathioprine, 6-mercaptopurine, and methotrexate), or infliximab.

❶ *Inflammatory bowel disease (IBD) encompasses both Crohn's disease (CD) and ulcerative colitis (UC). Both disorders are associated with inflammation of various regions within the gastrointestinal (GI) tract.* Differences exist between UC and CD with regard to the regions of the GI tract that may be affected as well as in the distribution and depth of inflammation. Some

patients with IBD may also have inflammation involving organs other than the GI tract, known as "extraintestinal" manifestations. Symptoms of IBD are associated with significant morbidity, reduction in quality of life, and substantial costs to the health care system. For purposes of this chapter, references made to IBD will include both UC and CD. Significant differences between UC and CD will be discussed separately when applicable.

EPIDEMIOLOGY

Inflammatory bowel disease is most common in westernized countries such as the United States. Ulcerative colitis affects up to 500,000 people and Crohn's disease affects up to 480,000 people in the United States.[2–4] The age of initial presentation of IBD is bimodal, with patients typically diagnosed between the age ranges of 20 to 40 years or 60 to 80 years.[5] The peak incidence of CD occurs in the second and third decades of life, with a smaller peak in the fifth decade.[2,5] Peak incidence of UC occurs between the ages of 15 and 25 years.[6]

Men and women are approximately equally affected by IBD. In general, whites are affected more often than blacks, and persons of Jewish descent also have higher reported incidences of IBD. One of the greatest risk factors for development of IBD is a positive family history of the disease. The incidence of IBD is 10 to 40 times greater in patients with a first-degree relative who has IBD compared to the general population.[4,5,7] A positive family history may be more of a contributing factor for development of CD than UC.[7–9]

ETIOLOGY

The exact cause of IBD is not fully understood. Processes thought to be involved in its development include genetic predisposition, dysregulation of the inflammatory response within the GI tract, or perhaps environmental or antigenic factors.[3] The fact that a positive family history is a strong predictor of IBD supports the theory that genetic predisposition may be responsible in many cases. Many potential candidate genes have been identified. An example is a gene found on chromosome 16 that encodes for nucleotide oligomerization domain 2 (NOD2). NOD2 is a cytoplasmic protein expressed in macrophages, monocytes, and gut epithelial cells thought to be involved in recognition and degradation of bacterial products by the gut wall. Presence of NOD2 mutations has been shown to predispose patients to development of CD.[9,10] Less is known about genetic alterations that may predispose patients to UC, but UC may share common genetic features with CD.

An alteration in the inflammatory response regulated by intestinal epithelial cells may also contribute to development of IBD. This may involve inappropriate processing of antigens presented to the GI epithelial cells.[3] The inflammatory response in IBD may actually be directed at bacteria that normally colonize the GI tract. Products derived from these bacteria may translocate across the mucosal layer of the GI tract and interact with various cells involved in immunologic recognition. The result is T-cell stimulation, excess production of proinflammatory cytokines, and persistent inflammation within the GI tract.

The intestinal mucosa of patients with CD has a preponderance of CD4+ type 1 helper T cells, while patients with UC have more CD4+ lymphocytes with atypical type 2 helper T cells.[9] Likewise, drugs such as non-steroidal anti-inflammatory drugs (NSAIDs) that disrupt the integrity of the GI mucosa may facilitate mucosal entry of intestinal antigens and lead to disease flares in patients with IBD.[11]

The role of antigens derived from dietary intake in the development of IBD is less well defined. There is some speculation that ingestion of large quantities of refined carbohydrates or margarine leads to higher rates of CD. Use of oral contraceptives has been associated with increased development of IBD in some cohort studies, but a strong causal relationship has not been proven.[7]

Lastly, positive smoking status has been shown to have protective effects in UC, leading to reductions in disease severity. The opposite is true in CD, as smoking may lead to increases in symptoms or worsening of the disease.[9]

PATHOPHYSIOLOGY

Ulcerative Colitis

The inflammatory response in UC is propagated by atypical type 2 helper T cells that produce proinflammatory cytokines such as interleukin-1 (IL-1), IL-6, and tumor necrosis factor (TNF).[7] As discussed previously, a genetic predisposition to UC may partially explain the development of excessive colonic and rectal inflammation. The finding of positive perinuclear antineutrophil cytoplasmic antibodies (pANCA) in association with the human leukocyte antigen (HLA)-DR2 allele in a large percentage of patients with UC supports this theory.[4,12]

The role of an immune response to intestinal bacteria in the development of UC may not be as strong a contributing factor as it is in CD. The potential role of environmental factors in the development of UC implies that the immune response is directed against an unknown antigen. The findings that development and severity of UC are reduced in patients who smoke, or in those with appendectomies, may support the theory that these factors may somehow modify either the genetic component or phenotypic response to immunologic stimuli.[11,13]

NSAID use is also implicated in disease flares in patients with UC. NSAIDs may affect production of both nuclear factor κβ and peroxisome proliferator activated receptors (e.g., PPAR-γ), both of which are involved in regulating the intestinal responses.[11]

The inflammatory process within the GI tract is limited to the colon and rectum in patients with UC (Fig. 16–1). Most patients with UC have involvement of the rectum (**proctitis**) or both the

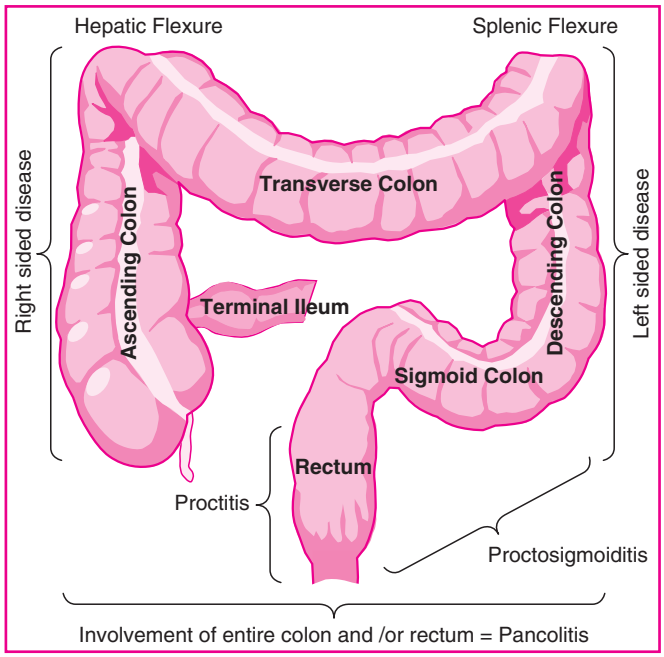

FIGURE 16–1. Major gastrointestinal landmarks and disease distribution in inflammatory bowel disease.

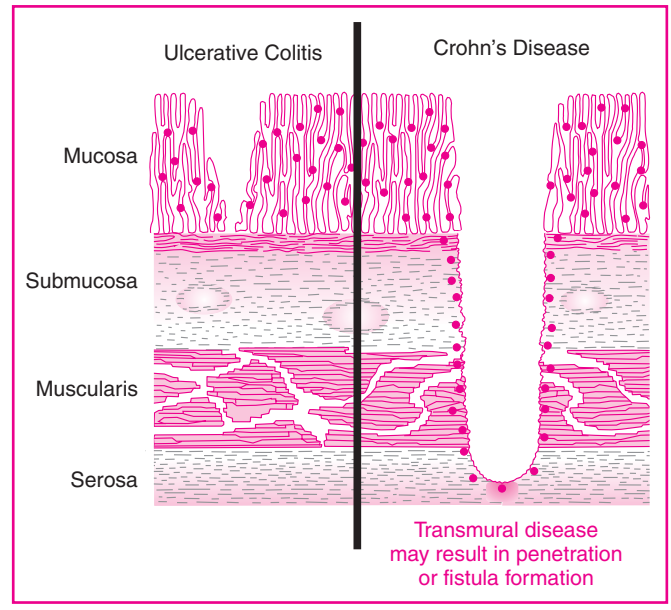

FIGURE 16–2. Depth of disease penetration in ulcerative colitis and Crohn's disease.

rectum and sigmoid colon (proctosigmoiditis). Inflammation involving the majority of the colon is referred to as **pancolitis**. Left-sided disease, defined as inflammation extending from the rectum to the splenic flexure, occurs in 30% to 40% of patients.[4] A small number of cases of UC involve mild inflammation of the terminal ileum, referred to as "backwash ileitis."

The pattern of inflammation in UC is continuous and confluent throughout the affected areas of the GI tract. The inflammation is also superficial and does not typically extend below the submucosal layer of the GI tract (Fig. 16–2). Ulceration or erosion of the GI mucosa may be present and varies with disease severity. The formation of **crypt abscesses** within the mucosal layers of the GI tract is characteristic of UC and may help to distinguish it from CD. Severe inflammation may also result in areas of hypertrophied GI mucosa, which may manifest as **pseudopolyps** within the colon.[12] The inflammatory response may progress in severity, leading to mucosal friability and significant GI bleeding.

Crohn's Disease

As with UC, the immune activation seen in CD involves the release of many proinflammatory cytokines. Cytokines thought to play major roles in CD are derived from T-helper type 1 cells and include interferon-γ, TNF-α, and IL-1, IL-6, and IL-12. TNF-α is a major contributor to the inflammatory process seen in CD. Its physiologic effects include activation of macrophages, procoagulant effects in the vascular endothelium, and increases in production of matrix metalloproteinases in mucosal cells.[9,15] Excessive production of both interferon-γ and TNF-α may account for the excessive clinical evidence of granulomatous disease in patients with CD.[10] TNF-α is also thought to induce production of nuclear factor κβ, which stimulates further production of TNF-α and other proinflammatory cytokines.[3,14]

The role of an immune response directed against endogenous bacteria as the initiating factor is more evident in CD, as evidenced by the apparent strong T-helper 1 activation against bacteria seen in animal models of this disease. Likewise, bacteria are often found deep in the intestinal mucosal layer of patients with CD. As mentioned previously, the finding of genetic mutations in NOD2 may result in excessive production of IL-12 and inhibition of intestinal phagocytes to break down bacterial antigens.[10]

Dysregulation of cytokines that normally downregulate inflammatory responses, such as transforming growth factor-β, may also be involved in the excessive inflammatory response seen in CD. As in UC, patients with CD may have disease flares due to ingestion of NSAIDs. The role of dietary antigens in the development of CD compared to UC is also another potential initiating factor. Excess ingestion of refined sugars or margarine may be higher in patients who develop CD.[7]

The distribution of inflammation in CD differs from that seen in UC, as any part of the entire GI tract may be affected in CD. The small intestine is the site most commonly involved. Within the small intestine, the terminal ileum and cecum are almost always affected. Approximately 20% of patients have isolated colonic involvement, whereas inflammation proximal to the small intestine is almost never seen without the presence of small or large intestinal disease.[12]

In contrast to UC, the pattern of inflammation in CD is described as discontinuous. Areas of inflammation are intermixed with areas of normal GI mucosa, resulting in characteristic "skip lesions." Superficial **aphthous ulcers** may also develop in the GI mucosa. These ulcers may coalesce into larger linear ulcers, resulting in fissure formation as they increase in depth, giving rise to the characteristic "cobblestone" pattern observed upon examination of the mucosa.

Furthermore, the inflammation may be **transmural**, penetrating to the muscularis or serosal layers of the GI tract (Fig. 16–2). The propensity for transmural involvement may lead to serious complications of CD, such as **strictures**, **fistulae**, and abscesses.[4,12] While rectal inflammation is typically less common in CD than UC, several types of perianal lesions may be observed in patients with CD. These include skin tags, hemorrhoids, fissures, anal ulcers, abscesses, and fistulae.[15]

CLINICAL PRESENTATION AND DIAGNOSIS

❷ *Differentiation of ulcerative colitis and Crohn's disease is based on signs and symptoms as well as characteristic endoscopic findings, including the extent, pattern, and depth of inflammation (see Presentation Box in second column).*

Extraintestinal Manifestations and Complications of IBD

❸ *Patients may manifest signs and symptoms of disease in areas outside the GI tract. These extraintestinal manifestations may occur in various body regions.*[5,8] Painful joint complications associated with IBD include sacroiliitis and ankylosing spondylitis. Ocular involvement with episcleritis, uveitis, or iritis may manifest as blurred vision, eye pain, and photophobia. Associated skin findings include pyoderma gangrenosum (involving papules and vesicles that develop into painful ulcerations) and erythema nodosum (red nodules of varying size typically found on the lower extremities). Nephrolithiasis may also develop at a higher rate in patients with IBD. Oxalate stones are more common in CD, and uric acid–containing stones are more common in UC.

Liver and biliary manifestations of IBD include an increased incidence of gallstone formation in patients with CD and development of sclerosing cholangitis or cholangiocarcinoma in patients with UC. Patients with UC are also at increased risk for development of colorectal cancer. Ongoing inflammation due to active IBD may induce a hypercoagulable state, resulting in higher rates of both arterial and venous thromboembolism. Likewise, inflammation and recurrent blood loss may result in the development of chronic anemia. Patients with IBD also have higher rates of osteopenia, osteoporosis, and fractures.[16]

A serious complication of UC is toxic megacolon, defined as dilation of the transverse colon of greater than 6 cm. Patients with toxic megacolon typically manifest systemic signs of severe inflammation such as fever, tachycardia, and abdominal distention.[3] Surgical intervention, including colonic resection, may be necessary to acutely manage toxic megacolon.

Formation of strictures, abscesses, fistulae, and obstructions in patients with CD is possible. Patients with CD may develop significant weight loss or nutritional deficiencies secondary to malabsorption of nutrients in the small intestine, or as a consequence of multiple small- or large-bowel resections. Common nutritional deficiencies encountered in IBD include vitamin B_{12}, fat-soluble vitamins, zinc, folate, and iron. Malabsorption in children with CD may contribute to significant reductions in growth and development.

Presentation of Inflammatory Bowel Disease

General
- Patients with CD or UC may present with similar symptoms.
- The onset may be insidious and subacute.
- Some patients present with extraintestinal manifestations before GI symptoms occur.
- In approximately 10% of cases it may not be possible to distinguish between UC and CD. These patients are described as having "indeterminate colitis."

Symptoms
- *Ulcerative colitis*: Diarrhea (bloody, watery, or mucopurulent), rectal bleeding, abdominal pain/cramping, weight loss and malnutrition, tenesmus, constipation (with proctitis)
- *Crohn's disease*: Diarrhea (less bloody than UC), rectal bleeding (less than UC), abdominal pain/cramping, weight loss and malnutrition (more common than UC), fatigue/malaise

Signs
- *Ulcerative colitis*: Fever, tachycardia (with severe disease), dehydration, arthritis, hemorrhoids, anal fissures, perirectal abscesses
- *Crohn's disease*: Fever, tachycardia (with severe disease), dehydration, arthritis, abdominal mass and tenderness, perianal fissure or fistula

Laboratory Tests
- *Ulcerative colitis*: Leukocytosis, decreased hematocrit/hemoglobin, elevated erythrocyte sedimentation rate (ESR), guaiac-positive stool, (+) perinuclear antineutrophil cytoplasmic antibodies (pANCA; up to 70% of patients)
- *Crohn's disease*: Leukocytosis, decreased hematocrit/hemoglobin, elevated ESR, guaiac-positive stool, (+) anti–*Saccharomyces cerevisiae* antibodies (up to 50% of patients), hypoalbuminemia with severe disease

Diagnosis

Because patients often present with nonspecific GI symptoms, initial diagnostic evaluation includes methods to characterize the disease and rule out other potential etiologies. This may include stool cultures to examine for infectious causes of diarrhea.

Endoscopic approaches are typically used and may include colonoscopy, proctosigmoidoscopy, or possibly upper GI endoscopy in patients with suspected CD. Endoscopy is useful for determining the disease distribution, pattern and depth of inflammation, and to obtain mucosal biopsy specimens. Supplemental information from imaging procedures, such as computed tomography (CT), abdominal x-ray, abdominal ultrasound, or intestinal barium studies may provide evidence of complications such as obstruction, abscess, perforation, or colonic dilation.[3]

After the diagnosis is made, the information derived from diagnostic testing and the patient's medical history and symptoms are used to gauge disease severity. The severity of active UC is generally classified as mild, moderate, severe, or fulminant.[1] Mild UC typically involves up to four bloody or watery stools per day without systemic signs of toxicity or elevation of ESR. Moderate disease is classified as more than four stools per day with evidence of systemic toxicity. Severe disease is considered more than six stools per day and evidence of anemia, tachycardia, or an elevated ESR. Lastly, fulminant UC may present as more than 10 stools per day with continuous bleeding, signs of systemic toxicity, abdominal distention or tenderness, colonic dilation, or a requirement for blood transfusion.

A similar classification scheme is used to gauge the severity of active CD.[2] Patients with mild to moderate CD are typically ambulatory and have no evidence of dehydration, systemic toxicity, loss of body weight, or abdominal tenderness, mass, or obstruction. Moderate to severe disease is considered in patients who fail to respond to treatment for mild to moderate disease, or those with fever, weight loss, abdominal pain or tenderness, vomiting, intestinal obstruction, or significant anemia. Severe to fulminant CD is classified as the presence of persistent symptoms or evidence of systemic toxicity despite outpatient corticosteroid treatment, or presence of cachexia, rebound tenderness, intestinal obstruction, or abscess.

Patient Encounter 1, Part 1

A 25-year-old Caucasian woman presents to the university student clinic with complaints of intermittent crampy abdominal pain and four to five loose stools per day. She describes some visible mucus and blood in the stool and states that these symptoms have been present for 6 to 8 weeks. She also has intermittent lower back pain, fatigue, fever, and a 10-lb (4.5 kg) weight loss. The back pain started about the same time as her gastrointestinal symptoms. She denies any sick contacts and has not eaten any take-out or restaurant food over the last 2 months. She takes nonprescription naproxen as needed for aches and pains. She has been using more naproxen recently because of the back pain. She also takes an oral contraceptive pill once daily. She consumes alcohol socially and currently smokes $^1/_2$ to 1 pack of cigarettes per day.

- What symptoms are suggestive of IBD in this patient?
- Are these symptoms more suggestive of UC or CD?
- What factors may be contributing to her IBD symptoms?
- What additional information would you acquire prior to recommending drug therapy?

TREATMENT

Desired Outcomes

Pharmacologic interventions for IBD are designed to target the underlying inflammatory response. Treatment goals involve both management of active disease and prevention of disease relapse. ❹ *Major treatment goals include alleviation of signs and symptoms and suppression of inflammation during acute episodes and maintenance of remission thereafter.* Addressing active IBD in a timely and appropriate manner may prevent major complications such as perforation and may reduce the need for hospitalization or surgical intervention. Once control of active disease is obtained, treatment regimens are designed to achieve the following long-term goals: (1) maintenance of remission and prevention of disease relapse; (2) improvement in the patient's quality of life; (3) prevention of surgical intervention or hospitalization; (4) management of extraintestinal manifestations; (5) prevention of malnutrition; and (6) prevention of treatment-associated adverse effects.

General Approach to Treatment

❺ *When designing a drug regimen for treatment of IBD, several factors should be considered, including the patient's symptoms, medical history, current medication use, drug allergies, and location and severity of disease.* A thorough patient history may also help to identify a family history of IBD or potential exacerbating factors, such as tobacco or NSAID use.

Nonpharmacologic Therapy

No specific dietary restrictions are recommended for patients with IBD, but avoidance of high-residue foods in patients with strictures may help to prevent obstruction. Nutritional strategies in patients with long-standing IBD may include use of vitamin and mineral supplementation. Administration of vitamin B_{12}, folic acid, fat-soluble vitamins, and iron may be needed to prevent or treat deficiencies. In severe cases, enteral or parenteral nutrition may be needed to achieve adequate caloric intake.

Patients with IBD, particularly those with CD, are also at risk for bone loss. This may be a function of malabsorption or an effect of repeated courses of corticosteroids. Patients with IBD should receive a baseline bone density measurement prior to receiving corticosteroids. Vitamin D and calcium supplementation should be used in all patients receiving long-term corticosteroids. Oral bisphosphonate therapy may also be considered in patients receiving prolonged courses of corticosteroids or in those with osteopenia or osteoporosis.

Surgical intervention is a potential treatment option in patients with complications such as fistulae or abscesses, or in patients with medically refractory disease. Ulcerative colitis is curable with performance of a total colectomy. Patients with UC may opt to have a colectomy to reduce the chance of developing colorectal cancer. Patients with CD may have affected areas of intestine resected. Unfortunately, CD may recur following surgical resection. Repeated surgeries may lead to significant malabsorption of nutrients and drugs consistent with development of short-bowel syndrome.

Pharmacologic Therapy

Several pharmacologic classes are available for the treatment and maintenance of IBD. Because there may be differences in the underlying disease process, distribution, and severity between CD and UC, response rates to drugs in the same pharmacologic class may differ between these two diseases. Therefore, initial selection of an appropriate agent for patients with active IBD should be designed to deliver maximum efficacy while minimizing toxicity. Response rates to individual classes of medications for both UC and CD will be discussed within the specific treatment section for each disease.

Symptomatic Interventions

Patients with active IBD often have severe abdominal pain and diarrhea. Medications used to manage these types of symptoms may have adverse consequences in patients with active IBD. ❻ *Antidiarrheal medications that reduce GI motility, such as loperamide, diphenoxylate/atropine, and codeine should be avoided in patients with active IBD due to the risk of precipitating acute colonic dilation (toxic megacolon).*[8] Drugs with anticholinergic properties, such as hyoscyamine and dicyclomine, are often used to treat intestinal spasm and pain, but these drugs may also reduce GI motility and should generally be avoided in active IBD. Once active disease is under control, antidiarrheal agents may be used with caution as adjunctive treatment.

Patients who have had multiple intestinal resections due to CD may have diarrhea related to the inability to reabsorb bile salts. Cholestyramine has been demonstrated to improve diarrheal symptoms in this population.[8,15] NSAIDs should be avoided for pain management due to their ability to worsen IBD symptoms. Narcotic analgesics should be used with caution, as they may significantly reduce GI motility.

Aminosalicylates

The aminosalicylates are among the most commonly used drugs for inducing and maintaining remission in patients with IBD (Table 16–1). These drugs are designed to deliver 5-aminosalicylate (5-ASA, mesalamine) to areas of inflammation within the GI tract. While the mechanism of mesalamine is not fully understood, it appears to have favorable anti-inflammatory effects. These effects may include reducing prostaglandin and leukotriene production, inhibiting bacteria-induced chemotaxis, scavenging of free radicals, and inhibiting nuclear factor κβ.[9] The delivery of mesalamine to the affected sites is accomplished by either linking mesalamine to a carrier molecule or altering the formulation to release drug in response to changes in intestinal pH. Topical suppositories and enemas are designed to deliver mesalamine directly to the distal colon and rectum.[17,18]

The prototypical aminosalicylate is sulfasalazine, which is comprised of mesalamine linked by a diazo bond to the carrier molecule sulfapyridine. This linkage prevents premature absorption of mesalamine in the small intestine. Once sulfasalazine is delivered to the colon, bacterial degradation of

TABLE 16–1. Aminosalicylates for Treatment of Inflammatory Bowel Disease

Drug	Trade Names	Formulation	Strengths	Daily Dosage Range	Site of Action
Sulfasalazine	Azulfidine®	Immediate-release or enteric-coated tablets	500 mg	2–6 g	Colon
	Azulfidine Entabs®				
	Sulfazine®				
	Sulfazine EC®				
Mesalamine	Rowasa®	Enema	4 g/60 mL	4 g	Distal left colon and rectum
	Asacol®	Delayed-release resin tablet	400 mg	1.6–4.8 g	Distal ileum and colon
	Canasa®	Suppository	500 and 1000 mg	1 g	Rectum
	Pentasa®	Microgranule controlled-release capsule	250 mg	2–4 g	Small bowel
			500 mg	2–4 g	Colon
Olsalazine	Dipentum®	Capsule	250 mg	1–3 g	Colon
Balsalazide	Colazal®	Capsule	750 mg	2–6.75 g	Colon

the diazo bond frees mesalamine from sulfapyridine. Sulfapyridine is then absorbed and excreted renally, while mesalamine acts locally within the GI tract.

Newer mesalamine products utilize non-sulfapyridine methods for drug delivery. Olsalazine uses two mesalamine molecules linked together, while balsalazide uses the inert carrier molecule 4-aminobenzoyl-β-alanine. Both drugs use a diazo bond similar to sulfasalazine. Other mesalamine formulations are pH-dependent formulations that release mesalamine at various points throughout the GI tract.

Sulfasalazine is associated with various adverse effects, most of which are thought to be due to the sulfapyridine component. Common adverse effects that may be dose related include headache, dyspepsia, nausea, vomiting, and fatigue.[19] Idiosyncratic effects include bone marrow suppression, reduction in sperm counts in males, hepatitis, and pulmonitis. Hypersensitivity reactions may occur in patients allergic to sulfonamide-containing medications.

The use of non-sulfapyridine–based aminosalicylates has led to greater tolerability. Although the adverse effects are similar to those of sulfasalazine, they occur at a much lower rate. Olsalazine, in particular, is associated with a higher incidence of secretory diarrhea. These agents can also be used safely in patients with a reported sulfonamide allergy.

Corticosteroids

Corticosteroids have potent anti-inflammatory properties and are used in active IBD to rapidly suppress inflammation. Corticosteroids have favorable effects in modulating several cell types involved in the inflammatory process.[20,21] They may be administered systemically or delivered locally to the site of action by altering the drug formulation (Table 16–2). Because these drugs usually improve symptoms and disease severity rapidly, they should be restricted to short-term management of active disease. Long-term use of systemic corticosteroids is associated with significant adverse effects, including cataracts, skin atrophy, hypertension, hyperglycemia, adrenal suppression, osteoporosis, and increased risk of infection, among others.[19,22]

Budesonide is a high-potency glucocorticoid used in CD that has low systemic bioavailability when administered orally.[23] The formulation releases budesonide in the terminal ileum for treatment of disease involving the ileum or ascending colon. Due to its reduced bioavailability, budesonide may prevent some long-term adverse effects in patients who have steroid-dependent IBD.[23,24]

TABLE 16–2. Corticosteroids for Treatment of Inflammatory Bowel Disease

Drug	Trade Names	Daily Dose
Prednisone	Generic	20–60 mg orally
Prednisolone	Generic	20–60 mg orally
Budesonide	Entocort EC®	Induction: 9 mg orally Maintenance: 6 mg orally
Methylprednisolone	Medrol® (PO) Solu-Medrol® (IV)	15–60 mg orally or IV
Hydrocortisone	Solu-Cortef®	300 mg IV in three divided doses
	Cortenema®	100 mg rectally at bedtime
	Cortifoam®	90 mg rectally once or twice daily
	Anucort® 25 mg	25–50 mg rectally twice daily
	Proctocort® 30 mg	25–50 mg rectally twice daily

Immunosuppressants

Agents targeting the excessive immune response or cytokines involved in IBD are potential treatment options (Table 16–3). Azathioprine and its active metabolite 6-mercaptopurine (6-MP) are inhibitors of purine biosynthesis and reduce IBD-associated GI inflammation. They are most useful for maintaining remission of IBD or reducing the need for long-term use of corticosteroids. Use in active disease is limited by their slow onset of action, which may be as long as 3 to 12 months. Adverse effects associated with azathioprine and 6-MP include hypersensitivity reactions resulting in pancreatitis, fever, rash, hepatitis, and leukopenia.[25,26]

Methotrexate is a folate antagonist used primarily for maintaining remission of CD. It may be administered orally, subcutaneously, or intravenously and may result in a steroid-sparing effect in patients with steroid-dependent disease.[26,27] Long-term methotrexate use may result in serious adverse effects, including hepatotoxicity, pulmonary fibrosis, and bone marrow suppression. Methotrexate is teratogenic and should not be used in pregnant women or those who plan to become pregnant.

Cyclosporine is a cyclic polypeptide immunosuppressant typically used to prevent organ rejection in transplant patients. Its use is restricted to patients with fulminant or refractory symptoms in patients with active IBD. Significant toxicities associated with cyclosporine are nephrotoxicity, risk of infection, seizures, hypertension, and liver function test abnormalities.[1,13,14]

TABLE 16–3. Immunosuppressant and Biologic Agents for Treatment of Inflammatory Bowel Disease

Drug	Trade Names	Dose
Azathioprine	Imuran®, Azasan®	1.5–2.5 mg/kg per day orally
6-Mercaptopurine	Purinethol®	1.5–2.5 mg/kg per day orally
Methotrexate	Rheumatrex®, Trexall®	15–25 mg weekly (IM/SC/orally)
Cyclosporine	Sandimmune®	4 mg/kg per day IV continuous infusion
Infliximab	Remicade®	Induction: 5 mg/kg IV at 0, 2, and 6 weeks; 10 mg/kg per dose IV for non-responders Maintenance: 5 mg/kg IV every 8 weeks

IM, intramuscular; IV, intravenous; SC, subcutaneous.

Biologic Agents

Infliximab is the only biologic agent routinely used for managing IBD. It is a murine-human IgG_1 antibody directed against TNF-α.[14] Reduction in TNF-α activity in patients with IBD is associated with improvement in the underlying inflammatory process. Disadvantages of infliximab include need for intravenous administration, significant drug cost, and potential for adverse effects. Adverse effects include infusion-related reactions such as fever, chest pain, hypotension, and dyspnea.[29] Infliximab has also been associated with reactivation of serious infections, particularly intracellular pathogens such as tuberculosis.[19,30] For this reason, infliximab should not be used in patients with current infections, and patients should be screened for tuberculosis prior to initiating therapy. Infliximab may also lead to the development or exacerbation of heart failure; it should be avoided in patients with advanced or decompensated heart failure.[31]

Other Agents

Antibiotics have been studied based on the rationale that they may interrupt the inflammatory response directed against endogenous bacterial flora. Metronidazole and ciprofloxacin have been the two most widely-studied agents.[32] Metronidazole may benefit some patients with pouchitis (inflammation of surgically-created intestinal pouches) and patients with CD who have had ileal resection or have perianal fistulas. Ciprofloxacin has shown some efficacy in refractory active CD. Both drugs may cause diarrhea, and long-term use of metronidazole is associated with the development of peripheral neuropathy.

Because smoking is associated with reduced symptoms of UC, nicotine has been studied as a potential treatment option. Transdermal nicotine may result in some improvement in mild to moderate UC symptoms. Daily doses between 15 and 25 mg appear to be most effective, but the role of nicotine therapy is not well defined.[1]

Probiotics, such as *Lactobacillus acidophilus* or *Bifidobacterium*, may offer possible benefit, based on the rationale that modification of the host flora may alter the inflammatory response. Some evidence exists for improvement in disease symptoms, but further well-controlled trials are needed.[26]

Treatment of Ulcerative Colitis

Drug and dosing guidelines based on disease severity and location are presented in Table 16–4.

Mild to Moderate Active UC

❼ *Treatment of acute episodes of ulcerative colitis is dictated by the severity and extent of disease, and first-line therapy of mild to moderate disease involves oral or topical aminosalicylate derivatives.* Topical suppositories and enemas are preferred for active distal UC (left-sided disease and proctitis), as they deliver mesalamine directly to the site of inflammation. Topical mesalamine is superior to both topical corticosteroids and oral aminosalicylates for inducing remission in active mild to moderate UC.[1,33,34] Enemas are appropriate for patients with

Patient Encounter 1, Part 2: The Medical History and Physical Examination

PMH
Tonsillectomy at age 5, fractured right clavicle (sports related)

FH
Both parents alive; father has history of hypertension, type 2 DM, and dyslipidemia; mother has a history of colon cancer with subtotal colectomy; brother with history of "indeterminate colitis"

SH
College student, social alcohol use and $^1/_2$ to 1 pack per day tobacco use for 6 years

Meds
Naproxen 220 mg PO as needed, Lo-Ovral PO once daily

ROS
(+) Diarrhea, abdominal pain, fatigue, back pain, fever, weight loss

PE
VS: blood pressure 118/65 mm Hg, pulse 92 beats per minute, respiratory rate 13/minutes, temperature 37.9°C (100.2°F)
CV: Tachycardia with normal rhythm, no murmurs, rubs, or gallops
HEENT: Dry mucous membranes
Abd: Soft, non-distended, mild diffuse tenderness, (+) bowel sounds, (–) hepatosplenomegaly, (–) masses, heme (+) stool
MS: Point tenderness over sacral area, (–) erythema, reduced lower back ROM

Labs
Sodium 139 mEq/L (139 mmol/L), potassium 3.2 mEq/L (3.2 mmol/L), chloride 100 mEq/L (100 mmol/L), bicarbonate 27 mEq/L (27 mmol/L), blood urea nitrogen 12 mg/dL (4.3 mmol/L urea), serum creatinine 1.0 mg/dL (88.4 μmol/L), albumin 4.2 g/dL (42 g/L), hemoglobin 11 g/dL (110 g/L or 6.82 mmol/L), hematocrit 33%, white blood cell count 11.0 x 10^3/mm^3 (11 × 10^9/L), platelets 300 × 10^3/mm^3 (300 × 10^9/L), ESR 120 mm/hour
Imaging: Abdominal x-ray: (–) obstruction, perforation, or colonic dilation
Colonoscopy: patchy "cobblestone" inflammation in the terminal ileum and ascending colon with evidence of recent bleeding, (–) polyps or strictures, biopsy taken
Path: Evidence of disease extension to muscularis with non-caseating granulomas

- What factors should you consider in choosing appropriate therapy for this patient?

TABLE 16–4. Treatment Recommendations for Ulcerative Colitis

Disease Severity and Location	Active Disease	Maintenance of Remission
Mild Disease		
Proctitis	Mesalamine suppository 1 g rectally daily	May reduce suppository frequency to 1 g 3 times/week
Left-sided disease	Mesalamine enema 1 g rectally daily, *or* Mesalamine 2.4–4.8 g/day or sulfasalazine 4–6 g/day orally	May reduce enema frequency to 1 g every other day, *or* Taper to mesalamine 1.6–2.4 g/day or sulfasalazine 2–4 g/day orally
Colitis	Mesalamine 2.4–4.8 g/day or sulfasalazine 4–6 g/day orally	Taper to mesalamine 1.6–2.4 g/day or sulfasalazine 2–4 g/day orally
Moderate Disease		
Proctitis	Mesalamine suppository 1 g rectally daily; If no response to mesalamine: • Prednisone 40–60 mg/day orally	May reduce suppository frequency to 1 g 3 times/week; taper prednisone as soon as possible; Consider adding azathioprine or 6-MP 1.5–2.5 mg/kg per day orally
Left-sided disease	Mesalamine enema 1 g rectally at bedtime daily, *or* Mesalamine 2.4–4.8 g/day or sulfasalazine 4–6 g/day orally	May reduce enema frequency to 1 g 3 times/week if symptoms permit; May reduce dose of oral agents if symptoms permit; Consider adding azathioprine or 6-MP 1.5–2.5 mg/kg per day orally
Colitis	Mesalamine 2.4–4.8 g/day or sulfasalazine 4–6 g/day orally; If no response to mesalamine or sulfasalazine: • Prednisone 40–60 mg/day orally; *or* • Infliximab 5 mg/kg IV at weeks 0, 2, and 6	Taper mesalamine to 1.6–2.4 g/day or sulfasalazine 2–4 g/day orally; If prednisone or infliximab were required: • Taper prednisone as soon as possible; • Give infliximab 5 mg/kg IV every 8 weeks Consider adding azathioprine or 6-MP 1.5–2.5 mg/kg per day orally
Severe or Fulminant Disease	Hydrocortisone 300 mg IV daily (or equivalent) × 7 days, *or* Infliximab 5 mg/kg IV at weeks 0, 2, and 6 If no response to IV corticosteroids or infliximab: • Cyclosporine 4 mg/kg per day IV	Change to oral corticosteroid and taper as soon as possible; Restart oral mesalamine or sulfasalazine May continue infliximab at maintenance doses of 5 mg/kg every 8 weeks

IV, intravenous; 6-MP, 6-mercaptopurine.

left-sided disease, as the medication will reach the splenic flexure. Suppositories deliver mesalamine up to approximately 20 cm and are most appropriate for treating proctitis.[6]

Topical mesalamine products provide a more rapid response than oral preparations. Improvement in symptoms may be seen in as little as 2 days, but 2 to 4 weeks of treatment may be necessary for maximal response. Response rates of up to 90% after 4 weeks of topical therapy have been reported, compared to 45% to 62% response rates with oral therapy.[6,18] Oral and topical mesalamine preparations may be used together to provide maximal effect. Oral mesalamine may also be used for patients who are unwilling to use topical preparations.

Topical corticosteroids are typically reserved for patients who do not respond to topical mesalamine. Patients should be properly educated regarding appropriate use of topical products. This includes proper administration and adequate retention of topical mesalamine products in order to maximize efficacy.

For patients with more extensive disease extending proximal to the splenic flexure, oral sulfasalazine or any of the newer oral mesalamine products is considered first-line therapy.[1] Doses should provide 4 to 6 g of sulfasalazine or 4.8 g of mesalamine. While little differences in efficacy exist between mesalamine products, sulfasalazine and olsalazine have a higher incidence of adverse effects.[18] Induction of remission may require 4 to 8 weeks of therapy at appropriate treatment doses.

Oral corticosteroids may be used for patients who are unresponsive to sulfasalazine or mesalamine. Prednisone doses of 40 to 60 mg per day (or equivalent) are recommended.[1] Azathioprine or 6-MP is used for patients unresponsive to corticosteroids or those who become steroid-dependent. Over a 12-month period, these agents have been shown to reduce the relapse rate to 36% versus 59% seen with placebo.[1] Infliximab 5 mg/kg may also be used for patients who are unresponsive to conventional oral therapies and may reduce the need for colectomy after 3 months of treatment.[35]

Severe or Fulminant UC

Patients with severe UC symptoms require hospitalization for management of their disease. If the patient is unresponsive to oral or topical mesalamine and oral corticosteroids, then a course of intravenous corticosteroids should be initiated.[1] Hydrocortisone 300 mg/day given in three divided doses or methylprednisolone 60 mg daily for 7 to 10 days are the preferred therapies.

Infliximab 5 mg/kg is also an option for severe UC. Cyclosporine 2 to 4 mg/kg per day given as a continuous intravenous infusion should be reserved for patients unresponsive to 7 to 10 days of intravenous corticosteroid therapy.

Patients with fulminant disease are treated similarly, although infliximab is not indicated for this population. Patients with fulminant UC should be assessed for signs of significant systemic toxicity or colonic dilation, which may require earlier surgical intervention.

Maintenance of Remission

Unfortunately, up to 50% of patients receiving oral therapies and up to 70% of untreated patients relapse within 1 year after achieving remission.[26] For this reason, patients may require maintenance drug therapy indefinitely to preserve remission.

❽ *Maintenance of remission of ulcerative colitis may be achieved with oral or topical aminosalicylates.* Mesalamine suppositories 1 g daily may prevent relapse in up to 90% of patients with proctitis.[1] Mesalamine enemas are appropriate for left-sided disease and may often be dosed three times weekly. Oral mesalamine at lower doses (e.g., 1.6 g per day) may be combined with topical therapies to maintain remission. Topical or oral corticosteroids are not effective for maintaining remission of distal UC and should be avoided.

Oral sulfasalazine or mesalamine is effective in maintaining remission in patients with more extensive disease.[1,26] Lower daily doses (e.g., 2 to 4 g sulfasalazine or 1.6 to 2.4 g mesalamine) may be used for disease maintenance. As with distal UC, oral corticosteroids are not effective for maintaining remission and should be avoided due to the high incidence of adverse effects.

❽ *Immunosuppressants such as azathioprine or 6-mercaptopurine can be used for unresponsive patients or those who develop corticosteroid dependency.* Remission may be maintained in up to 58% of patients after 5 years of treatment.[1,25] Intermittent infliximab dosing (5 mg/kg IV every 8 weeks) may be used to maintain disease remission and reduce the need for corticosteroids in patients with moderate to severe UC. Colectomy is an option for patients with progressive disease who cannot be maintained on drug therapy alone.

Treatment of Crohn's Disease

Drug and dosing guidelines based on disease severity and location are presented in Table 16–5.

Mild to Moderate Active CD

❾ *Induction of remission of mild to moderate active CD is accomplished with oral aminosalicylates.* Sulfasalazine 4 to 6 g per day is most effective for patients with colonic involvement, with response rates of 50%.[2,5] Mesalamine products have

TABLE 16–5. Treatment Recommendations for Crohn's Disease

Disease Location and Severity	Active Disease	Maintenance of Remission
Mild Disease		
Ileal or ileocolonic	Mesalamine 2.4–4.8 g/day or sulfasalazine 4–6 g/day orally	Taper mesalamine 1.6–2.4 g/day or sulfasalazine 2–4 g/day orally
Ileal +/– ascending colon	Budesonide 9 mg daily orally for up to 8 weeks	Taper budesonide to 6 mg daily for up to 3 months
Perianal	Mesalamine 2.4–4.8 g/day or sulfasalazine 4–6 g/day orally; May add metronidazole 10–20 mg/kg per day or ciprofloxacin 1 g daily	Taper mesalamine to 1.6–2.4 g/day or sulfasalazine 2–4 g/day orally
Moderate Disease	Same treatment as for mild disease; If inadequate response to aminosalicylate, consider; • Infliximab 5 mg/kg IV at 0, 2, and 6 weeks, *or* • Prednisone 40–60 mg/day orally, *or* • Budesonide 9 mg/day orally for up to 8 weeks; If fistulizing disease, consider: • Infliximab 5 mg/kg IV at 0, 2, and 6 weeks	Continue aminosalicylate at maintenance dose; May continue infliximab at maintenance doses of 5 mg/kg every 8 weeks; Taper prednisone as soon as possible; Taper budesonide to 6 mg daily for 3 months; Consider adding azathioprine or 6-MP 1.5–2.5 mg/kg per day orally or methotrexate 12.5–25 mg orally or IM/SC once weekly
Severe or Fulminant Disease	Hydrocortisone 300 mg IV daily (or equivalent) × 7 days, *or* Infliximab (severe or fistulizing disease) 5 mg/kg IV at 0, 2, and 6 weeks; Consider cyclosporine 4 mg/kg per day for refractory disease	Taper corticosteroid as soon as possible; May continue infliximab 5 mg/kg IV every 8 weeks; Consider adding azathioprine or 6-MP 1.5–2.5 mg/kg per day orally or methotrexate 12.5–25 mg orally or IM/SC weekly

IM; intramuscular; IV, intravenous; 6-MP, 6-mercaptopurine; SC, subcutaneous

Patient Encounter 2

A 57-year-old African-American man presents to the clinic for follow-up management of UC. He has had left-sided disease for 3 years and has been maintained in remission on maximal doses of oral mesalamine and prednisone 35 mg orally once daily. His provider has attempted several times to taper the prednisone dose, but the patient experiences a reappearance of symptoms if the dose is lowered below this level. Medical history is also significant for hypertension and heart failure. He has no known drug allergies.

- What are the risks of long-term corticosteroid use in this patient?
- What treatment options are available for reducing corticosteroid dependency in this patient?
- What other information is needed before recommending a pharmacologic intervention?

shown more variable results but may be used for patients with ileal, ileocolonic, or colonic CD.[2,36] These drugs are typically better tolerated than sulfasalazine at full treatment doses. Induction of remission may require up to 16 weeks of treatment at full doses.[36]

Budesonide 9 mg orally once daily for up to 8 weeks may be used for mild to moderate active CD in patients with involvement of the terminal ileum or ascending colon, with success expected in 50% to 60% of patients.[23] Because the formulation releases budesonide in the terminal ileum, it is not effective in reaching sites distal to the ascending colon.[23,36] Conventional oral corticosteroids such as prednisone and methylprednisolone may be used for patients who are unresponsive to aminosalicylates or budesonide.

Metronidazole or ciprofloxacin can be used in patients who do not respond to oral aminosalicylates. Response rates of up to 50% are reported, but the data are conflicting and these agents should generally not be considered first-line therapy.[2,36]

Moderate to Severe Active CD

❾ *Patients with moderate to severe active CD may be treated with oral corticosteroids, such as prednisone 40 to 60 mg daily.*[2] Budesonide 9 mg orally once daily may be used for moderate active CD involving the terminal ileum or ascending colon. Infliximab is an effective alternative to corticosteroid therapy for patients with moderate to severe CD, including patients with fistulizing or perianal disease.[15,37–39] The recommended regimen for induction of remission is infliximab 5 mg/kg at weeks 0, 2, and 6; it is effective in inducing remission in approximately 80% of patients at 8 weeks. Complete closure of existing enterocutaneous fistulae occurs in approximately 50% of patients. For patients with simple perianal fistulae, antibiotics and infliximab are appropriate treatment options. Complex perianal fistulae are those associated with multiple openings, abscess, stricture, or penetration into the vaginal wall. These types of perianal fistulae may require surgical intervention but may also be amenable to treatment with antibiotics, infliximab, azathioprine, or 6-MP.[2,15]

Severe to Fulminant Active CD

Most patients with severe to fulminant CD require hospitalization for appropriate treatment. Patients should be assessed for possible surgical intervention if abdominal distention, masses, abscess, or obstruction are present. Intravenous daily doses of corticosteroids equivalent to prednisone 40 to 60 mg are recommended as initial therapy to rapidly suppress severe inflammation.

If there are no contraindications, infliximab 5 mg/kg followed by 5 mg/kg at weeks 2 and 6 may be used for severe active CD. There is no evidence that infliximab is either safe or effective for fulminant disease.

Adjunctive therapy with fluid and electrolyte replacement should be initiated. Nutritional support with enteral or parenteral nutrition may be indicated for patients unable to eat for more than 5 to 7 days.[2] Some evidence suggests that enteral nutrition provides anti-inflammatory effects in patients with active CD.[40,41]

Limited evidence indicates that cyclosporine, or possibly tacrolimus, may be effective as salvage therapy for patients who fail intravenous corticosteroid therapy.[2] Surgical intervention may ultimately be necessary for medically refractory disease.

Maintenance of Remission in CD

Patients with CD are at high risk for disease relapse after induction of remission. Within 2 years, up to 80% of patients suffer a relapse; therefore, most patients should be evaluated for indefinite maintenance therapy. ❿ *Maintenance of remission of CD may be achieved with oral or topical aminosalicylate derivatives, immunosuppressants (such as azathioprine, 6-mercaptopurine, and methotrexate), or infliximab.*

In contrast to their use in UC, sulfasalazine and the newer aminosalicylates are marginally effective in preventing CD relapse in patients with medically-induced remission, with success rates of only 10% to 20% at 1 year.[26] Nevertheless, aminosalicylates are routinely used to maintain remission of CD. Some evidence does exist that the aminosalicylates may prevent or delay disease recurrence in patients with surgically-induced remisson.[2,26]

Several other treatment options exist for maintaining remission that may also reduce the need for corticosteroids.

Infliximab has been shown to maintain remission in 46% of patients compared to 23% of those treated with placebo over a 54-week period.[39] The dose used to maintain remission is 5 mg/kg IV given every 8 weeks. The dose may be increased to 10 mg/kg if patients lose response over time.

Azathioprine and 6-MP in oral doses up to 2.5 mg/kg per day have been shown to maintain remission in 45% of patients for up to 5 years.[2,25,26] These drugs may be used to prevent disease recurrence after surgically-induced remission. Methotrexate in doses ranging from 12.5 to 25 mg per week given orally, intramuscularly, or subcutaneously has resulted in remission rates of up to 52% at 3 years.[26,27]

Corticosteroids, while effective for rapidly inducing remission, are not effective for maintenance therapy and are associated with significant adverse effects with long-term use. Therefore, systemic or topical corticosteroids should not be used for maintaining remission in patients with IBD. Unfortunately up to 50% of patients treated acutely with corticosteroids become dependent on them to prevent symptoms.[2]

In place of conventional corticosteroids, budesonide 6 mg orally once daily may be used for up to 3 months after remission induction for mild to moderate CD. Remission rates decline significantly after this period.[23,24] The lower systemic bioavailability of budesonide results in a lower incidence of adverse effects than seen with conventional corticosteroids.

Treatment of IBD in Special Populations

Elderly Patients

Approximately 8% to 20% of patients with UC and 7% to 26% of patients with CD are elderly at initial diagnosis.[42] In general, IBD presents similarly in elderly patients compared to younger individuals. Elderly patients may have more comorbid diseases, some of which may make the diagnosis of IBD more difficult. Such conditions include ischemic colitis, diverticular disease, and microscopic colitis. Increased age is also associated with a higher incidence of adenomatous polyps, but the onset of IBD at an advanced age does not appear to increase the risk of developing colorectal cancer. Elderly patients may also use more medications, particularly NSAIDs, which may induce or exacerbate colitis.

Treatment of elderly patients with IBD is similar to that for younger patients, but special consideration should be given to some of the medications used. Corticosteroids may worsen diabetes, hypertension, heart failure, or osteoporosis. Infliximab should be used cautiously in patients with heart failure and should be avoided in New York Heart Association Class III or IV disease. Lastly, elderly patients requiring major surgical interventions may be at higher risk for surgical complications or may not meet eligibility criteria for surgery because of comorbid conditions, age-related organ dysfunction, or reduced functional status.

Children and Adolescents

CD occurs in approximately 4.56 per 100,000 pediatric patients, and UC occurs in about 2.14 cases per 100,000.[43] A major issue in children with IBD is the risk of growth failure secondary to inadequate nutritional intake. Failure to thrive may be an initial presentation of IBD in this population. Aggressive nutritional interventions may be required to facilitate adequate caloric intake. Chronic corticosteroid therapy may also be associated with reductions in growth.

Pediatric patients are also at higher risk for IBD-associated bone demineralization, which is accelerated by the use of systemic corticosteroids.

The aminosalicylates, azathioprine, 6-MP, and infliximab are all viable options for treatment and maintenance of IBD in pediatric patients. Use of immunosuppressive therapy or infliximab may help reduce overall corticosteroid exposure.

Pregnant Women

Inducing and maintaining remission of IBD prior to conception is the optimal approach in women planning to become pregnant. Active IBD may result in prematurity and low birth weight. Thus, pregnant women with IBD should be monitored closely, particularly during the third trimester.[44]

Patients do not need to discontinue drug therapy for IBD once they become pregnant, but certain adjustments may be required.[44,45] The aminosalicylates are considered safe to use in pregnancy, but sulfasalazine is associated with folate malabsorption. Because pregnancy results in a higher folate requirement, pregnant patients treated with sulfasalazine should be supplemented with folic acid 1 mg orally twice daily.[44] As with non-pregnant patients, corticosteroids may be used for treatment of active disease but not for maintenance of remission. Generally, corticosteroids confer no additional risk on the mother or fetus and are generally well tolerated. Both azathioprine and 6-MP have been used successfully in pregnant patients and do not appear to be associated with an increased risk, despite carrying a Food and Drug Administration (FDA) pregnancy category D rating. Cyclosporine has been used successfully for severe disease in pregnant patients and appears to be relatively safe; however, it should be reserved for fulminant disease unresponsive to conventional medical therapy.

Infliximab is FDA category B and also appears to carry minimal risk in pregnant patients. Little is known about excretion of infliximab in breast milk, so benefit versus risk should be considered if it is used during nursing.

Methotrexate is a known abortifacient and carries an FDA category X pregnancy rating. Thus, it is contraindicated during pregnancy. Metronidazole carries a theoretical risk of mutagenicity in humans, but short courses are safe during pregnancy. Prolonged use of metronidazole should be avoided in pregnant patients due to lack of safety data supporting its use.[45] First-trimester use of the antidiarrheal diphenoxylate has been associated with fetal malformations and should be avoided.

OUTCOME EVALUATION

- Monitor for improvement of symptoms in patients with active IBD, such as reduction in the number of daily stools, abdominal pain, fever, and heart rate.
- For patients in remission, assure that proper maintenance doses of medications are used and educate the patient to seek medical attention if symptoms recur or worsen.
- Evaluate patients receiving systemic corticosteroid therapy for improvement in symptoms and opportunities to taper or discontinue steroid therapy. For patients using more than 5 mg daily of prednisone for more than 2 months or for steroid-dependent patients consider the following:
  - Central bone mineral density testing to evaluate the need for preventive or therapeutic bisphosphonate therapy;
  - Periodic monitoring of blood glucose, lipids, and blood pressure;
  - Evaluation for evidence of cushingoid features or signs or symptoms of infection.
- When considering treatment with azathioprine or 6-MP, obtain baseline complete blood counts and liver function tests. These tests should be monitored closely (every 2 to 4 weeks) at the start of therapy and then approximately every 3 months during maintenance therapy.
- With azathioprine and 6-MP, monitor for hypersensitivity reactions, including severe skin rashes and pancreatitis. Educate the patient regarding signs and symptoms of pancreatitis (nausea, vomiting, and abdominal pain).
- Prior to initiating methotrexate therapy, obtain complete blood count, serum creatinine, liver function tests, chest x-ray, and pregnancy test (if female). Monitor blood counts weekly for 1 month, then monthly thereafter.
- Prior to initiating infliximab, obtain a tuberculin skin test to rule out latent tuberculosis. Assure that patients do not have a clinically significant systemic infection or New York Heart Association Class III or IV heart failure.
- In patients receiving infliximab, monitor for infusion-related reactions such as hypotension, dyspnea, fever, chills, or chest pain when administering intravenous doses.
- In patients with fistulae, monitor at every infliximab dosing interval for evidence of fistula closure and overall reduction in the number of fistulae.

Patient Care and Monitoring

1. Evaluate the patient's symptoms to determine if they are consistent with UC or CD. Determine whether the patient has evidence of extraintestinal manifestations or GI complications related to IBD. Identify any psychosocial problems related to the presence of IBD.
2. If the patient is presenting with an exacerbation of preexisting IBD, determine if the symptoms are similar in type and severity to the patient's previous episodes.
3. Assess the patient's medical history for pertinent drug allergies, tobacco use, and current prescription and nonprescription drug therapies. Determine if any of the medications could exacerbate IBD. If applicable, inquire about adherence or recent changes to the patient's current IBD drug regimen.
4. Use available diagnostic laboratory, endoscopic, and imaging data to gauge the extent and severity of the patient's disease.
5. Construct a drug treatment plan based on the disease severity and location. Identify potential contraindications or financial barriers to drug therapy. Inquire if the patient has an aversion to or inability to properly use certain drug formulations that you may wish to recommend, such as topical (rectal) products.
6. Assess whether the patient will require maintenance therapy after remission induction. If so, identify the treatment duration. Decide when the patient should receive follow-up care.
7. Outline parameters to evaluate the efficacy and toxicity of the drug regimen you are recommending. Determine whether the patient will need preventive drug therapy or diagnostic testing to prevent or screen for potential drug-related toxicities.
8. Educate the patient on proper use of drug therapy, including when to expect symptom improvement after initiation of treatment and which signs or symptoms to report that might be related to adverse drug effects.
9. Provide patient education on the proper use of aminosalicylate medications and assess regularly for adherence. Include the following:
   - Proper use of suppositories and enemas
   - The appropriate number of tablets or capsules to take per day
   - Appropriate dose titration, particularly with oral sulfasalazine
   - The time frame the patient can expect improvement based on drug dose and disease severity
   - Signs or symptoms of potential adverse effects
10. Once remission is achieved, evaluate the patient's drug regimen to determine if dose reductions or changes in frequency of administration are required. Reinforce the need for adherence to drug therapy in order to maximize effectiveness.
11. Educate patients about their disease state. Refer the patient to available support groups or IBD organizational resources if they are having difficulty in coping with their disease.

17 Nausea and Vomiting

Sheila Wilhelm

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Identify several causes of nausea and vomiting.
2. Describe the pathophysiologic mechanisms of nausea and vomiting.
3. Describe the three stages of nausea and vomiting.
4. Distinguish between simple and complex nausea and vomiting.
5. Identify the goals of treating nausea and vomiting.
6. Recommend a treatment regimen for a patient with nausea and vomiting associated with cancer chemotherapy, surgery, pregnancy, or motion sickness.
7. Outline a monitoring plan to evaluate the treatment outcomes for nausea and vomiting.

Key Concepts

❶ Nausea and vomiting are symptoms that can be due to a number of different causes.
❷ To treat nausea and vomiting most effectively, it is important to first identify the underlying cause of the symptoms.
❸ Nonpharmacologic approaches to treating nausea and vomiting include dietary, physical, and psychological changes.
❹ For prophylaxis of acute chemotherapy-induced nausea and vomiting, the combination of a 5-HT_3 antagonist and a corticosteroid is recommended for patients receiving highly emetogenic cisplatin or non–cisplatin-based chemotherapy.
❺ Droperidol or a 5-HT_3 receptor antagonist should be administered at the end of surgery to patients at high risk for developing postoperative nausea and vomiting.
❻ Nausea and vomiting of pregnancy affects the majority of pregnant women; the teratogenic potential of the therapy is the primary therapeutic consideration.
❼ Because the vestibular system is replete with muscarinic-type cholinergic and histaminic (H_1) receptors, anticholinergics and antihistamines are the most commonly used pharmacologic agents to prevent and treat motion sickness.

Nausea and vomiting are due to complex interactions of the gastrointestinal system, the vestibular system, and various portions of the brain. Nausea and vomiting have a variety of causes that can be simple or complex. Preventing and treating nausea and vomiting require pharmacologic and nonpharmacologic measures tailored to individual patients and situations.

ETIOLOGY AND EPIDEMIOLOGY

❶ *Nausea and vomiting are symptoms that can be due to a number of different causes.* Various disorders of the gastrointestinal, cardiac, neurologic, and endocrine systems can lead to nausea and vomiting (Table 17–1).[1–4] Cancer chemotherapy agents are rated according to their emetogenic potential, and antiemetic therapy is prescribed based on these ratings. Due to potentially severe nausea and vomiting, some patients are unable to complete their chemotherapy treatment regimen. Radiation therapy can induce nausea and vomiting, especially when it is used to treat abdominal malignancies.[5]

Oral contraceptives, hormone therapy, oral hypoglycemic agents, anticonvulsants, and opiates are other common therapies that can cause nausea and vomiting.[1] Some medications, such as digoxin and theophylline, cause nausea and vomiting in a dose-related fashion. Nausea and vomiting may indicate higher-than-desired drug concentrations. Ethanol and other toxins also cause nausea and vomiting.

Postoperative nausea and vomiting (PONV) occurs in 30% of surgical patients overall, and in up to 70% of high-risk patients.[6,7] This can be due to severing or disturbing the vagus nerve leading to gastric motility abnormalities. Additional risk

factors for PONV include female gender, history of motion sickness or PONV, non-smoking status, and use of opioids in the postoperative period.[8] The choice of anesthetic agents and the duration of surgery may also contribute to PONV.[6]

Pregnancy-associated nausea and vomiting is common, affecting 70% to 85% of pregnant women, especially early in pregnancy.[9] Approximately one-half of pregnant women experience nausea and vomiting of pregnancy (NVP), one-quarter experience nausea alone, and one-quarter are not affected.[9] In 0.5% to 2% of pregnancies, this can lead to **hyperemesis gravidarum**, a potentially life-threatening condition of prolonged nausea, vomiting, and consequently, malnutrition.[9]

PATHOPHYSIOLOGY

Nausea and vomiting consist of three stages: (1) **nausea**, (2) **retching**, and (3) **vomiting**. Nausea is the subjective feeling of a need to vomit.[1] It is often accompanied by autonomic symptoms such as pallor, tachycardia, diaphoresis, and salivation. Retching, which follows nausea, consists of diaphragm, abdominal wall, and chest wall contractions and spasmodic breathing against a closed glottis.[1] Retching can occur without vomiting, but this stage produces the pressure gradient needed for vomiting, although no gastric contents are expelled. Vomiting, or emesis, is a reflexive, rapid, and forceful oral expulsion of upper gastrointestinal contents due to powerful and sustained contractions in the abdominal and thoracic musculature.[1] Vomiting, like nausea, can be accompanied by autonomic symptoms.

Regurgitation, unlike vomiting, is a passive process without involvement of the abdominal wall and diaphragm wherein gastric or esophageal contents move into the mouth.[1] In patients with gastroesophageal reflux disease (GERD), one hallmark symptom is acid regurgitation.

Various areas in the brain and the gastrointestinal (GI) tract are stimulated when the body is exposed to noxious stimuli (e.g., toxins), gastrointestinal irritants (e.g., infectious agents), or chemotherapy. These areas include the **chemoreceptor trigger zone** (CTZ) in the area postrema of the fourth ventricle of the brain, the vestibular system, visceral afferents from the GI tract, and the cerebral cortex.[2,3] These in turn stimulate regions of the reticular areas of the medulla within the brain stem. This area is the central vomiting center, the area of the brain stem that coordinates the impulses sent to the salivation center, respiratory center, and the pharyngeal, GI, and abdominal muscles that lead to vomiting (Fig. 17–1).[10]

The CTZ, located outside the blood–brain barrier (BBB), is exposed to cerebrospinal fluid and blood.[2,3] Therefore it is easily stimulated by uremia, acidosis, and the circulation of toxins such as chemotherapeutic agents. The CTZ has many serotonin type 3 (5-HT_3), neurokinin-1 (NK_1), and dopamine (D_2) receptors.[2] Visceral vagal nerve fibers are rich in 5-HT_3 receptors. They respond to gastrointestinal distention, mucosal irritation, and infection.

Motion sickness is caused by stimulation of the vestibular system. This area contains many histaminic (H_1) and muscarinic cholinergic receptors. The higher brain (i.e., cerebral cortex) is affected by sensory input such as sights, smells, or emotions that can lead to vomiting. This area is involved in anticipatory nausea and vomiting associated with chemotherapy.

Nausea and vomiting can be classified as either simple or complex.[4] Simple nausea and vomiting occurs occasionally and is either self-limiting or relieved by minimal therapy. It does not have detrimental effects on hydration status, electrolyte balance, or weight because it is short-lived. Alternatively, complex nausea and vomiting requires more aggressive therapy because electrolyte imbalances, dehydration, and weight loss may occur. Unlike simple nausea and vomiting, complex nausea and vomiting can be caused by exposure to noxious agents.

CLINICAL PRESENTATION AND DIAGNOSIS

Clinical Presentation of Nausea and Vomiting

Symptoms

- Patients with nausea often complain of autonomic symptoms such as diaphoresis, general disinterest in surroundings, pallor or faintness, and salivation.

Signs

- With complex and prolonged nausea and vomiting, patients may show signs of malnourishment, weight loss, and dehydration (dry mucous membranes, skin tenting, tachycardia, and lack of axillary sweat).

Laboratory Tests

- Dehydration, electrolyte imbalances, and acid-base disturbances may be evident in complex and prolonged nausea and vomiting.
- Elevated blood urea nitrogen (BUN) and serum creatinine (SCr) concentrations, especially with a BUN to SCr ratio of 20:1 or greater, suggest dehydration.
- Calculated fractional excreted sodium (FeNa) less than 1% in patients with compromised baseline renal function, and less than 0.2% in patients with normal baseline renal function indicates dehydration and reduced renal perfusion.
- Low serum chloride and elevated serum bicarbonate levels indicate metabolic alkalosis.
- Arterial blood gases with a normal or elevated pH indicates metabolic alkalosis that may or may not be compensated.
- Hypokalemia may occur from gastrointestinal potassium losses and intracellular potassium shifts to compensate for alkalosis.

TREATMENT

Desired Outcomes

The primary goal of treatment is to relieve the symptoms of nausea and vomiting, which should increase the patient's quality of life. Drug therapy for nausea and vomiting should be safe, effective, and economical.

General Approach to Treatment

❷ *To treat nausea and vomiting most effectively, it is important to first identify the underlying cause of the symptoms.* Treating the cause (if possible) will in turn eliminate the nausea and vomiting.

Profuse or prolonged vomiting can lead to complications of dehydration and metabolic abnormalities. Patients must have adequate hydration and electrolyte replacement orally (if tolerated) or intravenously to prevent and correct these problems. Some pharmacologic treatments work locally in the GI tract (e.g., antacids and prokinetic agents), whereas others work in the central nervous system (e.g., antihistamines and antiemetics).[1]

Nonpharmacologic Therapy

A variety of effective pharmacologic treatments exist for nausea and vomiting, but they all have unwanted adverse treatment effects. For this reason, nonpharmacologic treatment options may be considered in selected patients.

Nonpharmacologic options are desirable for treating NVP due to concern for teratogenic effects with drug therapies. When treating PONV, the nonpharmacologic approach is appealing to minimize additive CNS depression with antiemetics and anesthetic agents. ❸ *Nonpharmacologic approaches to treating nausea and vomiting include dietary, physical, and psychological changes.*

Dietary approaches are the cornerstone of treatment for NVP.[11] They are included in treatment guidelines even though there is little evidence to support their effectiveness.[9] Recommendations include eating frequent, small meals; avoiding spicy or fatty foods; eating high-protein snacks; and eating bland or dry foods the first thing in the morning.[9,11] In addition to dietary changes, there is some evidence that women taking a multivitamin at the time of conception are less likely to seek medical attention for NVP.[9]

Acupressure and acupuncture have been investigated based on the theory that certain points on the body control specific bodily functions.[11] The P6 (Neiguan) point on the inside of the wrist has been used historically by acupuncturists to treat nausea and vomiting. While this approach seems safe and cost effective, efficacy data in the treatment of NVP are conflicting. The majority of studies showed a benefit to this approach, but the studies had methodologic flaws.[9,11,12]

Acupressure has also been investigated as a preventative tool for PONV and motion sickness.[13,14] Acupressure wrist bands may be effective in preventing PONV after short surgical procedures when applied prior to exposure to emetic stimuli such as anesthetic agents.[13] In contrast, the bands were not effective for preventing nausea and vomiting due to motion sickness in one study.[14]

Hypnosis may be effective for severe NVP.[11] Psychotherapy is another non-invasive treatment approach that is safe during pregnancy or in situations in which adverse treatment effects and drug interactions are a concern. One small study suggested that patients with hyperemesis gravidarum may benefit from the combination of psychotherapy and antiemetics.

Pharmacologic Therapy

Table 17–2 contains the names, usual adult dosages, and common adverse effects of the pharmacologic treatments for nausea and vomiting.[1,4,10]

Antacids and Antisecretory Agents

Antacids act locally in the stomach by neutralizing gastric acid and can be used to relieve nausea and vomiting related to gastric acid or heartburn.[4] Common antacids include magnesium hydroxide, aluminum hydroxide, and calcium carbonate. Antacids are generally safe when used infrequently but can cause diarrhea or constipation, which is product dependent (see Chapter 14 on gastroesophageal reflux disease for more detailed information on antacids). Because these agents are available over the counter (OTC), they are often used as first-line therapy.

The histamine$_2$-receptor antagonists or H_2RAs (cimetidine, famotidine, nizatidine, and ranitidine) and proton pump inhibitors (omeprazole, esomeprazole, lansoprazole, pantoprazole, and rabeprazole) reduce the amount of acid secreted into the stomach by gastric parietal cells. These agents are also helpful for nausea and vomiting related to gastric acid secretion.

Anticholinergics (Scopolamine)

The anticholinergic agent scopolamine blocks muscarinic receptors in the vestibular system, thereby halting signaling to the central nervous system (CNS). It is effective for preventing and treating motion sickness and perhaps for preventing PONV as well.[15,16] Scopolamine is available as an adhesive transdermal patch that is effective for up to 72 hours after application. This may be beneficial for patients unable to tolerate oral medications or those requiring continuous prevention of motion sickness (e.g., passengers on cruise ships). Scopolamine is associated with adverse anticholinergic effects such as sedation, visual disturbances, dry mouth, and dizziness.

Antihistamines

Antihistamines are commonly used to prevent and treat nausea and vomiting due to motion sickness, vertigo, or migraine headache.[1,17] Their efficacy is presumably due to the high concentration of histamine (H_1) and muscarinic cholinergic receptors within the vestibular system. Similarly to scopolamine, antihistamines such as diphenhydramine and

TABLE 17–2. Antiemetic Agents: Adult Doses and Adverse Effects

Drug	Adult Dosing	Adverse Effects[a]
Antacids		
Magnesium hydroxide, aluminum hydroxide, calcium carbonate, others	15–30 mL every 2–4 hours as needed	Diarrhea, constipation
H_2-Receptor Antagonists		
Cimetidine (Tagamet HB)	200 mg twice daily as needed	Most common: Headache, diarrhea
Famotidine (Pepcid AC)	10 mg twice daily as needed	Less common: Constipation
Nizatidine (Axid AR)	75 mg twice daily as needed	Rare: Anemia, elevated hepatic transaminases
Ranitidine (Zantac 75)	75 mg twice daily as needed	
Proton Pump Inhibitors		
Esomeprazole (Nexium)	20 mg once daily as needed	Most common: Headache
Lansoprazole (Prevacid)	15 mg once daily as needed	Less common: Diarrhea, abdominal pain, nausea, vomiting
Omeprazole (Prilosec)	20 mg once daily as needed	Rare: Elevated hepatic transaminases, hyperglycemia
Pantoprazole (Protonix)	40 mg once daily as needed	
Rabeprazole (Aciphex)	20 mg once daily as needed	
Anticholinergics		
Scopolamine (Transderm Scop)	0.5 mg every 72 hours as needed	Most common: Dry mouth, drowsiness, impaired eye accommodation Rare: Disorientation, memory disturbances, dizziness, hallucinations
Antihistamines		
Cyclizine (Marezine)	50 mg every 4–6 hours as needed	Most common: Sedation, dry mouth, constipation
Dimenhydrinate (Dramamine)	50–100 mg every 4–6 hours as needed	Less common: Confusion, blurred vision, urinary retention
Diphenhydramine (Benadryl)	10–150 mg every 4–6 hours as needed	
Hydoxyzine (Atarax, Vistaril)	25–100 mg every 6 hours as needed	
Meclizine (Bonine, Antivert)	25–50 mg every 24 hours as needed	
Phenothiazines		
Chlorpromazine (Thorazine)	10–25 mg every 4–6 hours as needed	Most common: Sedation, lethargy, skin sensitization
Chlorpromazine suppository	50–100 mg every 6–8 hours as needed	Less common: Cardiovascular effects, extrapyramidal effects, cholestatic jaundice, hyperprolactinemia
Prochlorperazine (Compazine)	5–10 mg 3–4 times daily as needed	Rare: Neuroleptic malignant syndrome, hematologic abnormalities
Prochlorperazine suppository	25 mg twice daily as needed	
Promethazine (Phenergan)	12.5–25 mg every 4–6 hours as needed	
Thiethylperazine (Torecan)	10 mg 3 times daily	
Butyrophenones		
Droperidol (Inapsine)	2.5–5 mg every 4–6 hours as needed	Most common: Sedation, hypotension, tachycardia
Haloperidol (Haldol)	1–5 mg every 12 hours as needed	Less common: Extrapyramidal effects, dizziness, increase in blood pressure, chills, hallucinations
Benzamides		
Domperidone (Motilium)[b]	10–20 mg 3 times daily as needed	Most common: Sedation, restlessness, diarrhea (metoclopramide), agitation, central nervous system depression
Metoclopramide (Reglan)	PONV: 10–20 mg 10 minutes prior to anesthesia; CINV: 1–2 mg/kg every 2 hours × 2, then every 3 hours × 3; Delayed CINV: 0.5 mg/kg *or* 20 mg every 6 hours as needed, days 2–4	Less common: Extrapyramidal effects (more frequent with higher doses), hypotension, neuroleptic syndrome, supraventricular tachycardia (with intravenous administration)
Trimethobenzamide (Tigan)	200–250 mg 3 to 4 times daily as needed	
Corticosteroids		
Dexamethasone (Decadron)	10 mg prior to chemotherapy, repeat with 4–8 mg every 6 hours for a total of 4 doses	Most common: Gastrointestinal upset, anxiety, insomnia Less common: Hyperglycemia, facial flushing,euphoria, perineal itching or burning (with dexamethasone, probably secondary to vehicle and rate of injection)
Methylprednisolone (Solu-Medrol)	125–500 mg every 6 hours for total of 4 doses	
Cannabinoids		
Dronabinol (Marinol)	5–7.5 mg/m^2 every 2–4 hours as needed	Most common: Drowsiness, euphoria, somnolence, vasodilation, vision difficulties, abnormal thinking, dysphoria
Nabilone (Cesamet)	1–2 mg 2–3 times daily as needed	Less common: Diarrhea, flushing, tremor, myalgia

(*Continued*)

TABLE 17-2. Antiemetic Agents: Adult Doses and Adverse Effects *(Continued)*

Drug	Adult Dosing	Adverse Effects[a]
Benzodiazepines		
Lorazepam (Ativan)	0.5–2 mg prior to chemotherapy	Most common: Sedation, amnesia Rare: Respiratory depression, ataxia, blurred vision, hallucinations, paradoxical reactions (weeping, emotional reactions)
Serotonin Antagonists		
Dolasetron (Anzemet)	1.8 mg/kg intravenously 30 minutes prior to chemotherapy *or* 100 mg orally within 1 hour before chemotherapy	Most common: Headache, asymptomatic prolongation of electrocardiographic interval Less common: Constipation, asthenia, somnolence, diarrhea, fever, tremor or twitching, ataxia, lightheadedness, dizziness, nervousness, thirst, muscle pain, warm or flushing sensation on intravenous administration Rare: Transient elevations in hepatic transaminases
Granisetron (Kytril)	10 mcg/kg intravenously prior to chemotherapy *or* 1 mg orally up to 1 hour prior to chemotherapy and 1 mg 12 hours after the first dose, or 2 mg up to 1 hour prior to chemotherapy	
Ondansetron (Zofran)	32 mg intravenously prior to chemotherapy as a single dose, or 0.15 mg/kg prior to chemotherapy, repeat at 4 and 8 hours *or* 8 mg orally 30 minutes prior to chemotherapy, repeat at 4 and 8 hours and every 12 hours for 1–2 days after chemotherapy completion	
Palonosetron (Aloxi)	0.25 mg intravenously 30 minutes prior to chemotherapy	
Neurokinin-1 Antagonist		
Aprepitant (Emend)	125 mg on day 1, 1 hour prior to chemotherapy; 80 mg on days 2 and 3	Most common: Fatigue, hiccups Less common: Dizziness, headache, insomnia Rare: Transient elevations in hepatic transaminases

[a]Most common, greater than 10%, less common, 1–10%, rare, less than 1%. Based on FDA-approved labeling and generalized to the drug class.
[b]Not available in the United States.
CINV, chemotherapy-induced nausea and vomiting; PONV, postoperative nausea and vomiting.

meclizine cause undesired effects including drowsiness and blurred vision. Cetirizine and fexofenadine, two second-generation antihistamines without CNS depressant properties, were found to be ineffective for treating motion sickness, perhaps because they lack CNS effects.[17]

Some antihistamines such as diphenhydramine, dimenhydrinate, and meclizine are available without a prescription, making self-treatment convenient for patients. Antihistamines are available in a variety of dosage forms, including oral capsules, tablets and liquids. Liquid formulations are convenient for children or adults who are unable to swallow solid dosage forms.

Dopamine Antagonists

Stimulation of dopamine (D_2) receptors in the CTZ leads to nausea and vomiting (Fig. 17–1). Phenothiazine antiemetics act primarily via a central antidopaminergic mechanism in the CTZ.[1] Common phenothiazines that have long been used for treating nausea and vomiting include promethazine, prochlorperazine, chlorpromazine, and thiethylperazine. They are available as oral solids and liquids, rectal suppositories, and parenteral formulations. This permits effective use of phenothiazines in a variety of settings including treatment of severe motion sickness or vertigo, gastritis or gastroenteritis, NVP, PONV, or CINV.[5,6,9,18–20]

Phenothiazines may cause sedation, orthostatic hypotension, and **extrapyramidal symptoms** (EPS) such as dystonia (involuntary muscle contractions), tardive dyskinesia (irreversible and permanent involuntary movements), and akathisia (motor restlessness or anxiety).[1,21,22] Chronic phenothiazine use has been associated with EPS, but single doses have also caused these effects.[23]

Akathisia is disturbing for patients and can be disruptive to patient care. Giving diphenhydramine with prochlorperazine may reduce the incidence of akathisia, but the combination increases the risk of sedation.[24] Slowing the intravenous infusion rate of prochlorperazine does not decrease akathisia.[22,23]

Droperidol, a butyrophenone derivative, is another centrally-acting anti-dopaminergic agent effective for preventing PONV and treating opioid-induced nausea and vomiting.[1,6] It is also used for treating CINV for patients who are intolerant to serotonin receptor antagonists and corticosteroids.[5]

Adverse effects of droperidol include sedation, agitation, and restlessness. In addition, droperidol carries a United States Food and Drug Administration (FDA) black box warning regarding the potential for QT interval prolongation and cardiac arrhythmias that may result in torsades de pointes and sudden cardiac death.[25] Droperidol should not be used in patients with a prolonged QT interval or in those who are at risk for developing a prolonged QT interval (e.g., heart failure, electrolyte abnormalities, or concurrently taking other medications that may prolong the QT interval).[25] A 12-lead electrocardiogram (ECG) is recommended prior to treatment with droperidol.

The substituted benzamides metoclopramide and domperidone (not available in the United States) act as dopamine (D_2) antagonists both centrally in the CTZ and peripherally in the GI tract.[1,26] They also display cholinergic activity, which increases lower esophageal sphincter tone and promotes gastric motility. Metoclopramide at high doses has antiserotonergic properties as well. Because metoclopramide and domperidone have both antiemetic and prokinetic effects, both are used for a variety of disorders including PONV, CINV, NVP, gastroparesis, GERD, and migraine headaches.[1,5,6,9,27–29] Metoclopramide is available in injectable, oral solid, and oral liquid dosage forms, allowing for its use in both hospitalized and ambulatory patients. Other substituted benzamides include trimethobenzamide and benzquinamide.

Metoclopramide crosses the BBB and has centrally-mediated adverse effects. Young children and the elderly are especially susceptible to these effects, which include somnolence, reduced mental acuity, anxiety, depression, and EPS (akathisia, dystonia, and tardive dyskinesia).[30] The overall incidence of adverse effects is estimated to be 10% to 20%.[1]

Domperidone minimally crosses the BBB; it acts in the CTZ which lies outside of the BBB. As such, domperidone is less likely to cause the centrally-mediated adverse effects seen with metoclopramide and has an estimated overall incidence of 5% to 10%.[1,30] However, domperidone has been associated with prolonged QT intervals, cardiac arrhythmias, and sudden death.[31] It should not be used for patients with underlying long QT interval or for those on other medications that prolong the QT interval. Both metoclopramide and domperidone can cause hyperprolactinemia, galactorrhea, and gynecomastia.

Corticosteroids

Corticosteroids, especially dexamethasone and methylprednisolone, are used alone or in combination with other antiemetics for preventing and treating CINV or radiation-induced nausea and vomiting.[5,10] They are administered either orally or intravenously. Their efficacy is thought to be due to release of 5-HT, reduction in the permeability of the BBB, and reduction of inflammation.[32] Common adverse effects with short-term use include gastrointestinal upset, anxiety, insomnia, and hyperglycemia.[10] Because treatment for CINV is generally of short duration, long-term adverse effects (e.g., reduction in bone mineral density, corticosteroid-related diabetes, and cataracts) are not usually seen.

Cannabinoids

Cannabinoids have antiemetic activity when used alone or in combination with other antiemetics.[5] Dronabinol and nabilone are commercially available oral formulations used for preventing and treating refractory CINV.[5,10] Dronabinol is also used to treat anorexia and weight loss associated with human immunodeficiency virus (HIV) infection. Cannabinoids are thought to exert their antiemetic effect centrally, although the exact mechanism of action is unknown.[1,10] Sedation, euphoria, hypotension, ataxia, dizziness, and vision difficulties can occur with cannabinoids.

Benzodiazepines

Benzodiazepines, especially lorazepam, are used to prevent and treat CINV.[5,10] Lorazepam is thought to prevent input from the cerebral cortex and limbic system from reaching the central vomiting center in the brain stem.[10] Sedation and amnesia are common side effects. Respiratory depression can occur with high doses or when other central depressants such as alcohol are combined with benzodiazepines.

Serotonin Antagonists

Chemotherapeutic agents cause release of 5-hydroxytryptamine (5-HT, serotonin) from enterochromaffin cells in the intestinal mucosa.[32] This increase in 5-HT concentrations leads to stimulation of the visceral vagal nerve fibers and CTZ, thereby triggering nausea and vomiting. Both the CTZ and the vagal visceral nerve fibers are rich in 5-HT_3 receptors.[2] Selective 5-HT_3 receptor antagonists (ondansetron, granisetron, dolasetron, and palonosetron) are available to prevent and treat nausea and vomiting due to stimulation of these receptors, especially for prevention and treatment of CINV.[5,10,32] They are also used to treat PONV.[6] These agents are well tolerated; the most common adverse effects are headache, somnolence, diarrhea, and constipation.[10] Asymptomatic electrocardiograph changes have also been reported.

Neurokinin-1 Receptor Antagonists

Aprepitant is the first NK_1 receptor antagonist antiemetic drug.[33] NK_1 receptors are present in the CTZ and GI tract and are involved

in the nausea and vomiting response, especially CINV.[10,32] Aprepitant is effective for preventing acute and delayed CINV when used with a 5-HT_3 antagonist and a corticosteroid.[33,34]

Chemotherapy-Induced Nausea and Vomiting

CINV is classified as: (1) acute (occurring within 24 hours after receiving chemotherapy); (2) delayed (occurring more than 24 hours after receiving chemotherapy); or (3) anticipatory (occurring prior to chemotherapy in patients who experienced acute or delayed nausea and vomiting with previous courses).[10] Risk factors for CINV include poor emetic control with prior chemotherapy, female gender, low chronic alcohol intake, and younger age.[5] Chemotherapeutic agents are classified according to their emetogenic potential (Table 17–3), which aids in predicting CINV.[35] Risk factors that are useful in predicting anticipatory nausea and vomiting include poor prior control of CINV and a history of motion sickness or NVP.[5,10]

Patient Encounter 1

A 28-year-old healthy woman seeks your advice. She is about to leave on a 7-day Caribbean cruise and is concerned about motion sickness. She recently experienced nausea and one episode of vomiting while on a sailboat on Lake Michigan for an afternoon. She is not allergic to any medications. She does not smoke and only occasionally drinks alcohol. She takes an oral contraceptive (ethinyl estradiol and norgestimate) and occasional ibuprofen for headaches.

- What nonpharmacologic and pharmacologic options are available for this woman?
- How would you instruct her to use the recommended modalities?
- What adverse effects would you discuss with her?

TABLE 17–3. Emetogenicity of Chemotherapeutic Agents

Lowest Emetogenic Potential
Androgens
Bleomycin
Busulfan (oral less than 4 mg/kg per day)
Capecitabine (oral)
Chlorambucil (oral)
Cladribine
Corticosteroids
Doxorubicin (liposomal)
Fludarabine
Hydroxyurea
Interferon
Melphalan (oral)
Mercaptopurine
Methotrexate (less than or equal to 50 mg/m^2)
Thioguanine (oral)
Tretinoin
Vinblastine
Vincristine
Vinorelbine
Low Emetogenic Potential
Asparaginase
Cytarabine (less than 1 g/m^2)
Docetaxel
Doxorubicin HCl (less than 20 mg/m^2)
Etoposide
Fluorouracil (less than 1 g/m^2)
Gemcitabine
Methotrexate (greater than 50 mg/m^2; less than 250 mg/m^2)
Mitomycin
Paclitaxel
Teniposide
Thiotepa
Topotecan
Moderate Emetogenic Potential
Aldesleukin
Cyclophosphamide (IV, less than or equal to 750 mg/m^2)
Dactinomycin (less than or equal to 1.5 mg/m^2)
Doxorubicin HCl (20–60 mg/m^2)
Epirubicin HCl (less than or equal to 90 mg/m^2)
Idarubicin
Ifosfamide
Methotrexate (250–1000 mg/m^2)
Mitoxantrone (less than or equal to 15 mg/m^2)
High Emetogenic Potential
Carboplatin
Carmustine (less than 250 mg/m^2)
Cisplatin (50 mg/m^2)
Cyclophosphamide (greater than 750 mg/m^2 to less than or equal to 1500 mg/m^2)
Cytarabine (greater than or equal to 1g/m^2)
Dactinomycin (greater than 1.5 mg/m^2)
Doxorubicin HCl (greater than 60 mg/m^2)
Irinotecan
Melphalan (IV)
Methotrexate (greater than 1 g/m^2)
Mitoxantrone (greater than 15 mg/m^2)
Oxaliplatin
Highest Emetogenic Potential
Carmustine (greater than 250 mg/m^2)
Cisplatin (greater than 50 mg/m^2)
Cyclophosphamide (greater than 1500 mg/m^2)
Dacarbazine (greater than or equal to 500 mg/m^2)
Lomustine (greater than 60 mg/m^2)
Mechlorethamine
Pentostatin
Streptozocin

Data from DiPiro CV, Taylor AT. Nausea and vomiting. In: DiPiro JT, Talbert RL, Yee GC, et al., (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 665–676, and Hesketh PJ, Kris MG, Grunberg SM, et al. Proposal for classifying the acute emetogenicity of cancer chemotherapy. J Clin Oncol 1997; 15:103–109.

❹ *For prophylaxis of acute CINV, the combination of a 5-HT$_3$ antagonist and corticosteroid is recommended for patients receiving highly emetogenic cisplatin or non–cisplatin-based chemotherapy.*[5,10] Patients receiving moderately emetogenic chemotherapy should receive a corticosteroid such as dexamethasone or methylprednisolone alone, whereas patients receiving chemotherapy unlikely to cause CINV should not require prophylaxis.[5,10]

Antiemetics can be administered either intravenously or orally in this situation, depending on patient characteristics such as ability to take oral medications, dosage form availability, and cost considerations.[5,10] The intravenous and oral routes are equally effective. When used at equipotent doses, the 5-HT$_3$ antagonists have similar efficacy in preventing acute CINV, despite pharmacokinetic and receptor binding affinity differences.[5,10,36]

Patients undergoing chemotherapy should have antiemetics available to treat breakthrough nausea and vomiting even if prophylactic antiemetics were given.[10] A variety of antiemetics may be used, including lorazepam, dexamethasone, methylprednisolone, prochlorperazine, promethazine, metoclopramide, and dronabinol. The 5-HT$_3$ antagonists are effective for treating breakthrough nausea and vomiting, but they have not been shown to be superior to more traditional and less expensive antiemetics.

Delayed nausea and vomiting is more difficult to prevent and treat. It occurs most often with cisplatin- and cyclophosphamide-based regimens, especially if delayed nausea and vomiting occurred with previous courses of chemotherapy.[10] Patients at greatest risk are those who previously had poorly-controlled acute CINV.[5] Patients receiving highly emetogenic chemotherapy should receive a corticosteroid plus metoclopramide or a 5-HT$_3$ antagonist to prevent delayed nausea and vomiting.[5,10] Intermediate or low emetogenic chemotherapy regimens do not require prophylactic regimens for delayed nausea and vomiting.

The NK$_1$ receptor antagonist aprepitant has shown promise for preventing delayed nausea and vomiting.[33,34,37,38] When aprepitant was added to a standard antiemetic regimen for patients receiving cisplatin-based highly emetogenic chemotherapy, complete response rates (no emesis and no rescue therapy) were significantly improved for both acute and delayed nausea and vomiting.[34,37] Aprepitant may also benefit patients receiving moderately emetogenic chemotherapy, but more data are needed.[33,39]

The 5-HT$_3$ antagonist palonosetron is the first 5-HT$_3$ antagonist to be approved for prevention of both acute and delayed CINV.[40] Compared to the other 5-HT$_3$ antagonists, palonosetron has a longer serum half-life (40 hours compared to 4 to 9 hours) and a higher receptor binding affinity, which may contribute to its efficacy in preventing delayed CINV.[41]

The best strategy for preventing anticipatory nausea and vomiting is to prevent acute and delayed CINV by using the most effective antiemetic regimens recommended based on the emetogenic potential of the chemotherapy and patient factors. CINV should be aggressively prevented with the first cycle of therapy rather than waiting to assess patient response to less effective regimens. If anticipatory nausea and vomiting occurs, benzodiazepines and behavioral therapy such as relaxation techniques are the suggested approaches.[1,5]

Postoperative Nausea and Vomiting

PONV is a common complication of surgery and can lead to delayed discharge and unanticipated hospitalization.[6] The overall incidence of PONV for all surgeries and patient populations is 25% to 30%, but PONV can occur in 70% to 80% of high-risk patients.[6,26] Risk factors for PONV include patient factors (female gender, non-smoking status, and history of PONV or motion sickness), anesthetic factors (use of volatile anesthetics, nitrous oxide, or intraoperative or postoperative opioids), and surgical factors (duration and type of surgery).[6,8,26]

The first step in preventing PONV is reducing baseline risk factors when appropriate.[6] Regional anesthesia rather than general anesthesia should be used. Opioids should be replaced

Patient Encounter 2

A 57-year-old woman is scheduled for an abdominal hysterectomy due to uterine fibroids. She is very anxious about her surgery.

PMH
Uterine fibroids
Hypertension × 6 years
Hypercholesterolemia × 6 years

FH
Father died of lung cancer; mother is still alive with a history of hypertension and cerebrovascular accident

SH
Works as a high school teacher; drinks one glass of wine with dinner three times per week; does not use tobacco

Med
Hydrochlorothiazide 25 mg PO once daily
Lisinopril 20 mg PO once daily
Simvastatin 40 mg PO once daily at bedtime
Aspirin 81 mg PO once daily
Acetaminophen as needed for headache or body aches

Labs
Within normal limits

ECG: Normal sinus rhythm
Anesthesia for the surgery will be thiopental 4.5 mg/kg, atracurium 0.5 mg/kg, and fentanyl 0.05 mg followed by tracheal intubation, 70% nitrous oxide, and 0.5% to 2% isoflurane in oxygen.

- What risk factors for PONV does this patient have?
- Identify your treatment goals for this patient.
- What nonpharmacologic and pharmacologic measures can be taken to prevent PONV?
- Discuss any contraindications or adverse effects associated with your recommended treatments.

with other analgesics such as non-steroidal anti-inflammatory drugs. Nitrous oxide and volatile inhaled anesthetics should be avoided.

❺ *Droperidol or a 5-HT_3 receptor antagonist should be administered at the end of surgery to patients at high risk for developing postoperative nausea and vomiting.*[1,6,7,26,42] Dexamethasone is also effective when given as a single dose prior to induction of anesthesia.[6,42,43] Anticholinergics and antihistamines are also effective for preventing PONV.[6]

Combinations of antiemetics may be the most effective method of preventing PONV for high-risk patients.[7,42] Droperidol plus a 5-HT_3 antagonist or dexamethasone plus a 5-HT_3 antagonist are effective combinations.[43,44] Three-drug combinations such as dexamethasone, droperidol, and a 5-HT_3 antagonist have not been formally studied but may be a reasonable approach.[42]

Nausea and Vomiting of Pregnancy

❻ *Nausea and vomiting of pregnancy affect the majority of pregnant women; the* ***teratogenic potential*** *of the therapy is the primary therapeutic consideration.*[9] Risks and benefits of any therapy must be weighed by the health care professional and the patient.

Nonpharmacologic therapy such as dietary, physical, and behavioral approaches should be considered first. Pyridoxine (vitamin B_6) 10 to 25 mg three to four times daily alone or in combination with an antihistamine such as doxylamine is often used for NVP.[9,11,12] This combination was previously marketed as Bendectin or Debendox but was withdrawn due to concerns over possible teratogenic effects, although the literature did not support this claim.[11,12] Pyridoxine is well tolerated, but doxylamine and other antihistamines commonly cause drowsiness. For more severe NVP, promethazine, metoclopramide, and trimethobenzamide may be effective and have not been associated with teratogenic effects.[9]

In rare instances (0.5% to 2% of pregnancies), NVP progresses to hyperemesis gravidarum.[9] Treatment may require the use of enteral or parenteral nutrition if weight loss is present. A corticosteroid such as methylprednisolone may be considered. Methylprednisolone is associated with oral clefts in the fetus when used during the first trimester; therefore, corticosteroids should be reserved as a last resort and should be avoided during the first 10 weeks of gestation.[9,11]

Motion Sickness and Vestibular Disturbances

Nausea and vomiting can be caused by disturbances of the vestibular system in the inner ear.[18] Vestibular disturbances can result from infection, traumatic injury, neoplasm, and motion. Patients may experience dizziness and vertigo in addition to nausea and vomiting. If a patient is susceptible to motion sickness, some general preventive measures include minimizing exposure to movement, restricting visual activity, ensuring adequate ventilation, reducing the magnitude of movement, and taking part in distracting activities.[45]

Patient Encounter 1, Part 2

Four months later, the patient returns to your practice. She is 8 weeks pregnant and complains of nausea and occasional vomiting. She is only taking prenatal vitamins. She does not smoke or drink alcohol. She was told at her last prenatal visit that she was appropriately gaining weight. She asks for your advice about preventing and treating nausea and vomiting.

- What general considerations about treating nausea and vomiting of pregnancy will you discuss with this patient?
- What nonpharmacologic and pharmacologic treatment options are available for her?

❼ *Because the vestibular system is replete with muscarinic-type cholinergic and histaminic (H_1) receptors, anticholinergics and antihistamines are the most commonly used pharmacologic agents to prevent and treat motion sickness.* Oral medications should be taken prior to motion exposure to allow time for adequate absorption. Once nausea and vomiting due to motion sickness occur, oral medication absorption may be unreliable, making the therapies ineffective. Scopolamine, the anticholinergic medication used for motion sickness, is available as a transdermal patch delivery system, which may be helpful for patients who cannot tolerate oral medications or who require treatment for a prolonged period. Drowsiness and reduced mental acuity are the most bothersome side effects of antihistamines and anticholinergics. Visual disturbances, dry mouth, and urinary retention can also occur.

OUTCOME EVALUATION

- The symptoms of simple nausea and vomiting are self-limited or can be relieved with minimal treatment. Monitor patients for adequate oral intake and alleviation of nausea and vomiting.
- Patients with complex nausea and vomiting may have malnourishment, dehydration, and electrolyte abnormalities.
  - Monitor patients for adequate oral intake. If the patient has weight loss, assess whether enteral or parenteral nutrition is needed.
  - Assess for dry mucous membranes, skin tenting, tachycardia, and lack of axillary sweat to determine if dehydration is present.
  - Obtain blood urea nitrogen (BUN), serum creatinine (SCr), calculated fractional excretion of sodium (FeNa), serum electrolytes, and arterial blood gases.
- Ask patients to rate the severity of nausea.
- Monitor the number and volume of vomiting episodes.
- Ask patients about adverse effects to the antiemetics used. Use this information to assess efficacy and tailor the patient's antiemetic regimen.

Patient Care and Monitoring

1. Identify the underlying cause of the nausea and vomiting and eliminate it if possible. Counsel the patient to avoid known triggers.
2. Assess the patient to determine whether the nausea and vomiting is simple or complex and whether patient-directed therapy is appropriate.
3. Obtain a thorough patient history including the prescription, non-prescription, and herbal medications being used. Identify any substances that may be causing or worsening nausea and vomiting. Determine which treatments for nausea and vomiting have been used in the past and their degree of efficacy.
4. Develop a treatment plan with the patient and other health care professionals if appropriate. Choose therapeutic options based on the underlying cause of nausea and vomiting, duration and severity of symptoms, comorbid conditions, medication allergies, presence of contraindications, risk of drug-drug interactions, and treatment adverse-effect profiles.
5. Use the oral route of administration if the patient has mild nausea with minimal or no vomiting. Seek an alternative route (e.g., transdermal, rectal suppository, or parenteral) if the patient is unable to retain oral medications due to vomiting.
6. Educate the patient about nonpharmacologic measures such as stimulus avoidance, dietary changes, acupressure or acupuncture, and psychotherapy.
7. To assess efficacy, ask the patient whether he or she is still experiencing nausea or vomiting while using the therapy. Assess whether treatment failure is due to inappropriate medication use or the need for additional or different treatments and proceed accordingly.
8. Assess for adverse effects by asking the patient what he or she has experienced. Also, patient observation or examination is useful for diagnosing adverse effects such as EPS.
9. Provide patient education regarding causes of nausea and vomiting, avoidance of triggers, potential complications, therapeutic options, medication adverse effects, and when to seek medical attention.

ABBREVIATIONS

BBB:	blood–brain barrier
BUN:	blood urea nitrogen

18 Constipation, Diarrhea, and Irritable Bowel Syndrome

Beverly C. Mims and Clarence E. Curry, Jr.

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Identify the causes of constipation.
2. Compare the features of chronic constipation with those of constipation-predominant irritable bowel syndrome (IBS).
3. Recommend lifestyle modifications and therapeutic interventions for the treatment of constipation.
4. Distinguish between acute and chronic diarrhea.
5. Compare and contrast diarrhea caused by different infectious agents.
6. Explain how medication use can lead to diarrhea.
7. Discuss nonpharmacologic strategies for treating diarrhea.
8. Identify the signs and symptoms of IBS.
9. Contrast diarrhea-predominant IBS and constipation-predominant IBS.
10. Discuss the goals of IBS treatment.
11. Evaluate the effectiveness of principal pharmaceutical therapies for IBS.

Key Concepts

❶ Constipation has been defined in many ways and it is important to know what is meant when the term is used.
❷ Chronic constipation exists when symptoms last for at least 3 months.
❸ Lifestyle modifications should be employed prior to the use of laxatives in most instances of constipation.
❹ Oral laxatives are the primary pharmacologic intervention for relief of constipation.
❺ When diarrhea is severe and oral intake is limited, dehydration can occur, particularly in the elderly and infants.
❻ The primary treatment of acute diarrhea includes fluid and electrolyte replacement, dietary modifications, and drug therapy.
❼ IBS is generally described as a functional disorder rather than a distinct disease entity.
❽ IBS symptoms typically cluster around two main types: diarrhea-predominant IBS and constipation-predominant IBS.
❾ Diagnosis of IBS is made by symptom-based criteria and the exclusion of organic disease.
❿ The principal goal of IBS treatment is to reduce or control symptoms.

CONSTIPATION

❶ *Constipation has been defined in many ways, and it is important to know what is meant when the term is used.* Constipation, when not associated with symptoms of irritable bowel syndrome (IBS), can be defined as a heterogeneous disorder characterized by disorganized passage of feces resulting in infrequent stools, difficult passage of stools or both.[1] It may be described as difficulty passing stool with too much effort, unproductive urges, too small amount of stool, too hard consistency of stool, painful elimination of stool, or a feeling of incomplete evacuation. The existence of some or all of these symptoms suggests the presence of constipation when the frequency of elimination of feces is limited to twice weekly or less or when more than 3 days have passed without elimination of stool. ❷ *Chronic constipation exists when symptoms last for at least 3 months.*

EPIDEMIOLOGY AND ETIOLOGY

Constipation is a common complaint of patients seeking medical attention, and about one-third of patients with constipation seek medical treatment. Constipation occurs in approximately 20% of the population.[2] Approximately 2.5 million physician visits and 90,000 hospitalizations per year in the United States are due to constipation[3,4] Many medications and some disease states are associated with constipation. Constipation is associated with high socioeconomic costs and has considerable quality-of-life ramifications.[5]

Elderly patients, non-Caucasians, women, and those of lower educational and socioeconomic levels are more likely to report being constipated. Constipation in children can occur because of a change in the usual diet or fluid intake, a deviation from usual toileting routines such as during vacations, or avoidance of bowel movements because of pain associated with having a stool. Children who are diagnosed with severe constipation at a young age are likely to continue to suffer through puberty.

PATHOPHYSIOLOGY

Constipation can be due to primary and secondary causes (Table 18–1). Primary or idiopathic constipation is typified by normal-transit constipation, slow-transit constipation, and **dyssynergic defecation**. In the normal-transit type, colonic motility is unchanged and patients tend to experience hard stools despite normal movements. In the slow-transit type, motility is decreased leading to infrequent harder, drier stools. In dyssynergic defecation (also known as pelvic floor dysfunction), patients have lost the ability to relax the anal sphincter while coordinating muscle contractions of the pelvic floor. Some causes of secondary constipation are listed in Table 18–1.

TABLE 18–1. Causes of Constipation

Primary Causes
Normal-transit constipation (includes idiopathic or functional disorders)
Slow-transit constipation (includes motility disorders)
Defecatory or rectal evacuation disorders (e.g., Hirschsprung's disease, pelvic floor dyssynergia)
Secondary Causes (selected)
Endocrine/metabolic conditions (diabetes mellitus, hypothyroidism, hypercalcemia)
Gastrointestinal conditions (irritable bowel syndrome, diverticulitis, hemorrhoids)
Neurogenic conditions (brain trauma, spinal cord injury, cerebrovascular accident, Parkinson's disease)
Psychogenic (postponing the urge to defecate, psychiatric conditions)
Medications (analgesics, anticholinergerics, calcium channel blockers, clonidine, diuretics, phenothiazines, tricyclic antidepressants, iron supplements, calcium- and aluminum-containing antacids)
Miscellaneous (immobility, poor diet, laxative abuse, hormonal disturbances)

Constipation affects about 50% of pregnant women. Progesterone levels may be responsible in part for slowing digestion. Reabsorption mechanisms may affect colon water during pregnancy leading to harder stools and more difficult bowel movements. Intake of iron supplements may also contribute to constipation during pregnancy.

CLINICAL PRESENTATION AND DIAGNOSIS

Diagnosis

A complete history should be obtained so that the patient's symptoms can be evaluated and the diagnosis of constipation confirmed. The diagnosis of constipation is suggested by fewer than three bowel movements per week, consistency of hard lumpy stool, excessive straining, prolonged defecation time, or need to support the perineum or digitally manipulate the anorectum.

Dietary habits should be evaluated and attention paid to psychosocial issues. A complete family history should be obtained,

Clinical Presentation of Constipation

Symptoms

- Functional constipation (constipation occurring in the absence of a demonstrated pathologic condition) involves the presence of at least two of the following symptoms: straining, lumpy or hard stools, sensation of incomplete evacuation, sensation of anorectal obstruction or blockage, need for manual maneuvers to facilitate defecation and/or, infrequent (fewer than three) bowel movements per week.
- Other complaints may include painful or difficult defecation, bloating, and absence of loose stools.
- Alarm (or red flag) symptoms include worsening of constipation, blood in the stools, weight loss, fever, anorexia, nausea, and vomiting.
- The patient should seek medical attention when symptoms are severe, last longer than 3 weeks, are disabling, when alarm symptoms occur, or whenever a significant change in usual bowel habits occurs.

Laboratory Tests (to identify secondary causes)

- Thyroid function tests; abnormal thyroid hormone levels may suggest hypo- or hyperthyroidism, either of which may be associated with constipation.
- Serum calcium; either increased or decreased serum calcium levels may be associated with constipation.
- Glucose; increased blood glucose may indicate diabetes mellitus, which may be associated with constipation.
- Serum electrolytes; dehydration may be associated with constipation.
- Urinalysis may also indicate dehydration, if present.
- Complete blood count; anemia may be due to cancer or another systemic disorder accompanied by constipation.

particularly as it relates to inflammatory bowel disease and colon cancer. A full record of prescription and over-the-counter medications is mandatory to identify drug-related causes of constipation.

In most cases, there is no underlying cause of constipation, and the physical examination and rectal examination are normal. Sigmoidoscopy, barium enema, or colonoscopy alone or in combination are required in patients who have weight loss, rectal bleeding, or anemia with constipation. These examinations can be used to exclude the presence of cancer or strictures, especially in patients over the age of 50 years. **Sigmoidoscopy** alone is appropriate in patients without alarm symptoms and those younger than 50 years of age. However, all adults older than 50 years of age who present with new-onset constipation should undergo **colonoscopy** to rule out malignancy. When bleeding is present, a double-contrast **barium enema** may be ordered.

TREATMENT

Desired Outcomes

In patients with constipation, the principal goals are to: (1) identify and treat secondary causes, (2) relieve symptoms, and (3) restore normal bowel function.

Nonpharmacologic Therapy

❸ *Lifestyle modifications should be employed prior to the use of laxatives in most instances of constipation.* Constipation usually responds to dietary fiber supplementation, hydration, and exercise. Increasing fiber intake to 20 to 35 grams/day may help overcome constipation. Foods high in fiber include beans, whole grains, bran cereals, fresh fruits, and vegetables such as asparagus, brussels sprouts, cabbage, and carrots. Persons with constipation should avoid excessively processed low-fiber foods such as luncheon meats, hot dogs, certain cheeses, and ice cream.

Adequate fluid intake is also important; the recommended intake for people who do not require fluid restriction is 6 to 8 eight-ounce glasses of water daily.

Walking and other aerobic exercises help to tone the muscles of the lower abdominal area, which promotes propulsion in the bowel. Constipation is a frequent complaint of sedentary persons.

Each day most persons experience a strong peristaltic wave known as the gastrocolic reflex. A bowel movement usually follows. When the urge to have a bowel movement occurs, it should not be ignored. Some people put off having a stool for various reasons, which may lead to more difficulty in passing stool. Time should be planned daily to attempt having a stool. A busy lifestyle should not be allowed to interfere with normal bowel function.

Pharmacologic Therapy

❹ *Oral laxatives are the primary pharmacologic intervention for relief of constipation* (Table 18–2). There are several different drug classes, as described below.

Bulk-Forming Laxatives

These agents are either naturally derived (psyllium) or synthetic (methylcellulose). They act by swelling in intestinal fluid, forming a gel that aids in fecal elimination and promoting peristalsis. They may cause flatulence (which is less common with methylcellulose) and abdominal cramping. Bulk-forming laxatives must be taken with sufficient water to avoid becoming lodged in the esophagus and producing an obstruction. Bulk-forming laxatives must be taken with sufficient water to avoid becoming lodged in the esophagus and producing obstruction or worsening constipation.

Osmotic Laxatives

These products cause water to enter the lumen of the colon. Lactulose and sorbitol are osmolar, non-absorbable sugars. Magnesium containing products increase secretion of electrolytes

TABLE 18–2. Dosage Recommendations for Selected Laxatives and Cathartics

Agent	Recommended Adult Dose
Agents That Cause Softening of Feces in 1–3 Days	
Bulk-forming agents	
Methylcellulose	4–6 g/day
Polycarbophil	4–6 g/day
Psyllium	Varies with product
Emollients	
Docusate sodium	50–360 mg/day
Docusate calcium	50–360 mg/day
Docusate potassium	100–300 mg/day
Lactulose	15–30 mL orally
Sorbitol	30–50 g/day orally
Mineral oil	15–30 mL orally
Agents That Result in Soft or Semifluid Stool in 6–12 Hours	
Bisacodyl (oral)	5–15 mg orally
Phenolphthalein	30–270 mg orally
Cascara sagrada	Dose varies with formulation
Senna	Dose varies with formulation
Magnesium sulfate (low dose)	Less than 10 g orally
Agents That Cause Watery Evacuation in 1–6 Hours	
Magnesium citrate	18 g in 300 mL water
Magnesium hydroxide	2.4–4.8 g orally
Magnesium sulfate (high dose)	10–30 g orally
Sodium phosphates	Varies with salt used
Bisacodyl (suppository)	10 mg rectally
Polyethylene glycol-electrolyte preparations	4 L

From Spruill WJ, Wade WE. Diarrhea, constipation and irritable bowel syndrome. In DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill, Inc; 677–692, with permission.

and water into gut lumen. Products containing magnesium or sodium phosphate derivatives (saline laxatives) are most useful for acute bowel evacuation. A principal concern with these agents is that improper use can cause dehydration and electrolyte disturbances. Osmotic agents may cause flatulence, abdominal cramping, and bloating. Magnesium may accumulate inpatients with renal dysfunction.

Polyethylene glycol (PEG, MiraLax) is an osmotic laxative available only by prescription. It is useful in patients who are experiencing acute constipation and who have had inadequate response to more traditional agents. Principal adverse effects include upset stomach, bloating, cramping, and gas.

Lubricants

Lubricant laxatives work by coating the stool, which allows it to be expelled more easily. The oily film covering the stool also keeps the stool from losing its water to intestinal reabsorption processes. Mineral oil (liquid petrolatum) is a non-prescription heavy oil that should be used with caution, if at all, since it may be aspirated into the lungs and cause lipoid pneumonia. This is of particular concern in the young or the elderly.

Stimulant Laxatives

Diphenylmethane derivatives (e.g., bisacodyl) and anthraquinones (e.g., senna) have a selective action on the nerve plexus of intestinal smooth muscle leading to enhanced motility. The onset of effect is rapid but the effects can be harsh (cramping), depending on the dose taken. Castor oil is another member of this class that is used less frequently.

Emollients

Also known as surfactants and stool softeners, emollients (e.g., salts of docusate) act by increasing the surface wetting action on the stool leading to a softening effect. They reduce friction and make the stool easier to pass. These agents are not recommended for treating constipation of long duration.

Tegaserod Maleate

Tegaserod maleate (Zelnorm) is a partial serotonin (5-HT_4) receptor agonist that causes an increase in peristaltic activity and intestinal secretion and moderation of visceral sensitivity. It increases the frequency of bowel movements and reduces abdominal discomfort, bloating, and straining. It is indicated for the treatment of patients younger than 65 years of age who experience chronic idiopathic constipation. The most common adverse effects include headache, abdominal pain, diarrhea, and nausea.

Lubiprostone

Lubiprostone (Amitiza), a bicyclic acid oral agent, is approved for treatment of chronic idiopathic constipation in adults. It has not been studied in children. Lubiprostone acts locally on intestinal chloride channels and increases intestinal fluid secretion, resulting in increased intestinal motility and thereby increasing the passage of stool.[6]

Lubiprostone is contraindicated in patients with a history of mechanical gastrointestinal obstruction. Safety has not been established in pregnant women; animal studies indicated the potential to cause fetal loss. Women who could become pregnant should have a negative pregnancy test result prior to beginning therapy with lubiprostone.

Gastrointestinal adverse events reported with lubiprostone include nausea, diarrhea, abdominal distention, abdominal pain, flatulence, vomiting, loose stools, and dyspepsia. Nausea is a prominent adverse effect and may be minimized when lubiprostone is taken with food.

The recommended dose of lubiprostone is 24 mcg orally twice daily with food. Early studies evaluated lubiprostone use for no longer than 4 weeks. Patients should be assessed periodically for the need to continue therapy.

Treatment Recommendations

Slow-transit constipation can be treated with chronic administration of osmotic laxatives. Tegaserod maleate 6 mg orally twice daily is an acceptable treatment. Senna, bisacodyl, and other stimulants should be used only when the others fail to deliver the desired effect.

Laxatives may provide appropriate relief when constipation occurs during the postpartum period, when not breastfeeding and in immobile patients. Patients who are not constipated but who need to avoid straining (e.g., patients with hemorrhoids, hernia, or myocardial infarction) may benefit from stool softeners or mild laxatives.

Laxatives should not be given to children younger than 6 years of age unless prescribed by a physician. Because children may not be able to describe their symptoms well, they should be evaluated by a physician before being given a laxative. Treating secondary causes may resolve the constipation without the use of laxatives. As in adults, children benefit from a healthy balanced diet, adequate fluid, and regular exercise.

Because many elderly persons experience constipation, laxative use is sometimes viewed as a normal part of daily life. However, mineral oil can be a special hazard in bedridden elderly persons because it can lead to pneumonia through inhalation of oil droplets into the lungs. Lactulose may be a better choice in this situation. Regular use of any laxative that affects fluid and electrolytes may result in significant unwanted adverse effects.

Bulk-forming laxatives are commonly used during pregnancy. Stool softeners (Category C) should not be used during pregnancy. To avoid constipation pregnant women should be advised to eat regular meals that are balanced among fruit, vegetables and whole grains; maintain adequate water intake; and get appropriate exercise.

Patients with the following conditions should use laxatives only under the supervision of a health care provider: (1) colostomy; (2) diabetes mellitus (some laxatives contain large amounts of sugars such as dextrose, galactose, and/or sucrose; (3) heart disease (some products contain sodium; (4) kidney disease; and (5) swallowing difficulty (bulk-formers may produce esophageal obstruction).

OUTCOME EVALUATION

- Ask the patient about the absence or improvement in symptoms to determine whether laxative therapy is effective. Patients should have an increase in stool frequency to more than three well-formed stools per week. Patients should report the absence of prolonged defecation time or the absence of the need for excessive straining.
- When acute overuse or chronic misuse of saline or stimulant laxatives is suspected, it may be necessary to check for electrolyte disturbances (e.g., hypokalemia, hypernatremia, hyperphosphatemia, or hypocalcemia).
- Some laxatives (e.g., bulk-forming agents) contain significant amounts of sodium or sugar and may be unsuitable for salt-restricted or diabetic patients. When low-sodium or sugar-free products are not used, monitor serum concentrations of sodium and glucose as needed with chronic use.
- Saline laxatives containing magnesium, potassium, or phosphates should be used cautiously in persons with reduced kidney function. Monitor appropriate serum electrolyte concentrations in patients with unstable renal function evidenced by changing serum creatinine or creatinine clearance.
- All laxatives are contraindicated in patients with abdominal pain, nausea, vomiting, symptoms of appendicitis or undiagnosed abdominal pain. Patients should consult their physicians if sudden changes in bowel habits persist for more than fourteen days or if use of a laxative for seven days results in no effect.

Patient Care and Monitoring for Constipation

1. Assess the patient's symptoms to determine if patient-directed therapy is appropriate or whether the patient should be evaluated by a physician. Determine type and frequency of symptoms.
2. Review available diagnostic data to determine the cause or type of constipation.
3. Obtain a thorough history of prescription, non-prescription, and dietary supplement use. Determine what treatments have been helpful in the past. Is the patient taking any medications that may contribute to constipation?
4. Remember that no single therapy has proven effective for all patients who present with constipation.
5. Develop a plan to assess the effectiveness of laxative use in cases of chronic constipation.
6. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.
7. Provide patient education about constipation, lifestyle modifications, and drug therapy.

DIARRHEA

Diarrhea is not a disease in itself but rather a symptom of some underlying problem. It is a condition marked by increased stool frequency (usually greater than 3 times daily), stool weight, liquidity, and decreased consistency of stools compared to a patient's usual pattern. Acute diarrhea is defined as diarrhea lasting for 14 days or less. Diarrhea lasting more than 30 days is called chronic diarrhea. Illness of 15 to 30 days is referred to as persistent diarrhea.[7]

EPIDEMIOLOGY AND ETIOLOGY

Most cases of diarrhea in adults are mild and resolve quickly. Infants and children (especially under 3 years of age) are highly susceptible to the dehydrating effect of diarrhea, and its occurrence in this age group should be taken seriously.

Acute Diarrhea

There are many possible causes of acute diarrhea, but infection is the most common cause. Infectious diarrhea occurs because of food and water contamination via the fecal-oral route. Viruses are the cause in a large proportion of cases. Likely viral suspects include Rotavirus, Norwalk, and adenovirus. Patients usually exhibit sudden low-grade fever, vomiting, and watery stools.

Bacteria are likely precipitants in many other cases including *Escherichia coli*, *Salmonella* species, *Shigella* species, *Vibrio cholerae*, and *Clostridium difficile*. The term dysentery has often been used to describe some of these bacterial infections when associated with serious occurrences of bloody diarrhea. Additionally, acute diarrheal conditions can be prompted by parasites–protozoa such as *Entamoeba histolytica*, *Microsporidium*, *Giardia lamblia*, and *Cryptosporidium parvum*. Most of these infectious agents can be causes of **traveler's diarrhea**, a common malady afflicting travelers worldwide. It usually occurs during or just after travel subsequent to the ingestion of fecally-contaminated food or water. It has an abrupt onset but usually subsides within 2 to 3 days.

Patient Encounter 1

A 70-year-old man complains of small, hard stools for the past 2 weeks. He also states that his bowel movements are less frequent than normal and that he has not had constipation previously. He has a history of hypertension, angina pectoris, and osteoarthritis and began a new medication 3 weeks ago. He asks for your recommendation of a laxative.

- What are the possible causes of his constipation?
- What are the special considerations in this older man?
- What nonpharmacologic and pharmacologic therapies would be appropriate for his condition?

TABLE 18–3. Selected Drugs and Substances That May Cause Acute Diarrhea

Drugs			
Antibiotics	Hydralazine	Metformin	Sorbitol
Colchicine	Laxatives	Misoprostol	Theophylline
Digitalis	Mannitol	Quinidine	
Dietary Supplements			
St. John's wort	Echinacea	Ginseng	Aloe vera
Poisons			
Arsenic	Cadmium	Mercury	

Noninfectious causes of acute diarrhea include drugs and toxins (Table 18–3), laxative abuse, food intolerance, irritable bowel syndrome (IBS), inflammatory bowel disease, ischemic bowel disease, lactase deficiency, Whipple's disease, pernicious anemia, diabetes mellitus, malabsorption, fecal impaction, diverticulosis, and celiac sprue.

Lactose intolerance is responsible for many cases of acute diarrhea, especially in patients of African descent, Asians, and Native Americans. Foods should be considered as possible causes, especially fat substitutes, dairy products, and products containing non-absorbable carbohydrates.

The diarrhea of IBS is sudden and perhaps watery but likely loose, usually accompanied by urgency, bloating, and abdominal pain occurring upon arising in the morning or immediately following a meal. Inflammatory bowel disease is typically associated with the sudden onset of bloody diarrhea accompanied by urgency, crampy abdominal pain, and fever. Patients who experience bowel ischemia may develop bloody diarrhea, particularly if they progress to shock.

Chronic Diarrhea

Chronic diarrhea lasts for longer than 4 weeks. Most cases result from functional or inflammatory bowel disorders, endocrine disorders, malabsorption syndromes and drugs (including laxative abuse). In chronic diarrhea, daily watery stools may not occur. Diarrhea may be either intermittent or persistent.

PATHOPHYSIOLOGY

During normal processes, approximately 9 liters of fluid traverse the gastrointestinal tract daily. Of this amount, 2 liters represent gastric juice, 1 liter is saliva, 1 liter is bile, 2 liters are pancreatic juice, 1 liter is intestinal secretions, and 2 liters are ingested. Of these 9 L of fluid presented to the intestine, only about 150 to 200 mL remain in the stool after reabsorptive processes occur.

Any event that leads to a significant increase in the amount of fluid retained in the stool may result in diarrhea. Large-stool diarrhea often signifies small intestinal involvement, whereas small-stool diarrhea usually originates in the colon. Diarrhea may be classified according to pathophysiologic mechanisms, which include osmotic, secretory, inflammatory, and altered motility.

Osmotic diarrhea results from the intake of unabsorbable but water-soluble solutes in the intestinal lumen leading to water retention. Common causes include lactose intolerance and ingestion of magnesium-containing antacids.

Secretory diarrhea results in an increase in the net movement (secretion) of ions into the intestinal lumen leading to an increase in intraluminal fluid. Medications, hormones, and toxins may be responsible for secretory activity.

Inflammatory (or exudative) diarrhea results from changes to the intestinal mucosa that damage absorption processes and lead to an increase in proteins and other products in the intestinal lumen with fluid retention. The presence of blood or fecal leukocytes in the stool is indicative of an inflammatory process. The diarrhea of inflammatory bowel disease (e.g., ulcerative colitis) is inflammatory in nature.

Increased motility results in decreased contact between ingested food and drink and the intestinal mucosa, leading to reduced reabsorption and increased fluid in the stool. Diarrhea resulting from altered motility is often established after other mechanisms have been excluded. IBS-related diarrhea is due to altered motility.

Although diarrhea can often be attributed to a specific mechanism, some patients develop diarrhea due to overlapping mechanisms. For example, malabsorption syndromes and traveler's diarrhea are associated with both secretory and osmotic diarrhea.

Drug-induced diarrhea can occur by several mechanisms. First, water can be drawn into the intestinal lumen osmotically. Second, the intestinal bacterial ecosystem can be upset leading to the emergence of invasive pathologic organisms triggering secretory and inflammatory processes. Saline laxatives are an example of the first mechanism and many antibiotics act by the second. A third way is through altered motility as may occur with tegaserod maleate. Other drugs such as procainamide or colchicine produce diarrhea through undetermined mechanisms. Discontinuation of the offending drug may be the only measure needed to ameliorate the diarrhea.

CLINICAL PRESENTATION AND DIAGNOSIS

Diagnosis

Patients with diarrhea should be questioned about the onset of symptoms, recent travel, diet, source of water, and medication use. Other important considerations include duration and severity of the diarrhea along with an accounting of the presence of associated abdominal pain or vomiting, blood in the stool, stool consistency, stool appearance, stool frequency, and weight loss. Although most cases of diarrhea are self-limited, infants, children, elderly persons, and immunocompromised patients are at risk for increased morbidity.

Findings on physical examination can assist in determining hydration status and disease severity. The presence of blood in

Clinical Presentation of Acute Diarrhea

Signs and Symptoms

- Patients with acute diarrhea have the abrupt onset of loose, watery, or semi-formed stools.
- Abdominal cramps and tenderness, rectal urgency, nausea, bloating, and fever may be present.
- The disorder is generally self-limited, lasting 3 to 4 days even without treatment.
- Patients with acute infectious diarrhea from invasive organisms also have bloody stools and severe abdominal pain.

Laboratory Tests in Acute Diarrhea

- Stool cultures can help identify infectious causes. Cultures are subject to time delay. New methodology using real-time polymerase chain reaction (PCR) shortens the reporting time.
- Stool may also be analyzed for mucus, fat, osmolality, fecal leukocytes, and pH. The presence of mucus suggests colonic involvement. Fat in the stool may be due to a malabsorption disorder. Fecal leukocytes can be found in inflammatory diarrheas including infections caused by invasive bacteria (e.g., *E. coli, Shigella,* and *Campylobacter* species). Stool pH (normally greater than 6) is decreased by bacterial fermentation processes.
- Stool volume and electrolytes can be assessed in large-volume watery stools to determine whether the diarrhea is osmotic or secretory.
- CBC and blood chemistries may be helpful in patients whose symptoms persist. The presence of anemia, leukocytosis, or neutropenia may provide further clues to the underlying cause.

Signs and Symptoms of Chronic Diarrhea

- In patients with chronic diarrhea, symptoms may be severe or mild. Weight loss can be demonstrated, and weakness may be present.
- Dehydration may be manifested by decreased urination, dark-colored urine, dry mucous membranes, increased thirst, and tachycardia.

Laboratory Tests in Chronic Diarrhea

- All of the tests described for acute diarrhea would be used to establish a diagnosis of chronic diarrhea because the differential diagnosis is more complicated. The data obtained can help categorize the diarrhea as watery, inflammatory, or fatty, narrowing the focus on a primary disorder.
- Colonoscopy allows visualization and biopsy of the colon and is preferred if blood has been found in the stool or if the patient has AIDS.

the stool suggests an invasive organism, an inflammatory process, or perhaps a neoplasm. Large-volume stools suggest a small-intestinal disorder, whereas small-volume stools suggest a colon or rectal disorder. Patients with prolonged or severe symptoms may require colonoscopic evaluation to identify the underlying cause.

TREATMENT

Most healthy adults with diarrhea do not develop dehydration or other complications and can be treated symptomatically by self medication. ❺ *When diarrhea is severe and oral intake is limited, dehydration can occur, particularly in the elderly and infants.* Other complications of diarrhea resulting from fluid loss include electrolyte disturbances, metabolic acidosis, and cardiovascular collapse.

Children are more susceptible to dehydration (particularly when vomiting occurs) and may require medical attention early in their course, especially if younger than the 3 years of age. Physician intervention is also necessary for elderly patients who are sensitive to fluid loss and electrolyte changes due to concurrent chronic illness.

Patients should undergo medical evaluation in the following circumstances: (1) moderate to severe abdominal tenderness, distention, or cramping; (2) bloody stools; (3) evidence of dehydration (e.g., thirst, dry mouth, fatigue, dark-colored urine, infrequent urination, reduced urine, dry skin, rapid pulse, rapid breathing, muscle cramps, muscle weakness, sunken eyes, or light-headedness); (4) high fever (greater than or equal to 101°F or 38°C); (5) evidence of weight loss greater than 5% of total body weight; and (6) diarrhea that lasts greater than 48 hours.

Desired Outcomes

The goals of treatment for diarrhea are to relieve symptoms, maintain hydration, treat the underlying cause(s), and maintain nutrition. ❻ *The primary treatment of acute diarrhea includes fluid and electrolyte replacement, dietary modifications, and drug therapy.*

Nonpharmacologic Therapy

Fluid and Electrolytes

Fluid replacement is not a treatment to relieve diarrhea but rather an attempt to restore fluid balance. In many parts of the world where diarrheal states are frequent and severe, fluid replacement is accomplished using oral rehydration solution (ORS), a measured mixture of water, salts, and glucose. The World Health Organization–recognized solution consists of 75 mEq/L sodium, 75 mmol/L glucose, 65 mEq/L chloride, 20 mEq/L potassium, and 10 mEq/L citrate, having a total osmolarity of 245 mOsm/L. A simple solution can be prepared from 1 L water mixed with 8 teaspoonfuls of sugar and 1 teaspoonful of table salt. Some commercial products include Pedialyte, Rehydralyte, and Ceralyte. Patients with diarrhea who are not dehydrated may replace fluid by drinking flat soft drinks such as ginger ale, tea, fruit juice, broth, or soup. Caution is advised in using sports drinks for dehydration, as they may not provide an appropriate amount of electrolytes. Severe diarrhea may require the use of parenteral solutions such as lactated Ringer's or normal saline solution to replace large and life-threatening fluid losses.[8]

Dietary Modifications

Once an acute diarrheal situation ensues, patients typically eat less as they become focused on the diarrhea. Both children and adults should attempt to maintain nutritional intake. Food provides not only nutrients but also fluid volume that helps replace what is lost. However, food-related fluid may not be enough to compensate for diarrheal losses. Some foods may be inappropriate if they irritate the gastrointestinal tract or if they are implicated as the cause of the diarrhea. Patients with chronic diarrhea may find that increasing bulk in the diet may help (e.g., rice, bananas, whole-wheat, and bran).

Pharmacologic Therapy

The goal of drug therapy is to control symptoms, enabling the patient to continue with as normal a routine as possible while avoiding complications (Table 18–4). Most infectious diarrheas are self-limited or curable with anti-infective agents.

Adsorbents and Bulk Agents

Attapulgite adsorbs excess fluid in the stool with few adverse effects. Calcium polycarbophil is a hydrophilic polyacrylic resin that also works as an adsorbent, binding about 60 times its weight in water and leading to the formation of a gel that enhances stool formation. Neither attapulgite nor polycarbophil is systemically absorbed. Both products are effective in reducing fluid in the stool but can also adsorb nutrients and other medications. Their administration should be separated from other oral medications by 2 to 3 hours. Psyllium and methylcellulose products may also be used to reduce fluid in the stool and relieve chronic diarrhea.

TABLE 18–4. Pharmacotherapy for Diarrhea

Drug	Usual Dose	Type of Diarrhea
Attapulgite	Adults: 1200–1500 mg after each loose stool Maximum 9000 mg in 24 hours Children ages 6–12: 750 mg after each loose stool Maximum 4500 mg in 24 hours	Acute and chronic Chronic
Calcium polycarbophil	Adults: 1000 mg 4 times daily or after each loose stool, not to exceed 12 tablets per day Children ages 6–12: 500 mg 3 times daily Children ages 3–6: 500 mg twice daily	
Loperamide	Adults: 4 mg initially, then 2 mg after each subsequent loose stool; maximum 16 mg in 24 hours Children's maximum doses: Ages 2–5: 3 mg Ages 6–8: 4 mg Ages 8–12: 6 mg	Acute and chronic
Diphenoxylate/atropine	Adults: Two tablets (5 mg) initially, then one tablet every 3–4 hours, not to exceed 20 mg in 24 hours Children 2–12 years old: Oral solution (avoid tablets) 0.3 to 0.4 mg/kg per day in divided doses Do not administer to children less than 2 years of age	Acute and chronic
Bismuth subsalicylate	Adults: 30 mL (regular strength) or 2 tablets, repeated every 30–60 minutes as needed Maximum 8 doses daily Children: Consumers should speak with a physician before giving to children under 12 years of age	Traveler's and nonspecific acute diarrhea

Antiperistaltic (Antimotility) Agents

Antiperistaltic drugs prolong intestinal transit time, thereby reducing the amount of fluid lost in the stool. The two drugs in this category are loperamide HCl (available over the counter as Imodium A-D and generically) and diphenoxylate HCl with atropine sulfate (available by prescription as Lomotil and generically). The atropine is included only as an abuse deterrent; when taken in large doses, the unpleasant anticholinergic effects of atropine negate the euphoric effect of diphenoxylate. Both loperamide and diphenoxylate are effective in relieving symptoms of acute non-infectious diarrhea and are safe for most patients experiencing chronic diarrhea. These products should be discontinued in patients whose diarrhea worsens despite therapy.

Antisecretory Agents

Bismuth subsalicylate is thought to have antisecretory and antimicrobial effects and is used to treat acute diarrhea. Although it passes largely unchanged through the gastrointestinal tract, the salicylate portion is absorbed in the stomach and small intestine. For this reason, bismuth subsalicylate should not be given to people who are allergic to salicylates, including aspirin. Caution should be exercised with regard to the total dose administered in patients who concurrently take salicylates for other reasons to avoid the possibility of salicylism. Patients taking bismuth subsalicylate should be informed that their stool will turn black.

Octreotide is an antisecretory agent that has been used for severe secretory diarrhea associated with cancer chemotherapy, HIV, diabetes, gastric resection, and gastrointestinal tumors. It is administered as a subcutaneous or intravenous bolus injection in an initial dose of 500 mcg three times daily to assess the patient's tolerance to gastrointestinal adverse effects. Biweekly serum levels of insulin-like growth factor-1 (IGF-1 or somatomedin C) can be used as a guide to dose titration. Possible adverse effects include nausea, bloating, pain at the injection site, and gallstones (with prolonged therapy).

Probiotics

Probiotics are dietary supplements containing bacteria that may promote health by enhancing the normal microflora of the gastrointestinal tract while resisting colonization by potential pathogens. Probiotics can stimulate the immune response and suppress the inflammatory response. Yogurt can provide relief from diarrhea due to lactose intolerance. It supports digestion of lactose because the bacteria used to make yogurt produce lactase and digest the lactose before it reaches the colon. The *Lactobacillus acidophilus* in yogurt, cottage cheese, and acidophilus milk improves digestion of lactose and may prevent or relieve diarrhea related to lactose deficiency and milk intake. Although lactase is not a probiotic, lactase tablets may also be used to prevent diarrhea in susceptible patients.

Patient Encounter 2

KW, a 31-year-old day care teacher, complains of nausea, vomiting, abdominal cramps, and frequent watery stools for the past 2 days. She also indicates that her heart has been "racing" and her mouth has been very dry. Although she looks ill, she does not have a fever.

- What is the likelihood that her diarrhea is due to an invasive microorganism?
- Which of her symptoms suggest the presence of dehydration?
- Discuss potential treatment measures for this woman.

Anti-Infectives

Empiric antibiotic therapy is an appropriate approach to traveler's diarrhea. Eradication of the causal microbe depends on the etiologic agent and its antibiotic sensitivity. Most cases of traveler's diarrhea and other community-acquired infections result from enterotoxigenic (ETEC) or enteropathogenic (EPEC) *Escherichia coli.* Routine stool cultures do not identify these strains; primary empiric antibiotic choices include fluoroquinolones such as ciprofloxacin or levofloxacin. Azithromycin may be a feasible option when fluoroquinolone resistance is encountered.

Although most cases of infectious diarrhea resolve with therapy, routine antibiotic use may contribute to antimicrobial resistance. Empiric treatment should be considered for other acute infectious diarrhea including those caused by non–hospital acquired invasive organisms such as Shiga toxin–producing *Escherichia coli* (STEC) O157, *Campylobacter, Salmonella,* and *Shigella* organisms producing moderate to severe fever, **tenesmus**, and bloody stools.[9]

OUTCOME EVALUATION

- Monitor the patient with diarrhea from the point of first contact until symptoms resolve, keeping in mind that most episodes are self-limiting.
- Question the patient to determine whether symptom resolution occurs within 48 to 72 hours in acute diarrhea.
- Monitor for the maintenance of hydration, particularly when symptoms continue for more than 48 hours. Look for increasing thirst, decreased urination, dark-colored urine, dry mucous membranes, and rapid heartbeat as suggestive of dehydration, especially when nausea and vomiting have been present.
- Monitor for symptom control in patients with chronic diarrhea.
- When antibiotics are used, monitor for completion of the course of therapy.

Patient Care and Monitoring for Diarrhea

1. Assess the patient's symptoms to determine if patient-directed therapy is appropriate or whether the patient should be evaluated by a physician. Determine the type of symptoms, severity, frequency, and exacerbating factors. Remember to inquire about recent foreign travel.
2. Determine if the patient is dehydrated.
3. Determine whether the patient has a history of disease that might be associated with diarrhea.
4. Obtain a thorough current history of prescription, nonprescription, and dietary supplement use. Remember to review the current therapy as a potential cause of diarrhea.
5. Determine if any diarrhea treatments have been attempted, including home remedies.
6. Medical referral is advised if the patient is pregnant, breast-feeding, younger than 3 or older than 70 years of age, or suffers from multiple medical conditions.
7. If home care is recommended, provide clear instructions about how to proceed if symptoms do not improve or new symptoms emerge.
8. Discuss the importance of maintaining nutrition by modifying the diet to include low-residue meals (low-fiber meals).
9. Educate the patient about: (1) the causes of acute and chronic diarrhea; (2) the possible complications of diarrhea; (3) the goals of treatment for diarrhea; (4) the antidiarrheal medication used to manage acute or chronic diarrhea; and (5) if appropriate, the circumstances when antibiotics are used to treat diarrhea.

IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is a disorder of the gastrointestinal tract that interferes with the normal functions of the colon. At various points in the past, IBS has been referred to as **mucous colitis**, spastic colon, irritable colon, or nervous stomach. ❼ *IBS is generally described as a functional disorder rather than a disease per se. A functional disorder involves symptoms that cannot be attributed to a specific injury, infection, or other physical problem.* A functional disorder occurs because of altered physiologic processes rather than structural or biochemical defects and may be subject to nervous system influence. IBS is associated with frequent fluctuation in symptoms, loss of productivity, and decreased quality of life. Although IBS has been referred to as **functional bowel disease**, true functional bowel disease may be more indicative of widespread gastrointestinal involvement including (but not limited to) the colon.

EPIDEMIOLOGY AND ETIOLOGY

IBS is one of the most common disorders seen in primary care and the most common reason for referral to gastroenterologists. Although between 15% and 20% of Americans suffer from IBS, only about one-quarter of those affected seek medical attention. The associated costs to society are significant, and the recurrent nature of IBS contributes to these costs through missed workdays, inattention on the job, and high consumption of health services.[10]

In the United States, IBS affects women about twice as often as men. However, this may reflect a woman's tendency to seek medical care more often than a man may. Irritable bowel syndrome can occur at any age, but presentation is most common between the ages of 20 and 50 years. Onset beyond 60 years of age is rare. However, prevalence for older adults is the same as for young persons. Prevalence is similar in Caucasians and African-Americans but may be lower in people of Hispanic origin. A genetic link is unproven, but IBS seems more common in certain families.

There is strong association between emotional distress and IBS. Psychosocial trauma (e.g., a history of abuse, recent death of a close relative or friend, or divorce) is more likely to be found in patients presenting with IBS than in the general population. An increased prevalence of psychiatric disorders such as anxiety, depression, personality disorders, and somatization (psychological distress expressed as physical symptoms) occurs among adult patients with IBS. Alcohol consumption and smoking have not been shown to be risk factors for developing IBS.[11]

Some people show first evidence of IBS after contracting gastroenteritis, which has led to speculation about whether an infection makes the gastrointestinal tract susceptible to functional problems. Women with IBS may have symptoms triggered by menstrual periods.

PATHOPHYSIOLOGY

Enteric nerves control intestinal smooth muscle action and are connected to the brain by the autonomic nervous system. IBS is thought to result from dysregulation of this "brain-gut axis." The enteric nervous system is composed of two ganglionated plexuses that control gut innervation: the submucous plexus (Meissner's plexus) and the myenteric plexus (Auerbach's plexus). The enteric nervous system and the central nervous system (CNS) are interconnected and interdependent. A number of neurochemicals mediate their function, including serotonin (5-hydroxytryptamine or 5-HT), acetylcholine, substance P, and nitric oxide, among others.

Two 5-HT receptor sub-types, 5-HT_3 and 5-HT_4, are involved in gut motility, visceral sensitivity, and gut secretion. The 5-HT_3 receptors slow colonic transit and increase fluid absorption, whereas 5-HT_4 receptor stimulation results in accelerated colonic transit.

Although no single pathologic defect has been found to account for the pattern of exacerbations and remissions seen in IBS, CNS abnormalities, dysmotility, visceral hypersensitivity, and a number of other factors have been implicated.[12]

The passage of fluids into and out of the colon is regulated by epithelial cells. In IBS, the colonic lining (epithelium) appears to work properly. However, increased movement of the contents in the colon can overwhelm its absorptive capacity.

Disturbed intestinal motility appears to be a central feature of IBS, which leads to altered stool consistency. Studies suggest that the colon of IBS sufferers is abnormally sensitive to normal stimuli.[13] This enhanced visceral sensitivity manifests as pain, especially related to gut distention.

IBS activity may be affected by the immune system. Some IBS patients have been found to have antibodies, which may indicate food hypersensitivity that might be involved in symptom production.[14] Specifically, sensitivity has been demonstrated to common foods such as wheat, beef, pork, soy, and eggs.

CLINICAL PRESENTATION AND DIAGNOSIS

Diagnosis

❾ *The diagnosis of IBS is made by symptom-based criteria and the exclusion of organic disease.* IBS is diagnosed by obtaining a careful and thorough history to identify symptoms characteristic of the disorder. It is equally important to distinguish between IBS and conditions having similar symptoms. Patients should be questioned about the character of their stools. This should include questions about frequency, consistency, color, and size. Moreover, because of the functional nature of IBS, a patient may present with symptoms of upper gastrointestinal problems such as gastroesophageal reflux disease (GERD) or with excessive flatulence. Patients should also be questioned about diet to determine whether symptoms seem to occur in relationship to meals or specifically after consumption of certain dietary products.

Barium enema, sigmoidoscopy, or colonoscopy may be indicated in the presence of red flag symptoms (fever, weight loss, bleeding, and anemia, which may be accompanied by persistent severe pain), which often point to a potentially serious non-IBS problem. A barium enema may identify polyps, diverticulosis,

Clinical Presentation of Irritable Bowel Syndrome

Symptoms

- Patients report a history of abdominal pain or discomfort that is relieved with defecation. Symptom onset is associated with change in frequency or appearance of stool. Some persons experience hard, dry stools whereas others experience loose or watery stools. Some stools may be small and pellet-like in appearance while others may be narrow and pencil-like.
- ❽ *Symptoms can typically be categorized as either diarrhea-predominant IBS (IBS-D) or constipation-predominant IBS (IBS-C). Patients with IBS-D usually report more than three loose or watery stools daily. Those with IBS-C usually have fewer than three bowel movements per week; stools are typically hard and lumpy and accompanied by straining.*
- While many patients fit into one of these categories, some patients report alternating episodes of diarrhea and constipation.
- Other common symptoms include: (1) feelings of incomplete evacuation; (2) abdominal fullness; (3) bloating; (4) flatulence; (5) passage of clear or white mucus with a stool; and (6) occasional fecal incontinence.
- Periods of normal stools and bowel function are punctuated by episodes of sudden symptoms.
- Symptoms are often exacerbated by stress.
- Left lower quadrant abdominal pain is often brought on or made worse by eating. Passage of stool or flatus may provide some relief.
- IBS-C can often be distinguished from chronic constipation primarily by the presence of abdominal pain and discomfort. Although pain and discomfort may be present in some patients with chronic constipation, it is an expected feature of IBS.
- Patients with IBS may experience comorbidities outside the gastrointestinal tract such as fibromyalgia, sleep disturbances, headaches, dyspareunia, and temporomandibular joint syndrome.

Signs

- The physical examination is often normal in IBS.
- The patient may appear to be anxious.
- Palpation of the abdomen may reveal left lower quadrant tenderness, which may indicate a tender sigmoid colon.
- Abdominal distention may be present in some cases.
- The following "red flag" or alarm features are *not* associated with IBS and may indicate inflammatory bowel disease, cancer, or other disorders: fever, weight loss, bleeding, and anemia, which may be accompanied by persistent severe pain.

Laboratory Tests

- In most cases, laboratory testing reveals no abnormalities in IBS, but certain tests can be used to identify other causes for the patient's symptoms.
- Complete blood cell count (CBC) may identify anemia, which may suggest blood loss and an organic source for GI symptoms.
- Serum electrolytes and chemistries may indicate metabolic causes of symptoms.
- Thyroid-stimulating hormone (TSH) should be ordered when thyroid dysfunction is suspected. Hypothyroidism may be responsible for constipation and related symptoms.
- Stool testing for ova and parasites may identify *Clostridium difficile* and amoeba as possible causes of diarrhea rather than IBS.
- Fecal leukocytes can be found in inflammatory diarrhea, especially when due to invasive microorganisms.
- A positive stool guaiac test indicating blood in the gastrointestinal tract does not support a diagnosis of IBS.
- An elevated erythrocyte sedimentation rate (ESR) is consistent with a systemic inflammatory process such as inflammatory bowel disease rather than IBS.
- Testing for lactose deficiency can confirm the presence of lactose intolerance, which may explain the symptoms.

Patient Encounter 3, Part 1

A 38-year-old woman presents complaining of headache, abdominal pain, bloating, occasional nausea, and excessive belching. These symptoms have occurred with increasing frequency over the past 2 to 3 weeks. The abdominal pain is crampy in character and located in the left lower abdominal area. She has also had alternating episodes of diarrhea and constipation and the presence of white threadlike material in her stool during some of the past 3 weeks.

- Which of the patient's symptoms are characteristics of IBS?
- How well does this woman fit the typical epidemiologic profile of patients with IBS?

tumors, or other abnormalities that might be responsible for the symptoms. In addition, exaggerated haustral contractions may be noted with barium enema. Such contractions impede stool movement and contribute to constipation.

Flexible sigmoidoscopy can be performed to identify obstruction in the rectum and lower colon, whereas colonoscopy can evaluate the entire colon for organic disease.

The diagnostic basis for IBS has long been centered on the presence of symptoms, first defined by the Manning criteria: (1) abdominal pain relieved by defecation with either (a) looser stools with pain onset, or (b) frequent stools with pain onset; (2) abdominal distention; (3) mucus in the stool; and (4) sensation of incomplete evacuation.[15,16] These practical criteria have been used widely.

The Rome II criteria (preceded by Rome I) are the most current diagnostic criteria for establishing the presence of IBS. They presume the absence of a structural or biochemical explanation for the symptoms. These rather stringent criteria can be applied clinically, but not as easily as the older Manning criteria.[17] The Rome II criteria define IBS as occurring when symptoms of abdominal discomfort or pain exist at least 12 weeks (*which need not be consecutive*) in the preceding 12 months that have two of the three following features: (1) relieved with defecation; (2) onset associated with a change in the frequency of stool; and/or (3) onset associated with a change in the form of stool. IBS is unlikely if symptom onset occurs in old age, the disorder has a steady but aggressive course, or the patient experiences frequent awakening because of symptoms.

TREATMENT

General Approach to Treatment

⓾ *The principal goal of IBS treatment is to reduce or control symptoms.* The treatment strategy is based on: (1) the prevailing symptoms and their severity; (2) the degree of functional impairment; and (3) the presence of psychological components. A standard treatment regimen is not possible because of the heterogeneous nature of the IBS patient population. Patients suffering from IBS can benefit from clinician support and reassurance, since specific pathology is unlikely to be found.

Nonpharmacologic Therapy

Diet and Other Lifestyle Modifications

Dietary modification is a standard therapeutic modality. Food hypersensitivities and adverse effects are thought to occur widely in IBS patients, especially those with diarrhea-predominant type. Elimination diets are the most commonly used strategy, usually focusing on milk and dairy products, fructose and sorbitol, wheat, and beef. Flatulence may be controlled by reducing gas-causing foods such as beans, celery, onions, prunes, bananas, carrots, and raisins. Response to elimination diets varies widely but they may be useful in individual patients. Care must be taken to avoid creating nutritional deficits while attempting to eliminate an offending food.

Psychological Treatments

Psychotherapy focused on reducing the influence of the CNS on the gut has been studied. Cognitive behavioral therapy (CBT), dynamic psychotherapy, relaxation therapy, and hypnotherapy have been reported to be effective in some patients. However, CBT and relaxation therapy do not appear to be better than standard approaches.[18] Biofeedback may provide relief in cases of severe constipation, but definitive evidence is lacking.[16] Psychotherapy interventions provide relief from pain and diarrhea but not constipation.[19]

Pharmacologic Therapy

Botanicals

Peppermint oil is widely advocated; it acts as an antispasmodic agent due to its ability to relax gastrointestinal smooth muscle. However, it also relaxes the lower esophageal sphincter, which could allow reflux of gastric contents into the esophagus. The usual dose is 1 to 2 enteric-coated capsules containing 0.2 mL of peppermint oil two to three times daily.

Matricaria recutita, known as German chamomile, is also purported to have antispasmodic properties. It is taken most often as a tea up to four times a day. Benzodiazepine, alcohol, and warfarin users should be cautioned against taking this product because it can cause drowsiness, and it contains coumarin derivatives.[20]

Antispasmodics

Antispasmodic agents such as dicyclomine or hyoscyamine have been among the most frequently used medications for treating abdominal pain in patients with IBS (Table 18–5).

TABLE 18–5. Common Pharmacologic Treatments for Irritable Bowel Syndrome

Generic (Brand) Name	Dose
Antispasmodics	
Dicyclomine (Bentyl)	10–20 mg every 4–6 hours as needed
Hyoscyamine (Levsin)	0.125–0.25 mg orally or sublingually every 4 hours as needed
Propantheline bromide (Pro-Banthine)	15 mg three times a day (before meals) and 30 mg at bedtime
Clidinium bromide plus chlordiazepoxide HCl (Librax)	5–10 mg three to four times a day
Hyoscyamine, scopolamine, atropine, phenobarbital (Donnatal)	1–2 tablets three to four times daily
Tricyclic Antidepressants	In Diarrhea-Predominant IBS:
Amitriptyline	50–150 mg daily
Doxepin	10–150 mg daily
Selective Serotonin Reuptake Inhibitors	In Constipation-Predominant IBS:
Paroxetine (others can be used)	10–40 mg daily
Bulk-Forming Laxatives	
Psyllium (Metamucil)	2.5–4 g daily
Methylcellulose (Citrucel)	4–6 g daily
Antimotility Agents	
Loperamide (Imodium A-D)	4 mg; then 2 mg after each loose stool; daily maximum 16 mg
5-HT_3 Receptor Antagonist	
Alosetron (Lotronex)	1 mg daily
5-HT_4 Receptor Agonist	
Tegaserod maleate (Zelnorm)	6 mg twice daily

5-HT, serotonin.

Side effects include blurred vision, constipation, urinary retention, and (rarely) psychosis. Although their effectiveness remains unconfirmed, these drugs may deserve a trial in patients with intermittent postprandial pain.[16]

Antidepressants

Tricyclic antidepressants (TCAs) such as amitriptyline and doxepin have been used with some success in the treatment of IBS-related pain (Table 18–5). They modulate pain principally through their effect on neurotransmitter reuptake, especially norepinephrine and serotonin. Their helpfulness in functional gastrointestinal disorders seems independent of mood-altering effects normally associated with these agents. Low-dose TCAs (e.g., amitriptyline, desipramine, or doxepin 10 to 25 mg daily) may help patients with IBS who predominantly experience diarrhea or pain.

The selective serotonin reuptake inhibitors (SSRIs) paroxetine, fluoxetine, and sertraline are potentially useful due to the significant effect of serotonin in the gut. SSRIs principally act on 5-HT_1 or 5-HT_2 receptors, but they can also have some effect on gut-predominant 5-HT_3 and 5-HT_4 receptors, perhaps reducing visceral hypersensitivity. They may be beneficial for patients with IBS-C or when the patient presents with IBS complicated by a mood disorder.[19] SSRIs should be reserved for use when TCAs are not effective because evidence supporting their use solely in IBS is lacking.

Bulk-Forming Agents

Bulk-forming agents may improve stool passage in constipation-predominant patients but are unlikely to have a favorable effect on pain or global IBS symptoms.[21] Psyllium may increase flatulence, which may worsen discomfort in some patients. Methylcellulose products are less likely to increase gas production. Although fiber-based supplements are more likely to be useful in constipation-predominant IBS, these products may be dose-adjusted in diarrhea to increase stool consistency. Other laxative products might be used in constipation-predominant IBS, but most are less desirable than bulking agents due to the potential for unwanted effects.

Anti-Motility Agents

Loperamide stimulates enteric nervous system receptors, inhibiting peristalsis and fluid secretion. It improves stool consistency and reduces the number of stools.[21] Consequently, it is most useful in patients who have diarrhea as a prominent symptom. However, it can occasionally aggravate abdominal pain.

Alosetron

Stimulation of 5-HT_3 receptors triggers hypersensitivity and hyperactivity of the large intestine. Alosetron (Lotronex) is a selective 5-HT_3 antagonist that blocks these receptors and is used to treat women with severe diarrhea-predominant IBS. Eligible patients should have frequent and severe abdominal pain, frequent bowel urgency or incontinence, and restricted daily activities. Alosetron has been shown to improve overall symptoms and quality of life. Alosetron can cause constipation in some patients.

Because alosetron has been associated with ischemic colitis, it may be prescribed only under strict guidelines, including signing of a consent form by both patient and physician. Patients selected for therapy should exhibit chronic IBS symptoms and have failed to respond to conventional therapy.

Tegaserod Maleate

Tegaserod maleate (Zelnorm) stimulates 5-HT_4 receptors in the GI tract, thereby increasing intestinal secretion, peristalsis, and small bowel transit. It also reduces sensitivity related to abdominal distention. It has been shown to be more effective than placebo in improving global IBS symptoms and altered bowel habits in constipation-predominant IBS.[21] Diarrhea is a possible adverse effect.

Patient Encounter 3, Part 2

Upon further questioning, the patient states that she had similar symptoms near the end of graduate school 6 years ago. The symptoms gradually subsided after graduation, so she did not seek medical attention. She is an accountant and recently received a promotion at work. As a result, she has taken on considerably more responsibility.

PMH
Anxiety; muscle contractions; headaches

FH
Mother has migraine headaches

SH
Non-smoker; drinks a glass of wine occasionally

Meds
Naproxen 220 mg every 12 hours as needed for headaches and menstrual pain
Loperamide 2 mg as needed for diarrhea

Allergies
No known drug allergies

Physical Exam
Gen: Alert and oriented, well developed and well nourished, anxious black woman
VS: blood pressure 137/88 mm Hg, pulse 80 beats per minute, respiratory rate 21/minutes, temperature 98.7°F (37.1°C), Ht 5′7″, Wt 74 kg
Integ: Hair and nails unremarkable; scalp dry and flaky; skin otherwise unremarkable
HEENT: PERRLA, EOMI
Chest: Clear to A & P bilaterally
CV: RRR, normal S_1 and S_2; no S_3 or S_4
Abd: (+) BS, mildly tender LLQ
Rectal: No palpable masses; no hemorrhoids; stool negative for occult blood

- What information is consistent with the diagnosis of IBS?
- Outline an appropriate therapeutic plan for this patient.

Ischemic colitis has been observed in some patients taking tegaserod. The drug should be discontinued promptly if rectal bleeding, bloody diarrhea, or worsening abdominal pain occurs.

In March of 2007, the FDA announced that tegaserod maleate would be voluntarily withdrawn from the market because of information indicating an increased risk of serious cardiovascular events (myocardial infarction, unstable angina, and stroke).

OUTCOME EVALUATION

- Because symptoms vary in intensity and among patients, a specific drug therapy may not lead to equivalent symptom abatement in different patients.
- Monitor for adequate relief of symptoms. Patients whose pain does not respond to drug therapy may have a psychological comorbid condition and may require psychiatric intervention.
- Specifically, monitor for relief of pain if present initially. Monitor patients with symptoms of constipation or diarrhea for frequency, appearance, and size of stools in relationship to their normal characteristics. As stools normalize, associated symptoms such as bloating and abdominal distention should resolve.
- For patients taking bulk-forming agents, monitor for relief of constipation. Hard stools should become softer within 72 hours.
- Monitor antidepressant therapy for relief of lower abdominal pain.
- Assess 5-HT_4 receptor agonists (tegaserod) for relief of crampy abdominal pain and bloating.
- Evaluate 5-HT_3 receptor antagonists (alosetron) for relief of abdominal pain and fecal incontinence.
- Antispasmodics may provide limited relief of crampy abdominal pain.
- Antimotility agents should be expected to reduce stool frequency and control diarrhea.
- Monitor complete blood cell count, serum electrolytes and chemistries, stool guaiac, and erythrocyte sedimentation rate yearly for changes that might signal an overlapping organic problem.
- Refer any patient presenting with red flag signs for medical evaluation.

Patient Care and Monitoring

1. Assess symptoms to determine if patient-directed therapy is appropriate or whether physician evaluation is needed.
2. Determine the type, severity, and frequency of symptoms and possible exacerbating factors.
3. Listen attentively to the patient's complaints and reassure the patient to allay fears about invasive disease.
4. Obtain a thorough current history of prescription, nonprescription, and dietary supplement use.
5. Determine if any IBS treatments have been attempted and how effective they have been.
6. Determine whether the patient has received educational intervention about IBS, health promotion, and symptom prevention measures.
7. Provide patient education about IBS symptoms, lifestyle modifications, and drug therapy for IBS:
   - Explain how to use medications relative to symptom intensity.
   - If taking alosetron, determine compliance with special use requirements.
   - Describe potential adverse effects.
   - List drugs that may interact with the therapy.
   - Discuss what to do if red flag symptoms occur.

ABBREVIATIONS

CBC: complete blood cell count
CBT: cognitive behavioral therapy
CNS: central nervous system
EPEC: enteropathogenic *Escherichia coli*
ESR: erythrocyte sedimentation rate
ETEC: enterotoxigenic *Escherichia coli*
GERD: gastroesophageal reflux disease
GI: gastrointestinal
5-HT_4: serotonin
IBS: irritable bowel syndrome
IBS-C: constipation-predominant irritable bowel syndrome
IBS-D: diarrhea-predominant irritable bowel syndrome
IGF-1: insulin-like growth factor-1
ORS: oral rehydration solution
PCR: polymerase chain reaction
PEG: polyethylene glycol
SSRI: selective serotonin reuptake inhibitor
STEC: Shiga toxin–producing *Escherichia coli*
TCA: tricyclic antidepressant
TSH: thyroid-stimulating hormone

19 Portal Hypertension and Cirrhosis

Laurajo Ryan

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Describe the epidemiology and social impact of portal hypertension and cirrhosis.
2. Explain the pathophysiology of cirrhosis and portal hypertension.
3. Outline the progression of liver damage from excessive alcohol intake.
4. Identify the signs and symptoms of liver disease in a given patient.
5. Clarify the consequences associated with decreased hepatic function.
6. List the treatment goals for a patient with portal hypertension and its complications.
7. Evaluate patient history and physical exam findings and recommend a specific regimen including both pharmacologic and nonpharmacologic therapy.

Key Concepts

❶ Portal hypertension is the precipitating factor for the complications of cirrhotic liver disease—ascites, spontaneous bacterial peritonitis (SBP), variceal bleeding, and hepatic encephalopathy. Lowering portal pressure can reduce the complications of cirrhosis and decrease morbidity and mortality.

❷ Chronic excessive ingestion of ethanol causes progressive liver damage because both ethanol and its metabolic products are direct hepatotoxins.

❸ Cirrhosis is irreversible; treatments are directed at limiting disease progression and minimizing complications.

❹ Non-selective β-blockers are first-line treatment for preventing variceal bleeding; they vasoconstrict the splanchnic bed through multiple mechanisms.

❺ The goals of treating ascites are to minimize acute discomfort, re-equilibrate ascitic fluid, and prevent SBP. Treatment should modify the underlying disease pathology; without directed therapy, fluid will rapidly reaccumulate.

❻ Cirrhosis is a high aldosterone state; spironolactone is a direct aldosterone antagonist and a primary treatment for ascites.

❼ During acute variceal hemorrhage, crucial desired outcomes include controlling bleeding, preventing rebleeding, and avoiding acute complications such as SBP.

❽ Long-term antibiotic prophylaxis for SBP decreases mortality in patients with a history of SBP and low-protein ascites [ascitic fluid albumin less than 1 g/dL (less than 10 g/L)].

❾ Lactulose is the foundation of pharmacologic therapy to prevent and treat hepatic encephalopathy because its unique mechanism binds ammonia in the gut and facilitates its excretion.

Cirrhosis is the progressive replacement of normal hepatic cells by fibrous scar tissue. This scarring is accompanied by the loss of viable **hepatocytes**, which are the functional cells of the liver. ❶ *Progressive cirrhosis is irreversible and leads to* ***portal hypertension*** *that is in turn responsible for many of the complications of advanced liver disease. These consequences include (but are not limited to)* ***spontaneous bacterial peritonitis (SBP), hepatic encephalopathy,*** *and* ***variceal bleeding.***[1]

EPIDEMIOLOGY AND ETIOLOGY

Cirrhosis is the result of long-term insult to the liver, so damage is typically not evident clinically until the fourth decade of life. Chronic liver disease and cirrhosis combined were the 12th leading cause of death in the United States in 2002. In patients between the ages of 25 and 64, damage from excessive alcohol use accounted for over one-half of the deaths.[2] Alcoholic liver disease and viral hepatitis are the most common causes of cirrhosis in the United States and worldwide.

Variations occur, but cirrhosis typically develops after 10 or more years of daily ingestion of 80 g of ethyl alcohol; this is an average of 6 to 8 drinks per day (a drink is equivalent to 1 ounce

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

of hard liquor, 4 ounces of wine, or a 12-ounce beer).[3] With equivalent alcohol intake, women tend to develop cirrhosis more quickly than men do. Differences in alcohol metabolism may account for this gender disparity; women metabolize less alcohol in the gastrointestinal (GI) tract, allowing delivery of higher levels of ethanol to the liver.[4] Genetic factors also play a role in development of alcoholic liver disease; some persons will progress to cirrhosis with much less cumulative alcohol use than is typical in a cirrhotic patient (either fewer drinks per day, or faster disease development) while others do not develop the disease with even more excessive intake.

Infection with one or more strains of viral hepatitis often causes acute inflammation of the liver, while chronic infection with hepatitis B or C can lead to cirrhosis. Hepatitis B and C are common in intravenous drug users and can also be transmitted through sexual contact, but many cases of hepatitis C are idiopathic.[5,6] Hepatitis C is a more common cause of cirrhosis than hepatitis B in the United States while hepatitis B is more common in the rest of the world.[7] See Chapter 21 on viral hepatitis for a complete discussion of infectious hepatitis.

Approximately 30% of patients with cirrhosis experience variceal bleeding at some point. Variceal bleeding carries a remarkably high mortality rate; up to 55% of patients with advanced disease die from their first bleeding episode. Mortality from variceal bleeding correlates with disease severity; risk factors for bleeding varices include poor liver function, large varices, and red signs (wales) on endoscopic examination.[8] In patients who survive the first incident of bleeding, more than two-thirds experience a repeat episode.

Development of ascites in cirrhotic patients is a particularly ominous marker; mortality 1 year after initial development of ascites is approximately 50%.[9]

In addition to the high mortality rate, cirrhosis carries an enormous social burden from hospitalizations, lost wages, and decreased productivity, not to mention the emotional strain of the disease on both patients and families.

Once cirrhosis is diagnosed, disease progression is relentless, regardless of the initial insult to the liver. Determining the specific cause of cirrhosis requires examination of both physical presentation and past medical history. An accurate social history is particularly important because few factors in the physical and laboratory examination aid in determining disease etiology. Understanding the cause of a patient's cirrhosis is imperative because it can affect therapeutic options and treatment decisions.

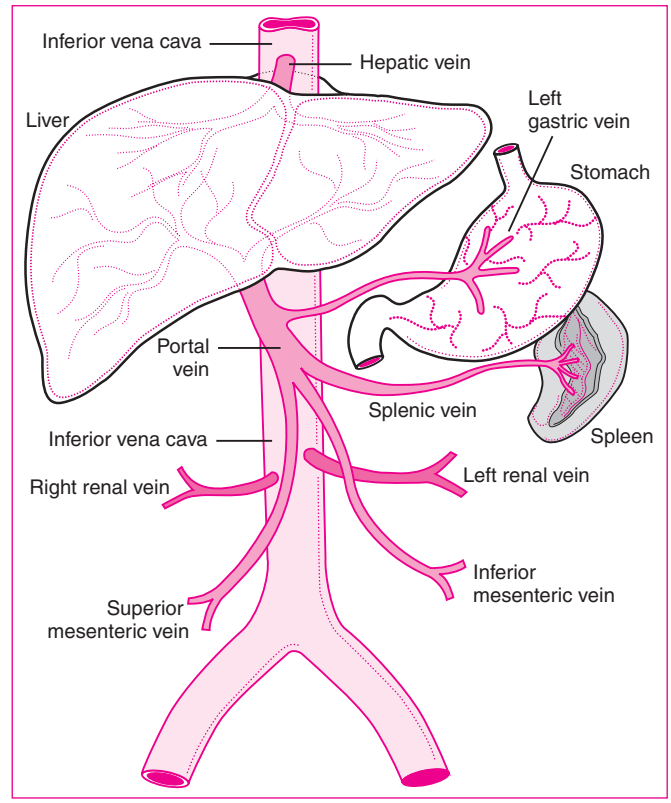

FIGURE 19–1. The portal venous system. (From Timm EJ, Stragand JJ. Portal hypertension and cirrhosis. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 694, with permission.)

PATHOPHYSIOLOGY

Portal Hypertension and Cirrhosis

The portal vein is the primary vessel leading into the liver; it receives deoxygenated venous blood flow from the small intestine, stomach, pancreas, and spleen (Fig. 19–1). The inflow from these organ systems accounts for approximately 75% of the blood delivered to the liver. The hepatic artery provides the remaining 25% of the blood supply in the form of oxygenated blood from the abdominal aorta. Normal portal vein pressure is between 5 and 10 mm Hg; this level maintains blood flow to the liver at approximately 1 L/minute. Portal hypertension occurs when portal vein pressure exceeds 10 to 12 mm Hg.[10,11]

Portal hypertension is a consequence of increased resistance to blood flow through the portal vein. Increased resistance is usually due to restructuring of intrahepatic tissue (sinusoidal damage) but may also be caused by presinusoidal damage such as portal vein occlusion from trauma, malignancy, or thrombosis. A third (and the least common) mechanism is outflow obstruction of the hepatic vein. This latter damage is posthepatic, and normal liver structure is maintained. This chapter will focus on portal hypertension caused by intrahepatic damage from cirrhosis.

Sinusoidal damage from cirrhosis is the most common cause of portal hypertension. The sinusoids are porous vessels within the liver that surround radiating rows of hepatocytes, the basic functional cells of the liver (Fig. 19–2). Progressive destruction of hepatocytes and an increase in fibroblasts and connective tissue surrounding the hepatocytes culminate in cirrhosis. Fibrosis and regenerative nodules of scar tissue

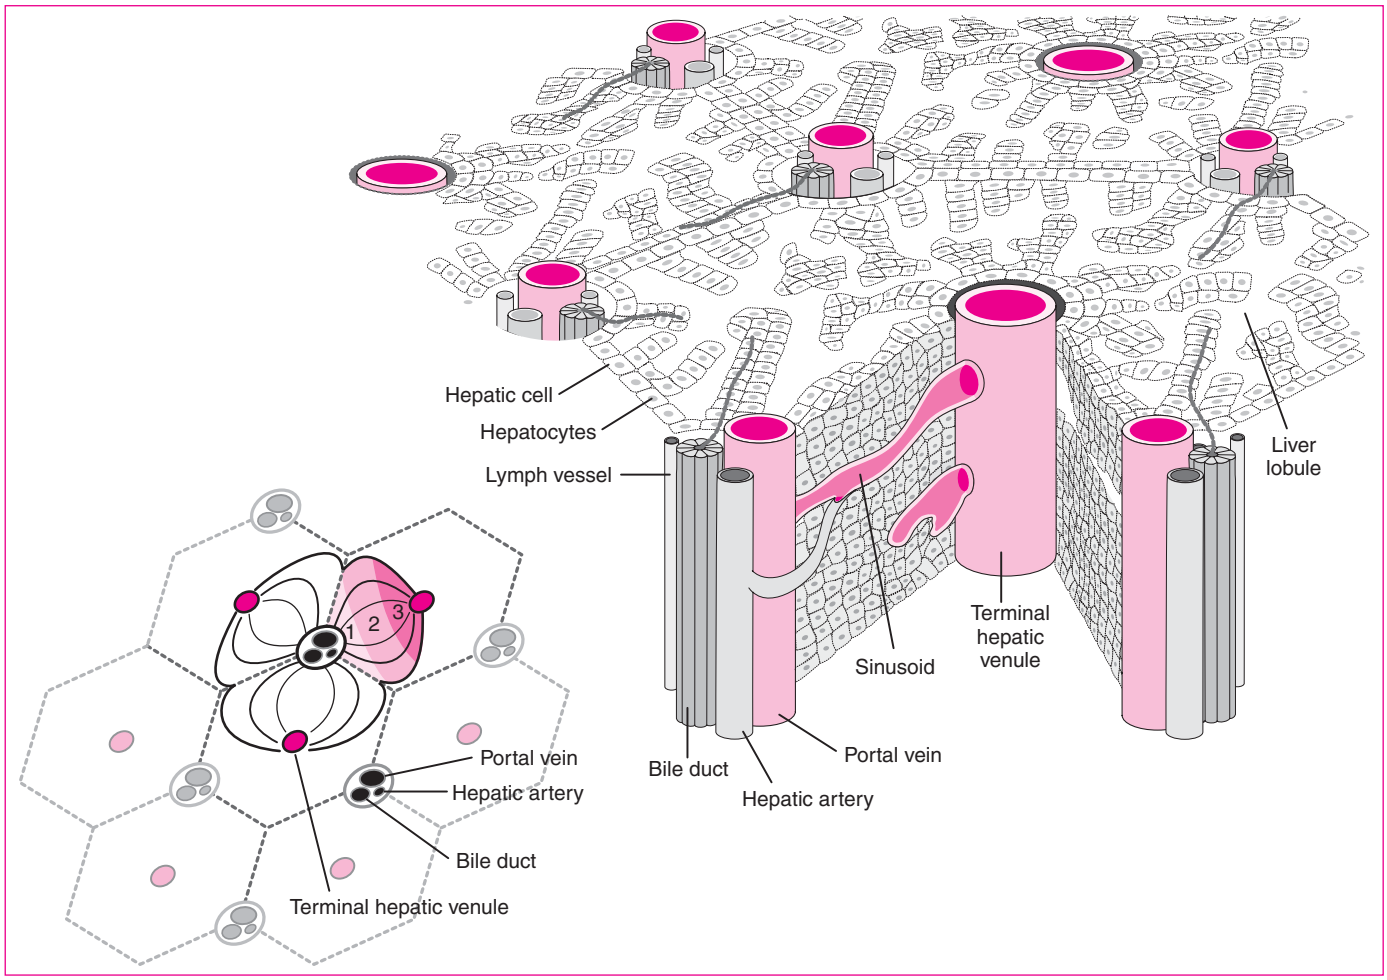

FIGURE 19–2. Relationship of sinusoids to hepatocytes and the venous system. (From Timm EJ, Stragand JJ. Portal hypertension and cirrhosis. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 695, with permission.)

modify the basic architecture of the liver, disrupting blood flow and liver function. Reduced hepatic blood flow alters normal metabolic breakdown processes and decreases protein synthesis within the liver.

The sinusoids transport both portal and arterial blood to the hepatocytes. The systemic blood delivered to the liver contains nutrients, drugs, and ingested toxins. The liver processes the nutrients (carbohydrates, proteins, lipids, vitamins, and minerals) for either immediate use or for storage, while the drugs and toxins are metabolized through a variety of processes known as "first-pass" metabolism. The liver also processes metabolic waste products for excretion. In cirrhosis, bilirubin (from the enzymatic breakdown of heme) can accumulate; this causes jaundice (yellowing of the skin), scleral icterus (yellowing of the sclera), and tea-colored urine (urinary bilirubin excretion).

Changes in steroidal hormone production, conversion, and handling are also prominent features of cirrhosis. These changes can result in decreased libido, gynecomastia (development of breast tissue in men), testicular atrophy, and features of feminization in male patients. Another deleterious effect of changes in sex hormone metabolism is the development of spider angiomata (nevi). Spider angiomata are vascular lesions found mainly on the trunk. The lesion has a central arteriole (body) surrounded by radiating "legs." When blanched, the lesions fill from the center body outward toward the legs. Spider angiomata are not specific to cirrhosis, but the number and size do correlate with disease severity and their presence relates to risk of variceal hemorrhage.[12]

Increased intrahepatic resistance to portal flow increases pressure on the entire splanchnic bed; an enlarged spleen (splenomegaly) is a common finding in cirrhotic patient and can result in thrombocytopenia due to splenic sequestration of the platelets. Portal hypertension mediates systemic and splanchnic arterial vasodilation through production of nitric oxide and other vasodilators in an attempt to counteract the increased pressure gradient. Nitric oxide causes a fall in systemic arterial pressure; unfortunately, this activates both the renin-angiotensin-aldosterone and sympathetic nervous systems and

increases antidiuretic hormone (vasopressin) production.[13] The activation of these systems is an attempt to maintain arterial blood pressure through increases in renal sodium and water retention. Increased systemic and portal pressure put increased pressure on the vascular system. The umbilical vein, which is usually eradicated in infancy, may become patent and increase blood flow to the abdominal veins. The prominent veins are called caput medusae because they resemble the head of the mythical Gorgon Medusa.

The aim of pharmacologic treatment in portal hypertension is to decrease portal pressure and reduce the effects of sympathetic activation.

Ascites

Ascites is the accumulation of fluid in the peritoneal space and is often one of the first signs of decompensated liver disease. Ascites is the most common complication of cirrhosis and portends a dire prognosis.[14]

The pathophysiologic mechanisms of portal hypertension and of cirrhosis itself are entwined with the mechanisms of ascites (Fig. 19–3). Cirrhotic changes and the subsequent decrease in synthetic function lead to a decrease in production of albumin (hypoalbuminemia). Albumin is the major intravascular protein involved in maintaining oncotic pressure in the vascular system; low serum albumin levels and increased capillary permeability allow fluid to leak from the vascular space into body tissues. This can result in peripheral edema, ascites, and fluid in the pulmonary system. The obstruction of hepatic sinusoids and hepatic lymph nodes allows fluid to seep into the peritoneal cavity, further contributing to ascitic fluid formation.

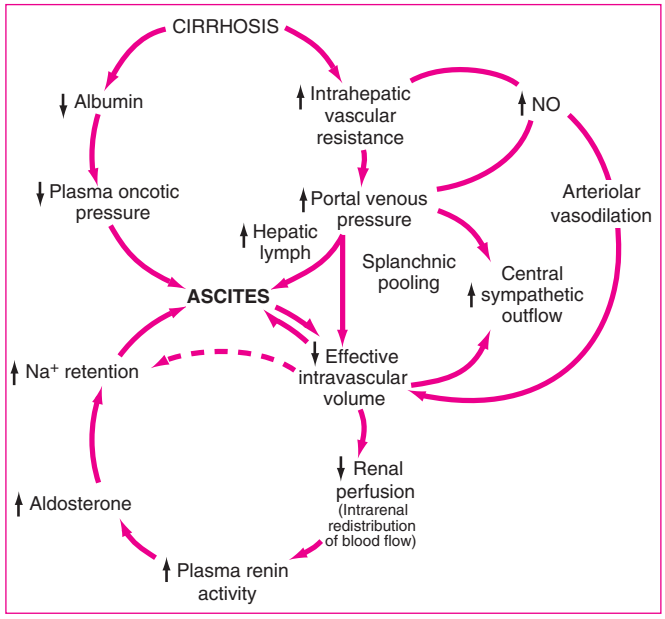

FIGURE 19–3. Factors involved in the development of ascites. NO, nitric oxide. (From Chung RT, Podolsky DK. Cirrhosis and its complications. In: Kasper DL, Braunwald E, Fauci AS, et al, (eds.) Harrison's Principles of Internal Medicine. 16th ed. New York: McGraw-Hill, 2005: 1858–1869, with permission.)

As previously discussed, increased portal pressure triggers the release of nitric oxide to directly vasodilate the splanchnic arterial bed and decrease portal pressure. Unfortunately, nitric oxide also dilates the systemic arterial system, causing a decrease in blood pressure and a decrease in renal perfusion by lowering the effective intravascular volume. The kidney reacts by activating the renin-angiotensin-aldosterone system, which increases plasma renin activity, aldosterone production, and sodium retention. This increase in intravascular volume furthers the imbalance of intravascular oncotic pressure, allowing even more fluid to escape to the extravascular spaces.

Vasodilation and decreased arterial pressure are also detected centrally. The sympathetic nervous system is activated to increase blood pressure, which in turn increases portal pressure. Unchecked, these combined effects enable the cycle of portal pressure and ascites to continue, setting up a self-perpetuating loop of ascites formation.

Most patients with large ascites also retain sodium avidly and may become hyponatremic if there is a decrease in free water excretion. Untreated, this can lead to a decrease in renal function and the hepatorenal syndrome.[4,13]

Varices

The splanchnic system drains venous blood from the GI tract to the liver. In portal hypertension there is increased resistance to drainage from the originating organ so collateral vessels (varices) develop in the esophagus, stomach, and rectum to compensate for the increased blood volume. Varices divert blood meant for hepatic circulation back to the systemic circulation; this has the unintended deleterious effect of decreasing clearance of medications and potential toxins through loss of first-pass metabolism. Varices are weak superficial vessels, and any additional increase in pressure can cause these vessels to rupture and bleed.[15]

Spontaneous Bacterial Peritonitis

Spontaneous bacterial peritonitis (SBP) is an acute bacterial infection of peritoneal fluid in the absence of intra-abdominal infection or intestinal perforation. Estimates of the prevalence of SBP in patients with ascites range from 10% to 30%.[16] Enteric gram-negative aerobes are the most common bacteria isolated from ascitic fluid; usually *Escherichia coli* or *Klebsiella pneumoniae*. One proposed cause is translocation of intestinal bacteria seeding the ascitic fluid.[17] Bacterial translocation correlates with the delay in intestinal transit time and increased intestinal wall permeability observed in cirrhotic patients. Another possible mechanism is the hematogenous spread of bacteria into the peritoneal space.[18] *Streptococcus pneumoniae* is the most common gram-positive pathogen associated with SBP.[19] Once a bacterial pathogen has been identified, the antibiotic spectrum can be narrowed; SBP is rarely polymicrobial.

Hepatic Encephalopathy

Decreased cognition, confusion, and changes in behavior combined with physical signs such as asterixis (characteristic flapping of hands upon extension of arms with wrist flexion) indicate hepatic encephalopathy (HE). To objectively stage the degree of impairment, the patient should be assessed in five distinct categories:

1. Level of consciousness
2. Cognition (attention, memory, and disorientation)
3. Behavior (e.g., mood, anger, and paranoia)
4. Motor function (e.g., coordination, reflexes, and asterixis)
5. Response to psychometric tests

These changes may be acute, and therefore possibly reversible, or they may be of a more chronic, insidious nature from which patients rarely recover.

Numerous factors, many of them poorly understood, are involved in the development of HE. In severe hepatic disease, systemic circulation bypasses the liver, so many of the substances normally metabolized by the liver remain in the systemic circulation and accumulate to toxic levels. In excess, these metabolic by-products, especially nitrogenous waste, cause alterations in central nervous system functioning.[20]

Ammonia (NH_3) is just one of the toxins implicated in HE. It is a metabolic by-product of protein catabolism and is also generated by bacteria in the GI tract. In a normally functioning liver, hepatocytes take up ammonia and degrade it to form urea, which is then renally excreted. In patients with cirrhosis, the conversion of ammonia to urea is retarded and ammonia accumulates, resulting in encephalopathy. This decrease in urea formation is manifest on laboratory assessment as decreased blood urea nitrogen (BUN), but BUN levels do not correlate with degree of HE. Patients with HE commonly have elevated serum ammonia concentrations, but the levels do not correlate well with the degree of central nervous system impairment.[20]

False neurotransmitters resulting from increased levels of aromatic amino acids, high levels of γ-aminobutyric acid, and endogenous benzodiazepines have also been implicated in HE. These substances bind to both the γ-aminobutyric acid and benzodiazepine receptors and act as agonists at the active receptor sites.[20]

Patients with previously stable cirrhosis who develop acute encephalopathy often have an identifiable precipitating event that can account for the increased production and/or decreased elimination of these toxins. Infections, variceal hemorrhage, renal insufficiency, electrolyte abnormalities, and increased dietary protein have all been associated with acute development of HE.

Bleeding Diathesis and Synthetic Failure

Coagulopathies signal end-stage liver disease. The liver manufactures coagulation factors essential for blood clotting and maintenance of blood homeostasis. With advanced disease the liver is unable to synthesize these proteins, resulting in extended clotting times (e.g., prothrombin time) and bleeding irregularities.[21] An additional coagulation abnormality seen in advanced liver disease is thrombocytopenia. This is a result of decreased platelet production and splenic sequestration of platelets. Macrocytic anemia may also occur because of decreased intake, metabolism, and storage of folate and vitamin B_{12}.

Alcoholic Liver Disease

Progression of alcoholic liver disease moves through several distinct phases from development of fatty liver to the development of alcoholic hepatitis and cirrhosis. Fatty liver and alcoholic hepatitis may be reversible with cessation of alcohol intake, but cirrhosis itself is irreversible. Although the scarring of cirrhosis is permanent, maintaining abstinence from alcohol can still decrease complications and slow development to end-stage liver disease.[22] Continuing to imbibe speeds the advancement of liver dysfunction and its complications.

Metabolism of ethanol begins even prior to absorption, when alcohol dehydrogenase (ADH) within the gastric mucosa oxidizes a portion of the alcohol to **acetaldehyde**. The remaining alcohol is rapidly absorbed from the GI tract, and since it is highly lipid-soluble, it enters the body tissues quite easily. ❷ *ADH metabolizes ethanol in body tissues, primarily the liver, producing hypoxic damage.*[23] High levels of ethanol saturate the ADH enzyme system; when the ADH system is overwhelmed, the microsomal ethanol oxidizing system must take over the detoxification process. The microsomal ethanol oxidizing system is an inducible cytochrome P-450 (CYP)450 enzyme system; it participates in phase 1 metabolism and also produces acetaldehyde as its end product.[24,25] Acetaldehyde exerts direct toxic effects on the liver by damaging hepatocytes, inducing fibrosis, and by directly coupling to proteins, interfering with their intended actions. Metabolism of large amounts of ethanol shifts hepatic metabolic processes away from oxidation and toward reduction. This shift produces a change in metabolism accounting for the fatty liver, hypertriglyceridemia, and acidemia observed in alcoholic liver disease.

Less Common Causes of Cirrhosis

Genetics and metabolic risk factors mediate other less common causes of cirrhosis. These diseases vary widely in prevalence, disease progression, and treatment options.

Primary biliary cirrhosis is characterized by progressive inflammatory destruction of the bile ducts. Immune-mediated inflammation of intrahepatic bile ducts results in remodeling and scarring, causing retention of bile within the liver and subsequent hepatocellular damage and cirrhosis. The number of patients affected with primary biliary cirrhosis is difficult to estimate because many people are asymptomatic and incidental diagnosis during routine health care visits is common.

Clinical Presentation of Cirrhosis and Complications of Portal Hypertension

General

- Most signs and symptoms that bring patients to the attention of medical personnel are specific to the complication the patient is experiencing and vary with severity and suddenness of onset.

Symptoms

- Patients with cirrhosis may exhibit nonspecific symptoms such as fatigue and weakness but may be asymptomatic until acute complications develop.
- Nonspecific symptoms include anorexia, fatigue, easy bruising and bleeding from minor injuries, decreased libido, and pruritus (particularly with biliary involvement).
- Patients with ascites may complain of abdominal pain, nausea, increasing tightness and fullness in the abdomen, shortness of breath and early satiety.
- Hemorrhage associated with variceal bleeding may be associated with nausea, vomiting, and hematemesis. Patients may also present with pallor, fatigue, and weakness from blood loss.
- In patients with bleeding varices, digestion of swallowed blood represents a high protein load; this causes nausea and can precipitate symptoms of HE.
- In patients with HE, neurologic changes can be overwhelming or so subtle that they are not clinically apparent except during a targeted clinical evaluation.
- Patients with HE may complain of disruption of sleep patterns and day-to-night inversion; patients have delayed to-bed and wake times, which may progress to complete inversion of the normal diurnal cycle.
- If SBP occurs, symptoms of infection may include fever, chills, and abdominal pain.

Signs

- Nonspecific signs on physical exam include jaundice, tea-colored urine, bruising, hepatomegaly, splenomegaly, spider angiomata, caput medusae, palmar erythema, gynecomastia, and testicular atrophy.
- Ascites can be detected by increased abdominal girth accompanied by shifting dullness and a fluid wave.
- Signs of variceal bleeding depend on the degree of blood loss and abruptness of onset. Rapid and massive blood loss is more likely to result in hemodynamic instability than is slow, steady bleeding. Signs of acute bleeding may include pallor, hypotension, tachycardia, mental status changes, and hematemesis.
- Markers of hepatic encephalopathy include decreased cognition, confusion, changes in behavior, and asterixis.
- Patients with SBP may present with fever, abdominal pain, and changes in mental status.
- Decreases in clotting factors may manifest as abnormal bruising and bleeding.
- Dupuytren's contracture is a contraction of the palmar fascia that usually affects the fourth and fifth digits.[27] It is not specific to cirrhosis and can be seen in repetitive use injuries.

Laboratory Abnormalities

- Hepatocellular damage manifests as elevated serum aminotransferases [alanine aminotransferase (ALT) and aspartate aminotransferase (AST)]. The degree of transaminase elevation does not correlate with the remaining functional metabolic capacity of the liver. An AST level two-fold higher than ALT is indicative of alcoholic liver damage.
- Elevated alkaline phosphatase is nonspecific and may correlate with liver or bone disease; it tends to be elevated in biliary tract disease.
- γ-Glutamyl transferase (GGT) is specific to the bile ducts, and in conjunction with an elevated alkaline phosphatase, suggests hepatic disease. Extremely elevated GGT levels further indicate obstructive biliary disease. GGT is also elevated in those who drink three or more alcoholic drinks daily.
- Increased total, direct, and indirect bilirubin concentrations indicate defects in transport, conjugation, or excretion of bilirubin.
- Lactate dehydrogenase (LDH) is a nonspecific marker of hepatocyte damage; disproportionate elevation of LDH indicates ischemic injury.
- Thrombocytopenia may occur because of decreased platelet production and splenic platelet sequestration.
- Anemia (decreased hemoglobin and hematocrit) occurs as a result of variceal bleeding, decreased erythrocyte production, and hypersplenism.
- Elevated prothrombin time (PT) and International Normalized Ratio (INR) are coagulation derangements that indicate loss of synthetic capacity in the liver and correlate with functional loss of hepatocytes.
- Decreased serum albumin and total protein occur in chronic liver damage due to loss of synthetic capacity within the liver.
- The serum albumin-to-ascites gradient is greater than or equal to 1.1 g/dL (11 g/L) in association with portal hypertension.
- Increased blood ammonia concentration is characteristic of hepatic encephalopathy, but levels do not correlate well with the degree of impairment.
- Signs and symptoms of SBP in a patient with cirrhosis and ascites should prompt a diagnostic paracentesis (Fig. 19–4). In SBP, there is decreased total serum protein, elevated white blood cell count (with left shift), and the ascitic fluid contains at least $0.250 \times 10^3/mm^3$ ($0.250 \times 10^9/L$) neutrophils. Bacterial culture of ascitic fluid may be positive, but lack of growth does not exclude the diagnosis.

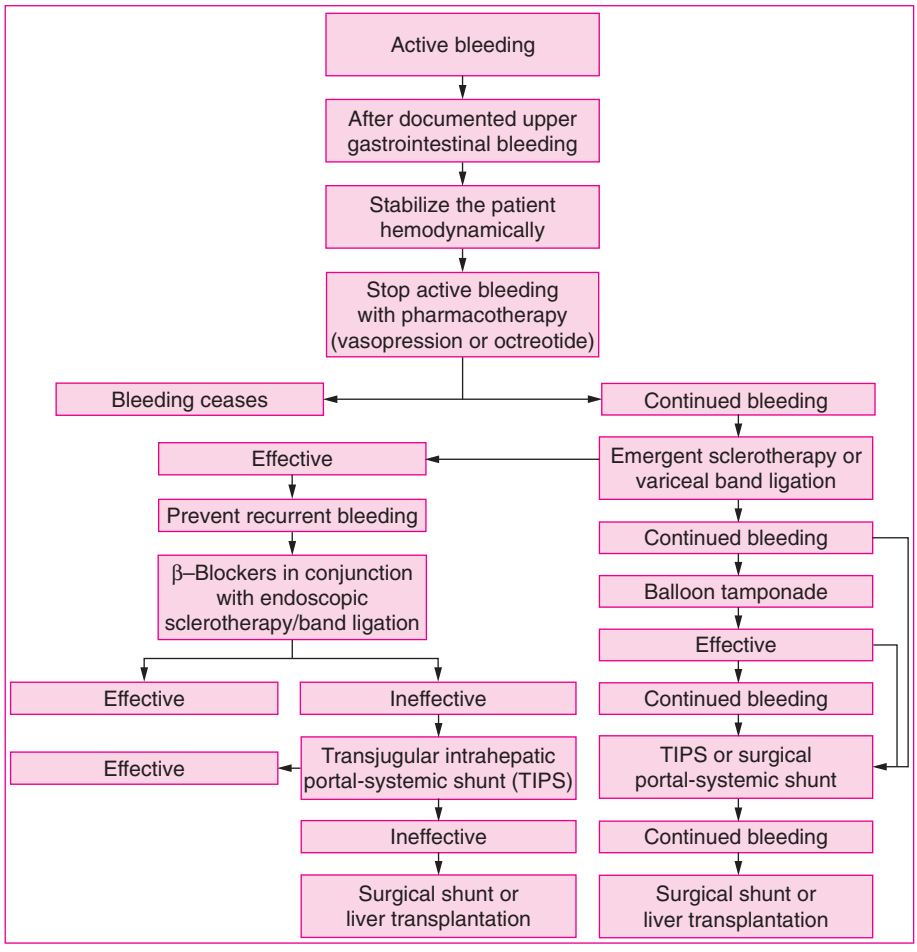

FIGURE 19–4. Treatment algorithm for active gastrointestinal bleeding resulting from portal hypertension. (From Schianotd, Bodenheimer HC. Complications of Chronic Liver Disease. In: Friedman SL, McQuaid KR, Grendell JH (eds.) Current Diagnosis & Treatment in Gastroenterology. 2nd ed. New York: McGraw-Hill, 2003, with permission)

Non-alcoholic fatty liver disease begins with asymptomatic fatty liver but may progress to cirrhosis. This is a disease of exclusion; elimination of any possible viral, genetic, or environmental causes must be made prior to making this diagnosis. Non-alcoholic fatty liver disease is related to numerous metabolic abnormalities. Risk factors include diabetes mellitus, dyslipidemia, obesity, and other conditions associated with increased hepatic fat.[26]

Hereditary hemochromatosis is an autosomal recessive disease of increased intestinal iron absorption and deposition in hepatic, cardiac, and pancreatic tissue. Hepatic iron overload results in the development of fibrosis, hepatic scarring, cirrhosis, and hepatocellular carcinoma. Hemochromatosis can also be caused by repeated blood transfusions, but this mechanism rarely leads to cirrhosis.

Wilson's disease is another autosomal recessive disease leading to cirrhosis. Protein abnormalities result in excessive copper deposition in body tissues. The faulty protein is responsible for facilitating copper excretion in the bile, so copper accumulates in hepatic tissue. High copper levels within hepatocytes are toxic, and fibrosis and cirrhosis may develop in untreated patients. Those with Wilson's disease usually present with symptoms of liver or neurologic disease while still in their teens.

A third autosomal recessive genetic disease is α_1-antitrypsin deficiency. Abnormalities in the α_1-antitrypsin protein impair secretion from the liver. α_1-Antitrypsin deficiency causes cirrhosis in children as well as adults; adults usually have concomitant pulmonary disease such as chronic obstructive pulmonary disease.

CLINICAL PRESENTATION AND DIAGNOSIS

Diagnosis of Cirrhosis

In some cases, cirrhosis is diagnosed incidentally before the patient develops symptoms or acute complications. Other patients may have decompensated cirrhosis at initial presentation; they may present with variceal bleeding, ascites, SBP, or HE. Patients may also have some of the laboratory abnormalities and/or signs and symptoms listed above that are associated with cirrhosis.[28]

Ultrasound examination is used routinely to evaluate cirrhosis; a small, nodular liver with increased echogenicity is consistent with cirrhosis. Liver biopsy is the only way to diagnose cirrhosis definitively, but it is often deferred in lieu of a

TABLE 19–1. Child-Pugh and MELD Classifications for Determining Severity of Liver Damage

Child-Pugh Classification[a] Variable	1 Point	2 Points	3 Points
Bilirubin (mg/dL)	Less than 2	2–3	Greater than 3
(μmol/L)	Less than 34	34–51	Greater than 51
Albumin (g/dL)	Greater than 3.5	2.8–3.5	Less than 2.8
(g/L)	Greater than 35	28–35	Less than 28
Prothrombin time (seconds prolonged)	1–3	4–6	Greater than 6
Ascites	None	Slight	Moderate
Encephalopathy	None	Stages 1–2	Stages 3–4

MELD Classification

The formula for the MELD score is $3.8 \times \log_e$ [bilirubin (mg/dL)] + $11.2 \times \log_e$ (INR) + $9.6 \times \log_e$ [creatinine (mg/dL)] + 6.4 × (etiology: 0 if cholestatic or alcoholic, 1 otherwise).

[a]Class A: 1–6 total points; B: 7–9 points; C: 10–15 points.
INR, International Normalized Ratio; MELD, Model for End-Stage Liver Disease.

presumptive diagnosis since it is an invasive procedure. The decision to perform a biopsy is based on the expected clinical utility of the biopsy results. If the results could change the course of treatment, it may be advisable to perform a biopsy. The Child-Pugh and Model for End-Stage Liver Disease (MELD) classification systems (Table 19–1) are used to classify disease severity and evaluate the need for transplantation.

Patients with ascites or known varices must be assumed to have portal hypertension and are treated as such, even if direct measurements of portal pressure have not been made.[29]

Diagnosis of Ascites

In obese patients or those with only small amounts of fluid accumulation, ultrasound evaluation may be necessary to detect ascites with certainty.

Analysis of ascitic fluid obtained during paracentesis provides diagnostic clues to the etiology of the ascites. Diagnostic evaluation should include cell count with differential, albumin, total protein, Gram stain, and bacterial cultures. In patients without an established diagnosis of liver disease, the serum-ascites albumin gradient (SAAG) is sensitive in determining if the ascites is caused by portal hypertension.[22] SAAG compares the serum albumin concentration to the ascitic fluid albumin concentration:

$$Alb_{serum} - Alb_{ascites} = SAAG$$

A value of greater than or equal to 1.1 g/dL (greater than or equal to 11 g/L) identifies portal hypertension as the cause of the ascites with 97% accuracy.[22,30] In portal hypertension the ascitic fluid is low in albumin; this balances the oncotic pressure gradient with the hydrostatic pressure gradient of portal hypertension. The differential diagnoses for SAAG values less than 1.1 g/dL (less than 11 g/L) include peritoneal carcinoma, peritoneal infection (tuberculosis, fungal, or cytomegalovirus), and nephrotic syndrome. Serum albumin measurements should be made at the same time ascitic fluid is obtained for an accurate comparison.[22]

TREATMENT OF CIRRHOSIS, PORTAL HYPERTENSION, AND COMPLICATIONS

Desired Outcomes

Recognizing and treating the cause of cirrhosis is paramount. ❸ *Cirrhosis is irreversible; treatments are directed at limiting disease progression and minimizing complications.* The immediate treatment goals are to stabilize acute complications such as variceal bleeding and prevent spontaneous bacterial peritonitis. Once life-threatening conditions have stabilized, the focus shifts to preventing complications and preventing further liver damage. Complication prevention involves both primary and secondary prophylaxis. To determine appropriate prophylactic therapy, a careful analysis of patient characteristics and disease history is mandatory. The sections that follow concentrate on treatment and prevention of cirrhotic complications.

Nonpharmacologic Therapy

Lifestyle modifications can limit disease complications and slow further liver damage. Avoidance of additional hepatic insult is critical for successful cirrhosis treatment. The only proven treatment for alcoholic liver disease is the immediate cessation of alcohol consumption. Patients who have cirrhosis from etiologies other than alcoholic liver disease should also abstain from alcohol consumption to prevent further liver damage.

All patients with ascites require counseling on dietary sodium restriction. Salt intake should be limited to less than 800 mg sodium (2 g sodium chloride) per day. More stringent restriction may cause faster mobilization of ascitic fluid, but adherence to such strict limits is very difficult. Patients usually respond well to sodium restriction accompanied by diuretic therapy.[14,22,31,32] The goal of therapy is to achieve urinary sodium excretion of at least 78 mEq (78 mmol) per day.[22] While a 24-hour urine collection provides this information, a spot urine sodium/ potassium ratio greater than 1.0 provides the same information and is much less cumbersome to perform.

Medication use must be monitored carefully for potential hepatotoxicity. Hepatically metabolized medications have the potential to accumulate in patients with liver disease. Little guidance is available on drug dosing in hepatic impairment because these patients are often excluded from drug trials. Daily acetaminophen use should not exceed 2 g. Dietary supplements have not been well studied in hepatic impairment and cannot be recommended.

Patient Encounter 1, Part 1

ES is a 44-year-old man who presents to the emergency department with complaints of abdominal pain.

Chief complaint
"My belly feels tight"

HPI
Increasing feelings of fullness and abdominal tightness that have become noticeable over the past 2 weeks, accompanied by nausea without vomiting and decreased food intake

PMH
Hypertension × 15 years, acute pancreatitis × 2 episodes

PSH
No surgeries

SH
Married, currently separated; denies tobacco and illicit drug use; typically drinks a 12-pack of beer daily and several shots of tequila; use has recently increased due to depression over marital separation

FH
Father died at age 45 from coronary disease, mother alive at age 62 with type 2 diabetes mellitus, hypertension, hyperlipidemia, and gastroesophageal reflux disease

Outpatient Meds
Chlorthalidone 25 mg daily

ROS
(+) Anorexia and nausea; denies vomiting, constipation, or diarrhea; patient endorses moderate shortness of breath and dyspnea on exertion

PE
VS: Blood pressure 125/75 mm Hg, pulse 84 beats per minute, temperature 37.3°C (99.1°F), respiratory rate 18/minutes, oxygen saturation 98% on room air
CV: RRR, no murmurs, rubs, or gallops
Chest: CTA bilaterally, no crackles or wheezes
Abd: Tense, distended abdomen that is tender to palpation, decreased bowel sounds, (+) hepatosplenomegaly
Exts: 2+ pedal pulses, 2+ pitting edema

- What are this patient's risk factors for liver disease?
- Identify features of his presentation that are consistent with cirrhosis.

In patients with variceal bleeding, nasogastric suction reduces the risk of aspirating stomach contents. Aspiration pneumonia is a major cause of death in patients with variceal bleeding. Nasogastric suction is also helpful in decreasing vomiting during acute episodes of variceal bleeding.[33,34] Blood within the gastrointestinal tract is very nauseating; removal of the blood can decrease vomiting.

In acute hepatic encephalopathy, temporary protein restriction to decrease the rate of ammonia production can be a useful adjuvant to pharmacologic therapy, but long-term protein restriction in cirrhotic patients is not recommended. These patients are already in a nutritionally deficient state, and prolonged protein restriction will exacerbate the problem.[20]

Vaccination against hepatitis A and B is recommended in patients with underlying cirrhosis to prevent additional liver damage from an acute viral infection.[35] Pneumococcal and influenza vaccination may also be appropriate and can reduce hospitalizations due to influenza or pneumonia.

Endoscopic band ligation and sclerotherapy are both means to stop acutely bleeding varices. Endoscopic band ligation is the application of a stricture around the varix, whereas sclerotherapy involves injecting the varix with substances designed to decrease blood flow to the area and prevent rebleeding. Endoscopic band ligation has replaced sclerotherapy as the preferred endoscopic treatment and is effective in stopping acute variceal bleeding in up to 90% of patients.[36] It is the standard of care for secondary prophylaxis of repeat bleeding in patients with a history of either esophageal or gastric variceal bleeding. Endoscopic band ligation is best used in conjunction with pharmacologic treatment.[37–39]

Balloon tamponade involves the application of direct pressure to the area of bleeding with an inflatable balloon attached to a nasogastric tube. It is an option for patients in whom drug therapy and band ligation fail to stop variceal bleeding. Balloon tamponade is used only when other methods have failed. Once the direct pressure of the balloon is removed, rebleeding often occurs, so balloon tamponade is only a temporary measure prior to more definitive treatment such as shunting.[11]

Shunts are long-term solutions to decrease elevated portal pressure. They divert blood flow either through or around the diseased liver, depending on the location and type of shunt employed. Transjugular intrahepatic portosystemic shunts (TIPS) create a communication pathway between the intrahepatic portal vein and the hepatic vein. TIPS procedures have an advantage over surgically-inserted shunts because they are placed through the vascular system rather than through an invasive surgical procedure, but they still carry a risk of bleeding and infection. TIPS placement is also associated with an increased incidence of hepatic encephalopathy.[40] This results from decreased detoxification of nitrogenous waste products because the shunt allows blood to evade metabolic processing.

Pharmacologic Therapy

Drug therapy for portal hypertension and cirrhosis can alleviate symptoms and prevent complications but it cannot reverse cirrhosis. Drug therapy is available to treat the complications of ascites, varices, spontaneous bacterial peritonitis, hepatic encephalopathy, and coagulation abnormalities.

Portal Hypertension

❹ *Non-selective β-blockers such as propranolol and nadolol are first-line treatments to reduce portal hypertension.* This effect reduces bleeding and decreases mortality in patients with known varices. Use of β-blockers to prevent variceal formation is controversial.

Only non-selective β-blockers reduce bleeding complications in patients with known varices. Blockade of β_1 receptors reduces cardiac output and splanchnic blood flow. β_2-Adrenergic blockade prevents β_2-receptor–mediated splanchnic vasodilation while allowing unopposed α-adrenergic effects; this enhances vasoconstriction of both the systemic and splanchnic vascular beds. The combination of β_1 and β_2 effects makes the non-selective β-blockers preferable to cardioselective agents in treating portal hypertension.[1,36,41]

Because β-blockers decrease blood pressure and heart rate, they should be started at low doses to increase tolerability. Propranolol is hepatically metabolized, and its half-life and pharmacologic effects are prolonged in portal hypertension. A reasonable starting dose of propranolol is 10 mg two to three times daily.

Doses should be titrated as tolerated with the goal of decreasing heart rate by 25% or to approximately 55 to 60 beats/minute.[11,36] Heart rate is not an accurate marker for portal pressure reduction, but it is the accepted surrogate marker for effectiveness because there are no other acceptable alternatives.

Nitrates have been suggested in patients who do not achieve therapeutic goals (heart rate reduction) with β-blocker therapy alone. Trials to evaluate the effects of nitrates (e.g., isosorbide mononitrate) on portal pressure, both alone and in combination with β-blockers, show enhanced reduction of portal pressure; however, there is an increase in mortality when nitrates are used alone. Adverse effects are significantly higher in patients treated with the combination of non-selective β-blockers and nitrates as opposed to β-blocker monotherapy.[42,43] Unfortunately, β-blockers either alone or in combination may be intolerable for many patients with cirrhosis.

Ascites

❺ *The goals of treating ascites are to minimize acute discomfort, re-equilibrate ascitic fluid, and prevent SBP. Treatment should modify the underlying disease pathology; without directed therapy, fluid will rapidly re-accumulate.*

In the case of tense ascites, relief of acute discomfort may be accomplished by therapeutic paracentesis. Often the removal of just 1 to 2 L of ascitic fluid provides relief of pain and fullness. When removing 5 L or more of fluid at once, volume resuscitation with 8 to 10 g of albumin given intravenously should be provided for each liter of fluid removed. If less than 5 L of fluid is removed in a hemodynamically stable patient, albumin is not warranted.[22]

Diuretics

Diuretics are often required in addition to the sodium restriction described previously. ❻ *Spironolactone and furosemide form the basis of pharmacologic therapy for ascites. Spironolactone is an aldosterone antagonist and counteracts the effects of activation of the renin-angiotensin-aldosterone system.* In hepatic disease not only is aldosterone production increased, but its half-life is prolonged because it is hepatically metabolized. Spironolactone acts to conserve the potassium that would be otherwise excreted because of elevated aldosterone levels.

Spironolactone is usually used in combination with a loop diuretic (e.g., furosemide) for more potent diuresis. A ratio of 40 mg furosemide (the most commonly used loop diuretic) to

Patient Encounter, Part 2

In the emergency department, a chest x-ray was normal. The following laboratory test results were obtained:

Sodium 128 mEq/L (mmol/L)	Platelets 178 × 10^3/mm^3 (× 10^9/L)
Potassium 3.1 mEq/L (mmol/L)	Albumin 2.7 g/dL (27 g/L)
Chloride 106 mEq/L (mmol/L)	Total bilirubin 2.3 mg/dL (39.3 μmol/L)
Bicarbonate 24 mEq/L (mmol/L)	Alk phos 177 IU/L (2.95 μKat/L)
BUN 27 mg/dL (9.64 mmol/L)	AST 443 IU/L (7.38 μKat/L)
Scr 1.1 mg/dL (97.2 μmol/L)	ALT 206 IU/L (3.43 μKat/L)
Glucose 145 mg/dL (8.05 mmol/L)	INR 1.6
Hemoglobin 12.5 g/dL (7.75 mmol/L)	GGT 185 IU/L (3.1 μKat/L)
Hematocrit 38% (0.38)	LDH 203 IU/L (3.38 μKat/L)
WBC count 7.4 × 10^3/mm^3 (× 10^9/L)	PT 29 seconds

- Which of these values are consistent with the diagnosis of cirrhosis?
- Does the current presentation imply the underlying cause of the disease?
- Are the laboratory results suggestive of complications related to cirrhosis?

ALT, alanine aminotransferase; AST, aspartate aminotransferase; GGT, gamma-glutamyl transferase; INR, international normalized ratio; LDH, lactate dehydrogenase; PT, prothrombin time.

Patient Encounter, Part 3

ES is found to have ascites. Therapeutic paracentesis is ordered to relieve shortness of breath and abdominal pain; 4 L of ascitic fluid is removed.

- What are the goals for treating ascites in this patient?
- What lifestyle modifications should the patient make that may decrease his risk of hospitalization and death from cirrhosis?
- What pharmacologic options are available to treat ascites in this patient?

each 100 mg spironolactone usually maintains serum potassium concentrations within the normal range. Therapy is commonly initiated with oral spironolactone 100 mg and furosemide 40 mg per day.

Doses should be titrated at intervals no more frequent than every 2 to 3 days. Because spironolactone is used for its anti-aldosterone effects, much higher doses (up to 400 mg/day) are used than those used when treating hypertension. If intolerable side effects such as gynecomastia occur with spironolactone, other potassium-sparing diuretics may be used, but clinical trials have not shown equivalent efficacy.[22]

The target in treating ascites is to effect a fluid loss of approximately 0.5 L per day.[22] Because ascites equilibrates with vascular fluid at a much slower rate than does peripheral edema, aggressive diuresis is associated with intravascular volume depletion and should be avoided unless patients have concomitant peripheral edema. Patients with peripheral edema in addition to ascites may require increasing furosemide doses until euvolemia is achieved; intravenous diuretics are often necessary.[22] Diuretic therapy in cirrhosis is typically lifelong.

Varices

Unfortunately, active variceal bleeding is common; it accounts for between 10% and 30% of all cases of upper GI hemorrhage. ❼ *During acute variceal hemorrhage, crucial desired outcomes include controlling bleeding, preventing rebleeding, and avoiding acute complications such as SBP; mortality from first bleeding episode is up to 55%, and patients must by treated aggressively.* A treatment algorithm for acute variceal bleeding is depicted in Fig. 19–3.

Octreotide

Octreotide is a synthetic analogue of somatostatin; it selectively causes vasoconstriction of the splanchnic bed, decreasing portal venous pressure with few serious side effects. Vasopressin has been used, but since it causes non-selective vasoconstriction, it carries the risk of systemic consequences, which limits its usefulness. The recommended octreotide dose is a 50- to 100-mcg intravenous (IV) loading dose followed by a continuous IV infusion of 25 to 50 mcg/hour. Therapy should continue for at least 24 to 72 hours after bleeding has stopped. Some clinicians continue octreotide for a full 5 days since this is the time frame during which the risk of rebleeding is highest. Octreotide combined with endoscopic therapy results in decreased rebleeding rates and transfusion needs when compared to endoscopic treatment alone.[36]

Spontaneous Bacterial Peritonitis

Initiation of prophylactic antibiotics is recommended during acute variceal bleeding; this is typically done with an oral fluoroquinolone (e.g., ciprofloxacin 500 mg twice daily × 7 days) or an IV third-generation cephalosporin. Prophylactic antibiotic therapy reduces in-hospital infections and mortality in patients hospitalized for variceal bleeding.[44]

If the presence of SBP is suspected, empiric antibiotic therapy with a broad-spectrum anti-infective agent should be initiated until cultures and susceptibilities are available (Fig. 19–5).[45,46] In the setting of presumed infection, delaying

Patient Encounter, Part 4

ES is brought to the emergency department by ambulance 2 months after the initial presentation.

Chief complaint

"I've been vomiting black stuff and I'm really tired"

HPI

Hematemesis for the past 2 days, worsening today and accompanied by profound weakness; patient is continuing to drink alcohol at the same rate

Outpatient Meds

Spironolactone 100 mg daily

Furosemide 40 mg daily

ROS

(+) Nausea, coffee-grounds emesis, and melena; denies constipation or diarrhea; (+) bilateral lower extremity edema

PE

VS: Blood pressure 98/60 mm Hg, pulse 122 beats per minute, temperature 37.1°C (98.8°F), respiratory rate 21/minutes, oxygen saturation 91% on room air
CV: Tachycardia, no murmurs, rubs, or gallops
Chest: CTA bilaterally
Abd: Mildly distended, tender to deep palpation, decreased bowel sounds, (+) hepatosplenomegaly and fecal occult blood test
Exts: Decreased pedal pulses, 3+ pitting edema

- What are the immediate treatment goals for ES?
- Does this presentation warrant prophylaxis to prevent further disease complications?

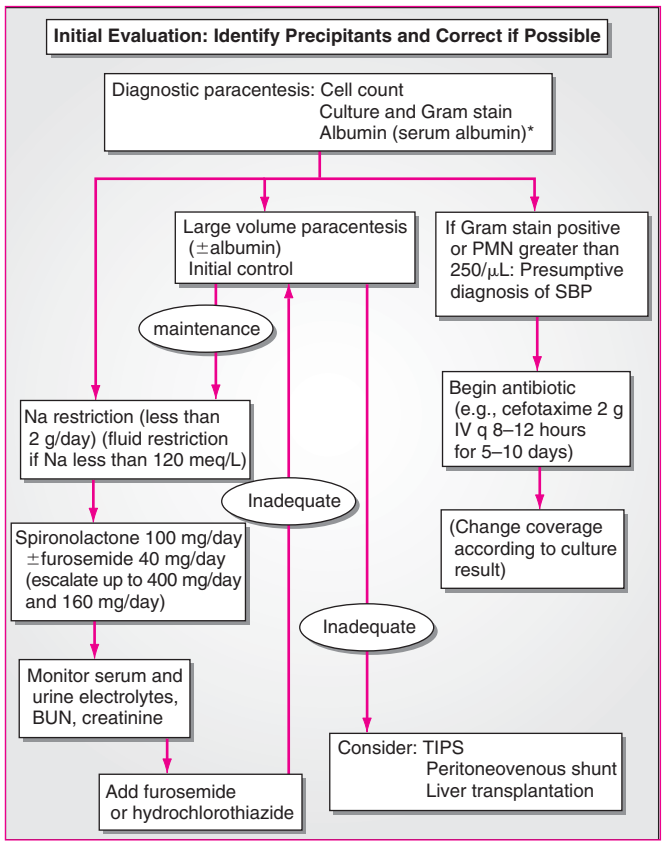

FIGURE 19–5. Approach to the patient with ascites and spontaneous bacterial peritonitis (SBP).
*If PMN greater than 250/μL but culture is negative (culture-negative neutrocytic ascites) begin empiric antibiotics and retap after 48 hours. If culture is positive but PMN less than 250/μL, treat as if PMN greater than 250/μL (presumed SBP). If polymicrobial infection exists, exclude SBP.
BUN, blood urea nitrogen; IV, intravenous; Na, sodium; PMN polymorphonuclear leukocyte; TIPS, transjugular intrahepatic portosystemic shunt. (From Chung RT, Podolsky DK. Cirrhosis and its complications. In: Kasper DL, Braunwald E, Fauci AS, et al, (eds.) *Harrison's Principles of Internal Medicine*. 16th ed. New York: McGraw-Hill, 2005: 1858–1869, with permission.)

treatment while awaiting laboratory confirmation is inappropriate and may result in death. The initial antibiotic should be an intravenous third-generation cephalosporin (e.g., cefotaxime 2 g every 4–8 hours, ceftriaxone 2 g every 24 hours), an intravenous extended-spectrum penicillin (e.g., piperacillin–tazobactam 3.375 g every 6 hours or 4.5 g every 8 hours), or an oral fluoroquinolone (e.g., levofloxacin 500 mg every day), since these agents cover the most common gram-negative and gram-positive agents. Third-generation cephalosporins are usually recommended as first-line therapy; fluoroquinolones are used if resistant (extended-spectrum β-lactamase positive) organisms are suspected. Once an infectious agent has been identified, antibiotic coverage can be narrowed to an agent that is highly active against that organism.

SBP has been associated with development of significant renal failure. Treatment with intravenous albumin can mitigate these effects when dosed at 1.5 g/kg of body weight initially, followed by 1 g/kg of body weight on day three of therapy.[47]

❽ *Patients who have previously experienced spontaneous bacterial peritonitis and have low-protein ascites* (ascitic fluid albumin less than 1 g/dL [less than 10 g/L]) *are candidates for long-term prophylactic therapy*. Recommended regimens include either a single trimethoprim-sulfamethoxazole double-strength tablet 5 days per week (Monday through Friday) or ciprofloxacin 750 mg once weekly.[19,46] Any patient who has experienced an episode of variceal bleeding should also receive prophylactic antibiotics.

Encephalopathy

Lactulose

❾ *Lactulose is the foundation of pharmacologic therapy to prevent and treat hepatic encephalopathy. It is a non-digestible synthetic disaccharide laxative that is hydrolyzed in the gut to an osmotically-active compound that draws water into the colon and stimulates defecation. Lactulose also lowers colonic pH, which favors the conversion of ammonia (NH_3) to ammonium (NH_4^+).*[48] *Ammonium is ionic and cannot cross back into systemic circulation; it is eliminated in the feces.* Lactulose is usually initiated at 15 to 30 mL two to three times per day and titrated to a therapeutic goal of two to four soft bowel movements daily.[20,49,50]

Patient Encounter, Part 5

During the hospital stay, ES had endoscopic band ligation to treat esophageal and gastric varices. Propranolol 20 mg three times a day was initiated; IV furosemide 60 mg twice daily resolved the pedal edema. Prescriptions for spironolactone 200 mg daily and furosemide 40 mg twice daily were provided at discharge. Three weeks later, ES is brought to clinic by his daughter who states that he is confused and "doesn't seem like himself." She is unsure if he has been taking his medication but says he continues to drink and has been eating poorly.

- What are the presenting signs and symptoms of hepatic encephalopathy?
- What factors could contribute to hepatic encephalopathy in this patient?
- What is the prognosis for this patient who has developed ascites, variceal bleeding, and hepatic encephalopathy within 3 months?

Flumazenil

Evidence for the false transmitter theory as the cause of encephalopathy is demonstrated by the fact that administration of flumazenil (a benzodiazepine antagonist) has resulted in functional improvement. Unfortunately, long-term benefit has not been shown, and since flumazenil can only be administered parenterally, it is not an appropriate choice for long-term therapy.

Coagulation Abnormalities

Vitamin K is an essential factor in the production of coagulation proteins within the liver. Elevated clotting times from decreased protein synthesis are indistinguishable from those produced by low vitamin K levels caused by malnutrition or poor intestinal absorption. Vitamin K (phytonadione) 10 mg subcutaneously daily for 3 days can help to establish whether the prolonged bleeding time results from loss of synthetic function in the liver or vitamin K deficiency.

OUTCOME EVALUATION

- Re-evaluate the pharmacotherapy regimen at each visit to assess effectiveness, adverse events, and need for drug titration.
- Assess the effectiveness of β-blocker therapy by measuring heart rate. Heart rate reduction of 25% from baseline or to 55 to 60 beats/minute is desirable. Ask the patient specific, directed questions regarding adverse effects of β-blockers; inquire about symptoms of orthostatic hypotension (e.g., lightheadedness, dizziness, or fainting).
- Evaluate effectiveness of diuretic therapy with regard to ascitic fluid accumulation and development of peripheral edema. Ask the patient directed questions about abdominal girth, fullness, tenderness, and pain. Weigh the patient at each visit, and ask the patient to keep a weight diary. Assess for peripheral edema at each visit.
- Measure spot urine sodium/potassium ratio to assess adherence to dietary sodium restrictions.
- Assess dietary sodium intake by patient food recall or by spot urine sodium/potassium ratio for appropriate sodium excretion.
- Obtain complete blood count and PT/INR to assess for anemia, thrombocytopenia, or coagulopathy. Ask about increases in bruising, bleeding, or development of hematemesis, hematochezia, or melena to assess for bleeding.
- Review biopsy reports and laboratory data. Transaminases and blood ammonia levels do not correlate well with disease progression, but increased coagulation times are markers of loss of synthetic function.
- Evaluate for signs and symptoms of hepatic encephalopathy. Mental status changes may be subtle; questioning family members or caregivers about confusion or personality changes may reveal mild hepatic encephalopathy even if the patient is unaware of the deficits.
- In patients taking lactulose therapy, titrate the dose to two to four soft bowel movements daily.

Patient Care and Monitoring

1. Obtain a complete history of alcohol intake and hepatotoxic drug use, including over-the-counter products and dietary supplements.
2. At each encounter, ask the patient specific questions about adherence to prescribed therapy, dietary restrictions and cessation of alcohol intake.
3. At each visit, evaluate the pharmacotherapy regimen for appropriate drug choice and dose, non-prescription drug use, adverse effects, and use of potentially hepatotoxic medications.
4. Question the patient about adverse effects, since hepatically metabolized medications may accumulate and cause adverse effects.
5. Consider antibiotic prophylaxis for SBP in patients with a history of variceal bleeding or prior SBP.
6. Conduct a review of systems and physical examination at each visit to determine if the patient has had progression of complications.
7. Ask specific questions about bleeding, bruising, and fatigue. There is a direct link between loss of synthetic function and disease progression.
8. Refer the patient to substance abuse counseling for education about alcohol cessation if appropriate.
9. Provide education regarding dietary sodium restrictions at each visit; consider a referral to a dietician if appropriate.

Joseph J. Kishel

LEARNING OBJECTIVES

UPON COMPLETION OF THE CHAPTER, THE READER WILL BE ABLE TO:

1. Describe the pathophysiology of acute and chronic pancreatitis.
2. Differentiate the signs and symptoms of acute from chronic pancreatitis.
3. Discuss the clinical implications of pancreatic fluid collections, pancreatic abscess, and pancreatic necrosis in acute pancreatitis.
4. Formulate care plans for managing acute pancreatitis.
5. Identify pharmacologic and nonpharmacologic means of preventing repeat episodes of chronic pancreatitis.
6. Choose appropriate pancreatic enzyme supplementation for patients with chronic pancreatitis.

KEY CONCEPTS

❶ The most common causes of acute and chronic pancreatitis in adults are ethanol abuse and biliary stones.
❷ Pancreatic necrosis occurs within the first 2 weeks of acute pancreatitis and develops in 10% to 30% of patients with acute pancreatitis.
❸ Primary therapy for acute pancreatitis is supportive, with fluid repletion, discontinuation of oral intake, and analgesia.
❹ Medications aimed at decreasing pancreatic enzyme release (e.g., somatostatin), nasogastric suction, and anticholinergic medications have all failed to show benefit in the treatment of acute pancreatitis.
❺ Treatment of chronic pancreatitis is aimed at removing the cause (ethanol abuse or biliary stones), providing analgesia, supplementing with pancreatic enzyme preparations, and implementing dietary restrictions.
❻ Long-term sequelae of chronic pancreatitis include dietary malabsorption, impaired glucose tolerance, cholangitis, and potential addiction to opioid analgesics.

The pancreas is a gland in the abdomen lying in the curvature of the stomach as it empties into the duodenum. The pancreas functions primarily as an exocrine gland, although it also has endocrine function. The exocrine cells of the pancreas are called acinar cells. They produce an alkaline fluid known as pancreatic juice that contains various digestive enzymes. These enzymes are produced and stored as inactive proenzymes within zymogen granules to prevent autolysis and digestion of the pancreas. The zymogen granules are also responsible for enzyme transport to the pancreatic duct. Amylase and lipase are released from the zymogen granules in the active form whereas the proteolytic enzymes are activated in the duodenum by enterokinase. Enterokinase triggers the conversion of trypsinogen to the active protease, trypsin. Trypsin then activates the other proenzymes to their active enzymes.

The pancreatic juice is released through the ampulla of Vater into the duodenum to aid in the digestive process as well as buffer acidic fluid released from the stomach (Fig. 20–1). The pancreas contains a trypsin inhibitor to prevent autolysis.

ACUTE PANCREATITIS

Epidemiology and Etiology

❶ In the Western hemisphere, *acute pancreatitis is caused mainly by ethanol use/abuse and gallstones.* Other common causes of acute pancreatitis include hypertriglyceridemia, endoscopic retrograde cholangiopancreatography (**ERCP**), and autodigestion due to early activation of pancreatic enzymes. Numerous medications have also been implicated as causes of acute pancreatitis (Table 20–1).

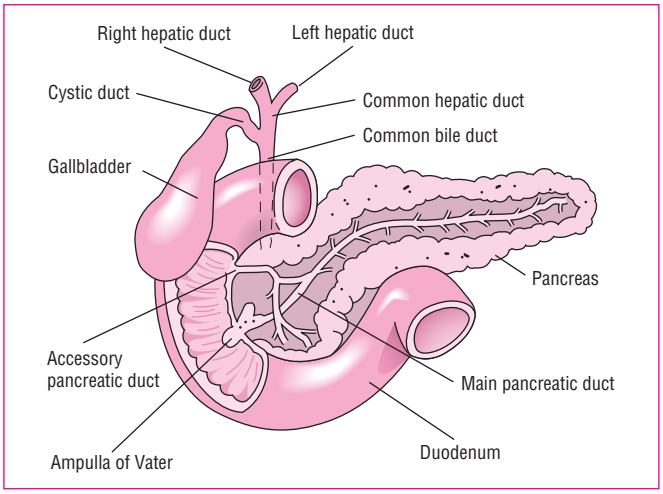

FIGURE 20–1. Anatomic structure of the pancreas and biliary tract. (From Berardi RR, Montgomery PA. Pancreatitis. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 722, with permission.)

Pathophysiology

Ethanol abuse may cause precipitation of pancreatic enzymes in the ducts of the pancreas leading to chronic inflammation and damage. Ethanol itself may be directly toxic to the pancreatic cells. Gallstones may obstruct the ampulla of Vater causing pancreatic enzymes or bile to move in a retrograde fashion into the pancreas.[1]

TABLE 20–1. Selected Medications Associated with Acute Pancreatitis

Definite Association	Probable Association
5-Aminosalicylic acid	Ampicillin
Asparaginase	Angiotensin-converting enzyme inhibitors
Azathioprine	Bumetamide
Didanosine	Calcium
Estrogens	Chlorthalidone
Furosemide	Cimetidine
Mercaptopurine	Cisplatin
Methyldopa	Clozapine
Metronidazole	Corticosteroids
Pentamidine	Cytarabine
Sulfonamides	Ethacrynic acid
Sulindac	Ifosfamide
Tetracycline	Interferon alfa-2b
Thiazides	Losartan
Valproic acid/salts	Meglumine antimoniate
	Piroxicam
	Procainamide
	Salicylates
	Sodium stibogluconate
	Zalcitabine

(From Berardi RR, Montgomery PA. Pancreatitis. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005:723, with permission.)

Autolysis of the pancreas can occur when zymogens are activated in the pancreas before being released into the duodenum. Acute pancreatitis can result from the initial injury to the zymogen-producing cells, which is followed by neutrophil invasion of the pancreas, and that ends in further activation of enzymes within the pancreas. This cascade of events can be destructive to the pancreas and harmful to the patient.

Acute pancreatitis can progress to several distinct consequences. Pancreatic fluid collections and pancreatic **abscesses** can form during the course of acute pancreatitis. Pancreatic necrosis can occur when pancreatic enzymes damage the pancreatic tissue or when pancreatic abscesses become secondarily infected. This infection is usually due to bacteria that are normally found in the gastrointestinal tract, including *Escherichia coli*, Enterobacteriaceae, *Staphylococcus aureus*, viridans group streptococci, and anaerobes.

Clinical Presentation and Diagnosis

Patients at greatest risk for mortality from acute pancreatitis are those who have multi-organ failure (e.g., hypotension, respiratory failure, or renal failure), pancreatic necrosis, obesity, volume depletion, greater than 70 years of age, and an elevated **APACHE II** score.[3,4] The Acute Physiology, Age, and Chronic Health Evaluation (APACHE) II score is a rating scale of disease severity in critically ill patients.

A patient with acute pancreatitis may develop many severe local and systemic complications. Local complications involve fluid collection, necrosis, or abscess in the pancreas. A pancreatic fluid collection (or pancreatic pseudocyst) is a collection of tissue, pancreatic enzymes, and blood that forms weeks after acute pancreatitis. Many pancreatic pseudocysts resolve spontaneously, but some require surgical drainage.[5] Rupture of a pancreatic pseudocyst with associated erosion and hemorrhage of major abdominal blood vessels can have a mortality approaching 60%; thus, continued monitoring of a pseudocyst is prudent.[6]

Pancreatic necrosis is a diffuse inflammation of the pancreas with infectious etiology. ❷ *Pancreatic necrosis occurs within the first 2 weeks of acute pancreatitis and develops in 10% to 30% of patients with acute pancreatitis.* The necrotic pancreas can become secondarily infected with enteric gram-negative bacteria (such as *E. coli*), and disseminated infection may result from pancreatic necrosis.[7,8]

Pancreatic abscess is a collection of pus that forms in the pancreas 4 to 6 weeks after acute pancreatitis. Pancreatic abscess is usually less life-threatening than pancreatic necrosis or pancreatic pseudocyst and can be managed with percutaneous drainage.[5]

Systemic complications can affect virtually any organ system but tend to target the pulmonary and cardiovascular systems and the kidneys. Multi-organ failure is a poor prognostic indicator. Acute respiratory distress syndrome (ARDS) is a life-threatening syndrome of acute lung injury with resulting hypoxia. ARDS may be due to the systemic release of pancreatic enzymes causing destruction of pulmonary surfactant, which is required for proper lung function.[9] Circulating pancreatic

Clinical Presentation of Acute Pancreatitis

Symptoms

- Abdominal pain radiating to the back is the most common presenting symptom. Pain can be due to intestinal immobility or chemical peritonitis induced by pancreatic enzymes.
- Other common symptoms include nausea, vomiting, and abdominal pain.

Signs

- Tachycardia, hypotension, fever, and abdominal distention may be present.
- There may be a positive Cullen's sign (bluish discoloration of the periumbilical skin indicating blood in the peritoneum).
- After 2 to 3 days of acute hemorrhagic pancreatitis, there may be a positive Turner's sign [local areas of discoloration (bruising) and induration of the skin near the umbilicus due to extravasation of blood].

Laboratory Tests

- The serum **amylase** can be elevated three times the upper limit of normal within the first 12 hours of the onset of acute pancreatitis. The degree of elevation does not predict the severity of disease.
- As acute pancreatitis progresses, the serum **lipase** can also become elevated.[2]
- Other possible laboratory abnormalities include elevated white blood cell count, hyperglycemia, hypocalcemia, hyperbilirubinemia, elevated serum lactate dehydrogenase (LDH), and hypertriglyceridemia.

Patient Encounter 1, Part 1

Presentation of Acute Pancreatitis

A 55-year-old man with a history of ethanol abuse is admitted to the emergency department complaining of sharp persistent pain in the right upper quadrant of the abdomen. The pain was milder 2 days ago but has progressed to the severe pain he has now. He was nauseated at home and has vomited twice in the emergency department; he is also febrile. The patient is overweight, a smoker, and has a history of dyslipidemia including hypertriglyceridemia.

- What information about the patient presentation is consistent with acute pancreatitis?
- What risk factors does the patient have for acute pancreatitis?
- What additional laboratory tests would you recommend?

enzymes can cause cardiovascular shock. Acute renal failure may result from hypovolemia and hyperkalemia.[10]

Diagnosis

Diagnosis of acute pancreatitis is based on the patient's history and presenting signs and symptoms. Evaluation of laboratory results, specifically the serum amylase and lipase, aids in diagnosis. Serum amylase is elevated early in the disease process but may return to normal within 12 hours.[10] Serum lipase will remain elevated for days after the acute event and may lend itself more to the diagnosis depending on when the patient presents for evaluation.[11]

The patient's history will identify risk factors for acute pancreatitis, such as age greater than 70 years or history of alcohol abuse. Finally, computed tomography (**CT**) scan or ultrasound of the abdomen can help to identify pancreatic fluid collections.[12]

Treatment

Desired Outcomes

The goals of treatment for acute pancreatitis include: (1) resolution of nausea, vomiting, abdominal pain, and fever; (2) ability to tolerate oral intake; (3) normalization of serum amylase, lipase, and white blood cell count; and (4) resolution of abscess, pseudocyst, or fluid collection as measured by CT scan.

Nonpharmacologic Therapy

Many medications can precipitate an attack of acute pancreatitis. If a medication is determined to be the cause of acute pancreatitis, it should be discontinued and alternative therapy considered.[13,14]

❸ *Therapy of acute pancreatitis is primarily supportive unless a specific etiology is identified (Fig. 20–2). Supportive therapy involves fluid repletion, discontinuation of oral intake, and analgesia.* Patients with acute pancreatitis are administered intravenous fluids to maintain hydration and blood pressure. Fluids may be given in the form of crystalloids (e.g., 0.9% sodium chloride for infusion) or colloids (e.g., dextran or albumin for infusion).[15] Sodium chloride 0.9% for infusion (normal saline) at a rate of 50 to 100 mL/hour is reasonable for patients with mild to moderate fluid depletion. However, as much as 200 mL/hour may be required for patients with severe fluid losses.[16] Electrolytes such as potassium and magnesium may be added to the infusions if necessary. Hyperglycemia can be managed with insulin-containing intravenous infusions.

It is common practice to discontinue oral feedings during an attack of acute pancreatitis. In theory, discontinuation of oral intake will decrease the secretory functions of the pancreas and minimize further complications from the disease. Some patients can be fed with minimal oral intake. Tube feeding delivered via a nasojejunal tube will feed the patient beyond the ampulla of Vater, minimizing stimulation of the pancreas.[15,16] If oral intake is discontinued for a protracted period, total parenteral nutrition must be used to maintain adequate nutrition.[17,18]

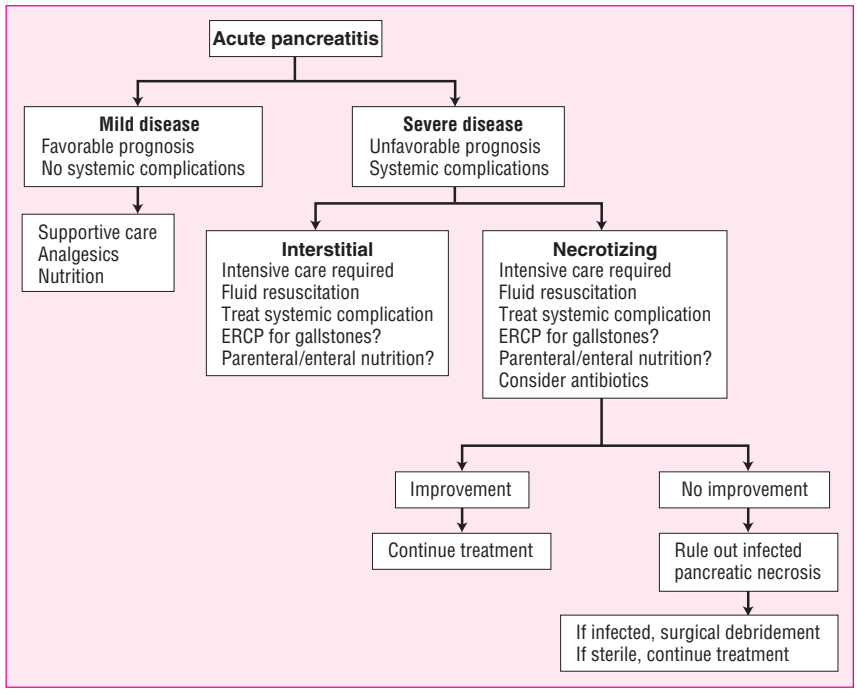

FIGURE 20–2. Algorithm for evaluation and treatment of acute pancreatitis. ERCP, endoscopic retrograde cholangiopancreatography. (From Berardi RR, Montgomery PA. Pancreatitis. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 726, with permission.)

If pancreatic necrosis has been identified, surgical debridement is necessary because mortality approaches 100% without drainage or surgical intervention. Percutaneous drainage is an option for managing pancreatic necrosis but is best used only in unstable patients as a bridge to surgery. Repeated surgery may be required in patients with a protracted or progressing disease state.[5,19]

Pharmacologic Therapy

Analgesics

Meperidine has historically been the most popular analgesic in acute pancreatitis since it is purported to cause less spasm and resulting pain in the **sphincter of Oddi** than other opioids. However, the clinical importance of this phenomenon is unclear.[15,20] As a result, patients with acute pancreatitis should be given the most effective analgesic. Morphine and fentanyl are reasonable alternatives to meperidine and may be more desirable due to other adverse effects associated with meperidine. Refer to Chapter 30 on pain management for guidance in selecting an analgesic dose.

Antibiotics

Empiric antibiotics are not necessary if the patient has mild disease or a non-infectious etiology of acute pancreatitis. Antibiotics have not been shown to prevent the formation of pancreatic abscess or necrosis when given early in the course of acute pancreatitis.

Antibiotics are appropriate for pancreatic necrosis, which can be infected initially or be susceptible to a secondary infection.[21] Selected intravenous antibiotic regimens are shown in Table 20–2. If necrosis is confirmed, antibiotics are insufficient as sole therapy; surgical debridement is necessary for cure.

Broad-spectrum antibiotics with activity against enteric gram-negative bacilli are appropriate. Imipenem/cilastatin reduces **sepsis** resulting from necrotizing pancreatitis and provides antibacterial coverage for the organisms likely to be causing pancreatic necrosis.[22]

It is often difficult to narrow the spectrum of activity of the antibiotic choice since the infections are usually polymicrobial. As such, patients may receive long courses of broad-spectrum antibiotics such as imipenem/cilastatin and

TABLE 20–2. Intravenous Antimicrobial Regimens for Pancreatic Necrosis

Drug	Usual Dose[a]	Notes
Imipenem/cilastatin	500 mg every 6 hours	~5% incidence of seizure; nausea is also a concern
Piperacillin/tazobactam	3.375 g every 6 hours	Avoid if allergic to penicillin
Cefepime + metronidazole	2 g every 12 hours + 500 mg every 6 hours	Will not cover enterococci
Aztreonam + vancomycin + metronidazole	1 g every 8 hours + 15 mg/kg every 12 hours + 500 mg every 6 hours	Option for penicillin-allergic patients

[a]Doses must be adjusted for the degree of renal impairment.

Patient Encounter 1, Part 2: Medical History, Physical Exam, and Diagnostic Tests in Acute Pancreatitis

PHM
Dyslipidemia, diagnosed "years ago"; obesity

FH
Father's whereabouts unknown; mother deceased at age 78 from heart failure; two half brothers, alive and well

SH
Consumes 6 to 9 alcoholic beverages per evening; smokes 1 pack cigarettes per day

Meds
No prescription medications; does not see a physician regularly

Maalox 15 mL PO 4 times daily as needed for heartburn, stomach upset

Loperamide 2 mg PO as needed diarrhea

Guaifenesin 200 mg PO 4 times daily as needed for cough
Ranitidine 75 mg PO once daily (when patient remembers to take it)

ROS
Positive for sharp right upper quadrant abdominal pain radiating to the back, nausea, vomiting, recent unintentional weight loss (although patient is still obese) and chronic cough; negative for chest pain or shortness of breath

PE
Wt: 120 kg, Ht: 5'10", blood pressure 100/66 mm Hg, pulse 120 beats per minute, respiratory rate 18/minutes, temperature 38.5°C
CV: Regular rate and rhythm, no murmurs
Abd: Distended, (+) rebound tenderness, (+) bowel sounds, marked hepatosplenomegaly

Labs
Amylase 200 units/L (3.3 µKat/L), lipase 1000 units/L
Abdominal CT: Pending

- Given this additional information, what is your assessment of the patient's condition?
- Why is the amylase low and the lipase high?
- What pharmacologic and nonpharmacologic goals are available for this patient?

may develop superinfections due to more resistant bacteria or bacteria not susceptible to imipenem/cilastatin. Antifungal agents such as fluconazole may be considered if peritonitis or gastrointestinal perforation develops due to the presence of fungi such *Candida albicans* in the gastrointestinal tract.[23]

Ineffective Therapies

❹ *Several pharmacologic therapies have been proven to be ineffective in reducing morbidity or mortality from the disease. Ineffective therapies include: reducing pancreatic secretion by administering somatostatin or atropine, reducing gastric acidity and decreasing pancreatic secretion with histamine$_2$-receptor antagonists, inhibition of pancreatic enzymes using* ***protease*** *inhibitors such as aprotinin, and immunomodulation.*[11,24–26] *Nasogastric suction has only been effective in patients with ileus or persistent vomiting.*[27]

Patient Encounter 1, Part 3: Treatment and Monitoring for Acute Pancreatitis

The patient has been transferred from the CT scanner to the surgical intensive care unit for mechanical ventilation, blood pressure support, and surgical evaluation. A diagnosis of acute pancreatitis with pancreatic necrosis is made.

- Formulate a care plan for this patient.
- What are some possible causes of respiratory failure and hypotension in this patient? Are these findings poor prognostic indicators?
- What is the recommended treatment for pancreatic necrosis?
- What empiric antibiotic regimen would be a reasonable choice in this patient? Provide a drug, dose, route, and frequency.
- Suppose a surgeon requested piperacillin/tazobactam 3.375 g IV every 6 hours for this patient. Would this be a reasonable choice? Why or why not?

Outcome Evaluation

Given the severity of acute pancreatitis, patients are monitored closely in the intensive care setting. Patients with mild disease can be managed more conservatively with observation and supportive care. Critically ill patients may require surgery and aggressive life support measures.[16,28]

CHRONIC PANCREATITIS

Epidemiology and Etiology

The incidence of chronic pancreatitis is approximately 1 in 10,000 people. ❶ *The most common cause of chronic pancreatitis in adults in Western countries is ethanol abuse.* The most common cause in children is cystic fibrosis, due to preexisting pancreatic insufficiency inherent in the disease. Gallstones can occur at the same time as chronic pancreatitis but are not often implicated as the cause. Unlike acute pancreatitis, chronic pancreatitis has an unknown etiology in a significant number of cases (30%).[29,30]

Pathophysiology

Chronic pancreatitis is an inflammatory process that occurs over a long period of time. The inflammation damages the enzyme-producing cells in the pancreas and can also disrupt or destroy the endocrine function of the pancreas by causing diffuse

scarring and fibrosis.[29] Ethanol abuse may cause precipitation of pancreatic enzymes in the ducts of the pancreas leading to chronic inflammation and damage. Ethanol may also be directly toxic to pancreatic cells.[31] Counterintuitively, the amount of ethanol consumed does not correlate with the incidence or progression of chronic pancreatitis. A patient who "binge drinks" by consuming large amounts of ethanol over short periods of time is as likely to develop chronic pancreatitis as someone who chronically consumes socially acceptable amounts of alcohol. Patients who die from the first diagnosed episode of chronic pancreatitis may have had undiagnosed chronic pancreatitis for some time.[32]

As patients lose exocrine function of the pancreas, they have decreased ability to absorb lipids and protein ingested with normal dietary intake. Weight loss from nutritional malabsorption is a common symptom of chronic pancreatitis not often seen in acute pancreatitis. Fatty- or protein-containing stools are also common; carbohydrate absorption is usually unaffected. Even though patients with chronic pancreatitis have decreased ability to absorb lipid from the gastrointestinal tract, there does not appear to be an increased incidence of fat-soluble vitamin deficiency in these patients.[34]

Clinical Presentation and Diagnosis

Clinical Presentation of Chronic Pancreatitis

General
- The presentation of chronic pancreatitis can be similar to that of acute pancreatitis.

Symptoms
- Pain is the most common chief complaint. Pain can be dull or sharp, and it may be localized to the area around the stomach or can radiate to the back. The pain is not relieved by antacids and can be provoked by ethanol ingestion or a fatty meal.[33]
- Weight loss can result from chronic fat and protein malabsorption.

Signs
- Patients often present with chronic fat-containing diarrhea due to dietary lipid malabsorption.
- Gastrointestinal bleeding can result from erosion of intestinal blood vessels by pancreatic enzymes or as a result of thrombosis.
- Chronic obstruction of the common bile duct by the inflamed pancreas can cause icterus, cholangitis, and biliary cirrhosis.[36]

Laboratory Tests
- Glucose intolerance may occur because of chronic destruction of the endocrine function of the pancreas.[35]
- Serum amylase and lipase levels are not usually elevated in chronic pancreatitis.
- The serum bilirubin or alkaline phosphatase may be elevated due to inflammation near the common bile duct.

Diagnosis

Differentiating an episode of acute pancreatitis from chronic pancreatitis may be difficult because the clinical presentations can be similar. The diagnosis of chronic pancreatitis is made by looking for the effects of chronic pancreatic inflammation and scarring on the pancreas and the patient as a whole. Computed tomography or ERCP will allow visualization of chronic calcified lesions in the pancreas when present.[37]

Treatment

Desired Outcomes

The goals of pharmacotherapy for chronic pancreatitis are: (1) prevention and resolution of chronic abdominal pain; and (2) correction of dietary malabsorption with exogenous pancreatic enzymes.

Nonpharmacologic Therapy

Lifestyle modifications are an important part of the therapy for chronic pancreatitis. ❺ *Avoidance of ethanol and fatty meals can decrease the pain of chronic pancreatitis.*

Many surgical procedures have been employed to reduce the inflammation or remove the strictures that cause pain in chronic pancreatitis. However, most procedures have not been proven effective in clinical trials and carry a high risk of morbidity and mortality.[39]

Pharmacologic Therapy

Analgesics

Pain management is an important component of therapy and is similar to that of acute pancreatitis. Non-opioid analgesics are preferred, but the severe and persistent nature of the pain often requires opioid therapy. Patients can require chronic doses of opioid analgesics, with a resulting risk of addiction. Pain can also be managed by removing the stimulus of exacerbation if identified.[31,38]

Pancreatic Enzymes

The goal of pancreatic enzyme supplementation is to deliver exogenous enzyme to the duodenum without causing further gastrointestinal side effects from the medication, risking noncompliance due to the large number of dosage units required, or causing undue medication expense.[40]

Supplementation with pancreatic enzymes may reduce the pain and fatty diarrhea associated with chronic pancreatitis (Table 20–3). Best results are achieved in patients who have mild non-alcoholic pancreatic disease. Common pancreatic enzyme supplements contain lipase, amylase, and protease in varying proportions. Thus, the dose can be tailored to the patient's requirement for exogenous enzyme supplementation and response to therapy.

Non–enteric-coated pancreatic enzyme supplements require high doses to compensate for loss of enzyme due to

TABLE 20–3. Frequently Used Pancreatic Enzyme Preparations

Product	Dosage Form	Enzyme Content (Units)[a]		
		Lipase	Amylase	Protease
Creon-10	ECMS	10,000	33,200	37,500
Creon-20	ECMS	20,000	66,400	75,000
Ku-Zyme HP	C	8000	30,000	30,000

Ultrase MT 20	ECMT	20,000	65,000	65,000
Viokase[b]	P	16,800	70,000	70,000
Viokase 8	UCT	8000	30,000	30,000
Viokase 16	UCT	16,000	60,000	60,000

[a]All listed products contain pancrelipase. Pancrelipase contains not less than 24 USP units of lipase activity, not less than 100 USP units of amylase activity, and not less than 100 USP units of protease activity per milligram.
[b]Units of 0.7 g of powder.
C, powder encased in a cellulose capsule; ECMS, enteric-coated microspheres encased in a cellulose or gelatin capsule; ECMT, enteric-coated microtablets encased in a cellulose capsule; UCT, uncoated tablet; P, powder.
(From Berardi RR, Montgomery PA. Pancreatitis. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 733, with permission.)

destruction by the low pH of the stomach. This effect can be minimized by administering a histamine$_2$-receptor antagonist or proton pump inhibitor. Non–enteric-coated pancreatic enzyme supplements may have an advantage in minimizing pain early in the disease state through regulation of proteases in the duodenum.

Non–enteric-coated pancreatic enzyme supplements can be used for initial therapy. The relative dose of amylase, lipase, and protease may be increased until control of pain and fatty diarrhea is achieved or the patient experiences intolerable side effects. If pain and diarrhea control are achieved, the patient can be transitioned to an enteric-coated supplement to maximize compliance. A reasonable example starting regimen is Viokase-8, six tablets with each meal and at bedtime, given with famotidine 20 mg at bedtime.

Most pancreatic enzyme supplements are enteric coated to release enzymes in the alkaline environment of the intestine; this minimizes enzyme destruction in the stomach. Enteric-coated pancreatic enzyme supplements require fewer daily dosage units, but delivery of the drug to the site of action and effectiveness may be delayed by gastric emptying time.[41]

Patient Encounter 2

Chronic Pancreatitis

The same patient described in the first encounter is now 57 years old. He presents to the clinic with right upper quadrant pain radiating to his back. He is also jaundiced and nauseated.

PMH

Dyslipidemia, with preponderance of hypertriglyceridemia
Hypertension
Weight loss, initially intentional through diet and exercise, but now unintentionally excessive
Type 2 diabetes, requiring insulin
Gastroesophageal reflux disease

SH

Consumes 1 to 2 alcoholic beverages per evening; quit smoking 2 years ago

Meds

Atorvastatin 40 mg PO once daily
Hydrochlorothiazide 25 mg PO once daily
Amlodipine 5 mg PO once daily
Lantus insulin 30 units per day
Multivitamin 1 tablet daily
Pantoprazole 40 mg PO once daily
Maalox 15 mL PO 4 times daily as needed for heartburn/stomach upset
Acetaminophen 325 mg PO every 6 hours as needed for pain/headache

ROS

Positive for sharp right upper quadrant abdominal pain radiating to the back, nausea, and recent unintentional weight loss; negative for chest pain or shortness of breath, fatty diarrhea present for months.

PE

Wt: 70 kg Ht 5′10″, blood pressure 130/86 mm Hg, pulse 80 beats per minute, respiratory rate 16/minute, temperature 37.0°C (98.6°F)
CV: Regular rate and rhythm, no murmurs noted
Abd: Distended, (+) rebound tenderness, (+) bowel sounds, marked hepatosplenomegaly

Labs

Amylase 100 units/L (1.67 μKat/L), lipase 100 units/L
CT scan: Diffuse pancreatic scarring and calcifications

- Formulate a care plan for this patient.
- Why are the serum amylase and lipase normal?
- What lifestyle modifications can this patient make to minimize impact from his disease state?
- Is this patient taking any medication(s) that could exacerbate pancreatitis? If so, what alternatives can you offer?
- What medications may help alleviate the fatty diarrhea the patient is experiencing?
- How would you monitor the effectiveness of your recommendations?

Pancreatic enzyme supplements should be taken immediately prior to meals to aid in the digestion and absorption of food. Alternately, patients can supplement their diet with medium chain triglycerides (MCTs) or ingest foods rich in MCTs since they do not require pancreatic enzymes for absorption. An appropriate regimen incorporates the successful doses of each enzyme (amylase, lipase, and protease) from the starting non–enteric-coated regimen. As with the previous example, a patient stabilized on Viokase-8, six tablets with each meal, can be transitioned to Pancrease MT-16 three tablets with meals. The famotidine can then be discontinued.

Outcome Evaluation

- Monitor for adequate pain control and the need for escalation or de-escalation of analgesia.
- If pain relief is achieved by avoiding ethanol or fatty meals, encourage continuation of these practices.
- When dietary malabsorption exists, monitor patients for weight gain or loss, activity level, and ability to perform activities of daily living.
- Ask patients to monitor the frequency and consistency of stool output as an indicator of malabsorption.
- Educate patients that compliance with and proper use of dietary pancreatic enzyme supplementation is key to improved outcomes.[31,33,38]

Patient Care and Monitoring

1. Determine whether ethanol is a contributing causative factor. If so, reinforce counseling on the need for abstinence and provide appropriate resources to maintain abstinence (e.g., professional counseling, alcoholics anonymous).
2. Obtain a thorough history of prescription, non-prescription, and dietary supplement use to identify products that may exacerbate chronic pancreatitis.
3. Refer the patient for nutritional counseling if there is decreased caloric intake and weight loss. Compare actual body weight to ideal body weight.
4. Make a plan for analgesia, in conjunction with a pain management service if possible, to control and prevent pain. Recommend an analgesic with ease of dosing and minimal side effects, realizing that patients with chronic pancreatitis may require large doses of opioids.
5. Optimize pancreatic enzyme supplementation, starting first with a non–enteric-coated enzyme supplement and an H_2RA. When pain and diarrhea are stabilized, consider switching to an enteric-coated enzyme supplement for ease of dosing.
6. Develop a plan for reassessing pancreatic enzyme supplementation and analgesia on an outpatient basis.
7. Assess improvement in quality of life measures such as physical, psychological, and social functioning and well-being.

ABBREVIATIONS

APACHE:	Acute Physiology, Age, and Chronic Health Evaluation

21 Viral Hepatitis

Juliana Chan

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Differentiate the five types of viral hepatitides by their epidemiology, etiology, pathophysiology, clinical presentation and natural history.
2. Identify modes of transmission and risk factors among the major types of viral hepatitis.
3. Evaluate hepatic serologies to diagnose the type of hepatitis infection a patient acquired.
4. Create treatment goals for a patient with viral hepatitis.
5. Recommend an appropriate pharmacotherapeutic agent for prevention of viral hepatitis.
6. Develop a pharmaceutical care plan for the treatment of viral hepatitis.
7. Formulate a monitoring plan to assess the untoward effects of agents used to treat viral hepatitis.

Key Concepts

❶ Prevention and treatment of viral hepatitis may prevent progression to chronic hepatitis, cirrhosis, and end-stage liver disease.
❷ There is no specific pharmacologic treatment for acute viral hepatitis A, B, C, D, or E; only supportive care is available.
❸ Good personal hygiene and proper disposal of sanitary waste are required to prevent the fecal-oral transmission of the hepatitis A virus.
❹ Individuals may minimize their risk of acquiring both hepatitis B and C infection by avoiding contaminated blood products and not indulging in high-risk behavior such as intravenous drug use.
❺ Persons at high risk of acquiring the hepatitis B virus should be vaccinated with the hepatitis B vaccine at months 0, 1, and 6.
❻ A vaccine that combines both inactivated hepatitis A and recombinant hepatitis B (Twinrix) is approved for immunizing individuals greater than 18 years of age with indications for both hepatitis A and B vaccines.
❼ The drug of choice for chronic hepatitis B depends on the patient's past medical history, aminotransferase level, HBV DNA level, and most importantly, HBeAg status.
❽ Hepatitis D infection is possible only if the patient also has the hepatitis B virus present; therefore, hepatitis B vaccination can indirectly prevent hepatitis D infection.

There are five types of viral hepatitis: hepatitis A (HAV), B (HBV), C (HCV), D (HDV), and E (HEV). These types may present as either acute or chronic illnesses, which are primarily differentiated based on disease duration. Acute hepatitis may be associated with all five types of hepatitis and rarely exceeds 6 months in duration.

Chronic hepatitis (disease lasting longer than 6 months) is usually associated with hepatitis B, C, and D. ❶ *Chronic viral hepatitis may lead to the development of* ***cirrhosis****, which may induce* ***end-stage liver disease*** *(ESLD).* Complications of ESLD include **ascites**, edema, jaundice, **hepatic encephalopathy**, infections, and bleeding **esophageal varices**. Therefore, prevention and treatment of viral hepatitis may prevent ESLD.

Viral hepatitis can occur at any age and is the most common cause of liver disease in the world. The true prevalence and incidence may be underreported because most patients are asymptomatic. The epidemiology, etiology, and pathogenesis vary depending on the type of hepatitis and will be considered separately below.

HEPATITIS A

Epidemiology and Etiology

Hepatitis A affects 1.4 million people yearly worldwide.[1] The prevalence is highest in underdeveloped countries including Africa, parts of South America, the Middle East, and Southeast

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

Asia. In contrast, developed parts of the world including Australia, parts of western and northern Europe, Japan, and the United States have a lower prevalence. This is primarily due to vaccination programs, but outbreaks still can happen as evidenced by an outbreak in Pennsylvania in 2003.[2,3]

Thirty-one percent of the American population has been infected with the HAV.[1] Overall, Mexican Americans are at greatest risk for HAV infection, and African Americans are more likely to be infected than Caucasians.

The hepatitis A virus is primarily detected in contaminated feces and infects people via the fecal-oral route. Outbreaks occur primarily in areas of poor sanitation.[1,4] Individuals at greatest risk of acquiring HAV are listed in Table 21–1. Approximately 50% of the reported cases have no identifiable risk factors.[1]

To date, there are no documented cases of chronic hepatitis A.[1] Death associated with HAV is rare and is mostly associated with fulminant hepatitis, with which approximately 100 people die annually.[1]

Pathophysiology

Hepatitis A is a non-enveloped single-stranded ribonucleic acid (RNA) virus classified as the Hepatovirus genus under the Picornaviridae family.[1] The only host for the HAV is humans, with hepatic cells as the primary site for viral replication. As part of the viral degradation process, the HAV is released into the biliary system causing elevated concentrations of the virus in the feces.[5]

TABLE 21–1. Risk Factors for Acquiring Viral Hepatitis

Hepatitis A
International travelers to endemic areas (e.g., Africa, Asia, and parts of South America)
Sexual contact with infected persons (e.g., men having sex with other men)
Shellfish infected with HAV (e.g., raw oysters)
Day care centers or household contacts with people infected with HAV
Health care workers
Intravenous drug users using unsterilized needles
Workers involved with non-human primates
Food service handlers
Patients with clotting factor disorders
Individuals residing in health care institutions
Hepatitis B and Hepatitis D
Men having sex with other men
Individuals with multiple heterosexual partners
Intravenous drug users using unsterilized needles
Recipients of blood products
Household contacts with acute hepatitis B with open cuts
Health care providers in contact with contaminated needles
Patients undergoing dialysis
Hepatitis C
Recipients of blood products
Health care providers in contact with infected needles
Individuals having multiple sexual partners
Perinatal transmission (less than 5%)
Unprofessional body piercing and tattooing
Hepatitis E
International travelers to endemic areas (e.g., parts of Asia, Africa, and Mexico)
Ingesting foods and drinks contaminated with bodily waste

HEPATITIS B

Epidemiology and Etiology

Hepatitis B is a blood-borne infection affecting more than 2 billion people in the world. Approximately 350 million people have chronic infection, which may lead to cirrhosis and complications of ESLD. Deaths related to hepatitis B range from 500,000 to 750,000 yearly.[6] Despite having an effective vaccine against HBV, more than 300,000 newly-diagnosed infections emerge each year. The prevalence of chronic hepatitis B is geographically dependent; the rate is about 1% in North America and Western Europe compared to 10% to 15% in developing areas such as Southeast Asia.[7]

The highest concentration of the HBV is found in blood and serous fluids. Therefore, the primary mode of hepatitis B transmission is either by blood or body fluids through perinatal, sexual, or percutaneous exposure.[8] Infants born of mothers who are infected with HBV that is actively replicating have a 90% risk of developing chronic hepatitis B. If an infant residing in an endemic area is not infected at birth, the risk of acquiring chronic hepatitis B is still 30% to 60% within the first 5 years of life from horizontal transmission.[9,10] Individuals at greatest risk of acquiring HBV are listed in Table 21–1. Approximately 33% of the reported hepatitis B cases have no identifiable risk factors.[8]

Pathophysiology

Hepatitis B (also known as the Dane particle) belongs to the Hepadnaviridae family that was first discovered by associating individuals who developed hepatitis from blood transfusions.[11] The HBV is unique in that it is a partially double-stranded deoxyribonucleic acid (DNA) virus with a phospholipid layer containing hepatitis B surface antigen (HBsAg) that surrounds the nucleocapsid. The nucleocapsid contains the core protein that produces hepatitis B core antigen (HBcAg), which is undetectable in the serum. The exact mechanism of hepatocellular injury from hepatitis B is still being investigated but it is thought that a cytotoxic immune reaction occurs when HBcAg is expressed on the surface of the hepatic cells. Fortunately, antibodies against hepatitis B core antigen (anti-HBc) are measurable in the blood, where anti-HBc to immunoglobulin M (IgM) indicates active infection and anti-HBc to IgG relates to either chronic infection or possible immunity against HBV.

Viral replication occurs when hepatitis B envelope antigen (HBeAg) is present and circulating in the blood. HBV DNA is utilized to measure viral infectivity and assess and quantify viral replication. Once the hepatitis B infection resolves, antibodies against hepatitis B envelope (anti-HBe) and

antibodies against hepatitis B surface antigen (anti-HBs) develop, and HBV DNA levels become undetectable. However, if these antibodies do not develop, then the likelihood of developing chronic hepatitis B increases. This is primarily dependent on the host's immune system at the time the infection was attained. If an individual is immunocompetent, the disease resolves spontaneously in most cases with no further sequelae. In an immunocompromised person, the infection is less likely to be eradicated.[11]

Natural History of Hepatitis B

Approximately 90% of adults infected with HBV develop anti-HBs resulting in lifelong immunity. About 2% develop acute infections leading to fulminant hepatitis, which has a 60% to 90% mortality rate.[7] Fifteen percent of individuals who do not develop anti-HBs develop chronic hepatitis B. Of this population, the chance of developing chronic disease is less than 20% if the infection was acquired during adulthood. The risk of developing chronic hepatitis B increases to greater than 40% if the infection occurred perinatally.[7] It may take 20 to 40 years from the time cirrhosis is confirmed before signs and symptoms associated with ESLD develop.

HEPATITIS C

Epidemiology and Etiology

More than 170 million people are infected with hepatitis C worldwide, and more than 4 million have the disease in the United States.[12,13] The prevalence is higher among non-Hispanic blacks (3.2%) than non-Hispanic whites (1.5%), and men are more likely to be infected than women.[14] Additionally, genotypes are geographically specific. For example, genotype 1 is commonly found in patients in the United States whereas genotype 4 is common in the Middle East.[12] Approximately 75% of those infected with HCV in the United States have genotype 1, and about 14% and 5% have genotypes 2 and 3, respectively. Genotype does not dictate disease severity or clinical outcomes but is used to determine the duration of therapy and the likelihood of therapeutic response.

Prior to routine screening of blood products in the early 1990s, the primary route of transmission of the HCV was blood transfusions, when the risk was 0.02% per unit transfused. Since then, the risk has decreased significantly (0.001% per unit transfused).[13] Today, intravenous drug users utilizing contaminated paraphernalia are responsible for most HCV transmission. Other populations at risk for acquiring HCV are listed in Table 21–1. Approximately 10% of the individuals infected with HCV have no identifiable risk factors.

Pathophysiology

Hepatitis C, first known as non-A, non-B hepatitis, is a bloodborne infection that is a single-stranded RNA virus belonging to the Flaviviridae family and the Hepacivirus genus.[12] The true mechanism of hepatic injury is still in question, but it is theorized that structural and nonstructural (NS) peptides may be responsible for RNA viral replication, specifically the NS5 peptide. Currently, there are six genotypes (numbered 1 to 6) and more than 90 subtypes (genotype 1a, 1b, 2a, 3b, etc.) that are unique to hepatitis C.

Antibodies against HCV (anti-HCV) in the blood indicate infection with the HCV. If the infection persists for more than 6 months and viral replication is confirmed by HCV RNA levels, then the person has chronic hepatitis C. Chronic disease may be due to an ineffective host immune system against the HCV. Cytotoxic T lymphocytes are ineffective in eradicating the HCV, thus allowing persistent damage to hepatic cells. Therefore, immunocompromised individuals are less likely to eliminate HCV.[12]

Natural History of Hepatitis C

Only 10% to 15% of patients have acute hepatitis C that resolves without any further sequelae.[10] In more than 85% of cases, hepatitis C develops into a chronic disease. Approximately 70% of chronic HCV cases progress to mild, moderate, or severe hepatitis. While the natural history of the progression to cirrhosis is not clear, it is estimated that 10% to 20% of cases may take up to 20 to 40 years from the time of exposure to advance from fibrosis to cirrhosis.[10] Fifteen to twenty percent of patients infected with HCV develop complications associated with cirrhosis. Once cirrhosis is confirmed, the rate of developing hepatocellular carcinoma increases to 1% to 4% per year.[10] The estimated death rate from HCV infection is 1.8 deaths per 100,000 persons per year.[12,15]

HEPATITIS D

Epidemiology and Etiology

Hepatitis D affects approximately 15 million people worldwide. The highest prevalence is in southern Italy, parts of Russia, and Romania; prevalence is moderate in northern Italy, Spain, Turkey, and Egypt.[16] Southeast Asia and China have the lowest prevalence of HDV despite having the highest prevalence of HBV infections.

There are three major HDV genotypes that are geographically specific. Genotype 1a primarily affects those residing in the United States, and genotype 1b affects the Asian population. Both 1a and 1b are equally represented in the Mediterranean Basin. Individuals residing in Japan and Taiwan are mostly diagnosed with genotype 2. Patients in South America (specifically Colombia, Venezuela, and Peru) are mostly infected with genotype 3.[16]

The most likely modes of transmitting the HDV are similar to those of HBV, including intravenous drug users using unsterilized needles and recipients of contaminated blood products. Sexual and perinatal transmission are rare for HDV.[16] Individuals at greatest risk of acquiring HDV are similar to those seen in HBV (Table 21–1).

Pathophysiology

Hepatitis D (originally referred to as delta hepatitis) belongs to the genus Deltavirus of the Deltaviridae family.[16] The HDV virion is a defective single-stranded circular RNA virus that requires the presence of HBV for HDV viral replication. This is because the hepatitis D virus antigen (HDVAg) is coated by the hepatitis B surface antigen (HBsAg).

The exact mechanism of hepatic damage induced by HDV is still being investigated, but it is known that replication of HDV cannot occur without HBV being present causing either co-infection (both hepatitis B and D infection occurring simultaneously) or superinfection (acquiring HDV after having long-standing disease with HBV).[17]

HEPATITIS E

Epidemiology and Etiology

Hepatitis E is associated with more than 50% of the acute hepatitis cases in endemic areas (Afghanistan, Bangladesh, Burma, China, India, Indonesia, Kazakhstan, Kyrgyzstan, Malaysia, Mongolia, Nepal, Pakistan, Tajikistan, Turkmenistan, Uzbekistan, Mexico, the Middle East, Northern Africa, and sub-Saharan Africa). The virus is primarily transmitted by the fecal-oral route. Transmission of HEV is more prominent in underdeveloped countries where sanitation is poor.

The mortality rate in pregnant women with acute infections may reach 25%. Rarely does HEV cause endemics in industrialized countries, where the prevalence rate is 1% to 5%.[18,19]

Pathophysiology

Hepatitis E is a non-enveloped single-stranded messenger RNA virus of unclassified genus.[18] The HEV is similar to HAV in that the virus is harvested in contaminated feces, thus infecting people via the fecal-oral route. High HEV levels in the bile often prompt viral shedding in the feces. The severity of hepatic damage is dependent on the HEV strain: Mex 14, Sar 55, or the US 2 strain.[19] No cases of chronic hepatitis E have yet been documented.

CLINICAL PRESENTATION AND DIAGNOSIS

Diagnosis of Viral Hepatitis

Diagnosing viral hepatitis may be difficult because most infected individuals are asymptomatic. Because symptoms cannot identify the specific type of hepatitis, laboratory serologies must be obtained (Table 21–2). In addition, liver function tests may be obtained to assess the extent of cholestatic and hepatocellular injury. However, the definitive test to determine the amount of damage and inflammation of hepatic cells is a **liver biopsy**.

Clinical Presentation of Viral Hepatitis

Symptoms

- Most patients infected with any type of viral hepatitis have no symptoms.
- Those who have symptoms may experience any of the following: flulike symptoms, fevers, fatigue/malaise, anorexia, nausea, vomiting, diarrhea, dark urine, pale-appearing stools, pruritus, and abdominal pain.

Signs

- Jaundice may be evident in the whites of the eyes (scleral icterus) or skin.
- An enlarged liver (hepatomegaly) and spleen (splenomegaly) may be present.
- In fulminant hepatitis with hepatic encephalopathy, patients may have asterixis and coma.
- In rare instances, extrahepatic symptoms may develop: arthritis, postcervical lymphadenopathy, palmar erythema, cryoglobulinemia, and vasculitis.

Hepatitis A

The diagnosis of hepatitis A is made by detecting immunoglobulin antibody to the capsid proteins of the HAV. The presence of IgM anti-HAV in the serum indicates an acute infection. IgM appears approximately 3 weeks after exposure and becomes undetectable within 6 months. In contrast, IgG anti-HAV appears in the serum at approximately the same time IgM anti-HAV develops but indicates protection and lifelong immunity against hepatitis A.[1]

Hepatitis B

Hepatitis B is diagnosed when HBsAg is detectable in the serum. The nucleocapsid of the HBsAg contains the core protein that produces HBcAg, which is undetectable in the serum. The presence of antibodies against anti-HBc to IgM indicates active infection, and anti-HBc to IgG relates to either chronic infection or possible immunity against HBV.

Viral replication occurs when HBeAg is present. Measurement of HBV DNA is used to determine viral infectivity and assess and quantify viral replication. Once the hepatitis B infection resolves, anti-HBe and anti-HBs develop, and HBV DNA levels becomes undetectable.

Hepatitis C

Hepatitis C is diagnosed by testing for anti-HCV in the serum. The disease is confirmed by the presence of HCV RNA. HCV RNA levels quantify viral replication and are used to determine if antiviral treatment for HCV is effective.

Hepatitis D

Hepatitis D infection requires the presence of HBV for HDV viral replication. Measuring HDV RNA levels in the serum by polymerase chain reaction (PCR) confirms the presence of

TABLE 21–2. Interpretation of Viral Hepatitis Serology Panels

Type	Laboratory Test	Result	Interpretation of Panel
Hepatitis A	IgM anti-HAV IgG anti-HAV	Negative Negative	Susceptible to infection
	IgM anti-HAV	Positive	Acutely infected
	IgG anti-HAV	Positive	Immune due to either natural infection or HAV vaccine
Hepatitis B[a]	HBsAg anti-HBc anti-HBs	Negative Negative Negative	Susceptible to infection
	HBsAg anti-HBc anti-HBs	Negative Positive Positive	Immune due to natural infection
	HBsAg anti-HBc anti-HBs	Negative Negative Positive	Immune due to hepatitis B vaccination
	HBsAg anti-HBc IgM anti-HBc anti-HBs	Positive Positive Positive Negative	Acutely infected
	HBsAg anti-HBc IgM anti-HBc anti-HBs	Positive Positive Negative Negative	Chronically infected
	HBsAg anti-HBc anti-HBs	Negative Positive Negative	Four interpretations possible[b]
Hepatitis C	anti-HCV	Negative	Susceptible to infection
	anti-HCV	Positive	Acutely or chronically infected
Hepatitis D[c]	IgM anti-HDV HDVAg HBsAg HBeAg anti-HBc	Positive Positive Positive Positive Positive	Acute HBV-HDV coinfection
Hepatitis E	IgM anti-HEV IgG anti-HEV	Negative Negative	Susceptible to infection
	IgM anti-HEV	Positive	Acutely infected
	IgG anti-HEV	Positive	Immune due to natural infection

[a]Centers for Disease Control and Prevention. Hepatology. Available at: http://www.cdc.gov/ncidod/diseases/hepatitis/b/Bserology.htm. Accessed February 19, 2006.
[b](1) May be recovering from acute HBV infection; (2) May be distantly immune and test is not sensitive enough to detect very low level of anti-HBs in serum; (3) May be susceptible with a false-positive anti-HBc; (4) May be undetectable level of HBsAg present in the serum and the person is actually a carrier.
[c]Hepatitis D should be suspected in those who have HBsAg positivity. Hepatitis D may present as either coinfection where both HDV and HBV serologies appear simultaneously whereas for superinfection, HBV has been present for some time, and later HDV develops.
anti-HAV, hepatitis A antibody; anti-HBc, hepatitis B core antibody; anti-HBs, hepatitis B surface antibody; HBsAg, hepatitis B surface antigen; anti-HCV, hepatitis C antibody; anti-HDV, hepatitis D antibody; anti-HEV, hepatitis E antibody; HAV, hepatitis A virus; HBV, hepatitis B virus; HDV, hepatitis D virus; HDVAg, hepatitis D antigen; IgG, immunoglobulin G; IgM, immunoglobulin M.

HDV and is the most accurate diagnostic test. The presence of IgM antibodies to HDV Ag (IgM anti-HD) indicates active disease, and IgG anti-HD also becomes detectable if the infection does not resolve spontaneously. Unlike the antibodies developed against HAV, HDV antibodies do not confer immunity.

Hepatitis E

The diagnosis of hepatitis E is based on the presence of anti-HEV antibodies. A test for hepatitis E RNA levels is not yet available for commercial use but is used in clinical trials.

Patient Encounter, Part 1

A 41-year-old Caucasian man is required by his employer to obtain a physical exam. He has no medical complaints but does report some stress from an impending divorce and from needing to take care of his five young children.

PMH
Non-contributory

PSH
Appendectomy in 1987 at the age of 27 that required blood transfusions

FH
Mother and father alive and well

SH
Smoked cigarettes 1 pack per day × 15 years but quit 5 years ago; used illicit drugs once in the past; drinks daily for the past 30 years; has 1 tattoo on the left arm done unprofessionally; works as a mail carrier

Meds
None

ROS
Complains only of irritability and mild depression; no nausea, vomiting, diarrhea, abdominal pain, or anorexia; never had an episode of jaundice, pale stools, or tea-colored urine

PE
VS: blood pressure 128/80 mm Hg, pulse 80 beats per minute, respiratory rate 20/minutes, temperature 37.0°C (98.6°F), Wt 81 kg (178 lbs), Ht 5′9″ (175 cm)
Abd: Soft, non-tender, normal liver span; no hepatosplenomegaly, no ascites.

Labs
All within normal limits except for aspartate aminotransferase 69 IU/L (1.15 µKat/L) and alanine aminotransferase 92 IU/L (1.53 µKat/L); anti-HCV (+), genotype 2; HCV RNA 91,230 IU/mL
Liver biopsy: Mild inflammation and minimal fibrosis (grade 1, stage 1 disease) that is consistent with chronic hepatitis C

- What information is suggestive of viral hepatitis?
- What risk factors does he have for viral hepatitis?
- What additional information do you need before creating a treatment plan for this patient?

PREVENTION AND TREATMENT OF VIRAL HEPATITIS

Desired Outcomes

General outcomes for treating hepatitis are to: (1) prevent the spread of the disease; (2) prevent and treat symptoms; (3) suppress viral replication; (4) normalize hepatic aminotransferases; (5) improve histology on liver biopsy; and (6) decrease morbidity and mortality by preventing cirrhosis, hepatocellular carcinoma, and ESLD.

For hepatitis B, additional treatment goals include: (1) seroconversion or loss of HBsAg; (2) seroconversion or loss of HBeAg; and (3) achieving undetectable HBV DNA levels. Additional goals for chronic hepatitis C include: (1) achieving undetectable HCV RNA; and (2) obtaining a sustained virologic response.

General Approach

Managing viral hepatitis involves both prevention and treatment. Prevention of hepatitis A and B (and indirectly for hepatitis D) can be achieved with immune globulin or vaccines. ❷ *There is no specific pharmacologic treatment for acute viral hepatitis A, B, C, D, or E; only supportive care is available.* Individuals with mild to moderate symptoms rarely require hospitalization. Occasionally, hospitalization is required in individuals experiencing significant nausea, vomiting, diarrhea, and encephalopathy. Liver transplantation may be required in rare instances if fulminant hepatitis develops.

Patients with viral hepatitis B, C, and D may develop chronic disease leading to ESLD. Treatment is only available for chronic liver disease associated with HBV, HCV, and HDV.[20,21]

Hepatitis A Prevention

❸ *Good personal hygiene and proper disposal of sanitary waste are required to prevent the fecal-oral transmission of the HAV.*[1,4] This includes frequent handwashing with soap and water after using the bathroom and prior to eating meals. Drinking bottled water and avoiding fruits, vegetables, and raw shellfish harvested from sewage-contaminated water in areas where HAV is most endemic will also minimize the risk of becoming infected with hepatitis A.

Individuals at high risk of acquiring hepatitis A (see Table 21–1) should receive either serum immune globulin or the hepatitis A vaccine, depending on their personal circumstances, as described below.[1,5]

Immune Globulin

Immune globulin (IG) is a solution containing antibodies from sterilized pooled human plasma that provides passive immunization against various infectious diseases, including hepatitis A.[5] Immune globulin is available for either intravenous (IVIG)

or intramuscular (IGIM) administration, but only IGIM is used for prevention of hepatitis A. IGIM does not confer lifelong immunity, but it is effective in providing pre-exposure and postexposure prophylaxis against HAV.[5]

Adverse effects of IGIM are rare. There have been reports of anaphylaxis in individuals who have immunoglobulin A deficiency after receiving repeated IG administration. Therefore, these patients should not receive IGIM. IGIM is not contraindicated in pregnant or lactating women or infants requiring hepatitis A immunization. The thimerosal-free preparation should be used in infants.[1]

IGIM should be injected into a deltoid or gluteal muscle. It does not affect the immune response of inactivated vaccines, oral polio virus, or yellow fever vaccine. The administration of live vaccines [e.g., measles, mumps, rubella (MMR) vaccine] concomitantly with IGIM may decrease the immune response significantly; thus, MMR and varicella vaccine should be delayed for at least 3 and 5 months, respectively, after IGIM has been administered. Additionally, IGIM should not be given within 2 weeks of the MMR administration or within 3 weeks of the varicella vaccine to maximize the efficacy of the immunization.[1]

Pre-exposure Prophylaxis

Pre-exposure prophylaxis with IGIM is indicated for individuals at high risk of acquiring the HAV who cannot receive the hepatitis A vaccine (e.g., because of allergy to the components alum or 2-phenoxyethanol). Additionally, travelers who plan to depart for endemic areas within 2 weeks and have not yet received the hepatitis A vaccine should receive IGIM because active vaccine immunity takes several weeks to develop.

The dose of the IGIM determines the duration of coverage. A dose of 0.02 mL/kg confers immunity against hepatitis A for less than 3 months and doses of 0.06 mL/kg provide immunity up to 5 months. If protection against HAV is required beyond 5 months, then readministration of IGIM may be indicated.[1,5]

Postexposure Prophylaxis

Individuals in contact with people infected with acute HAV, including household and sexual partners, staff and children from day care facilities, and food handlers of restaurant establishments may be candidates for postexposure prophylaxis. The risk of infection may be decreased by 90% if IGIM is given within 2 weeks of being exposed to the hepatitis A virus. IGIM may still be beneficial if it is given more than 2 weeks after exposure to a known case of HAV, as it may decrease the severity of hepatic damage.[1,5]

Hepatitis A Vaccine

Persons at risk of acquiring the HAV should receive the hepatitis A vaccine when appropriate.

There is no benefit in administering the vaccine after a person has been exposed to the HAV. Two inactivated hepatitis A vaccines, Havrix and VAQTA, are available in the United States and are effective in providing active immunization. The major difference between the two vaccines is that HAVRIX contains 2-phenoxyethanol as a preservative whereas VAQTA is preservative-free.[1] Either vaccine is effective in providing active pre-exposure prophylaxis when given in two injections 6 months apart (referred to as months 0 and 6). The two vaccines are considered interchangeable, and doses are dependent on age (Table 21–3).

Efficacy is defined by measuring antibody response. For HAVRIX, levels greater than 20 mIU/mL measured with the modified enzyme immunoassay, and for VAQTA, levels greater than 10 mIU/mL measured with the modified radioimmunoassay are considered protective. After the first dose of vaccine has been administered, 94% to 100% of adults and 97% to 100% of children and adolescents develop protective antibody concentrations against the HAV. All recipients over the 2 years of age receiving the second dose at month 6 have 100% antibody coverage, therefore, postvaccination measurement of antibody response is not required.[1]

The hepatitis A vaccine may provide effective immunity for 8 years in adults and children. Additionally, kinetic models have theorized that immunity with the vaccine may be longer than 20 years, but this has not been confirmed in clinical trials.[1]

The most common adverse effects in adults include injection site reactions (e.g., tenderness, pain, and warmth), headaches within 5 days after vaccination, and fatigue. Local reactions may be minimized by using an appropriate needle length based on the person's age and size and by administering the injection intramuscularly in the deltoid muscle. Children may also have feeding disturbances. Hepatitis A vaccine given

TABLE 21–3. Recommended Intramuscular Doses of Hepatitis A Vaccines

Product	Recipient Age (Years)	Dose	Volume (mL)	No. of Doses	Schedule (Months)
VAQTA	1–18	25 units	0.5	2	0, 6–18
	Greater than or equal to 19	50 units	1	2	0, 6
Havrix	1–18	720 EL units	0.5	2	0, 6–12
	Greater than or equal to 19	1440 EL units	1	2	0, 6–12

EL units, enzyme-linked immunosorbent assay units.

during pregnancy has not been evaluated in clinical trials. Since both brands of vaccine are made from inactivated HAV, the risk of developing fetal complications should be minimal.

Hepatitis B Prevention

❹ *Individuals may minimize their risk of acquiring the hepatitis B infection by avoiding contaminated blood products or indulging in high-risk behavior such as intravenous drug use.* In addition, those who are at high risk of acquiring the HBV (Table 21–1) should be vaccinated with the hepatitis B vaccine.[8] In some cases, postexposure prophylaxis with hepatitis B immune globulin (HBIG) may be recommended to prevent the development of acute infection and complications associated with HBV.

Hepatitis B Immune Globulin

Hepatitis B immune globulin (HBIG) is a sterile solution containing antibodies prepared from pooled human plasma that has a high concentration of anti-HBs (antibodies to hepatitis B surface antigen). HBIG provides passive immunization for postexposure prophylaxis against the HBV. Similar to IGIM, HBIG should only be administered intramuscularly.

The most common side effects of HBIG include erythema at the injection site, headaches, myalgia, fatigue, urticaria, nausea, and vomiting. Serious adverse effects are rare and may include liver function test abnormalities, arthralgias, and anaphylactic reactions. HBIG should be used with caution in individuals who have experienced hypersensitivity reactions to immune globulin or those who have immunoglobulin A deficiency. Similar to IGIM, concomitant administration of HBIG and live vaccines should be avoided because the efficacy of the immunization may decrease significantly.[8]

Hepatitis B Vaccine

The two hepatitis B vaccines available in the United States are Recombivax HB and Engerix-B. These vaccines are produced with recombinant DNA technology by inserting the gene for HBsAg into the plasmid that is synthesized by *Saccharomyces cerevisiae* cells. ❺ *Both vaccines are effective in providing protection against acquiring the HBV when the immunization is given at months 0, 1, and 6.* The two non-dialysis formulations of the hepatitis B vaccines are considered interchangeable, but the same brand should be used for the entire three-dose series. Additionally, the doses depend on the person's age (Table 21–4). The difference between the two vaccines is that Engerix-B contains trace amounts of thimerosal that is not used as a preservative but is produced during the manufacturing process; Recombivax HB is completely free of thimerosal.

For optimal response, the hepatitis B vaccine should be administered intramuscularly only (into the anterolateral thigh region in neonates and infants; the deltoid region in adults) and not intravenously or intradermally. The vaccine should not be given in the gluteal region, as it may result in lower rates of immunity. In rare cases, the vaccine may be given subcutaneously in individuals at risk for hemorrhage (e.g., hemophiliacs); however, this route of administration should be used with caution, as subcutaneous nodules have developed when other similar vaccines have been used.[8]

The efficacy of the hepatitis B vaccine is established when antibody concentrations are greater than 10 mIU/mL. After completing the vaccination series given at months 0, 1, and 6, 96% of recipients obtain adequate antibody levels; for this reason, postvaccination testing is not usually recommended. However, protective antibody levels may be decreased in immunocompromised patients (e.g., human immunodeficiency virus (HIV)-positive, hemodialysis, or immunosuppressive therapy); postvaccine testing may be warranted 1 to 6 months after completing the vaccination series in these patients.[8] The duration of immunity and whether a booster dose of the hepatitis B vaccine is required are still being investigated.

The most frequent adverse effects are local reactions at the injection site (pain, tenderness, erythema, swelling, and pruritus), fevers (greater than 37.5°C or 99.5°F), headaches, dizziness, and irritability. Anaphylaxis and hypersensitivity reactions have been reported rarely and occur within a few hours after vaccine administration. In rare instances, a serum sickness–like apparent hypersensitivity syndrome (arthralgia, urticaria, ecchymoses, erythema multiforme, and erythema nodosum) has been

TABLE 21–4. Recommended Intramuscular Dosing Regimens for Hepatitis B Vaccines

Product	Patient Categories	Dose (mcg)	Volume (mL)	No. of Doses	Schedule (months)
Recombivax HB	0–19 years of age	5	0.5	3	0, 1, 6
	11–15 years of age[a]	10	1	2	1, 4–6
	Greater than or equal to 20 years of age	10	1	3	0, 1, 6
	Hemodialysis	40	1	3	0, 1, 6
Engerix-B	0–19 years of age	10	0.5	3	0, 1, 6
	Greater than or equal to 20 years of age	20	1	3	0, 1, 6
	Hemodialysis	40[b]	2	4	0, 1, 2, 6

[a]Adolescents 11 through 15 years of age may receive either the 5 mcg, 3-dose pediatric formulation or a 10 mcg, 2-dose regimen using the adult formulation.
[b]Two × 20 mcg in one or two injections.

reported days to weeks postvaccination. Hepatitis B vaccine given during pregnancy has not been evaluated in clinical trials. However, if the mother is at risk of acquiring the hepatitis B virus, then vaccination should be considered.

Hepatitis A and B Combination Vaccine

❻ *A vaccine that combines both inactivated hepatitis A and recombinant hepatitis B (Twinrix) is approved for immunizing individuals greater than 18 years of age with indications for both hepatitis A and B vaccines.*[22] A 1 mL dose of Twinrix contains the antigenic components of not less than 720 ELISA units of Havrix and 20 mcg of recombinant HBsAg protein of Engerix-B and should be administered at months 0, 1, and 6. 2-Phenoxyethanol is used as a preservative, and trace amounts of thimerosal are present due to the manufacturing process. Antibody seroconversion for hepatitis A and B was greater than 98% in adult volunteers tested 1 month after a three-dose vaccine series. The side-effect profile of Twinrix is similar to giving each vaccine separately.[23]

Postexposure Prophylaxis

HBIG and hepatitis B vaccine are indicated after exposure to the HBV to prevent chronic hepatitis B disease. The dose and immunization regimen depend on how the individual acquired the virus.[8] Adults acutely exposed to blood containing HBsAg from an accidental needlestick, sexual contacts, or intravenous drug use should be immunized based on the source of exposure and the vaccination status of the exposed person (Table 21–5). A single dose of HBIG of 0.06 mL/kg is 75% effective in preventing chronic hepatitis B infections if administered within 14 days of exposure.

Postexposure prophylaxis for perinatal exposure depends upon the mother's HBsAg status.[24] Mothers who are HBsAg-positive should have their newborns immunized with both the hepatitis B vaccine and HBIG 0.5 mL. This regimen is 85% effective in preventing the hepatitis B carrier status if administered within 24 hours of birth.[8] If the mother is HBsAg negative, the newborn should be given only the hepatitis B vaccine (Table 21–6).

Chronic Hepatitis B Treatment

Persons with confirmed chronic hepatitis B should be evaluated for treatment, which may include interferon, pegylated interferon, lamivudine, adefovir dipivoxil, or entecavir. ❼ *The drug of choice for chronic hepatitis B depends on the patient's past medical history, aminotransferase level, HBV DNA level, and most importantly, HBeAg status.*

Patients who are hepatitis B carriers (defined as having a positive HBsAg, normal alanine aminotransferase (ALT) levels, and negative HBeAg) should not be treated because hepatitis B antiviral agents rarely result in HBeAg seroconversion, and long-term treatment leads to drug resistance. Patients with elevated ALT and HBV DNA levels (regardless of the presence or absence of HBeAg) require treatment to delay progression to cirrhosis and prevent the development of ESLD. The treatment response for a patient who is positive for HBeAg is different from that of a patient who is negative for HBeAg because obtaining seroconversion is less likely to occur.

Interferon and Peyglated Interferon

Interferon alfa is an antiviral agent that is effective in suppressing hepatitis B viral replication. Interferon alfa-2b and pegylated interferon alfa-2a are the only interferon therapies approved for the treatment of chronic hepatitis B.

Interferon therapy has an advantage over other antiretroviral treatment in that it is effective in suppressing, and in some cases ceasing, viral replication without inducing resistance. Approximately one-third of HBsAg-positive patients become seronegative after 4 to 6 months of treatment.[25] The HBeAg seroconversion rate is 18% greater than those who are not treated.[25]

TABLE 21–5. Recommendations for Prophylaxis after Exposure to Hepatitis B Virus

	Treatment to Administer if Serology Test of Source Person Is:		
Exposed Person's Vaccination Status	**HBsAg Positive**	**HBsAg Negative**	**Unknown or Unavailable for Testing**
Unvaccinated	HBIG × 1 and initiate HB vaccine series	Initiate HB vaccine series	Initiate HB vaccine series
Previously vaccinated:			
Known responder	No treatment	No treatment	No treatment
Known non-responder	HBIG × 1 and initiate HB revaccination or HBIG × 2	No treatment	If known high-risk source, treat as if source were HBsAg-positive
Antibody response unknown	Test exposed person for anti-HBs: (1) if adequate, no treatment; (2) if inadequate, HBIG × 1 and vaccine booster	No treatment	Test exposed person for anti-HBs: (1) if adequate, no treatment; (2) if inadequate, vaccine booster and recheck titer in 1–2 months

HB, hepatitis B; anti-HBs, hepatitis B surface antibody; HBsAg, hepatitis B surface antigen; HBIG, hepatitis B immune globulin.

TABLE 21–6. Recommendations for Hepatitis B Prophylaxis to Prevent Perinatal Transmission

	Mother's HBsAg Status:		
Treatment	**Positive**	**Negative**	**Unknown**
HBIG[a]	Given within 12 hours of birth	None	If positive, give within 7 days; if negative, give none
AND			
Hepatitis B vaccine[b]			
Dose 1	Within 12 hours of birth	Based on infant's weight[c]	Within 12 hours of birth
Dose 2	At month 1–2	At month 1–2	At month 1–2
Dose 3	At month 6	At month 6–18	At month 6

[a]0.5 mL intramuscularly.
[b]See Table 21–4 for appropriate hepatitis B vaccine dose.
[c]Full-term infants who are medically stable and weigh greater than or equal to 2000 grams born to HBsAg-negative mothers should receive the hepatitis B vaccine before hospital discharge. Preterm infants weighing less than 2000 grams born to HBsAg-negative mothers should receive the first dose of hepatitis B vaccine 1 month after birth or at hospital discharge.
From Centers for Disease Control and Prevention. A Comprehensive Immunization Strategy to Eliminate Transmission of Hepatitis B Virus Infection in the United States. Recommendations of the Advisory Committee on Immunization Practices (ACIP) Part 1: Immunization of Infants, Children, and Adolescents. http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5416a1.htm?s_cid=rr5416a1_e. Accessed February 16, 2006.

Additionally, the durability (likelihood of developing and sustaining HBeAg seroconversion) is greater than 80% after treatment has been discontinued. If interferon treatment duration is extended to 12 to 24 weeks, HBsAg loss is observed in about 10% of patients.

Pegylated interferon is interferon that is attached to a polyethylene glycol molecule that increases the half-life of the drug, thus allowing once-weekly dosing versus thrice-weekly administration required for the unmodified formulation. Pegylated interferon is well tolerated and is superior in efficacy to unmodified interferon for the treatment of chronic hepatitis B.[26]

Patients with chronic hepatitis B who are HBeAg-negative may achieve undetectable HBV DNA levels and normalize ALT levels during treatment with any of the antiviral therapies; however, once treatment has ceased, these endpoints return to pretreatment values.[27] Patients treated with unmodified interferon have an end-of-treatment response (defined as undetectable HBV DNA and normal ALT levels) ranging from 60% to 70%; however, the rate of sustaining virologic response once therapy has been discontinued is approximately 20%.[20] Patients with HBeAg-negative chronic hepatitis B should be treated with more than 12 months of therapy.[28] When the duration of interferon therapy is prolonged beyond 12 months, undetectable HBV DNA may be sustained, as well as increasing the chance of losing HBsAg.

Factors associated with a higher likelihood of response to interferon therapy are baseline HBV DNA levels less than 200 pg/mL and ALT concentrations greater than 5 times the upper limit of normal.[29]

The subcutaneous dose of interferon alfa-2b (Intron A) in patients who are HBsAg-positive is either 5 million units daily (better tolerated) or 10 million units three times weekly. The dose for HBsAg-negative patients is 5 to 6 million units three times weekly. The approved dose for pegylated interferon alfa-2a (Pegasys) for chronic hepatitis B is 180 mcg subcutaneously once weekly. Interferon doses may need to be adjusted in patients with renal impairment.

Even though the advantages of interferon therapy include a finite duration of treatment, lack of resistance, and possible HBsAg loss or seroconversion (development of anti-HBs), there are several significant disadvantages. These include the need for subcutaneous injections, and more importantly, the pronounced adverse-effect profile that may require treatment discontinuation. The most common complaints include injection site reactions and flulike symptoms of fevers, chills, joint pain, and muscle aches. Systemic adverse effects include anorexia, nausea, diarrhea, fatigue, headache, insomnia, irritability, depression, alopecia, and dermatitis. Hematologic abnormalities are common including neutropenia, anemia, and thrombocytopenia, which require either a dose reduction or treatment discontinuation.[28,29] Uncommon side effects include cardiac arrhythmias, diabetes, thyroid disorders, amenorrhea, and vision disturbances.

Lamivudine

Lamivudine (Epivir-HBV) is an oral synthetic cytosine nucleoside analogue having antiviral effects against HIV and hepatitis B virus. In patients with chronic hepatitis B, lamivudine is effective in suppressing hepatitis B viral replication, normalizing

ALT levels, and improving liver histology.[30,31] Patients with HBeAg-positive chronic hepatitis B may have a similar or a superior response in achieving these endpoints when compared to interferon. A significant loss of serum HBV DNA level was observed in 44% of subjects receiving lamivudine compared to 16% receiving placebo. Normalization of ALT levels and improvement in histology occurred in approximately 50% of patients with HBeAg-positive hepatitis B. HBeAg loss, 18% at the end of 52 weeks of treatment, is quite similar between interferon and lamivudine. However, prolonged lamivudine therapy may be needed to sustain seroconversion, as durability of response is only 50% to 80%.[32] Extending the duration of treatment is not without consequences, as lamivudine resistance has been reported at 14% after 1 year of treatment and increases to 70% at 5 years.[29]

Compared to those treated with placebo, 60% to 70% of patients with HBeAg-negative hepatitis B treated with lamivudine for 52 weeks have undetectable HBV DNA levels and normalization of ALT levels. However, the rate of relapse is 80% to 90% once the treatment has been discontinued.[20] Lamivudine therapy beyond 12 months may be considered to sustain response, but biochemical and virologic breakthrough commonly occurs due to the development of drug resistance.[29]

The dose of lamivudine is 100 mg orally once daily for treatment of chronic hepatitis B. The dose must be adjusted in patients with renal dysfunction [creatinine clearance (CrCl) less than 50 mL/minute].

Adverse effects are minimal and include fatigue, diarrhea, nausea, vomiting, and headaches. In rare cases, pancreatitis, hepatomegaly, and potentially fatal lactic acidosis have been reported. ALT levels should be monitored carefully, especially when lamivudine has been discontinued, as an elevation may indicate a flare in disease activity that may lead to liver failure.

The advantages of lamivudine over interferon are oral administration and low drug cost with minimal adverse effects. The major disadvantage is the prolonged treatment duration required to achieve and sustain HBeAg and HBsAg seroconversion. Even so, this approach increases the drug resistance rate significantly with each additional year of treatment.

Adefovir Dipivoxil

Adefovir dipivoxil (Hepsera) is a prodrug of adefovir, an adenosine nucleotide analog that inhibits DNA polymerase. It is effective against HIV and HBV, specifically lamivudine-resistant HBV. Treatment with adefovir dipivoxil 10 mg daily is comparable to lamivudine in normalizing aminotransferase levels and improving histologic activity.[33,34] Undetectable HBV DNA levels were observed in 21% of patients treated for 48 weeks and in 56% of patients when the treatment duration was extended to 144 weeks.[33] Unlike lamivudine, extending the duration of adefovir dipivoxil therapy resulted in a relatively low resistance rate, approximately 11% after 3 years. The percentage of seroconversion and loss of HBeAg are comparable to patients who received lamivudine.[20]

Patients infected with HBeAg-negative chronic hepatitis B have a significant response while on adefovir dipivoxil, but the response is not sustained after treatment discontinuation. Serum ALT levels normalized in 72% of patients treated for 48 weeks compared to 29% who received placebo. Additionally, 51% had undetectable HBV DNA levels with adefovir dipivoxil, whereas none achieved this in the placebo arm.[20,27,32]

Resistance rates to adefovir dipivoxil are lower than with lamivudine, potentially allowing for prolonged treatment duration. At present, the longest trial with adefovir dipivoxil is 5 years with a resistance rate of 29%,[35] compared to 5 years of lamivudine therapy with a resistance rate of 70%.

The dose of adefovir dipivoxil is 10 mg once daily. The most common side effects include asthenia, abdominal pain, diarrhea, dyspepsia, headaches, nausea, and flatulence. Lactic acidosis, pancreatitis, and hepatomegaly have been reported rarely. Unlike lamivudine, adefovir dipivoxil is associated with dose-related nephrotoxicity, which was most commonly seen in HIV patients receiving doses larger than 60 mg. Therefore, the dose of adefovir dipivoxil must be adjusted in patients with renal insufficiency (CrCl less than 50 mL/minute).

Entecavir

Entecavir (Baraclude) is a guanosine nucleoside analogue that inhibits HBV DNA polymerase, thereby inhibiting DNA replication. Unlike the other two oral antiretroviral agents, entecavir has no activity against HIV and is only effective against HBeAg-positive, HBeAg-negative, and lamivudine-resistant chronic hepatitis B. In treatment-naïve patients with either HBeAg-positive or HBeAg-negative HBV, doses of 0.5 mg once daily for 52 weeks are comparable to lamivudine 100 mg daily in histologic improvement, viral load reduction, and normalization of ALT levels.

Patients who develop resistance to lamivudine have significant improvement in histology while receiving entecavir, but higher doses (1 mg daily) are required. Additionally, 19% of lamivudine-resistant patients had undetectable HBV DNA levels compared to 1% of those who continued treatment with lamivudine.[36] At present, no resistance has been associated with entecavir in patients treated for 1 year, but the data beyond 1 year of therapy are unknown. Entecavir resistance has only been seen in patients who already had lamivudine resistance.[37]

The side-effect profile for entecavir is similar to lamivudine and adefovir dipivoxil and comparable to placebo. Patients treated with entecavir should be monitored for signs and symptoms associated with lactic acidosis and severe hepatomegaly with steatosis, because some cases have been fatal. Dosage adjustments are required in patients with renal dysfunction.

Hepatitis C Prevention

The risk factors for hepatitis C and hepatitis B are quite similar; thus, the risk of acquiring the HCV is minimized by avoiding contaminated blood products and high-risk behaviors

such as sharing needles among intravenous drug users. No vaccines are available for preventing hepatitis C. However, individuals at high risk (Table 21–1) should be tested for the hepatitis C virus because the disease presents asymptomatically.

Chronic Hepatitis C Treatment

Individuals with confirmed chronic hepatitis C should be evaluated for treatment with pegylated interferon with or without ribavirin.

Interferon or Peyglated Interferon plus Ribavirin

Interferon alfa-2a (Roferon A), interferon alfa-2b (Intron-A), and interferon alfacon-1 (Infergen) are approved for chronic hepatitis C. However, they are not prescribed alone because only 12% to 16% of patients achieve a sustained virologic response (SVR). Adding ribavirin, a synthetic guanosine analogue that inhibits viral polymerase, increases the SVR rate to 35% to 45%.

Pegylated interferon alfa-2a (Pegasys) and pegylated interferon alfa-2b (PEG-Intron) are also effective FDA-approved treatments for hepatitis C.[38,39] These pegylated interferons are similar to those used to treat hepatitis B, where the interferon is attached to a polyethylene glycol molecule that extends the interferon's half-life allowing for once-weekly administration. Pegylated interferon therapy alone for 48 weeks achieves a 25% to 40% SVR, which is similar to the unmodified interferon plus ribavirin regimen. Therefore, the combination of pegylated interferon and ribavirin would be expected to have SVR rates of 45% to 55% when used for treatment of hepatitis C.[38,39]

Patient variables associated with a higher virologic response include low baseline HCV RNA levels, female gender, acquiring the infection at a later age, lower body weight, and a minimal fibrosis score on liver biopsy.[40] However, the most important pretreatment factor is the patient's genotype. Individuals with genotype 2 or 3 achieve an SVR of 75% to 85% compared to 40% to 50% for patients with genotype 1.[38,39]

Genotype also determines the duration of therapy. Those with non–genotype 1 are treated for 24 weeks and genotype 1 patients are treated for 48 weeks. Additionally, for genotype 1 patients the dose of ribavirin is weight based (less than 75 kg or 165 lbs = 1,000 mg daily; greater than or equal to 75 kg or 165 lbs = 1200 mg daily), whereas non–genotype 1 patients receive 800 mg daily regardless of weight.[41]

Adherence to therapy is another important factor in increasing and maintaining SVR. Patients who were adherent with interferon and ribavirin therapy (taking more than 80% of doses for more than 80% of the treatment duration) had an SVR of 52% whereas those who were not compliant had an SVR of 44%.[42]

At present, pegylated interferon plus ribavirin is the regimen of choice for the treatment of hepatitis C.[41] Interferon, pegylated interferon, and ribavirin have significant adverse effects, as discussed below.

Management of the Adverse Effects of Interferon, Pegylated Interferon, and Ribavirin

The type and incidence of adverse effects associated with unmodified interferon and pegylated interferon are comparable. Approximately 10% to 30% of patients receiving interferon and/or ribavirin require a dosage reduction or treatment discontinuation to minimize side effects. Patients should be screened for uncommon adverse effects and laboratory abnormalities prior to starting interferon and ribavirin because treatment may exacerbate or worsen some medical conditions.

Most patients treated with either interferon or pegylated interferon experience flulike symptoms (fevers, chills, rigors, and myalgias). These symptoms may be mild to moderate in severity and usually occur with the first injection and diminish as the treatment continues. The flulike symptoms may be minimized by premedication with acetaminophen or a nonsteroidal anti-inflammatory drug.

Psychiatric adverse effects occur frequently and may include irritability, depression, and rarely, suicidal ideation. Individuals with a history of uncontrolled psychiatric disorders must weigh the risk versus benefit of treatment, as interferon may exacerbate or worsen the psychiatric condition. Patients who develop mild to moderate symptoms may require antidepressants or anxiolytics. Those with severe symptoms including suicidal ideation should have the treatment discontinued immediately.[43]

There are several hematologic abnormalities associated with either interferon or pegylated interferon plus ribavirin therapy. Up to 35% of patients treated for hepatitis require either a dosage reduction or drug discontinuation due to either thrombocytopenia, neutropenia, or anemia.[43] With either formulation of interferon, a decrease in platelet count of about 25% to 30% usually occurs within 6 to 8 weeks after initiation of treatment. Decreasing the dose or discontinuing interferon therapy is rarely required because of significant thrombocytopenia [(defined as a platelet count less than 50,000 cells/mm^3 less than 50×10^9/L)]. However, caution is required in patients with cirrhosis because they may already have low platelet counts prior to starting treatment. At present there are no adjunctive therapies for interferon-induced thrombocytopenia. Interferon should either be reduced or discontinued if the platelet counts significantly decline or symptoms of bruising and bleeding are present.

Neutropenia associated with interferon or pegylated interferon therapy is defined as an absolute neutrophil count (ANC) of less than 1000 cells/mm^3; in rare cases, an ANC less than 500 cells/mm^3 may be observed. The neutropenia is more common and in some cases more severe with pegylated interferon than with unmodified interferon. Neutropenia usually occurs within the first 2 weeks after initiating either formulation of interferon, with the WBC count stabilizing by week four or six. The neutropenia is reversible upon discontinuing therapy. Granulocyte colony-stimulating factor has been used as an adjunctive therapy for interferon-induced neutropenia in hepatitis patients.[44]

Ribavirin causes a dose-related hemolytic anemia. Once treatment has been initiated, the hemoglobin concentration may

decrease by 2.9 to 3.7 g/dL (29 to 37 g/L or 1.8 to 2.3 mmol/L) within 4 weeks. In addition, interferon may slightly suppress bone marrow erythroprogenitor cells. Therefore, a "mixed" anemia (hemolytic anemia and bone marrow suppression occurring simultaneously) develops when both interferon and ribavirin are used. This is a reversible process with the hemoglobin level returning to baseline within 7 to 8 weeks after either drug has been discontinued.

About 10% to 25% of patients treated with interferon and ribavirin require dosage reductions when hemoglobin levels decrease or they develop intolerable symptoms such as shortness of breath or severe fatigue. If warranted, erythropoietin may be used as adjunctive therapy for ribavirin-induced hemolytic anemia.[45]

All women of childbearing age and men who are able to father a child should use two forms of contraception during ribavirin therapy and 6 months after treatment because ribavirin has been documented to cause teratogenic and embryocidal effects.

Hepatitis D Prevention and Treatment

❽ *Hepatitis D infection is possible only if the patient also has the hepatitis B virus present; therefore, hepatitis B vaccination can indirectly prevent hepatitis D infection.*

While there are no FDA-approved treatments for hepatitis D, interferon has been shown to be effective.[46–48] Various doses have been evaluated, with the most effective treatment being 9 million units three times weekly.[47] Seventy-one percent of patients who were treated with this regimen for 48 weeks had normalized ALT levels.[47] Adverse effects and monitoring parameters for interferon therapy are similar to treatment for hepatitis C. In some situations, patients infected with hepatitis D who develop hepatic decompensation and ESLD may need to undergo liver transplantation.

Hepatitis E Prevention and Treatment

Hepatitis E is similar to hepatitis A in that the mode of transmission is via the fecal-oral route. Therefore, the most effective ways to prevent acquiring the virus are good personal hygiene and proper disposal of sanitary waste. Frequent handwashing and avoiding contaminated foods and vegetables decrease the risk of infection.

Patient Encounter, Part 2

Creating a Care Plan

Based on the information presented, create a care plan for this patient's hepatitis. Your plan should include: (1) a statement of the drug-related needs and/or problems; (2) the goals of therapy; (3) a patient-specific detailed therapeutic plan; and (4) a follow-up plan to determine whether the goals have been achieved and to identify potential adverse effects of therapy.

At present, only acute cases of hepatitis E have been documented. There are no vaccines available to prevent hepatitis E; however, a recombinant hepatitis E vaccine is undergoing Phase II/III study to determine its efficacy in preventing hepatitis E infections.[49] Supportive care is the only treatment available for acute hepatitis E infection.[19]

OUTCOME EVALUATION

- Monitoring for efficacy in patients treated for chronic hepatitis B or C includes evaluating aminotransferase levels and viral loads.

Hepatitis B

- In patients with either HBeAg-positive or HBeAg-negative hepatitis B, monitor hepatitis B serologies and HBV DNA levels every 3 months to determine treatment response regardless of the therapy given.[28,32]
- At month 3, if the viral count is still positive or fails to decrease at least 1 log, the patient is deemed a treatment failure. Reevaluate the patient for a different hepatitis B antiviral agent.
- Patients are considered responders if at least a 1-log drop in viral count and normalization of ALT levels occur. Continue treatment.
- Patients are considered to have relapsed if the viral load increases during treatment. The beginnings of drug resistance may also be evidenced by increasing ALT and HBV DNA levels during treatment.

Hepatitis C

- The National Institutes of Health Consensus Development Conferences in 1997 and 2002 defined several therapeutic endpoints in the management of hepatitis C:[40]
  - Virologic response is defined as having an undetectable viral load or HCV RNA level.
  - Biochemical response is defined as normalization of aminotransferase levels, specifically ALT concentrations.
  - Histologic response is defined as improving inflammation and fibrosis as noted by pretreatment and posttreatment biopsy scores.
- Measure these outcomes at the end of treatment to determine the end-of-treatment response and at 24 weeks after treatment has been discontinued to determine SVR.
- In patients with genotype 1 HCV, check the HCV RNA level at week 12 of therapy to determine the effectiveness of treatment.[41]
- Discontinue treatment if the HCV RNA has not decreased by at least 2 logs or become undetectable.
- Continue treatment for at least another 36 weeks (48 weeks total) if the HCV RNA level becomes negative or decreases by at least 2 logs.
- At the end of the 48-week treatment, obtain an HCV RNA level to determine end-of-treatment response and repeat at 6 months post-therapy to determine SVR.

- In patients infected with non–genotype 1 HCV disease, check the HCV RNA level at the end of treatment (24 weeks). If HCV RNA is undetectable, continue treatment for another 24 weeks. Repeat the HCV RNA 24 weeks after completion of therapy to determine SVR.[41]
- Monitor patients carefully during treatment with interferon or pegylated interferon with or without ribavirin.
  - Monitor the WBC count, ANC, platelets, and hemoglobin levels either weekly or biweekly during the first month of therapy and monthly thereafter if stable.
  - Monitor serum creatinine because patients with renal insufficiency (CrCl less than 50 mL/minute) may have reduced ribavirin elimination resulting in increased drug accumulation and toxicity (e.g., hemolytic anemia).

Patient Care and Monitoring

1. Evaluate the patient for risk factors for acquiring viral hepatitis (Table 21–1).
2. Educate patients to avoid hepatotoxic agents (e.g., some dietary supplements).
3. Educate patients to avoid consuming any alcohol if viral hepatitis has been diagnosed.
4. Determine if the patient has been vaccinated against hepatitis A and B. If not, then vaccinate accordingly (Tables 21–3 and 21–4).
5. Obtain a thorough past medical history focusing on psychiatric disorders, cardiac disorders, endocrine disease, and renal insufficiency.
6. Review the liver biopsy report (if available) to determine the severity of liver damage and need for chronic hepatitis B or C treatment.
7. Assess for adverse effects in patients with hepatitis C treated with interferon or pegylated interferon with or without ribavirin.
8. Encourage medication compliance with viral hepatitis treatments to increase sustaining virologic response.
9. Encourage patients to drink at least 8 glasses of water to prevent dehydration while on hepatitis C medications.
10. Educate all women of childbearing age and men who are able to father a child to use two forms of contraception during and 6 months after ribavirin therapy.
11. Provide patient education:
    - How to prevent viral hepatitis transmission
    - Who should be vaccinated against hepatitis A and B
    - The importance of taking all medications at scheduled times
    - Adverse effects of interferon, pegylated interferon, and ribavirin therapy
    - How to self-administer interferon and pegylated interferon injections
    - The importance of appropriate disposal of used needles

22 Acute Renal Failure

Mary K. Stamatakis

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Assess a patient's kidney function based on clinical presentation, laboratory results, and urinary indices.
2. Identify pharmacotherapeutic outcomes and endpoints of therapy in a patient with acute renal failure.
3. Apply knowledge of the pathophysiology of acute renal failure to the development of a treatment plan.
4. Design a diuretic regimen that considers the pharmacokinetic and pharmacodynamic characteristics of the drug.
5. Select pharmacotherapy to treat complications associated with acute renal failure.
6. Develop strategies to minimize the occurrence of acute renal failure.
7. Monitor and evaluate the safety and efficacy of the therapeutic plan.

Key Concepts

❶ Equations to estimate creatinine clearance that incorporate a single creatinine concentration (e.g., Cockcroft-Gault) may underestimate or overestimate kidney function depending on whether acute renal failure is worsening or resolving.
❷ There is no evidence that supports drug therapy in hastening the recovery period, decreasing length of hospitalization, or improving survival in acute renal failure.
❸ Loop diuretics are the diuretics of choice for the management of volume overload in acute renal failure.
❹ Renal dose dopamine is not recommended in the prevention or treatment of acute renal failure.
❺ Identifying patients at high risk for development of acute renal failure and implementing preventive methods to decrease its occurrence or severity is critical.

Acute renal failure (ARF) is a potentially life-threatening clinical syndrome that occurs primarily in hospitalized patients and frequently complicates the course of the critically ill. It is characterized by a rapid decrease in glomerular filtration rate (GFR) and the resultant accumulation of nitrogenous waste products (e.g., creatinine and urea nitrogen), with or without a decrease in urine output. A recent consensus statement defines ARF as a 50% increase in baseline serum creatinine concentration, a 25% decrease in GFR, or a urine output of less than 0.5 mL/kg per hour for at least 6 hours.[1] It should be noted that no single serum creatinine value is a threshold for ARF.

EPIDEMIOLOGY

Between 5% and 25% of all hospitalized patients develop ARF.[2] A greater prevalence of ARF is found in critically ill patients.[3] Despite improvements in the medical care of individuals with ARF, mortality generally exceeds 50%.[4]

PATHOPHYSIOLOGY

There are typically three categories of ARF: prerenal, intrinsic, and postrenal ARF. The pathophysiologic mechanisms differ for each of the categories.

Prerenal Acute Renal Failure

Prerenal ARF is characterized by reduced blood delivery to the kidney. A common cause is intravascular volume depletion due to conditions such as hemorrhage, dehydration, or

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

gastrointestinal fluid losses. Prompt correction of volume depletion can restore renal function to normal because no structural damage to the kidney has occurred. Conditions of reduced cardiac output (e.g., congestive heart failure or myocardial infarction) and hypotension can also reduce renal blood flow, resulting in decreased glomerular perfusion and prerenal ARF. With a mild to moderate decrease in renal blood flow, intraglomerular pressure is maintained by dilation of afferent arterioles (arteries supplying blood to the glomerulus), constriction of efferent arterioles (arteries removing blood from the glomerulus), and redistribution of renal blood flow to the oxygen-sensitive renal medulla.[5] Functional ARF occurs when these adaptive mechanisms are compromised and is often caused by drugs. Nonsteroidal anti-inflammatory drugs (NSAIDs) impair prostaglandin-mediated dilation of afferent arterioles. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) inhibit angiotensin II–mediated efferent arteriole vasoconstriction. Cyclosporine and tacrolimus, especially in high doses, are potent renal vasoconstrictors. All of these agents can reduce intraglomerular pressure, with a resultant decrease in GFR. Prompt discontinuation of the offending drug can often return renal function to normal. Other causes of prerenal ARF are renovascular obstruction (e.g., renal artery stenosis), hyperviscosity syndromes (e.g., multiple myeloma), or systemic vasoconstriction (e.g., hepatorenal syndrome). Prerenal ARF occurs in approximately 10% to 25% of patients diagnosed with ARF.[6]

Intrinsic Acute Renal Failure

Intrinsic renal failure, also referred to as intrarenal ARF, is caused by diseases that can affect the integrity of the tubules, glomerulus, interstitium, or blood vessels. Damage is within the kidney; changes in kidney structure can be seen on microscopy.[7] Acute tubular necrosis (ATN) represents a pathophysiologic condition that results from toxic (aminoglycosides, contrast agents, or amphotericin B) or ischemic insult to the kidney. ATN results in necrosis of the proximal tubule epithelium and basement membrane, decreased glomerular capillary permeability, and backleak of glomerular filtrate into the venous circulation.[8] Maintenance of ATN is mediated by intrarenal vasoconstriction.[8] The most common cause of intrinsic renal failure is ATN and it accounts for approximately 50% of all cases of ARF.[6] Glomerular, interstitial, and blood vessel diseases may also lead to intrinsic ARF, but occur with a much lower incidence. Examples include glomerulonephritis, systemic lupus erythematosus, interstitial nephritis, and vasculitis. In addition, prerenal ARF can progress to intrinsic ARF if the underlying condition is not promptly corrected.[7]

Postrenal Acute Renal Failure

Postrenal ARF is due to obstruction of urinary outflow. Causes include benign prostatic hypertrophy, pelvic tumors, and precipitation of renal calculi.[7] Rapid resolution of postrenal ARF without structural damage to the kidney can occur if the underlying obstruction is corrected. Postrenal ARF accounts for less than 10% of cases of ARF.[6]

ASSESSMENT OF RENAL FUNCTION

The most common measure of overall kidney function is GFR. It is defined as the volume of plasma filtered across the glomerulus per unit time and correlates well with the filtration, secretion, reabsorption, endocrine, and metabolic functions of the kidney. In addition to aiding in the diagnosis and assessment of the severity of ARF, an accurate estimate of GFR can assist in proper dosing of drugs that undergo renal elimination. In an individual with normal kidney function, GFR ranges from approximately 90 to 120 mL/minute. Because GFR is difficult to measure directly, it is routinely estimated by determining the renal clearance of a substance that is filtered at the glomerulus and which does not undergo significant tubular reabsorption or secretion. Creatinine is an endogenous substance that is a normal by-product of muscle metabolism. Ninety percent of creatinine is eliminated by glomerular filtration; tubular secretion is responsible for the remaining 10%.

Direct measurement of creatinine clearance (CrCl) requires collection of urine over an extended time interval (usually 24 hours) with measurement of urine volume, urine creatinine concentration, and serum creatinine concentration (Table 22–1). Because kidney function can fluctuate significantly during ARF, this method may underestimate or overestimate kidney function depending on whether ARF is worsening or resolving.

Numerous equations have been developed for a quick bedside estimate of creatinine clearance or GFR. They incorporate patient-specific variables such as serum creatinine concentration, body weight, age, gender, albumin, and blood urea nitrogen (BUN) concentration. Two of the most widely used equations are the Cockcroft-Gault equation and the Modification of Diet in Renal Disease (MDRD) equation (Table 22–1).[9,10] They are generally considered acceptable in individuals whose renal function is relatively constant. ❶ *Because only a single serum creatinine concentration is factored into these equations, the calculated creatinine clearance or GFR may underestimate or overestimate kidney function depending on whether acute renal failure is worsening or resolving.*

TABLE 22–1. Equations for Estimation of Creatinine Clearance (CrCl)

Urine Collection Method

$$\text{CrCl (mL/minute)} = \frac{(\text{Ucr})(\text{V})}{(\text{Scr})(\text{T})}$$

Ucr = urine creatinine concentration, mg/dL
V = volume of urine, mL
Scr = serum creatinine concentration, mg/dL
T = time of urine collection, minute
(Note: time equals 1440 minutes for a 24-hour collection)

Cockcroft-Gault Equation for Adults[9]

$$\text{CrCl (mL/minute)} = \frac{(140 - \text{age}) \times \text{BW}}{(\text{Scr}) \times 72} \quad (\times 0.85 \text{ if women})$$

Age, in years
BW = actual body weight (kg)[a]
Scr = serum creatinine concentration, mg/dL

MDRD[10]

4-Variable Method

$$\text{GFR} = 186 \times [\text{Scr}]^{-1.154} \times [\text{age}]^{-0.203} \times [0.742 \text{ if female}] \times [1.212 \text{ if African-American}]$$

6-Variable Method

$$\text{GFR} = 170 \times [\text{Scr}]^{-0.999} \times [\text{age}]^{-0.176} \times [0.762 \text{ if female}] \times [1.180 \text{ if African-American}] \times [\text{BUN}]^{-0.170} \times [\text{albumin}]^{+0.318}$$

Jelliffe Equation for Changing Renal Function[11]

Males

$E^{SS} = \text{IBW}\ [29.3 - 0.203\ (\text{age})]$
$E^{SS}_{corr} = E^{SS}[1.035 - 0.0337\ (\text{Scr}_2)]$
$E = E^{SS}_{corr} - [4 \times \text{IBW} \times (\text{Scr}_2 - \text{Scr}_1)/\Delta t$
$\text{CrCl (mL/minute/1.73 m}^2) = E/14.4\ (\text{Scr})$

Females

$E^{SS} = \text{IBW}\ [25.1 - 0.175\ (\text{age})]$
$E^{SS}_{corr} = E^{SS}\ [1.035 - 0.0337\ (\text{Scr})]$
$E = E^{SS}_{corr} - [4\ \text{IBW}\ (\text{Scr}_2 - \text{Scr}_1]/\Delta t$
$\text{CrCl (mL/minute/1.73 m}^2) = E/14.4(\text{Scr})$

E^{SS} = steady-state creatinine excretion
Δt = time in days between measurement of Scr_1 and Scr_2
IBW = ideal body weight, kg
age = years
E^{SS}_{corr} = corrected steady-state creatinine excretion
Scr_1 = first serum creatinine concentration
Scr_2 = second serum creatinine concentration
E = creatinine excretion

MDRD, per the Modification of Diet in Renal Disease study.
[a]Often substituted with ideal body weight, or adjusted body weight when body weight is significantly greater than ideal body weight.

Several equations have been developed to assess unstable kidney function. The Jelliffe equation (Table 22–1) estimates creatinine clearance by considering the change in serum creatinine over a specified time period.[11] While it is more mathematically difficult to calculate, it better estimates creatinine clearance in patients with rapidly changing kidney function compared to an equation that only includes a single creatinine concentration.

Estimating creatinine clearance is only one part of evaluating a patient's overall kidney function. Other factors, such as symptomatology, laboratory test results, urinary indices, and results of diagnostic procedures will aid in the diagnosis and assessment of the severity of disease. By monitoring serum creatinine concentrations on a routine basis, it can be estimated whether kidney function is improving or worsening. Kidney function can also be evaluated based on urine output. Oliguria and anuria are defined as urine outputs of less than 400 mL and 50 mL over 24 hours, respectively. Patients with reduced urine output often have an increased mortality and may represent a more severe form of ARF. Non-oliguric ARF is defined as a urine output of greater than 400 mL per day. It may still represent severe ARF but may be associated with better patient outcomes.[12]

Patient Encounter, Part 1

A 73-year-old man with a history of diabetes mellitus, chronic kidney disease, gout, osteoarthritis, and hypertension is hospitalized with possible urosepsis. He recently completed a 10-day course of antibiotics and was ready for discharge when his morning labs showed an increase in BUN and serum creatinine concentration. Upon examination, he was found to have 2+ pitting edema, weight gain, nausea, elevated blood pressure, and rales on chest auscultation.

- What sign and symptoms does the patient have that may indicate ARF?
- What risk factors does he have for the development of ARF?
- What additional information do you need to fully assess this patient?

Clinical Presentation and Diagnosis

While some clinical and laboratory findings assist in the general diagnosis of ARF, others are used to differentiate between prerenal, intrinsic, and postrenal ARF. For example, patients with prerenal ARF typically demonstrate enhanced sodium reabsorption, which is reflected by a low urine sodium concentration and a low fractional excretion of sodium. Urine is typically more concentrated with prerenal ARF and there is a higher urine osmolality and urine:plasma creatinine ratio compared to intrinsic and postrenal ARF.

Signs and Symptoms of Uremia

- Peripheral edema
- Weight gain
- Nausea/vomiting/diarrhea/anorexia
- Mental status changes
- Fatigue
- Shortness of breath
- Pruritus
- Volume depletion (prerenal ARF)
- Weight loss (prerenal ARF)
- Anuria alternating with polyuria (postrenal ARF)
- Colicky abdominal pain radiating from flank to groin (postrenal ARF)

Physical Examination Findings

- Hypertension
- Jugular venous distention
- Pulmonary edema
- Rales
- Asterixis
- Pericardial or pleural friction rub
- Hypotension/orthostatic hypotension (prerenal ARF)
- Rash (acute interstitial nephritis)
- Bladder distention (postrenal bladder outlet obstruction)
- Prostatic enlargement (postrenal ARF)

Laboratory Tests

- Elevated serum creatinine concentration (normal range approximately 0.6 to 1.2 mg/dL [53 to 106 µmol/L])
- Elevated BUN concentration (normal range approximately 8 to 25 mg/dL [2.9 to 8.9 mmol/L])
- Decreased creatinine clearance (normal 90 to 120 mL/minute)
- BUN:creatinine ratio (elevated in prerenal ARF)
  Greater than 20:1 (prerenal ARF)
  Less than 20:1 (intrinsic or postrenal ARF)
- Hyperkalemia
- Metabolic acidosis

Urinalysis

- Sediment
  Scant or bland (prerenal or postrenal ARF)
  Brown, muddy granular casts (highly indicative of ATN)
  Proteinuria (glomerulonephritis or allergic interstitial nephritis)
  Eosinophiluria (acute interstitial nephritis)
  Hematuria/red blood cell casts (glomerular disease or bleeding in urinary tract)
  White blood cells or casts (acute interstitial nephritis or severe pyelonephritis)

Urinary Indices

	Prerenal ARF	Intrinsic and Postrenal ARF
Urine osmolality (concentration of solutes in the urine)	Greater than 500 mOsm	Less than 350 mOsm
Urine sodium concentration (mEq/L)	Less than 20	Greater than 40
Fractional excretion of sodium (FENa)	Less than 1%	Greater than 1%
Specific gravity	Greater than 1.020	Less than 1.015
Urine:plasma creatinine ratio	Greater than 40:1	Less than 20:1

Loop diuretics such as furosemide enhance sodium excretion and increase FENa, confounding the interpretation of the test.

Common Diagnostic Procedures

- Urinary catheterization (insertion of a catheter into a patient's bladder; an increase in urine output may occur with postrenal obstruction)
- Renal ultrasound (uses sound waves to assess size, position, and abnormalities of the kidney; dilatation of the urinary tract can be seen with postrenal ARF)
- Renal angiography (administration of intravenous contrast dye to assess the vasculature of the kidney)
- Retrograde pyelography (injection of contrast dye into the ureters to assess the kidney and collection system)
- Kidney biopsy (collection of a tissue sample of the kidney for the purpose of microscopic evaluation; may aid in the diagnosis of glomerular and interstitial diseases)

TREATMENT

Desired Outcomes and Goals

A primary goal of therapy is ameliorating any identifiable underlying causes of ARF such as hypovolemia, nephrotoxic drug administration, or ureter obstruction. Prerenal and postrenal ARF can be reversed if the underlying problem is promptly identified and corrected, while treatment of intrinsic renal failure is more supportive in nature. ❷ *There is no evidence that drug therapy hastens patient recovery in ARF, decreases length of hospitalization, or improves survival.*[13] Therefore, options are limited to supportive therapy, such as fluid, electrolyte, and nutritional support, renal replacement

Patient Encounter, Part 2: The Medical History, Physical Examination, and Laboratory Tests

PMH
- Type 1 diabetes mellitus since the age of 32
- Chronic kidney disease (BUN and serum creatinine were 30 mg/dL [10.7 mmol/L] and 2.5 mg/dL [221 µmol/L], respectively, on admission)
- Hypertension
- Gout
- Osteoarthritis

FH
Father with a history of type 2 diabetes mellitus, hypertension, and stage 5 chronic kidney disease; he died from a myocardial infarction at age 68; mother with a history of hypertension; she died from injuries sustained in a motor vehicle accident at the age of 52

SH
Retired coal miner; no smoking, occasional alcohol use

Hospital Meds
Gentamicin 120 mg intravenous piggyback every 12 hours (dose discontinued after 3 days)
Gentamicin 120 mg intravenous piggyback every 24 hours (days 4 through 10, discontinued this morning)
Ampicillin 2 g intravenous piggyback every 8 hours (10-day course, discontinued this morning)
Sliding scale insulin
Allopurinol 100 mg orally daily
Ranitidine 150 mg orally every 12 hours
Atenolol 50 mg orally daily
Enalapril 2.5 mg orally daily

Home Meds
NPH insulin 20 units in the morning and 10 units in the evening
Regular insulin 10 units in the morning and 10 units in the evening
Allopurinol 100 mg orally daily
Naproxen 275 mg orally every 12 hours
Atenolol 50 mg orally daily

ROS
(–) fever or chills, (+) N, (–) V/D

PE
VS: blood pressure 154/95 mm Hg, pulse 80 beats per minute, respiratory rate 26/minute, temperature 37.7°C, current wt 79 kg (admission wt 75 kg), ht 5'10" (178 cm)
Chest: Basilar crackles, inspiratory wheezes
CV: S_1, S_2 normal, no S_3
MS/Exts: 2+ pedal edema

Urinalysis
Color, yellow; character, hazy; glucose (–); ketones (–); specific gravity 1.020; pH 5.0; (+) protein; coarse granular casts, 5 to 10/low-powered field; white blood cell (WBC) count, 5 to 10/high-powered field; red blood cell (RBC) count, 2 to 5/high-powered field; no bacteria; nitrite (–); blood small; osmolality 325 mOsm; urinary sodium 77 mEq/L (77 mmol/L); creatinine 63 mg/dL (5569 µmol/L)

Day 3 Labs

Gentamicin concentrations
3.4 mcg/mL (7.12 µmol/L) = trough concentration drawn immediately prior to the next dose
6.4 mcg/mL (13.38 µmol/L) = peak concentration drawn 1 hour after the end of the infusion
Urine (+) *Enterococcus* spp.

- Given this additional information, what is your assessment of the patient's condition?
- Identify your treatment goals for the patient.

therapy (RRT), and treatment of non-renal complications such as sepsis and gastrointestinal bleeding while regeneration of the renal epithelium occurs. In addition, prevention of adverse drug reactions by discontinuing nephrotoxic drugs or adjustment of drug dosages based on the patient's renal function is desired.

Pharmacologic Therapy

Loop Diuretics

There is significant controversy over the role of loop diuretics in the treatment of ARF. Theoretical benefits in hastening recovery of renal function include decreased metabolic oxygen requirements of the kidney, increased resistance to ischemia, increased urine flow rates that reduce intraluminal obstruction and filtrate backleak, and renal vasodilation.[6] Theoretically, these effects could lead to increased urine output, decreased need for dialysis, improved renal recovery, and ultimately, increased survival. However, there are conflicting reports in the literature over the efficacy of loop diuretics. Most studies demonstrate an improvement in urine output, but with no effect on survival or need for dialysis. There are some reports that loop diuretics may worsen renal function.[14] This may be due in part to excessive preload reduction that results in renal vasoconstriction. Thus, loop diuretics are limited to instances of volume overload and edema and are not intended to hasten renal recovery or improve survival.

Loop diuretics (furosemide, bumetanide, torsemide, and ethacrynic acid) are all equally effective when given in equivalent doses. Therefore, selection is based on the side-effect profile, cost, and pharmacokinetics of the agents. The incidence of ototoxicity is significantly higher with ethacrynic acid compared to the other loop diuretics; therefore, its use is limited to patients who are allergic to the sulfa component in the other loop diuretics.[15] While ototoxicity is a well-established side effect of furosemide, its incidence is greater when administered by the intravenous route at a rate exceeding 4 mg per minute.[16] Torsemide has not been reported to cause ototoxicity.

There are several pharmacokinetic differences between loop diuretics. Fifty to sixty percent of a dose of furosemide is excreted unchanged by the kidney with the remainder undergoing glucuronide conjugation in the kidney.[17] In contrast, liver metabolism accounts for 50% and 80% of the elimination of bumetanide and torsemide, respectively.[17] Thus, patients with ARF may have a prolonged half-life of furosemide. The bioavailability of both torsemide and bumetanide is higher than for furosemide. The intravenous (IV):oral ratio for bumetanide and torsemide is 1:1, bioavailability of oral furosemide is approximately 50%, with a reported range of 10% to 100%.[18]

Furosemide and bumetanide are both available in generic formulations and are generally less expensive than torsemide.

The pharmacodynamic characteristics of loop diuretics are similar when equivalent doses are administered. Because loop diuretics exert their effect from the luminal side of the nephron, urinary excretion correlates with diuretic response. Substances that interfere with the organic acid pathway, such as endogenous organic acids which accumulate in renal disease, competitively inhibit secretion of loop diuretics. Therefore, large doses of loop diuretics may be required to ensure that adequate drug reaches the nephron lumen. In addition, loop diuretics have a ceiling effect where maximal natriuresis occurs. Thus, very large doses of furosemide (e.g., 1 g) are generally not considered necessary and may unnecessarily increase the risk of ototoxicity.[16]

Several adaptive mechanisms by the kidney limit effectiveness of loop diuretic therapy. Postdiuretic sodium retention occurs as the concentration of diuretic in the loop of Henle decreases. This effect can be minimized by decreasing the dosage interval (i.e., dosing more frequently) or by administering a continuous infusion. Continuous infusion loop diuretics may be easier to titrate than bolus dosing, requires less nursing administration time, and may lead to fewer adverse reactions.

Prolonged administration of loop diuretics can lead to a second type of diuretic resistance. Enhanced delivery of sodium to the distal tubule can result in hypertrophy of distal convoluted cells.[17] Subsequently, increased sodium chloride absorption occurs in the distal tubule which diminishes the effect of the loop diuretic on sodium excretion. Addition of a distal convoluted tubule diuretic, such as metolazone or hydrochlorothiazide, to a loop diuretic can result in a synergistic increase in urine output. There are no data to support the efficacy of one distal convoluted tubule diuretic over another. The common practice of administering the distal convoluted tubule diuretic 30 to 60 minutes prior to the loop diuretic has not been studied, although this practice may first inhibit sodium reabsorption at the distal convoluted tubule before it is inundated with sodium from the loop of Henle.

A usual starting dose of IV furosemide for the treatment of ARF is 40 mg (Fig. 22–1). Reasonable starting doses for bumetanide and torsemide are 1 mg and 20 mg, respectively.[17] Efficacy of diuretic administration can be determined by comparison of a patient's hourly fluid balance. Other methods to minimize volume overload, such as fluid restriction and concentration of IV medications, should be initiated as needed. If urine output does not increase to about 1 mL/kg per hour, the dosage can be increased to a maximum of 160 to 200 mg of furosemide or its equivalent (Fig. 22–1).[18] Other methods to improve diuresis can be initiated sequentially, such as: (1) shortening the dosage interval; (2) adding hydrochlorothiazide or metolazone; and (3) switching to a continuous infusion loop diuretic. A loading dose should be administered prior to both initiating a continuous infusion and increasing the infusion rate.[17] When high doses of loop diuretics are administered, especially in combination with distal convoluted tubule diuretics, the hemodynamic and fluid status of the patient should be monitored every shift, and the electrolyte status of the patient should be monitored at least daily to prevent profound diuresis and electrolyte abnormalities, such as hypokalemia. Patients will not benefit from switching from one loop diuretic to another because of the similarity in mechanisms of action.

Thiazide diuretics, when used as single agents, are generally not effective for fluid removal when creatinine clearance is less than 30 mL/minute. Mannitol is also not recommended for the treatment of volume overload associated with ARF. Mannitol is removed by the body by glomerular filtration. In patients with renal dysfunction, mannitol excretion is decreased, resulting in expanded blood volume and hyperosmolality.[18] Potassium-sparing diuretics, which inhibit sodium reabsorption in the distal nephron and collecting duct, are not sufficiently effective in removing fluid. In addition, they increase the risk of hyperkalemia in patients already at risk. ❸ *Thus, loop diuretics are the diuretics of choice for the management of volume overload in ARF.*

Dopamine

Low-dose dopamine, in doses ranging from 0.5 to 3 mcg/kg per minute, predominantly stimulates dopamine-1 receptors, leading to renal vascular vasodilation and increased renal blood flow. While this effect has been substantiated in healthy, euvolemic individuals with normal kidney function, a lack of efficacy data exists in patients with ARF. Although there are more than 50 published reports evaluating the efficacy of low-dose dopamine in the treatment of ARF, numerous flaws in their study design limit their applicability to clinical practice. Most of the studies were retrospective, and lacked randomization, blinding, and inclusion of a control group. Lack of concise endpoints, insufficient power to detect a significant difference, and concurrent treatment with drugs that can affect study endpoints makes interpretation of the results difficult.

The most comprehensive study evaluating the efficacy of low-dose dopamine to date is the Australian and New Zealand Intensive Care Society (ANZICS) Clinical Trials Group study.[19] Low-dose dopamine was compared to placebo in critically ill

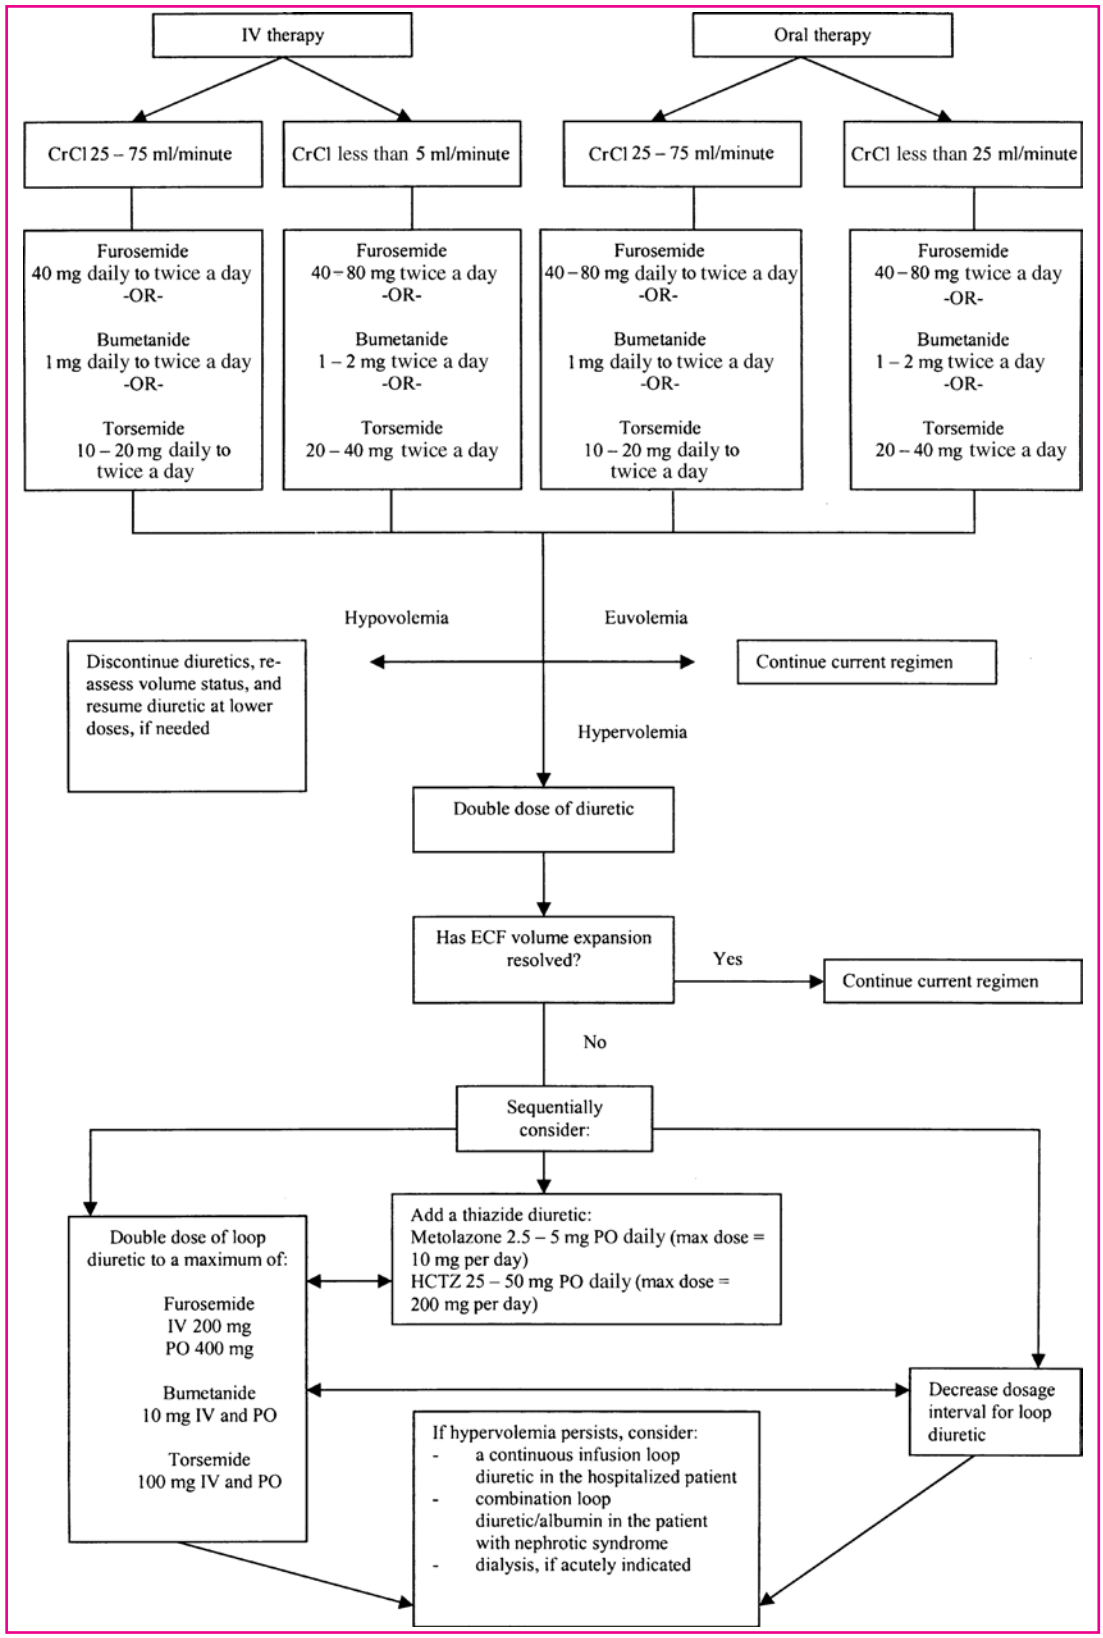

FIGURE 22–1. Algorithm for treatment of extracellular fluid expansion. CrCl, creatinine clearance; ECF, extracellular fluid; HCTZ, hydrochlorothiazide; IV, intravenous; PO, oral.

patients with at least one indicator of early renal failure and two indicators of the systemic inflammatory response. Results indicate that administration of low-dose dopamine compared to placebo did not alter peak serum creatinine concentration or secondary outcome endpoints such as need for renal replacement therapy (RRT), duration of stay in the intensive care unit (ICU), or survival to hospital discharge. Use of loop diuretics was similar between groups and may have been responsible for the increase in urine output demonstrated in the study. More than half of the patients in the study were non-oliguric. Therefore, the results cannot be directly extrapolated to the oliguric or anuric patient.

A recent meta-analysis was performed on all published human trials that used low-dose dopamine in the prevention or treatment of ARF.[20] A total of 61 studies were identified that randomized more than 3300 patients to low-dose dopamine or placebo. Results reveal no significant difference between the treatment and control groups for mortality, requirement for RRT, or adverse effects.

Low-dose dopamine is not without adverse reactions and most studies have failed to evaluate its potential toxicities. Adverse reactions that may be associated with low-dose dopamine include: tachycardia, arrhythmias, myocardial ischemia, depressed respiratory drive, and gut ischemia. Low-dose dopamine has also been postulated to impair resistance to infection through a reduction in prolactin concentrations.[21] Furthermore, significant overlap in receptor activation occurs. Therefore, doses considered to activate only dopamine receptors may increase cardiac output and blood pressure through dopamine's effect on β- or α-adrenergic receptors.

Based on the results of the ANZICS trial, the lack of conclusive evidence in many earlier studies, and several meta-analyses, routine use of low-dose dopamine solely for increasing renal blood flow is not recommended. ❹ *While recent surveys continue to show that low-dose dopamine is used in many ICUs, benefits of low-dose dopamine in the prevention or treatment of ARF remain unproven.*

Fenoldopam

Fenoldopam is a selective dopamine-1 receptor agonist that is approved for short-term management of severe hypertension. Because it does not stimulate dopamine-2, α-adrenergic, and β-adrenergic receptors, fenoldopam causes vasodilation in the renal vasculature with potentially fewer non-renal effects than dopamine. In normotensive individuals with normal kidney function, intravenous fenoldopam increases renal blood flow without lowering systemic blood pressure.[22] While preliminary studies in animal models of ARF are encouraging, few studies are available assessing its effectiveness in the treatment of ARF. A prospective randomized study comparing fenoldopam to placebo in early ATN did not find a difference in need for dialysis or mortality.[23] However, in two separate subset analyses, patients with ATN after cardiothoracic surgery and patients without diabetes mellitus demonstrated a decreased incidence of death or dialysis in the fenoldopam-treated group. Large, prospective trials are needed before fenoldopam can be recommended. Other agents that are under evaluation for the treatment of ARF include atrial natriuretic peptide, urodilatin, and nesiritide.

Nonpharmacologic Treatment

Renal Replacement Therapy

RRT may be necessary in patients with established ARF to treat volume overload that is unresponsive to diuretics, to minimize the accumulation of nitrogenous waste products, and to correct electrolyte and acid-base abnormalities while renal function recovers. Five to thirty percent of patients with ARF treated with dialysis will not have recovery of their renal function and will need to remain on long-term dialysis.[24] This may be due in part to underlying illnesses, as ARF is often seen in the setting of multiorgan failure. There are two types of dialysis modalities commonly used in ARF: intermittent hemodialysis (IHD) and continuous renal replacement therapy (CRRT). CRRT is a pump-driven form of dialysis which provides slow fluid and solute removal on a continuous, 24-hour basis. IHD is a higher-efficiency form of dialysis which is provided for several hours a day at a variable frequency (usually daily or 3 to 5 times per week) at a higher blood flow rate. The primary advantage of CRRT is hemodynamic stability and better volume control, particularly in patients who are unable to tolerate rapid fluid removal. The primary disadvantages associated with CRRT are continuous nursing requirements, continuous anticoagulation, frequent clotting of the dialyzer, patient immobility, and increased cost. There is no conclusive evidence that one type of dialysis is preferred to another in terms of mortality and recovery of renal function.[25] Thus, selection of CRRT over IHD is often governed by the critical illness of the patient and by the comfort level of the institution with one particular type of dialysis.

With either type of dialysis, studies suggest that recovery of renal function is decreased in ARF patients who undergo dialysis compared with those not requiring dialysis. Decreased recovery of renal function may be due to hemodialysis-induced hypotension causing additional ischemic injury to the kidney. Also, exposure of a patient's blood to bioincompatible dialysis membranes (cuprophane or cellulose acetate) results in complement and leukocyte activation which can lead to neutrophil infiltration into the kidney and release of vasoconstrictive substances that can prolong renal dysfunction.[26] Synthetic membranes composed of substances such as polysulfone, polyacrylonitrile, and polymethylmethacrylate are considered to be more biocompatible and would be less likely to activate complement. Synthetic membranes are generally more expensive than cellulose-based membranes. Several recent meta-analyses found no difference in mortality between biocompatible and bioincompatible membranes. Whether biocompatible membranes lead to better patient outcomes continues to be debated.

Patient Encounter, Part 3

Creating a Care Plan
Based on the information presented, create a care plan for this patient's ARF. Your plan should include: (1) a statement of the drug-related need and/or problems, (2) the goals of therapy, (3) a detailed patient-specific therapeutic plan, and (4) a plan for follow-up to determine whether the goals have been achieved and adverse effects avoided.

Supportive Therapy

Supportive therapy in ARF includes adequate nutrition, correction of electrolyte and acid-base abnormalities (particularly hyperkalemia and metabolic acidosis), fluid management, and correction of any hematologic abnormalities. Because ARF is often associated with multiorgan failure, treatment includes the medical management of infections, cardiovascular and gastrointestinal conditions, and respiratory failure. Finally, all drugs should be reviewed, and dosage adjustments made based on an estimate of the patient's glomerular filtration rate.

PREVENTION OF ACUTE RENAL FAILURE

Avoidance

The best preventive measure for ARF, especially in individuals at high risk, is to avoid medications that are known to precipitate ARF. Nephrotoxicity is a significant side effect of aminoglycosides, angiotensin-converting enzyme inhibitors, angiotensin receptor antagonists, amphotericin B, nonsteroidal anti-inflammatory drugs, cyclosporine, tacrolimus, and radiographic contrast agents.[6] Unfortunately, an effective, non-nephrotoxic alternative may not always be appropriate for a given patient and the risks and benefits of selecting a drug with nephrotoxic potential must be considered. For example, serious gram-negative infections may require double antibiotic coverage, and based on culture and sensitivity reports, aminoglycoside therapy may be necessary. In cases such as this, other measures to reduce the risk of ARF should be instituted. ❺ *Thus, identifying patients at high risk for development of ARF and implementing preventive methods to decrease its occurrence or severity is critical.*

Drug-Induced Acute Renal Failure

Aminoglycosides

Treatment with aminoglycosides (gentamicin, tobramycin, and amikacin) can cause non-oliguric intrinsic ARF. Injury is due to the binding of aminoglycosides to proximal tubular cells, and subsequent cellular uptake and cell death.[27] In clinical practice, all of the aminoglycosides are considered equally nephrotoxic, and the same precautions should be used for all the agents. High cumulative drug exposure increases the incidence of aminoglycoside-induced ARF. A prolonged course of aminoglycoside therapy (typically longer than 7 to 10 days) is a risk factor for the development of ARF, especially in those with preexisting chronic kidney disease and in the elderly.[28] Alternative antibiotics should be selected when culture and sensitivity reports are available. Methods to minimize drug exposure include maintaining trough concentrations less than 2 mcg/mL for gentamicin and tobramycin (less than 10 mcg/mL for amikacin), minimizing length of therapy, avoiding repeated courses of aminoglycosides, and utilizing extended-interval dosing methods.[29] There is conflicting evidence as to whether the combination of vancomycin and an aminoglycoside has a higher incidence of ARF than aminoglycoside therapy alone. ARF due to aminoglycosides can be mild if the drug is discontinued, although severe ARF requiring dialysis can occur.

The goal of extended-interval dosing is to provide greater efficacy against the microorganism with a lower incidence of toxicity. Because aminoglycosides demonstrate concentration-dependent killing and a post-antibiotic effect, extended-interval dosing of antibiotics can be efficacious in the treatment of most conditions. Extended-interval aminoglycoside dosing may reduce the incidence of nephrotoxicity by providing high concentrations of drug which saturate proximal tubule uptake sites. Once saturated, the remaining aminoglycoside molecules pass through the proximal tubule and are excreted in the urine with less tubular accumulation. A primary concern with extended-interval dosing is the risk of ototoxicity that can occur with high aminoglycoside concentrations. However, a consistent finding in studies is that extended-interval aminoglycoside dosing is as effective as traditional dosing and is not more toxic, and in some studies is less toxic than traditional dosing. Extended-interval dosing is not recommended in patients with preexisting renal dysfunction, conditions where high concentrations are not needed (e.g., urinary tract infections), hyperdynamic patients that may demonstrate increased drug clearance (e.g., burn patients), and others where you would suspect altered pharmacokinetics or increased risk of ototoxicity.

Amphotericin B

Amphotericin B–induced ARF occurs in as many as 40% to 65% of patients treated with the conventional desoxycholate formulation.[30] Nephrotoxicity is due to renal arterial vasoconstriction and distal renal tubule cell damage. Risk factors include high doses, treatment for at least 7 days, preexisting kidney dysfunction, and concomitant use of other nephrotoxic drugs.[31] Three lipid-based formulations of amphotericin B have been developed in an attempt to decrease the incidence of ARF: amphotericin B lipid complex, amphotericin colloidal dispersion, and liposomal amphotericin B. The range of

nephrotoxicity reported is 15% to 25% for these formulations. The mechanism for decreased nephrotoxicity has not been completely elucidated, but it is thought to be due to preferential release of amphotericin B from macrophages at the site of infection, with less of an affinity for the kidney.[30] Whether there are significant differences in nephrotoxicity between the three lipid-based formulations remains unclear, as there have been no head-to-head comparisons of the three agents in humans. In one prospective, randomized study, the incidence of nephrotoxicity was lower with liposomal amphotericin B (14%) compared to amphotericin B lipid complex (42%) in febrile, neutropenic patients.[32] Therefore, large, prospective studies comparing the incidence of nephrotoxicity between these agents are needed. Lipid-based formulations are recommended in individuals with risk factors for development of ARF. In addition, use of alternative antifungal agents should be considered in the presence of worsening renal function. Administration of intravenous normal saline may also attenuate nephrotoxicity associated with amphotericin B.

Radiocontrast Agents

Intravascular radiographic contrast agents are administered during radiologic studies and carry with them the well-documented risk of ARF. Patients at risk for developing ARF include patients with chronic kidney disease, diabetic nephropathy, dehydration, and higher dose of contrast dye.[33] Contrast agents are water-soluble, triiodinated, benzoic acid salts that cause an osmotic diuresis due to their osmolality, which exceeds that of plasma. The mechanism of nephrotoxicity is not fully understood; however, direct tubular toxicity, renal ischemia, and tubular obstruction have been implicated.[34] Diatrizoate and iothalamate are ionic contrast agents. Iohexol, iopamidol, ioversol, and iopromide represent non-ionic agents. The incidence of nephrotoxicity with ionic and non-ionic agents is similar in patients at low risk for developing ARF; however, in high-risk patients, nephrotoxicity is significantly greater when ionic contrast agents are used. In diabetic patients with chronic kidney disease and a serum creatinine concentration of greater than 1.5 mg/dL, nephrotoxicity occurred in 33.3% and 47.7% of patients receiving non-ionic and ionic contrast agents, respectively.[35] The cost of non-ionic agents is approximately 10-fold higher, which may limit their routine use in all patients undergoing radiographic studies.

Therapeutic measures that have been used to decrease the incidence of contrast-induced nephropathy include extracellular volume expansion, minimization of the amount of contrast administered, and treatment with oral acetylcysteine. Theophylline, fenoldopam, loop diuretics, mannitol, dopamine, and calcium antagonists have no effect or may worsen ARF.

The most common therapeutic maneuver to decrease the incidence of contrast-induced nephropathy is extracellular volume expansion.[36] Several recent studies have compared the efficacy of isotonic sodium chloride (0.9%) to half normal saline (0.45%) or to oral hydration.[37,38] Isotonic fluid appears to provide the best benefit for prevention of nephropathy. A common regimen is intravenous isotonic sodium chloride (1 mL per kilogram of body weight per hour) administered for 12 hours before and 12 hours after the procedure. Fluid should be administered cautiously to patients with congestive heart failure (CHF), left ventricular dysfunction, and significant renal dysfunction. Early evidence suggests that hydration plus sodium bicarbonate to alkalize renal tubule fluid may reduce free radical formation. More studies are needed before bicarbonate can be recommended.

Minimizing the quantity of contrast media administered may be beneficial in preventing nephropathy. Some studies, but not all, have directly associated dose of contrast media and nephrotoxicity. Avoidance of contrast dye with alternative diagnostic procedures should be considered in high-risk patients, but may not always be feasible. In addition, avoidance of multiple contrast studies in a short time period will allow renal function to return to normal between procedures.

Because production of reactive oxygen species have been implicated in the pathophysiology of contrast-induced ARF, prophylactic administration of the antioxidant acetylcysteine has been investigated. A dose of 600 mg twice daily the day before and the day of the procedure decreased the incidence of renal failure in one small study, although patient outcomes such as mortality and length of hospitalization were not evaluated.[39] Since then, approximately eight additional studies evaluating the efficacy of oral acetylcysteine have been conducted, with mixed results. In addition, a series of meta-analyses have also analyzed the results of the studies. The studies were varied in terms of study population, sample size, definition of contrast nephropathy, type of contrast agent used, hydration, and formulation of acetylcysteine administered, thus making collective interpretation of the results difficult. Although data are not conclusive, they suggest a beneficial effect of oral acetylcysteine in combination with adequate hydration.

Fenoldopam does not decrease the incidence of contrast nephropathy.[40] Due to its hypotensive effect, it may worsen kidney function.

Cyclosporine and Tacrolimus

Cyclosporine and tacrolimus are calcineurin inhibitors that are administered as part of immunosuppressive regimens in kidney, liver, heart, lung, and bone marrow transplant recipients. In addition, they are used in autoimmune disorders such as psoriasis and multiple sclerosis. The pathophysiologic mechanism for ARF is renal vascular vasoconstriction.[41] It often occurs within the first 6 to 12 months of treatment, and can be reversible with dose reduction or drug discontinuation. Risk factors include high dose, elevated trough blood concentrations, increased age, and concomitant therapy with other nephrotoxic drugs.[41] Cyclosporine and tacrolimus are extensively metabolized by

the liver through the cytochrome P-450 (CYP)3A4 pathway and drugs that inhibit their metabolism (e.g., erythromycin, clarithromycin, fluconazole, ketoconazole, verapamil, diltiazem, and nicardipine) can precipitate ARF. Because ARF is dose dependent, careful monitoring of cyclosporine or tacrolimus trough concentrations can minimize its occurrence; however, ARF can develop with normal or low blood concentrations. In addition, there is some evidence that calcium channel blockers have a renoprotective effect through dilation of the afferent arterioles and are often used preferentially as antihypertensive agents in kidney transplant recipients.

It is often difficult to differentiate ARF from acute rejection in the kidney transplant recipient, as both conditions may present with similar symptoms and physical examination findings. However, fever and graft tenderness are more likely to occur with rejection while neurotoxicity is more likely to occur with cyclosporine or tacrolimus toxicity. Kidney biopsy is often needed to confirm the diagnosis of rejection.[42]

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

In instances of decreased renal blood flow, production of angiotensin II increases, resulting in efferent arteriole vasoconstriction and maintenance of glomerular capillary pressure and GFR (Fig. 22–2). In patients initiated on ACE inhibitors or ARBs, angiotensin II synthesis decreases thereby dilating efferent arterioles and decreasing glomerular capillary pressure and GFR. Risk factors for developing ARF are preexisting renal dysfunction, severe atherosclerotic renal artery stenosis, volume depletion, and severe CHF.[43] ARF often develops within days, with a rapid rise in BUN and serum creatinine concentration. Discontinuation of the drug usually results in return of renal function to baseline, although a small decrease in kidney function may be acceptable in patients with severe CHF who would benefit from the hemodynamic effect of ACE inhibitors or ARBs.

Patient Encounter, Self-Study Questions

1. What would have been an appropriate gentamicin dosage regimen that would have avoided elevated plasma concentrations?
2. Based on the patient's renal function, would other drug therapy recommendations be warranted at this time?

Non-steroidal Anti-Inflammatory Drugs

Non-steroidal anti-inflammatory agents can likewise cause prerenal ARF through inhibition of prostaglandin-mediated renal vasodilation. Risk factors are similar to those of ACE inhibitors and ARBs. Additional risk factors include hepatic disease with ascites, systemic lupus erythematosus, and advanced age. The onset is often within days of initiating therapy and patients typically present with oliguria. It is usually reversible with drug discontinuation. Agents that preferentially inhibit cyclooxygenase-2 pose a similar risk as traditional, non-selective NSAIDs.[44]

Other Drugs

Other drugs that are commonly implicated in causing ARF include acyclovir, adefovir, carboplatin, cidofovir, cisplatin, foscarnet, ganciclovir, indinavir, methotrexate, pentamidine, ritonavir, sulfinpyrazone, and tenofovir.[45]

OUTCOME EVALUATION

Goals of therapy are to maintain a state of euvolemia with good urine output (at least 1 ml/kg per hour), to return serum creatinine and BUN to baseline, and to correct electrolyte and acid-base abnormalities. Vital signs, weight, fluid intake, urine output, BUN, creatinine, and electrolytes should be assessed daily in the unstable patient.

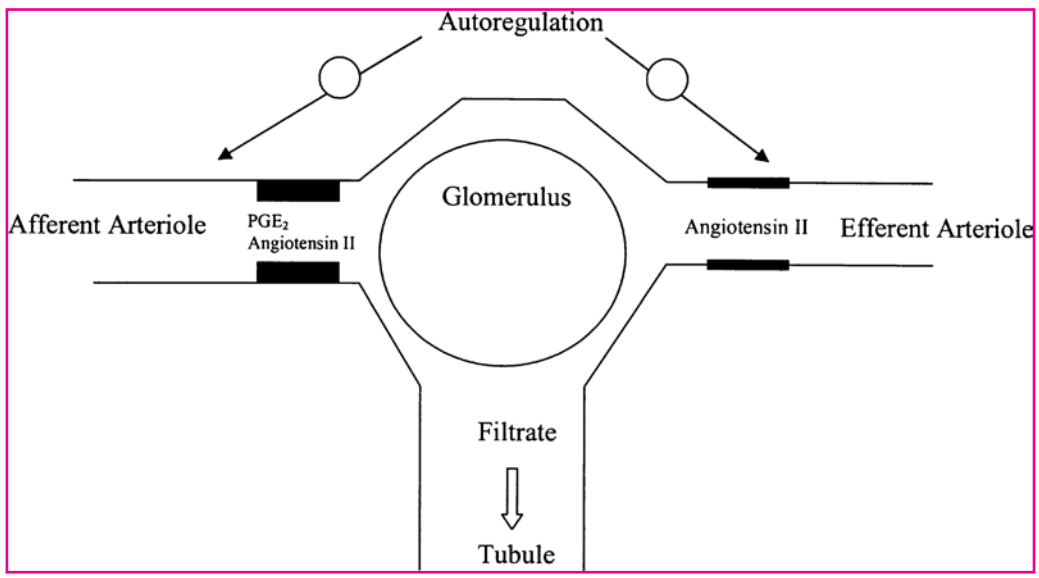

FIGURE 22–2. Normal glomerular autoregulation serves to maintain intraglomerular capillary hydrostatic pressure, glomerular filtration rate (GFR), and ultimately, urine output. This is accomplished by modulation of afferent and efferent arterioles. Afferent and efferent arteriolar vasoconstriction are primarily mediated by angiotensin II, whereas afferent vasodilation is primarily mediated by prostaglandins. PGE_2, prostaglandin E_2.

Patient Care and Monitoring

1. Assess kidney function by evaluating a patient's signs and symptoms, laboratory test results, and urinary indices. Calculate a patient's creatinine clearance to evaluate the severity of kidney disease.
2. Obtain a thorough and accurate drug history, including the use of non-prescription drugs such as NSAIDs.
3. Evaluate a patient's current drug regimen to:

- Determine if drug therapy may be contributing to ARF. Consider not only drugs that can directly cause ARF (e.g., aminoglycosides, amphotericin B, NSAIDs, cyclosporine, tacrolimus, ACE inhibitors, and ARBs), but also drugs that can predispose a patient to nephrotoxicity or prerenal ARF (i.e., diuretics and antihypertensive agents).
- Determine if any drugs need to be discontinued, or alternate drugs selected, to prevent worsening of renal function.
- Adjust drug dosages based on the patient's creatinine clearance or evidence of adverse drug reactions or interactions.

4. Develop a plan to provide symptomatic care of complications associated with ARF, such as diuretic therapy to treat volume overload. Monitor the patient's weight, urine output, electrolytes (such as potassium), and blood pressure to assess efficacy of the diuretic regimen.

CONCLUSION

ARF is a potentially life-threatening condition that can lead to significant morbidity and mortality. Supportive therapy, prompt correction of hypo- or hypervolemia, treatment of underlying conditions, and avoidance of nephrotoxic drugs is essential.

23 Chronic and End-Stage Renal Disease

Kristine S. Schonder

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. List the risk factors for progression of chronic kidney disease (CKD).
2. Explain the mechanisms associated with progression of CKD.
3. Identify the desired outcomes for treatment of CKD.
4. Develop a therapeutic approach to slow progression of CKD, including lifestyle modifications and pharmacologic therapies.
5. Identify specific consequences associated with CKD.
6. Design an appropriate therapeutic approach to specific consequences associated with CKD.
7. Recommend an appropriate monitoring plan to assess the effectiveness of pharmacotherapy for CKD and specific consequences.
8. Educate patients with CKD about the disease state, the specific consequences, lifestyle modifications, and pharmacologic therapies used for treatment of CKD.

Key Concepts

❶ Chronic kidney disease is a progressive disease that eventually leads to renal failure [end-stage renal disease (ESRD)].
❷ Early detection and treatment of CKD are fundamental factors in minimizing morbidity and mortality associated with CKD.
❸ Declining renal function disrupts the homeostasis of the systems regulated by the kidney, leading to fluid and electrolyte imbalances, anemia, and metabolic bone disease.
❹ Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin II receptor blockers decrease protein excretion and are the drugs of choice for hypertension in patients with CKD.
❺ The most common complication of CKD is anemia, which is caused by a decline in erythropoietin production by the kidneys and can lead to cardiovascular disease.
❻ The goal of anemia management is to increase hemoglobin levels to greater than 11 g/dL (6.82 mmol/L), which generally requires a combination of erythropoiesis-stimulating agents and iron supplements.
❼ Renal osteodystrophy stems from disruptions in calcium, phosphorus, and vitamin D homeostasis through the interaction with the parathyroid hormone.
❽ The management of secondary hyperparathyroidism involves correction of serum calcium and phosphorus levels, and decreasing parathyroid hormone secretion.
❾ Patient education and planning for dialysis should begin at stage 4 CKD, before end-stage renal disease is reached, to allow for time to establish appropriate access for dialysis.
❿ Dialysis involves the removal of metabolic waste products by diffusion and ultrafiltration from the bloodstream across a semipermeable membrane into an external dialysate solution.

The kidney is made up of approximately 2 million **nephrons** that are responsible for filtering, reabsorbing and excreting solutes and water. As the number of functioning nephrons declines, the primary functions of the kidney that are affected include:

- production and secretion of **erythropoietin**
- activation of vitamin D
- regulation of fluid and electrolyte balance
- regulation of acid-base balance

Chronic kidney disease (CKD), also known as chronic renal insufficiency, progressive kidney disease, or nephropathy, is defined as the presence of kidney damage or decreased

Patient Encounter, Part 1

A 62-year-old obese female with a history of diabetes and hypertension presents to clinic for routine follow-up. Her fasting blood sugars have been elevated recently, averaging 180 to 250 mg/dL (10 to 13.8 mmol/L).

PMH
- Diabetes mellitus for 8 years, not currently controlled
- Hypertension for 5 years, not currently controlled
- Hyperlipidemia, currently managed by diet therapy

FH
Mother is alive at age 87 with coronary artery disease; father is deceased from diabetes; she has no siblings.

SH
She does not work; she smokes 1 pack of cigarettes per day, but denies alcohol or illicit drug use; she is sedentary

Meds
Furosemide 20 mg orally daily
Nifedipine XL 30 mg orally daily
Glyburide 10 mg orally daily

ROS
Unremarkable

PE
VS: Blood pressure 145/92 mm Hg, pulse 82 beats per minute, temperature 36.9°C (98.4°F), Ht 5′4″ (162.5 cm), Wt 190 lb (86.4 kg)
CV: Regular rate and rhythm, normal S_1, S_2; no murmurs, rubs or gallops; lungs clear
Abd: Obese; no organomegaly, bruits or tenderness, (+) bowel sounds; heme (–) stool
Exts: Trace pedal edema bilaterally; decreased sensation in feet to light touch; no lesions

Labs (fasting)
Sodium 145 mEq/L (145 mmol/L); potassium 3.2 mEq/L (3.2 mmol/L); chloride 112 mEq/L (112 mmol/L); carbon dioxide 26 mEq/L (26 mmol/L); blood urea nitrogen 20 mg/dL (7.14 mmol/L urea); serum creatinine 1.4 mg/dL (123.76 µmol/L); glucose 240 mg/dL (13.32 mmol/L); total cholesterol 196 mg/dL (5.07 mmol/L); low-density lipoprotein cholesterol 112 mg/dL (2.90 mmol/L); high-density lipoprotein cholesterol 28 mg/dL (0.72 mmol/L); triglycerides 280 mg/dL (3.16 mmol/L); hemoglobin$_{A1c}$ (Hb_{A1c}) 10% (0.1); urine microalbumin 270 mg/dL (2.7 g/L)

- What risk factors does the patient have for the development of CKD?
- What signs and symptoms are consistent with CKD?
- How would you classify her CKD?
- Identify your treatment goals for the patient.
- What lifestyle modifications would you recommend for the patient with CKD?
- What pharmacologic alternatives are available for the patient for treatment of CKD?
- What other interventions are appropriate to minimize the progression of CKD?

glomerular filtration rate (GFR) for 3 months or more.[1] Generally, CKD is a progressive decline in kidney function (a decline in the number of functioning nephrons) that occurs over a period of several months to years. A decline in kidney function that occurs more rapidly, over a period of days to weeks, is known as acute renal failure (ARF), which is discussed in Chapter 22. The decline in kidney function in CKD is often irreversible. Therefore, measures to treat CKD are aimed at slowing the progression to end-stage renal disease (ESRD).

EPIDEMIOLOGY AND ETIOLOGY OF CKD

The National Kidney Foundation (NKF) developed a classification system for CKD (Table 23–1).[1] The staging system defines the stages of CKD based on GFR level, but also accounts for evidence of kidney damage in the absence of changes in GFR, as in stage 1 CKD. The GFR is calculated using the abbreviated Modification of Diet in Renal Disease (MDRD) study equation:

$$GFR = 186 \times (SCr)^{-1.154} \times (age)^{-0.203} \times (0.742 \text{ if female}) \times (1.21 \text{ if African-American})$$

Because of the slow onset of CKD and the lack of symptoms in earlier stages, the prevalence of CKD is difficult to determine until patients reach ESRD. It is estimated that approximately 19 million people (11% of the United States population) have some degree of CKD.[2] Approximately 8 million people have a GFR less than 60 mL/minute/1.73 m^2,[2] at which point CKD is generally diagnosed as a clinical condition. The prevalence of CKD is correlated with specific demographic factors: increased age, African-American race, and hypertension.

TABLE 23–1. NKF-DOQI Classification for Chronic Kidney Disease

State	Glomerular Filtration Rate (mL/minute/1.73 m^2)
1	Greater than or equal to 90[a]
2	60–89
3	30–59
4	15–29
5	Less than 15 (includes patients on dialysis)

[a]CKD can be present with a normal or near normal GFR if other markers of kidney disease are present, such as proteinuria, hematuria, biopsy results showing kidney damage, or anatomic abnormalities (e.g., cysts). NKF-DOQI, National Kidney Foundation-Dialysis Outcome Quality Initiative.

❶ *CKD is a progressive disease that eventually leads to ESRD*. The prevalence of ESRD has increased more than five-fold since 1980 to more than 450,000 people in 2003 with more than 100,000 new cases of ESRD diagnosed in 2003.[2] Although the incidence of ESRD is declining in certain populations, the incidence of ESRD is increasing in African-Americans to as much as 44% in patients with diabetes 30 to 39 years of age.

Because of the progressive nature of CKD, determination of risk factors for CKD is difficult. Risk factors identified for CKD are classified into three categories (Table 23–2):

- **Susceptibility factors**, which are associated with an increased risk of developing CKD, but are not directly proven to cause CKD. These factors are generally not modifiable by pharmacologic therapy or lifestyle modifications.
- **Initiation factors**, which directly cause CKD. These factors are modifiable by pharmacologic therapy.
- **Progression factors**, which result in a faster decline in kidney function and cause worsening of CKD. These factors may also be modified by pharmacologic therapy or lifestyle modifications to slow the progression of CKD.

Susceptibility Factors

Susceptibility factors can be readily used to develop screening programs for CKD. For example, older patients, those with low kidney mass or birth weight, and those with a family history of kidney disease should be routinely screened for CKD.

TABLE 23–2. Risk Factors Associated with Chronic Kidney Disease

Susceptibility
• Advanced age
• Reduced kidney mass
• Low birth weight
• Racial/ethnic minority
• Family history of kidney disease
• Low income or education
• Systemic inflammation
• Dyslipidemia
Initiation
• Diabetes mellitus
• Hypertension
• Autoimmune disease
• Polycystic kidney disease
• Drug toxicity
• Urinary tract abnormalities (infections, obstruction, stones)
Progression
• Hyperglycemia: Poor blood glucose control (in patients with diabetes)
• Hypertension: Elevated blood pressure
• Proteinuria
• Tobacco smoking

Minority and low socioeconomic communities may be targets for more widespread CKD screening programs. Other factors, such as hyperlipidemia, are not directly proven to cause CKD, but can be modified by drug therapies.

Hyperlipidemia

Patients with CKD have a higher prevalence of dyslipidemia compared to the general population. The dyslipidemia in CKD is manifested as an elevation in total cholesterol (TC) levels, low-density lipoprotein cholesterol (LDL-C) levels, triglycerides, and lipoprotein(a) levels, and decreases in high-density lipoprotein cholesterol (HDL-C) levels. The prevalence within the CKD population appears to be related somewhat to the degree of **proteinuria**. In nephrotic syndrome, with urine protein excretion rates that exceed 3 g/24 hours, almost all patients have some degree of dyslipidemia.[3] Mounting evidence suggests that hyperlipidemia can promote renal injury and subsequent progression of CKD. The mechanism is similar to that of atherosclerosis, whereby lipid deposition causes activation of macrophages and monocytes, which secrete growth factors that stimulate cell proliferation and oxidation of lipoproteins. These lead to endothelial dysfunction, cellular injury, and fibrosis in the kidney.[4]

Initiation Factors

The three most common causes of CKD in the United States are diabetes mellitus, hypertension, and **glomerulonephritis**. Together these account for about 75% of the cases of CKD (37% for diabetes, 24% for hypertension, and 14% for glomerulonephritis).[2] These are discussed in further detail below.

Diabetes

Diabetes mellitus (DM) is the most common cause of CKD.[2] The risk of developing nephropathy associated with DM is closely linked to hyperglycemia and is similar for both type 1 and type 2, although it is slightly higher in patients with type 2 DM.[5] An estimated 3% of patients with DM will develop ESRD, which is 12 times greater than those without DM.[6]

Hypertension

The second most common cause of CKD is hypertension.[2] It is more difficult to determine the true risk of developing CKD in patients with hypertension because the two are so closely linked, with CKD also being a cause of hypertension. The prevalence of hypertension is correlated with the degree of renal dysfunction (decreased GFR) with 40% of patients with CKD stage 1, 55% of patients with CKD stage 2, and over 75% of patients with CKD stage 3 presenting with hypertension.[1] The risk of developing ESRD is linked to both systolic and diastolic blood pressure.[7] A blood pressure greater than 210/110 mm Hg is associated with a 22% increased relative risk of developing ESRD, compared with a blood pressure less than 120/80 mm Hg.[7]

Glomerulonephritis

The etiologic and pathophysiologic features of glomerular diseases vary with the specific disease, making it difficult to extrapolate the risk for developing CKD in patients affected by glomerular diseases. Certain glomerular diseases are known to rapidly progress to ESRD, while others progress more slowly or may be reversible.

Progression Factors

Progression factors can be used as predictors of CKD. The most important predictors of CKD include proteinuria, elevated blood pressure, hyperglycemia, and tobacco smoking.

Proteinuria

The presence of protein in the urine is a marker of glomerular and tubular dysfunction and is recognized as an independent risk factor for the progression of CKD.[8] Furthermore, the degree of proteinuria correlates with the risk for progression of CKD. An increase of 1 g of protein excretion per day is associated with a five-fold increase in the risk of progression of CKD, regardless of the cause of CKD.[9] The mechanisms by which proteinuria potentiates CKD are discussed later. **Microalbuminuria** is also linked with vascular injury and increased cardiovascular mortality.[10]

Elevated Blood Pressure

Systemic blood pressure correlates with glomerular pressure and elevations in both systemic blood pressure and glomerular pressure contribute to glomerular damage. The rate of GFR decline is related to elevated systolic blood pressure and mean arterial pressure. The decline in GFR is estimated to be 14 mL/minute per year with a systolic blood pressure of 180 mm Hg. Conversely, the decline in GFR decreases to 2 mL/minute per year with a systolic blood pressure of 135 mm Hg.[11]

Elevated Blood Glucose

The reaction between glucose and protein in the blood produces advanced glycosylation end-products (AGEs), which are metabolized in the proximal tubules. Hyperglycemia increases the synthesis of AGEs in patients with diabetes and the corresponding increase in metabolism is suspected to be a cause of nephropathy associated with diabetes.[12]

Tobacco Smoking

Smoking is an independent risk factor for the development of microalbuminuria in primary hypertension. In patients with CKD, smoking is also an independent risk factor for progression to ESRD, with a relative risk ratio of up to 1.69 in heavy smokers, independent of other risk factors for the development and progression of CKD.[13] Patients with DM who smoke have more than a two- to three-fold increased risk of developing diabetic nephropathy compared to non-smokers.[13] In patients with CKD, smoking increases the risk of developing microalbuminuria, and increases the rate of progression to ESRD.[13]

The effects of smoking on the kidney are multifactorial and occur in both healthy individuals and those with CKD. Smoking induces glomerular hyperfiltration, produces an antidiuretic action that increases blood pressure, and can damage the proximal tubule, resulting in impaired cationic transport. Furthermore, systemic complications correlated with tobacco abuse, including increases in blood pressure, platelet activity, and thromboxane A_2 production, can also negatively impact kidney function.[13] These effects are related to the amount of cigarettes smoked, in terms of pack years.[13]

PATHOPHYSIOLOGY OF CKD

A number of factors can cause initial damage to the kidney. The resulting sequelae, however, follow a common pathway that promotes progression of CKD and results in irreversible damage leading to ESRD (Fig. 23–1).

The initial damage to the kidney can result from any of the initiation factors listed in Table 23–2. Regardless of the cause, however, the damage results in loss of nephron mass. The resultant effect is hypertrophy of the remaining nephrons to compensate for the loss of renal function and nephron mass. These adaptive changes result in an increase in glomerular filtration and tubular function, both reabsorption and secretion, in the remaining nephrons. Initially, these adaptive changes preserve many of the clinical parameters of renal function, including creatinine and electrolyte excretion. However, as time progresses, glomerular capillary pressure is increased, mediated by angiotensin II, to maintain the hyperfiltration state of the functioning nephrons. Angiotensin II is a potent vasoconstrictor of both the afferent and efferent arterioles, but has a preferential effect to constrict the efferent arteriole, thereby increasing the pressure in the glomerular capillaries. Increased glomerular capillary pressure expands the pores in the glomerular basement membrane, altering the size-selective barrier and allowing proteins to be filtered through the glomerulus.[14]

Protein excretion through the nephron, or proteinuria, increases nephron loss through various complex mechanisms. Filtered proteins are reabsorbed in the renal tubules, which activates the tubular cells to produce inflammatory and vasoactive cytokines and triggers complement activation.[14] These in turn cause interstitial damage and scarring within the renal tubules, leading to damage and loss of more nephrons. Ultimately, the process leads to progressive loss of nephron mass to the point where the remaining nephrons are no longer able to maintain clinical stability and renal function declines.

ASSESSMENT FOR CKD

Because CKD often presents without symptoms, assessment for CKD relies on appropriate screening strategies in all

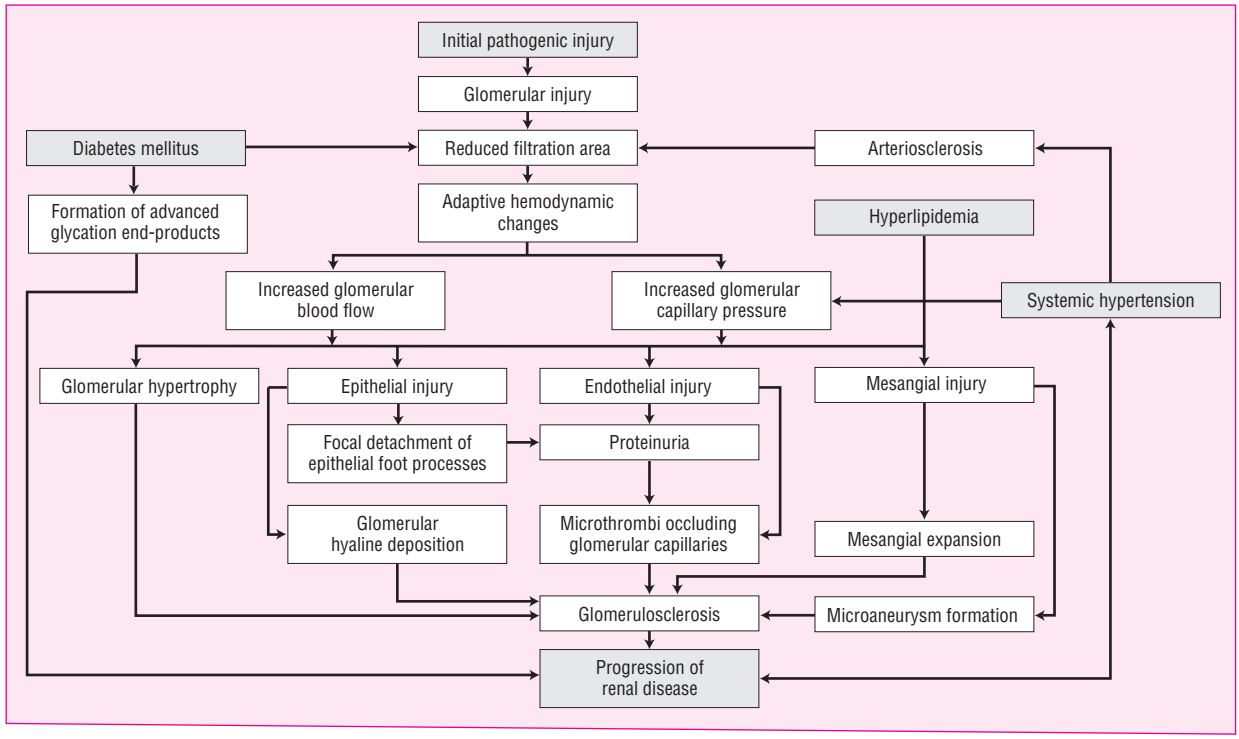

FIGURE 23–1. Proposed mechanisms for progression of renal disease. (From Joy MS, Kshirsagar A, Paparello J. Chronic kidney disease: Progression-modifying therapies. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 803, with permission.)

patients with risk factors for developing CKD (Table 23–2). Evaluation for CKD and the subsequent treatment strategies are dependent on the diagnosis, comorbid conditions, severity and complications of disease, and risk factors for the progression of CKD. ❷ *Early treatment of CKD and the associated complications of CKD are the most important factors to decrease morbidity and mortality associated with CKD.* However, the probability of patients not diagnosed with CKD to have an assessment of serum creatinine or urine protein excretion ranges from 0.01 to 0.04, depending on insurance coverage.[2] Screening for CKD should be performed in all people with an increased risk for developing CKD, including patients with DM, hypertension, genitourinary abnormalities, autoimmune disease, increased age, or a family history of kidney disease. The assessment for CKD should include measurement of serum creatinine, urinalysis, blood pressure, serum electrolytes, and/or imaging studies.

The primary marker of structural kidney damage is proteinuria, even in patients with normal GFR. Clinically significant proteinuria is defined as urinary protein excretion greater than 300 mg/day or greater than 20 mcg/minute in a timed urine collection. Significant proteinuria can also be determined by a spot urine dipstick greater than 30 mg/dL or a urine protein/creatinine ratio greater than 200 mg/g.[1] Microalbuminuria is defined as 30 to 300 mg of albumin excreted in the urine per day or a urine albumin/creatinine ratio greater than 30 mg/day.[1] The NKF recommends routine assessment of proteinuria to detect CKD. A urine dipstick positive for the presence of protein warrants quantification of proteinuria. Patients with a urine protein/creatinine ratio greater than 200 mg/g or urine albumin/creatinine ratio greater than 30 mg/g should undergo diagnostic evaluation; patients with values below these levels should be reevaluated routinely.[1]

Other markers for structural kidney damage that can be used in place of proteinuria include abnormalities in urinary sediment, such as hematuria, or abnormalities in imaging studies or kidney biopsy.[1]

Complications of CKD

❸ *The decline in renal function is associated with a number of complications, which will be discussed later in the chapter, including:*

- *Fluid and electrolyte disorders*
- *Anemia*
- *Metabolic bone disease*

Clinical Presentation of Chronic Kidney Disease

General
The development of CKD is usually subtle in onset, often with no noticeable symptoms.

Symptoms
Stages 1 and 2 CKD are generally asymptomatic.
Stages 3 and 4 CKD may be associated with minimal symptoms.
Typical symptoms associated with stage 5 CKD include pruritus, dysgeusia, nausea, vomiting, constipation, muscle pain, fatigue, and bleeding abnormalities.

Signs
Cardiovascular: Worsening hypertension, edema, dyslipidemia, left ventricular hypertrophy, electrocardiographic changes and chronic heart failure.

Musculoskeletal: Cramping.

Neuropsychiatric: Depression, anxiety, impaired mental cognition.

Gastrointestinal: Gastroesophageal reflux disease, gastrointestinal (GI) bleeding, and abdominal distention.

Genitourinary: Changes in urine volume and consistency, "foaming" of urine (indicative of proteinuria), and sexual dysfunction.

Laboratory Tests
Stages 1 and 2 CKD: Increased **blood urea nitrogen** (BUN) and serum **creatinine** (SCr) and decreased GFR
Stages 3, 4, and 5 CKD: Increased BUN and SCr; decreased GFR.

Advanced stages: Increased potassium, phosphorus, and magnesium; decreased bicarbonate (metabolic acidosis); calcium levels are generally low in earlier stages of CKD and may be elevated in stage 5 CKD, secondary to the use of calcium-containing phosphate binders.
Decreased albumin, if inadequate nutrition intake in advanced stages.
Decreased red blood cell (RBC) count, hemoglobin (Hgb) and hematocrit (Hct); iron metabolism may also be altered [iron level, total iron binding capacity (TIBC), serum ferritin level, and transferrin saturation (TSAT)]. Erythropoietin levels are not routinely monitored and are generally normal to low.
Urine positive for albumin or protein.
Increased parathyroid hormone (PTH) level; decreased vitamin D levels (stages 4 or 5 CKD).
Stool may be Hemoccult-positive if GI bleeding occurs from uremia.

Other Diagnostic Tests
Structural abnormalities of kidney may be present on diagnostic exams.

TREATMENT OF CHRONIC KIDNEY DISEASE

Desired Outcomes
The primary goal is to slow and prevent the progression of CKD. This requires early identification of patients at risk for CKD to initiate interventions early in the course of the disease.

Nonpharmacologic Therapy

Nutritional Management
Reduction in dietary protein intake has been shown to slow the progression of kidney disease.[8] However, protein restriction must be balanced with the risk of malnutrition in patients with CKD. Patients with a GFR less than 25 mL/minute/ 1.73 m^2 received the most benefit from protein restriction;[8] therefore, patients with a GFR above this level should not restrict protein intake. The NKF recommends that patients who have a GFR less than 25 mL/minute/1.73 m^2 who are not receiving dialysis, however, should restrict protein intake to 0.6 g/kg per day. If patients are not able to maintain adequate dietary energy intake, protein intake may be increased up to 0.75 g/kg per day.[15] Malnutrition is common in patients with ESRD for various reasons, including decreased appetite, hypercatabolism, and nutrient losses through dialysis. For this reason, patients receiving dialysis should maintain protein intake of 1.2 g/kg per day to 1.3 g/kg per day.

Pharmacologic Therapy

Intensive Blood Glucose Control (for Patients with Diabetes)
Intensive insulin therapy, the administration of insulin three or more times daily to maintain preprandial blood glucose levels between 70 and 120 g/dL and postprandial blood glucose levels less than 180 g/dL, has been shown to decrease the incidence of proteinuria and albuminuria in patients with diabetes, both with and without documented nephropathy. The development and progression of nephropathy is also delayed in patients with type 1 DM receiving intensive insulin therapy. Continued benefits of intensive insulin therapy have been demonstrated up to 8 years after the study.[16]

Optimal Blood Pressure Control
Reductions in blood pressure are associated with a decrease in proteinuria, leading to a decrease in the rate of progression of kidney disease. The NKF recommends a goal blood pressure of less than 130/80 mm Hg in patients with stages 1 through 4 CKD.[17] Stage 5 CKD patients who are receiving hemodialysis should achieve a goal blood pressure of less than 140/90 mm Hg before hemodialysis and less than 130/80 after hemodialysis.[17] Because hypertension and kidney dysfunction are linked, blood pressure control can be more difficult to attain in patients with

CKD compared to patients with normal kidney function. All antihypertensive agents have similar effects on reducing blood pressure. However, three or more agents are generally required to achieve the blood pressure goal of less than130/80 mm Hg in CKD patients.

Reduction in Proteinuria

The ability of antihypertensive agents to preserve kidney function differs. Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) decrease glomerular capillary pressure and volume because of their effects on angiotensin II. This, in turn, reduces the amount of protein filtered through the glomerulus, independent of the reduction in blood pressure,[18] which ultimately decreases the progression of CKD. ❹ *The ability of ACEIs and ARBs to reduce proteinuria is greater than that of other antihypertensives, up to 35% to 40%,[17] making ACEIs and ARBs the antihypertensive agents of choice for all patients with CKD.* All patients with documented proteinuria should receive an ACE-I or ARB, regardless of blood pressure.[17] Because diabetes is associated with an early onset of microalbuminuria, all patients with diabetes should also receive an ACE-I or ARB, regardless of blood pressure.[17] When initiating ACE-I or ARB therapy, the dose should be titrated to the maximum tolerated dose, even if the blood pressure is less than130/80 mm Hg. Patients who do not achieve adequate reductions in blood pressure or protein excretion may benefit from combination therapy with an ACE-I and an ARB.[17] Figure 23–2 depicts an algorithm for the treatment of hypertension in patients with CKD.

The nondihydropyridine calcium channel blockers have been shown to also decrease protein excretion in patients with diabetes,[20] but the reduction in proteinuria appears to be related to the reductions in blood pressure. The maximal effect of nondihydropyridine calcium channel blockers on proteinuria is seen with a blood pressure reduction to less than 130/80 mm Hg and no additional benefit is seen with increased doses. Dihydropyridine calcium channel blockers, however, do not have the same effects on protein excretion, and may actually worsen protein excretion.[17]

Other Interventions to Limit Progression of Chronic Kidney Disease

Hyperlipidemia Treatment

Hyperlipidemia plays a role in the development of cardiovascular disease (CVD) in patients with CKD. The primary goal of treatment of dyslipidemias is to decrease the risk of atherosclerotic cardiovascular disease. A secondary goal in patients with CKD is to reduce proteinuria and decline in kidney function. Treatment of hyperlipidemia in patients with CKD has been demonstrated to slow the decline in GFR by 1.9 mL/minute per year of treatment with antihyperlipidemic agents.[21]

The NKF suggests that CKD should be classified as a coronary heart disease (CHD) risk equivalent and the goal LDL-C level should be below 100 mg/dL in all patients with CKD.[22] The most frequently used agents for the treatment of dyslipidemias in patients with CKD are the 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors ("statins") and the fibric acid derivatives. However, other treatments have been studied in patients with CKD and should be considered if first-line therapies are contraindicated.

Another important consideration in treating lipid disorders in patients with CKD is management of proteinuria. Protein excretion in the nephrotic range (greater than 3 g/day) is associated with an increase in both total and LDL-C levels.[23] Triglyceride levels can also be elevated in patients with severe proteinuria. Results from clinical trials suggest that the use of ACEIs to reduce proteinuria can decrease total cholesterol levels.[24] While the use of ACEIs is unlikely to decrease cholesterol to goal levels, reducing proteinuria can aid in cholesterol reduction, particularly in patients with nephrotic syndrome or severe proteinuria. Conversely, treatment of hyperlipidemia can reduce protein excretion and subsequent progression of CKD.[4]

Smoking Cessation

While the effects of smoking on renal hemodynamics are well established, as discussed previously, the effect of smoking cessation on CKD progression has not been studied. Data are emerging that suggest that smoking cessation may be a practical approach to slow the progression of CKD. However, smoking cessation does not reverse existing renal dysfunction in former smokers.

Anemia Treatment

Anemia decreases oxygen delivery to the renal tubules, promoting the release of inflammatory and vasoactive cytokines, which contribute to the progression of CKD. Treatment of anemia in patients with CKD reduces the cardiovascular effects of anemia and has been demonstrated to decrease morbidity and mortality by as much as 20%.[25] Studies have demonstrated that treatment of anemia may slow the progression of CKD.[26] The management of anemia will be discussed later.

Outcome Evaluation

Monitor serum creatinine and potassium levels and blood pressure within 1 week after initiating angiotensin-converting enzyme inhibitor or angiotensin II receptor blocker therapy. Discontinue the medication and switch to another agent if a sudden increase in serum creatinine greater than 30% occurs, hyperkalemia develops, or the patient becomes hypotensive. Titrate the dose of the ACE-I or ARB every 1 to 3 months to the maximum tolerable dose. If blood pressure is not reduced to less than 130/80 mm Hg, add another agent to the regimen.

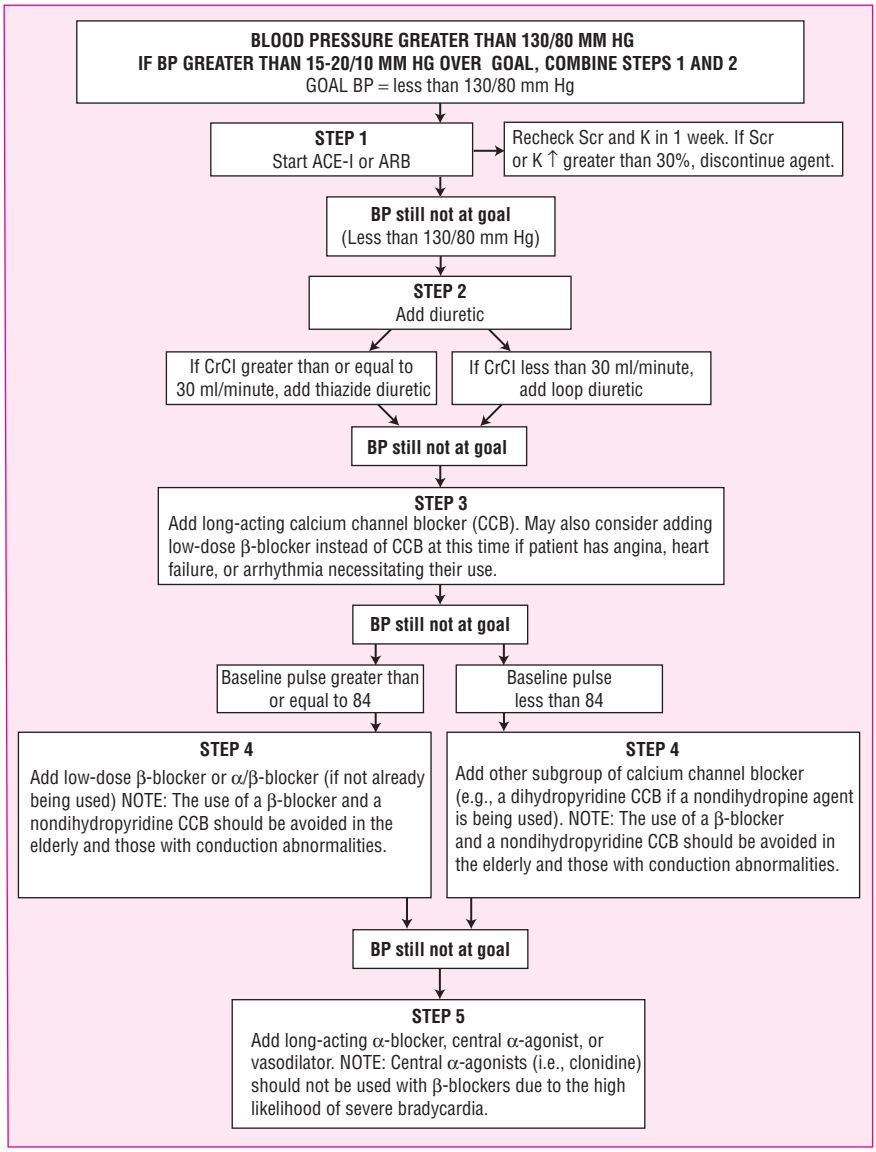

FIGURE 23–2. Hypertension management algorithm for patients with CKD. Dosage adjustments should be made every 2 to 4 weeks as needed. The dose of one agent should be maximized before another is added. ACE-I, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BP, blood pressure; CrCl, creatinine clearance; K, potassium; Scr, serum creatinine. (From Joy MS, Kshirsagar A, Paparello J. Chronic kidney disease: Progression-modifying therapies. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 808, with permission.)

Refer the patient to a nephrologist to manage complications associated with CKD. As CKD progresses to stage 4, begin discussion to prepare the patient for renal replacement therapy.

CONSEQUENCES OF CHRONIC AND END-STAGE KIDNEY DISEASE

Impaired Sodium and Water Homeostasis

Sodium and water balance are primarily regulated by the kidney. Reductions in nephron mass decrease glomerular filtration and subsequent reabsorption of sodium and water, leading to edema.

Pathophysiology

Sodium and water balance can be maintained despite wide variations in intake with normal kidney function. The fractional excretion of sodium (FE_{Na}) is approximately 1% to 3% with normal kidney function, allowing sodium balance to be maintained with a sodium intake of 120 to 150 mEq (120 to 150 mmol) per day. Urine osmolality can range from 50 to 1200 mOsm/L (50 to 1200 mmol/L) with normal kidney function, allowing for water balance to be maintained with a wide range of fluid intake. As nephron mass decreases, the remaining nephrons increase sodium excretion and FE_{Na} may increase up to 10% to 20%.[27] This produces an osmotic diuresis which impairs the ability of the kidneys to concentrate and dilute urine and the urine becomes fixed at an osmolality close to that of the plasma, approximately 300 mOsm/L (300 mmol/L). The inability of the kidney to concentrate the urine results in nocturia in patients with CKD, usually presenting as early as stage 3 CKD.

As nephron mass continues to decline, the sodium load overwhelms the remaining nephrons and total sodium excretion is decreased, despite the increase in sodium excretion by

Clinical Presentation of Impaired Sodium and Water Homeostasis

General
Alterations in sodium and water balance in CKD manifests as increased edema.

Symptoms
Nocturia can present in stage 3 CKD.
Edema generally presents in stage 4 CKD or later.

Signs
Cardiovascular: Worsening hypertension, edema.
Genitourinary: Change in urine volume and consistency.

Laboratory Tests
Increased blood pressure
Sodium levels remain within the normal range
Urine osmolality is generally fixed at 300 mOsm/L (300 mmol/L)

the functioning nephrons. Sodium retention causes fluid retention that manifests as systemic hypertension resulting from increased intravascular volume. Severe volume overload can lead to pulmonary edema.

Treatment

Nonpharmacologic Therapy

The kidney is unable to adjust to abrupt changes in sodium intake in patients with severe CKD. Therefore, patients should be advised to refrain from adding salt to their diet, but should not restrict sodium intake. Changes in sodium intake should occur slowly over a period of several days to allow adequate time for the kidney to adjust urinary sodium content. Sodium restriction produces a negative sodium balance, which causes fluid excretion to restore sodium balance. The resulting volume contraction can decrease perfusion of the kidney and hasten the decline in GFR. Saline-containing intravenous (IV) solutions should be used cautiously in patients with CKD because the salt load may precipitate volume overload.

Fluid restriction is generally unnecessary as long as sodium intake is controlled. The thirst mechanism remains intact in CKD to maintain total body water and plasma osmolality near normal levels. Fluid intake should be maintained at the rate of urine output to replace urine losses, usually fixed at approximately 2 L/day as urine concentrating ability is lost. Significant increases in free water intake orally or intravenously can precipitate volume overload and hyponatremia. Patients with stage 5 CKD require renal replacement therapy to maintain normal volume status. Fluid intake is often limited in patients receiving hemodialysis to prevent fluid overload between dialysis sessions.

Pharmacologic Therapy

Diuretic therapy is often necessary to prevent volume overload in patients with CKD. Loop diuretics are most frequently used to increase sodium and water excretion. Thiazide diuretics are ineffective when used alone in patients with a GFR less than 30 mL/minute/1.73 m^2. As CKD progresses, higher doses or continuous infusion of loop diuretics may be needed, or combination therapy with loop and thiazide diuretics to increase sodium and water excretion.

Outcome Evaluation

Monitor edema after initiation of diuretic therapy. Monitor fluid intake to ensure obligatory losses are being met and avoid dehydration. If adequate diuresis is not attained with a single agent, consider combination therapy with another diuretic.

Impaired Potassium Homeostasis

Potassium balance is also primarily regulated by the kidney via the distal tubular cells. Reduction in nephron mass decreases tubular secretion of potassium, leading to hyperkalemia. Hyperkalemia is estimated to affect more than 50% of patients with stage 5 CKD.[28]

Pathophysiology

The distal tubules secrete 90% to 95% of the daily dietary intake of potassium. The fractional excretion of potassium (FE_K) is approximately 25% with normal kidney function.[29] The GI tract excretes the remaining 5% to 10% of dietary potassium intake. Following a large potassium load, extracellular potassium is shifted intracellularly to maintain stable extracellular levels.

As nephron mass decreases, both the distal tubular secretion and GI excretion are increased because of aldosterone stimulation. Functioning nephrons increase FE_K up to 100% and GI excretion increases as much as 30% to 70% in CKD,[30] as a result of aldosterone secretion in response to increased potassium levels.[30] This maintains serum potassium concentrations within the normal range through stages 1 to 4 CKD. Hyperkalemia begins to develop when GFR falls below 20% of normal, when nephron mass and renal potassium secretion is so low that the capacity of the GI tract to excrete potassium has been exceeded.[30]

Medications can increase the risk of hyperkalemia in patients with CKD, including angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers, used for the treatment of proteinuria and hypertension. Potassium-sparing diuretics, used for the treatment of edema and chronic heart failure, can also exacerbate the development of hyperkalemia, and should be used with caution in patients with stage 3 CKD or higher.

Treatment

Nonpharmacologic Therapy

Patients with CKD should avoid abrupt increases in dietary intake of potassium because the kidney is unable to increase potassium excretion with an acute potassium load, particularly in latter stages of the disease. Hyperkalemia resulting

Clinical Presentation of Hyperkalemia

General
Hyperkalemia is generally asymptomatic in patients with CKD until serum potassium levels are greater than 5.5 mEq/L (5.5 mmol/L), when cardiac abnormalities present.

Symptoms
Mild hyperkalemia is generally not associated with overt symptoms.

Signs
Cardiovascular: Electrocardiogram (ECG) changes

Laboratory Tests
Increased serum potassium levels

from an acute increase in potassium intake can be more severe and prolonged. Patients who develop hyperkalemia should restrict dietary intake of potassium to 50 to 80 mEq (50 to 80 mmol) per day. Dialysate potassium concentrations can also be altered in patients receiving hemodialysis and peritoneal dialysis to manage hyperkalemia. Because GI excretion of potassium plays a large role in potassium homeostasis in patients with stage 5 CKD, a good bowel regimen is essential to minimize constipation, which can occur in 40% of patients receiving hemodialysis.[29] Severe hyperkalemia is most effectively managed by hemodialysis.

Pharmacologic Therapy

Patients with acute hyperkalemia usually require other therapies to manage hyperkalemia until dialysis can be initiated. Patients who present with cardiac abnormalities caused by hyperkalemia should receive calcium gluconate or chloride (1 g intravenously) to reverse the cardiac effects. Temporary measures can be employed to shift extracellular potassium into the intracellular compartment to stabilize cellular membrane effects of excessive serum potassium levels. Such measures include the use of regular insulin (5 to 10 units intravenously) and dextrose (5% to 50% intravenously), or nebulized albuterol (10 to 20 mg). Sodium bicarbonate should not be used to shift extracellular potassium intracellularly in patients with CKD unless severe metabolic acidosis (pH less than 7.2) is present. These measures will decrease serum potassium levels within 30 to 60 minutes after treatment, but potassium must still be removed from the body. Shifting potassium to the intracellular compartment, however, decreases potassium removal by dialysis. Often, multiple dialysis sessions are required to remove potassium that is redistributed from the intracellular space back into the serum.

Sodium polystyrene sulfonate (SPS, 15 to 30 g orally), a sodium-potassium exchange resin, promotes potassium excretion from the GI tract. The onset of action is within 2 hours after administration of SPS, but the maximum effect on potassium levels may not be seen for up to 6 hours, which limits the utility in patients with severe hyperkalemia. Of note, loop diuretics are often used to decrease potassium levels in patients with normal or mildly decreased kidney function, but are not useful in patients with stage 5 CKD to decrease potassium concentrations. Fludrocortisone is a mineralocorticoid that mimics the effects of aldosterone and increases potassium excretion in the distal tubules and through the GI tract. However, fludrocortisone causes significant sodium and water retention, which exacerbates edema and hypertension, and may not be tolerated by many CKD patients.

Outcome Evaluation

Monitor electrocardiogram continuously in patients with cardiac abnormalities until serum potassium levels drop below 5 mEq/L (5 mmol/L) or cardiac abnormalities resolve. Evaluate serum potassium and glucose levels within 1 hour in patients who receive insulin and dextrose therapy. Evaluate serum potassium levels within 2 to 4 hours after treatment with SPS or diuretics. Repeat doses of diuretics or SPS if necessary until serum potassium levels fall below 5 mEq/L (5 mmol/L). Monitor blood pressure and serum potassium levels in 1 week in patients who receive fludrocortisone.

Anemia of CKD

The progenitor cells of the kidney produce 90% of the hormone erythropoietin (EPO), which stimulates red blood cell (RBC) production. ❺ *Reduction in nephron mass decreases renal production of EPO, which is the primary cause of anemia in patients with CKD. The development of* ***anemia of CKD*** *results in decreased oxygen delivery and utilization, leading to increased cardiac output and left ventricular hypertrophy (LVH), which increase the cardiovascular risk and mortality in patients with CKD.*

Epidemiology and Etiology

Current NKF guidelines define anemia as a hemoglobin (Hgb) level less than 11 g/dL (6.8 mmol/L).[31] A number of factors can contribute to the development of anemia, including deficiencies in vitamin B_{12} or folate, hemolysis, bleeding, or bone marrow suppression. Many of these can be detected by alterations in RBC indices, which should be included in the evaluation for anemia. A complete blood cell count is also helpful in evaluating anemia to determine overall bone marrow function.

The prevalence of anemia is correlated with the degree of renal dysfunction. More than 26% of patients with a GFR greater than 60 mL/minute/1.73 m^2 are estimated to have anemia, and the number increases to 75% in patients with a GFR less than 15 mL/minute/1.73 m^2.[32] The risk of developing anemia also increases as GFR declines, doubling for patients with stage 3 CKD, increasing to 3.8-fold in patients with stage 4 CKD, and

Patient Encounter, Part 2

The patient returns to your clinic 2 years later with complaints of "feeling tired all of the time." She had been trying to exercise more, but has not had enough energy to exercise for the past 6 months or so. She also complains that she feels cold all of the time, despite increasing the temperature in her house.

Current Meds
Furosemide 80 mg orally daily
Lisinopril 40 mg orally daily
Metoprolol 50 mg orally twice daily
Insulin glargine 25 units subcutaneously at bedtime
Insulin lispro subcutaneously per sliding scale with meals

ROS
Slightly pale skin color; fatigue daily in the afternoon; otherwise unremarkable

PE
VS: Blood pressure 135/85 mm Hg, pulse 72 beats per minute, temperature 35.9°C (96.6°F); Wt 175 lb (79.5 kg)
Chest: Regular rate and rhythm, normal S_1, S_3 present.
Abd: Obese; no organomegaly, bruits or tenderness, (+) bowel sounds; heme (–) stool
Exts: 1+ pedal edema bilaterally; decreased sensation in feet; small lesion on left ankle that appears to be healing slowly

Labs
Sodium 142 mEq/L (142 mmol/L); potassium 4.8 mEq/L (4.8 mmol/L); chloride 103 mEq/L (103 mmol/L); carbon dioxide 20 mEq/L (20 mmol/L); BUN 58 mg/dL (20.71 mmol/L urea); SCr 3.2 mg/dL (282.88 µmol/L); glucose 130 mg/dL (7.28 mmol/L); WBC 4.8×10^3 cells/m^3 (4.8×10^9/L); RBC 2.5×10^3 cells/m^3 (2.5×10^{12}/L); Hgb 8.0 g/dL (4.96 mmol/L); Hct 25% (0.25); mean corpuscular volume (MCV) 88 fL; mean corpuscular hemoglobin concentration (MCHC) 35 g/dL (350 g/L); platelets 250×10^3 cells/m^3 (250×10^9/L); iron 35 mcg/dL (6.26 mmol/L); TIBC 150 mcg/dL (26.85 µmol/L); ferritin 75 ng/mL (168 pmol/L); TSAT 15% (0.15); Hb_{A1c} 7.5% (0.075)

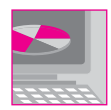
- How would you evaluate the effectiveness of treatment of anemia?

to 10.5-fold for patients with stage 5 CKD, compared to stages 1 and 2 CKD.[32]

Pathophysiology

The primary cause of anemia in patients with CKD is a decrease in EPO production. With normal kidney function, as Hgb, hematocrit (Hct), and tissue oxygenation decrease, the plasma concentration of EPO increases exponentially. As nephron mass decreases, EPO production also decreases. Thus, as Hgb, Hct, and tissue oxygenation decrease in patients with CKD, plasma EPO levels remain constant within the normal range, but low relative to the degree of hypoxia present. The result is a normochromic, normocytic anemia.



Several other factors also contribute to the development of anemia in patients with CKD. **Uremia**, a result of declining renal function, decreases the lifespan of RBCs from a normal of 120 days to as low as 60 days in patients with stage 5 CKD. Iron deficiency and blood loss from regular laboratory testing and hemodialysis also contribute to the development of anemia in patients with CKD.

Treatment

General Approach to Therapy

Studies have demonstrated that initiation of treatment for anemia before stage 5 CKD decreases mortality in patients with ESRD receiving dialysis, particularly in the elderly.[33] The treatment of anemia can decrease morbidity, increase exercise capacity and tolerance, and slow the progression of CKD if target Hgb levels are achieved.[34]

Patients with CKD should be evaluated for anemia when the GFR falls below 60 mL/minute or if the serum creatinine rises above 2 mg/dL (176.8 mmol/L). If the Hgb is less than 11 g/dL (6.8 mmol/L), an anemia work-up should be performed. The work-up for anemia should rule out other potential causes for anemia (see Chapter 63). Abnormalities found during the anemia work-up should be corrected before initiating **erythropoiesis-stimulating agents** (ESA),

Clinical Presentation of Anemia of CKD

General
Anemia of CKD generally presents with fatigue and decreased quality of life.

Symptoms
Anemia of CKD is associated with symptoms of cold intolerance, shortness of breath, and decreased exercise capacity.

Signs
Cardiovascular: Left ventricular hypertrophy, ECG changes, congestive heart failure
Neurologic: Impaired mental cognition
Genitourinary: Sexual dysfunction

Laboratory Tests
Decreased RBC count, Hgb, and Hct
Decreased serum iron level, TIBC, serum ferritin, and TSAT
Decreased erythropoietin levels relative to the degree of hypoxia that is present

particularly iron deficiency, as iron is an essential component of RBC production. If Hgb is still below the goal level when all other causes of anemia have been corrected, EPO deficiency should be assumed. EPO levels are not routinely measured and have little clinical significance in monitoring progression and treatment of anemia in patients with CKD.

❻ *Generally, treatment requires a combination of ESA and iron supplementation. The goal of treatment for anemia of CKD is to increase Hgb levels greater than 11 g/dL (6.8 mmol/L).* The goal for iron supplementation is to maintain serum ferritin levels between 100 and 500 ng/mL (225 to 1123.5 pmol/L) in patients not receiving hemodialysis and between 200 and 500 ng/mL (449.4 to 1123.5 pmol/L) in patients receiving hemodialysis and TSAT greater than 20% (0.2).[31] The approach to the management of anemia of CKD with ESA and iron supplementation is illustrated in Figs. 23–3 and 23–4.

Nonpharmacologic Therapy

Sufficient dietary iron intake must be maintained in patients with anemia of CKD. Approximately 1 to 2 mg of iron is

absorbed daily from the diet. This small amount is generally not adequate to preserve adequate iron stores to promote RBC production. RBC transfusions have been used in the past as the primary means to maintain Hgb and Hct levels in patients with anemia of CKD. This treatment is still utilized today in patients with severe anemia, but is considered a third-line therapy for anemia of CKD.

Pharmacologic Therapy

The first-line treatment for anemia of CKD involves replacement of erythropoietin with erythropoiesis-stimulating agents (ESAs). Use of ESAs increases the iron demand for RBC production and iron deficiency is common, requiring iron supplementation to correct and maintain adequate iron stores to promote RBC production. Androgens were used extensively before the availability of ESAs, but are now reserved as third-line agents because of toxicity; namely, hepatotoxicity.

Erythropoiesis-Stimulating Agents (ESAs) Erythropoietin is a growth factor that acts on erythroblasts formed from stem cells in the bone marrow, stimulating proliferation and differentiation into normoblasts, then reticulocytes, which are released into the bloodstream to eventually mature into erythrocytes (mature RBCs). The ESAs currently available in the United States are: epoetin alfa (distributed as Epogen® by Amgen, Inc., Thousand Oaks, CA; and Procrit® by Ortho Biotech, Johnson & Johnson, Raritan, NJ) and darbepoetin alfa (Aranesp® by Amgen, Inc.). Epoetin alfa and epoetin beta, which is available outside the United States, have the same biological activity as endogenous EPO. Darbepoetin alfa

differs from epoetin alfa by the addition of carbohydrate side chains that increase the half-life of darbepoetin alfa compared to epoetin alfa and endogenous EPO, allowing for less frequent dosing than that of epoetin alfa. All ESAs are equivalent in their efficacy and have a similar adverse-effect profile.

The most common adverse effect seen with ESA is increased blood pressure, which can occur in up to 23% of patients.[31] Antihypertensive agents may be required to control blood pressure in patients receiving ESAs. Caution should be used when initiating an ESA in patients with very high blood pressures (greater than 180/100 mm Hg). If blood pressures are refractory to antihypertensive agents, ESAs may need to be withheld.

Subcutaneous (SC) administration of ESA produces a more predictable and sustained response than IV administration, and is therefore the preferred route of administration for both agents. Intravenous administration is often utilized in patients who have established IV access or are receiving hemodialysis. Starting doses of ESAs depend on the patient's Hgb level, the target Hgb level, the rate of Hgb increase and clinical circumstances.[31] The initial increase in Hgb should be 1–2 g/dL (0.6206–1.2404 mmol/L) per month. The starting doses of epoetin alfa previously recommended are 80 to 120 units/kg per week for SC administration and 120 to 180 units/kg per week for IV administration, divided two to three times per week. The starting dose of darbepoetin alfa is 0.45 mcg/kg administered SC or IV once weekly (Table 23–3).

Iron Supplementation Use of ESAs can lead to iron deficiency if iron stores are not adequately maintained. If serum ferritin and TSAT fall below the goal levels, iron supplementation is required. Oral iron supplements are less costly than IV supplements and are generally the first-line treatment for iron supplementation. When administering iron by the oral route, 200 mg of elemental iron should be delivered daily to maintain adequate iron stores.

Oral iron supplementation is generally not effective in maintaining adequate iron stores in patients receiving ESAs because of poor absorption and an increased need for iron with ESA therapy, making the IV route necessary for iron supplementation. The IV iron products currently available are: iron dextran (distributed as INFeD® by Watson Pharmaceuticals, Inc., Morristown, NJ, and Dexferrum® by American Reagent, Inc., Shirley, NY); sodium ferric gluconate (Ferrlecit® by Watson Pharmaceuticals, Inc., Corona, CA); and iron sucrose (Venofer® by American Reagent, Inc., Shirley, NY). Initiation of IV iron should be based on evaluation of iron stores. A serum ferritin level less than 100 ng/mL in conjunction with a TSAT level less than 20% indicates absolute iron deficiency and is a clear indication for the need for iron replacement.[31] When TSAT is less than 20% in conjunction with normal or elevated serum ferritin levels, treatment should be based on the clinical picture of the patient, as serum ferritin is an acute phase reactant, which may become elevated with inflammation and stress. Iron supplementation may be indicated if Hgb levels are below the goal level.

When replacing iron stores in patients receiving ESA therapy, the general approach to treatment is to give a total of 1 g of IV iron, administered in smaller, sequential doses. Because iron stores deplete quickly in patients who do not receive iron supplementation, maintenance doses are often used, particularly in patients receiving hemodialysis. Maintenance doses consist of smaller doses of iron administered weekly or with each dialysis session (e.g., iron dextran or iron sucrose 20 to 100 mg per week; sodium ferric gluconate 62.5 to 125 mg per week).

Intravenous iron preparations are equally effective in increasing iron stores. Iron dextran has been associated with side effects, including anaphylactic reactions and delayed reactions, such as arthralgias and myalgias. A test dose of 25 mg iron dextran should be administered 30 minutes before the full dose to monitor for potential anaphylactic reactions. However, patients should be monitored closely when receiving iron dextran, as anaphylactic reactions can occur in patients who safely received prior doses of iron dextran. For this reason, use of iron dextran has decreased dramatically in CKD patients in favor of the newer iron preparations, sodium ferric gluconate and iron sucrose, which are associated with fewer severe reactions. The most common side effects seen with these preparations include hypotension, flushing, nausea, and injection site reactions. A test dose is not required prior to the administration of either sodium ferric gluconate or iron sucrose.

TABLE 23–3. Estimated Starting Doses of Darbepoetin Alfa Based on Previous Epoetin Alfa Dose

Previous Epoetin Alfa Dose (units/week)	Weekly Darbepoetin Alfa Dose (mcg/week)
Less than 2500	6.25
2500–4999	12.5
5000–10,999	25
11,000–17,999	40
18,000–33,999	60
34,000–59,999	100
60,000–89,999	150
Greater than or equal to 90,000	200

Outcome Evaluation

Evaluate Hgb every 1 to 2 weeks when ESA therapy is initiated or the dose is adjusted until Hgb is greater than 11 g/dL (6.82 mmol/L). Once goal Hgb is attained, evaluate Hgb every 2 to 4 weeks thereafter. While the patient is receiving ESA therapy, monitor iron stores monthly in patients who are not receiving iron supplements or every 3 months in patients who are receiving iron supplements. When the goal Hgb is reached, monitor iron stores every 3 months.

turnover lead to **renal osteodystrophy** (ROD). As many as 75% to 100% of patients with stage 3 CKD have ROD.[35] The type of bone disease can vary based on the degree of bone turnover. High bone turnover is the most common cause of bone abnormalities in patients with CKD, present in as many as 75% of patients receiving dialysis,[35] and is generally mediated by high levels of PTH. Adynamic bone disease, characterized by low bone turnover, is less common, although the prevalence appears to be increasing,[35] which may be related to more aggressive treatment of hyperparathyroidism. The development of ROD can dramatically affect morbidity in patients with CKD.

Pathophysiology

As renal function declines in patients with CKD, decreased phosphorus excretion disrupts the balance of calcium and phosphorus homeostasis. ❼ *The parathyroid glands release PTH in response to decreased serum calcium and increased serum phosphorus levels. The actions of PTH include:*

- *Increasing calcium resorption from bone*
- *Increasing calcium reabsorption from the proximal tubules in the kidney*
- *Decreasing phosphorus reabsorption in the proximal tubules in the kidney*
- *Stimulating activation of vitamin D by 1-α-hydroxylase to calcitriol (1,25-dihydroxyvitmin D_3) to promote calcium absorption in the GI tract and increased calcium mobilization from bone*

All of these actions are directed at increasing serum calcium levels and decreasing serum phosphorus levels, although the activity of calcitriol also increases phosphorus absorption in the GI tract and mobilization from the bone, which can worsen hyperphosphatemia. Calcitriol also decreases PTH levels through a negative feedback loop. These measures are sufficient to correct serum calcium levels in the earlier stages of CKD.

As kidney function continues to decline and the GFR falls less than 60 mL/minute/1.73 m^2, phosphorus excretion continues to decrease and calcitriol production decreases, causing PTH levels to begin to rise significantly, leading to **secondary hyperparathyroidism** (sHPT). The excessive production of PTH leads to hyperplasia of the parathyroid glands, which decreases the sensitivity of the parathyroid glands to serum calcium levels and calcitriol feedback, further promoting sHPT.

The most dramatic consequence of sHPT is alterations in bone turnover and the development of ROD. Other complications of CKD can also promote ROD. Metabolic acidosis decreases bone formation and aluminum toxicity causes aluminum uptake into bone in place of calcium, weakening the bone structure. The pathogenesis of sHPT and ROD are depicted in Fig. 23–5.

The increased serum phosphorus binds to calcium in the serum, which leads to deposition of hydroxyapatite crystals throughout the body. The calcium-phosphorus (Ca-P) product reflects serum solubility. A Ca-P product greater than 75 mg^2/dL^2 promotes crystal deposition in the joints and eye, leading to arthritis and conjunctivitis, respectively. Soft tissue deposition primarily affects the coronary arteries of the heart, lungs, and vascular tissue and is associated with a Ca-P product greater than 55 mg^2/dL^2.[36] The Ca-P product has been associated with increased mortality[37] and is a risk factor for calcification of vascular and soft tissues.[35]

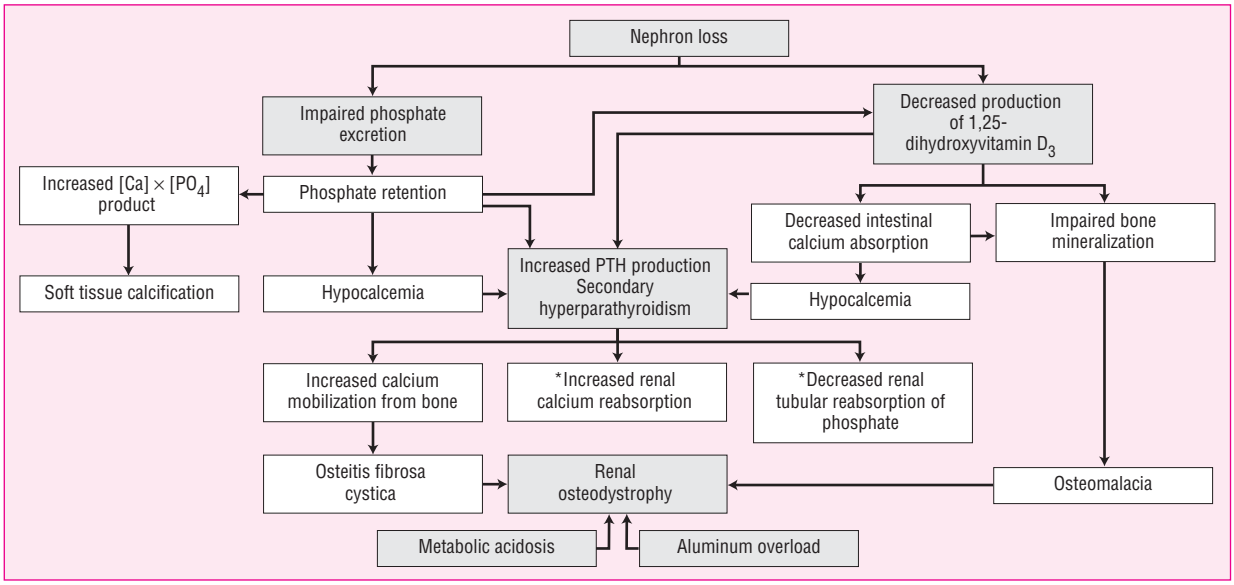

FIGURE 23–5. Pathogenesis of secondary hyperparathyroidism and renal osteodystrophy in patients with CKD. *These adaptations are lost as renal failure progresses. [Ca] × [PO_4] calcium-phosphorus product. (From Joy MS, Kshirsagar A, Paparello J. Chronic kidney disease: Progression-modifying therapies. Clinical Presentation of Secondary Hyperparathyroidism and Renal Osteodystrophy

General
Onset of sHPT and ROD is subtle and may not be associated with symptoms.

Symptoms
sHPT and ROD are usually asymptomatic in early disease.
Calcification in the joints can be associated with decreased range of motion.
Conjunctival calcifications are associated with a gritty sensation in the eyes, redness, and inflammation.

Signs
Cardiovascular: Increased stroke index, heart rate, and diastolic and mean arterial pressures
Musculoskeletal: Bone pain, muscle weakness
Dermatologic: Pruritus

Laboratory Tests
Increased serum phosphorus levels
Low to normal serum calcium levels
Increased Ca-P product
Increased PTH levels
Decreased vitamin D levels

Diagnostic Tests
Radiographic studies show calcium-phosphate deposits in joints and/or cardiovascular system
Bone biopsy of the iliac crest

Metabolic acidosis, a common complication of CKD, also contributes to ROD by altering the solubility of hydroxyapatite, promoting bone dissolution. Additionally, metabolic acidosis inhibits the activity of osteoblasts, which promote bone formation, while stimulating osteoclasts to promote bone resorption. Finally, metabolic acidosis can worsen sHPT by reducing the sensitivity of the parathyroid gland to serum calcium levels.[38]

Treatment

General Approach

℞ *Diagnosis and management of bone disease in CKD is based on corrected serum levels of calcium and phosphorus, the Ca-P (using corrected calcium levels), and intact PTH levels (iPTH).*[39] The target levels of each vary with the stage of CKD and are listed in Table 23–4. The primary target for treatment is control of serum phosphorus levels, as this is the initial parameter that disrupts homeostasis. However, serum phosphorus can be difficult to control, particularly in the latter stages of CKD. Management of sHPT often requires supplemental treatment in addition to phosphorus management.

Nonpharmacologic Therapy

The first-line treatment for the management of hyperphosphatemia is dietary phosphorus restriction to 800 to 1000 mg per day in patients with stage 3 CKD or higher who have phosphorus levels at the upper limit of the normal range or elevated iPTH levels.[39] Foods high in phosphorus are also high in protein, which can make it difficult to restrict phosphorus intake while maintaining adequate protein intake to avoid

TABLE 23–4. Target Levels for Calcium, Phosphorus, Calcium-Phosphorus Product, and Intact Parathyroid Hormone

Parameter	Stage 3 CKD	Stage 4 CKD	Stage 5 CKD
Corrected calcium	"Normal"	"Normal"	8.4–9.5 mg/dL (2.1–2.37 mmol/L)
Phosphorus	2.7–4.6 mg/dL (0.87–1.49 mmol/L)	2.7–4.6 mg/dL (0.87–1.49 mmol/L)	3.5–5.5 mg/dL (1.13–1.78 mmol/L)
Ca-P product	Less than 55 mg^2/dL^2	Less than 55 mg^2/dL^2	Less than 55 mg^2/dL^2
Intact PTH	35–70 pg/mL (35–70 ng/L)	70–110 pg/mL (70–110 ng/L)	150–300 pg/mL (150–300 ng/L)

Ca-P, calcium-phosphorus product; CKD, chronic kidney disease; PTH, parathyroid hormone.

malnutrition. Hemodialysis and peritoneal dialysis can remove up to 2 to 3 g of phosphorus per week. However, this is insufficient to control hyperphosphatemia and pharmacologic therapy is necessary in addition to dialysis treatment.

Other nonpharmacologic strategies to manage sHPT and ROD in patients with CKD include restriction of aluminum exposure and parathyroidectomy. Ingestion of aluminum-containing antacids and other aluminum-containing products should be avoided in patients with stage 4 CKD or higher (GFR less than 30 mL/minute/1.73m^2) because of the risk of aluminum toxicity and potential uptake into the bone. Purification techniques for dialysate solutions also minimize the risk of exposure to aluminum.

Parathyroidectomy is a treatment of last resort for sHPT, but should be considered in patients with persistently elevated iPTH levels above 800 pg/mL (800 ng/L) that is refractory to medical therapy to lower serum calcium and/or phosphorus levels.[39] A portion or all of the parathyroid tissue may be removed, and in some cases a portion of the parathyroid tissue may be transplanted into another site, usually the forearm. Bone turnover can be disrupted in patients undergoing parathyroidectomy whereby bone production outweighs bone resorption. The syndrome, known as "hungry bone syndrome," is characterized by excessive uptake of calcium, phosphorus, and magnesium for bone production, leading to hypocalcemia, hypophosphatemia, and hypomagnesemia. Serum ionized calcium levels should be monitored frequently (every 4 to 6 hours for the first 48 to 72 hours) in patients receiving a parathyroidectomy. Calcium supplementation is usually necessary, administered IV initially, then orally (with vitamin D supplementation) once normal calcium levels are attained for several weeks to months after the procedure.

Pharmacologic Therapy

Phosphate-Binding Agents When serum phosphorus levels cannot be controlled by restriction of dietary intake, phosphate-binding agents are used to bind dietary phosphate in the GI tract to form an insoluble complex that is excreted in the feces. Phosphorus absorption is decreased, thereby decreasing serum phosphorus levels. The drugs used for binding dietary phosphate are listed in Table 23–5. These agents should be administered with each meal and can be tailored to the amount of phosphorus that is typically ingested during each meal. For example, patients can take a smaller dose with smaller meals or snacks, and a larger dose with larger meals.

Calcium-based phosphate binders, including calcium carbonate and calcium acetate, are effective in decreasing serum phosphate levels, as well as increasing serum calcium levels. Calcium acetate binds more phosphorus than the carbonate salt, making it a more potent agent for binding dietary phosphate. Calcium citrate is usually not used as a phosphate-binding agent because the citrate salt can increase aluminum absorption. The calcium-containing phosphate binders also aid in the correction of metabolic acidosis, another complication of renal failure. Caution should be used with these agents if serum calcium levels are near the upper end of the normal range or are elevated because of the risk of increasing the Ca-P product and potentiating vascular and soft tissue calcifications. The dose of calcium-based phosphate binders should not provide more than 1500 mg of elemental calcium per day, and the total elemental calcium intake per day should not exceed 2000 mg, including medication and dietary intake.[39] The most common adverse effects of calcium-containing phosphate binders are constipation and hypercalcemia.

Phosphate-binding agents that do not contain calcium, magnesium, or aluminum include sevelamer hydrochloride and lanthanum carbonate. These agents are particularly useful in patients with hyperphosphatemia who have elevated serum calcium levels or who have vascular or soft tissue calcifications. Sevelamer is a cationic polymer that is not systemically absorbed and binds to phosphate in the GI tract, and prevents absorption and promotes excretion of phosphate through the GI tract via the feces. Sevelamer has an added benefit of reducing LDL-C by up to 30% and increasing HDL-C levels.[39] The most common side effects of sevelamer are GI complaints, including nausea, constipation, and diarrhea. The cost of sevelamer is significantly higher compared to calcium-containing phosphate binders, however, which often makes sevelamer a second-line agent for controlling phosphorus levels.

TABLE 23–5. Phosphate-Binding Agents Used in the Treatment of Hyperphosphatemia in CKD

Compound	Trade Name	Compound Content (mg)	Elemental Calcium Content (mg)	Starting Dose	Comments
Calcium carbonate (40% elemental calcium)	Tums	500, 750, 1000, 1250	200, 300, 400, 500	0.5–1 g (elemental calcium) three times a day with meals	First-line agent; dissolution characteristics and phosphorus-binding effect may vary from product to product; try to limit daily intake of elemental calcium to 1500 mg/day Approximately 39 mg phosphorus bound per 1 g calcium carbonate
	Oscal-500	1250	500		
	Caltrate 600	1500	600		
	Nephro-Calci	1500	600		
	LiquiCal	1200	480		
	CalciChew	1250	500		
Calcium acetate (25% elemental calcium)	Phos-Lo	667	167	0.5–1 g (elemental calcium) three times a day with meals	First-line agent; comparable efficacy to calcium carbonate with one-half the dose of elemental calcium; do not exceed 1500 mg elemental calcium intake per day Approximately 45 mg phosphorus bound per 1 g calcium acetate By prescription only
Sevelamer	Renagel	400, 800	—	800 mg three times a day with meals	First-line agent; lowers LDL-C More expensive than calcium products; preferred in patients at risk for extraskeletal calcification May require large doses to control phosphorus levels
Lanthanum	Fosrenol	250, 500 chewable tablets	—	750–1500 mg three times a day with meals	Second-line agent; more expensive than calcium products; preferred in patients at risk for extraskeletal calcification Most patients require 1500–3000 mg per day to control phosphorus
Aluminum hydroxide	Alterna GEL	600 mg/5 mL	—	300–600 mg three times a day with meals	Third-line agents; do not use concurrently with citrate-containing products Reserve for short-term use (4 weeks) in patients with hyperphosphatemia not responding to other binders
	Amphojel	300, 600 (tablet) 320 mg/5 mL (suspension)			
	Alu-Cap	400			
Aluminum carbonate	Basaljel	500 (tablet, capsule) 400 mg/5 mL (suspension)	—	450–500 mg three times a day with meals	Same as for aluminum hydroxide
Magnesium carbonate	Mag-Carb	70 (capsule)	—	70 mg three times a day with meals	Third-line agent; diarrhea common; monitor serum magnesium
Magnesium hydroxide	Milk of Magnesia	300, 600 (tablet) 400 mg/5 mL, 800 mg/5 mL (suspension)	—	300–400 mg three times a day with meals	Same as for magnesium carbonate
Magnesium carbonate/calcium carbonate	MagneBind 200	200 mg (elemental magnesium)	160	200 mg three times a day with meals	Same as for calcium carbonate and magnesium carbonate

LDL-C, low-density lipoprotein cholesterol.

Lanthanum is a naturally occurring trivalent rare earth element (atomic number 57). Lanthanum carbonate quickly dissociates in the acidic environment of the stomach, where the lanthanum ion binds to dietary phosphorus, forming an insoluble compound that is excreted in the feces. Lanthanum has been shown to remove more than 97% of dietary phosphorus from the GI tract.[40] Side effects of lanthanum include nausea, peripheral edema, and myalgias.

Aluminum- and magnesium-containing phosphate-binding agents are not recommended for chronic use in patients with CKD to minimize the risk of aluminum and magnesium accumulation. Aluminum-containing agents may be used for

a short course of therapy (less than 4 weeks) if phosphorus levels are significantly elevated greater than 7 mg/dL (2.26 mmol/L), but should be replaced by other phosphate-binding agents after no more than 4 weeks.[39] In addition to the risk of magnesium accumulation, the use of magnesium-containing agents is also limited by the GI side effects, primarily diarrhea.

Vitamin D Therapy Exogenous vitamin D compounds that mimic the activity of calcitriol act directly on the parathyroid gland to decrease PTH secretion. This is particularly useful when reduction of serum phosphorus levels does not sufficiently reduce PTH levels. The most active form of vitamin D is calcitriol (1,25-dihydroxyvitamin D_3), which is available commercially as an oral formulation (Rocaltrol® by Roche Laboratories, Inc., Nutley, NJ) and an injectable formulation (Calcijex® by Abbott Laboratories, North Chicago, IL). The effects of calcitriol are mediated by upregulation of the vitamin D receptor in the parathyroid gland, which decreases parathyroid gland hyperplasia and PTH synthesis and secretion. However, vitamin D receptor upregulation also occurs in the intestines, which increases calcium and phosphorus absorption, increasing the risk of hypercalcemia and hyperphosphatemia. It is important that serum calcium and phosphorus levels are within the normal range for the stage of CKD and the Ca-P product is less than 55 mg^2/dL^2 prior to starting calcitriol therapy.

Other vitamin D analogs available in the United States include paricalcitol (19-nor-1,25-dihydroxyvitamin D_2, Zemplar® by Abbott Laboratories, North Chicago, IL) and doxercalciferol (1-α-hydroxyvitamin D_2, Hectoral® by Bone Care International, Middleton, WI). Alfacalcidiol (1-α-hydroxyvitamin D_3) is only available outside the United States. Paricalcitol has less effect on vitamin D receptors in the intestines, decreasing the effects on intestinal calcium and phosphorus absorption, while retaining the effects on parathyroid gland hyperplasia and PTH synthesis and secretion.[41] This makes paricalcitol more useful in patients with an elevated Ca-P product. Doxercalciferol, on the other hand, has similar effects as calcitriol on vitamin D receptors in the parathyroid glands and intestines. Like calcitriol, calcium and phosphorus levels and the Ca-P product should be within the normal range for the stage of CKD prior to starting doxercalciferol. Recommendations for vitamin D analog therapy depend on the stage of CKD (Table 23–6).[39]

It is important to monitor vitamin D therapy aggressively to assure that PTH levels are not oversuppressed. Oversuppression of PTH levels can induce adynamic bone disease, which manifests as decreased osteoblast and osteoclast activity, decreased bone formation, and low bone turnover.

Calcimimetics

Cinacalcet is a calcimimetic that increases the sensitivity of receptors on the parathyroid gland to serum calcium levels to reduce PTH secretion. Cinacalcet may be beneficial in patients with an increased Ca-P product who have elevated PTH levels and cannot use vitamin D therapy. Because the effects of cinacalcet on PTH can reduce serum calcium levels and result in hypocalcemia, cinacalcet should not be used if serum calcium levels are below normal.

Reversal of Metabolic Acidosis

Studies have demonstrated that reversal of metabolic acidosis can improve bone disease associated with CKD.[38] Serum bicarbonate levels should be maintained at 22 mEq/L (22 mmol/L) in patients with bone disease associated with CKD.[39] The treatment of metabolic acidosis is described below.

TABLE 23–6. Dosing Recommendations for Vitamin D in Patients with CKD

Serum PTH (pg/mL)	Calcitriol Dose	Paricalcitol Dose	Doxercalciferol Dose
Stage 3 or 4 CKD			
70–300[a]	0.25 mcg orally daily	Not recommended	2.5 mg orally 3 times weekly
Stage 5 CKD on hemodialysis			
300–600[b]	0.5–1.5 mcg PO or intravenously per HD	2.5–5 mcg intravenously per HD	5 mcg orally per HD 2 mcg intravenously per HD
600–1000[b]	1–4 mcg orally per HD 1–3 mcg intravenously per HD	6–10 mcg intravenously per HD	5–10 mcg orally per HD 2–4 mcg intravenously per HD
Greater than 1000[c]	3–7 mcg orally per HD 3–5 mcg intravenously per HD	10–15 mcg intravenously per HD	10–20 mcg orally per HD 4–8 mcg intravenously per HD
Stage 5 CKD on peritoneal dialysis			
Greater than 300[b]	0.25 mcg orally daily 0.5–1 mcg orally 2–3 times weekly	Not recommended	2.5–5 mcg orally 2–3 times weekly

[a]If serum calcium less than 9.5 mg/dL (2.37 mmol/L), phosphorus less than 4.6 mg/dL (1.49 mmol/L), and Ca-P product less than 55 mg^2/dL^2
[b]If serum calcium less than 9.5 mg/dL (2.37 mmol/L), phosphorus less than 5.5 mg/dL (1.78 mmol/L), and Ca-P product less than 55 mg^2/dL^2
[c]If serum calcium less than 10 mg/dL (2.5 mmol/L), phosphorus less than 5.5 mg/dL (1.78 mmol/L), and Ca-P product less than 55 mg^2/dL^2
CKD, chronic kidney disease; HD, hemodialysis; PO, orally; PTH, parathyroid hormone.

Outcome Evaluation

Monitor serum calcium and phosphorus levels regularly in patients receiving phosphate-binding agents. When initiating therapy, monitor serum levels every 1 to 4 weeks, depending on the severity of hyperphosphatemia. Titrate doses of phosphate binders to achieve the target levels of serum calcium and phosphorus and the Ca-P product (Table 23–4). Once target levels are achieved, monitor serum calcium and phosphorus levels every 1 to 3 months. Monitor intact PTH levels monthly while initiating vitamin D therapy, then every 3 months once stable iPTH levels are achieved. When starting or increasing the dose of cinacalcet, monitor serum calcium and phosphorus levels within 1 week and iPTH levels should be monitored within 1 to 4 weeks. Once target levels are achieved, decrease monitoring to every 3 months.

Metabolic Acidosis

Epidemiology and Etiology

Approximately 80% of patients with a GFR less than 20 to 30 mL/minute develop metabolic acidosis.[38] Metabolic acidosis can increase protein catabolism and decrease albumin synthesis, which promote muscle wasting, and alter bone metabolism. Other consequences associated with metabolic acidosis in CKD include worsening cardiac disease, impaired glucose tolerance, altered growth hormone and thyroid function, and inflammation.[38]

Pathophysiology

The kidneys play a key role in the management of acid-base homeostasis in the body by regulating excretion of hydrogen ions. With normal kidney function, bicarbonate that is freely filtered through the glomerulus is completely reabsorbed via the renal tubules. Hydrogen ions are generated at a rate of 1 mEq/kg (1 mmol/kg) per day during metabolism of ingested food and are excreted at the same rate by the kidney via buffers in the urine created by ammonia generation and phosphate excretion. As a result, the pH of body fluids is maintained within a very narrow range.

As kidney function declines, bicarbonate reabsorption is maintained, but hydrogen excretion is decreased because the ability of the kidney to generate ammonia is impaired. The positive hydrogen balance leads to metabolic acidosis, which is characterized by a serum bicarbonate level of 15 to 20 mEq/L (15 to 20 mmol/L). This picture is generally seen when the GFR declines below 20 to 30 mL/minute.[38]

Treatment

Serum electrolytes should be monitored in patients with CKD for the development of metabolic acidosis. Metabolic acidosis in patients with CKD is generally characterized by an elevated anion gap greater than 17 mEq/L (17 mmol/L), due to the accumulation of phosphate, sulfate, and other organic anions.

Nonpharmacologic Therapy

Treatment of metabolic acidosis in CKD requires pharmacologic therapy. Other disorders that may contribute to metabolic acidosis should also be addressed. Altering bicarbonate levels in the dialysate fluid in patients receiving dialysis may assist with the treatment of metabolic acidosis, although pharmacologic therapy may still be required.

Pharmacologic Therapy

Pharmacologic therapy with sodium bicarbonate or citrate/citric acid preparations may be needed in patients with stage 3 CKD or higher to replenish body stores of bicarbonate. Calcium carbonate and calcium acetate, used to bind phosphorus in sHPT, also aid in increasing serum bicarbonate levels, in conjunction with other agents.

Sodium bicarbonate tablets are administered in increments of 325 and 650 mg tablets. A 650 mg tablet of sodium bicarbonate contains 7.7 mEq (7.7 mmol) each of sodium and bicarbonate. Sodium retention associated with sodium bicarbonate can cause volume overload, which can exacerbate hypertension and chronic heart failure. Patient tolerability of sodium bicarbonate is low because of carbon dioxide production in the GI tract that occurs during dissolution.

Solutions that contain sodium citrate/citric acid (Shohl's solution and Bicitra) provide 1 mEq/L (1 mmol/L) each of sodium and bicarbonate. Polycitra is a sodium/potassium citrate solution that provides 2 mEq/L (2 mmol/L) of bicarbonate, but contains 1 mEq/L (1 mmol/L) each of sodium and potassium, which can promote hyperkalemia in patients with severe CKD. The citrate portion of these preparations is metabolized in the liver to bicarbonate, while the citric acid portion is metabolized to CO_2 and water, increasing tolerability compared to sodium bicarbonate. Sodium retention is also decreased with these preparations. However, these products are liquid preparations, which may not be palatable to some patients. Citrate can also promote aluminum toxicity by augmenting aluminum absorption in the GI tract.

When determining the dose of bicarbonate replacement, the goal for therapy is to achieve a normal serum bicarbonate level of 24 mEq/L (24 mmol/L). The dose is usually determined by calculating the base deficit: [0.5 L/kg × (body weight)] × [(normal CO_2) – (measured CO_2)]. Because of the risk of volume overload resulting from the sodium load administered with bicarbonate replacement, the total base deficit should be administered over several days. Once the goal serum bicarbonate level is attained, a maintenance dose of bicarbonate is necessary and should be titrated to maintain serum bicarbonate levels.

Outcome Evaluation

Monitor serum electrolytes and arterial blood gases regularly. Correct metabolic acidosis slowly to prevent the development of metabolic alkalosis or other electrolyte abnormalities.

Other Therapeutic Considerations in CKD

Uremic Bleeding

Uremia can lead to a number of alterations in clotting ability, resulting in hemorrhage. Bleeding complications associated with CKD include ecchymoses, prolonged bleeding from mucous membranes and puncture sites used for blood collection and hemodialysis, GI bleeding, intramuscular bleeding, and others. Most bleeding complications associated with CKD are mild. However, serious bleeding events, including GI bleeds and intracranial hemorrhage, can occur.

Pathophysiology

Uremia alters a number of mechanisms that contribute to bleeding. Platelet function and aggregation is altered through decreased production of thromboxane.[42] Platelet–vessel wall interactions are also altered in patients with uremia because of decreased activity of von Willebrand factor.[42] and are exacerbated by anemia in CKD patients. With a normal RBC count in the plasma, platelets skim the surface of the endothelial tissue in the blood vessels. In patients with anemia, RBC count is decreased and platelets circulate closer to the center of the vessels, which decreases the interaction with the vessel wall. The risk of bleeding is increased in patients receiving hemodialysis. Anticoagulants administered to prevent or treat clotting during hemodialysis or in vascular access sites, including heparin, warfarin, aspirin, and clopidogrel, exacerbate the risk of bleeding in these patients.

Treatment

Nonpharmacologic Therapy The incidence and severity of bleeding associated with uremia has decreased since dialysis has become the mainstay of treatment for ESRD. Dialysis initiation improves platelet function and reduces bleeding time.[42] Improved care of the patient with ESRD, with anemia treatment and improvement in nutritional status, are also likely contributors to decreased uremic bleeding.

Pharmacologic Therapy Treatments used to decrease bleeding time in patients with uremic bleeding include cryoprecipitate, which contains various components important in platelet aggregation and clotting, such as von Willebrand factor and fibrinogen. Cryoprecipitate decreases bleeding time within 1 hour in 50% of patients. However, cost and the risk of infection have limited the use of cryoprecipitate.

Desmopressin (DDAVP) increases the release of factor VIII (von Willebrand factor) from endothelial tissue in the vessel wall. Bleeding time is promptly reduced, within 1 hour of administration, and is sustained for 4 to 8 hours.[42] Doses used for uremic bleeding are 0.3 to 0.4 mcg/kg intravenously over 20 to 30 minutes, 0.3 mcg/kg subcutaneously, or 2 to 3 mcg/kg intranasally. Repeated doses can cause tachyphylaxis by depleting stores of von Willebrand factor. Side effects of DDAVP include flushing, dizziness, and headache.

Estrogens have also been used to decrease bleeding time. The onset of action is slower than that of DDAVP, but more sustained, and depends on the route of administration. Intravenous doses of 0.6 mg/kg per day for 4 to 5 days decreases bleeding time within 6 hours of administration, and produces an effect that lasts up to 2 weeks after stopping therapy. The onset of action with oral doses of 50 mg/kg daily is within 2 days of treatment and is sustained for 4 to 5 days after stopping therapy. Transdermal patches providing 50 to 100 mcg per day have also been shown to be effective in decreasing bleeding time.[42] Side effects of estrogen use include hot flashes, fluid retention, and hypertension.

Pruritus

Pruritus can affect 25% to 86% of patients with advanced stages of CKD, and is not related to the cause of renal failure.[43] Pruritus can be significant and has been linked to mortality in patients receiving hemodialysis.[43]

Pathophysiology

The cause of pruritus is unknown, although several mechanisms have been proposed. Vitamin A is known to accumulate in the skin and serum of patients with CKD, but a definite correlation with pruritus has not been established. Histamine may also play a role in the development of pruritus, which may be linked to mast cell proliferation in patients receiving hemodialysis. Hyperparathyroidism has also been suggested as a contributor to pruritus, despite the fact that serum PTH levels do not correlate with itching. Accumulation of divalent ions, specifically magnesium and aluminum, may also play a role in pruritus in patients with CKD. Other theories that have been proposed include inadequate dialysis, dry skin, peripheral neuropathy, and opiate accumulation.[43]

Treatment

Nonpharmacologic Therapy Pruritus associated with CKD is difficult to alleviate. It is important to evaluate other potential dermatologic causes of pruritus to maximize the potential for relief. Adequate dialysis is generally the first line of treatment in patients with pruritus. However, this has not been shown to decrease the incidence of pruritus significantly. Maintaining proper nutritional intake, especially with regard to dietary phosphorus and protein intake, may lessen the degree or occurrence of pruritus. Patients who do not attain relief from other measures may benefit from ultraviolet B phototherapy.

Pharmacologic Therapy Topical emollients have been used as treatment for pruritus in patients with dry skin, but are often not effective in relieving pruritus associated with CKD. Antihistamines, such as hydroxyzine 25 to 50 mg or diphenhydramine 25 to 50 mg orally or intravenously, are used as

first-line oral agents used to treat pruritus. Cholestyramine has also been used at doses of 5 g twice daily. Oral activated charcoal has also been used in doses of 1 to 1.5 g four times daily with some demonstrated efficacy. Other therapies that are often used in combination with other agents include oral ondansetron or naltrexone and topical capsaicin. Each has been reported to have efficacy in the treatment of pruritus associated with CKD.

Vitamin Replacement

Water-soluble vitamins removed by hemodialysis (HD) contribute to malnutrition and vitamin deficiency syndromes. Patients receiving HD often require replacement of water-soluble vitamins to prevent adverse effects. The vitamins that may require replacement are ascorbic acid, thiamine, biotin, folic acid, riboflavin, and pyridoxine. Patients receiving HD should receive a multivitamin B complex with vitamin C supplement, but should not take supplements that include fat-soluble vitamins, such as vitamins A, E, or K, which can accumulate in patients with renal failure.

RENAL REPLACEMENT THERAPY

Patients who progress to ESRD require renal replacement therapy (RRT). The modalities that are used for RRT are dialysis, including HD and peritoneal dialysis (PD), and kidney transplantation. The United States Renal Data Service (USRDS) reported that the number of patients with ESRD was 452,957, with 102,567 new cases being diagnosed in 2003.[2] The most common form of RRT is dialysis, accounting for 72% of all patients with ESRD. The principles and complications associated with dialysis are discussed below. Chapter 52 discusses the principles of kidney transplantation.

Indications for Dialysis

❾ *Planning for dialysis should begin when creatinine clearance falls* less than *30 mL/minute/1.73 m^2 (stage 4 CKD),*[1] *when progression to ESRD is inevitable, to allow time to educate the patient and family on the treatment modalities and establish the appropriate access for the modality of choice.* Ideally, initiation of dialysis should be done at a point when the patient is ready to undergo treatment, rather than when the patient is in emergent need of dialysis.

Initiation of dialysis is dependent on the patient's clinical status. Symptoms that may indicate the need for dialysis include persistent anorexia, nausea, vomiting, fatigue, and pruritus. Other criteria that indicate the need for dialysis include declining nutritional status, declining serum albumin levels, uncontrolled hypertension, and volume overload, which may manifest as chronic heart failure, and electrolyte abnormalities, particularly hyperkalemia. Blood urea nitrogen (BUN) and serum creatinine (SCr) levels may be used as a guide for the initiation of dialysis, but should not be the absolute indicator. Dialysis is initiated in most patients when the GFR falls below 15 mL/minute/1.73 m^2.[1] Patient should determine which modality of dialysis to use based on their own preferences. Advantages and disadvantages of hemodialysis and peritoneal dialysis are listed in Tables 23–7 and 23–8, respectively.

Patient Encounter, Part 4

The patient presents to clinic several years later and complains that she "feels lousy." She states that she doesn't feel like eating and has lost 20 pounds (9 kg) in the last 6 months.

Current Meds
Furosemide 80 mg orally twice daily
Metolazone 5 mg orally twice daily
Lisinopril 40 mg orally daily
Metoprolol 75 mg orally twice daily
Insulin glargine 30 units subcutaneously at bedtime
Insulin lispro subcutaneously per sliding scale with meals
Darbepoetin 100 mcg subcutaneously weekly
Iron polysaccharide 150 mg orally daily
Sevelamer 800 mg orally three times daily with meals
Calcitriol 0.25 mcg orally daily
Sodium bicarbonate 1300 mg orally three times daily

ROS
Unremarkable

PE
VS: Blood pressure 160/85 mm Hg, pulse 70 beats per minute, temperature 36.8°C (98.2°F), Wt 150 lb (68.2 kg)
Chest: Regular rate and rhythm, normal S_1, S_3 and S_4 both present; slight pericardial friction rub
Exts: 3+ bilateral lower extremity edema which is present half-way up her calf

Labs
Sodium 142 mEq/L (142 mmol/L); potassium 5.8 mEq/L (5.8 mmol/L); chloride 102 mEq/L (102 mmol/L); carbon dioxide 16 mEq/L (16 mmol/L); BUN 85 mg/dL (30.34 mmol/L urea); SCr 9.5 mg/dL (839.8 µmol/L); glucose 112 mg/dL (6.22 mmol/L); calcium 8.2 mg/dL (2.05 mmol/L); phosphate 5.8 mg/dL (1.87 mmol/L); iPTH 438 pg/mL (1.87 ng/L); WBC 5.3 × 10^3 cells/mm^3 (5.3 × 10^9/L); RBC 3.2 × 10^3 cells/mm^3 (3.2 × 10^{12}/L); Hgb 9.8 g/dL (6.08 mmol/L); Hct 29% (0.29); platelets 390 × 10^3 cells/mm^3 (390 × 10^9/L)

- What indications does the patient have for dialysis?
- What alternatives for renal replacement therapy exist for the patient?
- What are the advantages and disadvantages of each modality for renal replacement?

TABLE 23–7. Advantages and Disadvantages of Hemodialysis

Advantages

1. Higher solute clearance allows intermittent treatment.
2. Parameters of adequacy of dialysis are better defined and therefore underdialysis can be detected early.
3. The technique's failure rate is low.
4. Even though intermittent heparinization is required, hemostasis parameters are better corrected with hemodialysis than peritoneal dialysis.
5. In-center hemodialysis enables closer monitoring of the patient.

Disadvantages

1. Requires multiple visits each week to the hemodialysis center, which translates into loss of control by the patient.
2. Dysequilibrium, dialysis, hypotension, and muscle cramps are common. May require months before patient adjusts to hemodialysis.
3. Infections in hemodialysis patients may be related to the choice of membranes, the complement-activating membranes being more deleterious.
4. Vascular access is frequently associated with infection and thrombosis.
5. Decline of residual renal function is more rapid compared to peritoneal dialysis.

From Elwell RJ, Foote EF. Hemodialysis and peritoneal dialysis. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 852, with permission.

TABLE 23–8. Advantages and Disadvantages of Peritoneal Dialysis

Advantages

1. More hemodynamic stability (blood pressure) due to slow ultrafiltration rate.
2. Increased clearance of larger solutes, which may explain good clinical status in spite of lower urea clearance.
3. Better preservation of residual renal function.
4. Convenient intraperitoneal route of administration of drugs such as antibiotics and insulin.
5. Suitable for elderly and very young patients who may not tolerate hemodialysis well.
6. Freedom from the "machine" gives the patient a sense of independence (for continuous ambulatory peritoneal dialysis).
7. Less blood loss and iron deficiency, resulting in easier management of anemia or reduced requirements for erythropoietin and parenteral iron.
8. No systemic heparinization requirement.
9. Subcutaneous versus intravenous erythropoietin or darbepoetin is usual, which may reduce overall doses and be more physiologic.

Disadvantages

1. Protein and amino acid losses through the peritoneum and reduced appetite owing to continuous glucose load and sense of abdominal fullness predispose to malnutrition.
2. Risk of peritonitis.
3. Catheter malfunction, and exit site and tunnel infection.
4. Inadequate ultrafiltration and solute dialysis in patients with a large body size, unless large volumes and frequent exchanges are employed.
5. Patient burnout and high rate of technique failure.
6. Risk of obesity with excessive glucose absorption.
7. Mechanical problems such as hernias, dialysate leaks, hemorrhoids, or back pain may occur.
8. Extensive abdominal surgery may preclude peritoneal dialysis.
9. No convenient access for intravenous iron administration.

From Elwell RJ, Foote EF. Hemodialysis and peritoneal dialysis. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 853, with permission.

The goals of dialysis are to remove toxic metabolites to decrease uremic symptoms, correct electrolyte abnormalities, restore acid-base status, and maintain volume status to ultimately improve quality of life and decrease the morbidity and mortality associated with ESRD.

Hemodialysis

Principles of Hemodialysis

⓾ *Hemodialysis (HD) involves the exposure of blood to a semipermeable membrane (dialyzer) against which a physiologic solution (dialysate) is flowing.* The dialyzer is composed of thousands of capillary fibers made up of the semipermeable membrane, which are enclosed in the dialyzer, to increase the surface area of blood exposure to maximize the efficiency of removing substances. The dialysate is composed of purified water and electrolytes, and is run through the dialyzer countercurrent to the blood on the other side of the semipermeable membrane. The process allows for the removal of several substances from the bloodstream, including water, urea, creatinine, uremic toxins, and drugs. Although the dialysate is not sterilized, the membrane prevents bacteria from entering into the bloodstream. However, if the membrane ruptures during hemodialysis, infection becomes a major concern for the patient.

Three types of membranes used for dialysis are classified by the size of the pores and the ability to remove solutes from the bloodstream. Conventional (standard) membranes have small pores, which limit solute removal to relatively small molecules, such as creatinine and urea. High-efficiency membranes also have small pores, but have a higher surface area that increases removal of small molecules, such as water, urea, and creatinine from the blood. High-flux membranes have larger pores that allow for the removal of high-molecular-weight substances, including some drugs, such as vancomycin.

Three primary processes are utilized for the removal of substances from the blood. Diffusion is the movement of a solute across the dialyzer membrane from an area of higher concentration (usually the blood) to a lower concentration (usually the dialysate). This process is the primary means for small molecules to be removed from the bloodstream, such as electrolytes. At times, solutes can be added to the dialysate that are diffused into the bloodstream. Changing the composition of the dialysate allows for control of the amount of electrolytes

that are being removed. Ultrafiltration is the movement of solvent (plasma water) across the dialyzer membrane by applying hydrostatic or osmotic pressure, and is the primary means for removing water from the bloodstream. Changing the hydrostatic pressure applied to the dialyzer or the osmotic concentration of the dialysate allows for control of the amount of water being removed. Convection is the movement of dissolved solutes across the dialyzer membrane by "dragging" the solutes along a pressure gradient with a fluid transport and is the primary means for larger molecules to be removed from the bloodstream, such as urea. Changing the pore size of the dialyzer membrane alters the efficiency of convection and allows for control of the amount of water removed in relation to the amount of solute being removed.

Vascular Access

Long-term permanent access to the bloodstream is a key component of HD. There are three primary techniques used to obtain permanent vascular access in patients receiving HD. Arteriovenous fistula (AVF) is the preferred access method because it has the longest survival rate and the fewest complications.[44] An AVF is made by creating an anastomosis between an artery and a vein, usually in the forearm of the non-dominant arm. An arteriovenous graft (AVG) results in a similar access site, but uses a synthetic graft, usually made of polytetrafluoroethylene, to connect the artery and vein in the forearm. The advantages of the AVG is that it is able to be used within 2 to 3 weeks, compared to 2 to 3 months for an AVF. However, AVGs are complicated by stenosis, thrombosis, and infections, which lead to a shorter survival time of the graft. Double-lumen venous catheters, placed in the femoral, subclavian, or jugular vein, are often used as temporary access while waiting for the AVF or AVG to mature. The catheters are tunneled beneath the skin to an exit site to reduce the risk of infection. Venous catheters can also be used as permanent access in patients in whom arteriovenous access cannot be established.

Complications of Hemodialysis

Complications associated with HD include hypotension, myalgia, thrombosis, and infection.

Hypotension

Hypotension is the most common complication seen during hemodialysis. It has been reported to occur with approximately 10% to 30% of dialysis sessions, but may be as frequent as 50% of sessions in some patients.[46]

Pathophysiology Hypotension associated with hemodialysis manifests as a symptomatic sudden drop of more than 30 mm Hg in mean arterial or systolic pressure or a systolic pressure drop to less than 90 mm Hg during the dialysis session. The primary cause is fluid removal from the bloodstream. Ultrafiltration removes fluid from the plasma, which promotes redistribution of fluids from extracellular spaces into the plasma. However, decreased serum albumin levels and removal of solutes from the bloodstream decrease the osmotic pressure of the plasma relative to the extracellular spaces, slowing redistribution during hemodialysis.[45] The decreased plasma volume causes hypotension. Other factors that can contribute to hypotension include antihypertensive medications prior to HD, a target dry weight that is too low, diastolic or autonomic dysfunction, low dialysate calcium or sodium, high dialysate temperature, or ingesting meals prior to HD.

Risk factors that may increase the potential for hypotension include elderly age, diabetes, autonomic neuropathy, uremia, and cardiac disease.[46] The symptoms associated with hypotension during dialysis include dizziness, nausea, vomiting, sweating, and chest pain.

Treatment Nonpharmacologic management of acute hypotension that occurs during dialysis involves placing the patient in the Trendelenburg position (with the head lower than the feet) and decreasing the ultrafiltration rate. Pharmacologic management of acute hypotension during dialysis includes administration of normal saline (100 to 200 mL), hypertonic saline (23.4%, 10 to 20 mL), or mannitol (12.5 g) to restore intravascular volume.

Preventive measures for patients who may be prone to hypotension include accurate determination of the "dry weight" and maintaining a constant ultrafiltration rate. Midodrine is an α-adrenergic agonist that is effective in reducing hypotension in patients with autonomic dysfunction that is taken with each dialysis session or as chronic therapy. Midodrine can be administered at doses of 2.5 to 10 mg prior to HD or 5 mg twice daily for chronic hypotension. Side effects of midodrine include pruritus and paresthesias.

Hypotension may be related to alterations in levocarnitine levels during dialysis. Patients who have low levels of levocarnitine may benefit from supplementation. Levocarnitine is administered as doses of 20 mg/kg intravenously at the end of each dialysis session. However, levocarnitine should not be used as a first-line agent for the treatment of hypotension because of the significant cost associated with the treatment. Patients receiving levocarnitine should be evaluated every 3 months for response to therapy.[47] Other preventive measures that have not been well studied include caffeine, sertraline, or fludrocortisone.

Muscle Cramps

Pathophysiology Muscle cramps can occur with up to 20% of dialysis sessions.[48] The cause is often related to excessive ultrafiltration, which causes hypoperfusion of the muscles. Other contributing factors to the development of muscle cramps include hypotension and electrolyte and acid-base imbalances that occur during hemodialysis sessions.

Treatment Nonpharmacologic treatments of muscle cramping that occurs during hemodialysis include decreasing the ultrafiltration rate and accurately determining the "dry weight." Pharmacologic measures include vitamin E, which is administered at doses of 400 IU daily. Other options that are not as well studied include oxazepam and prazosin.

Thrombosis

Thrombosis associated with hemodialysis most commonly occurs in patients with venous catheter access for dialysis and is a common cause of catheter failure. However, thrombosis can occur in synthetic grafts and less frequently in AV fistulas.

Nonpharmacologic management of thrombosis in a hemodialysis catheter involves saline flushes. Smaller clots may be managed by balloon angioplasty to mechanically open the catheter. In severe cases in whom clots cannot be removed by either mechanical or pharmacologic therapy, the catheter may require replacement.

Pharmacologic management of thrombosis includes local administration of thrombolytic agents. Alteplase (2 mg per port) and reteplase (0.5 unit per port) are the two most commonly used agents today. Urokinase has been used in the past, but after its reintroduction to the United States market, the larger dosed vial size makes it less cost effective than the newer agents.

Infection

Infections are an important cause of morbidity and mortality in patients receiving hemodialysis. The cause of infection is usually related to organisms found on the skin, namely *Staphylococcus epidermidis* and *S. aureus*. Other organisms have also been found to cause access-related infections. The greatest risk to patients receiving hemodialysis is the development of bacteremia. As with thrombosis, venous catheters are most commonly infected, followed by synthetic AV grafts, and finally AV fistulas.

Blood cultures should be obtained for any patient receiving hemodialysis who develops a fever. Nonpharmacologic management of infections involves preventive measures with sterile technique, proper disinfection, and minimizing the use and duration of venous catheters for hemodialysis access.

Pharmacologic management of infections should cover the gram-positive organisms that most frequently cause access-related infections. Patients who have positive blood cultures should receive treatment tailored to the organism isolated. Preventive measures for access-related infections include mupirocin at the exit site and povidone-iodine ointment. The recommendations of the NKF for treatment of infections associated with hemodialysis are listed in Table 23–9.

Peritoneal Dialysis

Principles of Peritoneal Dialysis

Peritoneal dialysis (PD) utilizes similar principles as hemodialysis in that blood is exposed to a semipermeable membrane against which a physiologic solution is placed. In the case of PD, however, the semipermeable membrane is the peritoneal membrane, and a sterile dialysate is instilled into the peritoneal cavity. The peritoneal membrane is composed of a continuous single layer of mesothelial cells that covers the abdominal and pelvic walls on one side of the peritoneal cavity, and the visceral organs, including the GI tract, liver, spleen, and diaphragm on the other side. The mesothelial cells are covered by microvilli that increase the surface area of the peritoneal membrane to approximate body surface area (1 to 2 m^2).

TABLE 23–9. Management of Hemodialysis Access Infections

AV fistula	Treat as subacute bacterial endocarditis for 6 weeks Initial antibiotic choice should always cover gram-positive organisms (e.g., vancomycin 20 mg/kg intravenously with serum concentration monitoring or cefazolin 20 mg/kg intravenously 3 times per week) Gram-negative coverage is indicated for patients with diabetes, HIV infection, prosthetic valves, or those receiving immunosuppressive agents (gentamicin 2 mg/kg intravenously with serum concentration monitoring).
Synthetic Grafts (AVG)	
Local infection	Empiric antibiotic coverage for gram-positive, gram-negative, and *Enterococcus* (e.g., gentamicin plus vancomycin, then individualize after culture results become available); continue for 2–4 weeks
Extensive infection	Antibiotics as above plus total resection
Access less than 1 month old	Antibiotics as above plus removal of the graft
Tunneled Cuffed Catheters (Internal Jugular, Subclavian)	
Infection localized to catheter exit site	No drainage: topical antibiotics (e.g., mupirocin ointment) Drainage present: gram-positive coverage (e.g., cefazolin 20 mg/kg IV 3 times per week)
Bacteremia with or without systemic signs or symptoms	Gram-positive coverage as above If stable and asymptomatic, change catheter and provide culture-specific antibiotic coverage for a minimum of 3 weeks.

AV, arteriovenous; HIV, human immunodeficiency virus; IV, intravenous.

Blood vessels that supply the abdominal organs, muscle, and mesentery serve as the blood component of the system.

The gaps between the mesothelial cells allow for large solutes to pass through into the bloodstream. Both the interstitium and endothelial cells of the blood vessels provide resistance to limit the solute size that is removed from the blood. Diffusion is the most important component of solute transport in PD, which is enhanced by the large surface area and volume of dialysate, as well as contact time with the peritoneal membrane. Ultrafiltration is achieved in PD by creating an osmotic pressure gradient between the dialysate and the blood. Traditionally, glucose has been used to create the osmotic gradient, but the solutions are not biocompatible with the peritoneal membrane, resulting in cytotoxicity of the cells. More recently, polymeric glucose derivatives, such as icodextrin, have been used to create a colloid-driven osmosis that results in ultrafiltration and convection of solute removal.

In PD, prewarmed dialysate is instilled into the peritoneal cavity where it "dwells" for a specified length of time (usually one to several hours, depending on the type of PD) to adequately clear metabolic waste products. At the end of the dwell time, the dialysate is drained and replaced with fresh dialysate. The continuous nature of PD provides for a more physiologic removal of waste products from the bloodstream, which mimics endogenous renal function by decreasing the fluctuations seen in serum concentrations of the waste products. Similarly, water is removed at a more constant rate, lessening the fluctuations in intravascular fluid balance and providing for more hemodynamic stability.

There are several types of PD that are used. The most common is continuous ambulatory peritoneal dialysis (CAPD), which requires the patient to exchange 1 to 3 L of dialysate four to six times per day. Exchanges are generally done every 4 to 6 hours throughout the day with a longer dwell time overnight. Automated peritoneal dialysis (APD) procedures involve the use of a cycler machine that performs sequential exchanges overnight while the patient is sleeping. Continuous cycling PD (CCPD) performs three to five exchanges throughout the night. The final exchange remains in the peritoneal cavity to dwell for the duration of the day. Nightly intermittent PD (NIPD) performs six to eight exchanges throughout the night. The final exchange of dialysate is drained in the morning and the peritoneal cavity remains empty throughout the day. Nocturnal tidal PD (NTPD) is similar to NIPD, with the exception that only a portion of the dialysate is exchanged throughout the night. The final exchange is drained in the morning and the peritoneal cavity remains empty throughout the day.

Peritoneal Access

Access to the peritoneal cavity requires placement of an indwelling catheter. There are several types of indwelling catheters available, but all require placement of the distal end into the peritoneal cavity. The central portion of the catheter is generally tunneled under the abdominal wall and subcutaneous tissue where it is held in place by cuffs that provide stability and mechanical support to the catheter. The proximal portion of the catheter exits the abdomen near the umbilicus. Placement and handling of the catheter during PD exchanges requires a sterile environment to minimize the risk of infectious complications.

Complications of Peritoneal Dialysis

Complications associated with PD include mechanical problems related to the PD catheter, metabolic problems associated with the components of the dialysate fluid, damage to the peritoneal membrane, and infections (Table 23–10). Strategies to manage infectious complications of PD are discussed below.

Peritonitis

Peritonitis is a leading cause of morbidity in PD patients, which often leads to loss of the catheter and subsequent change to HD as the treatment modality. However, recent advances with connectors used during instillation and drainage of dialysate and delivery systems have dramatically decreased the incidence of peritonitis. Peritonitis can be caused by chemical irritation or microorganisms.

TABLE 23–10. Common Complications during Peritoneal Dialysis

Mechanical Complications
Kinking in catheter
Catheter migration
Catheter adherence to peritoneal tissue
Excessive movement of catheter at exit site
Peritoneal Damage
Alterations in permeability of the peritoneal membrane
Sclerosis of the peritoneal membrane
Pain
Impingement of the catheter tip on visceral organs
Instillation pain
Rapid inflow of dialysate
Acidic pH of dialysate
Chemical irritation from dialysate additives (e.g., antibiotics)
Low dialysate temperature
Infections
Peritonitis
Exit-site infections
Tunnel infections
Metabolic Complications
Exacerbation of diabetes mellitus from glucose load
Fluid overload
Exacerbation of chronic heart failure
Edema
Pulmonary congestion
Electrolyte abnormalities
Malnutrition
Albumin and amino acid loss
Muscle wasting
Increased adipose tissue
Fibrin formation in dialysate

Pathophysiology Gram-positive organisms, namely *S. epidermidis*, are the most common cause of peritonitis. Other pathologic organisms include *S. aureus*, streptococcal species, enterococcus species, gram-negative organisms including *Escherichia coli* and *Pseudomonas* species, and fungal organisms. Peritonitis should be presumed if cloudy fluid is drained from the peritoneal cavity and the fluid should be evaluated by cultures. Antibiotic treatment should be initiated immediately, until cell counts and cultures prove otherwise.[49] Patients with peritonitis may also complain of abdominal pain, although pain may be absent in some cases.

Treatment The International Society of Peritoneal Dialysis (ISPD) revised the recommendations for the treatment of PD-related infections in 2005.[49] Drug selection for empiric treatment of peritonitis should cover both gram-positive and gram-negative organisms specific to the dialysis center and be based on the protocols and sensitivity patterns of organisms known to cause peritonitis, as well as the history of infections in the patient. First-generation cephalosporins, such as cefazolin, or vancomycin are recommended for empiric coverage of gram-positive organisms. Appropriate coverage for gram-negative organisms includes third- or fourth-generation cephalosporins, such as ceftazidime or cefepime, or aminoglycosides. Alternatives for gram-negative coverage include amikacin and oral fluoroquinolones. An example of an appropriate empiric treatment for peritonitis includes cefazolin in combination with ceftazidime, cefepime, or an aminoglycoside. If the patient has a cephalosporin allergy, vancomycin in combination with an aminoglycoside is an alternative empiric treatment.[49]

The preferred route of administration is intraperitoneal (IP) rather than IV to achieve maximum concentrations at the site of infection. Antibiotics can be administered IP intermittently as a single large dose in one exchange per day or continuously as multiple smaller doses with each exchange. Intermittent administration requires at least 6 hours of dwell time in the peritoneal cavity to allow for adequate systemic absorption and provides adequate levels to cover the 24-hour period. However, continuous administration is better suited for PD modalities that require more frequent exchanges (less than 6-hour dwell time). The reader should refer to the ISPD guidelines for dosing recommendations for IP antibiotics in CAPD and automated PD patients.[49] The dose of the antibiotics should be increased by 25% for patients with residual renal function who are able to produce more than 100 mL urine output per day.

Once the organism has been identified and sensitivities are known, drug selection should be adjusted to reflect the susceptibilities of the organism. Streptococcal, staphylococcal, and enterococcal species sensitive to β-lactam antibiotics should be treated with continuous IP dosing to increase efficacy and minimize resistance.[49] Peritonitis caused by *S. aureus* or *P. aeruginosa* are often associated with catheter-related infections, which are difficult to treat and often require removal of the catheter. Rifampin 600 mg orally daily (in a single or divided dose) may be added to IP vancomycin for the treatment of methicillin-resistant *S. aureus* (MRSA), but should be limited to duration of 1 week to minimize the development of resistance. Two antibiotics are required for treatment of *P. aeruginosa* peritonitis.[49] If multiple organisms are cultured, treatment should cover all of the organisms, including anaerobic organisms, and the patient should be evaluated for other intra-abdominal pathologies.[49]

Peritonitis caused by fungal organisms is associated with mortality in 25% of patients,[49] which can be reduced by removing the catheter after fungal organisms are identified. Empiric treatment should include amphotericin B and flucytosine.[49] Although amphotericin penetration into the peritoneal cavity is poor with IV administration, IP administration is associated with chemical irritation and pain. Fluconazole, voriconazole, or caspofungin may be suitable alternatives, depending on culture results.

Catheter-Related Infections

Catheter-related infections generally occur at the exit site or the portion of the catheter that is tunneled in the subcutaneous tissue. Previous infections increase the risk and incidence of catheter-related infections.

Pathophysiology The major pathologic organisms responsible for causing catheter-related infections are *S. aureus* and *P. aeruginosa*. These organisms also cause the most serious catheter-related infections. *S. epidermidis* is found in less than 20% of catheter-related infections. Other organisms include diphtheroids, anaerobic bacteria, *Legionella*, and fungi.[49]

Exit-site infections present with purulent drainage at the site. Erythema may or may not be present with an exit-site infection. Tunnel infections are generally an extension of the exit-site infection and rarely occur alone. Symptoms of a tunnel infection may include tenderness, edema, and erythema over the tunnel pathway, but are often asymptomatic. Ultrasound can be used to detect tunnel infections in asymptomatic patients. Exit-site infections caused by *S. aureus* and *P. aeruginosa* often spread to tunnel infections and are the most common causes of catheter-infection–related peritonitis.

Treatment Exit-site infections may be treated immediately with empiric coverage, or treatment may be delayed until cultures return. Empiric treatment of catheter-related infections should cover *S. aureus*. Coverage for *P. aeruginosa* should also be included if the patient has a history of infections with this organism.[49] Cultures and sensitivity testing are particularly important in tailoring antibiotic therapy for catheter-related infections to ensure eradication of the organism and prevent recurrence or related peritonitis.

Less severe infections may be treated with topical antibiotic cream, although this practice is controversial. Oral antibiotics

are also effective for treatment of catheter-related infections. Empiric or routine use of vancomycin for gram-positive infections should be avoided unless the infection is caused by MRSA. Rifampin may be added to therapy for severe infections or slowly-resolving *S. aureus* infections, but monotherapy is not recommended.[49] Oral fluoroquinolones are used as first-line agents to treat *P. aeruginosa*, which can be difficult to treat and require prolonged treatment. If the infection is slow to resolve or if it recurs, IP ceftazidime or a second agent should be added.[49] Treatment of catheter-related infections should be continued until the exit site appears normal with no erythema or drainage. Generally, at least 2 weeks of therapy or longer are required to ensure complete eradication of the organism and prevent future recurrence, which is common with *S. aureus* and *P. aeruginosa*. Infections that do not resolve may require replacement of the PD catheter. Catheter-related infections that present in conjunction with or progress to peritonitis with the same organism require removal of the PD catheter until the peritonitis is resolved.[49]

Prophylaxis of Peritonitis and Catheter-Related Infections

Prevention of peritonitis and catheter-related infections starts when the catheter is placed. The exit site should be properly cared for until it is well healed before it can be used for PD. Patients should receive proper instructions for care of the catheter during this time period, which can last up to 2 weeks. Patients should also be instructed on the proper techniques to use for dialysate exchanges to minimize the risk of infections during exchanges, which is the most common cause of peritonitis.

Intranasal *S. aureus* increases the risk of *S. aureus* exit-site infections, tunnel infections, peritonitis, and subsequent catheter loss.[49] Several measures have been used to decrease the risk of peritonitis caused by *S. aureus*, including mupirocin cream applied daily around the exit site, intranasal mupirocin cream twice daily for 5 days each month, or rifampin 300 mg orally twice daily for 5 days, repeated every 3 months.[49] Mupirocin use is preferred over rifampin to prevent the development of resistance to rifampin, although mupirocin resistance has also been reported.[49] Other measures that have been used to decrease both *S. aureus* and *P. aeruginosa* infections include gentamicin cream applied twice daily and ciprofloxacin otic solution applied daily to the exit site.[49]

Outcome Evaluation

Clinical improvement should be seen within 48 hours of initiating treatment for peritonitis or catheter-related infections. Perform daily inspections of peritoneal fluid or the exit site to determine clinical improvement. Peritoneal fluid should become clear with improvement of peritonitis and erythema and discharge should remit with improvement of catheter-related infections. If no improvement is seen within 48 hours, obtain additional cultures and cell counts to determine the appropriate alterations in therapy.

Patient Care and Monitoring

1. Assess the patient to determine if the patient should be evaluated for CKD. Does the patient have any risk factors for CKD?
2. Review any available laboratory data to determine the staging of CKD.
3. Obtain a thorough medical and medication history from the patient. Does the patient have any concomitant diseases, such as diabetes or hypertension, that should be treated to prevent the progression of CKD?
4. Determine if an ACE-I or ARB is appropriate for the patient. Does the patient have proteinuria?
5. Develop a plan to assess and optimize treatment of CKD.
6. Determine if the patient requires medical treatment for electrolyte imbalances. Does the patient have edema? Does the patient have an arrhythmia?
7. Educate the patient on dietary changes to manage electrolyte imbalances associated with CKD.
8. Assess the patient for the presence of anemia. Do the laboratory tests suggest the patient requires medical treatment?
9. Develop a plan to assess and optimize treatment for anemia.
10. Determine if the patient requires medical intervention to prevent the development of or treatment for secondary hyperparathyroidism.
11. Develop a plan to assess and optimize treatment for secondary hyperparathyroidism.
12. Establish if the patient requires renal replacement therapy.
13. Evaluate the patient for complications associated with dialysis. Does the patient develop hypotension or cramps during hemodialysis? Does the patient have symptoms consistent with peritonitis or a catheter infection?
14. Develop a plan to assess and optimize treatment for complications associated with dialysis.
15. Stress the importance of adherence with the treatments for CKD and associated complications, including lifestyle modifications and medications. Recommend a therapeutic regimen that is easy for the patient to accomplish.
16. Provide patient education with regard to CKD and the associated complications, lifestyle modifications, and drug therapy:

    - What causes CKD and what things to avoid.
    - Possible complications of CKD and symptoms associated with the complications.
    - When to take medications.
    - What potential adverse effects may occur.
    - Which drugs may interact with therapy.
    - Warning signs to report to the physician (edema, irregular heart beat, fatigue, unusual bleeding).

24 Fluids and Electrolytes

Mark A. Malesker and Lee E. Morrow

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Estimate the volumes of various body fluid compartments.
2. Calculate the daily maintenance fluid requirement for patients given their age, weight, and gender.
3. Differentiate among currently available fluids for volume resuscitation.
4. Identify the electrolytes primarily found in the extracellular and intracellular fluid compartments.
5. Describe the unique relationship between serum sodium concentration and total body water.
6. Review the etiology, clinical presentation, and management for disorders of sodium, potassium, calcium, phosphorus, and magnesium.

Key Concepts

❶ Total body water (TBW) is approximately 50% of lean body weight in the normal female and 60% of lean body weight in males. TBW is comprised of the intracellular fluid (two-thirds of TBW) and the extracellular fluid (one-third of TBW). The extracellular fluid is made up of two major fluid subcompartments: the interstitial space and the intravascular space.

❷ Therapeutic fluids include crystalloid and colloid solutions. The most commonly used crystalloids include normal saline, hypertonic saline, and lactated Ringer's solution. Examples of colloids include albumin, the dextrans, hetastarch, and fresh frozen plasma.

❸ The calculated serum osmolality helps determine deviations in TBW content.

❹ Hyponatremia is a very common finding in hospitalized patients and is defined as a serum sodium level below 136 mEq/L (136 mmol/L).

❺ Intravenous potassium infusions running at rates of greater than 10 mEq/hour require cardiac monitoring.

❻ Calcium gluconate is the preferred peripherally infused calcium supplement because it is less irritating to the veins. Calcium chloride must be infused via a central line.

❼ In the critical care setting, hypophosphatemia can result in impaired diaphragmatic contractility and acute respiratory failure.

❽ Concentrated electrolytes (potassium chloride, potassium phosphate, and sodium chloride greater than 0.9%) should not be stored in patient care areas as a patient safety measure.

❾ Serum magnesium levels do not correlate well with total body magnesium stores. For this reason, magnesium supplementation is often given empirically to critically ill patients.

BODY FLUID COMPARTMENTS

A thorough understanding of the fundamentals of fluid and electrolyte homeostasis is essential given the frequency with which clinical disturbances are seen and the profound effects these disturbances can have on various aspects of patient care. However, the interplay of body fluids, serum electrolytes, and clinical monitoring is complex, and a thorough command of these issues is a challenging task even for advanced practitioners.[1] Practitioners must be familiar with the key concepts of body compartment volumes, calculation of daily fluid requirements, and the various types of fluid available for replacement. The management of disorders of sodium, potassium, calcium, phosphorus, and magnesium integrates these concepts with issues of dose recognition and patient safety.

The most fundamental concept to grasp is an assessment of total body water (TBW), which is directly related to body

weight. ❶ *TBW constitutes approximately 50% of lean body weight in healthy females and 60% of lean body weight in males.* The percentage of TBW decreases as body fat increases and/or with age (75% to 85% of body weight is water for newborns). Unless the patient is obese (body weight greater than 120% of ideal body weight), clinicians typically use a patient's actual body weight when calculating TBW.[2] In this instance, it is customary to estimate TBW using lean body weight as calculated by the Devine-Devine method: males' lean body weight = 50 kg + [2.3 kg/inch × (height in inches – 60)] and females' lean body weight = 45.5 kg + [2.3 kg/inch × (height in inches – 60)].[3–5] Note that 1 kg is equivalent to 2.2 pounds and 1 inch is equivalent to 2.54 cm. One liter of water weighs 1 kg (2.2 lb).

The intracellular fluid (ICF) represents the water contained within cells and is rich in electrolytes such as potassium, magnesium, phosphates, and proteins. ❶ *The ICF is approximately two-thirds of TBW regardless of gender.* For a 70-kg man, this would mean that the TBW is 42 L and the ICF is approximately 28 L. For a 70-kg woman, these values would be 35 L and 24 L, respectively. Note that ICF represents approximately 40% of total body weight in men and approximately 33% of total body weight in women.

The extracellular fluid (ECF) is the fluid outside the cell and is rich in sodium, chloride, and bicarbonate. ❶ *The ECF is approximately one-third of TBW (14 L in a 70-kg man or 12 L in a 70-kg woman) and is subdivided into two compartments: the interstitial fluid and the intravascular fluid.* The interstitial fluid (also known as lymphatic fluid) represents the fluid occupying the spaces between cells, and is about 25% of TBW (10.5 L in a 70-kg man or 8.8 L in a 70-kg woman). The intravascular fluid (also known as plasma) represents the fluid within the blood vessels and is about 8% of TBW (3.4 L in a 70-kg man or 2.8 L in a 70-kg woman). The ECF is approximately one-third of TBW or 14 L in a 70-kg male. Because the exact percentages are cumbersome to recall, many clinicians accept that the ECF represents roughly 20% of body weight (regardless of gender) with 15% in the interstitial space and 5% in the intravascular space.[6] Note that serum electrolytes are routinely measured from the ECF.

The transcellular fluid includes the viscous components of the peritoneum, pleural space, and pericardium, as well as the cerebrospinal fluid, joint space fluid, and the gastrointestinal (GI) digestive juices. Although the transcellular fluid normally accounts for about 1% of TBW, this amount can increase significantly during various illnesses favoring fluid collection in one of these spaces (e.g., pleural effusions or ascites in the peritoneum). The accumulation of fluid in the transcellular space is often referred to as "third spacing." To review the calculations of the body fluid compartments in a representative patient, see Patient Encounter 1.

To maintain fluid balance, the total amount of fluid gained throughout the day (input, or "ins") must equal the total amount of fluid lost (output, or "outs"). Although most forms of the body's input and output can be measured, several cannot. For a normal adult on an average diet, ingested fluids are easily measured and average 1400 mL per day. Other fluid inputs, such as those from ingested foods and the water by-product of oxidation, are not directly measurable. Fluid outputs such as urinary and stool losses are also easily measured and are referred to as sensible losses. Other sources of fluid loss, such as evaporation of fluid through the skin and/or lungs, are not readily measured and are called insensible losses. Table 24–1 shows the estimated ins and outs (I&Os) for a healthy 150-lb (68-kg) man.[6] The measurable ins and outs are routinely measured in hospitalized patients and are used to estimate total fluid balance for each 24-hour period. It is important to realize that in hospitalized patients, multiple other forms of fluid loss must be considered. These include losses from enteric suctioning [most commonly, nasogastric (NG) tubes], from surgical drains (e.g., chest tubes, nephrostomy tubes, and pancreatic drains), via fistulous tracts, and enhanced evaporative losses (burns and fever).

ECF depletion tends to occur acutely. In this setting, rapid and aggressive fluid replacement is required to maintain adequate organ perfusion. Because ECF depletion is generally due to the loss of isotonic fluid (proportional losses of sodium and water), major disturbances of plasma **osmolality**

Patient Encounter 1, Body Fluid Compartments

Calculate the TBW, ICF, and ECF in a 70-kg male.
TBW = 0.5 × body weight (kg) for females and 0.6 × body weight (kg) for males
ICF = $^2/_3$ TBW
ECF = $^1/_3$ TBW

Example
TBW = 0.6 × 70 kg = 42 L
ICF = $^2/_3$ TBW = 0.67 × 42 L = 28 L
ECF = $^1/_3$ TBW = .33 × 42 L = 14 L
Interstitial fluid = $^3/_4$ ECF or 25% TBW = .25 × 42 L = 11 L
Plasma fluid = $^1/_4$ ECF or 8% TBW = .08 × 42 L = 3 L
TBW, total body water; ICF, intracellular fluid; ECF, extracellular fluid.

TABLE 24–1. Ins and Outs for a Healthy 150-lb (68-kg) Man

Input	mL/day	Output	mL/day
Ingested fluid[a]	1400	Urine[a]	1500
Fluid in food	850	Skin losses	500
Water of oxidation	350	Respiratory tract losses	400
		Stool	200
Total	**2600**	**Total**	**2600**

[a]Readily quantifiable.

are not common. ECF depletion manifests clinically as signs and symptoms associated with decreased tissue perfusion: dizziness, orthostasis, tachycardia, decreased urine output, increased hematocrit, decreased central venous pressure, and/or hypovolemic shock. Common causes of ECF depletion include external fluid losses (burns, hemorrhage, diuresis, GI losses, and adrenal insufficiency) and third-spacing of fluids (septic shock, anaphylactic shock, or abdominal ascites).

TBW depletion (often referred to as "dehydration") is typically a more gradual, chronic problem compared to ECF depletion. Because TBW depletion represents a loss of hypotonic fluid (proportionally more water is lost than sodium) from all body compartments, a primary disturbance of osmolality is usually seen. The signs and symptoms of TBW depletion include CNS disturbances (mental status changes, seizures, and coma), excessive thirst, dry mucous membranes, decreased skin turgor, elevated serum sodium, increased plasma osmolality, concentrated urine, and acute weight loss. Common causes of TBW depletion include insufficient oral intake, excessive insensible losses, diabetes insipidus, excessive osmotic diuresis, and impaired renal concentrating mechanisms. Long-term care residents are frequently admitted to the acute care hospital with TBW depletion secondary to lack of adequate oral intake, often with concurrent excessive insensible losses.

The volume of fluid required to correct TBW depletion equals the basal fluid requirement plus ongoing exceptional losses plus the fluid deficit. Basal daily fluid requirements are calculated using the formulas in Table 24–2. For an adult, this represents 1500 mL for the first 20 kg of body weight plus 20 mL for each additional kg. The volume of replacement fluids required for a given patient (the fluid deficit) can be estimated by the acute weight change in the patient (1 kg = 1 L of fluid). Because the precise weight change is not typically known, it is often calculated as follows: fluid deficit = normal TBW – present TBW. Normal TBW is estimated based on the patient's height using the formulas in Table 24–2, and the present TBW is estimated based on the patient's current body weight.

Once TBW has been restored, the volume of "maintenance" fluid equals the basal fluid requirement plus ongoing exceptional losses. If the pathophysiologic process leading to TBW depletion has not been identified and corrected (or accounted for in the calculation of maintenance fluid requirements), TBW depletion will quickly recur. To review the concepts involved in the calculation of replacement fluids for a representative patient (see Patient Encounter 2).

TABLE 24–2. Useful Calculations for the Estimate of Patient Maintenance Fluid Requirements

Neonate (1–10 kg) = 100 mL/kg
Child (10–20 kg) = 1000 mL + 50 mL for each kg greater than 10
Adult (greater than 20 kg) = 1500 mL + 20 mL for each kg greater than 20

Patient Encounter 2, Fluid Requirements

Calculate the daily fluid requirement for a 70-kg adult male. Use the equation from Table 24–2: Adult fluid requirement = 1500 mL + 20 mL for each kg greater than 20 The fluid requirements for a 70-kg adult would be 1500 mL + 20 mL (50 kg) = 2500 mL

Therapeutic Fluids

❷ *Therapeutic intravenous (IV) fluids include crystalloid solutions, colloidal solutions, and oxygen-carrying resuscitation solutions.* Crystalloids are composed of water and electrolytes, all of which pass freely through semipermeable membranes and remain in the intravascular space for shorter periods of time. As such, these solutions are very useful for correcting electrolyte imbalances but result in smaller hemodynamic changes for a given unit of volume.

Fluids can be classified further according to their tonicity. Isotonic solutions (i.e., normal saline or 0.9% sodium chloride [NaCl]) have a tonicity equal to that of the ICF (approximately 310 mEq/L or 310 mmol/L) and do not shift the distribution of water between the ECF and the ICF. Because hypertonic solutions (i.e., hypertonic saline or 3% NaCl) have greater tonicity than the ICF (greater than 376 mEq/L or 376 mmol/L), they draw water from the ICF into the ECF. In contrast, hypotonic solutions (i.e., 0.45% NaCl) have less tonicity than the ICF (less than 250 mEq/L or 250 mmol/L) leading to an osmotic pressure gradient that pulls water from the ECF into the ICF. The tonicity, electrolyte content, and glucose content of selected fluids are shown in Table 24–3.

The tonicity of crystalloid solutions is directly related to their sodium concentration. The most commonly used crystalloids include normal saline, hypertonic saline, and lactated Ringer's solution. Excessive administration of any fluid replacement therapy, regardless of tonicity, can lead to fluid overload, particularly in patients with cardiac or renal insufficiency.

Normal Saline (0.9% NaCl)

Normal saline is an isotonic fluid composed of water, sodium, and chloride. It provides primarily ECF replacement and can be used for virtually any cause of TBW depletion. Common uses of normal saline include: perioperative fluid administration; volume resuscitation of shock, hemorrhage, or burn patients; fluid challenges in hypotensive or oliguric patients; and hyponatremia.

Half-Normal Saline (0.45% NaCl)

Half-normal saline is a hypotonic fluid that provides free water in relative excess when compared to the sodium concentration. This crystalloid is typically used to treat patients

TABLE 24–3. Electrolyte and Dextrose Content of Selected Crystalloid Fluids

IV Solution	Osmolarity (mOsm)	Dextrose (g/L) (mmol/L)	Sodium (mEq/L) (mmol/L)	Potassium (mEq/L) (mmol/L)	Calcium (mEq/L) (mmol/L)	Chloride (mEq/L) (mmol/L)	Lactate (mEq/L) (mmol/L)
5% Dextrose	250	50 / 2.78					
10% Dextrose	505	100 / 5.55					
0.9% NaCl	308		154			154	
0.45% NaCl	154		77			77	
3% NaCl	1025		513			513	
D5% and 0.45% NaCl	405	50 / 2.78	77			77	
D5% and 0.2% NaCl	329	50 / 2.78	34			34	
Ringer's injection	310		147	4	5 / 2.5	156	
Lactated Ringer's	274		130	4	3 / 1.5	109	28
Lactated Ringer's and D5%	525	50 / 2.78	130	4	5 / 2.5	109	28

D, dextrose; NaCl, sodium chloride.

who are hypertonic with primary depletion of the ECF. Because half-normal saline is hypotonic, serum sodium must be closely monitored during administration.

Hypertonic Saline (3% NaCl)

Hypertonic saline is obviously hypertonic and provides a significant sodium load to the intravascular space. This solution is utilized very infrequently given the potential to cause significant shifts in the water balance between the ECF and the ICF. It is typically considered to treat patients with severe hyponatremia who have symptoms attributable to low serum sodium.

Ringer's Lactate

This isotonic volume expander contains sodium, potassium, chloride, and lactate that approximates the fluid and electrolyte composition of the blood. Ringer's lactate (also known as "lactated Ringer's" or LR) provides ECF replacement and is most often used in the perioperative setting, and for patients with lower GI fluid losses, burns, or dehydration. The lactate component of LR works as a buffer to increase the pH. Large volumes of LR may cause metabolic alkalosis. Because patients with significant liver disease are unable to metabolize lactate sufficiently, Ringer's lactate administration in this population may lead to accumulation of lactate with iatrogenic lactic acidosis. The lactate is not metabolized to bicarbonate in the presence of liver disease and lactic acid can result.

5% Dextrose in Water (D5W)

D5W is a solution of free water and dextrose that provides a modest amount of calories but no electrolytes. Although it is technically isotonic, it acts as a hypotonic solution in the body. It is commonly used to treat severe hypernatremia. D5W is used in small volumes (100 mL) to dilute many IV medications or at a low infusion rate (10 to 15 mL/hour) to "keep the vein open" (KVO) for IV medications.

Colloids do not dissolve into a true solution, and therefore do not pass readily across semipermeable membranes. As such, colloids effectively remain in the intravascular space and increase the oncotic pressure of the plasma. This effectively shifts fluid from the interstitial compartment to the plasma compartment. In clinical practice, these theoretical benefits are generally short lived and for most patients there is little therapeutic advantage of colloids over crystalloids or vice-versa. Examples of colloids include 5% albumin, 25% albumin, the dextrans, hetastarch, and fresh frozen plasma. Note that each of these agents contains a substance (proteins and complex sugars) that will ultimately be metabolized. When this ultimately occurs, the oncotic agent will be lost and only the remaining hypotonic fluid delivery agent will remain. As such, use of large volumes of colloidal agents is more likely to induce fluid overload compared to crystalloids. Although smaller volumes of colloids have equal efficacy as larger volumes of crystalloids, they generally must be infused more slowly. Often the net result is that the time to clinical benefit is the same regardless of which class of fluid is utilized. For example, 500 mL of normal saline is required to increase the systolic blood pressure to the same degree as seen with approximately 250 mL of albumin; however, the normal saline can be administered twice as fast.

Albumin

Albumin is a protein derived from fractionating human plasma. Because albumin infusion is expensive and may be associated with adverse events, it should be used for acute

volume expansion and *not* as a supplemental source of protein calories. Historically, albumin was used indiscriminately in the intensive care unit until anecdotal publications suggested that albumin may cause immunosuppression. However, the recently completed Safety After Fifty Evaluation (SAFE) trial randomized nearly 7000 hypovolemic patients to either albumin or normal saline therapy and found that the mortality for those who received albumin was the same as for those who received normal saline.[7] This finding confirmed the results of several previous reviews and meta-analyses of studies using human albumin versus normal saline therapy for resuscitation of critically ill patients.[8–10] Albumin combined with furosemide has been demonstrated to improve fluid balance, oxygenation, and hemodynamics in the subset of patients with acute lung injury who have low serum protein.[11]

While albumin is the most commonly used colloid, the other products are not without their own risks and benefits. Hetastarch (various manufacturers) contains 6% starch and 0.9% sodium chloride. This product has no oxygen-carrying capacity and is administered intravenously as a plasma expander. Limitations of this product include acquisition cost, hypersensitivity reactions, and bleeding. Dosing should be reduced in the presence of renal dysfunction. Low-molecular-weight dextran (various manufacturers) and high-molecular-weight dextran (various manufacturers) are polysaccharide plasma expanders. Anaphylactic reactions and prolonged bleeding times have historically limited the use of these products. Fresh frozen plasma (FFP) has been used in cases of excessive blood loss (surgery or trauma) and to prevent bleeding in the presence of abnormal coagulation studies. Fresh frozen plasma is now rarely used for volume expansion. Risks of fresh frozen plasma include anaphylaxis, the potential for viral transmission through plasma, hepatitis, and an increased nosocomial infection rate in the intensive care setting.

Fluid Management Strategies

Classic indications for IV fluid include maintenance of blood pressure, restoring the ICF volume, replacing ongoing renal or insensible losses when oral intake is inadequate, and the need for glucose as a fuel for the brain.[12] Although large volumes of fluid are given during the resuscitation of most trauma patients, a recent analysis reported uncertainty about the use of early large-volume fluid replacement in patients with active bleeding, calling into question our understanding of the need for fluids in various patient populations.[13]

When determining the appropriate fluid to be utilized, it is important to first determine the type of fluid problem (TBW versus ECF depletion), and start therapy accordingly. For patients demonstrating signs of impaired tissue perfusion, the immediate therapeutic goal is to increase the intravascular volume and restore tissue perfusion. The standard therapy is normal saline given at 150 to 500 mL/hour until perfusion is optimized. Although LR is a therapeutic alternative, lactic acidosis may arise with massive or prolonged infusions. In severe cases, a colloid or blood product may be indicated to increase oncotic pressure within the vascular space. Once isovolemia is achieved, patients may be switched to a more hypotonic solution (0.45% NaCl) at a rate that delivers estimated daily needs.

The clinical scenario and the severity of the volume abnormality dictate monitoring parameters during fluid replacement therapy. These may include a subjective sense of thirst, mental status, skin turgor, orthostatic vital signs, pulse rate, weight changes, blood chemistries, fluid input and output, central venous pressure, pulmonary capillary wedge pressure, and cardiac output. Fluid replacement requires particular caution in patient populations at risk of fluid overload, such as those with renal failure, cardiac failure, hepatic failure, or the elderly. Other complications of IV fluid therapy include infiltration, infection, phlebitis, thrombophlebitis, and extravasation.

In summary, the settings in which fluid replacement is used are: hypovolemic patients (e.g., sepsis or pneumonia); hypervolemic patients [e.g., congestive heart failure (CHF), cirrhosis, or renal failure]; euvolemic patients who are unable to take oral fluids in proportion to insensible losses (e.g., the perioperative period); and patients with electrolyte abnormalities (see below).

ELECTROLYTES

Normally, the number of anions and cations in each fluid compartment are equal. Cell membranes play the critical role of maintaining distinct ICF and ECF spaces which are biochemically distinct. Serum electrolyte concentrations reflect the stores of ECF electrolytes rather than that of ICF electrolytes. Table 24–4 lists the chief cations and anions along with their normal concentrations in the ECF and ICF. The principal cations are sodium, potassium, calcium, and magnesium, while the key anions are chloride, bicarbonate, and phosphate. In the ECF, sodium is the most common cation and chloride is the most abundant anion; while in the ICF, potassium is the primary cation and phosphate is the main anion. Normal serum electrolyte values are listed in Table 24–5.

Osmolality is a measure of the number of osmotically active particles per unit of solution, independent of the weight or nature of the particle. Equimolar concentrations of all substances in the undissociated state exert the same osmotic pressure. Although the normal serum osmolality is 280 to 300 mOsm/kg (280 to 300 mmol/kg), multiple scenarios exist where this value becomes markedly abnormal. ❸ *The calculated serum osmolality helps determine deviations in TBW content.* As such, it is often useful to calculate the serum osmolality as follows:

$$\text{Serum osmolality (mOsm/L)} = 2\,[Na^+] + [\text{glucose (mg/dL)}]/18 + [\text{blood urea nitrogen}]/2.8$$

TABLE 24–4. Normal Cation and Anion Concentrations in the ECF and ICF

ECF			ICF	
Ion Species	Plasma (mEq/L)	Interstitial Fluid (mEq/L)	Ion Species	mEq/L
Cations			**Cations**	
Na^+	142	144	K^+	135
K^+	4	4	Mg^{2+}	43
Ca^{2+}	5	2.5		
Mg^{2+}	3	1.5		
Total	154	152	Total	178
Anions			**Anions**	
Cl^-	103	114	$PO4^{2-}$	90
HCO_3^-	27	30	Protein	70
PO_4^{2-}	2	2	$SO4^{2-}$	18
SO_4^{2-}	1	1		
Organic acid	5	5		
Protein	16	0		
Total	154	152	Total	178

ECF, extracellular fluid; ICF, intracellular fluid.

Note: For glucose, multiply by a factor of 0.055 to convert conventional glucose units (mg/dL) to SI glucose units (mmol/L).

Because the body regulates water to maintain osmolality, deviations in serum osmolality are used to estimate TBW stores. Water moves freely across all cell membranes, making serum osmolality an accurate reflection of the osmolality within all body compartments. An increase in osmolality is equated with a loss of water greater than the loss of solute (TBW depletion). A decrease in serum osmolality is seen when water is retained in excess of solute (congestive heart failure or hepatic cirrhosis). The difference between the measured serum osmolality and the calculated serum osmolality, using the equation above, is referred to as the **osmolar gap.** Under normal circumstances the osmolar gap should be 10 mOsm/L or less. An increased osmolar gap suggests the presence of a small, osmotically active agent and is most commonly seen with the ingestion of alcohols (ethanol, methanol, ethylene glycol, or isopropyl alcohol) or during mannitol therapy. Patient Encounter 3 illustrates the utility of serum osmolality in a clinical setting.

Many of the electrolyte disturbances discussed in the remainder of this chapter represent medical emergencies that call for aggressive interventions including the use of concentrated electrolytes. However, these solutions are a frequent source of medical errors with significant potential for patient harm. *As such, the 2005 National Patient Safety Goals published by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) recommends that concentrated electrolyte solutions (potassium chloride, potassium phosphate, and sodium chloride greater than 0.9%) be removed from patient care areas.* In addition, JCAHO recommends standardizing and limiting the number of drug concentrations available in each institution so as to further reduce the risk of medication errors and improve outcomes.[14]

TABLE 24–5. Normal Ranges for Serum Electrolyte Concentrations

Sodium	136–145 mEq/L or 136–145 mmol/L
Potassium	3.5–5.0 mEq/L or 3.5–5.0 mmol/L
Chloride	98–106 mEq/L or 98–106 mmol/L
Bicarbonate	21–30 mEq/L or 21–30 mmol/L
Magnesium	1.4–1.8 mEq/L or 0.7–0.9 mmol/L
Calcium	
Total	4.4–5.2 mEq/L (9–10.5 mg/dL) or 2.25–2.5 mmol/L
Ionized	2.2–2.8 mEq/L (4.5–5.6 mg/dL) or 1.1–1.4 mmol/L
Phosphorus	3–4.5 mg/dL (1.0–1.4 mmol/L)

Patient Encounter 3, Calculate the Plasma Osmolality

A 50-year-old homeless man is brought to the emergency department staggering and smelling like beer. Rapid respiration, tachycardia, and a BP of 90/60 mm Hg were noted. The sodium is 142 mEq/L (142 mmol/L), potassium 3.6 mEq/L (3.6 mmol/L), chloride 100 mEq/L (100 mmol/L), bicarbonate 12 mEq/L (12 mmol/L), glucose 180 mg/dL (9.99 mmol/L), and BUN 28 mg/dL (9.99 mol/L). The measured osmolarity is 360 mOsm/L.

Calculate the osmolality.

$(2 \times Na) + (glucose/18) + (BUN/2.8) = (2 \times 142) + (180/18) + (28/2.8) = 304$ mOsm/L

Calculate the osmolar gap.

360 – 304 = 56 mOsm/L for gap

- What is the likely cause of an increased gap in this patient?
- Ethanol content of the ingested beer

Sodium

The body's normal daily sodium requirement is 1.0 to 1.5 mEq/kg (80 to 130 mEq, which is 80 to 130 mmol) to maintain a normal serum sodium concentration of 136 to 145 mEq/L (136 to 145 mmol/L).[15] Sodium is the predominant cation of the ECF and largely determines ECF volume. Sodium is also the primary factor in establishing the osmotic pressure relationship between the ICF and ECF. All body fluids are in osmotic equilibrium and changes in serum sodium concentration are associated with shifts of water into and out of body fluid compartments. When sodium is added to the intravascular fluid compartment, fluid is pulled intravascularly from the interstitial fluid and the ICF until osmotic balance is restored. As such, a patient's measured sodium level should *not* be viewed as an index of sodium need because this parameter reflects the balance between total body sodium content and TBW. Disturbances in the sodium level most often represent disturbances of TBW. Sodium imbalances cannot be properly assessed without first assessing the body fluid status.

❹ *Hyponatremia is very common in hospitalized patients and is defined as a serum sodium concentration below 136 mEq/L (136 mmol/L).* Clinical signs and symptoms appear at concentrations below 120 mEq/L (120 mmol/L) and typically consist of agitation, fatigue, headache, muscle cramps, and nausea. With profound hyponatremia (less than 110 mEq/L [110 mmol/L]), confusion, seizures, and coma may be seen. Because therapy is also influenced by volume status, hyponatremia is further defined as: (1) hypertonic hyponatremia; (2) hypotonic hyponatremia with an increased ECF volume; (3) hypotonic hyponatremia with a normal ECF volume; and (4) hypotonic hyponatremia with a decreased ECF volume.[16]

Hypertonic hyponatremia is usually associated with significant hyperglycemia. Glucose is an osmotically active agent that leads to an increase in TBW with little change in total body sodium. For every 60 mg/dL (3.33 mmol/L) increase in serum glucose above 200 mg/dL (11.1 mmol/L), the sodium is expected to decrease by approximately 1 mEq/L (1 mmol/L). Appropriate treatment of the hyperglycemia will return the serum sodium to normal.[15]

Hypotonic hyponatremia with an increase in ECF is also known as dilutional hyponatremia. In this scenario, patients have an excess of total body sodium and TBW; however, the excess in TBW is greater than the excess in total body sodium. Common causes include CHF, hepatic cirrhosis, and nephrotic syndrome. Treatment includes sodium and fluid restriction in conjunction with treatment of the underlying disorder—for example, salt and water restrictions are used in the setting of CHF along with loop diuretics, angiotensin-converting enzyme inhibitors, and spironolactone.[15]

In hypotonic hyponatremia with a decreased ECF volume, patients usually have a deficit of both total body sodium and TBW, but the sodium deficit exceeds the TBW deficit. Common causes include diuretic use, profuse sweating, wound drainage, burns, GI losses (vomiting or diarrhea), hypoadrenalism (low cortisol and low aldosterone), and renal tubular acidosis. Treatment includes the administration of sodium to correct the sodium deficit and water to correct the TBW deficit. The sodium deficit can be calculated with the following equation:[2]

$$\text{Sodium deficit (mEq)} = (\text{TBW})(\text{desired } Na^+ \text{ concentration} - \text{current } Na^+ \text{ concentration})$$

Although both water and sodium are required in this instance, sodium needs to be provided in excess of water to fully correct this abnormality. As such, hypertonic saline (3% NaCl) is often used. One can estimate the change in serum sodium concentration after 1 L of 3% NaCl infusion using the following equation:[16]

$$\text{Change in serum } Na^+ = (\text{infusate } Na^+ - \text{serum } Na^+)/(\text{TBW} + 1)$$

In this formula, TBW is increased by 1 to account for the addition of the liter of 3% NaCl. Patient Encounters 4 and 5 illustrate the concepts of calculating and correcting the sodium deficit.

Depending on the severity of the hyponatremia, 0.9%, 3%, or 5% NaCl can be utilized. Most patients can be adequately managed with normal saline rehydration, which is generally the safest agent. Hypertonic saline (3% or 5% NaCl) is generally reserved for patients with severe hyponatremia (less than 120 mEq/L [120 mmol/L]) accompanied by coma, seizures, or high urinary sodium losses. Roughly one-third of the sodium deficit can be replaced over the first 12 hours as long as the replacement rate is less than 0.5 mEq/hour (0.5 mmol/L). The remaining two-thirds of the deficit can be administered over several days. Overly aggressive correction of symptomatic hyponatremia (greater than 12 mEq/L [12 mmol/L] per day) can result in central pontine myelinolysis.[17] Given the potential

Patient Encounter 4, Calculation of Sodium Deficit

Calculate the sodium deficit for a 75-kg male with a serum sodium of 123 mEq/L (123 mmol/L).

Sodium deficit (mEq) = (TBW) (desired – current Na concentration)

TBW = 0.6 × 75 kg = 45 L

Desired sodium = 140 mEq/L (140 mmol/L)

Current sodium = 123 mEq/L (123 mmol/L)

Example

Sodium deficit = (45 L)(140 mEq/L – 123 mEq/L)
= 765 mEq (or 765 mmol)

Patient Encounter 5, Estimate the Anticipated Change in Serum Sodium

Estimate the anticipated change in serum sodium concentrations after the infusion of 1 L of 3% sodium chloride in a 75-kg male with a serum sodium of 123 mEq/L (123 mmol/L).

$$\text{Change in serum } Na^+ = \frac{(\text{Infusate sodium} - \text{serum sodium})}{\text{TBW} + 1}$$

Example

$$\text{Change in serum } Na^+ = \frac{512 - 123}{(0.6\ \text{L/kg})(75\ \text{kg}) + 1} = \frac{389}{46}$$

$$= 8.45\ \text{mEq (or 8.45 mmol)}$$

for irreversible neurologic damage if untreated or if improperly treated, acute hyponatremia is an urgent condition that should be promptly treated with careful attention to monitoring serial sodium values and adjusting therapeutic infusions accordingly.[18]

In hypotonic hyponatremia with a normal ECF volume, patients have an excess of TBW with relatively normal sodium content. In essence, there is a presence of excess free water. This is most frequently seen in patients with the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Common causes of SIADH include carcinomas (e.g., lung or pancreas), pulmonary disorders (e.g., pneumonias or tuberculosis), central nervous system disorders (e.g., meningitis, stroke, tumor, or trauma), and medications (e.g., sulfonylureas, antineoplastic agents, barbiturates, morphine, antipsychotics, tricyclics, non-steroidal anti-inflammatory agents, selective serotonin reuptake inhibitors, dopamine agonists, and general anesthetics). These types of medications can stimulate the release of antidiuretic hormone from the pituitary gland. When antidiuretic hormone is released, the body retains water and the sodium concentration drops. Treatment generally consists of fluid restriction alone. Hypertonic saline is used only when the sodium concentration is less than 110 mEq/L (110 mmol/L) and/or severe symptoms (e.g., seizures) are present. Refractory SIADH may respond to demeclocycline (Declomycin®, ESP Pharma) dosed at 900 to 1200 mg/day.

Hypernatremia is a serum sodium concentration greater than 145 mEq/L (145 mmol/L) and can occur in the absence of a sodium deficit (pure water loss) or in its presence (hypotonic fluid loss).[19] The signs and symptoms of hypernatremia are the same as those found in TBW depletion. Symptoms of hypernatremia are evident with a serum concentration greater than 160 mEq/L (160 mmol/L) and usually consist of thirst, mental slowing, and dry mucous membranes. Signs and symptoms become more profound as hypernatremia worsens, with the patient demonstrating confusion, hallucinations, acute weight loss, decreased skin turgor, intracranial bleeding, or coma. Many coexisting disorders and medications may complicate the diagnosis.

The classic causes of hypernatremia are associated with TBW depletion. These include dehydration from loss of hypotonic fluid from the respiratory tract or skin, decreased water intake, osmotic diuresis (e.g., mannitol, available as generic), and diabetes insipidus (e.g., decreased ADH; phenytoin, available as generic; lithium, available as generic). Hypernatremia in hospitalized patients occurs secondary to inappropriate fluid management in patients at risk for increased free water losses and impaired thirst or restricted water intake.[20] Iatrogenic hypernatremia is occasionally caused by the administration of excessive hypertonic saline. Treatment of hypernatremia includes calculation of the TBW deficit followed by the administration of hypotonic fluids as previously described. The fluid volume should be replaced over 48 to 72 hours depending on the severity of symptoms and the degree of hypertonicity.[21] For asymptomatic patients, the rate of correction should not exceed 0.5 mEq/L per hour (0.5 mmol/L per hour). One rule of thumb is to replace half the calculated TBW deficit over 12 to 24 hours and the other half of the deficit over the next 24 to 48 hours.[2,19] Excessively rapid correction of hypernatremia may lead to cerebral edema and death. Patient Encounters 6 and 7 reinforce the concepts of calculating TBW deficit and expected changes in serum sodium concentration with therapy.

Potassium

The body's normal daily potassium requirement is 0.5 to 1 mEq/kg (0.5 to 1 mmol/kg) or 40 to 80 mEq (40 to 80 mmol) to maintain a serum potassium concentration of 3.5 to 5 mEq/L (3.5 to 5 mmol/L). Potassium is the most abundant cation in the ICF, balancing the sodium contained in the ECF and maintaining electroneutrality of bodily fluids. Because the majority of potassium is intracellular, serum potassium concentration is not a good measure of total body potassium; however, clinical manifestations of potassium disorders correlate well with serum potassium. The acid-base balance of the body affects serum potassium concentrations. Hyperkalemia is routinely seen in

Patient Encounter 6, Calculate Water Deficit

Calculate the water deficit in a 75-kg male with a serum sodium of 154 mEq/L (154 mmol/L).

Water deficit (L) = TBW × [(serum sodium/140) – 1]

Example

$$\text{Water deficit} = (0.6\ \text{L/kg})(75\ \text{kg})\ [154/140 - 1] = 45 \times 0.1$$

$$= 4.5\ \text{L}$$

Patient Encounter 7, Calculate the Anticipated Change in Serum Sodium

Calculate the anticipated change in serum sodium concentration after IV infusion of 1 L of 5% dextrose in a 75-kg male with a serum sodium of 156 mEq/L (156 mmol/L).

$$\text{Change in serum } Na^+ = \frac{(\text{Infusate Na} - \text{serum Na})}{\text{TBW} + 1}$$

Example

$$\text{Change in serum } Na^+ = \frac{0 - 156}{45 + 1} = \frac{-156}{46}$$

$$= -3.39 \text{ mEq (or } -3.39 \text{ mmol)}$$

patients with decreased pH (acidosis). Potassium regulation is primarily under the control of the kidneys with excess dietary potassium being excreted in the urine. Although mild abnormalities of serum potassium are considered a nuisance, severe hyperkalemia and hypokalemia can be life-threatening.[22,23,32]

Hypokalemia (serum potassium less than 3.5 mEq/L [3.5 mmol/L]) is a common clinical problem. Signs and symptoms of hypokalemia include cramps, muscle weakness, polyuria, electrocardiogram (ECG) changes (flattened T-waves and presence of U-waves), and cardiac arrhythmias (bradycardia, heart block, atrial flutter, premature ventricular contractions, and ventricular fibrillation). Causes of hypokalemia include GI losses (vomiting, diarrhea, or NG tube suction), renal losses (high aldosterone and low magnesium), inadequate potassium intake (in IV fluids or PO), or alkalosis. Many medications can precipitate hypokalemia. β_2-Agonists (albuterol available as generic) and insulin (multiple product formulations) lower potassium via cellular redistribution. The use of loop diuretics (furosemide [Lasix®], also available as generic), thiazide diuretics (hydrochlorothiazide, available as generic), high-dose antibiotics (penicillin, available as generic), and corticosteroids (prednisone, available as generic) cause a renal potassium wasting. In addition, amphotericin B (available as generic), cisplatin (available as generic), and foscarnet (Foscavir®, AstraZeneca) can also produce hypokalemia secondary to depletion of magnesium. Hypomagnesemia diminishes intracellular potassium concentration and produces potassium wasting. Given the potential for significant morbidity and mortality, serum potassium concentrations should be monitored closely for patients with known (or suspected) hypokalemia.[2,24,32] Hypokalemia is a risk factor for digitalis toxicity.

A 1 mEq/L (1 mmol/L) fall in serum potassium (i.e., from 4 mEq/L to 3 mEq/L [4 mmol/L to 3 mmol/L]) represents a loss of approximately 200 mEq (200 mmol) of potassium. However, when the serum potassium is below 3 mEq/L (3 mmol/L), each 1 mEq/L fall in serum potassium represents a 200 to 400 mEq (200 to 400 mmol) reduction in serum concentration. Potassium repletion should be guided by close monitoring of serum concentrations instead of using empirically chosen predefined amounts. Of the five potassium salts available, potassium acetate (10.2 mEq/K^+ per gram or 10.2 mmol/K^+ per gram) and potassium chloride (13.4 mEq/K^+ per gram or 13.4 mmol/K^+ per gram) are the most commonly used forms. When hypokalemia occurs in the setting of alkalosis, potassium chloride is the preferred agent; in acidosis, potassium should be provided in the form of acetate, citrate, bicarbonate, or gluconate salt. Table 24–6 outlines the potassium content of each potassium salt preparation, and Table 24–7 lists each of the oral potassium replacement products. Potassium acetate and chloride are available for IV infusions as premixed solutions. The usual dose of these agents is 10 to 20 mEq (10 to 20 mmol) diluted in 1000 mL of normal saline.[2,24,25]

Moderate hypokalemia is defined as a serum potassium of 2.5 to 3.5 mEq/L (2.5 to 3.5 mmol/L) without ECG changes. In this setting, potassium replacement can usually be given orally at a dose of 40 to 120 mEq/day (40 to 120 mmol/day). Anecdotally, oral potassium supplementation (see Table 24–7) is often more effective in repleting moderate hypokalemia. For patients with an ongoing source of potassium loss, chronic replacement therapy should be considered. The potassium

TABLE 24–6. Potassium Content in Various Potassium Salt Preparations

Potassium Salt	mEq/g (mmol/L)
Potassium gluconate	4.3
Potassium citrate	9.8
Potassium bicarbonate	10.0
Potassium acetate	10.2
Potassium chloride	13.4

Hypokalemia and alkalosis: Use potassium chloride
Hypokalemia and acidosis: Use potassium bicarbonate, potassium citrate, potassium acetate, or potassium gluconate salts

TABLE 24–7. Oral Potassium Replacement Products[a]

Product	Salt	Strength
Extended/controlled-release tablets	Chloride	8 mEq (600 mg) 10 mEq (750 mg) 15 mEq (1125 mg) 20 mEq (1500 mg)
Effervescent tablets	Chloride and bicarbonate	20 mEq 25 mEq 50 mEq
Liquid	Chloride	20 mEq/15mL (10%) 30 mEq/15mL (15%) 40 mEq/15mL (20%)
Powder packets	Chloride	15 mEq 20 mEq 25 mEq

[a]For potassium, 1 mEq = 1 mmol.

deficit is a rough approximation of the amount of potassium needed to be replaced and can be estimated as follows:

$$\text{Potassium deficit(mEq)} = (4.0 - \text{current serum potassium}) \times 100$$

Severe hypokalemia is defined as a serum potassium less than 2.5 mEq/L (2.5 mmol/L) or hypokalemia of any severity that is associated with ECG changes (e.g., flattening of T wave or elevation of U wave) and cardiac arrhythmias. In these situations, IV replacement should be initiated urgently. ❺ *Potassium infusion at rates exceeding 10 mEq/hour requires cardiac monitoring given the potential for cardiac arrhythmias.* Although the maximally concentrated solution for potassium replacement is 80 mEq/L (80 mmol/L), the maximum infusion rate is 40 mEq/hour (40 mmol/hour), and must be administered via a central line. Table 24–8 outlines current IV potassium replacement guidelines.

Caution must be exercised when repleting potassium with IV agents given possible vein irritation and/or thrombophlebitis. The risk of these complications is minimized by using less concentrated solutions and by giving infusions via central access if possible. Administration of potassium in vehicles containing glucose is discouraged, as glucose facilitates the intracellular movement of potassium. Post-therapy improvements in serum potassium may be transient and continuous monitoring is required. Patients with a low serum magnesium will have exaggerated potassium losses from the kidneys and GI tract leading to refractory hypokalemia. In this situation, the magnesium deficit must be corrected in order to successfully treat the concurrent potassium deficiency. In the hypokalemic patient with concurrent acidosis, potassium is often given as acetate, which is metabolized to bicarbonate. In the patient with depleted phosphorus and potassium, therapy with potassium phosphate is the natural choice.[22,26,27]

Hyperkalemia is defined as a serum potassium concentration greater than 5 mEq/L (5 mmol/L). Manifestations of hyperkalemia include muscle weakness, paresthesias, hypotension, ECG changes (e.g., peaked T waves, shortened QT intervals, and wide QRS complexes), cardiac arrhythmias, and a decreased pH. Causes of hyperkalemia fall into three broad categories: (1) increased potassium intake; (2) decreased potassium excretion; and (3) potassium release from the intracellular space.

Increased potassium intake results from excessive dietary potassium (salt substitutes), excess potassium in IV fluids, and other select medications (potassium-sparing diuretics or cyclosporine, available as generic), angiotensin-converting enzyme inhibitors, non-steroidal anti-inflammatory agents, pentamidine (available as generic), unfractionated heparin, and low-molecular-weight heparins. Decreased potassium excretion results from acute renal failure, chronic renal failure, or Addison's disease. Excess potassium release from cells results from tissue breakdown (surgery, trauma, hemolysis, or rhabdomyolysis), blood transfusions, and metabolic acidosis.

In addition to discontinuing all potassium supplements, potassium-sparing medications, and potassium-rich salt substitutes, management of hyperkalemia addresses three concurrent strategies: (1) agents to antagonize the pro-arrhythmic effects of hyperkalemia; (2) agents to drive potassium into the intracellular space and acutely lower the serum potassium; and (3) agents that will definitively (but more gradually) lower the total body potassium content.[28] If the serum potassium concentration is greater than 7 mEq/L (7 mmol/L) and/or ECG changes are present, IV calcium is provided to stabilize the myocardium. Depending on the acuity of the situation, 1 g of calcium chloride (13.5 mEq or 6.75 mmol) is administered by direct injection or diluted in 50 mL of D5W and delivered IV over 15 minutes. Clinical effects are seen within 1 to 2 minutes of infusion and persist for 10 to 30 minutes. Repeat doses may be administered as necessary. Because most patients with clinically significant hyperkalemia receive multiple boluses of calcium directed by electrocardiogram findings, iatrogenic hypercalcemia is a potential complication of hyperkalemia treatment. As such, total calcium concentration is commonly checked with each potassium concentration measurement. Ionized calcium measurements should be obtained in patients who have comorbid conditions that would lead to inconsistency between total serum calcium and free calcium (abnormal albumin, protein, or immunoglobulin concentrations).

Dextrose and insulin (with or without sodium bicarbonate) are typically given at the time of calcium therapy in order to redistribute potassium into the intracellular space. Dextrose 50% (25 g in 50 mL) can be given by slow IV push over 5 minutes or dextrose 10% with 20 units of regular insulin can be given by continuous IV infusion over 1 to 2 hours. The onset of action for this combination is 30 minutes and the duration of clinical effects

TABLE 24–8. Recommended Potassium Dosage/Infusion Rate Guidelines[a]

Clinical Scenario	Maximum Infusion Rate	Maximum Concentration	Maximum 24-hour Dose
K^+ greater than 2.5 mEq/L *AND* No ECG changes of hypokalemia	10 mEq/hour	40 mEq/L	200 mEq
K^+ less than 2.5 mEq/L *OR* ECG changes of hypokalemia	40 mEq/hour	80 mEq/L	400 mEq

[a]For potassium, 1 mEq = 1 mmol.

is 2 to 6 hours. High-dose inhaled β_2-agonists (e.g., albuterol, available as generic) may also be used to acutely drive potassium into the intracellular space.

It is critically important to recognize that the treatments of hyperkalemia discussed thus far are transient, temporizing measures. They are intended to provide time to institute definitive therapy aimed at removing excess potassium from the body. Agents that increase potassium excretion from the body include sodium polystyrene sulfonate, loop diuretics, and hemodialysis or hemofiltration (used only in patients with renal failure). Sodium polystyrene sulfonate (Kayexalate®, various manufacturers) can be given orally, via NG tube, or as a rectal retention enema and is dosed at 15 to 60 grams in four divided doses per day.

Calcium

More than 99% of total body calcium is found in bone; the remaining less than 1% is in the ECF and ICF. Calcium plays a critical role in the transmission of nerve impulses, skeletal muscle contraction, myocardial contractions, maintenance of normal cellular permeability, and the formation of bones and teeth. There is a reciprocal relationship between the serum calcium concentration (normally 8.6 to 10.2 mg/dL [2.15 to 2.55 mmol/L]) and the serum phosphate concentration that is regulated by a complex interaction between parathyroid hormone, vitamin D, and calcitonin. About one-half of the serum calcium is bound to plasma proteins; the other half is free ionized calcium. Given that the serum calcium has significant protein binding, the serum calcium concentration must be corrected in patients who have low albumin concentrations (the major serum protein). The most commonly used formula adds 0.8 mg/dL (0.2 mmol/L) of calcium for each gram of albumin deficiency as follows:

$$\text{Corrected [Ca]} = \text{Measured [Ca mg/dL]} + [0.8 \times (4 - \text{measured albumin})]$$ [29–31]

Note: To convert conventional units (mg/dL) to SI calcium units multiply by a factor of 0.25.

Hypocalcemia is caused by inadequate intake (vitamin deficiency, poor dietary calcium sources, and alcoholism) or excessive losses (hypoparathyroidism, renal failure, alkalosis, and pancreatitis). Clinical manifestations of hypocalcemia are seen with total serum concentrations less than 6.5 mg/dL (1.63 mmol/L) and include: tetany, circumoral tingling, muscle spasms, hypoactive reflexes, anxiety, hallucinations, hypotension, myocardial infarction, seizures, lethargy, stupor, and **Trousseau's sign or Chvostek's sign.**[32,37] Trousseau's sign is elicited by inflating a blood pressure cuff on the patient's upper arm, whereby hypocalcemic patients will experience tetany of the wrist and hand as evidenced by thumb adduction, wrist flexion, and metacarpophalangeal joint flexion. Chvostek's sign is elicited by tapping on the proximal distribution of the facial nerve (adjacent to the ear). This will produce a brief spasm of the upper lip, eye, nose, or face in hypocalcemic patients.

Causes of hypocalcemia include hypoparathyroidism, hypomagnesemia, alcoholism, hyperphosphatemia, blood product infusion (due to chelation by the citrate buffers), chronic renal failure, vitamin D deficiency, acute pancreatitis, alkalosis, and hypoalbuminemia. Medications that cause hypocalcemia include phosphate replacement products, loop diuretics, phenytoin (Dilantin, available as generic), phenobarbital (available as generic), corticosteroids, aminoglycoside antibiotics, and acetazolamide (available as generic).[34,39,42]

Oral calcium replacement products include calcium carbonate (OsCal®, GlaxoSmithKline and various generics; Tums®, GlaxoSmithKline and various generics) and calcium citrate (Citrical®, Mission Pharmacal, and various generics). IV calcium replacement products include calcium gluconate and calcium chloride (both products available as generic). ❻ *Calcium gluconate is preferred for peripheral use because it is less irritating to the veins; it may also be given intramuscularly.* Each 10 mL of a 10% calcium gluconate solution provides 90 mg (4.5 mEq or 2.25 mmol) of elemental calcium. Calcium chloride is associated with more venous irritation and is generally reserved for administration via central line. Each 10 mL of a 10% calcium chloride solution contains 270 mg (13.5 mEq or 6.75 mmol) of elemental calcium. IV calcium products are given as a slow push or added to 500 to 1000 mL of 0.9% normal saline for slow infusion.[37,42]

For acute symptomatic hypocalcemia, 200 to 300 mg of elemental calcium is administered IV and repeated until symptoms are fully controlled. This is achieved by infusing 1 g of calcium chloride or 2 to 3 grams of calcium at a rate no faster than 30 to 60 mg of elemental calcium per minute. More rapid administration is associated with hypotension, bradycardia, or cardiac asystole. Total calcium concentration is commonly monitored in critically ill patients. Under normal circumstances, about half of calcium is loosely bound to serum proteins while the other half is free. Total calcium concentration measures bound and free calcium. Ionized calcium measures free calcium only. Under usual circumstances, a normal calcium level implies a normal free ionized calcium level. Ionized calcium should be obtained in patients with comorbid conditions that would lead to inconsistency between total calcium and free serum calcium (abnormal albumin, protein, or immunoglobulin concentrations). For chronic asymptomatic hypocalcemia, oral calcium supplements are given at doses of 2 to 4 g/day of elemental calcium. Many patients with calcium deficiency have concurrent vitamin D deficiency that must also be corrected in order to restore calcium homeostasis.[2,37,38]

Hypercalcemia is defined as a calcium concentration greater than 10.2 mg/dL (2.55 mmol/L). It may be categorized as mild if total serum calcium is 10.3 to 12 mg/dL (2.575 to 3 mmol/L), moderate if total serum calcium is 12.1 to 13 mg/dL

(3.025 to 3.25 mmol/L), or severe when serum concentration is greater than 13 mg/dL (3.25 mmol/L). Causes of hypercalcemia include hyperparathyroidism, malignancy, Paget's disease, granulomatous diseases (e.g., tuberculosis, sarcoidosis, or histoplasmosis), hyperthyroidism, immobilization, multiple bony fractures, acidosis, and milk-alkali syndrome. Multiple medications cause hypercalcemia and include thiazide diuretics, estrogens, lithium (available as generic), tamoxifen (Nolvadex®, available as generic), vitamin A, vitamin D, and calcium supplements.[2,33,37,42]

Because the severity of symptoms and the absolute serum concentration are poorly correlated in some patients, institution of therapy should be dictated by the clinical scenario. All patients with hypercalcemia should be treated with aggressive rehydration: normal saline at 200 to 300 mL/hour is a routine initial fluid prescription. For patients with mild hypocalcemia, hydration alone may provide adequate therapy. The moderate and severe forms of hypercalcemia are more likely to have significant manifestations and require prompt initiation of additional therapy. These patients may present with anorexia, confusion, and/or cardiac manifestations (bradycardia and arrhythmias with ECG changes). Total calcium concentrations greater than 13 mg/dL (3.25 mmol/L) are particularly worrisome, as these levels can unexpectedly precipitate acute renal failure, ventricular arrhythmias, and sudden death.

Once fluid administration has repleted the ECF, forced diuresis (with associated calcium loss) can be initiated with a loop diuretic. For this approach to be successful, normal kidney function is required. In renal failure patients, the alternative therapy is emergent hemodialysis. Other treatment options include bisphosphonates (zoledronic acid [Zometa®, Novartis], pamidronate [Aredia®, available as generic]), hydrocortisone (available as generic), mithramycin (Mithracin®), calcitonin, and gallium. Given their efficacy and favorable side-effect profile, bisphosphonates are typically the agents of choice. Table 24–9 outlines the treatment options for hypercalcemia including time to onset of effect, duration of effect, and efficacy.[2,34,37,38]

Phosphorus

Phosphorus is primarily found in the bone (80% to 85%) and ICF (15% to 20%): the remaining less than 1% is found in the ECF. Note that phosphorus is the major anion within the cells. Given this distribution, serum phosphate concentration does not accurately reflect total body phosphorus stores. Phosphorus is expressed in milligrams (mg) or millimoles (mmol), not as milliequivalents (mEq). Because phosphorus is the source of phosphate for adenosine triphosphate (ATP) and phospholipid synthesis, manifestations of phosphorus imbalance are variable.

Dietary intake, parathyroid hormone levels, and renal function are the major determinants of the serum phosphorus concentration, which is normally 2.7 to 4.5 mg/dL (0.87 to 1.45 mmol/L).[2,35–37] Hypophosphatemia is defined by a serum phosphorus concentration less than 2.5 mg/dL (0.81 mmol/L); severe hypophosphatemia occurs when the phosphorus concentration is less than 1 mg/dL (0.323 mmol/L). Hypophosphatemia can be caused by increased distribution to the ICF (hyperglycemia, insulin therapy, or malnourishment), decreased absorption (starvation, excessive use of phosphorus-binding antacids, vitamin D deficiency, diarrhea, or laxative abuse) or increased renal loss (diuretic use, diabetic ketoacidosis, alcohol abuse, hyperparathyroidism, or burns).[38,39] ❼ *In the critical care setting, hypophosphatemia can result in impaired diaphragmatic contractility and acute respiratory failure.* Medications that cause hypophosphatemia include diuretics (acetazolamide [Diamox, available as generic], furosemide [Lasix, available as generic], hydrochlorothiazide [Hydrodiuril, available as generic]), sucralfate (Carafate, available as generic), corticosteroids, cisplatin (available as generic), antacids (aluminum carbonate, calcium carbonate, and magnesium oxide [antacids all available as generic]), foscarnet (Foscavir, Astra Zeneca), phenytoin (Dilantin, available as generic), phenobarbital (available as generic), and phosphate binders (sevelamer [Renagel, Genzyme Corp.], and calcium acetate [PhosLo, Nabi]).

Signs and symptoms of hypophosphatemia include paresthesias, muscle weakness, myalgias, bone pain, anorexia, nausea, vomiting, RBC hemolysis, acute respiratory failure, seizures, and coma.[38,40] For mild hypophosphatemia, patients should be encouraged to eat a high-phosphorus diet including eggs, nuts, whole grains, meat, fish, poultry, and milk products. For moderate hypophosphatemia (1 to 2.5 mg/dL) (0.323 to 0.808 mmol/L), oral supplementation of 1.5 to 2 g/day

TABLE 24–9. Selected Treatment Options for the Management of Hypercalcemia

Therapy	Dose	Onset	Duration	Efficacy[a]
Normal saline	3–6 L/day	Hours	Hours	1–2 mg/dL
Furosemide (Lasix®, available as generic)	80–160 mg/day	Hours	Hours	1–2 mg/dL
Hydrocortisone (available as generic)	200 mg/day	Hours	Days	Mild
Calcitonin (Miacalcin®, Novartis)	4–8 units/kg	Hours	Hours	1–2 mg/dL
Mithramycin (Mithracin®)	25 mcg/kg	12 hours	Days	1–5 mg/dL
Pamidronate[b] (Aredia®, available as generic)	30–90 mg/week	Days	1–4 weeks	1–5 mg/dL
Zoledronic acid (Zometa®, available as generic)	4–8 mg	Days	Weeks	1–5 mg/dL
Gallium (Ganite®, Genta Inc.)	200 mg/m^2	Days	Days–Weeks	1–5 mg/dL

[a]Expected decrease in serum Ca.
[b]Preferred bisphosphonate.

(30 to 60 mmol/day) is usually adequate. Diarrhea may be a dose-limiting side effect with oral phosphate replacement products. Injectable phosphate products are reserved for patients with severe hypophosphatemia or those in the intensive care unit.[41] The available agents are provided as sodium or potassium salts; however, unless concurrent hypokalemia is present, sodium phosphate is usually used. Empirically, if the serum phosphorus is 2.3 to 2.7 mg/dL (0.74 to 0.87 mmol/L), the corresponding IV phosphorus dose is 0.08 to 0.16 mmol/kg; for a serum phosphorus of 1.5 to 2.2 mg/dL (0.48 to 0.71 mmol/L), the replacement dose is 0.16 to 0.32 mmol/kg; and the dose is 0.32 to 0.64 mmol/kg when the serum phosphorus is less than 1.5 mg/dL (0.48 mmol/L).[2] IV phosphorus preparations are usually infused over 4 to 12 hours. Table 24–10 compares the available phosphate replacement products.

Hyperphosphatemia is defined by a serum phosphorus concentration greater than 4.5 mg/dL (1.45 mmol/L). The manifestations of hyperphosphatemia include findings of hypocalcemia (see above), paresthesias, ECG changes (prolonged QT interval and prolonged ST segment), and metastatic calcifications. Causes of hyperphosphatemia include impaired phosphorus secretion (hypoparathyroidism or renal failure), redistribution of phosphorus to the ECF (acid-base imbalance, rhabdomyolysis, muscle necrosis, or tumor lysis during chemotherapy), and increased phosphorus intake (various medications).[38] Medications that can cause hyperphosphatemia include enemas containing phosphorus (e.g., Fleet®, Fleet), laxatives containing phosphate or phosphorus, oral or parenteral phosphorus supplements (e.g., Neutra-Phos®, Ortho McNeil), vitamin D supplements, and the bisphosphonates (e.g., pamidronate, various manufacturers).[42]

Hyperphosphatemia is generally benign and rarely needs aggressive therapy. Dietary restriction of phosphate and protein is effective for most minor elevations. Phosphate binders such as aluminum-based antacids, calcium carbonate, calcium acetate (PhosLo®, Nabi), sevelamer (Renagel®, Genzyme), and lanthanum carbonate (Fosrenol®, Shire) may be necessary for some patients.[43] If patients exhibit findings of hypocalcemia (tetany), IV calcium should be administered empirically.

Magnesium

The body's normal daily magnesium requirement is 300 to 350 mg/day to maintain a serum magnesium concentration of 1.5 to 2.4 mg/dL (0.75 to 1.2 mmol/L). Because magnesium is the second most abundant ICF cation, serum concentrations are a relatively poor measure of total body stores. Magnesium catalyzes and/or activates more than 300 enzymes, provides neuromuscular stability, and is involved in myocardial contraction. Magnesium is generally not part of standard chemistry panels, and therefore must be ordered separately.[2,37,42,44,45]

Hypomagnesemia is defined as a serum magnesium less than 1.5 mg/dL (0.75 mmol/L), and is most frequently seen in the intensive care and postoperative settings. Hypomagnesemia results from inadequate intake (alcoholism, dietary restriction, or inadequate magnesium in total parenteral nutrition [TPN]), inadequate absorption (steatorrhea, cancer, malabsorption syndromes, or excess calcium or phosphorus in the GI tract), excessive GI loss of magnesium (diarrhea, laxative abuse, NG tube suctioning, or acute pancreatitis), or excessive urinary loss of magnesium (primary hyperaldosteronism, certain medications, diabetic ketoacidosis, and renal disorders). Medications that potentially can cause hypomagnesemia include aminoglycoside antibiotics, amphotericin B (available as generic), cisplatin (available as generic), insulin, cyclosporine (available as generic), loop diuretics, and thiazide diuretics. There is also a strong correlation between hypokalemia and hypomagnesemia.[38,42,46]

The findings of hypomagnesemia include muscle weakness, cramps, agitation, confusion, tremor, seizures, ECG changes (increased PR interval, prolonged QRS complex, and increased QT interval), findings of hypocalcemia (see above), refractory hypokalemia (see above), metabolic alkalosis, and digoxin toxicity.[42,47,48]

Asymptomatic mild magnesium deficiencies (1 to 1.5 mg/dL) (0.5 to 0.75 mmol/L) can be managed with increased oral intake of magnesium-containing foods or with oral supplementation. Magnesium oxide (MagOx®, Blaine Pharmaceuticals and various manufacturers) 400 mg tablets contain 241 mg (20 mEq or 10 mmol) of magnesium. Diarrhea is often a dose-limiting side effect of oral supplementation. Severely deficient patients (less than 1.0 mg/dL) (0.5 mmol/L) and all deficient

TABLE 24–10. Phosphate Replacement Products

Product	Route	mg $PO4^-$	mmol $PO4^-$	mEq (mmol) Na^+	mEq (mmol) K^+

IV = intravenous; PO = oral.

critically ill patients should be managed with IV magnesium sulfate. Ten milliliters of a 10% magnesium sulfate solution contains 1 g of magnesium, which is equivalent to 98 mg (8.12 mEq or 4.06 mmol) of elemental magnesium. ❾ *Because magnesium concentration does not correlate well with total body magnesium stores, magnesium is often administered empirically to critically ill patients.*[2,37] Intravenous magnesium has been utilized for the treatment of acute asthma in the emergency department in patients not responding to standard therapy. High doses of IV magnesium sulfate are effective in reducing the risk of eclampsia in women with pre-eclampsia and is routinely administered in this setting.

The most common causes of hypermagnesemia are renal failure, often in conjunction with magnesium-containing medications (cathartics, antacids, or magnesium supplements), and lithium therapy (available as generic). Hypermagnesemia is defined as a serum magnesium concentration greater than 2.4 mg/dL (1.2 mmol/L). Mild hypermagnesemia is present if the serum magnesium concentration is between 2.5 and 4 mg/dL (1.25 to 2 mmol/L) and manifests as nausea, vomiting, cutaneous vasodilation, and bradycardia. Moderate hypermagnesemia is present if the serum magnesium concentration is between 4 and 12 mg/dL (2 to 6 mmol/L) and may manifest with hyporeflexia, weakness, somnolence, hypotension, and ECG changes (increased QRS interval). Severe hypermagnesemia is present if the serum magnesium concentration is greater than 13 mg/dL (6.5 mmol/L) and can manifest as muscle paralysis, complete heart block, asystole, respiratory failure, refractory hypotension, and death.[2,49]

All patients with hypermagnesemia should have all magnesium supplements or magnesium-containing medications discontinued.[2,37] Mild hypermagnesemia and moderate hypermagnesemia without cardiac findings can be treated with normal saline infusion and furosemide therapy (assuming the patient has normal renal function). Moderate hypermagnesemia with cardiac irritability and severe hypermagnesemia require IV calcium gluconate to reverse the neuromuscular and cardiovascular effects. Calcium gluconate given at typical doses of 1 to 2 g IV will have transient effects and can be repeated as clinically indicated. Hemodialysis may be necessary for those with severely compromised renal function.

CONCLUSION

Because disturbances in fluid balance are routinely encountered in clinical medicine, it is essential to have a thorough understanding of body fluid compartments and the therapeutic use of fluids. Similarly, disturbances in serum sodium, potassium, calcium, phosphorus, and magnesium are ubiquitous and must be mastered by all clinicians. Dysregulation of fluid and/or electrolyte status has serious implications regarding the concepts of drug absorption, volumes of distribution, and toxicity. Similarly, many medications can disrupt fluid and/or electrolyte balance as an unintended consequence.

Patient Encounter 8

TO, a 77-year-old male nursing home resident is admitted to the hospital with a 3-day history of altered mental status. The patient was unable to give a history or review of systems. On physical examination the vital signs revealed a blood pressure of 100/60 mm Hg, pulse 110 beats per minute, respirations 14/minutes, and a temperature of 101°F (38.3°C). Rales and dullness to percussion were noted at the posterior right base. The cardiac exam was significant for tachycardia. No edema was present. Laboratory studies included: sodium 160 mEq/L (160 mmol/L), potassium 4.6 mEq/L (4.6 mmol/L), chloride 120 mEq/L (120 mmol/L), bicarbonate 30 mEq/L (30 mmol/L), glucose 104 mg/dL (5.77 mmol/L), BUN 34 mg/dL (12.14 mmol/L), and creatinine 2.2 mg/dL (194.5 µmol/L). The CBC was within normal limits. Chest x-ray indicated a right lower lobe pneumonia.

The patient is 5′10″ (152.4 cm) and currently weighs 160 lb (72.6 kg). His normal weight is 170 pounds (77.1 kg).

- What is the likely cause for the increased sodium concentration in this patient?
- Increased insensible losses (from his fever caused by bacterial pneumonia) and lack of access to water (from his altered level of consciousness)

Calculate the TBW, ICF and ECF for this patient.
IBW = 73 kg. Normal weight = 77 kg (170 lb)
TBW = 77 kg × 0.6 = 46 L
ICF = 46 L × 0.33 = 15 L
ECF = 46 L × 0.67 = 31 L
Calculate TO's fluid deficit if one is present.
170 – 160 = 10/2.2 = 4.5 L, or using the sodium equation
0.6 (77) × [160/140 – 1] = 6.6 L
The fluid deficit is between 4.5 and 6.6 L. We will base our calculations upon a 5 L deficit

In the next 24 hours, the medical team wants to give 50% of the fluid deficit plus an extra 240 mL to account for insensible losses in addition to the patient's maintenance needs. Using the equation (1500 mL + 20 mL for each kg greater than 20 kg), calculate the rate of fluid administration for the total fluids needed in this 24-hour period and over the next 48 hours.

Calculate TO's daily maintenance fluids.

1500 mL + (20 mL/kg × 57 kg) = 2640 mL

Calculate TO's fluids for the first 24 hours.

0.5(5000) + 2640 + 240 = 5380 mL

5380/24 = 225 mL per hour × 24 hours

Calculate TO's fluids for the next 48 hours.

0.5(5000) + 2(2640) + 2(240) = 82,600 mL

8260/48 = 175 mL per hour × 48 hours

- What type of fluid should be used to treat TO's fluid disorder?
- Hypotonic solution such as dextrose 5% and $^1/_2$ normal saline or similar fluid

25 Acid-Base Disturbances

Lee E. Morrow and Mark A. Malesker

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Define primary acid-base disturbances within the human body.
2. Apply simple formulas in order to determine the etiology of simple acid-base disturbances and the adequacy of compensation.
3. Integrate the supplemental concepts of the anion gap and the excess gap to help assess complex acid-base disturbances.
4. Discuss the most common causes of each primary acid-base irregularity.
5. Determine the appropriate management for patients with acid-base disorders.

Key Concepts

❶ Acid-base homeostasis is tightly regulated by the complex, but predictable, interactions of the kidneys, the lungs, and various buffer systems. The kidneys control serum bicarbonate (HCO_3^-) concentration through the excretion or reabsorption of filtered HCO_3^-, the excretion of metabolic acids, and synthesis of new HCO_3^-. The lungs control arterial carbon dioxide levels through changes in the depth and/or rate of respiration.

❷ Respiratory acidosis and alkalosis result from primary disturbances in the arterial carbon dioxide (CO_2) levels. Metabolic compensation of respiratory disturbances is a slow process, often requiring days for the serum HCO_3^- to reach the steady state.

❸ Respiratory acidosis is caused by respiratory insufficiency resulting in an increased arterial CO_2 concentration. The compensation for respiratory acidosis (if present for prolonged periods) is an increase in serum HCO_3^-.

❹ Respiratory alkalosis is caused by hyperventilation resulting in a decreased arterial CO_2 concentration. The compensation for respiratory alkalosis (if present for prolonged periods) is a decrease in serum HCO_3^-.

❺ Metabolic acidosis and alkalosis result from primary disturbances in the serum HCO_3^- concentration. Respiratory compensation of metabolic disturbances begins within minutes and is complete within 12 hours.

❻ Metabolic acidosis is characterized by a decrease in serum HCO_3^-. The anion gap is used to narrow the differential diagnosis, as this acidosis may be caused by addition of acids (increased anion gap) or loss of HCO_3^- (normal anion gap). The compensation for metabolic acidosis is an increase in ventilation with a decrease in arterial CO_2.

❼ Metabolic alkalosis is characterized by an increase in serum HCO_3^-. This disorder requires loss of fluid that is low in HCO_3^- from the body or addition of HCO_3^- to the body. The compensation for metabolic alkalosis is a decrease in ventilation with an increase in arterial CO_2.

❽ Arterial blood gases, serum electrolytes, physical examination findings, the medical history, and the patient's recent medications must be reviewed in order to establish the etiology of a given acid-base disturbance.

❾ It is critical to treat the underlying causative process to effectively resolve most observed acid-base disorders. However, supportive treatment of the pH and electrolytes is often needed until the underlying disease state is improved.

Given its reputation for complexity and the need to memorize innumerable formulas, acid-base analysis intimidates many health care providers. In reality, acid-base disorders always obey well-defined biochemical and physiologic rules. The pH determines a patient's acid-base status and an assessment of the bicarbonate (HCO_3^-) and arterial carbon dioxide ($PaCO_2$) values identifies the underlying process. This makes them easy to recognize and interpret if a practical strategy is rigorously applied. This chapter will outline a clinically useful approach to acid-base abnormalities and then apply this approach in a series of increasingly complex clinical scenarios.

Disturbances of acid-base equilibrium occur in a wide variety of illnesses and are among the most commonly encountered disorders in critical care medicine. The importance of a thorough command of this content cannot be overstated given that acid-base disorders are remarkably common and may result in significant morbidity and mortality. Although severe derangements may affect virtually any organ system, the most serious clinical effects are cardiovascular (arrhythmias and impaired contractility), neurologic (coma and seizures), pulmonary (dyspnea, impaired oxygen delivery, and respiratory fatigue), and/or renal (hypokalemia). Changes in acid-base status also affect multiple aspects of pharmacokinetics (clearance and protein binding) and pharmacodynamics.

ACID-BASE HOMEOSTASIS

Acid-base homeostasis is responsible for maintaining blood hydrogen ion concentration [H^+] near normal despite the daily acidic and/or alkaline loads derived from the intake and metabolism of foods. Acid-base status is traditionally represented in terms of pH, the negative logarithm of [H^+]. Because [H^+] is equal to 24 times the ratio of $PaCO_2$ to HCO_3^-, the pH can be altered by a change in either the bicarbonate concentration or the dissolved carbon dioxide. A critically important concept is that [H^+] is dependent only on the *ratio* of $PaCO_2$ to HCO_3^- and not the absolute amount of either. As such, a normal $PaCO_2$ or HCO_3^- alone does not guarantee that the pH will be normal. Conversely, a normal pH does not imply that either the $PaCO_2$ or HCO_3^- will be normal.

❶ *Blood pH is normally tightly regulated by three distinct mechanisms:*

1. *Extracellular bicarbonate and intracellular protein buffering systems*
2. *Pulmonary regulation of $PaCO_2$, effectively allowing carbonic acid to be eliminated by the lungs as CO_2*
3. *Renal reclamation or excretion of HCO_3^- and excretion of acids such as ammonium.*

Because the kidneys excrete less than 1% of the estimated 13,000 mEq of H^+ ions generated in an average day, renal failure can be present for prolonged periods before life-threatening imbalances occur. Conversely, cessation of breathing for minutes results in profound acid-base disturbances.[1]

The best way to assess a patient's acid-base status is to review the results of an arterial blood gas (ABG) specimen. Blood gas analyzers directly measure the pH and $PaCO_2$ while the HCO_3^- value is calculated using the Henderson-Hasselbalch equation. A more direct measure of serum HCO_3^- is obtained by measuring the total venous carbon dioxide (tCO_2). Because dissolved carbon dioxide is almost exclusively in the form of HCO_3^-, tCO_2 is essentially equivalent to the measured serum HCO_3^- concentration. This value is routinely reported on basic chemistry panels. In the remainder of this chapter the pH and $PaCO_2$ values should be assumed to come from an arterial blood gas while HCO_3^- values should be considered to be measured serum concentrations.

BASIC PATHOPHYSIOLOGY

Under normal circumstances the arterial pH is tightly regulated between 7.35 and 7.45. **Acidemia** is an abnormally low arterial blood pH (less than 7.35) while **acidosis** is a pathologic process that acidifies body fluids. Similarly, **alkalemia** is an abnormally high arterial blood pH (less than 7.45) while **alkalosis** is a pathologic process that alkalinizes body fluids. As such, although a patient can simultaneously have acidosis *and* alkalosis, the end result will be acidemia *or* alkalemia.

Changes in the arterial pH are driven by changes in the $PaCO_2$ and/or the serum HCO_3^-. Carbon dioxide is a volatile acid that is regulated by the depth and rate of respiration. Because CO_2 can be either "blown off" or "retained" by the respiratory system, it is referred to as being under respiratory control. ❷ *A respiratory acid-base disorder is a pH disturbance caused by pathologic alterations of the respiratory system or its central nervous system control.* ❸❹ *Such an alteration may result in the accumulation of $PaCO_2$ beyond normal limits (greater than 45 mm Hg or 6 kPa), a situation termed respiratory acidosis, or it may result in the loss of $PaCO_2$ beyond normal limits (less than 35 mm Hg or 4.7 kPa), a condition termed respiratory alkalosis. Variations in respiratory rate and/or depth allow the lungs to achieve changes in the $PaCO_2$ very quickly (within minutes).*

Bicarbonate is a base that is regulated by renal metabolism via the enzyme carbonic anhydrase. As such, bicarbonate is often referred to as being under metabolic control. ❺ *A metabolic acid-base disorder is a pH disturbance caused by derangement of the pathways responsible for maintaining a normal HCO_3^- level.* ❻❼ *This may result in a pathologic accumulation of HCO_3^- (greater than 26 mEq/L or mmol/L), a condition termed metabolic alkalosis, or it may result in the loss of HCO_3^- beyond normal (less than 22 mEq/L or mmol/L), a condition termed metabolic acidosis. In contrast to the lungs' rapid effects on CO_2, the kidneys change the HCO_3^- very slowly (hours to days).*

TABLE 25–1. The Six Simple Acid-Base Disorders

Type of Disorder	pH	$PaCO_2$[d]	HCO_3^-
1. Metabolic acidosis	↓	Decreased[b] $PaCO_2 = (1.5 \times HCO_3^-) + 8$	Decreased[a]
2. Metabolic alkalosis	↑	Increased[b] $PaCO_2 = (0.9 \times HCO^{3-}) + 15$	Increased[a]
3. Acute respiratory acidosis	↓	Increased[a]	~Normal $\Delta HCO_3^- = 0.1 \times \Delta PaCO_2$[d]
4. Chronic respiratory acidosis	↓	Increased[a]	Increased[c] $\Delta HCO_3^- = 0.35 \times \Delta PaCO_2$[d]
5. Acute respiratory alkalosis	↑	Decreased[a]	~Normal $\Delta HCO_3^- = 0.2 \times \Delta PaCO_2$[d]
6. Chronic respiratory alkalosis	↑	Decreased[a]	Decreased[c] $\Delta HCO_3^- = 0.4 \times \Delta PaCO_2$[d]

[a]Primary disorder.
[b]Respiratory compensation: If inappropriate, see Table 25–2.
[c]Metabolic compensation: If inappropriate, see Table 25–2.
[d]$PaCO_2$ in millimeters of mercury.

Respiratory and metabolic derangements can occur in isolation or in combination. If a patient has an isolated primary acid-base disorder that is not accompanied by another primary acid-base disorder, a **simple (uncomplicated) disorder** is present. The most common clinical disturbances are simple acid-base disorders. If two or three simple acid-base disorders are simultaneously present the patient has a **mixed (complicated) disorder**. More complex clinical situations lead to mixed acid-base disturbances.

Because CO_2 is a volatile acid, it can rapidly be changed by the respiratory system. If a respiratory acid-base disturbance is present for minutes to hours it is considered an **acute disorder** while if it is present for days or longer it is considered a **chronic disorder**. By definition, the metabolic machinery that regulates HCO_3^- results in slow changes in serum bicarbonate and all metabolic disorders are chronic. This means that there are six simple acid-base disorders as outlined in Table 25–1.[2]

Changes that follow the primary disorder and attempt to restore the blood pH to normal are referred to as compensatory changes. It should be stressed that compensation never normalizes the pH. ❺ *Because all metabolic acid-base disorders are chronic and the normal respiratory system can quickly alter the $PaCO_2$, essentially all metabolic disorders are accompanied by some degree of respiratory compensation.*[3] ❷ *Similarly, chronic respiratory acid-base disorders are typically accompanied by attempts at metabolic compensation.*[4,5] *However, with acute respiratory acid-base disorders there is insufficient time for the metabolic pathways to compensate significantly.*[6] *As such, acute respiratory derangements are essentially uncompensated.*

The amount of compensation (metabolic or respiratory) can be reliably predicted based on the degree of derangement in the primary disorder. Table 25–1 outlines the simple acid-base disorders and provides formulas for calculating the expected compensatory responses. Although it isn't mandatory to memorize these formulas in order to interpret acid-base problems, they can be helpful tools. If the measured values differ markedly from the calculated values (the measured serum HCO_3^- is greater than 2 mEq/L from the calculated value or the measured $PaCO_2$ is more than 4 mm Hg from the calculated value), a second acid-base disorder is present as outlined in Table 25–2.

APPLICATION OF BASIC PATHOPHYSIOLOGY

When given an ABG for interpretation, it is essential to use an approach that is focused yet comprehensive. An algorithm illustrating this concept is shown in Fig. 25–1. The first step is to identify all abnormalities in the pH, $PaCO_2$, and/or HCO_3^- and then decide which abnormal values are primary and which are compensatory. This is best done by first looking at the pH. Whichever side of 7.40 the pH is on, the process that

TABLE 25–2. Diagnosis of Concurrent Acid-Base Disturbances when Compensation Is Inappropriate

Primary Acid-Base Disturbance	Assessment of Compensation	Concurrent Acid-Base Disturbance
Metabolic acidosis	$PaCO_2$ too low	Respiratory alkalosis
	$PaCO_2$ too high	Respiratory acidosis
Metabolic alkalosis	$PaCO_2$ too low	Respiratory alkalosis
	$PaCO_2$ too high	Respiratory acidosis
Respiratory acidosis	HCO_3^- too low	Metabolic acidosis
	HCO_3^- too high	Metabolic alkalosis
Respiratory alkalosis	HCO_3^- too low	Metabolic acidosis
	HCO_3^- too high	Metabolic alkalosis

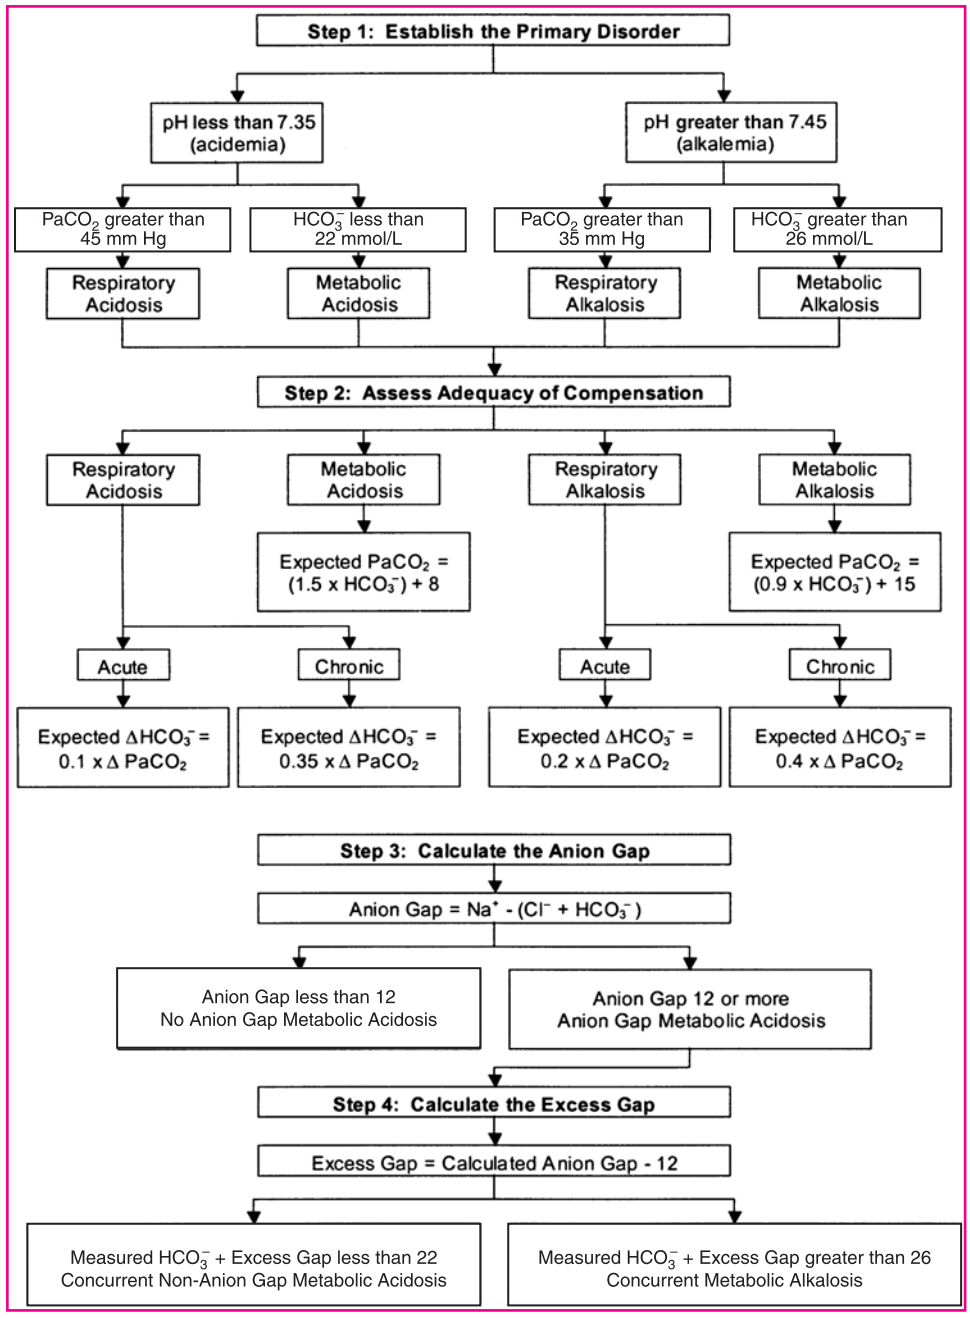

FIGURE 25–1. An algorithmic approach to acid-base disorders. Normal values: pH 7.35 to 7.45, $PaCO_2$ 35 to 45 mm Hg (4.7 to 6 kPa), HCO_3^- 22 to 26 mEq/L (mmol/L), anion gap less than 12 mEq/L (mmol/L). Note that $PaCO_2$ should be in millimeters of mercury to use the equations in the figure. Cl^-, chloride ion; HCO_3^-, bicarbonate; Na^+, sodium ion; $PaCO_2$, partial pressure of arterial carbon dioxide.

caused it to shift to that side is the primary abnormality. If the arterial pH is lower than 7.40 (acidemia), an elevated $PaCO_2$ (greater than 45 mm Hg or 6 kPa, **respiratory acidosis**) or a lowered HCO_3^- (less than 22 mEq/L or mmol/L, **metabolic acidosis**) would be the primary abnormality. If the arterial pH is higher than 7.40 (alkalemia), a decreased $PaCO_2$ (less than 35 or 4.7 kPa, **respiratory alkalosis**) or an increased HCO_3^- (greater than 25 mEq/L or mmol/L, **metabolic alkalosis**) would be the primary abnormality. Once the primary disorder is established, the second step is to apply the formulas from Table 25–1 to assess whether compensation is appropriate and to look for concurrent processes.[2]

An alternative to a diagnostic algorithm is use of a graphic nomogram. Nomograms are plots of the pH, $PaCO_2$, and

HCO_3^- that allow the user to rapidly determine whether arterial blood gas values are consistent with one of the six simple primary acid-base disturbances. Although nomograms are commonly used to identify acid-base disturbances in clinical practice, only individuals who fully comprehend the concepts of acid-base assessment should use these tools. Furthermore, nomograms have limited utility when dealing with complex acid-base derangements.

Acid-base disturbances are always manifestations of underlying clinical disorders. It is useful to specifically define the primary acid-base abnormality, as each disorder is caused by a limited number of disease processes. Establishing the specific disease process responsible for the observed acid-base disorder is clinically important because treatment of a given acid-base disorder will only be accomplished by correcting the underlying disease process.

Patient Encounters 1 through 5: Application of Basic Pathophysiology

Case Study 1

First, consider a patient with a pH of 7.16, a $PaCO_2$ of 70 mm Hg (9.3 kPa), and an HCO_3^- of 27 mEq/L (mmol/L). This person is acidemic (the pH is less than 7.35) with an increased $PaCO_2$ (greater than 45 mm Hg or 6 kPa) and an HCO_3^- that is minimally elevated (normal range 22 to 26 mEq/L or mmol/L). This appears to represent an acute respiratory acidosis with metabolic compensation. To ensure that the value of the serum HCO_3^- represents appropriate compensation, the formulas shown in Table 25–1 are applied. Because the $PaCO_2$ has increased by 30 mm Hg (4 kPa) and the expected change (Δ) in the HCO_3^- is 0.1 x $\Delta PaCO_2$ (in millimeters of mercury), our expected ΔHCO_3^- is 3 mEq/L or mmol/L (0.1 x 30 mEq/L or mmol/L). By adding this expected compensation (3 mEq/L or mmol/L) back to a normal HCO_3^- (24 mEq/L or mmol/L), it becomes evident that this patient's measured HCO_3^- of 27 mEq/L (or mmol/L) is consistent with metabolic compensation. These blood gases were obtained from a patient who had overdosed on heroin, a potent respiratory depressant.

Case Study 2

The next patient has a pH of 7.34, a $PaCO_2$ of 70 mm Hg (9.3 kPa), and an HCO_3^- of 35 mEq/L (mmol/L). Now both the $PaCO_2$ and the HCO_3^- are significantly elevated, two abnormalities with opposite effects on the pH. Because the pH is lower than 7.40, the primary disorder is the elevated $PaCO_2$—again a respiratory acidosis. The markedly elevated bicarbonate and the near-normal pH suggest that metabolic compensation has occurred and that the respiratory acidosis is chronic. Again, this degree of compensation (11 mEq/L or mmol/L) is appropriate. Because the $PaCO_2$ has increased by 30 mm Hg (4 kPa) and the expected ΔHCO_3^- is 0.35 x $\Delta PaCO_2$ (in millimeters of mercury) (see Table 25–1), the expected ΔHCO_3^- is 0.35 x 30 or ~11 mEq/L (mmol/L).

The changes in this patient's pH and HCO_3^- should be compared with the values from the patient in Case Study 1. It is critical to differentiate acute and chronic respiratory acidosis, as the acute form is often a medical emergency that requires intubation and mechanical ventilation, whereas the chronic form is typically a stable condition. The blood gases in Case Study 2 came from a patient with advanced emphysema who is a "CO_2 retainer" due to ineffective ventilation. Because this patient's disease is chronic, the elevated $PaCO_2$ developed very slowly and allowed for metabolic compensation.

Case Study 3

Now consider a patient whose ABG shows a pH of 7.50, a $PaCO_2$ of 29 mm Hg (3.86 kPa), and an HCO_3^- of 22 mEq/L (mmol/L). Because this person is alkalemic, the low $PaCO_2$ is the primary disturbance. Again, this degree of metabolic compensation (2 mEq/L or mmol/L) is appropriate. Because the $PaCO_2$ has decreased by 11 mm Hg (1.46 kPa) and the expected ΔHCO_3^- is 0.2 x $\Delta PaCO_2$ (in millimeters of mercury) (see Table 25–1) the HCO_3^- is expected to change by 0.2 x 11 or ~2 mEq/L (mmol/L). This ABG represents acute respiratory alkalosis with minimal metabolic compensation. These blood gases were obtained from a normal, healthy individual who was having an ABG collected as part of a research protocol. Anxiety caused by the anticipation of an arterial puncture for blood gas collection often causes hyperventilation with acute respiratory alkalosis.

Case Study 4

This patient has an ABG with the following values: pH of 7.50, a $PaCO_2$ of 47 mm Hg (6.3 kPa), and an HCO_3^- of 36 mEq/L (mmol/L). Again, both the $PaCO_2$ and the HCO_3^- are elevated, two abnormalities with opposite effects on the pH. Because the pH is higher than 7.40 the primary disorder is the elevated HCO_3^- (a metabolic alkalosis). In this instance the elevated $PaCO_2$ is consistent with respiratory compensation. From Table 25–1, the formula for the expected compensatory level of the $PaCO_2$ is (0.9 x HCO_3^-) + 15. In this case the predicted $PaCO_2$ would be (0.9 x 36) + 15, or 47 mm Hg (6.3 kPa). These blood gases are from a patient with congestive heart failure who is on chronic diuretic therapy that has caused her metabolic alkalosis. Although respiratory compensation has occurred, this compensation did not (and should not) return the pH entirely to normal.

Case Study 5

The final patient in this section has an ABG with a pH of 7.20, a $PaCO_2$ of 20 mm Hg (2.7 kPa), and an HCO_3^- of 8 mEq/L (mmol/L). Because the patient is acidemic the low bicarbonate is the primary abnormality and a metabolic acidosis is present. The $PaCO_2$ is consistent with respiratory compensation, as the expected value is $PaCO_2$ = (1.5 x HCO_3^-) + 8 which equals (1.5 x 8) + 8, or 20 mm Hg (2.7 kPa) (see Table 25–1). These blood gases came from a patient with chronic renal insufficiency who was hospitalized for gastroenteritis with profound diarrhea. In this instance, the patient had lost extensive amounts of HCO_3^- in her stool and was unable to adequately regenerate HCO_3^- given her underlying renal disease.

ADVANCED PATHOPHYSIOLOGY

The concepts in this section will be used to further expand the diagnostic algorithm shown in Fig. 25–1. Under normal circumstances the serum is in the isoelectric state. This means that the positively charged entities reported in a standard chemistry panel (cations: sodium and potassium) should be exactly balanced by the negatively charged entities (anions: chloride and bicarbonate). However, this relationship is consistently incorrect, as the measured cations are higher than the measured anions by 10 to 12 mEq/L (mmol/L). This discrepancy results from the presence of unmeasured anions (e.g., circulating proteins, phosphates, and sulfates). This apparent difference in charges, the serum **anion gap**, is calculated as follows:

$$\text{Anion gap} = \text{sodium} - (\text{chloride} + \text{bicarbonate})$$

Because the serum potassium content is relatively small and is tightly regulated, it is generally omitted from the calculation.

It is important to realize that the serum HCO_3^- concentration may be affected by the presence of unmeasured endogenous acids (lactic acidosis or ketoacidosis). Bicarbonate will attempt to buffer these acids, resulting in a 1 mEq loss of serum HCO_3^- for each 1 mEq of acid titrated. Because the cation side of the equation is not affected by this transaction, the loss of serum HCO_3^- results in an increase in the calculated anion gap. Identification of an increased anion gap is very important for identifying the etiology of the acid-base disorder. The concept of the increased anion gap will be applied later in the case studies section.

Any time an ABG is analyzed it is wise to concurrently inspect the serum chemistry values to calculate the anion gap. The body does not generate an anion gap to compensate for a primary disorder. As such, if the calculated anion gap exceeds 12 mEq/L (mmol/L) there is a primary metabolic acidosis regardless of the pH or the serum HCO_3^- concentration. The anion gap may be artificially lowered by decreased serum albumin, multiple myeloma, lithium intoxication, or a profound increase in the serum potassium, calcium, or magnesium.

Calculation of the anion gap also facilitates determination of the **excess gap** or the degree to which the calculated anion gap exceeds the normal anion gap. The excess gap is calculated as follows:

$$\text{Excess gap} = [\text{sodium} - (\text{chloride} + \text{bicarbonate})] - 12$$

The excess gap represents the amount of HCO_3^- that has been lost due to buffering unmeasured cations. The excess gap can be added back to the measured HCO_3^- to determine what the patient's bicarbonate would be if these endogenous acids were not present. This is a very valuable tool that can be used in narrowing the differential diagnosis of certain acid-base disorders as well as in uncovering occult or mixed acid-base disorders.

In summary, the approach to assessment of acid-base status involves four key steps: (1) initial inspection of the pH, $PaCO_2$, and HCO_3^-; (2) assessment of the adequacy of compensation; (3) calculation of the anion gap; and (4) calculation of the excess gap.

ETIOLOGY AND TREATMENT

❽ *After an acid-base disorder has been completely characterized, the patient's medical history, physical exam, and medications should be reviewed in order to establish the etiology of the given disorder.* Tables 25–3 through 25–7 outline the most commonly encountered causes of the primary acid-base disorders. The therapeutic approach to each of these acid-base derangements should emphasize a search for the cause, as opposed to immediate attempts to normalize the pH. ❾ *Although supportive measures to prevent the sequelae of marked acid-base abnormalities is often required, these therapies will be required indefinitely if the causative process is not also identified and corrected.*[7,8]

All patients with significant disturbances in their acid-base status require continuous cardiovascular and hemodynamic monitoring. Because frequent assessment of the patient's response to treatment is critical, an arterial line is often placed to minimize patient discomfort with serial ABG collections. If

TABLE 25–3. Common Causes of Metabolic Acidosis

Elevated Anion Gap[a]	Normal Anion Gap[a]
Intoxications	Bowel fistula
Methanol	Diarrhea
Ethylene glycol	Dilutional acidosis
Salicylates	Drugs
Paraldehyde	Acetazolamide[b]
Isoniazid	Ammonium chloride[b]
Ketoacidosis	Amphotericin B[b]
Diabetic	Arginine hydrochloride[c]
Ethanol	Cholestyramine[b]
Starvation	Hydrochloric acid[b]
Lactic acidosis	Lithium[b]
Carbon monoxide poisoning	Parenteral nutrition[b]
Drugs	Topiramate[b]
IV lorazepam (due to vehicle)[c]	Zonisamide[b]
Metformin[b]	Lead poisoning
Nitroprusside (due to cyanide accumulation)[b]	Renal tubular acidosis
Nucleoside reverse transcriptase inhibitors[b]	Surgical drains
Propofol[c]	Ureteral diversion
Seizures	Villous adenomas (some)
Severe hypoxemia	
Shock	
Renal failure	

[a]Anion gap = serum sodium concentration – (serum chloride concentration + serum bicarbonate concentration). Under normal circumstances the anion gap should be 10 mEq/L (mmol/L) or less.
[b]May be observed with therapeutic doses or overdoses.
[c]Typically observed only with overdoses.

Patient Encounters 6 through 10: Application of Advanced Pathophysiology

Case Study 6

Now consider a psychiatric patient who presents with a pH of 7.50, a $PaCO_2$ of 20 mm Hg (2.7 kPa), an HCO_3^- of 16 mEq/L (mmol/L), a sodium concentration of 140 mEq/L (mmol/L), and a chloride level of 103 mEq/L (mmol/L). Because this person is alkalemic, the low $PaCO_2$ is the primary disturbance and represents respiratory alkalosis. If this disturbance is a chronic respiratory alkalosis with metabolic compensation, the expected ΔHCO_3^- is 0.4 x $\Delta PaCO_2$ (in millimeters of mercury) or 0.4 x 20, which is 8 mEq/L (mmol/L). As such, the predicted HCO_3^- concentration should be 24 mEq/L (mmol/L) [normal] – 8 mEq/L (mmol/L) [expected compensation] or 16 mEq/L (16 mmol/L).

Given the ABG values shown, most clinicians would stop at this point and erroneously conclude that the patient has a chronic respiratory alkalosis with metabolic compensation. However, calculation of the anion gap reveals a "hidden" disorder. The anion gap for this patient is 140 – (103 + 16) = 21 mEq/L (mmol/L). The presence of this abnormally large anion gap indicates that a second primary disorder (an anion gap metabolic acidosis) is also present. The excess anion gap (21 – 12 = 9 mEq/L [mmol/L]) should be added back to the measured serum HCO_3^- (16 mEq/L [mmol/L]) to tell us the patient's baseline HCO_3^- level (before buffering the acid that has widened the anion gap). Doing so provides a normal starting HCO_3^- of 25 mEq/L (mmol/L), indicating that no further primary abnormalities are present.

This patient had ingested a large quantity of aspirin resulting in the classic findings of a salicylate overdose: a centrally mediated respiratory alkalosis with a concurrent anion gap metabolic acidosis.

Case Study 7

These values come from an unconscious man in the intensive care unit: pH of 7.40, $PaCO_2$ of 40 mm Hg (5.3 kPa), HCO_3^- of 24 mEq/L (mmol/L), sodium concentration of 145 mEq/L (mmol/L), and chloride level of 100 mEq/L (mmol/L). In this case, all of the ABG and electrolyte values are surprisingly normal. However, the anion gap is elevated [145 – (100 + 24) = 21 mEq/L or mmol/L]. The increased anion gap identifies a metabolic acidosis even though the pH is normal. The excess anion gap is 21 – 12 = 9 mEq/L (mmol/L). Adding the excess gap back to the measured HCO_3^- (24 mEq/L or mmol/L) gives a baseline HCO_3^- value of 33 mEq/L (mmol/L). This abnormally high value tells us that the patient has a concurrent metabolic alkalosis. This patient had end-stage kidney disease and after missing several dialysis sessions developed increasing uremia (causing the anion gap metabolic acidosis) with intense vomiting (causing the metabolic alkalosis). The acute alkalosis from his vomiting offset his chronic acidosis of renal failure, resulting in a normal pH. This is another example of a "hidden" acid-base derangement that would routinely be missed by clinicians who do not utilize a systematic approach to ABG interpretation.

Case Study 8

This intoxicated patient has a pH of 7.50, a $PaCO_2$ of 20 mm Hg (2.7 kPa), an HCO_3^- of 15 mEq/L (mmol/L), a sodium concentration of 145 mEq/L (mmol/L), and a chloride level of 100 mEq/L (mmol/L). Here the pH is high, the $PaCO_2$ and HCO_3^- are low, and there is an anion gap of 30 mEq/L (mmol/L). Because the patient is alkalemic, the low $PaCO_2$ is the primary disturbance and the patient has a respiratory alkalosis. By definition, the increased anion gap is consistent with a metabolic acidosis. The excess gap is 18 mEq/L (mmol/L), indicating that the patient's original HCO_3^- was 33 mEq/L (mmol/L), indicating a concurrent metabolic alkalosis. Despite this "triple disorder," the pH is only mildly abnormal. This man had alcoholic ketoacidosis (causing the anion gap metabolic acidosis), with persistent vomiting (causing metabolic alkalosis), and an aspiration pneumonia (causing respiratory alkalosis). Triple disorders represent the most complex acid-base derangements. A patient *cannot* have four primary acid-base disorders, as it is impossible to simultaneously hyperventilate (respiratory alkalosis) and hypoventilate (respiratory acidosis).

Case Study 9

The next labs are from a patient who was brought to the hospital unconscious and was quickly intubated. The blood work drawn prior to intubation shows a pH of 7.10, a $PaCO_2$ of 50 mm Hg (6.7 kPa), an HCO_3^- of 15 mEq/L (mmol/L), a sodium concentration of 145 mEq/L (mmol/L), and a chloride level of 100 mEq/L (mmol/L). This person is acidemic and has an elevated $PaCO_2$ with a low bicarbonate. Furthermore, the anion gap is markedly abnormal at 30 mEq/L. As such, the patient has a respiratory acidosis and an anion gap metabolic acidosis as primary disorders. Adding the excess gap (18 mEq/L or mmol/L) to the measured HCO_3^- (15 mEq/L or mmol/L) gives a starting bicarbonate of 33 mEq/L. This represents a concurrent primary metabolic alkalosis and the presence of a triple disorder. This patient had diabetic ketoacidosis (anion gap metabolic acidosis) with prominent vomiting (metabolic alkalosis) who became obtunded and was hypoventilating (respiratory acidosis).

Case Study 10

The final patient is a young woman with a pH of 7.15, a $PaCO_2$ of 15 mm Hg (2 kPa), an HCO_3^- of 5 mEq/L (mmol/L), a sodium concentration of 140 mEq/L (mmol/L) , and a chloride level of 110 mEq/L (mmol/L). She is acidemic with a low $PaCO_2$, a low bicarbonate, and an increased calculated anion gap (25 mEq/L or mmol/L). The expected $PaCO_2$ with respiratory compensation is (1.5 x HCO_3^-) + 8 or 15.5 mm Hg (2.1 kPa). As such, these values look like a simple anion gap metabolic acidosis with respiratory compensation. However, after adding the excess gap (13 mEq/L or mmol/L) back to the measured serum bicarbonate (5 mEq/L or mmol/L) it is apparent that this patient had a baseline HCO_3^- of 18 mEq/L (mmol/L). This patient has a concurrent anion gap metabolic acidosis and a non-anion gap metabolic acidosis. This woman was in the recovery phase of diabetic ketoacidosis. During this period, a non-anion gap acidosis can be present due to the kidneys' inability to regenerate bicarbonate from the ketoacids lost in the urine.

the anion gap was initially abnormal, serial chemistries should be followed to ensure that the anion gap resolves with treatment. Specific treatment decisions depend on the underlying pathophysiologic state (e.g., dialysis for renal failure, insulin for diabetic ketoacidosis, or improving tissue perfusion and oxygenation for lactic acidosis).

Metabolic Acidosis

❻ *Metabolic acidosis is characterized by a reduced arterial pH, a primary decrease in the HCO_3^- concentration, and a compensatory reduction in the $PaCO_2$. The etiologies of metabolic acidosis are divided into those that lead to an increase in the anion gap and those associated with a normal anion gap and are listed in Table 25–3.* Although there are numerous mnemonics to recall the differential diagnosis of metabolic acidosis, two simple ones are shown in Table 25–4. High anion gap metabolic acidosis is most frequently caused by lactic acidosis, ketoacidosis, and/or renal failure. Although there is considerable variation, the largest anion gaps are caused by ketoacidosis, lactic acidosis, and methanol or ethylene glycol ingestion.[9]

Symptoms of metabolic acidosis are attributable to changes in the cardiovascular, musculoskeletal, neurologic, or pulmonary function. Respiratory compensation requires marked increases in minute ventilation and may lead to dyspnea. Acidemia predisposes to ventricular arrhythmias and reduces cardiac contractility, each of which can result in pulmonary edema and/or systemic hypotension. Neurologic symptoms range from lethargy to coma and are usually proportional to the severity of the pH derangement. Chronic metabolic acidosis leads to a variety of musculoskeletal problems including impaired growth, rickets, osteomalacia, or osteopenia. These changes are believed to be caused by the release of calcium and phosphate during bone buffering of excess H^+ ions.

As previously discussed, in anion gap metabolic acidosis, the isoelectric state is maintained because unmeasured anions are present. With a *normal* anion gap metabolic acidosis, the isoelectric state is maintained by an increase in the measured chloride. Because of this, normal anion gap metabolic acidosis is often referred to as hyperchloremic acidosis.

In patients with a normal anion gap metabolic acidosis it is often helpful to calculate the urine anion gap (UAG). The UAG is calculated as follows:

$$UAG = (Urine\ Na^+ + Urine\ K^+) - Urine\ Cl^-$$

TABLE 25–4. Mnemonics for the Differential Diagnoses of Metabolic Acidosis

Elevated Anion Gap[a]	Normal Anion Gap[a]
M – Methanol	**U** – Ureteral diversion
U – Uremia	**S** – Saline infusion
D – Diabetic ketoacidosis	**E** – Exogenous acid
P – Paraldehyde	**D** – Diarrhea
I – Isoniazid	
L – Lactic acidosis	**C** – Carbonic anhydrase inhibitors
E – Ethylene glycol	**A** – Adrenal insufficiency
S – Salicylates	**R** – Renal tubular acidosis

[a]Anion gap = serum sodium concentration – (serum chloride concentration + serum bicarbonate concentration). Under normal circumstances the anion gap should be 10 mEq/L (mmol/L) or less.

TABLE 25–5. Common Causes of Metabolic Alkalosis

Urine Cl^- less than 10 mEq/L (less than10 mmol/L)	Urine Cl^- greater than 10 mEq/L (greater than10 mmol/L)
Alkali administration	Drugs[a]
IV bicarbonate therapy	Corticosteroid therapy
Oral alkali therapy	Diuretics
Parenteral nutrition with acetate	Hypokalemia
"Contraction alkalosis" post-diuretic use	Mineralocorticoid excess
Decreased chloride intake	Hyperaldosteronism
Loss of gastric acid	Bartter's syndrome
Vomiting	Cushing's syndrome
Nasogastric suction	
Post-hypercapnia	
Villous adenomas (some)

Panic disorder	

[a]May be observed with therapeutic doses or overdoses.

The normal UAG ranges from 0 to 5 mEq/L (mmol/L) and represents the presence of unmeasured urinary anions. In metabolic acidosis, the excretion of NH_4^+ and concurrent Cl^- should increase markedly if renal acidification is intact. This results in UAG values from –20 to –50 mEq/L (mmol/L). This occurs because the urinary Cl^- concentration now markedly exceeds the urinary Na^+ and K^+ concentrations. Diagnoses consistent with an excessively negative UAG include proximal (type 2) renal tubular acidosis, diarrhea, or administration of acetazolamide or hydrochloric acid (HCl). Excessively positive values of the UAG suggest a distal (type 1) renal tubular acidosis.

In order to effectively treat metabolic acidosis, the *causative process* must be identified and treated.[17] The role of adjunctive therapy with sodium bicarbonate ($NaHCO_3$) is not universally agreed upon. However, most individuals would agree that $NaHCO_3$ is indicated when renal dysfunction precludes adequate regeneration of HCO_3^- or when severe acidemia (pH less than 7.10) is present. The metabolic acidosis seen with lactic acidosis and ketoacidosis generally resolves with therapy targeted at the underlying cause and $NaHCO_3$ may be unnecessary regardless of the pH. The metabolic acidosis of renal failure, renal tubular acidosis, or intoxication with ethylene glycol, methanol, or salicylates is much more likely to require $NaHCO_3$ therapy.

If $NaHCO_3$ is used, the plasma HCO_3^- should not be corrected entirely. Instead, aim at increasing HCO_3^- above an absolute value of 10 mEq/L. The total HCO_3^- deficit can be calculated from the current bicarbonate level ($HCO_{3\,curr}^-$), the desired bicarbonate level ($HCO_{3\,post}^-$), and the body weight (in kilograms) as follows:

$$HCO_3^- \text{ deficit} = [(2.4/HCO_{3\,curr}^-) + 0.4] \times \text{weight} \times (HCO_{3\,curr}^- - HCO_{3\,post}^-)$$

No more than half of the calculated HCO_3^- deficit should be given initially to avoid volume overload, hypernatremia, hyperosmolarity, overshoot alkalemia, and/or hypokalemia. The calculated HCO_3^- deficit reflects only the present situation and does not account for ongoing H^+ production and HCO_3^- loss. When giving HCO_3^- therapy, serial blood gases are needed to monitor therapy.

Another option for patients with severe acidemia is tromethamine (THAM). This inert amino alcohol buffers acids and CO_2 through its amine ($-NH_2$) moiety:

$$THAM\text{-}NH_2 + H^+ = THAM\text{-}NH_3^+$$

$$THAM\text{-}NH_2 + H_2O + CO_2 = THAM\text{-}NH_3^+ + HCO_3^-$$

Protonated THAM (with Cl^- or HCO_3^-) is excreted in the urine at a rate that is slightly higher than creatinine clearance. As such, THAM augments the buffering capacity of the blood without generating excess CO_2. THAM is less effective in patients with renal failure and toxicities may include hyperkalemia, hypoglycemia, and possible respiratory depression.

Metabolic Alkalosis

❼ *Metabolic alkalosis is characterized by an increased arterial pH, a primary increase in the HCO_3^- concentration, and a compensatory increase in the $PaCO_2$.* Patients will always hypoventilate to compensate for metabolic alkalosis—even if it results in profound hypoxemia. For a metabolic alkalosis to persist there must concurrently be a process that elevates serum HCO_3^- concentration (gastric or renal loss of acids) and another that impairs renal HCO_3^- excretion (hypovolemia, hypokalemia, or mineralocorticoid excess). The etiologies of metabolic alkalosis are listed in Table 25–5.

Patients with metabolic alkalosis rarely have symptoms attributable to alkalemia. Rather, complaints are usually related to volume depletion (muscle cramps, positional dizziness, and weakness) or to hypokalemia (muscle weakness, polyuria, and polydipsia).

In order to effectively treat metabolic alkalosis, the *causative process* must be identified and treated. The major causes of metabolic alkalosis are often readily apparent after carefully reviewing the patient's history and medication list. Always look for administration of compounds such as citrate in blood products and acetate in parenteral nutrition that can raise the HCO_3^- level. If the etiology of the metabolic alkalosis is still unclear, measurement of the urinary chloride may be useful. Some processes leading to metabolic alkalosis (vomiting, nasogastric suction losses, and factitious diarrhea) will have low urinary Cl^- levels (less than 25 mEq/L or mmol/L), while others (diuretics, hypokalemia, and mineralocorticoid excess) will have higher urinary Cl^- levels (greater than 40 mEq/L or mmol/L).

In general, contributing factors such as diuretics, nasogastric suction, and corticosteroids should be discontinued if possible. Any fluid deficits should be treated with IV normal saline. Recognize that patients with varieties of metabolic

alkalosis with high urine Cl^- (though rather uncommon) will be resistant to saline loading. Potassium supplementation should always be given if it is also deficient.

In patients with mild or moderate alkalosis who require ongoing diuresis but have rising HCO_3^- levels, the carbonic anhydrase inhibitor acetazolamide can be used to reduce the HCO_3^- concentration. Acetazolamide is typically dosed at 250 mg every 6 to 12 hours as needed to maintain the pH in a clinically acceptable range. If alkalosis is profound and potentially life-threatening (due to seizures or ventricular tachyarrhythmias) consideration can be given to hemodialysis or transient HCl infusion. The hydrogen ion deficit (in milliequivalents or millimoles) can be estimated from the current bicarbonate level ($HCO_3^-{}_{curr}$), the desired bicarbonate level ($HCO_3^-{}_{post}$), and the body weight (in kilograms) as follows:

$$H^+ \text{ deficit} = 0.4 \times \text{weight} \times (HCO_3^-{}_{curr} - HCO_3^-{}_{post})$$

After estimating the H^+ deficit, 0.1 to 0.2 N HCl is infused at 20 to 50 mEq/hour (mmol/hour) into a central vein. Arterial pH must be monitored at least hourly and the infusion stopped as soon as clinically feasible. Ammonium chloride and arginine hydrochloride, agents that result in the formation of HCl, should not be given, as they may lead to significant toxicity. Ammonium chloride causes accumulation of ammonia and is associated with encephalopathy. Arginine hydrochloride can induce life-threatening hyperkalemia through unclear mechanisms.

Respiratory Acidosis

❸ *Respiratory acidosis is characterized by a reduced arterial pH, a primary increase in the arterial $PaCO_2$ and, when present for sufficient time, a compensatory rise in the HCO_3^- concentration.* Because increased CO_2 is a potent respiratory stimulus, respiratory acidosis represents ventilatory failure or impaired central control of ventilation as opposed to an increase in CO_2 production. As such, most patients will have hypoxemia in addition to hypercapnia. The most common etiologies of respiratory acidosis are listed in Table 25–6.

Severe, acute respiratory acidosis produces a variety of neurologic abnormalities. Initially these include headache, blurred vision, restlessness, and anxiety. These may progress to tremors, asterixis, somnolence, and/or delirium. If untreated, terminal manifestations include peripheral vasodilation leading to hypotension and cardiac arrhythmias. Chronic respiratory acidosis is typically associated with cor pulmonale and peripheral edema.

In order to effectively treat respiratory acidosis, the *causative process* must be identified and treated. If a cause is identified, specific therapy should be started. This may include naloxone for opiate-induced hypoventilation or bronchodilator therapy for acute bronchospasm. Because respiratory acidosis represents ventilatory failure, an increase in alveolar ventilation is required. This can often be achieved by controlling the underlying disease (e.g., bronchodilators and corticosteroids in asthma) and/or physically augmenting ventilation.

Although their precise role and mechanisms of action are unclear, agents such as medroxyprogesterone, theophylline, and doxapram stimulate respiration and have been used to treat mild to moderate respiratory acidosis. Moderate or severe respiratory acidosis requires assisted ventilation. This can be provided to spontaneously breathing patients via bilevel positive airway pressure (BiPAP) delivered via a tight-fitting mask, or by intubation followed by mechanical ventilation. In mechanically ventilated patients, respiratory acidosis is treated by increasing the minute ventilation. This is achieved by increasing the respiratory rate and/or tidal volume.

As with the treatment of metabolic acidosis, the role of $NaHCO_3$ therapy is not well defined for respiratory acidosis. Realize that administration of $NaHCO_3$ can paradoxically result in increased CO_2 generation ($HCO_3^- + H^+ \rightarrow H_2CO_3 \rightarrow H_2O + CO_2$) and worsened acidemia. Careful monitoring of the pH is required if $NaHCO_3$ therapy is started for this indication. The use of THAM in respiratory acidosis (see metabolic acidosis, above) has unproven safety and benefit.

The goals of therapy in patients with chronic respiratory acidosis are to maintain oxygenation and to improve alveolar ventilation if possible. Because of the presence of renal compensation it is usually not necessary to treat the pH, even in patients with severe hypercapnia. Although the specific treatment varies with the underlying disease, excessive oxygen and sedatives should be avoided, as they can worsen CO_2 retention.

Respiratory Alkalosis

❹ *Respiratory alkalosis is characterized by an increased arterial pH, a primary decrease in the arterial $PaCO_2$ and, when present for sufficient time, a compensatory fall in the HCO_3^- concentration.* Respiratory alkalosis represents hyperventilation and is remarkably common. The most common etiologies of respiratory acidosis are listed in Table 25–7 and range from benign (anxiety) to life-threatening (pulmonary embolism). Some causes of hyperventilation and respiratory acidosis are remarkably common (hypoxemia or anemia).

The symptoms produced by respiratory alkalosis result from increased irritability of the central and peripheral nervous systems. These include light-headedness, altered consciousness, distal extremity paresthesias, circumoral paresthesia, cramps, carpopedal spasms, and syncope. Various supraventricular and ventricular cardiac arrhythmias may occur in extreme cases, particularly in critically ill patients. An additional finding in many patients with severe respiratory alkalosis is hypophosphatemia, reflecting a shift of phosphate from the extracellular space into the cells. Chronic respiratory alkalosis is generally asymptomatic.

It is imperative to identify serious causes of respiratory alkalosis and institute effective treatment. In spontaneously breathing patients, respiratory alkalosis is typically only mild or moderate in severity and no specific therapy is indicated. Severe alkalosis generally represents respiratory acidosis imposed on metabolic alkalosis and may improve with sedation. Patients receiving mechanical ventilation are treated with reduced minute ventilation achieved by decreasing the respiratory rate and/or tidal volume. If the alkalosis persists in the ventilated patient, high-level sedation or paralysis is effective.

SUMMARY

Acid-base disturbances are common clinical problems that are not difficult to analyze if approached in a consistent manner. The pH, $PaCO_2$, and HCO_3^- should be inspected to identify all abnormal values. This should lead to an assessment of which deviations represent the primary abnormality and which represent compensatory changes. The serum electrolytes should always be used to calculate the anion gap. In cases in which the anion gap is increased, the excess anion gap should be added back to the measured HCO_3^-. The anion gap and the excess gap are useful tools that can identify hidden disorders. This rigorous assessment of the patient's acid-base status, incorporated with the available clinical data, increases the likelihood that the clinician will successfully determine the cause of each identified disorder. Although supportive therapy is often required for profound acid-base disturbances, definitive therapy must target the underlying process that has led to the observed derangements.

Patient Care and Monitoring

1. Every patient with a suspected acid-base disturbance should have an arterial blood gas and a serum chemistry panel drawn concurrently. The results of these tests should be reviewed using a systematic approach to ensure proper interpretation.
2. What is the primary disorder? Has compensation occurred?
3. Is the anion gap excessively large? If so, does calculation of the excess gap identify another acid-base disorder?
4. Continuous cardiovascular and hemodynamic monitoring should be used for significant pH disturbances, as the most serious sequelae of acid-base disorders include electrolyte abnormalities, cardiac dysrhythmias, and systemic hypotension.
5. All acid-base abnormalities result from underlying disease processes. Definitive therapy for these disturbances requires treatment of the illness that has disrupted the pH equilibrium.
6. Review each patient's history, physical exam, and current medication list for potential causes of the observed acid-base disorder.
7. Serial arterial blood gases and serum chemistries should be compared, as every patient's acid-base status is continuously changing based on the underlying disease state and any therapy initiated.

ABBREVIATIONS

ABG:	arterial blood gas
BiPAP:	bilevel positive airway pressure
Cl^-:	chloride ion
CO_2:	carbon dioxide
Δ(delta):	change
H^+:	hydrogen ion
HCl:	hydrochloric acid
HCO_3^-:	bicarbonate
$HCO_{3\,curr}^-$:	current bicarbonate
$HCO_{3\,post}^-$:	post-therapy bicarbonate
Hg:	mercury
K^+:	potassium ion
kg:	kilogram
kPa:	kilopascal
L:	liter
mEq:	milliequivalent
mm:	millimeter
mmol:	millimole
Na^+:	sodium ion
$NaHCO_3$:	sodium bicarbonate
NH_2:	terminal amine group
NH_4^+:	ammonium
pH:	logarithm of the hydrogen ion concentration
$PaCO_2$:	partial pressure of arterial carbon dioxide
tCO_2:	total venous carbon dioxide
THAM:	tromethamine
UAG:	urine anion gap

26 Multiple Sclerosis

Melody Ryan

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Identify risk factors for multiple sclerosis.
2. Describe pathophysiologic findings of multiple sclerosis.
3. Recognize common presenting symptoms of multiple sclerosis.
4. Distinguish between the forms of multiple sclerosis based on the patient presentation and course of disease.
5. Compare and contrast multiple sclerosis disease-modifying treatment choices for a specific patient.
6. Determine appropriate symptomatic treatment choices and a detailed therapeutic plan for a specific patient.
7. Develop a monitoring plan for a patient placed on specific medications.

Key Concepts

❶ Multiple sclerosis symptoms are a function of the position of lesions within the central nervous system (CNS).
❷ The McDonald criteria allow the clinician to use the clinical exam in combination with magnetic resonance imaging (MRI) and cerebrospinal fluid data to make a diagnosis sooner, and thus begin treatment earlier.
❸ The clinical course of multiple sclerosis has been described in four basic patterns: relapsing remitting, secondary progressive, primary progressive, and progressive relapsing.
❹ Acute relapses are treated with corticosteroids to speed recovery of the patient.
❺ Disease-modifying therapies are used to decrease the number of relapses, prevent permanent neurologic damage, and prevent disability.
❻ Symptomatic treatment minimizes the impact of multiple sclerosis on quality of life.
❼ Dose-response curves have been observed with the beta interferons.
❽ There is no consensus on the best medication for initial therapy.
❾ Mitoxantrone should be reserved for patients with rapidly advancing disease who have failed other therapies.
❿ Multiple sclerosis patients must be treated with agents specific for upper motor neuron spasticity.

Multiple sclerosis (MS) is a complex inflammatory disease of the central nervous system (CNS) that is variable in terms of symptoms and presentation. The name refers to two features of the disease: multiple describes the number of CNS lesions; and sclerosis refers to the demyelinated lesions. Today, these lesions are usually called plaques, rather than scleroses. Although scientific understanding of MS has progressed at a rapid pace, there are still many areas of evolving knowledge.

Patient Encounter, Part 1

CN is a 28-year-old woman who complains of a 2-day history of weakness and tingling in her right arm and leg. These symptoms began over a 4-hour period. She also reports an episode 2 years ago of right eye pain and blurred vision that resolved over 1 month. She was diagnosed with optic neuritis at that time. Following an MRI, she is diagnosed with relapsing remitting MS today.

- What is optic neuritis?
- Why was her MS classified as relapsing remitting?
- How would you treat the episode today?

EPIDEMIOLOGY AND ETIOLOGY

Epidemiology

Approximately 400,000 Americans have MS. Most are diagnosed with MS between the ages of 20 and 50 years. Twice as many women as men develop MS.[1] Risk factors associated with developing MS include: family history of MS, autoimmune diseases, or migraine; and personal history of autoimmune diseases or migraine.[2]

MS prevalence decreases with decreases in latitude.[3] The geographic risk of developing MS is not fixed. When people move from a higher- to a lower-risk area, the migrants' MS risk is intermediate between the risk of the original and the new areas. However, when individuals move from a lower- to higher-risk area, there is not much change in the migrants' MS risk.[3] Furthermore, future risk of developing MS may depend on the age at the time of the move; adolescence is the critical time period.[3]

Etiology

Inheritance Theory

MS probably has a genetic component; there is a 5% risk for family members of MS patients. Monozygotic twins, who share the same genetic material, are at highest risk, with a 25% to 30% concordance rate.[4] However, a straightforward inheritance pattern cannot fully explain the etiology of MS, because only a small proportion of patients have a known family member with MS.[4]

Environment Theory

Over 20 infectious agents have been incriminated as etiologic agents; for many the causal relationship has been disproved, and for others there is conflicting evidence. Human herpesvirus 6 (HHV-6) is currently the most likely causative virus. HHV-6 may initiate the autoimmune processes of MS in one of two ways. First, HHV-6 is structurally similar to myelin basic protein. When T cells become sensitive to HHV-6, the cells may attack myelin basic protein. Second, HHV-6 may directly stimulate the complement cascade, activating autoimmune processes.[5] Infection with HHV-6 alone cannot fully explain MS, because HHV-6 is found in 75% of all people, but MS is much more rare.

PATHOPHYSIOLOGY

While the actual causative agent of MS is not clear, the final result is the development of an autoimmune disorder with areas of CNS demyelination and axonal transection.

Demyelination

An unknown antigen presented by the major histocompatibility complex (MHC) class II molecules causes T cells to become autoreactive (Fig. 26–1). Once activated, T cells penetrate the blood–brain barrier by attachment to upregulated adhesion molecules and production of matrix metalloproteinases that cause blood–brain barrier breakdown. In the CNS, the T cells come into contact with antigen-presenting cells and proliferate. The T-helper cells differentiate into proinflammatory T helper-1 (Th1) cells and anti-inflammatory T helper-2 (Th2) cells.[7] T helper-1 cells secrete cytokines that enhance macrophage and microglial cells that may attack **myelin**.[7]

B cells likely cross previously damaged sections of the blood–brain barrier to arrive in the CNS, an area normally free of B cells. Autoreactive T cells cause B cells to form autoantibodies to myelin. B-cell antibodies also initiate the complement cascade which causes myelin degradation.[7]

Axonal Transection

Transection or severing of the axon disrupts nerve signals completely and irreversibly.[8] There is growing evidence that cytotoxic (CD8+) T cells cause axonal injury.[5] Axonal transection begins as early as 2 weeks after diagnosis and continues throughout the course of the disease.[9]

CLINICAL PRESENTATION, DIAGNOSIS, AND CLINICAL COURSE

Diagnosis

MS diagnostic criteria were revised in 2001 and are known as the McDonald criteria (Fig. 26–2).[18–20] MS diagnosis requires that plaques be disseminated in time and space. Previously, diagnosis relied heavily on clinical examination. ❷ *The McDonald criteria allow the clinician to use the clinical exam in combination with magnetic resonance imaging (MRI) and cerebrospinal fluid (CSF) data to make a diagnosis sooner, and thus begin treatment earlier (Table 26–1).*

Clinical Course

❸ *The clinical course of MS has been described in four basic patterns: relapsing remitting, secondary progressive, primary progressive, and progressive relapsing* (Fig. 26–3). Relapsing remitting MS develops into secondary progressive MS in 50% of patients within 10 years and 75% of patients within 25 years of initial diagnosis.[22] Rating scales used to assess the clinical effects of MS are shown in Table 26–2. MS reduces overall life expectancy 6 to 7 years.[24] Suicide is disproportionately high in MS patients, accounting for about 15% of MS-related deaths.[25]

TREATMENT

Desired Outcomes and General Approach to Treatment

The overall goal of MS treatment is to prevent permanent neurologic damage. There are three general approaches to

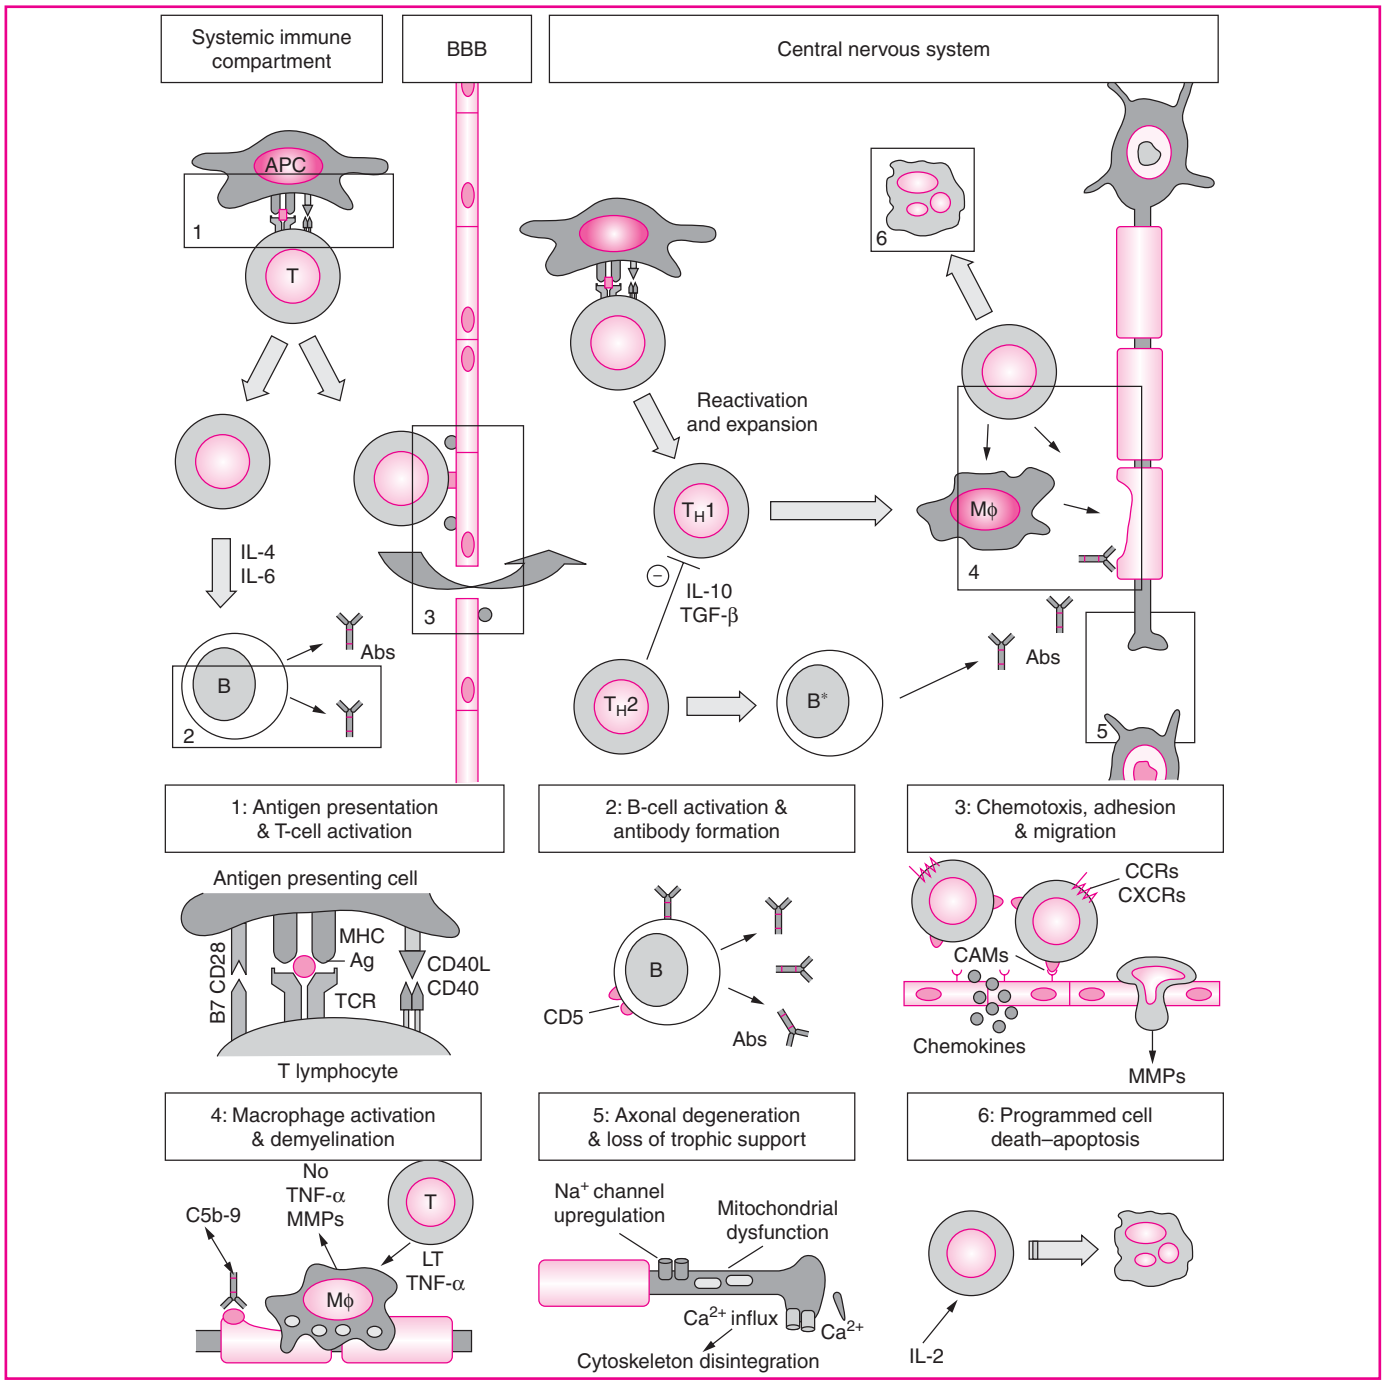

FIGURE 26–1. Synoptic view of the immune response in the pathogenesis of multiple sclerosis. Autoreactive T cells recognize with their TCR a specific autoantigen presented by MHC class II molecules and the simultaneous delivery of co-stimulatory signals (CD 28, B7, CD40, CD 40L) on the cell surface of APCs, such as macrophages, in the systemic immune compartment (*panel 1*). Activated T lymphocytes can cross the BBB in order to enter the CNS. The mechanisms of transendothelial migration is mediated by the complex interplay of CAMs, chemokines, and their receptors (CCRs, CXCRs) and MMPs (*panel 3*). Within the CNS, T cells activate microglia cells/macrophages (Mϕ) to enhanced phagocytic activity; production of cytokines, such as TNF-α and LT; and the release of toxic mediators, such as NO, propagating demyelination and axonal loss. Abs crossing the BBB or locally produced by B cells or mast cells (B*) contribute to this process. Autoantibodies activate the complement cascade resulting in the formation of the membrane-attack complex (C5b-9) and its subsequent lysis of the target structure (*panels 2 and 4*). The upregulation of Na^+ and Ca^{2+} channels on the axon as well as mitochondrial dysfunction and loss of trophic support contribute to axonal disintegration and degeneration (*panel 5*). The inflammatory response is regulated by anti-inflammatory cytokines, such as IL-10 or TGF-β, as well as IL-2, inducing programmed cell death (apoptosis) in immunoreactive T lymphocytes (*panel 6*). Abs, autoantibodies; Ag, antigen; APC, antigen-presenting cells; BBB, blood–brain barrier; CAM, cellular adhesion molecule; CNS, central nervous system; IL, interleukin; LT, lymphotoxin; MHC, major histocompatibility complex; MMP, matrix metalloproteinases; NO, nitric oxide; T, T cell; TCR, T-cell receptor; TGF, transforming growth factor; TNF, tumor necrosis factor. (From Wiendl H, Kieseier BC, Disease-modifying therapies in multiple sclerosis: An update on recent and ongoing trials and future strategies. Expert Opin Investig Drugs 2003;12:689–712, with permission.)

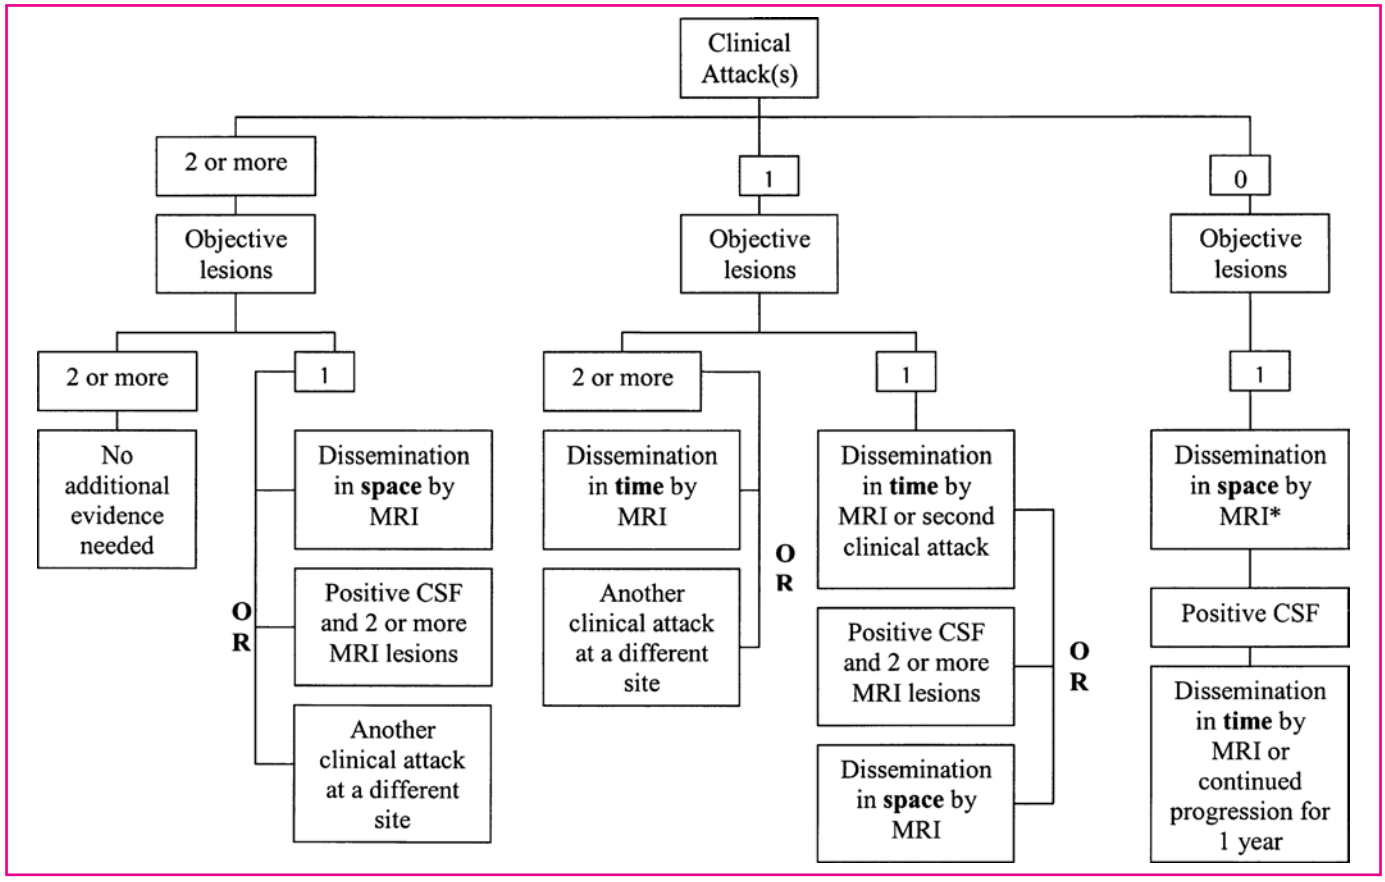

FIGURE 26–2. McDonald diagnostic criteria for MS. MRI evidence of dissemination over time is a gadolinium-enhancing lesion on a MRI done at least 3 months following onset of clinical attack at a site different from the initial attack, or a gadolinium-enhancing lesion or new T2-weighted lesion 6 months following onset of clinical attack. Positive CSF is oligoclonal immunoglobulin G bands in CSF but not serum or elevated immunoglobulin G index. Positive evoked potentials are delayed, but maintain a well-preserved wave form.
*Dissemination in space by MRI evidence of nine or more T2-weighted brain lesions, or two or more cord lesions, or four to eight brain and one cord lesion, or positive visual evoked potentials with four to eight MRI lesions, or positive visual evoked potentials with less than four brain lesions plus one cord lesion.
MRI, magnetic resonance imaging; CSF, cerebrospinal fluid.

treatment. ❹ First, *acute relapses are treated with corticosteroids to speed recovery.* ❺ Second, *disease-modifying therapies are used to decrease the number of relapses, prevent permanent neurologic damage, and prevent disability.* ❻ Third, *symptomatic treatment minimizes the impact of MS on quality of life.*

TABLE 26–1. Diagnostic Tests for MS[21]

Test	Findings in Multiple Sclerosis
Magnetic resonance imaging	
T2 weighted	Demyelinated plaques, both active and inactive
Gadolinium enhanced	Active demyelinating plaques
Cerebrospinal fluid analysis	Oligoclonal bands of immunoglobulin G
	Elevated immunoglobulin G index
Evoked potentials	Slowed nerve impulse conduction

Pharmacologic Treatment

Treatment of Acute Relapses

The mechanism of action of corticosteroids used for acute relapses is not completely clear, but may involve the following actions:

- Prevention of inflammatory cytokine activation;
- Inhibition of T-cell activation;
- Prevention of immune cells from entering the CNS; and
- Increased death of activated immune cells.[26]

Corticosteroids hasten functional recovery after relapses.[27] Intravenous adrenocorticotropic hormone, intravenous methylprednisolone, or oral prednisone are used for treatment of relapses. Generally, intravenous methylprednisolone is considered the drug of choice for acute relapses.[28]

Recent studies show equal efficacy of equivalent doses of intravenous and oral dosage forms.[30,31] Some clinicians are now using oral prednisone for patients experiencing relapses to avoid the discomfort, inconvenience, and expense of intravenous therapy.

Adverse Effects

Short-term use of corticosteroids is not associated with most of the adverse effects of chronic steroid use. The most common adverse effects encountered are gastrointestinal upset, insomnia, and mood swings.[28]

Dosing and Administration

Methylprednisolone is usually given 1 g/day intravenously as one or divided doses for 3 to 5 days. Oral prednisone 1250 mg/day provides an equivalent dose.

Clinical improvement usually begins during corticosteroid treatment. No standard exists for the administration of an oral prednisone taper after the intravenous methylprednisolone treatment. If a taper is given, it is usually completed over 1 to 2 weeks.

Outcome Evaluation

- Monitor the patient for improvement of relapse symptoms.
- Educate the patient regarding possible adverse effects of acute use of corticosteroids and have her or him report any unexpected occurrences.

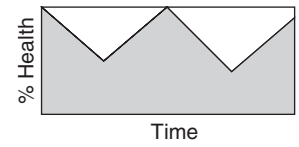
Disease-Modifying Therapies

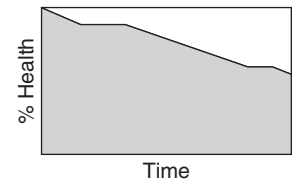
A number of agents have been used to modify the disease course of MS. This chapter will focus on the five agents that have an indication for use in MS: subcutaneous interferon beta 1a (Rebif); intramuscular interferon beta 1a (Avonex); interferon

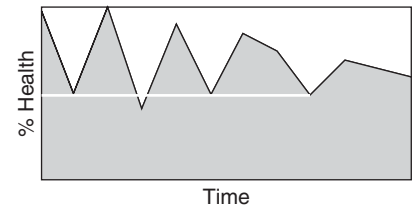
Clinical Presentation[10–17]

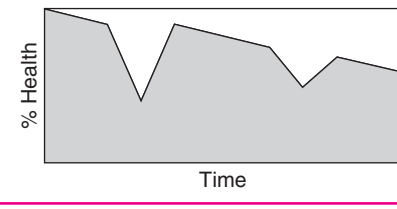
❶ *MS symptoms are a function of the position of lesions within the CNS.* Because myelin increases the speed of nerve impulse transmission, demyelination slows the speed of transmission. No impulses can be transmitted if the axon is transected. The primary symptoms of MS are caused by this delay or cessation of impulses. Secondary symptoms of MS result from the primary symptoms.

Primary Symptoms	Frequency of Occurrence	Related Secondary Symptoms
Urinary symptoms	90%	
Incontinence		Decubitus ulcers
Urinary retention		Urinary tract infections
Spasticity	60%	Falls, care difficulties, pain, gait problems
Visual symptoms		
Optic neuritis	55%	Falls, care difficulties
Diplopia		
Bowel symptoms		
Incontinence	29–51%	Decubitus ulcers
Constipation	35–54%	Pain
Depression	50%	Suicide
Cognitive deficits	50%	Care difficulties
Weakness		Falls, care difficulties, gait problems
Fatigue	76–92%	
Uhthoff's phenomenon	80%	
Sexual dysfunction		
Erectile dysfunction	70%	
Female sexual dysfunction	72%	
Tremor	25%	
Pain		
Trigeminal neuralgia	2%	
Lhermitte's sign	9%	
Dysesthetic pain	18%	









MS Type	Definition	Patients Affected	Example
Relapsing Remitting	Episodes of acute worsening of neurologic function (relapses) followed by a varying degree of recovery, with a stable course between attacks (remissions)	85%	
Primary Progressive	Gradual, nearly continuous, worsening with minor fluctuations but no distinct relapses	10%	
Secondary Progressive	Initial relapsing-remitting disease course followed by progression with or without occasional relapses, minor remissions, and plateaus	50% of relapsing remitting patients within 10 years of diagnosis	
Progressive Relapsing	Progressive disease from onset, with clear acute relapses, with or without recovery, with periods between relapses characterized by continuing progression	5%	

FIGURE 26–3. Comparison of clinical course of multiple sclerosis by type.

beta 1b (Betaseron); glatiramer acetate (Copaxone); and mitoxantrone (Novantrone). A broad look across all studies of these immunomodulators shows about 30% reduction in relapses.[32]

Beta Interferons

Pharmacology and Mechanism of Action The mechanism of action of beta interferons is complex and not completely understood. The following properties are thought to be important to the mechanism of action:

- Decrease in T-cell activation, decreasing cytokine secretion and preserving myelin;
- Prevention of upregulation of adhesion molecules on activated T cells, limiting the number of T cells that can get into the brain;
- Suppression of matrix metalloproteinases, maintaining the integrity of the blood–brain barrier;
- Decrease in microglial proliferation, preserving myelin;
- Promotion of formation of Th-2 cells rather than Th-1 cells, decreasing inflammation; and
- Inhibition of viruses, important if MS has a viral etiology.[7,33]

Efficacy ***Patients with relapsing remitting MS:*** A meta-analysis of all beta interferons determined that treated patients were 27% and 19% less likely to have a relapse during the first and second years of treatment, respectively, than those who had

Patient Encounter, Part 2

CN begins to improve after 2 days of methylprednisolone 1 g intravenously daily. The treatment team wants to begin a disease-modifying treatment.

- Do you agree that she should be on a disease-modifying treatment? Why?
- If so, which treatment would you choose? Recommend a dosing regimen.
- How should the patient be counseled on the chosen treatment?
- Develop a care plan for the patient.

TABLE 26–2. Clinical Rating Scales Used in MS[23]

Expanded Disability Status Scale (EDSS)
Rates functional systems from 0 (normal) to 10 (death due to MS)
Emphasis is on ambulation over other symptoms
Multiple Sclerosis Functional Composite (MSFC)
Three-part tool rating ambulation, limb function, and cognitive function
Composite score is compared to standardized population
Correlates better with magnetic resonance imaging data than EDSS

TABLE 26–3. Comparison of Disease-Modifying Therapies[27,38–40,43,46]

Drug	Dose	Route	Frequency	Adverse Effects
Interferon beta 1a (Avonex)	30 mcg	IM	Weekly	Flu-like symptoms 61% Anemia 8%
Interferon beta 1a (Rebif)	44 mcg	SQ	Three times per week	Flu-like symptoms 28% Injection site reactions 66% Leukopenia 22% Increased aspartate aminotransferase/ alanine transaminase 17–27%
Interferon beta 1b (Betaseron)	0.25 mg	SQ	Every other day	Flu-like symptoms 60–76% Injection site reactions 50–85% Asthenia 49% Menstrual disorder 17% Leukopenia 10–16% Increased aspartate aminotransferase/ alanine transaminase 4–19%

Mitoxantrone (Novantrone)	12 mg/m^2 up to 140 mg/m^2	IV	Every 3 months	Nausea 76% Alopecia 61% Menstrual disorders 61% Urinary tract infection 32% Amenorrhea 25% Leukopenia 19% γ-Glutamyl transpeptidase increase 15%

received placebo.[34] Early treatment after a first clinical attack delayed time to a second attack by 9 to 13 months compared to placebo.[35,36] ***Patients with secondary progressive MS who experience relapses:*** Beta interferons have mixed results for slowing disease progression in secondary progressive MS. The MS Therapy Consensus Group states that treatment is most likely to be effective if clinical relapses or MRI signs of inflammatory activity are present.[37]

Adverse Effects Adverse effects are common with the beta interferons (Table 26–3). Commonly, flulike symptoms consist of fever, fatigue, muscle aches, malaise, and chills. Symptoms begin a few hours after the injection and dissipate 8 to 24 hours later.[38] Preventive measures can be employed (Table 26–4). In temperature-sensitive patients, beta interferon–induced fever can transiently worsen MS symptoms.[39] Injection site reactions can range from redness to necrosis. There are preventative and treatment measures for injection site reactions (see Table 26–4). At the threshold laboratory values shown in Table 26–4, interferon should be temporarily discontinued. When values return to normal, interferon can be resumed with gradual dose increases and careful monitoring.[39] Alpha and gamma interferons have been associated with depression. MS patients also commonly are depressed, even without beta interferon treatment. Because of conflicting data, it is difficult to determine whether beta interferons cause or worsen MS-related depression.[15]

Neutralizing Antibodies Antibodies to beta interferons can form over time and reduce the clinical effect of beta interferons.[40] The clinical effect of neutralizing antibodies is seen 18 to

TABLE 26–4. Prevention or Treatment Strategies for Beta Interferon Adverse Effects[38,39]

Flu-like Symptoms	Injection Site Reaction	Laboratory Abnormalities[a]
• Inject dose in the evening • Begin at $^1/_4$ – $^1/_2$ dose for 2 weeks of treatment, then increase to a full dose • Use ibuprofen 200 mg before and 6 and 12 hours after injection • Alternatives to ibuprofen include acetaminophen, prednisone taper, and pentoxifylline	• Bring medication to room temperature • Ice injection site prior to the injection • Rotate injection sites • If severe, use hydrocortisone 1% cream on the site • If necrotic: temporarily discontinue; consult dermatologist; do not use topical corticosteroids	• Hemoglobin less than 9.4 g/dL (94 g/L or 5.8 mmol/L) • White blood cells less than 3×10^3/mm^3 (less than 3×10^3/μL or less than 3×10^9/L) • Absolute neutrophil count less than 1.5×10^3/mm^3 (less than 1.5×10^3/μL or less than 1.5×10^9/L) • Platelets less than 75×10^3/mm^3 (less than 75×10^3/μL or less than 75×10^9/L) • Bilirubin greater than 2.5 times baseline • AST/ALT greater than 5 times baseline • Alkaline phosphatase greater than 5 times baseline

[a]At these threshold values, beta interferon should be temporarily discontinued and laboratory values monitored.
ALT, alanine aminotransferase; AST, aspartate aminotransferase.

24 months after treatment begins.[40] **Neutralizing antibodies** can form against all of the beta interferons, but frequency and route of administration affect neutralizing antibody development: 28% to 47% for subcutaneous interferon beta-1b; 12% to 28% for subcutaneous interferon beta-1a; and 2% to 6% for intramuscular interferon beta-1a.[40]

Many issues surrounding neutralizing antibodies remain such as standardization of the neutralizing antibody assay, testing recommendations, and treatment recommendations for positive tests.[41] Neutralizing antibodies may disappear even with continued treatment. Neutralizing antibodies exhibit cross-reactivity with the other beta interferons.[41]

Dosing and Administration Dose, frequency, and route of administration differ between the beta interferon products (see Table 26–3). ❼ *Dose-response curves have been observed with the beta interferons.* However, it is not known if the total weekly dose or the frequency of administration is most important.[37]

Glatiramer Acetate

Pharmacology and Mechanism of Action The mechanism of action of glatiramer acetate is not fully known; however, the following properties have been observed:

- Binds to MHC class II, blocking the activation of T cells;
- Activates Th-2 cells, preventing inflammation; and
- Activated Th-2 cells secrete brain-derived neurotrophic factor, which may be neuroprotective.[7,33]

Efficacy Glatiramer acetate reduces relapses by 28% each year compared to placebo. Additionally, relapses occurred later compared to placebo (322 days versus 219 days).[42]

Adverse Effects Patients commonly report pain, redness, itching, swelling, and bruising at injection sites (see Table 26–3). Icing the injection site before and after the injection improves these reactions. If the patient experiences significant pain at the injection site, topical anesthetics can be used. The systemic reaction may involve flushing, chest tightness, palpitations, anxiety, and shortness of breath. This reaction usually occurs within 30 minutes of the injection and lasts no longer than 30 minutes. Many patients may experience this reaction only once. If desired, doses can be reduced by 75% for the week following the reaction, then increased by 25% per week until the patient returns to the full dose.[43]

Issues with Self-Injected Disease-Modifying Therapies

Adherence Adherence and continuation of these injectable medications can be a significant problem. Overall, there is no significant difference between the rates of discontinuation for the products (17% to 41%). The main reasons for discontinuation are adverse effects and lack of efficacy. Realistic expectations regarding therapy improve adherence rates.[44]

Choosing Therapy ❽ *There is no consensus on the best medication for initial therapy.* Comparative beta interferon trials indicate better efficacy with more frequent and/or higher dosing.[37] This consideration must be balanced with neutralizing antibody development and patient acceptance and tolerance.

Patient Education Refer to Table 26–5 for key components of patient education for self-injection.

Mitoxantrone

Pharmacology and Mechanism of Action Mitoxantrone is an anthracenedione antineoplastic that is indicated for multiple sclerosis. The mechanisms of action thought to be important for MS are as follows:

- Causes **apoptosis** in T and antigen-presenting cells, preventing initial T cell activation;
- Inhibits DNA and RNA synthesis, decreasing the proliferation of T cells, B cells, and macrophages;
- Decreases cytokine release, preventing inflammation; and
- Inhibits macrophages, preventing myelin degradation.[45]

Efficacy Mitoxantrone is indicated for secondary progressive MS, progressive relapsing MS, and for patients with worsening relapsing remitting MS. It reduces the clinical attack rate and attack-related MRI outcome measures in patients with relapsing disease. ❾ Because of significant potential for toxicities, *mitoxantrone should be reserved for patients with rapidly advancing disease who have failed other therapies.*[27]

Adverse Effects Adverse effects are seen regularly in patients given mitoxantrone (see Table 26–3). Patients often experience bluish discoloration of the sclera and the urine for 24 hours after infusion.[46] Transient leukopenia and neutropenia are common with a nadir 10 to 14 days after the infusion. Patients should avoid exposure to infectious individuals during this time.[46] Patients taking mitoxantrone should not receive live virus vaccines; other vaccines should be held for 4 to 6 weeks after a mitoxantrone dose.[46] Amenorrhea, caused by a direct toxic effect on the ovary, may be permanent, an important consideration because the MS population includes women of childbearing potential.[27]

TABLE 26–5. Patient Education for Self-Injection

Keep all non-refrigerated supplies together and out of the reach of children and pets
Allow medications to warm to room temperature
Wash hands thoroughly
Choose injection site, rotating between sites
Ice area to be injected for no more than 15 minutes, if desired
Clean injection site thoroughly with alcohol or soap and water
Administer injection
Ice injection site for no more than 15 minutes after injection, if desired

Cardiotoxicity is a serious, rare adverse effect of mitoxantrone. The incidence of congestive heart failure was 0.15% in patients with normal left ventricular ejection fraction and 2.18% in those who had asymptomatic left ventricular ejection fraction of less than 50% at baseline.[46] Therefore, mitoxantrone should not be used in patients with baseline cardiomyopathy, even if asymptomatic. The risk of cardiotoxicity is dose-related. The maximum lifetime dose of mitoxantrone is 140 mg/m^2, or about 3 years of MS therapy. The use of cyclooxygenase-2 inhibitors should be avoided in patients receiving mitoxantrone because of a potential for worsening cardiac toxicity.[46]

Acute myelogenous leukemia has been observed in 0.07% of MS patients treated with mitoxantrone.[46] This form of acute leukemia appears within 2 to 4 years of initiating mitoxantrone and is generally responsive to standard antileukemic therapy.

Dosing and Administration Mitoxantrone is infused intravenously over 30 minutes to reduce the chance of cardiotoxicity.[46] Mitoxantrone is administered every 3 months, if cardiac function and laboratory values are normal (Table 26–6).

Monitoring Disease-Modifying Therapies

- Assess the patient periodically for changes in primary or secondary symptoms.
- Monitor the patient for adverse effects according to the specific medication (see Tables 26–3 and 26–6).
- Assess regularly for adherence with appointments and all components of therapy.

Symptomatic Therapies

MS patients develop many symptoms that require treatment. The symptoms most unique to MS are fatigue and **spasticity**; these will be discussed in more depth. Other important symptoms such as urinary incontinence, pain, and depression, are discussed only briefly because there are other chapters in this text devoted to the management of these symptoms.

Patient Encounter, Part 3

After 3 years of treatment, CN has had one additional relapse, but otherwise is doing fairly well. At her routine clinic appointment, she describes some difficulty walking due to leg spasticity and urinary incontinence episodes that occur about twice a week.

- What treatment options are available for spasticity, and which would you choose?
- Should this patient's incontinence be treated?
- If so, what medication would you recommend?
- Recommend a dosing regimen and monitoring plan.

Fatigue

There are nonpharmacologic and pharmacologic strategies for decreasing the impact of fatigue on the lifestyle of MS patients (Table 26–7). Pharmacologic management of fatigue may include amantadine or stimulants; however, evidence of efficacy from randomized controlled trials is limited.

Spasticity

The goals of treating spasticity can be patient-specific. For ambulatory patients, reducing spasticity may improve mobility. For bed-bound patients, treating spasticity may relieve pain and

TABLE 26–6. Monitoring Disease-Modifying Therapies

Therapy	Tests	Frequency
Beta interferons (Avonex, Betaseron, Rebif)	Complete blood count, bilirubin, electrolytes, AST, ALT, γ-glutamyl transferase, alkaline phosphatase	Baseline, 4–6 weeks, 12 weeks, then every 3 months
	EDSS, MSFC, neurologic history and examination	Every 3 months during the first year of therapy then every 6 months
Mitoxantrone (Novantrone)	Complete blood count, bilirubin, AST, ALT, alkaline phosphatase, pregnancy test	Before each infusion
	Electrocardiogram	Baseline
	Echocardiogram or multiple gated acquisition (MUGA) scan	Baseline and every 6–12 months; prior to each infusion after 100 mg/m^2
	EDSS, MSFC, neurologic history and examination	Every 3 months during the first year of therapy then every 6 months
Glatiramer acetate (Copaxone)	EDSS, MSFC, neurologic history and examination	Every 3 months during the first year of therapy then every 6 months

ALT, alanine aminotransferase; AST, aspartate aminotransferase; EDSS, Expanded Disability Status Scale; MSFC, Multiple Sclerosis Functional Composite.

TABLE 26–7. Pharmacologic and Nonpharmacolgic Treatments for Fatigue[47]

Nonpharmacologic	Pharmacologic
• Appropriate rest:activity ratio • Use of assistive devices to conserve energy • Environmental modifications to make activities more energy-efficient • Cooling strategies to avoid the fatigue caused by elevations in core body temperature due to heat, exercise-related exertion, and fever • Regular aerobic exercise, geared to the person's ability, to promote cardiovascular health, strength, improved mood, and reduce fatigue • Stress management techniques	*First-line therapies:* Amantadine 100 mg orally every morning and early afternoon Modafinil 200 mg orally daily *Second-line therapies:* Pemoline 75–140 mg/day divided into 2–3 doses Methylphenidate 10–20 mg every morning and noon

ease transfers and care. Physical therapy is a nonpharmacologic treatment for spasticity.[11]

MS patients usually have upper motor neuron spasticity. This type of spasticity cannot be treated with muscle relaxants such as carisoprodol. ⑩ *MS patients must be treated with agents specific for upper motor neuron spasticity* (Table 26–8).[48] MS spasticity is classified as focal or generalized. If the spasticity primarily involves only one muscle group, it is focal and may benefit from botulinum toxin administration.[11] Systemic medications are used for generalized spasticity. No clear conclusion can be reached regarding the superiority in efficacy of one antispasticity agent over another; medication selection is usually based on adverse effects (see Table 26–8).[11,48]

Other Symptoms

Two types of urinary tract symptoms are commonly seen in MS: incomplete bladder emptying and incontinence. Incomplete bladder emptying is due to dyscoordination of the external urethral sphincter and detrusor activity.[14] Most patients who develop this condition require intermittent or permanent urinary catheterization.[14] Incontinence in most MS patients is caused by neurogenic detrusor overactivity. First-line treatment is anticholinergics such as oxybutynin, tolterodine, flavoxate, or tricyclic antidepressants with antimuscarinic properties.

Bowel symptoms in MS patients can include both fecal incontinence and constipation. Fecal incontinence is difficult to treat. Some patients may have improvement if they use a regular schedule for emptying the bowel with laxative suppositories or enemas. Alternatively, antidiarrheal medications such as loperamide can be used.[14]

Desipramine and sertraline are efficacious for MS-related depression.[15] If beta interferon treatment appears to be causing depression, discontinuation could be considered.

Phosphodiesterase 5 inhibitors such as sildenafil are effective for MS-induced erectile dysfunction.[14] In women, vaginal dryness or dyspareunia may respond to lubricating jellies.

Outcome Evaluation

- Assess patient for improvement of primary and secondary symptoms.
- Monitor for adverse effects of prescribed medications.
- Monitor for adherence with regimen.
- Monitor for emergence of symptoms of depression

TABLE 26–8. Comparison of Antispasticity Agents[11]

Place in Therapy	Medication	Mechanism of Action	Dose
First-line	Baclofen	Pre- and postsynaptic γ-aminobutyric acid β receptor blocker	5 mg orally three times daily, increase by 5 mg/dose every 3 days to a maximum of 80 mg/day
	Tizanidine	Centrally-acting α_2-receptor agonist	4 mg orally daily, increase by 2–4 mg 3–4 times daily to a maximum of 36 mg/day
Second-line	Dantrolene	Direct inhibitor of muscle contraction by decreasing the release of calcium from skeletal muscle sarcoplasmic reticulum	25 mg orally daily, increase to 25 mg 3–4 times daily, then increase by 25 mg every 4–7 days to a maximum of 400 mg/day
	Diazepam	γ-Aminobutyric acid agonist	2–10 mg orally 3–4 times/day
Third-line	**Intrathecal** baclofen	Pre- and postsynaptic γ-aminobutyric acid β receptor blocker	Titrated individually, usual range 62–749 mcg/day
Focal spasticity	Botulinum toxin	Prevents release of acetylcholine in the neuromuscular junction	Individualized

Patient Care and Monitoring

1. Once diagnosed, work with the patient to select either a beta interferon or glatiramer acetate, considering:

- Route of administration
- Frequency of administration
- Adverse-effect profile and other concerns (e.g., neutralizing antibodies and concomitant depression)

2. Obtain the required baseline laboratory studies (Table 26–6).
3. Educate the patient regarding self-injection (Table 26–5).
4. Assess the patient for symptomatic treatment needs.
5. Initiate needed symptomatic treatments.
6. Refer the patient to the National MS Society for information, newsletters, and local support groups (www.nmss.org).
7. Instruct the patient to contact the clinician for any sudden changes in symptoms that may suggest a relapse.
8. Monitor the patient for efficacy and adverse effects of disease-modifying and symptomatic therapies every 3 months for the first year and every 6 months thereafter and as required for selected therapy (Table 26–6).
9. Treat any relapses with methylprednisolone intravenously or prednisone orally.

ABBREVIATIONS

Abs: autoantibodies
ALT: alanine aminotransferase
APC: antigen-presenting cell
AST: aspartate aminotransferase
BBB: blood–brain barrier
CAM: cellular adhesion molecule
CNS: central nervous system
CSF: cerebrospinal fluid
EDSS: Expanded Disability Status Scale
HHV-6: human herpesvirus 6
IL: interleukin
LT: lymphotoxin
MHC: major histocompatibility complex
MMP: matrix metalloproteinase
MRI: magnetic resonance imaging
MS: multiple sclerosis
MSFC: Multiple Sclerosis Functional Composite
MUGA: multiple gated acquisition
NO: nitric oxide
TCR: T-cell receptor
TGF: transforming growth factor
Th-1: T helper-1 cells
Th-2: T helper-2 cells
TNF: tumor necrosis factor

27 EPILEPSY

Timothy E. Welty and Edward Faught

LEARNING OBJECTIVES

UPON COMPLETION OF THE CHAPTER, THE READER WILL BE ABLE TO:

1. Describe the epidemiology and social impact of epilepsy.
2. Define terminology related to epilepsy, including seizure, convulsion, and epilepsy.
3. Describe the basic pathophysiology of seizures.
4. Describe the basic pathophysiology of epilepsy.
5. Differentiate and classify seizure types when provided a description of the clinical presentation of the seizure and electroencephalogram.
6. Identify key therapeutic decision points in the treatment of epilepsy.
7. Establish therapeutic goals for pharmacotherapy in a patient with epilepsy.
8. Discuss nonpharmacologic treatments for epilepsy.
9. Recommend an appropriate pharmacotherapeutic regimen for the treatment of epilepsy.
10. Select appropriate monitoring parameters for a pharmacotherapeutic regimen of epilepsy.
11. Devise a plan for switching a patient from one antiepileptic regimen to a different regimen.
12. Recognize complications of pharmacotherapy for epilepsy.
13. Analyze potential drug interactions with antiepileptic drugs.
14. Determine when and how to discontinue antiepileptic drug therapy.
15. Educate a patient or caregiver on epilepsy and pharmacotherapy for this disorder.

KEY CONCEPTS

❶ A distinction between convulsions, a single seizure, pseudoseizure, and epilepsy should be made in patients presenting with possible seizures.

❷ Selection of appropriate pharmacotherapy is dependent upon distinguishing, identifying, and understanding different seizure types.

❸ Prior to starting pharmacologic therapy, it is essential to determine the risk of the patient having a subsequent seizure.

❹ Mechanisms of action, effectiveness for specific seizure types, common adverse effects, and potential for drug interactions are key elements in selecting medications for individual patients.

❺ Patients receiving antiepileptic drugs for seizures should have regular monitoring for seizure frequency, seizure patterns, acute adverse effects, chronic adverse effects, and possible drug interactions.

❻ Antiepileptic drug therapy should usually be initiated carefully using a titration schedule to minimize adverse events.

❼ Changes in antiepileptic drug regimens should be done in a stepwise fashion, keeping in mind drug interactions that may be present and necessitate dosage changes in concomitant drugs.

❽ Discontinuation of antiepileptic drugs should be done gradually, only after the patient has been seizure-free for 2 to 5 years and with careful consideration of factors predictive of seizure recurrence.

❾ Children and women with epilepsy have unique problems related to the use of antiepileptic drugs.
