Most patients treated for lymphoma with chemotherapy or radiation notice a regression of palpable lymphadenopathy within days. This is due to the high sensitivity of the rapidly proliferating malignant lymphocytes to chemotherapy and radiotherapy. This necessitates implementation of tumor lysis syndrome precautions with aggressive sodium bicarbonate–containing intravenous fluid resuscitation and allopurinol for patients with moderate to high tumor burdens. Most chemotherapy treatments for lymphoma have a significant risk of infectious complications. Combination chemotherapy for both HL and NHL is associated with rates of severe leukopenia and/or neutropenia ranging from 20% to 100% of patients. Consideration must be given to supportive care with prophylactic antibiotics and myeloid colony-stimulating factors (CSFs). The American Society of Clinical Oncology has published guidelines stating that colony-stimulating factors (CSFs) may be used as primary prevention when the incidence of febrile neutropenia with the chemotherapy is approximately 20% and no other equally effective and less myelosuppresive regimen is available or for secondary prevention where the patient already has experienced febrile neutropenia with the previous cycle of chemotherapy.[34] Effective antiemetic support is currently available that can control chemotherapy-induced nausea and vomiting reasonably well for most standard-dose regimens.[35]

For female survivors of HL who are treated with radiation, there is an increase in the incidence of breast cancer, and baseline mammograms are recommended at the conclusion of treatment.[36] For HL patients, exposure to bleomycin can induce pulmonary fibrosis, which often is subclinical. Patients who relapse and require high-dose chemotherapy and are treated with the drug carmustine in the conditioning regimen are at a higher risk of morbidity and mortality from idiopathic pulmonary syndrome/diffuse alveolar hemorrhage during SCT treatment. These patients are also at risk for exacerbation of underlying bleomycin-induced pulmonary damage if they ever require mechanical ventilation with high oxygen requirements. Combination chemotherapy that contains alkylating agents or etoposide carries the risk of a secondary acute myeloid leukemia or myelodysplastic syndrome. The cumulative dose of doxorubicin used for most lymphoma regimens is unlikely to cause cardiac toxicity with the standard six cycles. Neuropathy with vincristine or vinblastine may necessitate its removal from subsequent cycles if severe. Historically, it is more severe with vincristine. Treatment with fludarabine can harbor the risk of opportunistic infections such as *Pneumocystis carinii* pneumonia (PCP) for months following completion of therapy.

A limitation of rituximab treatment is the severe and potentially fatal infusion-related reactions. To date, eight deaths have

been reported, resulting from the profound hypotension and circulatory collapse seen with the drug, particularly on the first dose. The package labeling recommends premedication with acetaminophen and diphenhydramine before each infusion. For the first infusion, the drug should be administered at 50 mg/hour. The infusion rate may be increased by 50 mg/hour every 30 minutes to a maximum of 400 mg/hour if no infusion-related reactions occur. If infusion-related reactions do occur, the manufacturer recommends stopping the infusion or temporarily slowing it until symptoms resolve. The infusion should be reinstituted at a rate that is one-half the previous rate. For subsequent rituxamab infusions, the rate may commence at 100 mg/hour and be increased at 100 mg/hour increments every 30 minutes for a maximum of 400 mg/hour as tolerated. Other associated toxicities of rituxamab include fever, chills, headache, asthenia, nausea, vomiting, angioedema, bronchospasm, and skin reactions. ❽ *Despite these toxicities, rituximab is an effective treatment option for patients with indolent low-grade NHL as a single agent or in combination with standard chemotherapy regimens for more aggressive NHL histologies.* Radiolabled rituximab causes more myelosuppression than rituximab alone and, similar to combination cytotoxic chemotherapy regimens, has a long-term risk of inducing secondary leukemias.[37]

Patient Care and Monitoring

1. Verify chemotherapy regimen dosages with a standardized reference, and assess for dose adjustment for renal or hepatic dysfunction.
2. Assess appropriateness of supportive care for each chemotherapy regimen, including antiemetics and colony-stimulating factors.
3. Prior to initiation of treatment with chemotherapy, determine if tumor lysis syndrome precautions need to be implemented.
4. Take a thorough medication history with particular attention to over-the-counter and herbal medications.
5. Provide patient education regarding common toxicities associated with chemotherapy, such as nausea/vomiting, mucositis, myelosuppression, and alopecia.
6. For doxorubicin-containing regimens, total the cumulative dosage received by the patient to monitor for cardiac toxicity.
7. For bleomycin-containing regimens, total the cumulative dosage received by the patient to monitor for pulmonary fibrosis.
8. Educate patients regarding short- and long-term complications associated with radiation therapy.
9. Monitor patient for signs of response of tumor to chemotherapy.
10. Provide contact numbers for patient in the event of fever and a response plan if the patient is considered to be at risk for neutropenic fever.

91 Ovarian Cancer

Judith A. Smith

Learning Objectives

Upon completion of the chapter, the reader will be able to

1. Demonstrate understanding of the etiology and risk factors associated with the development of ovarian cancer.
2. Justify the risk and benefits of the surgical and chemoprevention options available for decreasing the potential risk of developing ovarian cancer.
3. Interpret and understand the utility of the screening tests and serologic markers for diagnosing ovarian cancer.
4. Distinguish the non-specific physical signs and symptoms of ovarian cancer.
5. Recommend the appropriate surgical and chemotherapy treatment options for newly diagnosed and relapsed ovarian cancer patients.
6. Compare and contrast chemotherapy options for women with recurrent platinum-resistant ovarian cancer.
7. Compare and contrast the treatment options for management of hot flushes in ovarian cancer patients.
8. Devise a plan for the management of common complications associated with advanced and recurrent ovarian cancer.

Key Concepts

1. Ovarian cancer is a sporadic disease; fewer than 10% of ovarian cancers can be attributed to heredity.
2. Since CA-125 is a non-specific marker, there is no standard recommendation for routine screening for prevention of ovarian cancer.
3. Ovarian cancer is denoted the "silent killer" because of the non-specific signs and symptoms.
4. Although most patients will achieve a complete response initially, more than 50% of cancers will recur within the first 2 years.
5. Surgery is the primary treatment intervention for ovarian cancer.
6. Ovarian cancer is staged surgically using the International Federation of Gynecology and Obstetrics (IFGO) staging algorithm.
7. After initial surgery, the gold standard of care is six cycles of a taxane/platinum-containing regimen for patients with advanced ovarian cancer.
8. Single-agent chemotherapy is standard practice for recurrent platinum-resistant ovarian cancer.
9. Since the efficacy of the agents is similar, selection of an agent for the treatment of recurrent platinum-resistant ovarian cancer depends on residual toxicities, physician preference, and patient convenience.
10. In ovarian cancer patients, small bowel obstruction is a common complication of progressive disease. In general, laxatives should not be used in patients with small bowel obstructions.

Ovarian cancer is relatively uncommon but is the most fatal gynecologic cancer. The primary reason for the high mortality associated with ovarian cancer is the non-specific symptoms and difficulty of early detection or screening that result in patients presenting with advanced disease. Most ovarian cancers are of epithelial origin. Each time ovulation occurs, the epithelium of the ovary is broken, followed by cell repair. The *incessant-ovulation hypothesis* proposes that the increasing number of times the ovary epithelium undergoes cell repair is associated with the increasing risk of mutations and, ultimately, ovarian cancer. Ovarian cancer often is denoted as the "silent killer" because although most patients will achieve a

Patient Encounter 1, Part 1

A 67-year-old woman with a history of coronary artery disease, diabetes, and gastrointestinal reflux presents to your clinic complaining of persistent flatulence and bloating and the feeling that she is "getting fat." After discussing her symptoms with her, you learn that her reflux symptoms are of recent onset and that her proton pump inhibitor is not "working yet." For the past 3 or 4 months, she also has had irregular bleeding and occasional "cramping," which has been frustrating to her because she thought that ended years ago when she went through menopause. She reports that her menses began when she was 9 years old and lasted all the way until she was 61 years old. She has two sisters in good health and a brother with diabetes. She has been married for 25 years with no children. The physician orders a CA-125 and computed tomographic (CT) scan that both come back positive and suggestive of ovarian cancer.

- What symptoms could be associated with ovarian cancer?
- Does she have any known risk factors?
- What are your treatment options for this patient after surgery?

complete response to primary surgery and chemotherapy, over 50% of the cancers will recur in the first year. Ovarian cancers will **metastasize** often via the lymphatic and blood systems to the liver and/or lungs. Common complications of advanced and progressive ovarian cancer include **ascites** and small bowel obstruction (SBO), which often are associated with end of life.

EPIDEMIOLOGY AND ETIOLOGY

In 2006, there were an estimated 20,180 new cases of ovarian cancer with an associated 15,310 deaths.[1] Ovarian cancer remains the number one gynecologic killer and the fifth leading cause of cancer-related deaths in women. Despite great efforts and extensive research, there has been little change in the mortality rate associated with ovarian cancer over the past three decades. The high mortality associated with ovarian cancer can be attributed to its insidious onset of non-specific symptoms resulting in most patients not presenting until the cancer has progressed to stage III–IV disease.

As with many other disease states, a significant risk factor associated with ovarian cancer is aging. A woman's risk increases from 15.7% to 54% per 100,000 as her age advances from 40 to 79 years, with the mean age at diagnosis being 59 years.[2]

❶ *Ovarian cancer is a sporadic disease; fewer than 10% of ovarian cancers can be attributed to heredity.* Most cases of ovarian cancer occur sporadically, thus making it difficult to screen and prevent. Although heredity accounts for less than 10% of all ovarian cancer cases, when there is a family history, it appears to be an important risk factor in the development of ovarian cancer in some patients.[3] If one family member has a diagnosis of ovarian cancer, the associated risk is about 9%, but this risk increases to greater than 50% if two or more first-degree relatives, i.e., mother and sister, have a diagnosis of ovarian cancer or multiple cases of ovarian and breast cancer.[3] Both *BRCA1* and *BRCA2* mutations have been associated with ovarian cancer. However, *BRCA1* is more prevalent, being associated with 90% of hereditary and 10% of sporadic cases of ovarian cancer.[3] Hereditary breast and ovarian cancer syndrome (HBOC) is one of the two different forms of hereditary ovarian cancer and is associated with germ-line mutations in *BRCA1* and *BRCA2*.[3,4] Hereditary non-polyposis colorectal cancer (HNPCC), or Lynch syndrome, is a familial syndrome with germ-line mutations causing defects in enzymes involved in DNA mismatch repair (MMR) that has been associated with up to 12% of hereditary ovarian cancer cases.[4]

Although it is not clearly defined, hormones and reproductive history are associated with the risk of developing ovarian cancer. **Nulliparity,** infertility, early menarche, and late menopause are associated with an increased risk of ovarian cancer.[5–7]

Ovarian cancer is associated with certain dietary and environmental factors as well. A diet that is high in galactose and animal fat and meat increases the risk of ovarian cancer, whereas a vegetable-rich diet is suggested to decrease risk.[4,8] Although controversial, exogenous factors such as asbestos and talcum powder use on the perineal area also have been suggested to increase the risk of ovarian cancer.[4,8]

Screening and Prevention

Screening

Currently, there is no standard, effective screening tool that is adequately predictive or sensitive for early detection.

Pelvic examinations are effective in detecting obvious tumors with a sensitivity of 67% for detecting all tumors; minimal or microscopic disease cannot be detected on physical examination.[9] Pelvic examinations are non-invasive and well accepted, but they do not usually detect ovarian cancer until it is in an advanced stage. Therefore, routine pelvic examinations will not improve earlier diagnosis or help to decrease overall mortality.[9]

Serum cancer antigen 125 (CA-125) is the most extensively evaluated tumor marker for ovarian cancer. Unfortunately, the CA-125 determination is non-specific, and elevated levels can be associated with a number of other gynecologic and gastrointestinal diseases. CA-125 levels in a woman without ovarian cancer, though, are static or tend to decrease over time, whereas levels associated with malignancy will continue to rise.[10] ❷ *Since CA-125 is a non-specific marker, there is no standard recommendation for routine screening for prevention of ovarian cancer.*

Transvaginal ultrasound (TVUS) is a component of current screening practices. Typically, it is used in combination with CA-125 determination, but it can be used as a single

Patient Encounter 2

A 36-year-old woman who has been in good health presents to your clinic complaining of constipation and abdominal pain. She explains to you that she has been feeling stressed lately because her 40-year-old sister is undergoing chemotherapy for breast cancer, and they just lost there mother to ovarian cancer a few years ago.

- Does she have a hereditary risk factor?
- What screening tools could be used to monitor this patient?
- Identify the treatment options for prevention of ovarian cancer available to this patient?

modality. TVUS releases sonic sound waves that create an image of the ovary to evaluate the size and shape and to detect the presence of cystic or solid masses. Limitations of this technique are lack of specificity and an inability to detect peritoneal cancer or cancer in normal-sized ovaries.[2,10] Most prevention clinics use the multimodality approach to screen high-risk women and recommend yearly ultrasound in combination with a CA-125 blood test every 6 months.

Prevention

Ovulation is considered a hostile event to the ovarian epithelium, making it more susceptible to damage and cancer. Interventions or conditions that limit the number of ovulations in a woman's reproductive history will have a protective effect. For instance, **multiparity** would decrease the number of ovulations.

Chemoprevention

Chemoprevention strategies used for ovarian cancer include oral contraceptives, aspirin and non-steroidal anti-inflammatory agents, and retinoids. The theory that oral contraceptives (OCs) reduce the number of ovulatory events is a basic explanation for its protective effect. Recent data suggest that the mechanism of action is more complex. Recent studies have indicated that progestin-induced apoptosis of the ovarian epithelium is responsible for the chemopreventive effect of OCs. The theory is that cells that have genetic damage but are not yet neoplastic have an increased chance of undergoing apoptosis.[11] OCs decrease the relative risk to less than 0.4% in women who use them for greater than 10 years.[12,13] However, at the same time, OC use has been associated with an increased risk of breast cancer.[12,13] Thus, women with a family history of breast cancer would not be ideal candidates for this preventive measure.

Non-steroidal anti-inflammatory agents, aspirin, and acetaminophen have been suggested for use in the prevention of different cancers, especially hereditary non-polyposis colon cancer.[14] While there have been observational studies linked to a reduction of ovarian carcinoma risk, evidence is still lacking. Potential mechanisms include effects on normal ovulation shed and inhibition of ovulation.[14,15] Other pharmacologic interventions that have been suggested but are still being evaluated include vitamin A, luetin, and other carotenoids.[16–18] The protective effect of these agents is associated with inhibition of cell growth, as well as promotion of cellular differentiation.[17]

Prophylactic Surgery

Surgical strategies are also used in the prevention of ovarian cancer. The goal is to remove healthy, at-risk organs and ultimately reduce the risk of developing cancer. These surgeries include prophylactic **oophorectomy** or **bilateral salpingo-oophorectomy** (BSO) and tubal ligation.

Prophylactic oophorectomy should be considered in any woman with a high risk of developing ovarian cancer.[19] The criteria for defining high risk include any woman with two or more first-degree relatives with epithelial ovarian carcinoma; a family history of multiple occurrences of **non-polyposis** colon cancer, endometrial cancer, and ovarian cancer; and a family history of multiple cases of breast and ovarian cancer.[19] Patients undergoing prophylactic oophorectomy need to be made aware that complete protection is not guaranteed.[13,20] Although a 67% reduction in risk has been shown, a potential 2% to 5% risk of peritoneal **carcinomatosis** remains.[19,21]

Tubal ligation is another procedure that has shown potential for risk reduction. However, it is not recommended as a sole procedure in prophylaxis. Protective effect may be due to limiting exposure of the ovary to environmental carcinogens. A case-control study conducted by Narod and colleagues found that a history of tubal ligation in *BRCA*-positive women was associated with a statistically significant 63% reduction in risk.[22]

Genetic Screening

Genetic screening is another option available for high-risk patients to consider. Patients could be screened for genes such as *BRCA1* and *BRCA2* or other genes such as those associated with HNPCC or HBOC syndrome.[3,22–26] Patient/family counseling and genetic counseling should be available for the patient/family to prepare to deal with the health and psychosocial implications of the genetic test results. Prior to this decision, the potential preventive options should be discussed, such as prophylactic bilateral salpingo-oophorectomy and/or total **hysterectomy.** Patients specifically positive for *BRCA1* or *BRCA2* also may consider a mastectomy.[27] Again, all risk factors and the patient health need to be evaluated, but typically surgery can be held off until after the childbearing years.[28–30]

PATHOPHYSIOLOGY

The three recurrent theories proposed are the incessant-ovulation hypothesis, the pituitary gonadotropin hypothesis, and the chronic inflammatory processes hypothesis.[2,31] The incessant-ovulation hypothesis proposes that the pathogenesis of ovarian

cancer is connected to continual ovulation. Ovulation is considered a "hostile" event to the ovary, perhaps with not enough time for adequate repair. Each time ovulation occurs, the ovary epithelium is disrupted, and cell damage occurs. Thus, repeated ovulations may lead to a greater number of repairs of the ovarian epithelium and increase the possibility of aberrant repairs, mutation, and **carcinogenesis.**[31–34] The pituitary gonadotropin hypothesis associates the disease with elevations in gonadotropin and estrogen levels.[2,31] This leads to an increased number of follicles and therefore an increased risk of malignant changes. There is also some evidence suggesting that chronic inflammatory processes and various environmental carcinogens play a role.[2,13]

The three major pathologic categories of ovarian tumors include sex-cord stromal, germ cell, and epithelial. About 85% to 90% of ovarian cancers are of epithelial origin. Epithelial ovarian tumors are composed of cells that cover the surface of the ovary, such as serous, mucinous, endometrioid, clear cell, and poorly differentiated adenocarcinomas. Germ-cell tumors involve the precursors of ova, with the most common type being dygerminoma, and are diagnosed most commonly in women under 40 years of age; generally, however, they have a better prognosis.[2] Sex-cord stromal tumors are indolent tumors that produce excess estrogen and androgens but also have a better overall prognosis.[2] Although, the histologic type of the tumor is not a significant prognostic factor, it is important to know the histopathologic grade. Undifferentiated tumors are associated with a poorer prognosis than lesions that are considered to be well or moderately differentiated.

Ovarian cancer usually is confined to the abdominal cavity, but spread can occur to the lung, liver, and less commonly, bone or brain. Disease is spread by direct extension, peritoneal seeding, lymphatic dissemination, and blood-borne metastasis. Lymphatic seeding is the most common pathway and frequently causes ascites.

Mechanisms of Resistance

The common mechanisms of drug resistance in ovarian cancer include: (1) alteration of drug inactivation by agents such as glutathione-*S*-transferase (GST), (2) enhanced DNA repair, (3) dysregulation of apoptotic pathways through activation of oncogenes or loss of tumor suppressor gene functions, (4) P-glycoprotein multidrug resistance (Pgp-MDR) that leads to decreased drug accumulation, and (5) steroid xenobiotic receptor (SXR) that leads to enhanced drug metabolism. At this time, our understanding about the mechanism of drug resistance in ovarian cancer is incomplete and limited mostly to in vitro studies. Ongoing improvements in current technology have allowed development of in vivo studies to evaluate mechanisms of drug resistance in ovarian cancer. MDR has been one of the major limitations and is one of the ongoing challenges for the successful therapeutic treatment of recurrent and persistent ovarian cancer.

CLINICAL PRESENTATION AND DIAGNOSIS

Clinical Presentation of Ovarian Cancer

General

❸ *Ovarian cancer often has been denoted as the "silent killer" because of the non-specific signs and symptoms.* By the time symptoms become unrelenting and bothersome, patients have advanced stage disease.

Symptoms

Patients may experience episodes or persistent symptoms of abdominal pain, constipation or diarrhea, flatulence, and urinary frequency.

Signs

The degree of abdominal swelling secondary to fluid accumulation may present like "pregnant abdomen" with irregular vaginal bleeding.

Laboratory Tests

- Cancer antigen 125 (CA-125). The normal level is less than 35 units/mL (35 kU/L). This test is associated with a lack of specificity. CA-125 can be elevated in a number of other states, such as different phases of the menstrual cycle, endometriosis, and non-gynecologic cancers. It is important to rule out other cancers associated with the abdominal cavity.
- *Carcinoembryonic antigen (CEA).* CEA is a marker for colon cancer. Normal value is less than 2.5 ng/mL (2.5 mcg/L).
- *CA19-9.* This is a marker for many gastrointestinal tumors such as cholangiocarcinomas.

Chemistries with Liver Function Tests (LFTs)

LFTs and serum creatinine may be suggestive of extent of disease. Most of this information is needed to determine if a patient is a surgical candidate. Labs should be within normal limits.

Complete Blood Count (CBC)

Abnormalities in CBC are not associated with ovarian cancer, but this information is needed to determine if the patient is a surgical candidate. Labs should be within normal limits.

Other Diagnostic Tests

To characterize local disease, one or both of the following are completed:

- Transvaginal ultrasound
- Abdominal ultrasound

To evaluate extent of disease, only one of the following is completed:

- Compute tomographic (CT) scan
- Magnetic resonance imaging (MRI)
- Positron-emission tomographic (PET) scan

Chest x-ray is also often done as part of clearance for surgery.

TREATMENT

Desired Outcomes

Health care providers use a multimodality approach including surgery and chemotherapy in the initial treatment of ovarian cancer with a curative intent. ❹ *Although most patients will achieve a complete response initially, more than 50% of cancers will recur within the first 2 years.*[2,35] Complete response to treatment is defined as no evidence of disease can be detected by physical examination or diagnostic tests, and patient has a normalized CA-125 value.

The histology of the disease is a prognostic factor. For instance, clear-cell and undifferentiated tumors do not respond as well to chemotherapy.[2] The extent of residual disease and tumor grade are also predictive of response to chemotherapy and overall survival.[2] There are other prognostic factors that may predict how well a patient will respond to adjuvant chemotherapy.

Generally, younger patients with a better performance status tolerate chemotherapy better than elderly patients. Caucasian women tend to have a worse prognosis and response to therapy compared with other ethnic backgrounds.[2,4,5]

The treatment goals shift when a patient presents with recurrent ovarian cancer. The desired outcomes focus on relief of symptoms such as pain or discomfort from ascites, slowing of disease progression, and prevention of serious complications such as small bowel obstructions. When a patient relapses, the prognostic factors are similar to those after initial surgery, except that the amount of time that has lapsed since the completion of chemotherapy should be considered to determine if drug resistance is emerging in the tumor. For example, recurrent platinum-sensitive ovarian cancer patients generally have a better prognosis than platinum-resistant patients.

Nonpharmacologic Therapy

❺ *Surgery is the primary treatment intervention for ovarian cancer.*[36–40] A total abdominal hysterectomy with bilateral salpingo-oophorectomy (TAH-BSO; Fig. 91–1), **omentumectomy,** and lymphonectomy (or lymph node dissection) is the standard initial surgical treatment of ovarian cancer.[36,38] The objective of the surgery is to debulk the patient until less than 1 cm of residual disease remains. Residual disease of less than 1 cm correlates with better complete response rates to chemotherapy and better overall survival compared with patients with bulky residual disease (less than or equal to 1 cm).[39,40] Indeed, the size of residual tumor mass after primary surgery is found to be the most important prognostic factor in patients with advanced ovarian cancer.[40]

A thorough exploratory **laparotomy** is essential for the accurate staging of patients.[36–38] ❻ *Ovarian cancer is staged surgically using the International Federation of Gynecology and Obstetrics (IFGO) staging algorithm* (Fig. 91–2). For certain patients with limited-stage disease, surgery may be curative.

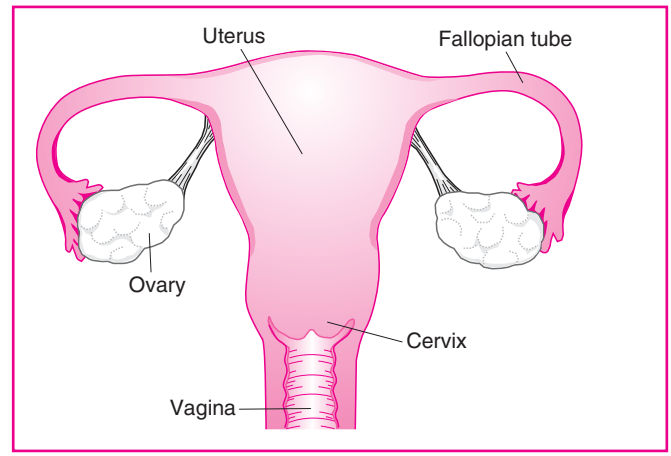

FIGURE 91–1. Diagram of female reproductive tract (uterus, fallopian tubes, ovaries, vagina). Dashed-line box outlines what is removed during the total abdominal hysterectomy with bilateral salpingo-oophorectomy (TAH-BSO).

Other surgical procedures have been evaluated to improve overall survival. Interval debulking that is completed after two to three cycles of chemotherapy has not translated into an improved survival benefit. Often debated, the benefit of the second-look laparotomy to evaluate residual disease after completing chemotherapy remains controversial because it has been difficult to establish any impact on patient overall survival. It has questionable benefit because although approximately 40% of patients with advanced disease will have a negative second look, 50% still relapse.[2] The role of **laparoscopic** surgery is somewhat controversial as initial surgery but is considered more often for debulking of recurrent or advanced disease when the intent is palliative rather than curative.[39]

Debulking surgery is intended to relieve symptoms associated with complications such as small bowel obstructions and to help improve the patient's quality of life but does not have a curative intent.

Pharmacologic Therapy

First-Line Chemotherapy

❼ *After initial surgery, the gold standard of care is six cycles of a taxane/platinum-containing regimen for patients with advanced ovarian cancer.*[41–43] Patients with limited disease will have observation alone after surgery (Fig. 91–3). Most often, paclitaxel is the taxane agent used in combination with carboplatin as the preferred platinum agent.[41–43] Depending on the patient's preexisting comorbidities and how well the patient tolerates chemotherapy regimens, substitution with docetaxel or cisplatin may be considered. The route of administration also should be discussed. Most often, intravenous (IV) administration will be used; however, in some patients, **intraperitoneal** (IP) administration may have an advantage in terms of overall survival[44]

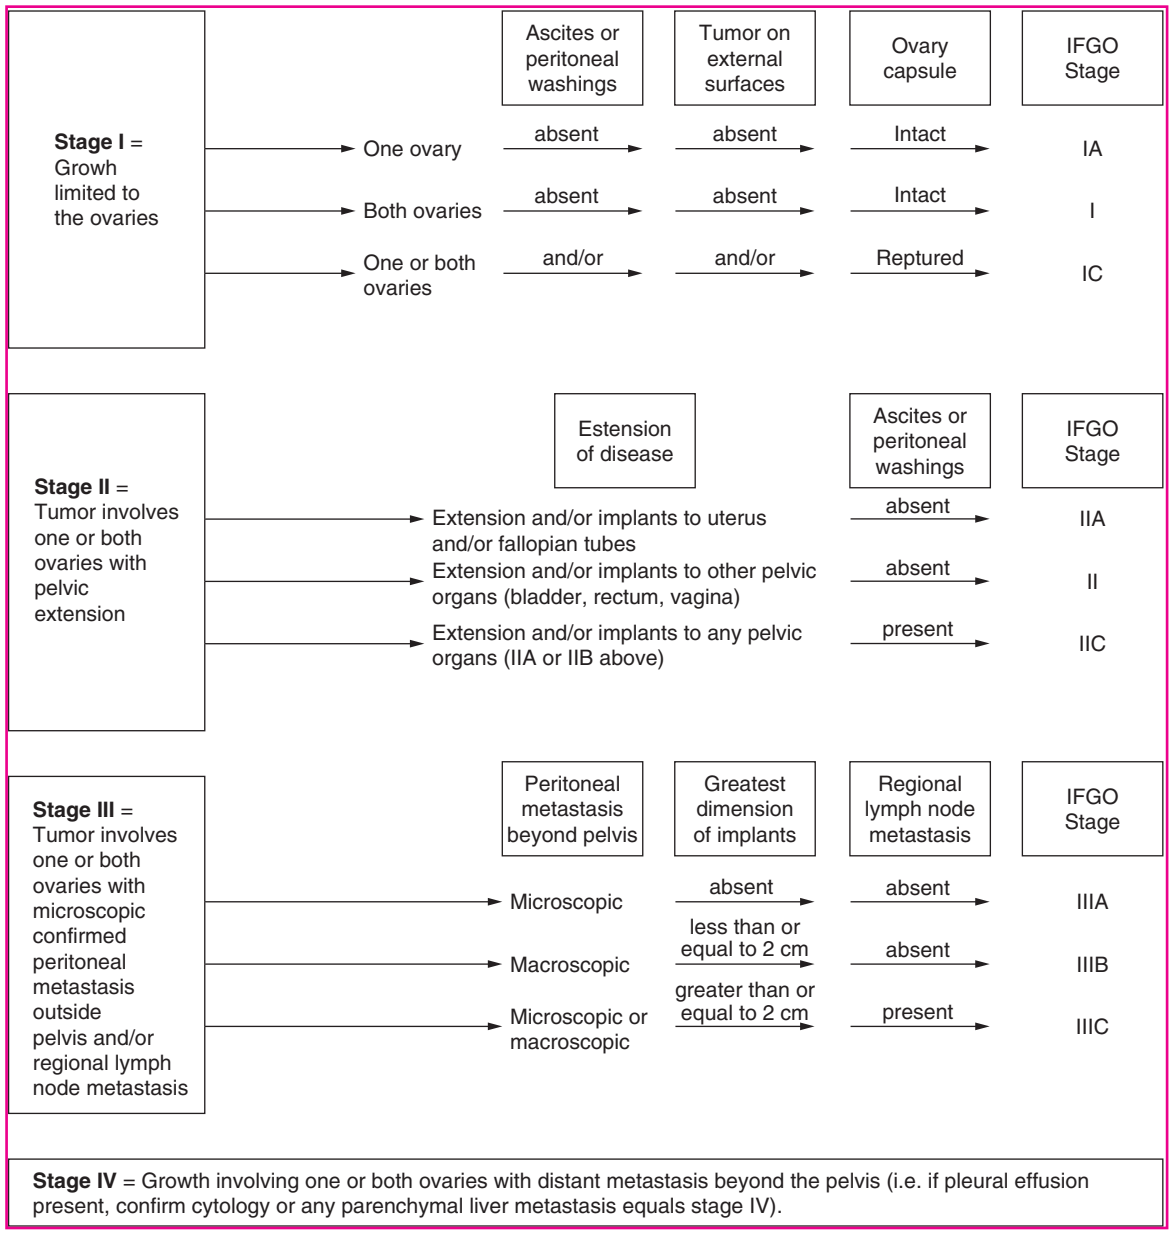

FIGURE 91–2. International Federation of Gynecology and Obstetrics (IFGO) staging algorithm.

(Table 91–1). Close monitoring of organ function, nausea and vomiting, myelosuppression, and neuropathies is necessary for all taxane/platinum regimens (Table 91–2).

Neoadjuvant Chemotherapy

In patients who are deemed poor surgical candidates or patients with a bulky or significant tumor burden, neoadjuvant chemotherapy would be the first-line treatment.[35] For patients who are poor surgical candidates because of significant comorbidities, a combination of taxane and a platinum agent will be administered every 3 to 4 weeks as tolerated with the intent to relieve symptoms and slow progression of the disease. In some cases, especially elderly patients, single-agent carboplatin will be used as palliative treatment instead. Chemotherapy alone has not been curative for patients with advanced ovarian cancer.[35]

In patients with bulky disease or a significant tumor burden, neoadjuvant chemotherapy can be used to decrease tumor burden to increase the likelihood of optimal tumor debulking during surgery.[35] Typically, three cycles of the standard combination taxane/platinum regimen is administered once every 3 weeks. After surgery, the patient will receive another three to six cycles depending on response to chemotherapy.

Consolidation Chemotherapy

Consolidation chemotherapy is the addition of cycles of the taxane/platinum regimen or the addition of single-agent platinum or a single taxane after completion of first-line chemotherapy.[45] If the tumor has a partial response to first-line chemotherapy evident by a significant decline in CA-125 by more than 50% of the preoperative level and/or

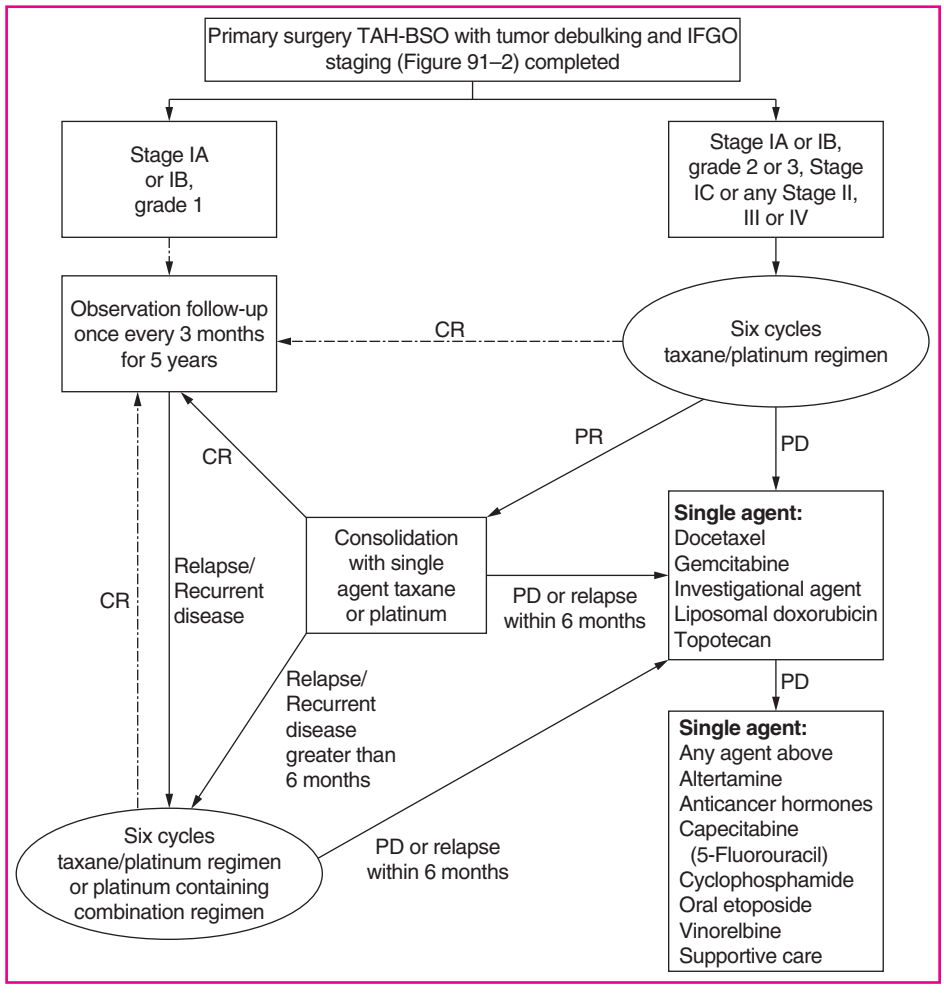

FIGURE 91–3. Summary of chemotherapy treatment algorithm for epithelial ovarian cancer. CR, complete response; PR, partial response; PD, progressive disease.

TABLE 91–1. Summary of First-Line Chemotherapy Regimens for Advanced Ovarian Cancer

Gold standard first-line chemotherapy after initial surgery for treatment of ovarian cancer.

Paclitaxel 175 mg/m^2 IV infused over 3 hours + carboplatin AUC = 5 IV infused over 1 hour. Regimen is given once every 21 days × six cycles.

Alternative first-line regimen: Addition of IP therapy. Patient selection is critical: Must have optimally debulked disease (less than or equal to 2 cm), no significant comorbidities, younger patients tolerate better.

Day 1: Paclitaxel 135 mg/m^2 IV infused over 24 hours + day 2: cisplatin 100 mg/m^2 IP infused over 1 hour + day 8: Paclitaxel 60 mg/m^2 IP infused over 1 hour. Regimen is given once every 21 days × six cycles.

Alternative first-line regimen: Substitution of cisplatin in place of carboplatin. Consider for patients experiencing difficulty with maintaining platelet counts.

Paclitaxel 135 mg/m^2 IV infused over 24 hours + day 2: cisplatin 75 mg/m^2 IV infused over 4 hours. Regimen is given once every 21 days × six cycles.

Alternative first-line regimen: Substitution of docetaxel in place of paclitaxel. Consider for patients with preexisting or increased risk of neuropathies.

Docetaxel 75 mg/m^2 IV infused over 1 hours + carboplatin AUC = 5 IV infused over 1 hour. Regimen is given once every 21 days × six cycles.

tumor regression/decrease in size, then the cancer still is considered taxane/platinum-sensitive. Additional cycles of chemotherapy are given until complete response is achieved (see Fig. 91–3).

Recurrent Chemotherapy

In the recurrent setting, the first question to address is whether or not the ovarian cancer is platinum-sensitive or platinum-resistant. If it has been less than 6 months or the disease progresses while receiving a platinum-based regimen, the cancer is considered to be platinum-resistant (see Fig. 91–3). These parameters are also used to determine taxane sensitivity or resistance. However, patients resistant to paclitaxel still may respond to docetaxel.[46] If the treatment goal is palliative care, then often single-agent therapy will be used, whereas curative care typically is an aggressive combination regimen (see Fig. 91–3).

Platinum-Sensitive

In patients who experienced a complete response to first-line chemotherapy and have had greater than a 6-month platinum-free interval, retreatment with a platinum-containing regimen is appropriate. Current National Comprehensive Cancer Network (NCCN) guidelines recommend the combination of carboplatin

TABLE 91–2. Summary of Chemotherapy Agents Used for First-Line Treatment of Advanced Ovarian Cancer

Mechanism of action of first-line agents:
Platinum analogs: Produce intra- and interstrand cross-links and DNA adducts to disrupt DNA replication
Taxane agents: Stabilize microtubules and prevent de-polymerization of tubulin

Agent	Common Adverse Effects	Monitoring/Comments
Paclitaxel	Peripheral neuropathy (DLT), nausea/vomiting, alopecia, hypersensitivity reactions	Use caution with any elevation in AST (SGOT). Give proper dosing for liver dysfunction. Premedicate: dexamethasone, diphenhydramine, and cimetidine.
Docetaxel	Neutropenia (DLT), hyperlacrimation, fluid retention, nail disorders, myelosuppression	Use with caution in liver dysfunction. Do not give if biliary tract is obstructed. Premedicate: dexamethasone.
Carboplatin	Myelosuppression (DLT), nephrotoxicity, nausea/vomiting, electrolyte wasting, diarrhea, stomatitis, hypersensitivity reactions	Prehydration not required. Give proper dosing for renal dysfunction. Premedicate: dexamethasone, diphenhydramine, and cimetidine.
Cisplatin	Neurotoxicity (DLT), nausea/vomiting, ototoxicity, nephrotoxicity, myelosuppression, electrolyte wasting, diarrhea	Prehydration required. Do not use if ScCr greater than 1.5 mg/dL or BUN greater than 25. Give proper dosing for renal dysfunction.

DLT, dose-limiting toxicity.

with either gemcitabine or paclitaxel for the treatment of platinum-sensitive recurrent ovarian cancer with a curative intent.[44] However, in patients unable to tolerate additional combination chemotherapy regimens, carboplatin alone or any one of the second-line agents would be appropriate[47] (Table 91–1).

Platinum-Resistant

Recurrent or persistent ovarian cancer after platinum-based regimens has a discouraging prognosis. Second-line agents have not been successful to date, but any active agent that has not been used during initial treatment is available for use. ❽ *Single-agent chemotherapy is standard practice for recurrent platinum-resistant ovarian cancer.* Active agents include altretamine (formerly hexamethylmelamine), anastrozole, capecitabine (5-fluorouracil), cyclophosphamide, docetaxel, gemcitabine, liposomal doxorubicin, oral etoposide, vinorelbine, and topotecan or investigational agents (Fig. 91–3). ❾ *Since the efficacy of the agents is similar, selection of an agent for treatment of recurrent platinum-resistant ovarian cancer depends on residual toxicities, physician preference, and patient convenience.* Table 91–3 gives a short summary of the adverse effects and monitoring parameters for chemotherapy agents commonly used for the treatment of recurrent ovarian cancer.

Patient Encounter 1, Part 2: One Year Later after Initial Diagnosis

This 67-year-old patient was optimally debulked and completed six cycles of paclitaxel/carboplatin after her surgery. Her CA-125 normalized (12 U/mL, 12 kU/L) on completion of her chemotherapy treatment, and her CT scan was negative. This patient returns to your clinic for her first 3-month follow-up appointment. Her CA-125 is (45 U/mL, 45 kU/L), and she reports some mild bloating. CT scan report states mild fluid accumulation in the pelvic cavity.

- List the possible chemotherapy treatment options for this patient
- Discuss the side-effect profile and administration schedule of each agent and how this information would help in selection of her next chemotherapy regimen
- What is the goal of treatment for this patient?

OUTCOME EVALUATION

Overall survival is affected by the success of the initial surgery to debulk the tumor to less than 1 cm of disease and response to first-line chemotherapy. The CA-125 level should be monitored with each cycle, and at least a 50% reduction in CA-125 after four cycles of taxane/platinum chemotherapy is related to an improved prognosis. Patients who achieve a complete response should have follow-up examinations every 3 months, including CA-125 determination, physical examination, pelvic examination, and appropriate diagnostic scans (e.g., CT scan, MRI, or PET scan) and should be evaluated for the detection of disease. Evaluate patients for resolution of any residual chemotherapy-related side effects, including neuropathies, nephrotoxicity, ototoxicity, myelosuppression, and nausea/vomiting.

In the progressive disease or recurrent setting, CA-125 levels still should be monitored with each cycle, but no change in therapy is recommended until after a minimum of three cycles of chemotherapy. In addition, appropriate diagnostic scans (e.g., CT scan, MRI, or PET scan) should be evaluated once every three cycles. Patients also should have routine physical examinations with each cycle of chemotherapy to evaluate for any physical

TABLE 91–3. Summary of Chemotherapy Agents Used for Second-Line Treatment of Progressive and Recurrent Platinum-Resistant Ovarian Cancer

Agent	Dose	Response Rate(%)	Common Adverse Effects	Monitoring/Comments
Docetaxel	75 mg/m^2 IV over 1 hour repeat every 21–28 days *vs.*	22%	Neutropenia (DLT), hyperlacrimation, fluid retention, nail disorders, myelosuppression	1. Premedicate: dexamethasone. 2. Use with caution in liver dysfunction. 3. Do not give if biliary tract is obstructed.
	30–40 mg/m^2 IV over 1 hour once every week	NR		
Gemcitabine	800 mg/m^2 IV infused over 30 minutes once a week on days 1, 8, & 15, followed by 1 week of rest	13.9%–27%	Myelosuppression (DLT), flulike symptoms, headache, somnolence, nausea/vomiting, stomatitis, diarrhea, constipation, rash	
Liposomal Doxorubicin	40 mg/m^2 IV infused over 3 hours cycles 1 & 2 and then infused over 1 hour thereafter; repeat every 28 days	12.3%–18%	Myelosuppression, stomatitis, mucositis, alopecia, flushing, shortness of breath, hypotension, headaches, cardiotoxicity, hand-foot syndrome	1. Give proper dosing for liver dysfunction. 2. Do not give if total bilirubin is greater than 5 mg/dL.
Topotecan	1.5 mg/m^2 IV infused over 30 minutes on days 1, 2, 3, 4, & 5; repeat every 21 days *or*	6.5%–17%	Myelosuppression (DLT), nausea/vomiting, diarrhea, Stomatitis, abdominal pain, alopecia, SGOT/SGPT elevation	1. Give proper dosing for renal dysfunction
	4 mg/m^2 IV infused over 30 minutes once a week for 3 consecutive weeks, followed by 1 week rest	31%		
Altretamine (Hexalen™)	260 mg/m^2 PO daily for 14–21 days; repeat every 28 days	9.7%	Nausea/vomiting, diarrhea, abdominal cramping, myelosuppression	1. Monitor for potential CYP450 drug interactions.
Capecitabine	1800–2500 mg/m^2 PO as divided dose twice for 14 consecutive days, followed by 1 week of rest	29%	Myelosuppression, hand-foot syndrome, nausea/vomiting, edema, stomatitis, diarrhea, cardiotoxicity, rash	1. Monitor for PPE and recommend regular use of lotions on hands and feet.
Cyclophos-phamide	750 mg/m^2 IV over 30 minutes	NR	Nausea/vomiting, nephrotoxicity, myelosuppression, cardiotoxicity, alopecia, hemorrhagic cystitis	1. Monitor for potential CYP450 drug interactions. 2. Monitor for any signs of blood in urine.
Etoposide	50 mg/m^2 per day PO in divided doses given daily for 3 consecutive weeks, followed by 1 week of rest	18%	Myelosuppression, nausea/vomiting, anorexia, alopecia, headache, fever, hypotension	1. Give proper dosing for liver dysfunction. 2. Do not give if total bilirubin is greater than 5 mg/dL. 3. Give proper dosing for renal dysfunction.
Letrozole	2.5 mg once daily	15%	Headache, nausea, dyspepsia, skin rash	1. No protective effect on bone; recommend calcium supplementation.
Tamoxifen	20 mg PO twice a day continuously until progressive disease	10%	Thrombocytopenia, anemia, thromboembolism, hot flashes, decreased libido, nausea/vomiting	1. Protective effect on bone and lipids. 2. Increased risk for endometrial cancer.
Vinorelbine	30 mg/m^2 IV infused over 15 minutes on days 1 and 8; repeat every 21 days	29%	Constipation, neutropenia, anemia, thrombocytopenia, neurotoxicity	1. Consider bowel regimen to prevent constipation.

NR, not reported.

toxicity associated with the chemotherapy, such as neuropathies, fluid retention, PPE, myelosuppresion, or nausea/vomiting.

Unfortunately, patients eventually will progress through all chemotherapy options, and then supportive-care measures should be provided to maintain patient comfort and quality of life. Develop a plan for treatment of common complications of advanced/progressive ovarian cancer, including ascites, uncontrollable pain, and SBO. Caution should be used in the removal of ascites because of the potential complications associated with rapid fluid shifts. Liberal use of opioids to control

pain is appropriate as ovarian cancer patients cope with progressive disease and approach end of life. Appropriate bowel regimens with laxatives and stool softeners should be used to prevent constipation. However, when a patient with a well-controlled bowel regimen presents with new onset of constipation, additional work-up is required prior to altering the bowel regimen. ⑩ *In ovarian cancer patients, small bowel obstruction is a common complication of progressive disease. In general, laxatives should not be used in patients with small bowel obstructions.* Prior to treating constipation, the patient should have a physical examination and abdominal x-ray to rule out SBO. Often, palliative surgery is required to correct SBO and alleviate patient pain. Patients should not eat any solids or liquids until resolution of the SBO. If inoperable SBO exists, then parenteral nutrition can be considered, but it should be weighed against ultimate treatment objectives. Overall, providing any measures needed to maintain patient comfort is the priority for patients with progressive ovarian cancer.

Patient Care and Monitoring

1. Assess patient history of non-specific symptoms to determine if patient should be evaluated by a gynecologist.
2. Determine if patient is at high risk for development of ovarian cancer, and make appropriate recommendations for screening and prevention.
3. Evaluate patient comorbidities and medications to determine if additional work-up is necessary prior to tumor debulking surgery. Do any medications need to be stopped or changed prior to surgery (e.g., aspirin, warfarin, or non-steroidal anti-inflammatory agents)?
4. Develop a plan for preventing and treating nausea and vomiting in patients receiving emetogenic chemotherapy.
5. Monitor the patient for signs of hypersensitivity reactions to taxane or platinum chemotherapy regimens.
6. Monitor appropriate labs to determine
   - Changes in organ function: adjust chemotherapy doses as indicated.
   - Electrolyte wasting: replace and supplement electrolytes intravenously or orally as indicated.
7. Provide appropriate patient education on respective chemotherapy agents that will be given for treatment of recurrent ovarian cancer.
   - What the chemotherapy is and how this agent works.
   - Explain plan for monitoring response to treatment.
   - What side effects to expect during chemotherapy
   - Precautions to take to prevent infection when neutropenic.
   - Monitor for signs/symptoms of infection.
   - When to contact the physician/clinic between cycles of chemotherapy
   - Drug or food interactions to avoid with chemotherapy.

92 Acute Leukemias

Nancy Heideman

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Compare the classification systems for acute lymphocytic leukemia (ALL) and acute nonlymphocytic leukemia (ANLL).
2. Describe the pathogenesis of acute leukemia.
3. Identify the prognostic factors for acute lymphocytic leukemia (ALL).
4. Explain the purpose of induction, consolidation, and maintenance phases for acute leukemia.
5. Explain the role of central nervous system (CNS) preventive therapy for acute leukemia.
6. Explain the treatment complications associated with therapy for acute leukemia.
7. Recognize the late effects of the treatment for long-term survivors of acute leukemias.

Key Concepts

❶ The acute leukemias are hematologic malignancies of bone marrow precursors characterized by excessive production of immature hematopoietic cells. This proliferation results in a large number of immature cells (blasts) appearing in the peripheral blood and bone marrow causing failure of normal hematopoiesis.

❷ Acute leukemias are classified according to their cell of origin. Acute lymphocytic leukemia (ALL) arises from the lymphoid line. Acute nonlymphocytic leukemia (ANLL) or acute myelogenous leukemia (AML) arises from the myeloid line.

❸ Children with acute lymphocytic leukemia (ALL) are classified according to their risk of relapse. Risk assessment is an important factor in the selection of treatment. The goal is to match treatment to risk and minimize over- or undertreatment.

❹ The initial treatment for acute leukemias is called ***induction.*** The purpose of induction is to induce a **remission**, a lack of identifiable leukemic cells in the bone marrow or peripheral blood with light microscopy. This definition may change as more sensitive techniques come into play.

❺ The current induction therapy for acute lymphocytic leukemia (ALL) typically consists of vincristine, asparaginase, and a steroid (prednisone or dexamethasone). An anthracycline is added for higher-risk patients.

❻ The current induction therapy for acute myelogenous leukemia (AML) usually consists of a combination of cytarabine and daunorubicin, with the frequent addition of a steroid and/or an antimetabolite such as 6-thioguanine. The risk of infection is so high during this period that patients receive antibiotic and fungal prophylaxis.

❼ Because the risk of central nervous system (CNS) involvement is high, regardless of cerebrospinal fluid (CSF) cytology, all patients with acute lymphocytic leukemia (ALL) receive intrathecal prophylaxis.

❽ Although survival in pediatric cancers has improved dramatically over the last 35 years, 50% to 60% of cancer survivors are estimated to have at least one chronic or late-occurring complication of treatment.

❶ *The acute leukemias are diseases of bone marrow resulting from aberrant proliferation of hematopoietic precursors. The hallmark of these malignancies is the leukemic blast cell, a visibly immature and abnormal cell in the peripheral blood that often replaces the bone marrow and interferes with normal hematopoiesis.* These blast cells proliferate in the marrow and inhibit normal cellular elements, resulting in anemia, neutropenia, and thrombocytopenia. Leukemia also may infiltrate other organs, including the liver, spleen, bone, skin, lymph nodes, and central nervous system (CNS). Virtually anywhere there is blood flow, the potential for extramedullary (outside the bone marrow) leukemia exists.

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

❷ *Acute leukemias are categorized according to the cell of origin. Acute lymphocytic leukemia (ALL) arises from the precursor lymphoid cells. Acute myelogenous leukemia (AML), also called acute nonlymphocytic leukemia (ANLL), arises from the precursor myeloid cells.* As a result of the treatment of acute leukemias, especially ALL, the number of survivors has increased dramatically in the last 30 or more years.[1] ❸ *Risk-based treatment strategies have been developed that attempt to match the aggressiveness of therapy with the presumed risk of relapse and death.* This approach is based on the identification of multiple **phenotypic** and biologic risk factors. If left untreated, most patients with acute leukemia will die of their disease within 2 to 3 months.

EPIDEMIOLOGY AND ETIOLOGY

Epidemiology

Leukemia is a relatively uncommon disease overall. The current overall age-adjusted annual incidence of acute leukemia in the United States is 10 per 100,000. Of the estimated 1.4 million new cancers diagnosised in 2005, only 1% to 2% were acute leukemia,[2,3] with 4000 cases of ALL and about 12,000 cases of AML. Interesting age-related patterns of disease exist in ALL and AML. The average age of diagnosis for AML is about 65 years, whereas the average age for ALL is 10 years. This is a result of an increasing incidence of AML with age from about 1.8 per 100,000 in childhood to a peak of 17.7 per 100,000 adults 65 years of age and older.[4] ALL occurs in only about 20% of adult acute leukemia.[5] ALL is the most common malignancy of childhood; the peak incidence is in the 2- to 5-year range.[6]

In the pediatric population, leukemia is a common disease, accounting for almost one-third of all childhood malignancies. ALL accounts for 75% to 80% of all cases of childhood leukemia, whereas AML accounts for no more than 20%. Males generally are affected more often than females in all but the infant age group, and its incidence is higher in Caucasians than among other racial groups. The incidence of AML in children is bimodal: It peaks at 2 years of age, decreases steadily thereafter to age 9 years, and then peaks again at around age 16.[3]

The 5-year **event-free survival** rate for ALL is nearly 80% in children and approximately 40% for adults.[1] The success rate for children with ALL is attributed to risk-directed therapy and enrollment in clinical trials. For patients with AML younger than 20 years of age, the 5-year survival is 50%.[6] Patients with AML older than age 60 generally have a poorer prognosis of less than 20%.

Etiology

The cause of the acute leukemias is unknown; multiple influences related to genetics, socioeconomics, infection, environment, hematopoietic development, and chance all may play a role.[3] Table 92–1 lists the major conditions that have been implicated in the acute leukemias. In most cases, however, there is no explanation for the development of leukemia.

Patient Encounter, Part 1

RH is a 7-year-old girl who presents to her pediatrician with a 1-week history of runny nose and fever. Her mom has noted a lot of bruising on her lower exytremities. Physical examination reveals splenomegaly, multiple petechiae, and pallor. A complete blood count reveals a normochromic, normocytic anemia with a hemoglobin of 6 g/dL (60 g/L, 3.6 mmol/L; normal 11.7–15.7 g/dL, 117–150 g/L, 7.3–9.7 mmol/L), hematocrit of 18% (0.18; normal 35%–47%, or 0.35–0.47), and white blood cell (WBC) count of $2.6 \times 10^3/\mu L$ ($2.6 \times 10^9/\mu L$). The differential on the WBC count reveals 75% (0.75) lymphocytes (normal 20%–40%, or 0.2–0.4), 20% (0.2) neutrophils (normal 55%–62%, or 0.55–0.62), and 5% (0.05) lymphoblasts (normal 0%). Based on this information, a bone marrow aspirate and biopsy are performed, which reveal 85% (0.85) lymphoblasts and a DNA index of 1.17. A lumbar puncture is also performed, which shows no evidence of leukemia.

- What information is suggestive of acute lymphocytic leukemia?
- What are the prognostic factors for RH?
- What is the goal of induction therapy?

TABLE 92–1. Clinical Conditions Associated with an Increased Frequency of Acute Leukemias

Adapted from Leather HL, Bickert B. Acute leukemias. In: DiPiro JT, Talbert RL, Yee GC, et al., (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 2458–2511.

The influence of genetics in leukemia is supported by several observations. For example, among identical twins, the occurrence of ALL is associated with a 20% to 25% chance of the disease developing in the other twin within 1 year. In fraternal twins, there is a fourfold increase in the risk of leukemia compared with the normal population. Additionally, leukemia is known to be increased in several chromosomally abnormal populations. Patients with Down's syndrome have a 20 times increased risk of developing leukemia compared with the rest of the population. Patients with Klinefelter's syndrome and Bloom's syndrome also have an increased incidence of leukemias.[7]

Even though exposure to environmental agents such as agricultural chemicals, pesticides, and radiation has been associated with leukemia, none of these agents is linked conclusively with the development of leukemia. An increased frequency of ALL is associated with higher socioeconomic status. It is postulated that less social contact in early infancy and thus a late exposure to some common infectious agents may have some impact.[7] In most individual instances, there is no reasonable or obvious explanation for the development of leukemia.

Risk factors for the development of AML include exposure to environmental toxins, Hispanic ethnicity, and genetics.[6] Of greater concern is the increased prevalence of AML as a secondary malignancy, resulting from chemotherapy and radiation treatment for other cancers. Alkylating agents, such as ifosfamide and cyclophosphamide, and topoisomerase inhibitors, such as etoposide, are linked to an increased risk of **myelodysplastic syndrome** (MDS) and AML.[8]

PATHOPHYSIOLOGY

Hematopoiesis is defined as the development and maturation of blood cells and their precursors. In utero, hematopoiesis may occur in the liver, spleen, and bone marrow. However, after birth, it occurs exclusively in the bone marrow. All blood cells are generated from a common hematopoietic precursor, or *stem cell.* These stem cells are self-renewing and pluripotent and thus are able to commit to any one of the different lines of maturation that give rise to platelet-producing megakaryocytes, lymphoid, erythroid, and myeloid cells. The myeloid cell line produces monocytes, basophils, neutrophils, and eosinophils, whereas the lymphoid stem cell differentiates to form circulating B and T lymphocytes. In contrast to the ordered development of normal cells, the development of leukemia seems to represent an arrest in differentiation at an early phase in the continuum of stem cell to mature cell.[1]

Both AML and ALL are presumed to arise from clonal expansion of a single "arrested" cell. As these cells expand, they acquire one and often more chromosomal aberration, including translocations, inversions, deletions, point mutations, and amplifications.[3] An example is the t(9;22) translocation, which underlies the *BCR-ABL* fusion protein. The normal *ABL* gene encodes a growth-promoting protein kinase whose activity is tightly controlled. By contrast, the translocation and fusion of the *BCR* and *ABL* gene sequences produce a kinase that leads to uncontrolled proliferation, survival, and self-renewal of cells. Imatinib is a tyrosine kinase inhibitor that inhibits the activity of *ABL.* It has shown great success given the pathogenic role of *BCR-ABL* tyrosine kinase in chronic myelogenous leukemia (CML). Imatinib also has shown activity in patients with acute lymphoblastic leukemia in patients who are *BCR-ABL*-positive.[3]

AML represents a group of disorders in which both failure to differentiate and overproliferation in the stem cell compartment produce an overabundance of nonfunctional cells termed myeloblasts. While the specific cause for this biologic abnormality is unknown, an understanding of the genetic influence of leukemia is leading to a wide variety of targeted therapies.[9]

In AML, there is a substantial difference in clinical and biologic features, as well as in response to and tolerance of therapy, by age group. In the elderly, trilineage leukemic involvement is common, indicating that the cell of origin is probably a stem or very early progenitor cell. In the younger population, a more differentiated progenitor becomes malignant, permitting maturation of some granulocytic and erythroid populations. These two forms of AML show different patterns of resistance to chemotherapy, with resistance more frequent in the older adults with AML.[6]

For patients with myelodysplastic syndrome or AML as a secondary neoplasm, there are a number of key features characteristic of the leukemia. Alkylator-related secondary leukemias after Hodgkin's disease usually have a myelodysplastic prodrome and a monosomy 5 or monosomy 7. Secondary ANLL with the use of epipodophyllotoxin (etoposide) demonstrates mainly M4 or M5 morphology and exhibits translocations within the *MLL* gene with 11q23 chromosomal alterations.[8]

Leukemia Classification

For all newly diagnosed patients with leukemia, an aspirate of the liquid marrow and a bone marrow core biopsy are obtained.[5] Morphologic and cytochemical analysis of these samples distinguishes three subtypes of ALL (L1, L2, and L3) and eight subtypes of AML (M0–M7) as classified by the French-American-British (FAB) scheme. See Tables 92–2 and 92–3 for the FAB classification of acute myelogenous leukemia and acute lymphocytic leukemia.

Classification methods for leukemia have evolved from simple schemes that were largely phenotypic and considered only age, gender, WBC count, and blast morphology to now-complex methods that include biologic features such as cell-surface receptor features and cytogenetics.

TABLE 92–2. Morphologic (FAB) Classification of Acute Myelogenous Leukemia

Sub-type		Frequency of FAB Sub-type[a] Adults (%)	Children less than 2 years (%)	Children less than 2 years (%)
M0	Acute myeloblastic leukemia, without maturation	5	Low	Low
M1	Acute myeloblastic leukemia with minimal maturation	15	17	25
M2	Acute myeloblastic with maturation	25		27
M3	Acute promyelocytic leukemia	10		5
M4	Acute myelomonocytic leukemia	25	30	26
M5a	Acute monoblastic leukemia, poorly differentiated	5	52	16
M5b	Acute monoblastic leukemia, well differentiated	5		
M6	Acute erythroleukemia	5		2
M7	Acute megakaryoblastic leukemia	10		5–7

[a]Percentages should be compared vertically and not horizontally. FAB, French-American-British.
Adapted from Leather HL, Bickert B. Acute Leukemias. In: DiPiro JT, Talbert RL, Yee GC, et al., (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 2458–2511.

Markers on the cell surface or membrane of the lymphoblast can be used to classify ALL. Among the early classification system was the FAB scheme, which was based purely on morphology and cytochemistry. This system considered nuclear appearance and degree of differentiation. This is no longer used, and the current classification of acute leukemias is based on features that can be identified only by immunologic and molecular analyses.[3]

Immunophenotyping by **flow cytometry** has taken on an increasingly important role in the diagnosis of leukemia. Owing to the ease of application, sensitivity, and quantifiable results, flow cytometry is the preferred method for lineage assignment.[7] This approach takes advantage of the development of monoclonal antibodies (MABs) to cell-surface antigens that are differentially expressed during hematopoietic differentiation. The antigens are referred to as antibody *cluster determinants* (CDs) that define cells at various stages of development and can easily separate ALL from AML and T-cell from pre-B-cell ALL.[5] The combined approach of using blast cell morphology and immunophenotype has facilitated diagnosis and delivery of specific treatments for the major subtypes of acute leukemia. The detailed information offered by flow cytometry and recognition of several prognostic cytogenetic features has combined to more narrowly predict prognosis and develop risk-directed therapies in ALL and AML. Common immunophenotypic markers seen in AML and ALL are provided in Table 92–4

TABLE 92–3. Morphologic (FAB) Classification and Immunophenotype of Acute Lymphocytic Leukemia

Sub-type	Cell of Origin	Frequency of FAB Sub-type[a] Adults (%)	Children (%)
L1	Early pre-B cell Pre-B cell B cell T cell	30	85
L2	Early pre-B cell Pre-B cell B cell T cell	60	14
L3	B cell	10	1

[a]Percentages should be compared vertically and not horizontally. FAB, French-American-British.

CLINICAL PRESENTATION

Clinical Presentation of Acute Myelogenous Leukemia[3,6,10]

General

Patients may have symptoms of AML for 1 to 3 months prior to presentation. These include fatigue, fever, and pallor**,** but patients generally are in no obvious distress.

Symptoms

- The patient may present with weakness, malaise, bleeding, and weight loss.
- Neutropenic patients are often febrile and highly susceptible to infection.
- Anemia usually presents as pallor, tiredness, and general fatigue.
- Patients with thrombocytopenia usually present with bruising, petechiae, and ecchymosis.
- Chloromas (localized leukemic deposits named after their color) may be seen, especially in the periorbital regions and as skin infiltrates.
- Gum hypertrophy is indicative of AML M4 and AML M5 subtypes.
- Disseminated intravascular coagulation is common in AML M3 and is associated with generalized bleeding or hemorrhage.
- Lymphadenopathy, massive **hepatosplenomegaly**, and bone pain are not as common in AML as in ALL.

Signs

- Temperature may be elevated secondary to a low WBC count.
- Petechiae and bleeding are indicative of thrombocytopenia.

Laboratory Tests

- Complete blood count with differential is performed.
- The anemia is usually **normochromic** and **normocytic.**
- Approximately 50% of children present with platelet counts of less than $50 \times 10^3/\mu L$ ($50 \times 10^9/L$).
- The WBC count may be normal, decreased, or high. About 20% of patients have WBC counts of over $100 \times 10^3/\mu L$ ($100 \times 10^9/L$), which places them at risk for **leukostasis.**
- Uric acid is increased in approximately 50% of patients secondary to rapid cellular turnover.
- *Electrolytes:* Potassium and phosphorus are often elevated. Calcium is usually low.
- *Coagulation disorders:* Elevated prothrombin time, partial thromboplastin time, D-dimers; hypofibrinogenemia

Other Diagnostic Tests

Flow cytometric evaluation of bone marrow and peripheral blood to characterize the type of leukemia, as well as to detect specific chromosomal rearrangements. The bone marrow at diagnosis usually is hypercellular, with normal hematopoiesis being replaced by leukemic blasts. The presence of greater than 20% blasts in the bone marrow is diagnostic for AML.

- At diagnosis, a lumbar puncture is performed to determine if CNS leukemia is present.

Prognostic Factors

❸*The survival of patients with leukemia has improved markedly in the last 30 years. This is a result of intensive classification and risk assessment that is a prerequisite in the selection of treatment aimed at ensuring that patients are neither over- nor undertreated.*[11] *Risk-adapted therapy tailors treatment based on the predicted risk of relapse.* Age, WBC count, leukemic cell **genotype,** and response to induction therapy are used commonly in risk classification, each possessing different and sometimes overlapping prognostic significance.[3] On the basis of these prognostic variables, patients are assigned to one of three risk groups (e.g., standard-, high-, or very high-risk groups) that determine the aggressiveness of treatment.

TABLE 92–4. Common Immunophenotypes in Acute Leukemia

Leukemia	Common Immunophenotypes
Acute myeloid leukemia	CD13, CD15, CD33, CD14, CD64, and C-KIT
B-cell acute lymphoblastic leukemia	CD19, CD20, CD10, and CD22
T-cell acute lymphoblastic leukemia	CD2, CD3, CD4, CD5, and CD7

Adapted from Leather HL, Bickert B. Acute Leukemias. In: DiPiro JT, Talbert RL, Yee GC, et al., (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 2458–2511.

Prognostic Factors in Acute Lymphocytic Leukemia

In both children and adults with ALL, clinical trials have identified several risk factors that correlate with outcome (Table 92–5). Prognostic features include age, WBC count, cytogenetic abnormalities, ploidy, leukemic cell immunophenotype, and degree of initial response to therapy.[7] When these factors are combined, they predict groups of patients with varying degrees of risk for treatment failure.

Clinical Presentation of Acute Lymphocytic Leukemia[3,6,10]

General

Typically, patients have symptoms for 1 to 3 months before presentation. These include fatigue, fever, and pallor, but patients generally are in no obvious distress.

Symptoms

- The patient may present with weakness, malaise, bleeding, and weight loss.
- Neutropenic patients are often febrile and highly susceptible to infection.
- Anemia usually presents as pallor, tiredness, and general fatigue.
- Patients with thrombocytopenia usually present with bruising, petechiae, and ecchymosis.
- Patients often present with bone pain secondary to expansion of the marrow cavity from leukemic infiltration.
- CNS involvement is common at diagnosis.

Signs

- Temperature may be elevated secondary to a low WBC count.
- Petechiae and bleeding are indicative of thrombocytopenia.
- Patients may present with organ involvement, such as peripheral adenopathy, hepatomegaly, and **splenomegaly.**
- T-lineage ALL may present with a mediastinal mass.

Laboratory Tests

- Complete blood count with differential is performed.
- The anemia is usually normochromic and normocytic. Approximately 50% of children present with platelet counts of less than $50 \times 10^3/\mu L$ ($50 \times 10^9/L$). The WBC count may be normal, decreased, or high. About 20% of patients have WBC counts over $100 \times 10^3/\mu L$ ($100 \times 10^9/L$), which places them at risk for leukostasis.
- Uric acid is increased in approximately 50% of patients secondary to rapid cellular turnover.
- *Electrolytes:* Potassium and phosphorus often are elevated. Calcium usually is low.
- *Coagulation disorders:* Elevated prothrombin time, partial thromboplastin time, D-dimers; hypofibrinogenemia.

Other Laboratory Tests

Flow cytometric evaluation of bone marrow and peripheral blood is performed to characterize the type of leukemia as well as to detect specific chromosomal rearrangements. The bone marrow at diagnosis usually is hypercellular, with normal hematopoiesis being replaced by leukemic blasts. At diagnosis, a lumbar puncture is performed to determine if CNS leukemia is present.

In adults, there is a steady decline in the rate of complete remission (CR) following initial induction therapy with increasing age. While induction treatment produces 95% CR in children, it decreases to 40% to 60% in patients older than 60 years of age. The prognostic implication is due in part to decreased tolerance of stringent induction/consolidation regimens in older patients, but it is mostly due to biologic differences, particularly the presence of Philadelphia chromosome (Ph^+) or t(9;22), which confers higher-risk disease.[5] *BCR-ABL* fusions are strongly associated with chemoresistant leukemia in all age groups but are much more prevalent in adults with ALL than in children (30% versus less than 5%).[10]

TABLE 92–5. Prognostic Factors in Acute Lymphocytic Leukemia

	Risk for Leukemic Relapse	
Factor	**Low**	**High**
Morphology	L1	L2, L3
Immunologic phenotype	Early pre-B cell	Null cell, T cell, pre-B cell, B cell
WBC count at diagnosis	Less than $10 \times 10^3/\mu L$ ($10 \times 10^9/L$)	Greater than $50 \times 10^3/\mu L$ ($50 \times 10^9/L$)
Platelets	Greater than $100 \times 10^3/\mu L$ ($100 \times 10^9/L$)	Less than $30 \times 10^3/\mu L$ ($30 \times 10^9/L$)
Patient age	3–7 years	Less than 1 year or greater than 10 years
Cytogenetics	Normal karyotype	t(9;22); t(4;11); –7; +8
Myeloid markers	Absent	Present
CNS leukemia	Absent	Present
Node/liver/spleen enlargement	Absent	Massive
Mediastinal mass	Absent	Present
Time to remission	Less than 4 weeks	Greater than 4 weeks

CNS, central nervous system; WBC, white blood cell.

TABLE 92–6. Risk Category According to Cytogenetic Abnormalities Present

	Risk Category		
Disease	**Good Risk**	**Intermediate Risk**	**High Risk**
AML	t(8;21)(q22;q22); inv(16); t(15;17); t(9;11) trisomy 21	Normal karyotype; trisomy 8; 11q23; del(7q); del(9q); trisomy 22	Complex karyoptype; –5; –7; del (5q); inv(3P)
Probability of relapse	Less than or equal to 25%	50%	Greater than 70%
4-Year survival	Greater than or equal to 70%	40–50%	Less than or equal to 20%
ALL	Hyperdiploidy; t(10;14); or 6q		t(9;22); t(8;14); t(4;11); t(1;9)

Adapted from Leather HL, Bickert B. Acute Leukemias. In: DiPiro JT, Talbert RL, Yee GC, et al., (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 2458–2511.

Like age, the WBC count at presentation is a reliable indicator of CR rate and outcome. WBC count is indicative of tumor burden, although the underlying biologic mechanisms that account for the unfavorable outcomes associated with an elevated WBC count are unclear. Patients with WBC counts of less than $50 \times 10^3/\mu L$ ($50 \times 10^9/L$) are considered standard risk, and a higher WBC count at presentation is associated with higher risk of treatment failure (Table 92–6).

Specific chromosomal abnormalities in leukemic cells also possess prognostic significance. Blast cells with a translocation of parts of chromosome 12 and 21 (the *TEL-AML1* fusion) or trisomies of 4, 10, and 17 are considered to have favorable genetic features.[3] The presence of specific translocations between chromosome 9 and 22 (Philadelphia chromosome, or Ph^+) is a high-risk feature. Other cytogenetic abnormalities, such as translocation of the *MLL* gene that occurs primarily in infant ALL, exist with varying degrees of prognostic significance.

The DNA content of blast cells, hyper-, hypo-, or diploid, corresponding to increased, decreased, or normal chromosome numbers, has been considered prognostic. Lower-risk patients with hyperdiploidy (greater than 50 chromosomes) generally are between the ages of 1 and 9 years, whereas the higher-risk patients with normal diploidy (50 chromosomes) generally are older.

Patients with cell-surface markers indicating that the blasts are early in the B-cell lineage (CD markers) are standard risk, whereas those with mature B-cell and T-cell blasts are considered high risk.

Patients completing induction treatment and in apparent remission still harbor malignant cells in their bone marrow, even though they are disease-free by peripheral blood and bone marrow morphology. These residual leukemic cells are below the limits of detection using standard morphologic examination. Measurement of this population of cells has become an increasingly significant prognostic factor and a determinant of the aggressiveness of postinduction therapy. Thus flow cytometric analysis for the determination of minimal residual disease (MRD) has become increasingly important.[12] Several studies in children, in whom ALL is common, have evaluated disease levels at the end of induction and correlated these values with event-free survival (EFS). For example, a patient with no detectable MRD at the end of induction has an EFS greater than 90% at 3 years. Conversely, a patient with a high MRD (1%) has a 3-year EFS of only about 25%.[13] Assessment of MRD is also emerging as an important indicator of disease recurrence in the adult population.

Prognostic Factors in Acute Myelogenous Leukemia

The major prognostic factors in newly diagnosed AML are age, sub-type (FAB M2), and chromosome status. Older adults with AML (greater than 60 years), in comparison with younger patients with the same disease, have a dismal prognosis and represent a distinct population in terms of disease biology, treatment-related complications, and overall survival. These older patients have a higher incidence of unfavorable chromosomal abnormalities, such as aberrations of chromosomes 5, 7, or 8, and fewer abnormalities that are associated with a more favorable outcome, such as t(8;21) or inv(16) (see Table 92–6).[9]

Even though chromosomal abnormalities correlate with prognosis in adult AML, they appear to have less influence on outcome. Among children, the male gender, platelet count of less than $20 \times 10^3/\mu L$ ($20 \times 10^9/L$), hepatomegaly, more than 15% bone marrow blasts on day 14 of induction, myelodysplastic syndrome (MDS), and FAB sub-type M5 all were associated with lower CR rates. The absence of these features and abnormal chromosome 16 were associated with more favorable outcomes.[6]

TREATMENT

Desired Outcome

The primary objective in treating patients with acute leukemia is to achieve a complete and continuous remission (CCR). **Remission** is defined as the absence of all clinical evidence of

Patient Encounter, Part 2

RH is admitted to the pediatric oncology service. She is started on allopurinol and intravenous fluids with sodium bicarbonate to prevent tumor lysis syndrome. According to her risk status, she will receive a three-drug induction with vincristine, dexamethasone, and pegylated asparaginase. She also will receive intrathecal (IT) chemotherapy for CNS prophylaxis with methotrexate, cytarabine, and hydrocortisone.

- What is the role of CNS prophylaxis?

leukemia with the restoration of normal hematopoiesis. For both ALL and AML, remission induction is achieved with the use of highly myelosuppresive chemotherapy that induces a state of bone marrow aplasia.[10] Following this period, hematopoiesis is restored. Failure to achieve remission in the first 7 to 14 days of therapy is highly predictive of disease recurrence.

Pharmacologic Therapy

Acute Lymphoblastic Leukemia (ALL)

The treatment for ALL consists of three main elements: remission induction, intensification (**consolidation**), and continuation (maintenance) phases of treatment.[3] Therapy to eradicate subclinical CNS leukemia is also an integral part of therapy for ALL (Table 92–7).

Remission Induction

❹*The primary objective of treatment is to eliminate all morphologic evidence of disease and restore normal hematopoiesis.*[15] ❺*Induction consists of a standard three-drug regimen: glucocorticoid (prednisone or dexamethasone), vincristine, and asparaginase or pegylated asparaginase. For patients with high-risk ALL, daunorubicin is added to the standard three-drug regimen.* Since adults are considered to be at high risk, their induction regimens include anthracycline (daunorubicin or doxorubicin).[5] Dexamethasone is replacing prednisone in some standard-risk protocols owing to its longer half-life and better CNS penetration.[6,16] Even though dexamethasone possesses more favorable pharmacologic characteristics than prednisone, its use may be associated with more life-threatening infections and septic deaths.[16]

Intensification (Consolidation)

After completion of induction and restoration of normal hematopoiesis, patients begin intensification (consolidation). The goal of intensification is to administer dose-intensive chemotherapy in an effort to further reduce the burden of

Patient Encounter, Part 3

RH had a bone marrow aspiration performed on days 15 and 29 that showed morphologic remission. The MRD on day 29 was less than 0.1%. RH completed her induction therapy and started intensification therapy.

- What is the significance of MRD?
- What is the purpose of intensification therapy?

residual leukemic cells.[12] It is in this and subsequent treatment phases that the presence of MRD is reduced by increasing the aggressiveness of the drug regimen. Several regimens use agents and schedules designed to minimize the development of drug cross-resistance. Studies have demonstrated that this phase of treatment has proven to be an effective strategy in the prevention of relapse in children with ALL, but its benefits in adults are less clear.

❸ *In children, the intensity of the consolidation treatment is now determined not only by the child's risk classification but also by the rate of cytoreduction during induction.*[5] Patients who respond slowly to induction therapy (as determined by bone marrow examination early in induction) are at higher risk of relapse and are treated on more aggressive regimens.

The Berlin-Frankfurt-Munster (BFM) Study Group introduced a treatment element called *delayed intensification* (or *reinduction*) *therapy.* This therapy consisted of repetition of the initial remission induction therapy administered approximately 3 months after remission. Most institutions have adopted this regimen.[12]

Intensification regimens may vary in their aggressiveness and the drugs they use depending on the patient's risk group and immunophenotype. For example, the use of very-high-dose methotrexate (5 g/m^2) appears to improve outcome in patients with T-cell ALL. The use of intensive asparaginase treatment in T-cell ALL patients also has improved outcome significantly.[12]

Continuation (Maintenance)

The purpose of maintenance therapy is to further eliminate leukemic cells and produce an enduring CCR. The two most important agents in maintenance chemotherapy are a combination of oral methotrexate and 6-mercaptopurine. Improved outcome has been associated with increasing 6-mercaptopurine dosages to the limits of individual tolerance based on absolute neutrophil count. The use of 6-mercaptopurine at doses that cause neutropenia has been associated with increased rates of infection, an inability to deliver planned therapy, and a higher relapse rate. 6-Mercaptopurine is metabolized by thiopurine methyltransferase (TPMT). TPMT deficiency is inherited as an autosomal recessive trait, with 89% to 94% of Caucasians having high activity, 6% to 11% having intermediate activity, and

Patient Encounter, Part 4: Creating a Care Plan

After completion of induction and intensification therapy, RH will begin maintenance therapy for 2.5 years.

- Which agents are used in maintenance therapy?
- Why is maintenance therapy of such a long duration?
- Create a care plan to include (1) monitoring parameters during maintenance therapy, (2) a list of drug-related problems to access toxicity during maintenance therapy, and (3) goals of maintenance therapy.

0.3% having very low or no activity. This deficiency is explained largely by three polymorphisms in the *TPMT* gene (**2*, **3A*, and **3C*) that also have a profound influence on 6-mercaptopurine tolerance and dose intensity in children with ALL. While these polymorphisms are rare, they are certainly important, with case reports of toxic deaths attributed to 6-mercaptopurine dating back several decades.

Children who were homozygous for one of the alleles require 6-mercaptopurine dose reductions of 91%, whereas heterozygotes require a dose reduction of approximately 50%. Children with dose reductions had equivalent overall survival when compared with children receiving full-dose 6-mercaptopurine, suggesting that TPMT polymorphisms are important for drug metabolism and toxicity but play no role in the pathogenesis of ALL. TPMT screening is recommended for children starting therapy with 6-mercaptopurine, with empirical dose reductions for those with genotypes associated with a deficiency. The addition of intermittent "pulses" of vincristine and a steroid (usually dexamethasone) to the antimetabolite backbone improves outcome and is encouraged in most modern continuation regimens.[12]

The optimal duration of maintenance therapy in both children and adults is unknown, but most regimens are given for 2 to 3 years; extension of the regimen beyond 3 years has not shown any additional benefit.

Central Nervous System Prophylaxis

❼ *CNS prophylaxis is necessary in any treatment regimen for ALL. At diagnosis, the incidence of CNS disease is less than 10%, but it increases to 50% to 75% after 1 year in patients without CNS prophylaxis.*[3] *The justification for CNS prohylaxis is based on two clinical findings. First, many chemotherapeutic agents do not cross the blood-brain barrier easily. Second, the CNS is a frequent sanctuary for leukemia, and undetectable leukemic cells are present in the CNS in many patients at the time of diagnosis.*[6]

CNS prophylaxis relies on intrathecal chemotherapy (e.g., methotrexate, cytarabine, and corticosteroids), systemic chemotherapy with dexamethasone and high-dose methotrexate, and craniospinal irradiation (XRT) in selected high-risk patients.[11] Even though XRT is the most effective modality, its use is associated with learning disabilities, growth retardation, secondary brain tumors, and other complications. Thus intrathecal therapy largely has replaced cranial irradiation for all except patients at very high risk of CNS relapse.

The treatment of CNS leukemia has had a remarkable impact on the overall survival for childhood ALL. While also effective at reducing the incidence of CNS relapse in adults, CNS prophylaxis has not shown measurable effects on overall survival.[10]

Acute Lymphocytic Leukemia in Infants

Infants account for approximately 5% of all children with ALL, and they experience the worst prognosis of any group of children with the disease. These patients have several poor prognostic features at diagnosis, including hyperleukocytosis, hepatomegaly, splenomegaly, and CNS leukemia.[6] The bone marrow of infants at day 14 usually shows poor response to therapy. Infants with ALL have increased frequencies of cytogenetic abnormalities; 60% to 70% have a translocation that involves the *MLL* gene located at 11q23. The 11q23 breakpoint abnormality, t(4,11), is the most common structural karyotypic abnormality in infants with ALL. In vitro, blasts from infants with ALL showed greater drug resistance to prednisolone and L-asparaginase than those from older patients, although they are more sensitive to cytarabine.[12] Based on this information, several studies are testing the efficacy of intensified chemotherapy that includes high-dose cytarabine. Another achievement is the prevention of CNS relapse using intrathecal cytarabine in conjunction with high-dose systemic cytarabine. This combination has eliminated the need for cranial irradiation in this young population. Even with major advances in cure rates for the general pediatric ALL population, where survival is 80% or more, the long-term EFS of infants is only about 40% (Tables 92–8, 92–9).

Acute Lymphocytic Leukemia in the Elderly

The proportion of ALL in patients older than age 60 years constitutes between 16% and 31% of all adult leukemias. Treatment of adults largely has followed the conventional chemotherapeutic regimes used in childhood ALL. However, the intensification regimens common in childhood are not suitable for this population because of their associated toxicities in older patients. The adverse prognostic factor, the Philadelphia chromosome, occurs in 15% to 30% of adults and thus is more common in the over 60 age group.[17] Based on the experience achieved in CML, the use of imatinib, a potent inhibitor of the Ph^+-associated *BCR-ABL* tyrosine kinase, is becoming a common practice for these older adults. Results show that the combination of imatinib with conventional chemotherapy has improved remission rates compared with the use of conventional chemotherapy alone,

TABLE 92–8. Representative Chemotherapy Regimens for Pediatric Acute Lymphocytic Leukemia

Induction (1 month)
Intrathecal cytarabine on day 0
Prednisone 40 mg/m^2 per day or dexamethasone 6 mg/m^2 per day orally for 28 days
Vincristine 1.5 mg/m^2 per dose (max 2 mg) IV weekly for 4 doses
Pegaspargase 2,500 units/m^2 per dose IM for 1 dose or asparaginase 6,000 units/m^2 per dose IM Mon, Weds, and Fri for 6 doses
Intrathecal methotrexate weekly for 2–4 doses
Consolidation (1 month)
Mercaptopurine 50–75 mg/m^2 per dose orally at bedtime for 28 days
Vincristine 1.5 mg/m^2 per dose (max 2 mg) IV on day 0
Intrathecal methotrexate weekly for 1–3 doses
Patients with CNS or testicular disease may receive radiation
Interim maintenance (1 or 2 cycles) (2 months)
Methotrexate 20 mg/m^2 per dose orally at bedtime weekly
Mercaptopurine 75 mg/m^2 per dose orally daily on days 0–49
Vincristine 1.5 mg/m^2 per dose (max 2 mg) IV on days 0 and 28
Dexamethasone 6 mg/m^2 per day orally on days 0–4 and 28–32
Delayed intensification (1 or 2 cycles) (2 months)
Dexamethasone 10 mg/m^2 per day orally on days 0–6 and 14–20
Vincristine 1.5 mg/m^2 per dose (max 2 mg) IV weekly for 3 doses
Pegaspargase 2,500 units/m^2 per doses IM for 1 dose
Doxorubicin 25 mg/m^2 per dose IV on days 0, 7, and 14
Cyclophosphamide 1,000 mg/m^2 per dose IV on day 28
Thioguanine 60 mg/m^2 per dose orally at bedtime on days 28–41
Cytarabine 75 mg/m^2 per dose SC or IV on days 28–31 and 35–38
Intrathecal methotrexate on days 0 and 28
Consolidation option 2(3-week intervals for 6 courses on weeks 5–24)
Mercaptopurine 50 mg/m^2 per dose orally at bedtime
Prednisone 40 mg/m^2 per day for 7 days on weeks 8 and 17
Vincristine 1.5 mg/m^2 per dose (max 2 mg) IV on the first day of weeks 8, 9, 17, and 18
Methotrexate 200 mg/m^2 per dose IV + 800 mg/m^2 dose over 24 hours on day 1 of weeks 7, 10, 13, 16, 19, and 22
Intrathecal methotrexate on weeks 5, 6, 9, 12, 15, and 18
Late intensification (weeks 25–52)
Methotrexate 20 mg/m^2 per dose IM weekly or 25 mg/m^2 per dose orally every 6 hours for 4 doses every other week
Mercaptopurine 75 mg/m^2 per dose orally at bedtime
Prednisone 40 mg/m^2 per day orally for 7 days on weeks 25 and 41
Vincristine 1.4 mg/m^{2}w per dose (max 2 mg) IV on the first day of weeks 25, 26, 41, and 42
Intrathecal methotrexate on day 1 of weeks 25, 33, 41, and 49
Maintenance (12-week cycles)
Methotrexate 20 mg/m^2 per dose orally at bedtime or IM weekly with dose escalation as tolerated
Mercaptopurine 75 mg/m^2 per dose orally at bedtime on days 0–83
Vincristine 1.5 mg/m^2 per dose (max 2 mg) IV on days 0, 28, and 56
Dexamethasone 6 mg/m^2 per day orally on days 0–4, 28–32, and 56–60
Intrathecal methotrexate on day 0

Adapted from Leather HL, Bickert B. Acute Leukemias. In: DiPiro JT, Talbert RL, Yee GC, et al., (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 2458–2511.

although the effect on long-term disease-free survival is unclear. Improving the outcomes of these elderly patients with ALL continues to be a challenge.

Treatment: Acute Myelogenous Leukemia

As with ALL, the primary aim in treating patients with AML is to induce remission and thereafter prevent relapse. Treatment of AML is conventionally divided into two phases: induction and postremission. Despite several strategies to increase the intensity of therapy, the overall survival rate has reached a plateau at 50% to 60%, suggesting that further intensification of therapy will not improve survival rates greatly.[11]

Remission Induction

The goal of induction chemotherapy in AML is essentially identical to that in ALL: "Empty" the bone marrow of all hematopoietic precursors, and allow repopulation with normal cells. ❻*The combination of an anthracycline (e.g., daunorubicin, doxorubicin, or idarubicin) and the antimetabolite cytarabine forms*

TABLE 92–9. Chemotherapy for the Acute Leukemias

Agent/Major Uses	Class/Mechanism	Major Side Effects	Drug Interactions
Asparaginase (L-asparaginase; Elspar) Pegaspargase (Oncospar)[b] ALL	Antitumor enzyme, hydrolyzes L-asparagine in bloodstream, depriving tumor cells of the essential amino acid; results in inhibition of protein, DNA, and RNA synthesis and cell proliferation; derived from *Escharichia coli*	Hypersensitivity reactions (fever, hypotension, rash, dyspnea in 25%), much lower risk with polyethylene gycol form; low emetogenic potential; pancreatitis; decreased synthesis of proteins, clotting factors; CNS: lethargy	Increased toxicity has been noted when given concurrently with vincristine and prednisone. Decreased metabolism when used with cyclophosphamide. Increased hepatotoxicity when used with mercaptopurine.
Cylarabine (Ara-C; cytosine arabinoside; Cytosar U)[d] ANLL; ALL; Lymphomatous meningitis; NHL; MDS High-dose ara-C (HDAC) liposomal cytarabine (Depocyt) for intrathecal use for lymphomatous meningitis	Antipyrimidine antimetabolite; inhibits DNA polymerase with inhibition of DNA strand elongation and replication; activated in tumor cells in triphosphate form; competes with conversion of cytidine to deoxycytidine nucleotides, further blocking polymerization of DNA; leads to production of short DNS strands; cell-cycle specific (S phase): acts only on proliferating cells.	Myelosuppression; alopecia; moderate emetogen; worse with high dose (greater than 1 g/m^2) or IT administration; diarrhea; mucositis; flu-like syndrome with fever and arthralgias; rash often followed by desquamation on palms and soles *HDAC toxicities;* cerebellar direct neurotoxicity:ataxia, slurred speech, nystagmus; conjunctivitis (drug is excreted into tears and blocks corneal DNA synthesis)	Possible increased toxicity when given concurrently with alkylating agents, radiation, purine analogs, and methotrexate.
Daunorubicin (daunomycin, Dauno, Creubidine)[c] Liposomal daunorubicin (DaunoXome) ANLL; ALL; KS (liposomal)	Antitumor antibiotic; topoisomerase II inhibitor; DNA intercalator; free-radical formation (thought to be related to cardiac toxicity and tissue injury)	Myelosuppression (dose-related); mucositis (worse with continuous infusion); moderate emetogenic potential; alopecia; vesicant: severe extravasation injury; cardiac toxicities: *acute*—not related to cumulative dose; arrhythmias, pericarditis; chronic—cumulative injury to myocardium (total dose greater than 550 mg/m^2; lower total cumulative doses cause damage to myocardium in children (e.g., 350 mg/m^2)	
Etoposide (VP-16; Vepesid), Etoposide phosphate (Etopophos)[d] Testicular cancer; SCLC; NSCLC; ANLL; KS; HD; NHL; BMT preparative chemotherapy; gastric cancer	Plant alkaloid, epipodophyllotoxin; inhibits DNA binding activity of topoisomerase II, resulting in multiple DNA double-strand breaks	Myelosuppression; moderately emetogenic: may be worse with oral and high-dose regimens; alopecia; mucositis; hypotension: infusion rate-related; etoposide phosphate can be given IV push without hypotension risk; hypersensitivity reactions: especially common in children	Substrate of P-450 3A4 Cyclosporine may increase levels of etoposide.
Gemtuzumab ozogamicin (Mylotarg)[i]	Humanized anti-CD33 antibody linked to calicheamicin, a potent toxin; binding to the CD33 receptor results in internalization of the antibody-antigen complex; calicheamicin is then released intracellularly and exerts cytotoxicity by causing DNA double-strand breaks, resulting in cell death	Infusion reactions: fevers, chills, nausea, vomiting, hypotension, dyspnea; myelosuppression may be severe and prolonged; tumor lysis syndrome: WBCs should be reduced to less than 30,000/mm^3 prior to administration if possible, to decrease risk; increased liver function tests and bilirubin, hepatic veno-occlusive disease	

(Continued)

TABLE 92–9. Chemotherapy for the Acute Leukemias (*Continued*)

Agent/Major Uses	Class/Mechanism	Major Side Effects	Drug Interactions
Imatinib mesylate (Gleevec, STI 571)[d] CML (adults and pediatrics) ; GIST; Ph+ ALL	Tyrosine kinase inhibitor; relatively specific for the tyrosine kinase coded for by the *bcr-abl* translocation in CML patients	Moderate emetogenic potential: take with meals and a full glass of water; edema; periorbital edema is characteristic; pleural effusions, ascites, or pulmonary edema also occur; rash; diarrhea; neutropenia, thrombocytopenia (sometimes difficult to distinguish from CML-induced cytopenias); increased liver function tests	Drug interactions are minimal. Substrate of P450 3A4 Serum concentrations of imatinib may be increased by drugs which inhibit CYP3A4.
6-Mercaptopurine (Purinethol; 6-MP)[c] ALL	Antipurine antimetabolite; purine analog; inhibits DNA, RNA, protein synthesis; metabolized by xanthine oxidase	Myelosuppression: mild, anorexia, low emetoginic potential; dry skin rash, photosensivity; hepatotoxicity: jaundice and hyperbilirubinemia occur after 1–2 months of therapy and may be dose-limiting	Allopurinol can increase levels of mercaptopurine. Aminosalicylates may inhibit TPMT.
Methotrexate (MTX) ALL CNS leukemia (IT) Breast cancer NHL Osteosarcoma Head and neck cancer Bladder cancer Rheumatoid arthritis	Folic acid antagonist; inhibits dihydrofolate reductase (DHFR); blocks reduction of folate to tetrahydrofolate; inhibits de novo purine synthesis; results in arrest of DNA, RNA, and protein synthesis Leucovorin provides reduced folate to bypass the metabolic block	Myelosuppression: can be prevented with leucovorin rescue Mucositis: can be prevented with leucovorin Renal dysfunction: (high dose regimens) caused by precipitation of drug in renal tubules; hydration (3 L/m^2/day) and alkalinization of urine	Salicylates, sulfonamides, probenecid, and high dose penicillin may decrease clearance of methotrexate.
Vincristine (VCR, Oncovin)[b] ALL; HD; NHL; multiple myeloma; breast cancer; SCLC, KS; brain tumors; soft tissue sarcomas; osteosarcomas; neuroblastoma; Wilms' tumor	Antimicrotubule agent/vinca alkaloid; derived from periwinkle plant; disrupts formation of microtubules	Peripheral neuropathy: primary dose-limiting toxicity; motor sensory, autonomic, and cranial nerves may all be affected (paresthesias, ileus, urinary retention, facial palsies); may be irreversible; mild emetogen; SIADH; vesicant: extravasation injury	Vincristine levels may be increased when given with drugs that inhibit cytochrome P450 3A enzyme (itraconazole).

Adapted from McManus Balmer C, Wells Valley A, Iannucci A. Cancer Treatment and Chemotherapy. In: DiPiro JT, Talbert RL, Yee GC, et al., (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 2458–2511.

the backbone of AML induction therapy. The most common induction regimen (7 + 3) combines daunorubicin for 3 days with cytarabine on days 1 to 7. The remission rate for this combination is approximately 80% in children and younger adults but declines to 40% to 50% in patients older than 60 years of age.[6] Despite studies that have used alternative anthracyclines or substituted high-dose for conventional-dose cytarabine and added etoposide and/or thioguanine, the 7 + 3 regimen remains the standard induction regimen.

Postremission Therapy

Once an initial remission is achieved, further intensive therapy is imperative to prevent relapse. Induction therapy fails to provide adequate cell kill, and leukemia cells survive the initial treatment. Three options available for patients include high-dose chemotherapy, allogeneic bone marrow transplantation from an HLA-matched related or unrelated donor, and autologous bone marrow transplantation.[8]

Postremission Chemotherapy

Several cycles of intensive postremission chemotherapy combining non-cross-resistant agents given every 4 to 6 weeks improves disease-free survival. One of three cytarabine-based regimens has been used in current treatment programs, either alone or in combination with L-asparaginase, mitoxantrone, or etoposide. The following dosing schedule is used: 100 mg/m^2 per day for 5 days by continuous infusion (standard arm), 400 mg/m^2 per day for 5 days by continuous infusion (intermediate-dose arm),

or 3 g/m^2 twice daily over 3 hours on days 1, 3, and 5 (high-dose arm). The higher-dose regimen for cytarabine can be tolerated only by younger patients (less than 60 years of age). While the optimal number of courses remains to be determined, at least three are probably required.[11]

Gemtuzumab ozogamicin is a monoclonal antibody that binds to the CD-33 antigen. Almost all AML cells express this antigen. Phase I and II trials using this agent have shown some success, and current studies using this agent alone or with chemotherapy for the treatment of AML are ongoing.[18]

Allogeneic Hematopoietic Stem Cell Transplantation

Allogeneic hematopoietic stem cell transplantation (HSCT) has been used in the treatment of pediatric AML in first complete remission. In most clinical trials, the availability of HLA-matched sibling donors determined whether patients underwent HSCT as postremission treatment. To facilitate this process, it is important to obtain HLA typing on all younger patients with AML and siblings shortly after diagnosis. Patients who do not have an HLA-matched sibling will proceed to postremission therapy.

In HSCT, very high doses of chemotherapy with or without total-body radiation (TBI) are given in an attempt to potentiate leukemia cell kill. Hematopoiesis is restored by the infusion of stem cells harvested from an HLA-compatible donor, thereby rescuing the patient from the consequences of total aplasia.[13] It is the most effective antileukemic therapy currently available.

Transplantations from nonidentical sources have many complications, including graft-versus-host disease (GVHD), delayed or incomplete engraftment, and an increased likelihood of opportunistic infections that increase morbidity and mortality substantially. An immunologic effect of the donor marrow on residual host leukemic cells may translate into antileukemic activity, however, as indicated by the lower relapse rates in patients with GVHD. The graft-versus-leukemia (GVL) also accounts for the success of allogeneic HSCT.

Transplant-related mortality following matched-sibling allogeneic HSCT is 20% to 30% in most series. Complications from transplantation increase with age; therefore, patients older than 60 years of age are uncommonly considered to receive an allogeneic HSCT. Since the average age of AML patients is 65 years, it is obvious that most patients with this disease are not candidates for this form of therapy.

HSCT in first remission is often recommended for patients with a matched-sibling donor because of the lower relapse rate with transplant versus postremission chemotherapy. However, only 30% of patients will have an HLA-matched sibling. Some types of AML patients may be curable with conventional-dose chemotherapy alone. Thus indiscriminate use of allogeneic HSCT could reduce the rate and quality of survival in these individuals.

Autologous Hematopoietic Stem Cell Transplantation

Since the majority of AML patients lack a HLA-identical donor, investigators began to consider the use of the patient's own bone marrow, obtained while in CR, as a source of hematopoietic regeneration. However, relapse continues to be a problem secondary to the presence of residual disease in the graft. The **disease-free survival** for patients undergoing autologous bone marrow transplantation in first remission has been reported at 40% to 60%, with a relapse rate of 30% to 50%. Thus few investigators recommend the use of autologous transplantation, because it failed to improve outcome substantially versus standard postremission chemotherapy.[3,10]

CNS Therapy

The prevalence of CNS disease at diagnosis of AML ranges from 5% to 30% in various treatment series. Features associated with the risk of CNS leukemia include hyperleukocytosis, monocytic or myelomonocytic leukemia (FAB M4 or M5), and young age. In most cases, intrathecal cytarabine with or without methotrexate and systemic high-dose cytarabine provide adequate CNS prophylaxis.[3] Results from studies have shown that patients with CNS disease at diagnosis can be cured with intrathecal therapy alone without the use of cranial irradiation.[11]

Acute Myelogenous Leukemia in Infants

AML in infants younger than 12 months shows clinical and biologic characteristics different from AML in older children. The phenotype is more commonly monoblastic or myelomonoblastic (M4, M5), and the patients usually present with hyperleukocytosis. Extramedullary involvement is common, often involving skin and other organs. As in infant ALL, there is a high incidence of translocations involving the *MLL* gene in infant AML. The number of infant AML trials reported is limited, but the EFS is similar to that of older children with AML. This is in marked contrast to the outcomes for infants with ALL, for whom the EFS is much lower than in older children (Tables 92–8, 92–9).[19]

Acute Myelogenous Leukemia in the Elderly

AML is the most common leukemia in the elderly. In comparison with younger patients with the same disease, older adults have a poor prognosis and represent a distinct population with regard to disease biology. Older adults have a lower incidence of favorable chromosomal aberrations and a higher incidence of unfavorable aberrations.[9]

In older adults, AML is either more likely to arise from a proximal bone marrow stem cell disorder, such as myelodysplastic syndrome (MDS), or present as a secondary leukemia resulting from treatment with prior chemotherapy or radiation for an earlier malignancy. These forms of AML are notoriously less responsive to chemotherapy and thus have a lower CR rate and EFS.[20]

Older adults are not as tolerant of or as responsive to remission induction and consolidation chemotherapy as younger patients. Younger adults treated with a standard induction regimen of an anthracycline and cytarabine have approximately 70% probability of attaining a CR, whereas patients older than 60 years of age have only a 38% to 62% probability. Further, long-term survival for patients older than 60 years is only 5% to 15% compared with 30% DFS for younger adults.[9]

Treatment of Relapsed Leukemias

Relapse is the recurrence of leukemic cells at any site after remission has been achieved. Most relapses occur during treatment or within the first 2 years of its completion. The bone marrow is the most frequent site of relapse in both ALL and AML and accounts for 90% or more of relapses. Extramedullary relapse, such as the CNS and the testes, while once common, has decreased to 5% or less because of effective prophylaxis.[21]

Bone marrow relapse predicts a poor outcome for most patients. In either ALL or AML, the duration of the second remission depends on the duration of the first remission. Factors predicting a relapse and poor prognosis for children with ALL are short initial remission, T-cell immunophenotype, high leukocyte count at relapse, t(9;22), and other high-risk features. Once a patient has obtained a second remission with conventional chemotherapy, allogeneic HSCT is the therapy of choice. For patients without an HLA-matched sibling, matched unrelated marrow or cord blood transplantation may be a reasonable alternative. The combination of myeloablative high-dose chemotherapy and the graft-versus-leukemia effect is thought to offer the best chance of survival in either AML or ALL.

Complications of Treatment

Tumor Lysis Syndrome

Tumor lysis syndrome (TLS) is an oncologic emergency that is characterized by metabolic abnormalities resulting from the death of blast cells and the release of large amounts of purines, pyrimidines, and intracellular potassium and phosphorus. Uric acid, the ultimate breakdown product of purines, is poorly soluble in plasma and urine. Deposition of uric acid and calcium phosphate crystals in the renal tubules can lead to acute renal failure. Many patients with acute leukemia, especially those with a high tumor burden, are at risk for TLS during the first few days of chemotherapy. Measures to prevent TLS include aggressive hydration, alkalinization to help solubulize uric acid, allopurinol, and on some occasions, the use of rasburicase. Rasburicase is an enzyme that catalyzes the oxidation of uric acid to allantoins, which are more soluble and excreted more easily than uric acid.[22] Given its high cost, rasburicase generally is restricted to patients with a high WBC count (greater than $50 \times 10^3/\mu L$, $50 \times 10^9/L$) and uric acid levels greater than 8 g/dL (476 μmol/L).

Infection

Infection is a primary cause of death in acute leukemia patients. The majority of chemotherapy used to treat ALL and AML can cause severe myelosupression, placing the patient at risk for sepsis from otherwise normal bacteria. It is important to recognize that symptoms and signs of infection may be absent in a severely immunosuppressed or neutropenic patient. Fever (greater than 38.3°C, 100.9°F) in a neutropenic patient is a medical emergency. Following chemotherapy, the period of neutropenia usually reaches its nadir approximately 14 days after the beginning of a course of chemotherapy and usually lasts another 7 to 14 days. In a newly diagnosed leukemic, the period of neutropenia may persist until remission is obtained. The most common sites of infection include the gastrointestinal tract and vascular access devices.[6]

Because the progression of infection in neutropenic patients can be rapid, empirical antibiotic therapy should be administered quickly to such patients once fever is documented. Currently, the most commonly used initial antibiotic agent is cefipime, a fourth-generation cephalosporin that has good antipseudomonal coverage as well as adequate coverage against *viridans* streptococci and pneumococci.[23]

❻ *The therapy for AML is extremely myelosuppressive. Children with AML have a 10% to 20% induction mortality rate secondary to infection and bleeding complications.* Therefore, patients receiving induction therapy usually are hospitalized for the first 4 to 6 weeks of therapy. The induction therapy for ALL is less myelosuppressive; therefore, these patients recover their counts quicker and usually do not require prolonged hospitalizations.[6]

Trimethoprim-sulmethoxazole is started in all patients with acute leukemia for the prevention of *Pneumocystis carrinii* pneumonia. Patients normally continue this therapy for 6 months after completion of treatment. The use of additional antibiotic prophylaxis is not encouraged in all patients with leukemia because of concerns for antibiotic resistance.

Secondary Malignancies

In children, secondary malignancies are a risk of the successful treatment for cancer. The chemotherapy agents used, especially alkylating agents and topoisomerase II inhibitors, predispose the patient to secondary hematopoietic neoplasms. As the aggressiveness of treatment and the number of survivors of ALL increase, the risk of secondary neoplasms also may rise. There are two different types of second malignancies: acute leukemia, which generally is myeloid in orgin (or myelodysplastic syndrome), and solid tumors. The latency period between treatment and the development of a secondary leukemia is often several years, with leukemia being the earlier and solid tumors being the later of such events.

Secondary neoplasms induced by epipodophyllotoxins are characterized by balanced chromosomal translocations and short latency periods (2–4 years). The risk of this leukemia is related to schedule (dose intensity) and the concomitant use of other agents (L-asparaginase, alkylating agents, and possibly antimetabolites). The prognosis for topoisomerase II inhibitor–related secondary leukemia is extremely poor. Only about 10% of these patients survive after chemotherapy, and only 20% survive after HSCT. The incidence of second cancers attributed to alkylators peaks 4 to 6 years after exposure and plateaus after 10 to 15 years. Higher cumulative doses and older age at the time of treatment are risk factors for this type of cancer.[24]

Ionizing radiation therapy is also a cause of secondary malignancies. These secondary tumors generally develop within or adjacent to the previous radiation field. These cancers often have

a prolonged latency, typically 15 to 30 years, but shorter latencies (5–14 years) are known. Higher doses of radiation and younger age are associated with an increased risk of secondary malignancy.

Unlike children, adults may have other factors that predispose them to secondary malignancies. Lifestyle choices such as tobacco use, alcohol use, and diet have been implicated in influencing the development of secondary neoplasms in the adult population.

Now that 80% or more of children survive their primary cancers, the incidence of secondary neoplasms may increase. Recognizing this potential, many treatment regimens for children are being modified appropriately to reduce exposure to alkylators, topoisomerase inhibitors, and radiation. Late effects clinics screen for secondary malignancies and other disease and treatment-related disabilities that accompany childhood cancer. Similar screening and educational opportunities are not currently established in adult survivors.

Late Effects

❽ *With increased success in pediatric clinical trials, the overall survival rate for pediatric cancers has increased significantly over the last 35 years. For certain disease states, the overall survival rate for specific pediatric malignancies is now up to 80%. Unfortunately, the consequences of success are that approximately two-thirds of childhood cancer survivors have at least one chronic or late-occurring complication of treatment.* Long-term follow-up of survivors treated decades ago also has revealed very late sequelae.[24]

In leukemia, the intensified use of methotrexate and glucocorticoids is responsible for causing an increased frequency of neurotoxicity and, in older children and adults, avascular necrosis of bone. High cumulative doses of anthracyclines can cause cardiomyopathy. Cranial irradiation causes neuropsychologic deficits and endocrine abnormalities that lead to obesity, short stature, precocious puberty, and osteoporosis.[3] As newer and more intensive treatments enter clinical trials, close observation for long-term side effects will assume even greater importance.[24]

Supportive Care

Because of the need for repeated venous access, a central venous catheter or infusion port is placed prior to starting treatment. These devices are useful not only for delivery of chemotherapy but also to support patients during periods of myelosuppression. Infection and bleeding complications are the primary cause of mortality in patients with leukemia.

Platelet transfusions are used to prevent hemorrhage. Patients with uncomplicated thrombocytopenia can be transfused when the platelet count falls below 10,000/μL (10×10^9/L). Patients who are either highly febrile or actively bleeding may require transfusions at higher levels. Red blood cell transfusions generally are not necessary for a hemoglobin concentration greater than 8 g/dL (80 g/L, 4.96 mmol/L).

There is much controversy regarding the routine use of colony-stimulating factors (e.g., G-CSF and GM-CSF) in neutropenic patients. Even though several clinical trials have shown the time to absolute neutrophil count (ANC) recovery is increased with a colony-stimulating factor, none have demonstrated that CSFs stastistically influence infection-related mortality. At present, the use of colony-stimulating factors (G-CSF most commonly) generally is limited to those chemotherapy regimens that place the patient at highest risk for prolonged neutropenia.[6]

OUTCOME EVALUATION

Developing strategies for the treatment and monitoring of acute leukemias begins with risk stratification. Knowing the likely risk determines the aggressiveness and length of therapy. First to monitor for is remission status following the induction phase of treatment. Failure to obtain morphologic bone marrow remission by day 28 is a bad prognostic sign that dictates further induction treatment. For those with morphologic remission, quantification of submicroscopic residual disease (MRD) is being used increasingly as a prognostic factor.

It is important to develop a plan to educate patients and families about their drugs and doses. If modifications are necessary secondary to toxicity or inadequate response, establish a plan for treatment change. Remember that individual patients often do not fit the "average" patient profile, and dose modifications frequently are needed. The practitioner should be familiar with dosing ranges, WBC count, and other parameters that indicate "appropriate" treatment response. Based on response to prior phases of treatment, the clinician should recognize potential toxicities in subsequent phases of treatment with the same or different drugs at similar or different doses.

Patient Care and Monitoring

1. Evaluate the patient for response to therapy during induction, consolidation, and maintenance by following hematologic indices closely.
2. Review the treatment plan closely with the patient.
3. Educate the patient on potential adverse reactions and drug interactions.
4. Stress the importance of medication compliance.
5. Provide patient education regarding disease state and drug therapy:

- Possible complications of leukemia, especially infectious.
- Potential side effects of drug therapy that may occur
- Warning signs to report to the physician (e.g., temperature, bruising, or bleeding).

6. Based on WBC counts during ALL maintenance, is the patient receiving the appropriate dose of mercaptopurine?
7. Provide education regarding the long-term sequelae associated with the treatment for the acute leukemias.

93 Chronic Leukemias and Multiple Myeloma

Amy M. Pick and Timothy R. McGuire

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Explain the role of the Philadelphia chromosome in the pathophysiology of chronic myelogenous leukemia (CML).
2. Describe the natural history of chronic myelogenous leukemia (CML).
3. Identify the clinical signs and symptoms associated with chronic myelogenous leukemia (CML).
4. Discuss treatment options for chronic myelogenous leukemia (CML) with special emphasis on imatinib.
5. Describe the clinical course of chronic lymphocytic leukemia (CLL).
6. Describe patients who may be observed without treatment and those who receive aggressive treatment for chronic lymphocytic leukemia (CLL).
7. Discuss the various treatment options available for chronic lymphocytic leukemia (CLL).
8. Describe the clinical presentation of multiple myeloma.
9. Discuss treatment options available for multiple myeloma.

Key Concepts

❶ A chromosomal translocation, the Philadelphia chromosome, is responsible for chronic myelogenous leukemia (CML).
❷ The Philadelphia chromosome results in the formation of an abnormal fusion gene, *BCR-ABL*, that encodes an overly active tyrosine kinase.
❸ Allogeneic stem cell transplantation is the only curative treatment for chronic myelogenous leukemia (CML).
❹ Imatinib is a tyrosine kinase inhibitor that produces high complete response rates and is first-line treatment for chronic myelogenous leukemia (CML).
❺ Chronic lymphocytic leukemia (CLL) can have a variable disease course, but most patients survive many years.
❻ Chemotherapy does not improve overall survival in early-stage chronic lymphocytic leukemia (CLL).
❼ Fludarabine-based chemotherapy is used increasingly as first-line therapy for younger patients with chronic lymphocytic leukemia (CLL).
❽ Chronic lymphocytic leukemia (CLL) patients who receive fludarabine-based combination chemotherapy and rituximab may have long-term disease-free survival.
❾ Myeloma is a plasma cell cancer associated with bone disease that can be improved by bisphosphonates.
❿ Autologous transplant either as a single or double transplant offers younger patients with myeloma longer disease-free survival.

CHRONIC LEUKEMIA

Chronic leukemia consists of a number of disorders, including chronic myelogenous leukemia (CML) and chronic lymphocytic leukemia (CLL).

CHRONIC MYELOGENOUS LEUKEMIA

CML is a hematologic cancer that results from an abnormal proliferation of an early myeloid **progenitor** cell.[1] The clinical course of CML has three phases: chronic phase, accelerated

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

TABLE 93–1. Clinical Course of CML

Phase	Characteristics	Median Duration (with Treatment)
Chronic	Elevated WBC count Responsive to treatment	4–6 years[a]
Accelerated	Elevated WBC count Unresponsive to treatment Increased symptoms	6–9 months
Blast	Disease transformation to acute leukemia	3–6 month survival

[a]Prior to imatinib therapy

phase, and **blast** crisis. Chemotherapy can be used to control CML in the chronic phase, but as the disease progresses, the cancer may no longer respond to treatment. Blast crisis resembles acute leukemia, and immediate aggressive treatment is required. Table 93–1 describes each of the phases of CML.

Epidemiology and Etiology

It is estimated that 4570 new cases of CML were diagnosed in 2007, accounting for 15% of all adult leukemias.[2] The incidence of CML increases with age, with the median age of diagnosis in the fifth decade of life.[3] In most newly diagnosed cases, the etiology cannot be determined, but high doses of ionizing radiation and exposure to solvents such as benzene are recognized risk factors.

Pathophysiology

Cell of Origin

CML arises from a defect in an early progenitor cell. Several cell lines may be affected, including myeloid, erythroid, megakaryocyte, and rarely, lymphoid lineages. These cells remain functional in chronic-phase CML, which is why patients in this phase are at low risk for developing infectious complications.

Ph Chromosome

❶ *The Philadelphia chromosome (Ph) results from a translocation between chromosomes 9 and 22, leaving a shortened chromosome 22.* ❷ *The Ph results in the formation of an abnormal fusion gene between the breakpoint cluster region and the Abelson protooncogene (BCR-ABL) that encodes an overly active tyrosine kinase. The loss of control of tyrosine kinase activity causes abnormal cellular proliferation and inhibition of apoptosis.*[3,4] Molecular tools such as reverse transcriptase polymerase chain reaction (RT-PCR) and fluorescence in situ hybridization (FISH) are used in the detection and monitoring of CML.[3]

Clinical Presentation and Diagnosis

Clinical Presentation

Signs and Symptoms

- Approximately 50% of patients are asymptomatic at diagnosis.[5]
- Symptoms may include fatigue, fever, weight loss, and bleeding.
- Organomegaly consisting of splenomegaly and hepatomegaly is common.

Diagnostic Procedures

- Peripheral blood smear
- Bone marrow biopsy (required for diagnosis)
- Cytogenetic studies
- Molecular testing (RT-PCR and FISH)

Laboratory Findings

- Peripheral blood smear
  - Leukocytosis (WBC count greater than $100 \times 10^3/\mu L$, or $100 \times 10^9/L$)
  - Thrombocytosis (approximately 50% of patients in chronic phase)
  - Anemia
  - Presence of blasts
- Bone marrow
  - Hypercellularity with presence of blasts
  - Presence of Ph

Poor Prognostic Factors (Sokal Risk Model)[6]

- Older age
- Splenomegaly
- High percent blasts in the blood
- High platelet count

Treatment

Desired Outcome

The primary goal in the treatment of CML is to eradicate the Ph-positive clones. Elimination of the Ph is termed *cytogenetic complete remission.* If treatment produces RT-PCR-negative disease, this is termed *molecular complete remission* and indicates a several-log reduction over cytogenetic complete remission. An early goal of therapy is to achieve *hematologic complete remission* or to normalize peripheral blood.

General Approach to Treatment

There have been significant advances in the treatment of CML. The success of therapy depends in part on the clinical phase of the disease. Nearly all patients with CML are treated initially with imatinib. Hydroxyurea may be used after diagnosis to rapidly reduce high white blood cell (WBC) counts and to prevent complications associated with large numbers of circulating neutrophils. Imatinib also can reduce peripheral WBC counts over

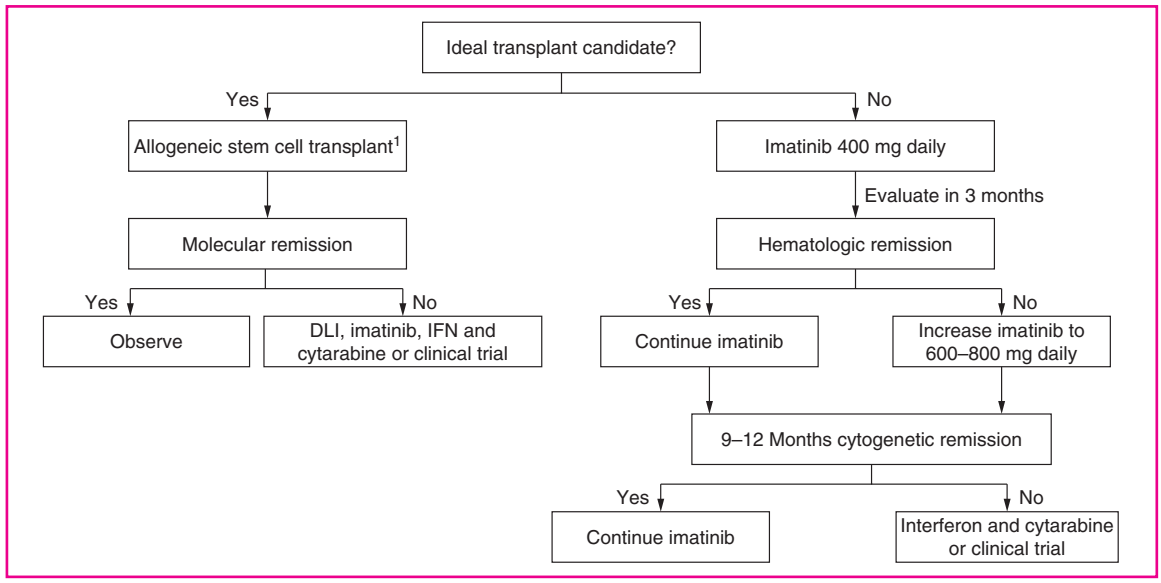

FIGURE 93–1. Algorithm for primary therapy in newly diagnosed CML patients. DLI, donor lymphocyte infusion; IFN, interferon.
[1]Nearly all patients will have had a course of imatinib prior to transplant.

several weeks; thus many patients are started on imatinib alone. Interferon-alfa is not used in newly diagnosed patients and is used largely in patients who do not respond to imatinib therapy. **Allogeneic** stem cell transplantation is the only curative therapy for CML and is used in younger patients with a matched donor. Figure 93–1 illustrates one common method of clinically managing CML patients.

Nonpharmacologic Therapy

Allogeneic Stem Cell Transplantation

❸ *Allogeneic stem cell transplantation is the only curative treatment option for CML.*[5] It is an option for younger patients (younger than 50 years of age) in chronic-phase CML who have an HLA-matched donor. Cure rates are superior when patients are transplanted in chronic phase within the first year of diagnosis and may be as high as 70%.[5,12] Unfortunately, only 30% to 40% of patients will be candidates for transplantation. There are significant risks associated with allogeneic transplantation, with a 10% to 20% early mortality (100 days).[12] Patients also may have a significant decline in quality of life from chronic **graft-versus-host disease** and other long-term complications associated with allogeneic stem cell transplantation. For those patients who do not achieve a molecular complete remission or have a relapse after transplantation, the infusion of donor lymphocytes usually will place the patient back into a durable remission.

Pharmacologic Therapy

Imatinib Mesylate (Gleevec®)

The treatment of CML has experienced a dramatic change since the introduction of imatinib. ❹ *Imatinib mesylate (STI-571; Gleevec®) is a tyrosine kinase inhibitor used as first-line therapy in the majority of patients with CML.* As a potent tyrosine kinase inhibitor, imatinib inhibits phosphorylation of various proteins involved in cell proliferation. Imatinib works by binding to the ATP-binding pocket of *BCR-ABL*.[7] The drug induces complete hematologic responses in more than 95% of patients and complete cytogenetic responses in about 80% of patients in chronic phase.[8] Most patients have traces of the disease when measured by RT-PCR and are not cured of their disease.

As expected in more aggressive disease, lower response rates are reported in the accelerated phase and blast crisis.[9,10] The clinical dosing of imatinib depends on the phase, with 400 mg/day used in chronic phase and 600 to 800 mg/day in accelerated phase and blast crisis (see Table 93–2). Therapy with imatinib generally is well tolerated. Common side effects include **myelosuppression** (phase and dose related), rash, nausea, edema, fatigue, arthralgias, myalgias, and headaches. Imatinib is metabolized by cytochrome CYP3A4, and possible drug interactions include those agents which inhibit or induce CYP3A4, such as erythromycin, ketoconazole, and phenytoin.[11]

Interferon-Alfa and Cytarabine

Prior to the introduction of imatinib, the combination of interferon-alfa and low dose cytarabine was the nontransplant treatment of choice for patients in chronic phase CML. The precise mechanism of action of interferon-alfa remains unknown. The addition of cytarabine to interferon-alfa improves the response compared with interferon alone. This combination produces cytogenetic response rates of 30%, much lower than imatinib.[13] One of the major drawbacks, in addition to the low response rates, is interferon's toxicity,

TABLE 93–2. Drugs Used in CML

Drug	Adverse Effects	Comments
Imatinib mesylate (Gleevec, STI 571)	Neutropenia, thrombocytopenia, rash, nausea, edema, fatigue, arthralgias, myalgias, headache, increased liver function tests	Dose range: 400–800 mg orally per day depending on phase Take with meals and a full glass of water Drug interactions: Metabolized by CYP450 3A4 (e.g., cyclosporine, erythromycin, itraconazole, phenytoin, St. John's wort)
Interferon-alfa (Intron A, Roferon-A, IFN)	Flulike symptoms: fever, chills, myalgias; fatigue; depression; insomnia; thrombocytopenia	Premedicate with acetaminophen or a NSAID to lessen flulike symptoms. Dose is given subcutaneously or intramuscularly daily.

including flulike symptoms, depression, and thrombocytopenia. Today, interferon-alfa and cytarabine remain an alternative therapy for patients who do not respond to imatinib and are not candidates for stem cell transplantation.

Outcome Evaluation

Successful treatment for CML depends on the elimination of the Ph. Allogeneic transplant offers a cure for the minority of patients who have a matched donor and are young enough to tolerate transplant. Nearly all newly diagnosed CML patients are placed on imatinib. If patients fail to obtain a cytogenetic response within 9 to 12 months, dose escalation of imatinib or a switch to alternative therapies is recommended.[14] Patients who do not respond to imatinib and cannot be transplanted should be encouraged to enroll in investigational trials. Some patients will not respond to imatinib and will progress to blast crisis, where they will receive treatment for acute leukemia.

Patient Encounter 1

A 40-year-old woman well known to you comes into your pharmacy complaining of fatigue. You suggest she see her doctor to have some blood work done. A complete blood count (CBC) shows the following:

- Total WBC count: 158 × 10^3/μL (158 × 10^9/L), 20% (0.20) blasts, 70% (0.70) segs, 10% (0.10) lymphs
- HgB/Hct: 9 g/dL (5.6 mmol/L), 32% (0.32)
- Platelets: 650 × 10^3/μL (650 × 10^9/L)
- Bone marrow biopsy: Hypercellular; FISH is positive for Ph.

- What is the treatment of choice for this chronic-phase CML patient?
- How would you evaluate response to therapy?
- If this patient has suboptimal response to initial therapy, what would you recommend?

CHRONIC LYMPHOCYTIC LEUKEMIA

CLL is a cancer that results in the accumulation of functionally incompetent lymphocytes.[15] CLL is considered an indolent, incurable disease in which treatment should be initiated when patients have symptoms. However, some patients have aggressive disease and need to be treated with intensive therapy.

Epidemiology and Etiology

CLL is the most common type of leukemia diagnosed in adults. It is estimated that in 2007, 15,340 new cases were diagnosed in the United States.[2] Median age at diagnosis is the sixth decade, with the incidence increasing with age. The etiology of CLL is unknown, but hereditary factors may have a role, with family members of CLL patients having a two- to sevenfold increased risk of CLL.[3]

Pathophysiology

Cell of Origin

CLL is characterized by small, relatively incompetent B lymphocytes that accumulate in the blood and bone marrow over time. The exact cell of origin is controversial but has been described as an antigen-activated B lymphocyte.[3]

Clinical Course

❺ *CLL can have a variable clinical course, with survival ranging from months to decades.* Low-risk disease is asymptomatic, and median survivals exceed 10 years; intermediate risk is associated with lymphadenopathy and has median survivals of about 7 years; and high-risk patients with anemia have median survivals of only 3 years.[16,17] The typical low-risk patient is an elderly person without symptoms who is diagnosed on routine blood draw. The typical high-risk patient is middle-aged, and symptoms have brought the patient to his or her physician.

Clinical Presentation and Diagnosis

Clinical Presentation

Signs and Symptoms
- Fatigue, chills, bleeding, and lymphadenopathy
- Chronic infections owing to immature lymphocytes
- Organomegaly consisting of splenomegaly and hepatomegaly

Diagnostic Procedures
- Peripheral blood smear
- Bone marrow biopsy
- Cytogenetic studies
- Molecular testing

Laboratory Findings
- Peripheral blood
  - Leukocytosis
  - Anemia
  - Thrombocytopenia
  - **Hypogammaglobulinemia**
  - Bone marrow: Must have at least 30% lymphocytes.

Poor Prognostic Factors
- Lymphocytosis with accompanying
  - Anemia [hemoglobin less than 11 g/dL (110 g/L, 6.8 mmol/L)]
  - Thrombocytopenia (platelets less than 100×10^3 /μL, 110 g/L or 100×10^9/L)
- *ZAP-70* mutation

Prognostic Factors

Two staging systems, Rai's and Binet's, have been developed to help practitioners determine the overall prognosis of patients with CLL. They are comparable systems and useful when broadly determining good, intermediate, and poor prognostic disease.[16,17] These systems are less useful in accurately determining prognosis in an individual patient. Increasingly, molecular characteristics of the disease such as cytogenetics and ***ZAP-70* expression** are being used to predict likely clinical course.[18]

Treatment

Desired Outcome

The primary goals in the treatment of CLL are to provide palliation of symptoms and to improve overall survival. Since the current treatments for CLL are not curative, reduction in tumor burden and improvement in disease symptoms are reasonable end points, particularly in older patients. A response to therapy can be evaluated by a resolution of lymphadenopathy and organomegaly, normalization of peripheral blood counts, and elimination of lymphoblasts in the bone marrow.

Nonpharmacologic Therapy

❻ *Chemotherapy does not improve overall survival in early-stage CLL.* In addition, deferring therapy until a patient becomes symptomatic does not alter overall survival.[19,20] For this reason, the notion of "watch and wait" is considered reasonable for older patients with indolent disease.

Stem Cell Transplantation

Stem cell transplantation is an option for younger patients. Currently, allogeneic transplant offers longer disease-free remissions than **autologous** transplantation, but neither has demonstrated the ability to cure patients.[30] Several factors must be considered before allogeneic transplantation. The lack of a donor, older age, and poor performance status make transplant an uncommon procedure in this population. In addition, early mortality after allogeneic transplant can be as high as 40% in CLL.[31] Reduced-intensity allogeneic transplant may reduce this high early mortality, but it is unclear whether it will produce long-term disease-free survival.

Pharmacologic Therapy

Single-Agent Chemotherapy

The treatment for CLL has changed with the development of the purine analog fludarabine (Fludara®) (see Table 93–3). Historically, chlorambucil (Leukeran®), an alkylating agent, was considered standard treatment for CLL. ❼ *Today, fludarabine-based chemotherapy is used as first-line therapy for younger patients with CLL.* Randomized clinical trials have shown that fludarabine is superior to chlorambucil in achieving higher response rates and producing a longer duration of response (CR 20% versus 4%, respectively).[20] Fludarabine is effective in previously untreated patients, as well as in patients who have chlorambucil-resistant disease.[21]

The most commonly used dose for fludarabine is 20 mg/m^2 intravenously daily for 5 consecutive days, whereas chlorambucil can be taken daily as an oral tablet with the dose ranging from 4 to 10 mg/day.[21] Fludarabine is associated with more toxicities than chlorambucil, including myelosuppression and prolonged immunosuppression.[19] Resulting infectious complications may occur during the periods of prolonged immunosuppression. The ease of administration and limited side effects make chlorambucil a practical option for symptomatic elderly patients who require palliative therapy.

Monoclonal Antibodies

Rituximab (Rituxan®) Rituximab is a chimeric monoclonal antibody directed against the CD20 molecule on B lymphocytes.[21] Similar to other B-cell malignancies, CLL

TABLE 93–3. Drugs Used in CLL

Drug	Adverse Effects	Comments
Alemtuzumab (Campath)	Infusion-reactions: fever, chills, nausea, vomiting; rash hypotension; prolonged immunosuppression (resulting in infectious complications)	Antiviral and PCP prophylaxis should be initiated during treatment. Premedicate with acetaminophen, diphenhydramine, with or without a steroid to alleviate infusion-related reactions. Subcutaneous dosing may lessen acute toxicity. Initially 3 mg/day as a 2-hour infusion, increase to 10 mg/day, then 30 mg/day as tolerated.
Chlorambucil (Leukeran)	Myelosuppression; allergic reactions (skin rash); secondary malignancies	Take on an empty stomach because food decreases absorption. Dose range: 4–10 mg PO daily.
Fludarabine (Fludara)	Myelosuppression; prolonged immunosuppression resulting in secondary infectious complications; edema; neurotoxicity	Dose: 20 mg/m^2 IV daily for 5 days.
Rituximab (Rituxan)	Infusion reactions: fever, chills, rigors, hypotension	Premedicate with acetaminophen, diphenhydramine, with or without a steroid to alleviate infusion-related reactions. Rate of infusion should be increased gradually to minimize reactions.

expresses CD20 surface markers. Rituximab alone can induce partial responses in untreated and previously treated CLL patients.[22,23] Dose-escalation studies suggest that higher doses are required than those used in non-Hodgkin's lymphoma; however, the typical 375 mg/m^2 dose is still used commonly.[24] The higher doses which may be used in CLL is probably a combined effect of lower CD20 expression and higher concentrations of soluble CD20 than in non-Hodgkin's lymphoma.[25] Combination therapies with rituximab result in higher complete responses than rituximab alone.[26] The most commonly observed side effects of rituximab include infusion reactions consisting of fever, chills, hypotension, nausea, vomiting, and headache.[23] Premedication with diphenhydramine and acetaminophen is recommended to minimize infusion reactions.

Alemtuzumab (Campath®) Alemtuzumab is a humanized monoclonal antibody directed against CD52.[27] CD52 is expressed on the majority of B and T lymphocytes. Alemtuzumab is FDA approved as a single agent for the treatment of CLL in patients who have failed alkylating agents and fludarabine. It is being evaluated in combination with other CLL therapies. Infusion-related reactions can be significant and typically occur with the initial dose and lessen in severity with subsequent doses. To limit acute allergic reactions, subcutaneous administration may be given instead of intravenous dosing. Premedication with oral antihistamines and acetaminophen is recommended. Since alemtuzumab also suppresses T cells, prolonged immunosuppression is a major toxicity. Infectious complications may occur from the reactivation of cytomegalovirus and herpes virus and from infection with *Pneumocystis*. Patients should receive trimethoprim-sulfamethoxazole and famciclovir or valacyclovir to prevent these infections.[21,27]

Combination Therapy

❽ *Combination therapy may provide improvement in long-term disease-free survival.* The combination of fludarabine, cyclophosphamide, and rituximab improves CR rates compared with fludarabine alone (70% versus 20%) but at the expense of increased infections.[28,29] Combinations of fludarabine and alemtuzumab are also being investigated, with the hope of improving overall survival.[21]

Outcome Evaluation

Successful treatment in the older CLL patient depends on the reduction of malignant lymphocytes. Treatment often begins when a patient becomes symptomatic. A desirable response to therapy includes a reduction in lymphocytes, decrease in stage of the disease, and resolution of symptoms. Since CLL is not a curable disease, palliation of symptoms is a reasonable goal in older patients, and aggressive therapies are reserved for younger patients with high-risk CLL.

MULTIPLE MYELOMA

❾ *Multiple myeloma is a malignancy of* ***plasma cells*** *that is characterized by an abnormal production of a monoclonal protein. Features of the disease include bone lesions, anemia, and*

Patient Encounter 2

A 72 year-old man presents to his primary care physician for his yearly check-up. He reports feeling fine over the past year. A physical examination appears normal, but the patient had an abnormal WBC count of $20 \times 10^3/\mu L$ ($20 \times 10^9/L$) with 80% (0.80) lymphocytes. The bone marrow examination reports 60% (0.60) lymphocytes, and the diagnosis of CLL is made.

- What treatment approach do you recommend?
- Would your treatment options change if the patient becomes symptomatic? If so, what are your new options?

renal insufficiency.[32] Multiple myeloma is an incurable disease; however, advancements in the treatment of myeloma have extended survival significantly.

Epidemiology and Etiology

Multiple myeloma is the second most common hematologic malignancy. It is estimated that approximately 19,900 new cases of multiple myeloma were reported in 2007, accounting for 1% to 2% of all cancers.[2] The median age at diagnosis is 68 years, but a small percentage of those diagnosed are under age 45. The incidence of myeloma is highest in African Americans and lowest in Asians, and the disease occurs more frequently in men than in women.[32] The etiology of multiple myeloma is unknown.

Pathophysiology

The pathogenesis of multiple myeloma is poorly understood but must be distinguished from a condition called *monoclonal gammopathy of unknown significance* (MGUS), which is characterized by a monoclonal immunoglobulin without malignant plasma cells. Yearly, about 1% of patients with MGUS will develop multiple myeloma. The pathophysiology of multiple myeloma involves complex bone marrow microenvironment and cytokine interactions. Interleukin 6, tumor necrosis factor, vascular endothelial growth factor, and stroma-derived factor 1 support the establishment and proliferation of myeloma cells.[32,33] It is the understanding of these interactions that has led to the newer agents used in the treatment of multiple myeloma.

Clinical Presentation and Diagnosis

Clinical Presentation

Signs and Symptoms
- Fatigue (anemia)
- Bone pain (fractures, lytic lesions)
- Recurrent infections
- Renal failure

Diagnostic Procedures
- Peripheral blood smear
- Serum protein electrophoresis and immunofixation
- Urine protein electrophoresis and immunofixation
- Radiologic evaluation (MRI, bone densitometry)
- Bone marrow biopsy (required for diagnosis)
- Cytogenetic studies
- Molecular testing

Laboratory Findings
- Peripheral blood
  - Monoclonal protein in serum (usually IgG or IgA)
  - High β_2-microglobulin
  - Low platelets and hemoglobin
  - High creatinine, urea, LDH, C-reactive protein, and calcium
- Urinalysis: **Bence-Jones protein**
- Bone marrow
  - Plasma cells (greater than or equal to 10%)
  - Abnormal cytogenetics
- Other findings: Bone lesions, fractures, osteoporosis

Poor Prognostic Factors
- High serum β_2-microglobulin and low serum albumin
- Elevated C-reactive protein
- Elevated LDH
- IgA isotype
- Low platelet count
- Chromosome 13 deletions and other cytogenetic abnormalities

Prognostic Factors

Prognostic factors include tumor load and patient performance status. High β_2-microglobulinemia, high lactate dehydrogenase (LDH), and extensive plasma cell infiltration of the bone marrow are all poor prognostic factors and are indicative of high tumor load. The older-aged patient, renal impairment, and other comorbidities also predict for poorer outcome.[34] Increasingly, chromosomal changes are being used to predict the high-risk patient, with perhaps the most important being deletion of the long arm of chromosome 13.[33]

Treatment

Desired Outcome

The primary goal in the treatment of multiple myeloma is to decrease tumor burden and minimize complications associated with the disease. A "watch and wait" approach is an option for asymptomatic patients who have no lytic lesions in the bone. Once symptoms occur, treatment is required. Chemotherapy can be used to reduce tumor burden in patients with symptomatic disease, but increasingly, immunomodulators such as thalidomide and dexamethasone are initial therapy. Almost all patients will become refractory to initial treatment and will require the use of salvage therapies such as bortezomib. Autologous stem cell transplantation prolongs overall survival in patients who can tolerate high-dose chemotherapy and may be the treatment of choice for many patients.

Nonpharmacologic Therapy

⓾ *Autologous stem cell transplantation results in higher response rates and extends overall survival compared with those who receive conventional therapy such as vincristine, doxorubicin, and dexamethasone (VAD).* Since overall median survival is prolonged from 42 to 54 months, stem cell transplant should be considered in all patients who can tolerate high-dose chemotherapy.[40] High-dose melphalan is the most common preparative regimen. Two sequential transplants (tandem transplants) improve overall survival in patients who do not have a good response after one transplant.[41] The use of maintenance therapy after autologous transplantation with thalidomide or bortezomib is under investigation.

Pharmacologic Therapy

Conventional-Dose Chemotherapy

Patients who present with symptomatic disease will be started on therapy. Two regimens used are VAD and melphalan and prednisone (MP). VAD like chemotherapy regimens are used most often in transplant candidates because it avoids the alkylating agent melphalan, thus minimizing damage to the stem cell compartment. These two regimens produce equivalent response rates of approximately 50% to 70% in previously untreated patients with myeloma (see Table 93–4).[35,36]

Corticosteroids

High-dose dexamethasone (40 mg/day) is an option for patients who cannot tolerate chemotherapy or have few high-risk features. Response rates are approximately 40% to 50% in previously untreated patients.[37] Advantages of this regimen include ease of administration and lack of hematologic adverse effects.

Thalidomide (Thalomid®)

Thalidomide as monotherapy or combination therapy is beneficial in the treatment of multiple myeloma. The precise mechanism of action of thalidomide is unknown, but its antimyeloma activity may be due to its **antiangiogenic** and

TABLE 93–4. Drugs Used in Multiple Myeloma

Drug	Adverse Effects	Comments
Bortezomib (Velcade)	Constipation, decreased appetite, asthenia, fatigue, fever, thrombocytopenia, dose-related, reversible peripheral neuropathy	Dose: 1.3 mg/m^2 IV bolus twice weekly for two weeks; week 3 off; repeat
Dexamethasone	Hyperglycemia, edema, adrenal cortical insufficiency	Dose given orally once daily
Doxorubicin (Adriamycin)	Myelosuppression, alopecia, cumulative dose-limiting toxicity, myocardium damage	Given in combination with vincristine and dexamethasone (VAD)
Lenalidomide (Revlimid)	Possible birth defects (since analogue of thalidomide), neutropenia, thrombocytopenia, deep vein thrombosis, pulmonary embolism, pruritis, fatigue	Dose is 10 mg orally taken with water once daily Women of childbearing age must use two forms of contraception Pregnancy test must be taken before and during use
Melphalan (Alkeran)	Myelosuppression, secondary malignancies, pulmonary fibrosis, sterility, alopecia	Dose of 0.15 mg/kg for 7 days given orally once daily, repeated every 4–6 weeks IV formulation used for stem cell transplantation
Thalidomide (Thalomid)	Severe birth defects, peripheral neuropathy, deep vein thrombosis, somnolence, constipation	Start at 50 mg by mouth daily and titrate to a maximum of 800 mg; doses are taken nightly Women of childbearing age must use two forms of contraception Pregnancy test must be taken before and during use
Vincristine (Oncovin)	Dose limiting toxicity: peripheral neuropathies, paresthesias, constipation, alopecia	Given in combination with doxorubicin and dexamethasone (VAD)

anticytokine properties.[33] Thalidomide may be given in combination with dexamethasone, resulting in greater response rates than when given alone. Thalidomide and steroid combinations produce responses in 60% to 80% of previously untreated patients.[37] Common side effects of thalidomide therapy include somnolence, constipation, peripheral neuropathy, and deep vein thrombosis. Prophylactic anticoagulation should be considered to prevent deep vein thrombosis associated with thalidomide therapy. There are substantial teratogenic effects of thalidomide if used during pregnancy.[33]

Bortezomib (Velcade®)

Bortezomib is a member of a new class of agents known as **proteosome** inhibitors. Proteosome inhibitors induce myeloma cell death by modulating ***NF-κB*** products, including inflammatory cytokines and adhesion molecules that support myeloma cell growth. Approved for the treatment of relapsed disease, bortezomib has been shown to produce response rates of 35% in heavily pretreated individuals.[38] Side effects of bortezomib include fatigue, nausea, peripheral neuropathy, and hematologic effects.[33] Currently, the investigation of bortezomib in untreated patients is underway, with preliminary results indicating about an 80% response when it is used in combination with steroids, thalidomide, or cytotoxic agents.[39]

Lenalidomide (Revlimid®)

Lenalidomide is an immunomodulating agent related to thalidomide that was recently approved for the treatment of patients with multiple myeloma and myelodysplastic syndrome (MDS). Lenalidomide lacks the common side effects of thalidomide, such as constipation and peripheral neuropathy. Interim analyses of two phase III trials show that lenalidomide in combination with dexamethasone produces higher response rates than dexamethasone alone in relapsed and refractory myeloma. Adverse effects of lenalidomide include diarrhea, nausea, muscle cramps, hematologic side effects and deep vein thrombosis.[42]

Bisphosphonates

❾ *Bone disease is a common manifestation of multiple myeloma. Bisphosphonates should be initiated in symptomatic patients with bone lesions to slow osteopenia and reduce the fracture risk associated with the disease.* Pamidronate and zolendronic acid have equivalent efficacy in the management of osteolytic lesions, but because of relative ease of administration, zolendronic acid is used most frequently.[43] The use of zolendronic acid decreases pain and bone-related complications and improves quality of life. The suggestion that bisphosphonates have direct antimyeloma activity, based on the ability to inhibit *NF-κB* signaling, remains controversial. Recent cases of osteonecrosis of the jaw have been a major concern. Risk factors are unclear, but osteonecrosis of the jaw is more common in patients receiving intravenous administration of bisphosphonates and having dental procedures performed. It is recommended that patients have dental restoration work done prior to starting bisphosphonate therapy.[43]

WALDENSTRÖM'S MACROGLOBULINEMIA

Waldenström's macroglobulinemia is a rare immunoglobulin disorder that is associated with non-Hodgkin's lymphoma. Approximately 4 per 1 million individuals are affected with the disease. Waldenström's is characterized by an elevation of serum IgM and involvement of the lymph nodes, bone marrow, and spleen. Patients typically are asymptomatic at the time of diagnosis, with the disease being discovered by routine laboratory examination. Similar to indolent lymphomas, the "watch and wait" approach is employed for asymptomatic patients. Symptomatic patients experience anemia, fatigue, hepatosplenomegaly, lymphadenopathy, and hyperviscosity syndrome. When these symptoms arise, treatment is necessary, with the goal being palliation. Systemic therapy includes alkylating agents, nucleoside analogs, and rituximab. These treatment options have similar efficacy. Treatment often is continued until a desired response (reduction in symptoms) is achieved. **Plasmapheresis** may be required in addition to systemic therapies in the treatment of hyperviscosity syndrome.[44]

Outcome Evaluation

Newly diagnosed, asymptomatic patients may be observed without treatment. This asymptomatic period may last for months to a couple years. All patients with multiple myeloma will become symptomatic, and once this occurs, treatment is required. First-line treatment may be one of several therapies, including VAD, thalidomide plus steroids, and autologous transplant. Nearly all patients will progress at some point, and second-line therapy usually will include bortezomib. All patients who have bone lesions should receive monthly bisphosphonates, with the hope of reducing pain and fractures.

Patient Encounter 3

A 50-year-old male presents with fatigue and back pain. A CBC reveals the following: hemoglobin 8.7 g/dL (87 g/L, 5.4 mmol/L), platelets $128 \times 10^3/\mu L$ ($128 \times 10^9/L$), corrected calcium 11.8 mg/dL (2.95 mmol/L), serum creatinine 1.4 mg/dL (124 μmol/L), and serum IgG 3500 mg/dL (35 g/L; normal 620–1500 mg/dL, or 6.2–15 g/L). A subsequent bone marrow biopsy confirms multiple myeloma.

- Given this information, identify treatment options.
- Discuss whether this patient is a candidate for autologous stem cell transplantation.

Patient Care and Monitoring

CML

1. Patients are placed on imatinib at the time of diagnosis. Patients should be monitored for a dose-dependent myelosuppression, GI intolerance, edema, and rash. Drug interactions with CYP450 3A4 inducers are clinically important and should be monitored.
2. An increase in imatinib dose may be required if patients have no hematologic response at 3 months or no complete cytogenetic response at 9 to 12 months.
3. Early in the diagnosis, patients should be evaluated for allogeneic stem cell transplantation. Ideal candidates include younger patients in chronic-phase CML who have an HLA-matched related or unrelated donor.

CLL

1. Observation is reasonable if the patient is asymptomatic.
2. Monitor WBC count, and watch for infection if patients are receiving chemotherapy.
3. Watch for infusion reactions with rituximab and alemtuzumab. Premedicate with acetaminophen and diphenhydramine to prevent these reactions.
4. Prophylactic trimethoprim-sulfamethoxazole is recommended for all patients receiving alemtuzumab.

Multiple Myeloma

1. During chemotherapy, monitor myeloma monoclonal protein in urine and serum, renal function, hemoglobin, and platelets.
2. Bisphosphonates should be initiated in patients with lytic bone lesions. Renal function must be monitored. Patients may need pain medication for bone pain.
3. If a reduction in myeloma protein is not seen on one chemotherapy regimen, another regimen should be used.
4. Evaluate the patient for adverse effects, including peripheral neuropathy and deep vein thrombosis. Prophylactic anticoagulation therapy should be considered in thalidomide or lenalidomide based therapy.

ABBREVIATIONS

CLL:	chronic lymphocytic leukemia

94 Skin Cancer

Trinh Pham

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Identify the risk factors associated with skin cancer.
2. Describe the common signs and symptoms of skin cancer and identify the features of a mole that are suspicious for melanoma.
3. Identify the key features in the different stages of melanoma and their correlation with prognosis.
4. Explain the goals of therapy for the treatment of nonmelanoma and melanoma skin cancer.
5. Devise a plan of lifestyle modifications for the prevention of skin cancer.
6. Discuss the pros and cons of interferon-α therapy for melanoma, and formulate a monitoring plan for patients receiving interferon-α.
7. Discuss the pros and cons of interleukin 2 therapy for melanoma, and formulate a monitoring plan for patients receiving interleukin 2.
8. Discuss the different treatment options for melanoma with brain metastasis.
9. Discuss the role of temozolomide in the treatment of stage IV melanoma with or without central nervous system (CNS) metastasis.
10. Discuss the different treatment options for nonmelanoma skin cancer.

Key Concepts

❶ Exposure to ultraviolet radiation from the sun is recognized as one of the primary triggers for skin cancer development.

❷ Staging of malignant melanoma is important to determine prognosis, categorize patients with regard to metastatic potential and survival probability, and aid in clinical decision making.

❸ Determination of lymph node status is important in melanoma staging because it is an independent prognostic factor, and it provides the oncologist with guidance for therapy decisions.

❹ Surgery is the primary treatment modality for nonmelanoma and melanoma skin cancer.

❺ Stage IIB, IIC, and III melanoma are considered to be high risk because of their potential for recurrence and distant metastasis. The primary treatment modality is surgical excision of the tumor and a lymphadenectomy for patients with positive lymph nodes.

❻ Interferon-α2b is approved by the Food and Drug Administration (FDA) as adjuvant therapy for high-risk melanoma. It is controversial if it should be offered to every patient at high risk for recurrence.

❼ Stage IV melanoma is not curable, and the primary goal of therapy is local control of the disease and relief of identifiable symptoms.

❽ Interleukin 2 therapy is approved by the Food and Drug Administration (FDA) for the treatment of metastatic melanoma, and it is a reasonable option for patients with this stage of the disease.

❾ Combination chemotherapy or biochemotherapy increases toxicity significantly without offering overall survival benefit; thus they are not standard of care for stage IV melanoma.

❿ Brain metastasis is common in melanoma, and treatment options for brain metastasis include surgery, radiation, and chemotherapy. The choice of therapy depends on the number of metastatic lesions, accessibility of the lesions for surgery, the presence of neurologic symptoms, and the status of extracranial disease.

Skin cancer is the most prevalent of all malignancies occurring in humans, and in the United States it accounts for more than 50% of all cancers.[1] The most common cutaneous malignancies are basal cell carcinoma (BCC), squamous cell carcinoma (SCC), and malignant melanoma (MM). BCC and SCC are categorized as nonmelanoma skin cancer. Worldwide, the incidence of nonmelanoma skin cancer (NMSC) and MM is increasing at a rate of 3% to 8% per year in fair-skinned Caucasian populations.[2] The mortality rate for MM is on the rise in North America, Australia, and New Zealand at pace of 2% to 4% annually.[2] Ultraviolet (UV) radiation exposure is the leading environmental factor causing skin cancer.[3] This is a modifiable risk factor, and prevention of skin cancer development is possible through a sun protection regimen that includes wearing protective clothing, avoidance of prolonged, intense sun exposure, and regular application of sunscreen. If skin cancer is detected in its early stage, survival is improved, and the disease is curable. Therefore, campaigns for primary and secondary prevention of skin cancer are important in combating this tumor. NMSC and MM differ with regard to prognosis, metastatic potential, mortality, curability and treatment options. This chapter will review the pathogenesis and risk factors for the development of skin cancer and provide current data on the recommendations for the prevention and treatment of both NMSC and MM.

Patient Encounter, Part 1

KM is a 71-year-old man being evaluated in the dermatology clinic for a recent change in a mole on his shoulder. The mole has been on his shoulder for as long as he can remember. A year ago it began to itch, and his wife noted that it seemed to be getting darker in color. On physical examination, it is noted that the primary lesion is a nodule, the border is ragged and irregular, and it is brown, black, and white in color. There is no oozing, bleeding, or crusting around the lesion. A couple of years ago, he had a complete excision of an in situ melanoma on his back.

KM has light-brown hair, blue eyes, and fair skin. He has a history of numerous severe blistering sunburns in his childhood. As a teenager and young adult, he spent many hours outdoors as a construction worker and a lifeguard. He lives with his wife in Denver, Colorado, and they enjoy outdoor activities such as hiking, skiing, and canoeing. He does not have a family history of melanoma.

- What are KM's risk factors for malignant melanoma?
- What information is suggestive of malignant melanoma?
- What should be done to confirm the diagnosis of malignant melanoma?
- How is the stage of the melanoma determined?
- What primary prevention measures are recommended to prevent skin cancer?

EPIDEMIOLOGY AND ETIOLOGY

Nonmelanoma Skin Cancer

NMSC accounts for nearly half of all newly diagnosed cancers in the United States each year, and it is estimated that more than 1 million cases will be diagnosed in 2006.[1] The true prevalence of NMSC may be underestimated because it is treated in outpatient settings, and no formal reporting to cancer registries is required.[4] BCC is the most common form of NMSC in Caucasians and comprises 75% of newly diagnosed NMSC. SCC accounts for 20% of NMSC.[4] NMSCs occur at a lower incidence in darker-skinned people or in descendants of African, Asian, and Mediterranean countries. In African Americans, the most common form of NMSC is SCC.[5] The majority of NMSCs are curable, and the mortality rate is low; cure rates approach 98%, and the overall 5-year survival rate is greater than 95%.[5] **Metastasis** occurs in less than 0.1% of BCCs compared with an average of 3.6% of SCCs. Seventy-five percent of all NMSC deaths are attributed to SCC.[5] NMSC is associated with considerable morbidity owing to functional and cosmetic deformity. In addition, it is an economic burden to the health care system because costs associated with NMSC treatment are estimated at approximately US$426 million per year.[6]

Malignant Melanoma

Malignant melanoma is ranked as the fifth most common cancer among men and sixth most common cancer in women.[1] In 2006, it is estimated that 62,190 new cases of invasive melanoma will be diagnosed. MM is a major public health problem of significant worldwide concern because of its dramatic rise in incidence and mortality. In the United States in 1935, the lifetime risk of melanoma was estimated at 1 in 1500; in 2002, the lifetime risk was 1 in 68 persons.[2] In Australia, the country with the highest incidence of melanoma in the world, the hazard is even higher at an estimated lifetime risk of 1 in 25 persons.[7] The incidence of melanoma is not evenly dispersed among all populations. Race, gender, and age confer different incidence rates.[7] Caucasians have higher risks than Asians, Hispanics, and African Americans.[7] The rate of MM is 10 times higher in whites than in African Americans.[1] From 1985 to 1994, data from the United States National Cancer database show that African Americans comprise 5.4% and Hispanics 3.4% of total melanoma cases.[8] MM generally occurs in the young, and it is diagnosed primarily in the third or fourth decades of life.[8] Sixty-two percent of cases are diagnosed before patients reach 65 years of age, and the median age of death is 67 years.[9] Overall, in the United States, males have higher incidence rates than females.[8] The incidence rises with age, and older men have the highest melanoma risk in the United States.[8]

Risk Factors (Table 94–1)

The maintenance of cellular homeostasis involves a balance of cell division, differentiation, senescence, and apoptosis.

TABLE 94–1. Risk Factors for the Development of Skin Cancer[10]

Exogenous/Environmental Factors	Endogenous/Host Factors	
UV Radiation exposure	**Age (Older)**	
History of blistering sunburn	**Surrogate Measures of Sun Sensitivity**	
Ionizing radiation	Red or blonde hair	RRM = 2.4
Chemical carcinogens	Blue eyes	RRM = 1.6
Arsenic (BCC)	Fitzpatrick Skin (Type I)	RRM = 1.7
Hydrocarbons, soot, tobacco (SCC)	Tendency to develop freckles	RRM = 2.5
Human papilloma virus	Fair skin	
(HPV 6,11, 16, 18) (SCC)	**Family History**	
	Three or more first-degree relatives affected	RRM = 35–70
	Three or more first-degree relatives affected	RRM = 3
	Presence of Nevi	
	Benign melanocytic nevi (greater than 100)	RRM = 11
	Familial dysplastic nevus syndrome	RRM = 11
	Congenital melanocytic nevi	
	Previous Skin Cancer	
	Previous melanoma	RRM = 8.5
	Previous nonmelanoma skin cancer	RRM = 2.9
	Immunosuppression	
	Transplant recipients	RRM = 3
	AIDS patients	RRM = 1.5
	Inherited Medical Disorders	
	Gorlin's syndrome (BCC)	
	Xeroderma pigmentosum (BCC)	
	Genetic Mutations	
	CDKN2A, CDK4, B-RAF (MM)	
	P53 (NMSC)	
	PTCH gene, *Bcl-2* (BCC)	

RRM, relative risk for melanoma; BCC, basal cell carcinoma; NMSC, nonmelanoma skin cancer; MM, malignant melanoma.

Cancer occurs when the growth and function of cells are "out of control" in relation to normal tissue. The combination of genetic alterations and environmental toxins is the most frequent contributor to the process of carcinogenesis. In the development of skin cancer, the risk factors are categorized as environmental (solar UV radiation), genetic (family history), immunosuppression, and previous history of melanoma.[10]

Environmental

Ultraviolet Radiation Exposure

❶ *Exposure to ultraviolet radiation from the sun is recognized as one of the primary triggers for skin carcinogenesis.* Based on their wavelengths, UV radiation is divided into three components: UVA (320–400 nm), UVB (280–320 nm), and UVC (200–280 nm).[15] UVB accounts for only 5% of the solar radiation that reaches the earth, but it is the primary carcinogenic component in the UV spectrum.[15] The following sequence of events describes the process in which UV radiation causes skin cancer: (1) UV radiation reaches the earth, and on the skin, it reaches the cells in the epidermal layer (i.e., squamous cells, basal cells, and melanocytes),[16] (2) the UV radiation (specifically UVB) is absorbed by DNA in the cells and may induce DNA lesions by forming dimers between neighboring pyrimidine bases, resulting in the development of cyclobutane pyrimidine dimers (CPDs) and pyrimidine-pyrimidone(6-4) photoproducts,[17] and (3) if this critical step of damage to the DNA is not repaired, gene mutations may transpire, leading to carcinogenesis.[17] Another mechanism of UV radiation–induced DNA damage is via generating reactive oxygen species (ROS), e.g., 8-hydroxydeoxyguanosine (8-OHdG), which can cause oxidative stress to DNA base pairs. The DNA damage from ROS increases with increasing wavelength over the UV band; therefore, exposure to UVA radiation may be more critical in this pathway.[17] Other modes of DNA damage caused by UV radiation include protein-DNA cross-links and single-strand breaks.[17]

Greater exposure to solar UV radiation by the general population, owing to increased outdoor activities, changes in clothing style, longer lifespan, and ozone depletion, is thought to be a major reason for the rising number of skin cancer diagnoses.[4] It is estimated that 90% of NMSCs and 60% to 70% of MMs are linked to UV exposure.[18] Data from epidemiologic studies indicate that greater cumulative lifetime exposure is associated with a higher risk of developing SCC, whereas severe

sunburns and intense intermittent (recreational or vacation) exposure correlates more with BCC and MM.[9] Geography, as it relates to proximity to the equator, is also linked to melanoma. Among the Caucasian population, the risk of melanoma is inversely related to the distance from the equator.[9] The association between sun exposure and melanoma is not clearly defined, though, because cutaneous melanoma can arise frequently in areas of the body not exposed to the sun.[10]

Tanning Devices: Artificial Sunlamps

Tanning devices provide a source of artificial UV radiation, mainly UVA and UVB, and have been popular since the 1970s.[10] In a large cross-sectional study involving more than 10,000 United States children and adolescents and a telephone survey of more than 1000 people aged 11 to 18 years, it was revealed that at least 10% of the subjects have used a sun bed in the last year.[19,20] There are limited data on the effect of sunlamps or sunbeds on skin cancer risk. In order to assess if there is a correlation between MM and exposure to UV radiation through the use of sun beds, Young[21] conducted a review of 14 epidemiologic case-control studies in melanoma patients. The author concluded that although recent data demonstrate that there is a relationship between MM development and the use of tanning devices, the results are not overwhelmingly conclusive.[21] The same is true for analysis of studies assessing the risk of NMSC and tanning beds.[21] Nevertheless, since there is no clinical benefit to tanning and there is a possibility of an increased risk of skin cancer, some states and France have made the use of tanning beds illegal for anyone under the age of 18.[13]

Genetics and Family History

There is a strong correlation between a family history of MM and the development of MM, yet only 10% of melanoma cases report having a first- or second-degree relative with the diagnosis.[22] Patients with two or more family members with melanoma are significantly more likely to develop melanoma at a younger age and to develop multiple melanomas.[98] The inherited mutation of two highly penetrant melanoma genes has been identified in families with melanoma susceptibility: the *CDKN2A* gene (also known as *INK4/ARF, MTS1,* and *CDK1*) and the *CDK4* gene. The *CDKN2A* gene is located on chromosome 9 (9p21) and encodes for the p16 protein. The *CDK4* gene is located on chromosome 12 (12q13).[2] The *CDKN2A* mutation is present in 30% to 40% of families with three or more members affected by melanoma, and the risk of melanoma is between 50% and 90% by 80 years of age for those who have the mutation.[2] Worldwide, only three families have been reported to be carriers of *CDK4* mutation.[22]

Polymorphism of the *MC1R* gene on chromosome 16 (16q24), which is associated with red hair, also increases susceptibility to melanoma.[23] Mutations affecting the serine–threonine kinase *B-RAF* gene have been reported with high rates in individuals with MM.[24] The *RAF* serine–threonine kinases affect the mitogen-activated protein kinase (MAPK) pathway, mediating cell proliferation, angiogenesis, metastasis, and survival,[25] and confer growth advantage to melanoma cells.[16]

Most cases of BCC are sporadic; however; it occurs frequently in the rare individuals with hereditary disorders such as basal cell nevus syndrome (also known as *Gorlin's syndrome*) and xeroderma pigmentosum (XP). Gorlin's syndrome is an autosomal dominant condition manifesting as pitting of the palms and soles of the feet, jaw cysts, spine and rib abnormalities, calcification of the falx cerebri, and cataracts. XP is a DNA-repair-deficient syndrome.[16] The *patched* gene (*PTCH*), a tumor-suppressor gene, has been shown to be mutated in XP and 50% to 60% of sporadic BCCs.[17] The oncogene *bcl-2,* which suppresses programmed cell death (apoptosis), also has been found to be expressed in high levels in patients with BCC.[26]

Skin Cancer Phenotype

Generally, the phenotype that predisposes an individual to an increased risk of skin cancer is red or blond hair, blue eyes, and fair skin. These characteristics are surrogate measure of the sensitivity of the skin to sun exposure and the tendency to develop nevi, freckles, and sunburns based on the skin type. Freckles, which may appear abruptly after the first high dose of UV radiation sun exposure, represent clones of mutated melanocytes, and their presence is associated with an increased risk of melanoma.[12] The Fitzpatrick classification of skin type is used to determine the response pattern of the skin to UV radiation and assess the risk for melanoma. There are six Fitzpatrick skin types: Type I skin always burns and never tans, type II skin burns easily and tans rarely, type III skin burns sometimes and tans usually, type IV skin burns rarely and always tans, type V skin always tans and is moderately pigmented (brown), and type VI skin always tans and is darkly pigmented (black). Fitzpatrick I and II skin types are commonly affected by NMSC and MM. The susceptibility to skin cancer, both NMSC and MM, is related to the melanin content of the skin and the skin's response to UV radiation.

In individuals without a family history of melanoma (sporadic melanoma), the presence of benign melanocytic nevi (benign moles) is consistently identified as the strongest risk factor for the future development of melanoma.[9] The greater the number of benign nevi (greater than 20), the greater the susceptibility to melanoma growth.[15] There is an inverse relationship between melanin content, which correlates with the ability to tan, and incidence of skin cancers.[15] Melanin functions as a photoprotectant, and this is evidenced by the observation that people with skin types that tan poorly are more susceptible to sunburn, photoaging, and photocarcinogenesis.[12] For example, epidemiologic studies show that Scandinavians, who have fair complexions, have a low incidence of BCC because they have good tanning capacity. On the other hand, Irish people, who are also fair, have a higher incidence of BCC because they tan poorly.[15]

Another risk factor for the development of melanoma is having the dysplastic nevus syndrome (also known as *B-K syndrome, familial atypical mole,* or *Clark's nevus*). This is an autosomal dominant disorder with incomplete penetrance,[19] and the dysplastic nevus is a mole that shares clinical features common to melanoma. Microscopic examination of the nevi shows disordered proliferation of melanocytes with varying degree of atypia without evidence of invasion.[27] The nevi ranges from 6 to 15 mm in diameter, and an individual typically may have 25 to 75 abnormal nevi present on his or her body.[27] The cumulative lifetime risk for melanoma development in individuals with dysplastic syndrome is almost 100%.[27] Congenital melanocytic nevi are nevi that are present at birth, and the risk of developing melanoma is linked with the size of the nevus. Congenital melanocytic nevi that are less than 20 cm have a reported 0% to 4.9% lifetime risk for developing melanoma, and congenital melanocytic nevi that are larger than 20 cm have a lifetime risk of 4.5% to 10%.[20]

Age

Aging is a risk factor for skin carcinogenesis because the passage of time allows more instances for the initiation and promotion of tumor formation through exposure to UV radiation. Furthermore, the capacity to repair DNA decreases with age, and the capability to remove DNA photoproducts such as CPDs and pyrimidine-pyrimodone(6-4) from UV irradiated skin also diminishes with age, leading to an increased rate of genetic mutations.[18] These characteristics may account for the exponential increase in the incidence of NMSC and MM in the elderly population.[18]

The age of exposure to intense UV radiation and experience of severe sunburn has an important significance in the development of skin cancer. The process of skin carcinogenesis is initiated with sunburn episodes, especially when it occurs before the age of 15 years, and the manifestation of the skin cancer may be as late as 40 to 60 years later.[26] The incidence of BCC is more frequent after freckling and severe sunburn in childhood. Sunburns occurring in adulthood do not seem to be associated with BCC development.[17] The same is also true for melanoma, as demonstrated by studies that show that people who migrate to more sunny climates in the first decade of their lives have a higher risk for developing melanoma as compared with people who move as teenagers or young adults.[23]

Immunosuppression

There is clear evidence linking defects of the immune system to the development of NMSC. For example, it is observed that patients receiving chronic immunosuppressant therapy for organ transplantation have a 50% risk of developing SCC within 20 years of transplantation, and 30% of these cancers are highly aggressive.[21] Additionally, patients with human immunodeficiency virus (HIV) infection are predisposed to melanoma.[18] Data also support the idea that UV radiation exposure induces immunosuppression and that this is associated with carcinogenesis.[30] Langerhans' cells are responsible for antigen processing and initiation of the immune cascade in the skin, and it has been demonstrated that UVB alters their function.[30] UV radiation also induces suppressor T cells and activates biologic response modifiers by initiating cytokine cascades, ultimately leading to a state of immune tolerance and unsuppressed tumor growth.[22]

Other Risk Factors

Other factors associated with the risk of NMSC include exposure to ionizing radiation and arsenic, which is connected with BCC. Chemical carcinogens that give rise to NMSC include industrial hydrocarbons that are found in coal tars, soot, asphalt, paraffin waxes, and tobacco.[21] Exposure to the human papilloma virus (HPV-6, -11, -16, and -18) has been linked to SCC.[31] Lastly, a personal history of previous melanoma is a risk factor for developing another primary melanoma.

PATHOPHYSIOLOGY

Skin Anatomy

The skin contains three layers: the epidermis (top layer), the dermis (middle layer), and the subcutis (innermost layer).[23] The epidermis serves as a barrier to the environment to protect internal organs, and within its layers are squamous cells that produce keratin to provide its protective effect.[23] Melanocytes, cells that synthesize melanin, also reside in the epidermis.[23] Melanin is a brown-black pigment that is distributed to surrounding keratinocytes within the dermis and epidermis via dendritic projections.[18] The dermis gives the skin its strength, resiliency, and resistance to tearing.[23] It is made up of a dense network of collagen and elastic fibers that anchors hair follicles, sweat glands, blood vessels, and nerves. Basal cells separate the epidermis from the dermis, and these cells divide continually to replace the older cells that slough off the skin. The subcutis is composed of collagen and loose adipose connective tissue. It serves to conserve heat and act as a shock absorber to protect the inner organs[23] (Fig. 94–1).

NMSCs arise from epidermal keratinocytes and involve primarily squamous cells and basal cells of the epidermis and dermis skin layers. BCCs arise from basal cells or keratinocytes in hair follicles or sebaceous glands. MM involves the abnormal growth and proliferation of melanocytes and begins with the proliferation of a single melanocyte from within the epidermis. After a series of intraepithelial events, the melanocyte migrates to the dermis, possibly deeper into the cutis, and proliferates therein.[25] From within the dermis and subcutis, melanoma may metastasize and spread to distant sites via lymphatic and vascular channels.[25] The overwhelming majority of MMs originate from the skin, although they also may arise less commonly from the retina, meninges, or gastrointestinal tract.

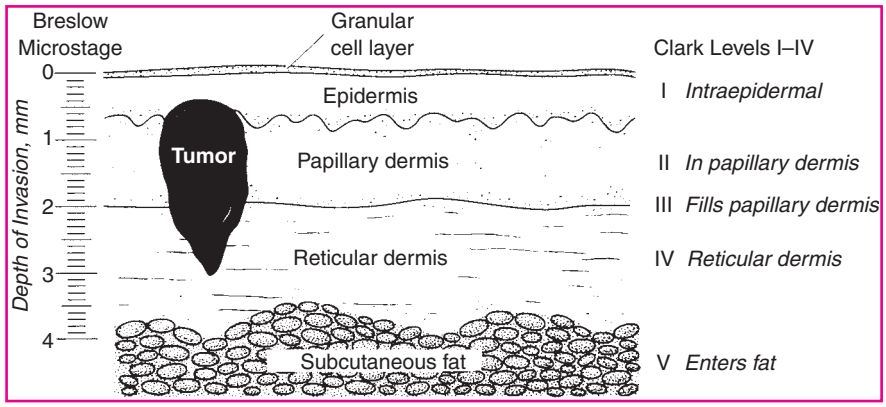

FIGURE 94–1. Skin anatomy: Breslow microstaging and Clark levels. (Reprinted from Langley RGB, Barnhill RL, Mihm Jr MC, et al. Neoplasms: Cutaneous melanoma. In: Freedberg IM, Eisen AZ, Wolff K, et al, (eds.) Fitzpatrick's Dermatology in General Medicine. 6th ed. New York: McGraw-Hill; 2003: 938.)

CLINICAL PRESENTATION AND DIAGNOSIS

Malignant Melanoma

There are four major subtypes of MM: *superficial spreading, nodular, lentigo maligna melanoma,* and *acral lentiginous* (Table 94–2). They each vary in clinical and growth characteristics. Superficial spreading melanoma is the most common histologic sub-type, and it occurs frequently in individuals in their 40s and 50s. When superficial spreading melanoma is confined to the epidermis, it is known as *melanoma in situ.* It has a long horizontal growth phase and may take months to years before it invades deeper into the skin vertically.[32] The most common sites of manifestation for this sub-type of MM are the trunk for men and the lower extremities for women.[9] These sites reflect the differences in skin exposure to sunlight by the clothing men and women wear.[9] Nodular melanoma is the second most common sub-type of MM, and it may occur at any age, although it usually arises in the fifth to sixth decade of life. It grows very rapidly without an identifiable horizontal growth phase and may be deeply invasive at the time of diagnosis. Nodular melanoma is associated with a poor prognosis. Clinically, it presents as an enlarging papule or nodule and often has a history of bleeding.[32] Lentigo maligna is an in situ form of MM before it thickens, becomes invasive, and transforms into lentigo maligna melanoma. The lifetime risk of transformation ranges from 5% to 50%, and it may take months to years for this to occur. The peak incidence for this sub-type of MM is in the seventh decade of life, and it usually arises on the surface of sun-damaged skin of an elderly person.[32] Acral lentiginous melanoma accounts for 50% of all MMs in blacks, Asians, and Hispanics; it comprises only 10% of MMs in Caucasians. The site of manifestation of this sub-type is unique because most lesions occur underneath the nails (subungual melanoma) and on the plantar aspect of the feet.[32]

Basal Cell Carcinoma

BCC has indolent growth characteristics, with a very low metastatic rate, ranging from 0.0028% to 0.55%.[5] Paradoxically, BCCs can cause extensive local destruction and significant disfigurement. Like MM, BCC is also divided into four main histologic subtypes: *nodular, superficial, morpheaform,* and *pigmented* (or *metatypical*) (see Table 94–2). Each sub-type has its own unique characteristic. The most common sub-type is nodular BCC, accounting for 50% to 55% of BCCs. Nodular BCC is mostly red or flesh-colored, but it also may be mistaken for MM because it shows variable amounts of pigmentation.[15] Superficical BCC accounts for 10% of all cases and is the least aggressive of all subtypes because it is very slow growing. Its appearance is similar to plaque, psoriasis, or eczema, and these benign disorders should be included as part of the differential diagnosis. Morpheaform BCC accounts for 2% to 5% of BCCs. It is the most aggressive sub-type because these tumors can be large and difficult to remove surgically.[5] Pigmented BCC may have melanin deposits and may be confused with aggressive melanoma.[5]

Squamous Cell Carcinoma

SCCs are more aggressive than BCCs (see Table 94–2). The rate of metastasis for SCC is 2% to 6% and may be as high as 10% to 14% in high-risk sites such as the ear and lip and 30% in the genital area.[5] SCCs are preceded by leukoplakia, actinic keratosis, radiation damage, or sun damage to the skin.[33] Actinic keratosis, a small papule that appears on areas of sun damage on the skin, has a 1 in 400 risk of transforming to SCC.[5] Common locations for SCCs are on the backs of the hands and the bare scalp. They also may appear on other less common sites such as the lips, ears, genitals, and soles of the feet.

Skin Examination

The *ABCD* acronym is a helpful mnemonic for recognizing the signs and symptoms of early MM (Fig. 94–2). It was devised in 1985 by clinicians working in the Melanoma Clinical Cooperative Group at New York University School of Medicine and is used to educate health care professionals who are not dermatologists in differentiating common moles from cancer.[34] It is

TABLE 94–2. Characteristics of Different Types of Skin Cancer[5, 8, 9, 20, 23]

	Malignant Melanoma				Nonmelanoma Skin Cancer	
	Superficial Spreading	**Nodular**	**Lentigo Maligna Melanoma**	**Acral Lentiginous**	**Basal Cell Carcinoma**	**Squamous Cell Carcinoma**
Frequency	70%	15–30%	4–10%	Less than 10%	60–80%	20%
Location	Trunk in men Legs in women Upper back	Trunk, head, neck	Sun-exposed areas, face	Palms of the hands, soles of feet, nailbeds	Head/neck trunk/lower limbs	Backs of the hand, bare scalp, lips, ears
Age/gender at presentation	Middle 40s Women more than men	Any age (fifth to sixth decades) Men more than women	70s Rare before 50	60s	Incidence increases after age 40	Incidence increases after age 40
Ethnicity	Caucasian	Caucasian	Caucasian	African-American, Asians, Hispanics	Most common in Caucasians, rare in dark-skinned people	Most common in African descendants
Initial growth	Radial	Pure vertical	Radial	Radial	Radial	Radial
Clinical features	Long horizontal growth phase, months to years before invading vertically. *Melanoma in situ*—confined to the epidermis.	Very aggressive without identifiable horizontal growth phase, deeply invasive at the time of diagnosis, associated with poor prognosis.	Lentigo maligna—in situ form of lentigo maligna melanoma; 5–50% transform to malignant melanoma.	50% of all melanomas in blacks, Asians, and Hispanics; 10% of melanomas in Caucasians.	Four subtypes: 1. Nodular BCC (50–55%), most common sub-type 2. Superficial BCC (10%), least aggressive 3. Morpheaform (2–5%), most aggressive 4. Pigmented or metatypical BCC	Usually presents as a painless, erythematous, poorly defined lesion with elevated borders.

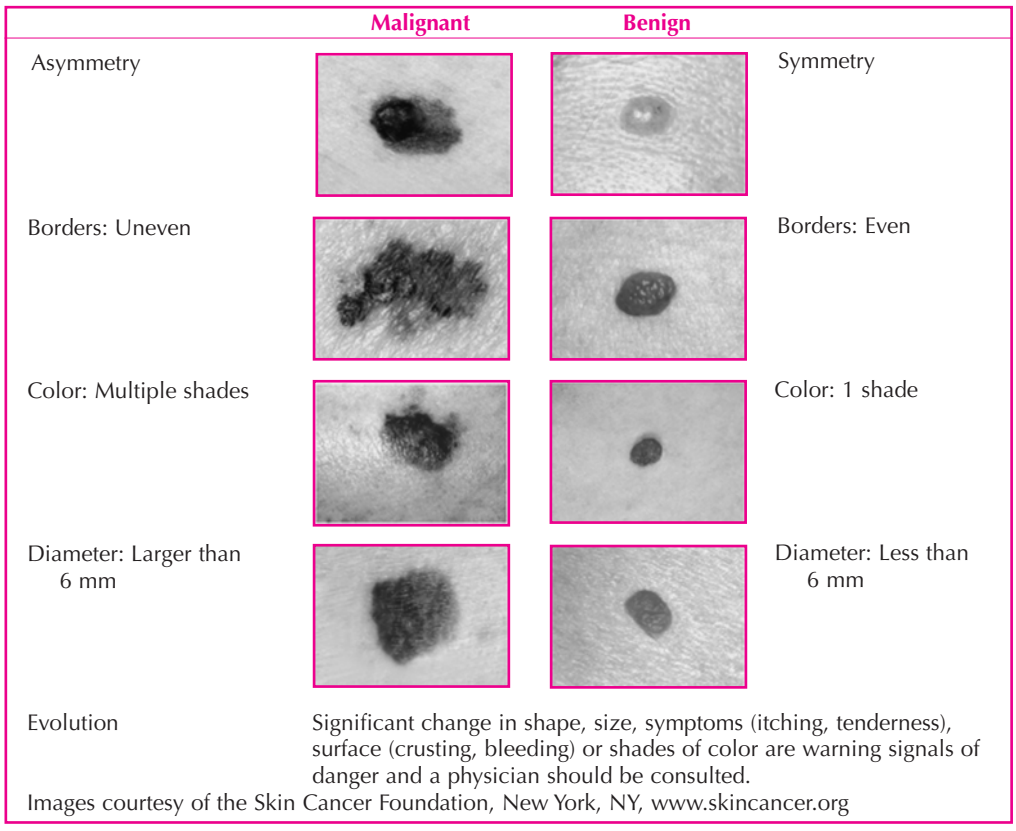

FIGURE 94–2. ABCDE features of early melanoma[25] images courtesy of the Skin Cancer Foundation, New York, NY, www.skincancer.org.

also a useful tool to educate the lay public to assess pigmented lesions and screen for suspicious moles to help identify the MM in its early stage when it is curable. It should be noted that this is only a guide. Not all MMs, including nodular melanoma, have all four ABCD characteristics, and it is not meant to provide a comprehensive list of all MM features. It should be noted that the nodular type may not fit ABCD characteristics.[34] The characteristics for each of the letters are described in the "Clinical Presentation" box. The newest letter that is being proposed to be added to the ABCD acronym is *E,* which stands for "evolving." Evolving lesions are those that have changed significantly in size, shape, symptoms (e.g., itching or tenderness), surface (e.g., crusting or bleeding), or shades of color.[34] Evolution of a lesion is one of the most important warning signs of danger in the assessment of moles for MM.

Early diagnosis of skin cancer is the key to improved prognosis. Diagnostic accuracy and clinical skills are two essential factors in the appropriate management of skin cancer. On presentation to a clinician's office, patients may offer a history of a new growth or an area of irritation. Conversely, the skin cancer may have been present for years undetected by the patient. The definitive diagnosis of any suspected cutaneous malignancy should be confirmed by a biopsy prior to treatment.

STAGING AND PROGNOSIS OF MELANOMA

Data from the Surveillance, Epidemiology, and End Results (SEER) study show that 82% of patients diagnosed with MM present with localized disease, 9% with regional disease, and 4% with distant disease.[7] ❷ *Once skin cancer is diagnosed, it is important to determine the stage of the cancer to find out if the cancer is confined to the original tumor site or has spread to other sites, such as the lymph nodes, liver, brain, lungs, or bone. The purpose of staging cancer is to determine prognosis, categorize patients with regard to metastatic potential and survival probability, and aid in clinical decision making.* As with most solid tumors, the tumor-node-metastasis (TNM) classification is used to stage MM, and the latest guidelines for staging MM proposed by the American Joint Committee on Cancer were implemented in 2002 (see Table 94–3).[36]

Sentinel Lymph Node in Melanoma

For patients with melanomas that are at risk of spreading to the lymph nodes, a **sentinel lymph node** (SLN) biopsy is performed. The SLN, the first lymph node to receive lymph draining from the tumor, is identified by injecting a radioactive material, technetium-99m-labeled radiocolloids, and vital

TABLE 94–3. 2002 AJCC Revised Melanoma Staging System[31]

Stage	Histologic Features	Overall Survival 5 Years	Overall Survival 10 Years
0	Melanoma in situ (involves only the epidermis layer)	**100%**	**100%**
IA	1mm thickness, no ulceration and Clark level[a] II or III		
IB	1mm with ulceration Or 1mm with ulceration or Clark level IV or V Or between 1.01 and 2 mm with no ulceration	**89–95%**	**79–88%**
IIA	Between 1.01 and 2 mm with ulceration Or between 2.01 and 4 mm with no ulceration	**45–79%**	**32–64%**
IIB	Between 2.01 and 4 mm with ulceration Or greater than 4 mm with no ulceration		
IIC	Greater than 4 mm with ulceration		
IIIA	Any tumor thickness with no ulceration with one lymph node involved and micrometastases Or any tumor thickness with no ulceration with two to three lymph nodes involved and micrometastases	**63–70%**	**57–63%**
IIIB	Any tumor thickness with ulceration and one to three lymph nodes involved and micrometastases Or any tumor thickness without ulceration and one to three lymph nodes involved and macrometastases Or any tumor thickness ulceration with in transit metastases/satellite lesions without metastatic lymph nodes	**46–59%**	**36–48%**
IIIC	Any tumor thickness with ulceration with one lymph node involved and macrometastases Any tumor thickness with ulceration with two to three lymph nodes involved and macrometastases Any tumor thickness with four or more metastatic lymph nodes or in transit metastases/satellite lesions with metastatic lymph nodes	**24–29%**	**15–24%**
IV	M_{1a}: Skin, subcutaneous tissue, or distant lymph nodes with normal lactate dehydrogenase M_{1b}: Lung with normal lactate dehydrogenase M_{1c}: To all other visceral sites (liver) or distant metastasis at any site with elevated serum LDH	**7–19%**	**3–16%**

[a]**Clark's level** refers to the level of penetration into the dermis (see Fig. 94–1). **Breslow classification** measures tumor thickness, in millimeters, from the epidermis to the deepest depth of penetration into the dermis (see Fig. 94–1.)

blue dye into the skin next to the tumor and tracing the flow of lymph from the tumor site to the nearest lymph node chain. Once the SLN is located, it is removed and analyzed for the presence of MM cells. If it is positive for the presence of MM, then the whole lymph node basin in that area is dissected; this is also known as a **lymphadenectomy.** A SLN biopsy is the initial procedure to assess the status of lymph node involvement to prevent the morbidity associated with a total lymphadenectomy.

❸ *The status of the SLN is one of the most powerful independent prognostic factors predicting survival. It also provides the oncologist with guidance for therapy decisions.* Furthermore, a SLN biopsy provides accurate staging of the MM.[31] An SLN biopsy should be considered in patients with clinically localized MM that is 1 mm or greater in size (Table 94–4). It also may be considered for patients whose MM is less than 1 mm but has any of the following characteristics: ulceration, extensive vertical regression to at least 1 mm, young age, or high mitotic rate.[31]

TABLE 94–4. Surgical Margins of Excision for Malignant Melanoma[39]

Melanoma Thickness	Margin of Excision	Sentinel Lymph Node Biopsy
Melanoma in situ	0.5 cm	No
Less than 1mm	1 cm	Yes if associated with ulceration, regression on histologic evaluation, positive deep margin on initial biopsy, Clark's level IV or V, and previous history of melanoma
1–2 mm	1–2 cm	Yes
2–4 mm	2 cm	Yes
Greater than 4 mm	Greater than 2 cm	Controversial

Clinical Presentation of MM[26,27]

Patients with skin cancer generally present with a lesion that may be located anywhere on the body. The most common sites are the head, neck, trunk, and extremities. Changes in any characteristics of a lesion are important danger warning signals. Abnormal presentations of a mole/lesion indicate the need for further assessment.

- *A*symmetry*:* Half the lesion does not mirror the other half.
- *B*order*:* Sharp, ragged, uneven, and irregular borders.
- Color*:* Multiple colors of various hues of light brown, dark brown, black, red, blue, or gray.
- *D*iameter*:* Larger than 6 mm or the size of a pencil head eraser.
- *E*volving*:* Significant change in shape, size, symptoms, surface, or shades of color.

Other signs and symptoms to monitor for in a lesion, in addition to ABCDE, include:

- Sudden or continuous enlargement of a lesion or elevation of a lesion
- Changes in the skin surrounding the nevus
- Redness, swelling, itching, tenderness, or pain
- Ulceration: friability of the lesion with bleeding or oozing. This is a danger signal.

Less Common Sites and Manifestations of MM

It is important to examine these sites for "hidden" MM:

- Nailbed
- Mucosal tissue
- Scalp
- Eye

In the nailbed, a black streak or wide variegated brown streak, elevation of nailbed, skin next to nail becomes darker, nail looks deformed or is being destroyed; size of nail streak increases over time.

Diagnosis of MM

- Dermoscopy[29]
- Biopsy[30]

Clinical Presentation of NMSC[27]

Five Warning Signs of BCC

The appearance of some BCCs is similar to plaque, psoriasis, or eczema, and these benign disorders are included in the differential diagnosis.

- An open sore that bleeds, oozes, or crusts and remains open for 3 or more weeks
- A reddish patch or irritated area that may crust, itch, hurt, or persist with no noticeable discomfort
- A shiny bump or nodule that is pearly or translucent and may be pink, red, or white. In dark-haired people, it may be tan, black, or brown and can be confused with a mole.
- A pink growth with slightly elevated, rolled border and a crusted indentation in the center
- A scarlike area that is white, yellow, or waxy with poorly defined borders

Warning Signs and Symptoms of SCC[5,26]

- A wartlike growth, a persistent scaly red patch with irregular borders, or an open sore that crusts or bleeds
- An elevated growth with a central depression that bleeds occasionally. This growth type increases in size rapidly.
- In situ SCC: red scaling macule or plaque
- Invasive SCC: firm or friable red papule or nodule covered with scale or crust
- Precursor of invasive SCC (actinic keratosis): scaly erythematous macule or papule on areas of chronic sun exposure

Lymph Node Consideration in NMSC

In patients with SCC, metastatic spread to the lymph nodes occurs in less than 5%.[32] The lymph nodes of the head and neck are the most common sites of metastasis. Patients are still curable with this stage of the disease, but they are at high risk of experiencing regional relapse and distant metastasis to the bones and lungs. As may be expected, survival is decreased compared with patients who do not present with nodal involvement. Factors that may be useful in predicting lymph node involvement include depth of tumor invasion and tumor thickness. A tumor thickness of greater than 4 mm has been suggested as the threshold at which nodal metastasis should be suspected and an SLN biopsy should be considered.[32]

Other Prognostic Factors

In addition to the stage of the disease and the status of disease involvement in the lymph nodes, other prognostic factors for outcome in MM include patient age and gender, tumor location, and histology of the MM. Table 94–5 provides complete information on factors that confer good prognosis for a patient diagnosed with malignant melanoma.[33]

Additional Diagnostic Work-up Tests

A baseline chest x-ray, lactate dehydrogenase (LDH) level, and computed tomographic (CT) scan of the chest, abdomen, and pelvis may be ordered by the oncologist as indicated clinically, depending on the patient's symptoms, the presence of lymph

TABLE 94–5. Prognostic Factors in Melanoma[31]

Factor (Better Prognosis)	
Age (less than 65 years)	5-year survival (%)
Less than 30 years	87
60 years	78
70 years	71
80 years	60
Gender (female)	10-year survival (%)
Female	86
Male	68
Tumor location (extremities)	10-year survival (%)
Extremities	90
Trunk, head, or neck	70

Histologic Factors (Better Prognosis)	
Tumor thickness (less than 1 mm)	Clark's level (level I)
Ulceration (none)	Tumor vascularity (absent)
Nodal status (none)	Regression (absent)
Vascular invasion (none)	Mitotic rate (low)
Microsatellites (none)	Tumor infiltrating lymphocytes (present)

node involvement, or the stage of the cancer. Positron-emission tomography (PET) and magnetic resonance imaging (MRI) are additional imaging techniques that may be used.

TREATMENT

The modality of treatment for skin cancer depends on the size, location, and stage of the tumor; the age of the patient; and the type of skin cancer. Treatment options for skin cancer include surgery, radiation, chemotherapy, and immunotherapy.

Desired Outcome

The primary goals of therapy for skin cancer are to completely eradicate the tumor and minimize the risk of tumor recurrence and metastasis. Secondary goals of therapy include preserving normal tissue, maintaining function, and providing optimal cosmetic outcomes.[5]

Patients with local disease (stage I and IIA) are curable with surgical resection of the tumor. Thus the aim is to diagnose patients at the earliest stage in order to increase the probability of cure. Patients with regional disease (stage IIB, IIC, and III) have a high recurrence risk, and the goal of therapy is to prevent relapse of the disease. Disseminated, metastatic MM is not curable, and the goal of therapy is local control of the disease and palliation of symptoms.

In patients diagnosed with BCC, metastases and death are rare. SCC is more aggressive than BCC, with metastases occurring in 2% to 6% of patients.[5] The primary goal of therapy for both these types of NMSC is to cure the patient and to prevent recurrence for SCC. Although NMSC has a low mortality rate, morbidity owing to tissue destruction, functional impairment, and disfigurement is a significant issue. Therefore, secondary goals of therapy for NMSC are preservation of function and restoration of cosmesis.[5]

Nonpharmacologic Therapy

Lifestyle Modifications

Primary Prevention of Skin Cancer

Ultraviolet (UV) radiation exposure from the sun is the major cause of NMSC and MM. **Primary prevention** strategies for skin cancer aim at educating people against excessive exposure to the sun and are spearheaded by the American Academy of Dermatology, the American Cancer Society, the Environmental Protection Agency, and the Centers for Disease Control and Prevention. Comprehensive cancer prevention programs sponsored by these organizations include the National Skin Cancer Prevention Educational Program, National Skin Cancer Prevention and Detection Month, The Skin Cancer Foundation's Self Examination Program, and the California and United States Food and Drug Administration sunscreen legislation.[34] The aims of these programs are to increase public awareness about the harmful effects of sun exposure and the risk of skin cancer, change attitudes about the social norms related to sun protection and tanned skin, and decrease the incidence of skin cancer and deaths related to this malignancy.[34] Recommendations for prevention of skin cancer are universal and include a variety of simple strategies to minimize exposure to UV rays:[34]

- Avoid direct exposure to the sun between the hours of 10 AM to 4 PM, when UV rays are most intense.
- Wear hats with a broad enough brim to shade the face, ears, and neck.
- Wear protective clothing (especially tightly woven apparel) that covers as much as possible the arms, legs, and torso.
- Cover skin with a sunscreen lotion with a skin protection factor (SPF) of at least 15, protecting against UV radiation (both UVA and UVB).
- Reapply sunscreens every 2 hours (especially if sweating or swimming).
- Avoid sun lamps and tanning beds, which provide an additional source of UV radiation.
- Seek shade when outdoors.

The use of chemical sunscreen is only one of many strategies, and it should not be the sole agent used for cancer prevention. The lay public should be warned not to use sunscreen with a higher SPF with the intent to extend the duration of exposure because it is observed that DNA damage can occur long before sunburn appears, and the long term-effects of increased sun exposure are not known.[35] Sunscreen protective agents have been proven only to reduce the risk of actinic keratosis and SCC. There is no convincing evidence that sunscreen application has protective effect against BCC or MM.[35]

Routine self-examination of the skin is a method in which individuals can take responsibility for identifying MM early when it is curable. Pamphlets and online information describing the method of skin self-examination are available from agencies such as the American Cancer Society (www.cancer.org), the American Academy of Dermatology (www.AAD.org), and the Skin Cancer Foundation (www.skincancer.org). Patients should be given the following instructions for doing total skin self-examination:[36]

- Make sure that you have good lighting, a full-length mirror, and a hand-held mirror.
- Your fingers, spaces between your fingers, fingernails, palms, backs of your hands, forearms, upper arms, and nails should be examined.
- Examine the entire front of your body in a full-length mirror. Look at your eyes, lips, hairline, chest, abdomen, pubic area, thighs, and lower legs. Lift your arms over your head and examine the right and left sides of your body.
- Turn around and look at the backs of your legs, buttocks, and back. Use a hand-held mirror angled to see in the full-length mirror to examine your ears, neck, scalp, back, and buttocks.
- Sitting on a chair, look on the insides of your legs, feet, toes, toenails, spaces between the toes, and soles of your feet.

Secondary Prevention of Skin Cancer

Secondary prevention of skin cancer involves early detection of premalignant cancers for early intervention with the hope that it will reduce mortality and increase cure. Skin cancer screening consistently identifies MMs that are, on average, thinner than those found during usual care. Unfortunately, at this time, there is no evidence that skin cancer screening reduces morbidity or mortality.[37] Given this lack of evidence for a beneficial effect of skin cancer screening, recommendations vary with different agencies. The American Cancer Society recommends skin examination as part of cancer-related check-ups every 3 years for people between 20 and 40 years of age and on a yearly basis for those over 40 years of age. The American College of Preventive Medicine recommends total-body skin examination only in high-risk individuals. High-risk individuals are defined as those with a family or personal history of skin cancer, predisposing phenotypic characteristics, increased occupational or recreational exposure to sunlight, or clinical evidence of precursor lesions. The National Institutes of Health Consensus Panel recommends screening for MM as part of routine primary care.[37]

Surgery

❹ *Surgery is the primary treatment modality for NMSC and MM.* Surgical approaches for skin cancer are divided into two different categories: (1) superficial ablative techniques that include *electrodesiccation and curettage (ED&C)* and *cryotherapy* and (2) full-thickness ablative techniques that include *primary surgical excision* and *Mohs' micrographic surgery*.[38]

Superficial Ablative Procedures

Electrodesiccation and curettage (ED&C) is a simple, cost-effective technique that requires minimal equipment for ablating NMSC. The curette is either an oval, semisharp, spoon-shaped instrument or an open ring connected to a handle that is available in many sizes to allow the physician to deal with different tumor dimensions. Malignant tissue usually is softer and more friable than normal skin, and the curette is designed to cut through the abnormally soft or friable tissue with minimum force so that the diseased tissue can be selectively removed. Electrodesiccation involves the application of high voltage, low current to the skin, causing drying or desiccation of the tissue. Electrodesiccation usually is performed first, followed by curettage. ED&C is most appropriate for well-defined superficial lesions that are not located in areas with increased risk for metastasis. It is generally well tolerated, but it does produce a large scar and should not be performed on sites where cosmetically unattractive scars are unacceptable.[5] This procedure is contraindicated in tumors that are recurrent, larger than or equal to 2 cm, extending into subcutaneous fat, in high-risk sites, or aggressive subtypes of BCC such as metatypical or morpheaform BCC.[38]

Cryotherapy is a procedure used primarily for smaller, low-risk NMSCs with clearly defined margins. It involves delivering liquid nitrogen at subzero temperatures as a spray or with a supercooled metal probe to destroy the malignant tissue.[5] It is contraindicated in metatypical or morpheaform BCC, in tumors that are invasive or recurrent, in hair-bearing skin that is susceptible to cryotherapy-induced alopecia, or in tumors with poorly defined borders. Cryotherapy is a cost-effective treatment that is easy for clinicians to deliver, but the recurrence rate is high with this procedure.[5]

Full-Thickness Ablative Procedures

Primary excision of the tumor is the most common treatment option for most MMs and a large percentage of NMSCs. Surgical excision involves surgical removal of the cancer along with a margin of normal tissue surrounding the tumor. Obtaining negative surgical margins is critical for cure and decreasing the risk of tumor recurrence. The appropriate margin of resection is not clear and depends on the tumor size, degree of differentiation, and invasion of surrounding structures. For lesions that are less than 2 cm in diameter, a minimum margin of 4 mm probably is adequate.[39] See Table 94–4 for margin recommendations depending on the tumor size.

Mohs' micrographic surgery (MMS) is a surgical technique performed by surgeons trained in this procedure for the removal of both NMSC and MM.[5] The goal of this therapy is complete removal of the cancer with preservation of as much surrounding normal tissue as possible. This procedure is preferred for high-risk or cosmetically sensitive areas such as the

face, ears, or hands. MMS involves careful dissection, staining, and anatomic mapping of the tumor specimen. Sections of the tumors are frozen and assessed immediately under the microscope in the operating theater. If residual tumors are detected microscopically in the frozen section, additional tissue is excised where the residual tumor is found. This process is repeated until a tumor-free margin is attained.[5] MMS conserves normal tissue for preservation of function and cosmesis. It is, however, a tedious procedure and requires exceptional skill on the part of the surgeon.[5]

Radiation

Radiation is not standard therapy for the treatment of skin cancer; however, there are circumstances in which radiation may be preferred. It is used as adjunctive therapy after surgical resection for patients with head and neck MM with metastasis to regional lymph nodes.[40] Radiation is also indicated for patients with unresectable metastases or brain metastases or for palliation of symptoms from metastases.[40] Older patients or patients who are poor candidates for surgery may be offered radiation as an option.[40] Radiation offers good cosmetic results,

Patient Encounter, Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH
- Hypertension, currently controlled
- Gastroesophageal reflux disease

FH
No known family history of cancer; specifically, no NMSC, MM, or hereditary dysplastic nevus syndrome.

SH
Patient is a retired. His sun-exposure history is as described in Patient Encounter, Part 1.

Meds
- Hydrochlorothiazide 25 mg PO once daily
- Famotidine 20 mg PO twice daily

ROS
No changes in vision, headaches, SOB, cough, fever, nausea, vomiting, diarrhea

PE
- **VS:** BP 126/84, P 80, RR 16, T 37°C (98.6°F), ht 68 in (173 cm), wt 72 kg (158 lb)
- **Skin:** Fair complexion, multiple scattered nevi, apparent shoulder wound
- **HEENT:** PERRLA, EOMI, sclera nonicteric, nose and throat clear without exudates or lesions
- **Neck and lymph nodes:** Supple, no lymphadenopathy
- **Lungs:** CTA bilaterally
- **CV:** RRR without murmurs
- **Abdomen:** Soft, nontender, nondistended, no hepatosplenomegaly
- **Exts:** No cyanosis, clubbing, edema
- **Neuro:** Alert and oriented × 3. Cranial nerves II–XII are intact, nonfocal.
- **Labs:** Within normal limits
- **CT scan of chest, abdomen and pelvis:** Negative
- **Chest x-ray:** Negative

Treatment
KM underwent surgical resection of the primary tumor, and an SLN biopsy was positive for lymph node involvement. A lymphadenectomy was performed. After extensive discussion with his oncologist, the decision was made to start KM on interferon-α2b.

- Given this additional information, what is KM's stage of malignant melanoma?
- What is the goal of therapy for KM?
- What are the treatment options for KM after surgery?
- What data support the use of high-dose interferon-α2b in KM?

but it requires multiple visits over the course of several months, making it inconvenient for patients.[38] In the treatment of NMSC, radiation results in poorer cosmetic outcomes than surgery or electrodesiccation and curettage.[17] Disadvantages of radiation include radiation-induced dermatitis, high cost, and the increased risk of secondary malignancy, including SCC and BCC.[17]

Stereotactic Radiosurgery

Stereotactic radiosurgery (SRS) is a local treatment option for brain metastases that delivers high doses of focused ionizing external-beam radiation to a well-defined target area in one session of radiation therapy.[41] This technique maximizes the dose of radiation to the tumor with a rapid dose falloff outside the target area, resulting in sparing of the surrounding nontarget normal tissue. SRS is limited to tumor volumes of less than 3 cm and for the treatment of no more than three lesions. Brain metastasis is an ideal target for SRS because of its small size, spherical shape, and minimal invasion of surrounding tissue. SRS is more convenient than surgery because it is performed as an outpatient procedure, and multiple lesions may be treated simultaneously.[41]

Treatment Options for MM (Fig. 94–3)

Stage I and IIA MM

The primary treatment modality for *carcinoma in situ* (stage I and IIA cutaneous MM) is surgical excision of the tumor.[38] The 5-year survival rates for patients with stage I and II tumors are 78% to 95%.[31] Achieving adequate surgical margins for the primary tumor is important in preventing local recurrence and improving overall survival. The thickness of the MM dictates the extent of the surgical margin[39] (see Table 94–4). For tumors that are greater than 1 mm, or if the tumor is less than 1 mm but has ulceration, it is recommended that an SLN biopsy be performed to rule out occult nodal metastasis.[31] There is no recommendation for systemic therapy in patients with stage I or IIA MM.

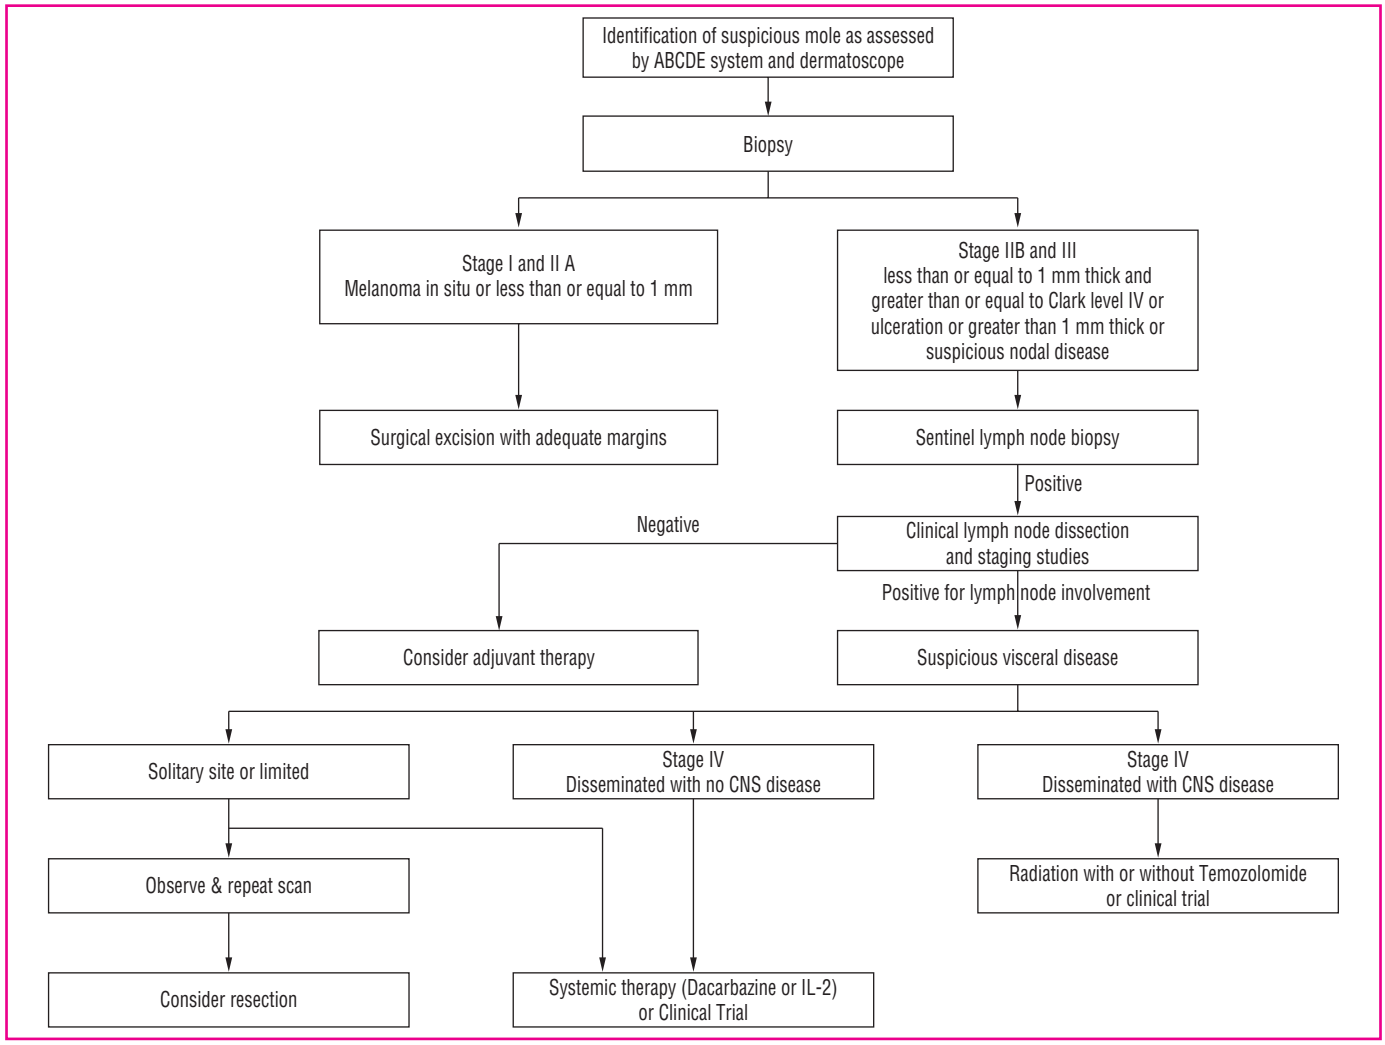

FIGURE 94–3. Algorithm for management of cutaneous melanoma.[58]

Stage IIB, IIC, and III MM (High-Risk MM)

❺ *Excision of the tumor with clear margins is the primary treatment modality for stage IIB and IIC. In addition to surgical excision of the primary tumor site, removal of the involved lymph node chain, a lymphadenectomy, is the standard treatment for stage III MM.*[38] *Patients at these stages are considered to be high risk because of their potential for recurrence and distant metastases.* The role of adjunctive immunotherapy after surgery to decrease the incidence of recurrence for high-risk melanoma is controversial.

Interferon-α2b for High-Risk MM

Interferon-α2b has diverse mechanisms of action, including antiviral activity, impact on cellular metabolism and differentiation, and antitumor activity.[42] The antitumor activity is due to a combination of direct antiproliferative effect on tumor cells and indirect immune-mediated effects.[42] Interferon-α2b is currently approved by the Food and Drug Administration (FDA) as **adjuvant therapy** for patients who are free of disease after curative surgical resection but are at high risk of MM recurrence. This includes patients with bulky disease or regional lymph node involvement such as stage IIB, IIC, or III disease.[43] ❻ *It is controversial if interferon-α2b (IFN) should be offered as adjuvant therapy for every high-risk MM patient. The reason is because clinical trials with different doses of IFN have not proved definitively that IFN improves overall patient survival.*

The doses of IFN used in clinical trials can be classified into three groups: high-dose (HDI), intermediate-dose (IDI), and low-dose (LDI) interferon (Table 94–6). Data from many clinical trials assessing LDI in patients with high or intermediate risk of recurrence did not demonstrate an impact on overall survival, and it is unclear if disease-free survival is improved.[44–46] Therefore, at this time, LDI cannot be considered efficacious as adjuvant therapy for high-risk MM. There are several ongoing trials with IDI and a trial evaluating the use of a slow-release pegylated form of interferon (polyethylene glycol–Intron or PEG-Intron). Until results for these studies are mature, IDI and PEG-Intron cannot be recommended as adjuvant therapy for patients with high-risk MM.[47]

In the evaluation of HDI for high-risk MM, data from a pooled analysis of four major clinical trials that randomized patients to either HDI or observation recently became available. The results showed improved relapse-free survival, with an approximate 10% reduction in the risk of recurrence, but no effect on overall survival in patients receiving HDI.[48] A pooled analysis of several high-dose IFN trials and a trial comparing HDI with vaccine (E1694) also confirmed a reduction in the risk of recurrence with HDI without significant improvement in overall survival.[49,50]

HDI has substantial side effects (Table 94–7) and is an expensive therapy. The constellation of side effects associated with the administration of IFN can be divided into acute and chronic manifestations and categorized into four major side-effect groups: constitutional, neuropsychiatric, hematologic, and hepatic.[42] In the acute setting, the constitutional symptoms of fevers, chills, rigors, and myalgia, along with headache, nausea, and vomiting, usually occurs after initial dosing of IFN and last up to 8 hours.[51] Tolerance may develop with these symptoms. Treatment breaks, however, even for as short as a few days, result in redevelopment of these acute side effects.[42] Neutropenia and elevated liver enzymes may occur acutely and at anytime during chronic administration. Frequent monitoring of hematologic parameters and liver function tests is recommended. The chronic symptoms of IFN include fatigue (70%–100% of patients), anorexia (40%–70%), and neuropsychiatric symptoms (up to 30%).[42] The chronic symptoms do not exhibit tolerance, worsen with continued therapy, and are dose-related. However, most IFN-related toxicities are manageable with appropriate supportive care. The most common side effects and recommendations for monitoring and treatment of these side effects are listed in Table 94–7. It is very important to educate patients on the side effects to expect and the interventions that are available to minimize the toxicities in order to reassure the patient.

The clinical dilemma in the use of HDI as adjuvant therapy for high-risk MM patients becomes: Is the benefit of preventing recurrence in only a small portion of patients without much improvement in overall survival worth the risk of considerable disabling toxicity? Given the modest efficacy, significant toxicity, and considerable expense with HDI therapy, which MM patient at risk for recurrence should receive HDI as adjuvant therapy? The answer possibly may be addressed by using the following decision rules proposed by Kilbridge and colleagues.[47] The intent of these rules is to assist clinicians and

TABLE 94–6. Immunotherapy Dosing [a,38]

Interferon Regimes Used in Clinical Trials	
High dose (HDI)	20 million units (MU)/m^2 intravenously (IV) daily × 5 days/week for 4 weeks, followed by 10 MU/m^2 subcutaneously (SQ) 3 times/week for 48 weeks
Intermediate dose (IDI)	10 MU SQ × 5 days/week for 4 weeks, followed by 10 MU SQ 3 times/week for varying durations
Low dose (LDI)	3 MU SQ 3 times/week for varying durations 1 MU SQ every other day for 1 year
Interleukin 2 Dosing Regimens[a 53, 54]	
IL-2 600,000 or 720,000 units/kg by 15-minute infusion every 8 hours for 14 consecutive doses over 5 days as tolerated.	
Chemotherapy[a, 56]	
Dacarbazine 250 mg/m^2 per day intravenous, days 1 to 5, every 21 days	
Temozolomide 150 to 200 mg/m^2 per day by mouth × 5 days, every 28 days	

[a]The doses presented here are general. Clinicians should refer to clinical trials to determine the specific dose based on the regimen the patient is receiving.

TABLE 94–7. Interferon-α2b Toxicities

Common Acute Toxicity	Management
Fever, rigors, chills, malaise headaches, myalgia	Acetaminophen (APAP). NSAID if APAP is not effective. Meperidine for severe chills and rigors. Bedtime administration.
Nausea, emesis	5-HT_3 antagonist, prochlorperazine, metoclopramide, fluids
Neutropenia	Weekly complete blood count; reduce dose by 30–50%
Hepatic enzyme elevation	Liver function tests (LFTs) weekly; withhold treatment until LFTs normalize; restart at 30–50% dose reduction; reversible on dose reduction or cessation.
Cutaneous—alopecia, transient, mild rashlike reaction	Interferon is contraindicated in patients with psoriasis because exacerbation of psoriasis has been noted during IFN therapy.

Common Chronic Toxicity	Management
Fatigue, weight loss, anorexia	Light exercise, good nutritional intake—small frequent meals; oral supplementation; noncaffeinated fluid intake; stress management technique; **pharmacologic intervention**—megesterol acetate, methylphenidate, to help with either fatigue or anorexia.
Depression, cognitive dysfunction. Rare—mania, mood instability	Psychiatric history prior to therapy and reassess every 4 to 6 weeks; antidepressants—SSRIs, mood stabilizer, gabapentin.
Thyroid dysfunction	Initial thyroid function test (TSH), then monthly; if three sequential values are stable or normal, bimonthly or quarterly TSH.

patients in making decisions regarding HDI. The patient may be treated with HDI if he or she agrees with the statements "If I had a serious disease, I would gladly accept feeling lousy for a year if it improved my chances of having a longer period without the disease" and "I would put up with the side effects of HDI treatment only if it decreased the chance of MM returning in 5 years time by at least *x*%," and the answer for *x* should be 10% or less.[47] Other factors that should be considered in the decision include the patient's comorbidities and/or contraindications to receiving HDI.[47] Information covered during the discussion should include the fact that HDI is the only agent showing activity against MM in the adjuvant setting and that it prolongs 5-year relapse-free survival by approximately 10% at the expense of significant but reversible toxicity.[47] If the patient is eligible, encouragement to participate in clinical trials designed to address the issues of survival, quality of life, and treatment costs is also reasonable.[47]

Stage IV MM

The prognosis for patients diagnosed with stage IV MM varies with the location of the metastases and the number of metastatic sites. Treatment options for stage IV metastatic MM include surgical excision of the lesion and radiation therapy for palliation of symptoms. ❼ *Surgical excision of the tumor is not curative for metastatic MM, and the primary goal of therapy is local control of the disease and relief of identifiable symptoms.* In highly selected patients, such as those with good performance status, less aggressive tumor biology, prolonged period of disease-free interval from the time of primary tumor treatment, and limited disease that is contained within

Patient Encounter, Part 3: Create a Care Plan

Create a care plan while KM is receiving interferon-α2b therapy. Your plan should include (1) the goal of therapy with interferon-α2b and (2) a plan related to dealing with the side effects to expect from this therapy.

What supportive measures should be used to minimize side effects?
What laboratory parameters need to be monitored?
What are the indications to discontinue or hold therapy?
When may the therapy be restarted after the doses were held?
What are the pharmacologic and nonpharmacologic recommendations for managing side effects?
How frequently should KM be monitored while on therapy?
Be able to discuss with the patient the following for interferon-α2b:

- The differences between acute and chronic side effects
- The side effects that the patient will develop tolerance to
- The best time of the day to administer the drug
- The importance of keeping regular follow-up appointments to monitor for long-term side effects of the therapy and draw blood for routine lab tests
- Reassure the patient that therapy may be stopped at any time if side effects are intolerable

- What is the follow-up plan for KM after he has completed therapy with interferon-α2b?

a single location, complete surgical resection results in a median survival of 2 years and a 5-year survival rate of 10% to 25%.[52] For most other patients with stage IV MM, unfortunately, the survival rate is measured in months rather than years, with overall median survival of 5 to 8 months and a 5-year survival rate of less than 5%.[52]

Interleukin 2 for Stage IV MM

❽ *Interleukin 2 (IL-2) therapy is approved by the FDA for the treatment of metastatic MM, and it is a reasonable option for patients with this stage of the disease.* IL-2 does not have a direct toxic effect on MM cells. It indirectly causes tumor cell lysis by proliferating and activating cytotoxic T lymphocytes.[53] The overall objective response rate for patients with metastatic MM receiving high-dose IL-2 is 16%, with a complete response in 6% of patients and a partial response in 10% of patients.[54] The median duration of response is 8.9 months for all responding patients and 5.9 months for patients with a partial response.[54] The median duration of complete response has not been reached but is at least 59 months. Disease progression is not observed in any patient responding for longer than 30 months.[54] Good performance status and no prior systemic therapy are the only prognostic factors that are associated with response, with objective response rate being twice that of patients with poor performance status and who received prior chemotherapy.[55] The site of metastasis did not influence response, and patients had responses in all organ sites, including lung, liver, adrenal, bone, liver, kidney, and spleen.[55] The data are encouraging because for the small number of patients who responded to therapy, the effect is of a long duration, and some patients may be considered to be cured of the disease (Refer to Table 94–6 for an example dosing regimen).

High-dose IL-2 therapy is associated with severe toxicities.[55,56] All patients will experience a flulike syndrome that consists of fever [reaching as high as 39–40°C (102.2–104°F)], chills, myalgia, and malaise and occurs 3 to 6 hours after the first injection of IL-2.[56] The most common cardiovascular toxicities are hypotension and capillary leak syndrome (CLS). The cause for this is the release of nitric oxide from endothelial cells, resulting in vasodilation and increased permeability of the blood vessels.[56] The early signs and symptoms of CLS include hypotension and tachycardia, which are observed 2 hours after the first dose of IL-2. Within the first 8 hours of IL-2, there is decreased urine output owing to hypotension, as well as decreased intravascular volume.[56] Pulmonary congestion, manifested as progressive shortness of breath, is also attributed to the increased vascular permeability from CLS. Total-body edema and consequent weight gain, between 5 and 10 kg, are also due to CLS.[56] The other common side effects of IL-2 are gastrointestinal, neuropsychiatric, hematologic, and dermatologic.[56] Table 94–8 lists the most common side effects experienced by patients receiving IL-2 therapy and recommendations for management. Patients receiving IL-2 may be managed on the oncology unit as long as telemetry is available; however, it is important that all medical staff involved with the care of patients receiving IL-2 be well educated on the side effects to monitor for and are well trained in management of critical-care issues such as hypotension.[55]

Chemotherapy for Stage IV MM

Dacarbazine, an alkylating agent, is the most active single-agent chemotherapy against MM, achieving response rates of 15% to 25%.[57] It is the only chemotherapy agent approved by the FDA for the treatment of metastatic MM. A recent phase III clinical trial in patients with advanced metastatic MM demonstrated a response rate of 12% and stable disease in 16% of patients treated with dacarbazine alone.[57] The response duration was not long-standing, with a median survival time of 6.4 months.[57] Nausea and vomiting are the most common side effects of dacarbazine. Combining dacarbazine with other chemotherapy agents with activity against MM in single-institution phase 2 trials resulted in response rates of between 30% and 50%.[58] Two phase III clinical trials assessing the CVD (cisplatin, vinblastine, and dacarbazine) regimen and the Dartmouth regimen (carmustine, cisplatin, dacarbazine, and tamoxifen) versus single-agent dacarbazine showed that there was a trend toward improved response rate, but the results were not statistically significant.[51] Furthermore, there was no significant survival advantage over single-agent dacarbazine alone, but toxicity was greater with the combination chemotherapy.[53] Therefore, combination chemotherapy is not a standard of care for stage IV MM.

Biochemotherapy for Stage IV MM

Clinical trials combining chemotherapy and immunotherapy are based on the observations of independent clinical activity of each of these treatment modalities in treating metastatic MM. This combination is known as *biochemotherapy.* Only one phase III clinical trial showed significant improvement in response rate, time to progression, and median survival favoring the biochemotherapy arm versus the combination-chemotherapy arm.[59] Currently, the use of biochemotherapy is not justified outside a clinical trial in patients with stage IV MM.[53,58,60]

In summary, systemic therapy for stage IV MM is controversial. ❾ *Combination chemotherapy and biochemotherapy increase toxicity significantly without offering overall survival benefit; thus they are not the standard of care for stage IV MM.* Both high-dose IL-2 and dacarbazine are approved for the treatment of stage IV MM. High-dose IL-2 may be preferred in patients with a good performance status. Enrollment in a clinical trial and best supportive care are also reasonable alternatives.[61]

MM with Brain Metastases

Radiation for Brain Metastases

One of the most common sites of metastasis for MM is the brain, and MM is reported to be the third most common cause

TABLE 94–8. Interleukin 2 Toxicities[53,54]

Toxicity (% of Patients)	Management
Cardiovascular Toxicity	
Hypotension (64%), supraventricular tachycardia (17%)	Discontinue antihypertensive medications IV fluids to maintain systolic blood pressure greater than 80–90 mm Hg or vasopressor support with an α-agonist such as phenylephrine as indicated.
Gastrointestinal	
Vomiting and diarrhea (55%), nausea (24%), stomatitis (14%)	5-HT_3 antagonist, prochlorperazine for emesis (avoid corticosteroids), H_2 blocker for gastritis, antidiarrheal as needed (loperamide, diphenoxylate/atropine, codeine).
Neurologic	
Confusion (30%), somnolence	Haldol for agitation, lorazepam for anxiety, temazepam or zolpidem for insomnia.
Pulmonary	
Dyspnea (31%), pulmonary edema, and adult respiratory distress syndrome	Advise smokers to quit 2 weeks before therapy; be judicious in use of IV fluids for hypotension; discontinue therapy if requiring greater than 4 L O_2 or 40% O_2 mask for saturation greater than 95%.
Hepatic	
Elevated bilirubin (51%), transaminase (39%), alkaline phosphatase	Consider discontinuing therapy if severe.
Renal	
Oliguria (49%), elevated serum creatinine (35%), anuria (8%)	Normal saline or dopamine at renal perfusion dose of 2 mcg/kg per minute for oliguria; monitor for electrolyte abnormalities and replace as indicated.
Hematologic	
Thrombocytopenia (43%), anemia (29%), leukopenia (21%)	Transfuse with packed red blood cells and platelets as needed
Skin	
Rash (27%), exfoliative dermatitis (15%), pruritus	Hydroxyzine, diphenhydramine, oatmeal powder baths, lubriderm lotion
General	
Fever and or chills (47%), malaise (34%), infection (15%)	Acetaminophen and NSAID around the clock for fever and chills; add meperidine if chills are severe; clindamycin or cefazolin to prevent infection.
Hypothyrodism	May occur in one third of patients; thyroid function tests.

of brain metastasis.[62] The incidence of brain metastasis is reported to range from 10% to 40% in clinical studies.[62] ⑩ *Treatment options for brain metastases include surgery, radiation [which includes whole-brain radiotherapy and stereotactic surgery (SRS)], or chemotherapy. The choice of therapy depends on the number of metastatic lesions, accessibility of the lesion for surgery, the presence of neurologic symptoms, and the status of extracranial disease.*

Surgery followed by whole-brain radiotherapy (WBRT) is best indicated for patients with an accessible single brain lesion and controlled or limited systemic MM.[62] Two randomized studies reported improved survival in patients treated with combination surgery and WBRT compared with WBRT alone.[62,63] For those patients with multiple metastatic brain lesions and systemic disease, surgery generally is not considered to be appropriate.[61] In some cases, however; it may be necessary to resect the one "dominant" lesion that is causing symptoms such as intracranial hypertension, seizures, hemorrhage, or other severe neurologic side effects.[62,63] SRS may be considered over surgery for patients with fewer than three metastatic central nervous system (CNS) lesions that are deep, nonsymptomatic, and less than 3 cm in size.[41] WBRT is indicated for patients with multiple (more than three) CNS metastases, surgically inaccessible lesions, and extensive systemic disease.[41] WBRT for metastatic CNS MM does not improve survival or provide a cure; however, it is effective in relieving neurologic symptoms.[41]

The median survival for patients with CNS metastasis is 3.5 months with best supportive care and corticosteroids.[40] Patients

treated with WBRT and SRS or SRS alone have a median survival of 28 to 40 weeks, and the cause of death for most of these patients is progressive extracranial disease.[62] Median survival of 5 to 12 months has been reported for surgical patients, with 1-year disease-free survival rates of 28% to 36%.[64]

Systemic Therapy for Brain Metastases

Temozolomide (TMZ) is an oral chemotherapy agent that is structurally and functionally similar to dacarbazine, and it belongs to a new class of alkylating agents known as *imidazotetrazines.* Temozolomide possesses activity against MM cells and the ability to cross the blood-brain barrier because of its lipophilicity, thus making it an ideal chemotherapy agent to be investigated for the treatment of MM with CNS metastases.[65] It is stable in the acidic pH of the stomach and is absorbed readily in the digestive tract with 100% bioavailability. Once it is in the CNS, temozolomide is hydrolyzed to the active metabolite MTIC [5-(3-dimethyl-1-triazenyl) imidazole-4-carboxamide].[65] MTIC breaks down rapidly to form the reactive methyldiazonium ion, which methylates guanine residues in the DNA molecule causing cytotoxicity. TMZ does not cause cross-linking of DNA strands, making it less toxic to hematopoetic progenitor cells in the bone marrow than the nitrosoureas, platinum compounds, procarbazine, and dacarbazine.[65]

A recent phase III clinical trial comparing single-agent TMZ with dacarbazine demonstrated that TMZ is at least as effective as dacarbazine against advanced metastatic MM without CNS involvement.[57] The role of TMZ, either alone or as combination therapy, in the prevention and treatment of MM CNS metastasis is an area of active research.[66–68] In a phase II trial involving patients who have not received prior systemic chemotherapy for the treatment of MM brain metastases, single-agent TMZ showed a response rate of 7%, stable disease in 29% of patients, and a median overall survival of 3.5 months.[69] When TMZ was administered in combination with WBRT in patients with CNS metastasis, the response rate was only 10%, with the duration of response ranging from 2 to 7 months.[66] The combination of TMZ and a biochemotherapy regimen that included cisplatin, IL-2, and interferon-α2b was evaluated in a phase II outpatient clinical trial for metastatic MM.[67] The results suggest that the rate of CNS metastasis may be decreased in patients who have either a complete or partial response owing to the addition of a CNS-active agent (TMZ).[67] Thalidomide is an agent that possesses antiangiogenic and immunomodulatory properties, and since MM metastases tend to be very vascular, they may respond to antiangiogenic therapy. In a phase II trial that combined TMZ and thalidomide for the treatment of chemotherapy-naive patients with brain metastases, a response rate of 12% was observed, with a median duration of response of 4 months.[68] In light of these promising data with TMZ, further trials are being conducted to confirm the benefit of TMZ in preventing progression or treating CNS metastases.

Treatment Options for NMSC

Surgery

Surgery is the primary treatment modality for all patients diagnosed with either BCC or SCC. Full-thickness ablative procedure is the preferred method for high-risk tumors. Low-risk tumors can be treated with superficial ablative techniques.[38] NMSC is considered to be high risk if it has any of the following features: it is recurrent, the location is at a high-risk site (e.g., mask areas of the face, lips, ears, hands, and feet), it is larger than 2 cm in diameter or greater than or equal to 4 mm in depth, it is moderately or poorly differentiated, it is fast growing, it has ill-defined borders, there is positive perineural or vascular invasion, the patient is immunosuppressed, or it is the morpheaform or metatypical sub-type of BCC.[38] If the tumor is located on the trunk or extremities, less than 2 cm in diameter and less than 4 mm in depth, well differentiated, slow growing, has well-defined borders, and is the nodular or superficial sub-type of BCC, then it is considered to be low risk.[38] The 5-year survival rate for surgical excision, electrodesiccation and curettage, and Mohs' micrographic surgery is 90% or better for NMSC.[38]

Photodynamic Therapy

Photodynamic therapy is a noninvasive treatment option for superficial BCC and SCC. This method uses a combination of a photosensitizing drug and light to cause selective damage to target tissues.[70] The sensitizer absorbs energy directly from a light source. The energy then is transferred to molecular oxygen to create an activated form of oxygen called *singlet oxygen* that reacts with cellular component to cause cell damage and death.[70] The photosensitizing agent is administered intravenously or topically. In the treatment of skin cancer, the topical agent 5-aminolevulinic acid is approved by the FDA for the treatment of actinic keratosis, and studies are evaluating its role in the treatment of BCC and SCC. 5-Aminolevulinic acid is available in the United States as a solution that is applied for 14 to 18 hours to the lesion.[71] Then the lesion is irradiated with a blue light for 5 to 20 minutes.[71] The most common side effects are a burning, stinging, or prickling sensation restricted to the area of treatment. Erythema, hypo- or hyperpigmentation, and edema at the lesion also may occur. The thickness of the tumor is a determinant of response to therapy.[71] Superficial BCC has a complete response rate of 90% to 100% compared with a response rate of 10% to 70% for nodular BCC.[17] There is no evidence of its effectiveness with SCC at present.

Imiquimod

Imiquimod is an immune response modifier that has the ability to activate acquired and innate immune response. It is a topical agent that has been shown to be effective for SCC in case reports. It has been studied more extensively in superficial and nodular BCC, with response rates of 70% to 88%.[72] The most common side effects are erythema, itching, pain, and crusting

that are mild to moderate. At this time, the optimal frequency of application, duration of treatment, and recurrence rates after long-term follow-up still need to be determined before it can be recommended as standard of care for NMSC.[72]

OUTCOME EVALUATION

The outcome of patients diagnosed with MM depends on the stage of the disease at diagnosis. The overall 5-year survival rate for patients with localized disease (stage I and IB) is the best at 89% to 95%.[31] For patients with stage IIA to IIIA disease, the 5-year survival rate is greater than 50%, ranging from 63% to 77%.[31] In patients with more advanced regional metastatic disease (stage IIIB to IIIC), the 5-year survival rate ranges from 27% to 53%.[31] Patients with stage IV distant metastatic disease have the worst 5-year survival rate at only 10% to 19%.[31] BCC and SCC have excellent outcomes, with cure rates approaching 98%.[5]

After diagnosis and treatment of skin cancer, the next crucial step in the management of this diagnosis is monitoring for recurrence. The risk of recurrence depends on the stage of the disease, and recurrences may develop even decades after the initial diagnosis. However, most recurrences materialize in the first 5 years, and the majority appear within the first 2 to 3 years following treatment.[38] The site of recurrence can be at the original site of the disease or in a different, distant anatomic location. Early detection of tumor recurrence is crucial because response rate is decreased significantly with tumor relapse.[5] Recurrences are found equally by physicians and patients, and one study demonstrated that 94% of recurrences were detected by the patient.[73] Thus it is imperative to educate patients on how to perform a total skin self-examination appropriately. Additionally, patients need to understand the importance of scheduling regular follow-up visits with the oncologist or dermatologist after the diagnosis and treatment of skin cancer. The purpose of these visits is for the clinician to monitor for new tumor appearance or recurrence of the original cancer. During the follow-up visit, the clinician will perform a total skin examination with special attention to previous biopsy and lesion sites. A palpation of the lymph nodes and careful review of system also are performed.[38]

There is no universal guideline for follow-up care for MM. The National Comprehensive Cancer Network recommends annual skin examination for all patients.[61] Educate patients with stage IA disease to have a history and physical examination every 3 to 12 months as clinically indicated and an annual skin examination for life. For stage IB to III disease, schedule a history and physical examination every 3 to 6 months for 3 years, every 4 to 12 months for 2 years, and then annually as indicated. It is optional to obtain a chest x-ray, LDH, complete blood count (CBC), and liver function tests (LFTs) every 3 to 12 months. CT scan can be obtained as indicated clinically.[61] For NMSC, educate patients to schedule follow-up visits with the oncologist after treatment every 3 months for the first year and then every 6 months thereafter for at least 5 years.[5]

Patients who received immunotherapy after stage III or IV MM may experience fatigue and other chronic side effects. Develop a plan to order laboratory tests such as LFTs, thyroid-stimulating hormone, and white blood cell count at baseline and on a weekly or monthly basis as indicated. Monitor and evaluate patients for side effects of IL-2 or interferon-α2b, and educate patients on what to expect and how the side effects will be managed. Assess the patients' psychological, physical, and social functioning. Counsel patients to contact the hospital's social service department or the American Cancer Society for assistance in dealing with the disease emotionally, and recommend that patients consider attending support group meetings or talking to a counselor if or before they become overwhelmed with the diagnosis.

Patient Care and Monitoring

1. Obtain a thorough patient medication history, both prescription and nonprescription, to prevent drug interactions with the current therapy the patient is receiving.
2. Obtain the appropriate baseline laboratory tests, and determine a time interval for reevaluation of specific laboratory tests to determine toxicity.
3. Provide education on the side effects of therapy.
   - What to administer/take to prevent side effects
   - When to administer/take the medication to decrease side effects
   - Nonpharmacologic recommendations to minimize side effects
   - Drugs that may interact with therapy
   - Lab tests that need to be monitored on a regular basis
   - What are the parameters for discontinuing or holding therapy?
   - If therapy is to be reinitiated, what should the new dose of therapy be?
4. Assess the patient for adverse drug reactions and drug-drug interactions.
5. Educate the patient on the signs and symptoms of infection.
6. Assess for changes in the patient's quality of life owing to side effects of drug therapy.
7. Educate the patient on measures that should be undertaken to limit sun exposure and prevent skin cancer.
8. Educate the patient on how to do skin self-examination for suspicious moles.
9. Educate the patient on follow-up recommendations after treatment for skin cancer is completed.

ABBREVIATIONS

BCC: basal cell carcinoma
CLS: capillary leak syndrome
CNS: central nervous system
CTL: cytotoxic T lymphocyte
FDA: Food and Drug Administration
HDI: high-dose interferon-α2b
IDI: intermediate dose interferon-α2b
IFN: interferon-α2b
IL-2: interleukin 2
LDI: low-dose interferon-α2b
MM: malignant melanoma
MMS: Mohs' micrographic surgery
NMSC: nonmelanoma skin cancer
SCC: squamous cell carcinoma
SLN: sentinel lymph node
SRS: stereotactic radiosurgery
SSRI: selective serotonin reuptake inhibitor
TMZ: temozolamide
UV: ultraviolet
WBRT: whole-brain radiation therapy

95 Hematopoietic Cell Transplantation

Jeannine S. McCune

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Explain the rationale for using hematopoietic cell transplant (HCT) to treat cancer.
2. Compare the different types of HCTs, specifically (a) the types of donors (i.e., autologous and allogeneic), (b) the source of hematopoietic cells (i.e., umbilical cord, peripheral blood progenitor cells, and bone marrow), and (c) the type of preparative regimen (i.e., myeloablative and nonmyeloablative).
3. List the nonhematologic toxicity to high-dose chemotherapy used in myeloablative preparative regimens, specifically busulfan-induced seizures, hemorrhagic cystitis, gastrointestinal toxicities, and sinusoidal obstruction syndrome.
4. Develop a plan for monitoring and managing engraftment of hematopoiesis.
5. Explain graft-versus-host disease (GVHD).
6. Recommend a prophylactic and treatment regimen for graft-versus-host disease (GVHD).
7. Choose an appropriate regimen to minimize the risk of infectious complications in HCT patients.
8. Evaluate the long-term health care of hematopoietic cell transplant (HCT) survivors.

Key Concepts

❶ Hematopoietic cell transplantation (HCT) is a procedure used mainly to treat hematologic malignancies via high-dose chemotherapy and/or a graft-versus-tumor effect.

❷ An autologous HCT involves the infusion of a patient's own hematopoietic cells and allows for the administration of higher doses of chemotherapy, radiation, or both to treat the malignancy. Infusion of another's hematopoietic cells is an allogeneic HCT; these cells can be from donors related or unrelated to the recipient.

❸ Umbilical cord blood, peripheral blood progenitor cells (PBPC) and bone marrow can serve as the source of hematopoietic cells. The optimal cell source differs based on the donor and recipient characteristics but has not been clearly identified for all patients.

❹ A myeloablative preparative regimen involves the administration of sublethal doses of chemotherapy to the recipient. The recipient will not regain his or her own hematopoiesis (i.e., graft failure or graft rejection) and will be at risk for substantial life-threatening nonhematologic toxicity.

❺ A nonmyeloablative preparative regimen is less toxic than a myeloablative regimen in hopes of being able to offer the benefits of an allogeneic HCT to more patients. A nonmyeloablative HCT is based on the concept of donor immune response having a graft-versus-tumor effect.

❻ Nonhematologic toxicity differs based on the preparative regimen administered.

❼ Engraftment is the reestablishment of functional hematopoiesis. It is commonly defined as the point at which a patient can maintain a sustained absolute neutrophil count (ANC) of greater than 500 cells/mm^3 (0.5×10^9/L) and a sustained platelet count of greater 20,000/mm^3 (20×10^9/L) lasting for 3 or more consecutive days without transfusions.

❽ Graft-versus-host disease (GVHD) is caused by the activation of donor lymphocytes leading to immune damage to the skin, gut, and liver in the recipient. An immunosuppressive regimen is administered to prevent GVHD in recipients

of an allogeneic graft; this regimen is based on the type of preparative regimen and the source of the graft.

❾ Recipients of HCT are at higher risk of bacterial, viral, and fungal infections and usually receive a prophylactic or preemptive regimen to minimize the morbidity and mortality owing to infectious complications.

❿ Long-term survivors of HCT should be monitored closely, particularly for infections and secondary malignant neoplasms.

❶ *Hematopoietic cell transplantation (HCT) is a procedure used mainly to treat hematologic malignancies via high-dose chemotherapy and/or a graft-versus-tumor effect.* An essential component of this procedure is the infusion of hematopoietic cells into the recipient to treat disease and/or restore normal hematopoiesis and lymphopoiesis. HCT developed from allogeneic bone marrow transplant (BMT), which involved administration of a high-dose myeloablative preparative regimen followed by true "transplantation" of bone marrow from one individual to another. Bone marrow contains pluripotent stem cells and postthymic lymphocytes, which are responsible for, respectively, long-term hematopoietic reconstitution, immune recovery, and its associated graft-versus-host disease (GVHD).[1] Subsequently, the dose-intensity concept for cancer treatment was expanded to using myeloablative preparative regimens followed by autologous HCT.

The type of HCT performed depends on a number of factors, including type and status of disease, availability of a compatible donor, patient age, performance status, and organ function. In addition to bone marrow, hematopoietic cells may be obtained from the peripheral blood progenitor cells (PBPCs) and umbilical cord blood. The essential properties of the hematopoietic cells are their ability to engraft, the speed of **engraftment,** and the durability of engraftment.[1]

Examples of diseases treated with HCT are listed in Table 95–1. **Autologous HCT,** or infusion of a patient's own hematopoietic cells, allows for the administration of higher doses of chemotherapy, radiation, or both to treat the malignancy or autoimmune disorder. In this setting, the hematopoietic cells "rescue" the recipient from otherwise dose-limiting hematopoietic toxicity. Autologous HCT is used to treat intermediate- and high-grade non-Hodgkin's lymphoma (NHL), acute myeloid leukemia (AML), multiple myeloma (MM), neuroblastoma, and relapsed or refractory Hodgkin's disease.[2] ❷ *Allogeneic HCT involves the transplantation of hematopoietic cells obtained from a different person's (termed the donor) bone marrow, peripheral blood, or umbilical cord blood to the recipient.* Unless the donor and the recipient are identical twins (referred to as a *syngeneic HCT*), they are dissimilar genetically. **Allogeneic HCT** is used to treat both nonmalignant (e.g., aplastic anemia, thalassemia major, severe combined immunodeficiency disease, Wiskott-Aldrich syndrome, Fanconi's anemia, and infantile osteopetrosis) and malignancies [e.g., AML and chronic myeloid leukemia (CML)].[2]

The infusion of hematopoietic cells follows the administration of a combination of chemotherapy and/or radiation—termed the *conditioning* or ***preparative regimen.*** ❹ *A* ***myeloablative preparative regimen*** *involves the administration of sublethal doses of chemotherapy to the recipient. The recipient will not regain his or her own hematopoiesis (i.e., graft rejection) and will be at risk for substantial life-threatening nonhematologic toxicity.* For those undergoing an autologous HCT, their hematopoietic cells must be obtained (i.e., harvested) before the myeloablative preparative regimen is administered and stored subsequently. After administration of the preparative regimen is completed, these hematopoietic cells serve as a rescue intervention to reestablish bone marrow function and avoid long-lasting life-threatening marrow aplasia that results from the myeloablative preparative regimen.[3] In the setting of an allogeneic HCT, the preparative

TABLE 95–1. Diseases Commonly Treated with HCT

	Autologous Graft	Allogeneic Graft
Cancers	Multiple myeloma Non-Hodgkin's lymphoma Hodgkin's disease Acute myeloid leukemia Neuroblastoma Germ cell tumors	Acute myeloid leukemia Acute lymphoblastic leukemia Chronic myeloid leukemia Myelodysplastic syndrome Myeloproliferative disorders Non-Hodgkin's lymphoma Hodgkin's disease Chronic lymphocytic leukemia Multiple myeloma
Other diseases	Autoimmune diseases Amyloidosis	Aplastic anemia Paroxysmal nocturnal hemoglobinuria Fanconi's anemia Thalassemia major Sickle cell anemia Severe combined immunodeficiency Inborn errors of metabolism

regimen is designed to suppress the recipient's immunity, eradicate residual malignancy, or create space in the marrow compartment. At most HCT centers, normal renal, hepatic, pulmonary, and cardiac function and age younger than 65 years are necessary for eligibility for myeloablative allogeneic HCT. A myeloablative or nonmyeloablative preparative regimen may be used with allogeneic HCT; only myeloablative preparative regimens are used for autologous HCT. Allogeneic HCT offers the potential for a graft-versus-tumor (GVT) effect in which immune effector cells from the donor recognize and eliminate residual tumor in the recipient.[4]

The recognition of GVT effect, which likely is caused by cytotoxic T lymphocytes in the donor stem cells, led to investigations with nonmyeloablative transplants (NMTs), in which less toxic preparative regimens are used in the hope of expanding the availability of HCT to recipients whose medical condition or age prohibits use of myeloablative regimens.[4]

EPIDEMIOLOGY AND ETIOLOGY

Each year, the number of allogeneic HCTs is less than the number of autologous HCTs. Worldwide, approximately 25,000 autologous HCTs and 15,000 allogeneic HCTs were performed in 2000.[5] Since 1998, the number of allogeneic HCTs reached a plateau, most likely owing to the limited availability of suitable donors, limited success to date with HLA-disparate donors, and the increasing availability of targeted therapies for diseases that traditionally were treated with HCT (e.g., imatinib for newly diagnosed chronic-phase chronic myelogenous leukemia).[5] In the year 2000, NMT represented approximately 25% of allogeneic HCTs.[5]

Autologous peripheral blood progenitor cell (PBPC) use has increased and essentially has replaced bone marrow in many transplant centers. In 2000, over 95% of autologous HCTs in adults and 80% in children used PBPCs as the source of hematopoietic cells.[5] Autologous HCT is used to treat a variety of malignancies; non-Hodgkin's lymphoma (NHL) and multiple myeloma are the most common indications for this procedure and represent over one-third of all autologous HCTs.[5] Autologous HCT circumvents the need for histocompatible donors, is associated with lower mortality, and is not restricted by age to patients younger than 50 years.[6] The use of allogeneic PBPCs is increasing; in the year 2000, 40% of allogeneic HCTs performed worldwide used PBPCs as the source of hematopoietic cells rather than bone marrow.[5]

PATHOPHYSIOLOGY

For an allogeneic HCT, the recipient and the donor are dissimilar genetically unless they are identical twins (referred to as a *syngeneic HCT*). The tissue transplanted is immunologically active, and thus there is potential for bidirectional graft rejection.[7] In the first scenario, cytotoxic T cells and natural killer (NK) cells belonging to the host (recipient) recognize minor histocompatibility (MHC) antigens of the graft (donor hematopoietic cells) and lead to a rejection response. In the second scenario, immunologically active cells in the graft recognize host MHC antigens and elicit an immune response. The former is referred to as *host-versus-graft disease* and the latter as **graft-versus-host disease (GVHD).** Host-versus-graft effects are more common in solid-organ transplantation. When host-versus-graft effects occur in allogeneic HCT, they are referred to as *graft failure* or *rejection,* which results in ineffective hematopoiesis (i.e., adequate ANC and/or platelet counts were not obtained). ❼ *Engraftment is defined as the point at which a patient can maintain a sustained absolute neutrophil count (ANC) of greater than 500 cells/mm^3 (0.5 × 10^9/L) and a sustained platelet count of greater than or equal to 20,000/mm^3 (20 × 10^9/L) lasting greater than or equal to 3 consecutive days without transfusions.*[8] Therefore, an essential first step for patients eligible for HCT is finding a human leukocyte antigen (HLA)–compatible graft with an acceptable risk of graft failure and GVHD. GVHD is caused by the activation of donor lymphocytes, leading to immune damage in the recipient.

Histocompatibility

Histocompatibility differences between the donor and the recipient necessitate immunosuppression after an allogeneic HCT because considerable morbidity and mortality are associated with graft failure and GVHD.[9] Rejection is least likely to occur with a syngeneic donor, meaning that the recipient and host are identical (monozygotic) twins. In patients without a syngeneic donor, initial HLA typing is conducted on family members because the likelihood of complete histocompatibility between unrelated individuals is remote. Siblings are the most likely individuals to be histocompatible within a family. The chance for complete histocompatibility occurring in an individual with only one sibling is 25%. Approximately 40% of patients with more than one sibling will have an HLA-identical match. Having a matched sibling donor is no longer a requirement for allogeneic HCT because improved immunosuppressive regimens and the National Marrow Donor Program have allowed an increase in the use of unrelated or related matched or mismatched HCTs.[10] The use of alternative sources of allogeneic hematopoietic cells, such as related donors mismatched at one or more HLA loci or phenotypically (i.e., serologically) matched unrelated donors, has been evaluated.[10] Establishment of the National Marrow Donor Program has helped to increase the pool of potential donors for allogeneic HCT.[10] Through this program, an HLA-matched unrelated volunteer donor might be identified. Recipients of an unrelated graft are more likely to experience graft failure and acute GVHD relative to recipients of a matched-sibling donor.[11] Thus work is ongoing to identify factors that predict for graft failure or GVHD to improve the availability and safety of unrelated-donor transplants.[12]

Determination of histocompatibility between potential donors and the patient is completed before allogeneic HCT. Initially, HLA typing performed using blood samples and compatibility for class I MHC antigens (i.e., HLA-A, HLA-B, and HLA-C) is determined through serologic and DNA-based testing methods.[13] In vitro reactivity between donor and recipient also can be assessed in mixed-lymphocyte culture, a test used to measure compatibility of the MHC class II antigens (i.e., HLA-DR, HLA-DP, HLA-DQ).[13] Currently, most clinical and research laboratories are also performing molecular DNA typing using polymerase chain reaction methodology to determine the HLA allele sequence.[13,14]

The preparative regimen or GVHD prophylaxis may be altered based on the mismatch between the donor and the recipient. The risk of graft failure decreases with better matches such that those with a class I (i.e., HLA-A, -B, or -C) antigen mismatch have the highest risk of rejection, whereas those with just one class I allele mismatch have a minimal risk. Graft failure does not appear to be associated with mismatch at a single class II antigen or allele.[14] GVHD, both acute and chronic, and survival also have been associated with disparity for class I and II antigens and alleles.[15,16]

Autologous hematopoietic stem cells are obtained (or "harvested") from bone marrow or peripheral blood. The technique for harvesting autologous hematopoietic cells depends on the anatomic source (i.e., bone marrow or peripheral blood). A surgical procedure is necessary for obtaining bone marrow. Multiple aspirations of marrow are obtained from the anterior and posterior iliac crests until a volume with a sufficient number of hematopoietic cells is collected (i.e., 600–1200 mL of bone marrow). The bone marrow then is processed to remove fat or marrow emboli and usually is infused intravenously into the patient like a blood transfusion.

The shift to the use of PBPCs over bone marrow for autologous HCT is primarily because of the more rapid engraftment and decreased health care resource use. Because the harvest occurs before administering the preparative regimen, autologous hematopoietic cells must be cryopreserved and stored for future use.

Transplantation with PBPCs essentially has replaced bone marrow transplantation (BMT) as autologous rescue after myeloablative preparative regimens.[17] Autologous PBPCs are obtained by administering a mobilizing agent(s) followed by apheresis, which is an outpatient procedure similar to dialysis. Hematopoietic growth factors (HGFs) alone or in combination with myelosuppressive chemotherapy are used for mobilization of autologous PBPCs with similar results.[18] The HGFs granulocyte-macrophage colony-stimulating factor (sargramostim, Leukine®) and granulocyte colony-stimulating factor (filgrastim, Neupogen®) are used as mobilizing agents.[17] In this setting, the most frequently used filgrastim doses are in the range of 5 to 16 mcg/kg per day, administered subcutaneously, with higher doses (greater than 10 mcg/kg per day) of filgrastim yielding more PBPCs.[18,19] The highest values of mobilized progenitor cells are observed 5 to 6 days after mobilization with filgrastim alone.[18]

The combination of chemotherapy with an HGF enhances PBPC mobilization relative to HGF alone.[18,20] In addition to treating the underlying malignancy, this approach lowers the risk of tumor cell contamination and the number of apheresis collections required, but there is a greater risk of neutropenia and thrombocytopenia.[18] The HGF is initiated after completion of chemotherapy and continued until apheresis is complete. Many centers monitor the number of cells that express the CD34 antigen (i.e., CD34+ cells) to determine when to start apheresis.[17] Apheresis is continued daily until the target number of PBPCs per kilogram of the recipient's weight is obtained. For adult recipients, the number of CD34+ cells correlates with time to engraftment.[21] The CD34 antigen is expressed on almost all unipotent and multipotent colony-forming cells and on precursors of colony-forming cells but not on mature peripheral blood cells. In adults, the target number of 1.5 to 5 $\times$ 10^6 CD34+ cells per kilogram of recipient weight is needed for autologous PBPC transplant.[22] Lower yield of CD34+ cells is associated with administration of stem cell toxic drugs (e.g., carmustine and melphalan) and intensive prior chemotherapy or radiotherapy.[18] There is a paucity of information regarding the parameters associated with engraftment in children undergoing an autologous PBPC transplant.[23]

TREATMENT

Desired Outcome

The desired outcome with HCT is to cure the patient of his or her underlying disease, typically cancer, while minimizing the short- and long-term morbidity associated with HCT. Nonpharmacologic therapies include choosing the optimal source of hematopoietic cells, whether autologous or allogeneic, and if an allogeneic donor is used, finding a donor with the closest HLA match to lower the risk of graft failure and GVHD. The pharmacologic therapies include the preparative regimen with the necessary supportive care measures for its hematologic and nonhematologic toxicity and the regimens to prevent and treat GVHD.

Nonpharmacologic Therapy

Harvesting, Preparing, and Transplanting Allogeneic Hematopoietic Cells

❸ *Bone marrow, peripheral blood progenitor cells (PBPCs) and umbilical cord blood can serve as the source of hematopoietic cells. The optimal cell source differs based on the donor and recipient characteristics but has not been clearly identified for all patients.*

Bone Marrow

Harvesting the bone marrow from an allogeneic donor is conducted via the same process as for an autologous HCT. The harvest occurs on day 0 of the HCT such that it is infused into the recipient immediately after processing. The marrow may

need additional processing if the donor and recipient are ABO-incompatible, which occurs in up to 30% of HCTs. Red blood cells (RBCs) may need to be removed before infusion into the recipient to prevent immune-mediated hemolytic anemia and thrombotic microangiopathic syndromes.[24]

Peripheral Blood Progenitor Cells (PBPCs)

The allogeneic (healthy) donor first undergoes mobilization therapy with an HGF to increase the number of hematopoietic cells circulating in the peripheral blood.[25] The most commonly used regimen to mobilize allogeneic donors is a 4- to 5-day course of filgrastim, 10 to 16 mcg/kg per day, administered subcutaneously, followed by leukopheresis on the fourth or fifth days when peripheral blood levels of CD34+ cells peak. An adequate number of hematopoietic cells usually is obtained with one to two apheresis collections, with the optimal number of CD34+ collected being a minimum of 5 to 8×10^6 cells/kg of recipient body weight.[26] Higher cell doses have been associated not only with more rapid engraftment but also with fewer fungal infections and improved overall survival.[27] Hematopoietic cells obtained from the peripheral blood are processed like bone marrow–derived stem cells and may be infused immediately into the recipient or frozen for future use. In comparison with bone marrow donation, allogeneic PBPC donation leads to quicker recovery.[26] The donor may experience musculoskeletal pain, headache, mild increases in hepatic enzyme or lactate dehydrogenase levels owing to filgrastim administration, and hypocalcemia owing to citrate accumulation, which decreases ionized calcium concentrations during apheresis.[25,28]

Allogeneic PBPC grafts contain approximately 10 times more T and B cells than bone marrow grafts. Because these cells survive long term, lymphocytes subsets are higher, and the rate of severe infections after engraftment is lower with a PBPC graft.[29] Historically, there also has been significant concern that the greater T- and B-cell content of PBPCs could increase the risk of acute and/or chronic GVHD. In patients with a hematologic malignancy who have an HLA-matched sibling donor, a PBPC graft is optimal relative to bone marrow graft because the PBPC graft is associated with quicker neutrophil and platelet engraftment, lower relapse rates, and improved disease-free survival rates.[30] Grafts from PBPCs are associated with a similar incidence of acute GVHD but an approximately 20% increase in the incidence of extensive-stage and overall chronic GVHD.[30] Similar trends for engraftment and GVHD have been found with unrelated donors.[31]

Umbilical Cord Blood

Transplant with umbilical cord blood (UCB) offers an alternative stem cell source to patients who do not have an acceptable matched related or unrelated donor. When allogeneic hematopoietic cells are obtained from UCB, the cord blood is obtained from a consenting donor in the delivery room after birth and delivery of the placenta.[32] The cord blood then is processed, a sample is sent for HLA typing, and the cord blood is frozen and stored for future use. Numerous UCB registries exist, with the goal of providing alternative sources of allogeneic stem cells.[33] Functional hematopoietic progenitor and stem cells can be found in UCB cryopreserved for up to 15 years; however, their ability to engraft successfully in a patient is unknown.[34] UCB transplantation, from a related or unrelated donor, is effective in children with cancer and nonmalignant conditions.[34] Engraftment is slower in UCB transplants, with a lower risk of GVHD and similar survival rates relative to BMT.[35–37] In children receiving a UCB graft from an unrelated donor, cell dose (e.g., nucleated cells) is related to engraftment, transplant-related morbidy, and survival.[38] Although there were initial concerns regarding whether a UCB transplant could provide enough nucleated cells to engraft adequately within an adult, there is growing experience to indicate that a UCB transplant is feasible when at least 1×10^7 nucleated cells per kilogram of recipient body weight are administered.[38,39]

T-Cell Depletion

Immunocompetent T lymphocytes may be depleted from the donor bone marrow ex vivo before infusion (referred to as *T-cell-depleted hematopoietic cells*) into the recipient as a means of preventing GVHD. Depletion of T lymphocytes in donor hematopoietic cells is completed ex vivo using physical (e.g., density-gradient fractionation) and/or immunologic [e.g., antithymocyte globulin (ATG) and CAMPATH-1 antibodies] methods.[40] Functional recovery of T cells in the recipient is delayed, and the risk of Epstein-Barr virus–associated lymphoproliferative disorders is higher with the use of T-cell-depleted bone marrow.[40] The use of T-cell-depleted grafts reduces the incidence of GVHD,[40] but graft failure and relapse are more common. The use of donor lymphocyte infusion (DLI) in patients who relapse after receiving a T-cell-depleted BMT also is under study.[41]

Engrafment

After chemotherapy and radiation, pancytopenia lasts until the infused stem cells reestablish functional hematopoiesis (i.e., engraftment is attained). The median time to engraftment is a function of several factors, including the source of stem cells with peripheral blood progenitor cells (PBPCs), which can result in earlier engraftment than bone marrow.[42,43] Myeloablative preparative regimens have significant regimen-related toxicity and morbidity and thus usually are limited to healthy, younger (i.e., usually younger than 50 years) patients. Alternatively, nonmyeloablative transplants (NMT), also referred to as *nonablative stem cell transplants* or *minitransplants,* are being performed with the hope of curing more patients with cancer by increasing the availability of HCT with less regimen-related toxicity and by using the GVT effect.[6]

A delicate balance between host and donor effector cells is necessary, and residual host-versus-graft effects may lead to graft failure, which is also known as *graft rejection. Graft failure* is defined as the lack of functional hematopoiesis after HCT and can occur early (i.e., lack of initial hematopoietic

recovery) or late (i.e., in association with recurrence of the disease or reappearance of host cells after initial donor cell engraftment).[44] The incidence of graft rejection is higher in patients with aplastic anemia and in patients undergoing allogeneic HCT with histoincompatible marrow or T-cell-depleted marrow. Engraftment usually is evident within the first 30 days in patients undergoing an NMT with this preparative regimen; however, rejection can occur after initial engraftment.[4] Therapeutic options for the treatment of graft rejection are limited, and a second HCT is the most definitive therapy, although the toxicities are formidable.[45]

Graft-versus-Tumor (GVT) Effect

A GVT effect occurs owing to the donor lymphocytes, as supported by three observations after myeloablative allogeneic HCT. Namely, (1) lower relapse rates in patients with GVHD relative to those who did not have GVHD, (2) a higher rate of leukemia relapse after T-cell-depleted BMT, and (3) the effectiveness of donor lymphocyte infusions (DLIs) in reinducing a remission (i.e., no evidence of cancer) in patients who relapsed after allogeneic HCT. In DLI, lymphocytes are collected from the peripheral blood of the donor and administered to the recipient. Eradication of the recurrent malignancy is due to either specific targeting of the tumor antigens or to GVHD, which may affect cancer cells preferentially. Patients with hematologic malignancies and certain solid tumors (e.g., renal cell carcinoma) appear to benefit from a GVT effect. These data gave rise to the use of nonmyeloablative preparative regimens.

Patient Encounter 1

LL, a 47-year-old man, was diagnosed with high-risk diffuse large cell B-cell non-Hodgkin's lymphoma (NHL) 12 months ago. LL had a complete response to his initial treatment of six cycles of RCHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone). LL is participating in a clinical trial and is randomized to receive a myeloablative autologous HCT: TBI days 8 to 5, etoposide day 4, rest day 3, cyclophosphamide day 2, rest day 1, with infusion of autologous PBPC on day 0.

What additional data do you need to know before creating a monitoring plan for LL?
What nonhematologic toxicity should be monitored?
What pharmacologic management is necessary during administration of the preparative regimen?

It is day +1, and LL has a white blood cell (WBC) count with differential of 0/mm^3, ANCs 0/mm^3 (0 × 10^9/L), platelets 30,000/mm^3 (30 × 10^3/μL), and hemoglobin 9 g/dL (5.6 mmol/L). Renal clearance and liver function are within normal limits. Vital signs are bp 130/80, RR 18, and T 39°C (102.2°F). Medications include ceftazidime 2 g IV tid and filgrastim 480 mcg subcutaneously daily.

- Develop a monitoring plan for LL's hematologic function.
- Identify your treatment goals for LL's hematologic function.

Pharmacologic Therapy

Preparative Regimens for HCT

Examples of commonly used preparative regimens are included in Table 95–2. ❻ *The nonhematologic toxicity differs based on the preparative regimen administered.*

Myeloablative Preparative Regimens

In both autologous and allogeneic HCT, infusion of stem cells circumvents dose-limiting myelosuppression, maximizing the potential value of the steep dose-response curve to alkylating agents and radiation, suppressing the host immune system, and creating space in the marrow compartment to facilitate engraftment. The preparative regimen is designed to eradicate immunologically active host tissues (lymphoid tissue and macrophages) and to prevent or minimize the development of host-versus-graft reactions. A myeloablative preparative regimen may not be necessary if a histocompatible

TABLE 95–2. Commonly Used Preparative Regimens for HCT[a]

Type of HCT	Preparative Regimen	Dose/Schedule for Adults
Allogeneic[108]	Myeloablative CY-TBI	CY 60 mg/kg per day IV on 2 consecutive days before TBI 1000–1575 rads fractionated over 1–7 days
Allogeneic, autologous[109]	Myeloablative BU-CY	BU: 1 mg/kg per dose PO or 0.8 mg/kg per dose IV q6hours × 16 doses; CY 60 mg/kg per day IV QD × 2 days following BU
Autologous[110]	Myeloablative BEAM (carmustine/etoposide/-cytarabine/melphalan)	Carmustine 150 mg/m^2 per day IV × 2, days –6 to –5 Etoposide 200 mg/m^2 per day IV bid × 4, days –5 to –2 Cytarabine 200 mg/m^2 per day IV bid × 4, days –5 to –2 Melphalan 140 mg/m^2 per day IV × 1, day –2
Allogeneic[64]	Nonmyeloablative FLU-TBI	Fludarabine 30 mg/m^2 per day IV on 3 consecutive days (–4, –3, –2), TBI2 Gy as a single fraction on day 0
Allogeneic	Nonmyeloablative	CY 60 mg/kg per day IV on 2 consecutive days (–7, –6), fludarabine 25 mg/m^2 per day IV (days –5 to –1)

[a]BU, busulfan; CY, cyclophosphamide; FLU, fludarabine; TBI, total body irradiation.

allogeneic HCT is performed on a patient with a poorly functioning immune system [e.g., severe combined immunodeficiency disease (SCID)]. In the absence of a functioning immune system, the likelihood of a host-versus-graft reaction to histocompatible donor hematopoietic cells is small. Similarly, patients undergoing syngeneic transplantation do not require immunosuppressive preparative regimens before HCT because the donor and the patient are genetically identical. Thus the preparative regimen is tailored to the primary disease and to HLA compatibility between the recipient-donor pair.

Most allogeneic preparative regimens for the treatment of hematologic malignancies contain either cyclophosphamide or radiation or both. The combination of cyclophosphamide and total-body irradiation (TBI) was one of the first preparative regimens developed and is still used widely today. This regimen is immunosuppressive and has inherent activity against hematologic malignancies (e.g., leukemias and lymphomas). TBI has the added advantage of being devoid of active metabolites that might interfere with the activity of donor hematopoietic cells. In addition, TBI eradicates residual malignant cells at sanctuary sites such as the central nervous system (CNS). Modifications of the cyclophosphamide-TBI preparative regimen include replacing TBI with other agents (e.g., busulfan) or adding other chemotherapeutic or monoclonal agents to the existing regimen in hopes of minimizing long-term toxicities. In the case of a mismatched allogeneic HCT with a substantially increased chance of graft rejection, ATG also may be added to the preparative regimen to further immunosuppress the recipient.

The optimal myeloablative preparative regimen is challenging to study because several indications for HCT (e.g., SCID and thalassemia) are rare enough that it is not feasible or is cost-prohibitive to conduct clinical trials that are powered adequately to detect clinically relevant differences. The long-term outcomes of busulfan-cyclophosphamide (BU-CY) and cyclophosphamide-TBI (CY-TBI) in patients with AML and CML, the more common indications for allogeneic HCT, have been compared in a meta-analysis of four clinical trials.[46] Equivalent rates of long-term complications were present between the two preparative regimens, except that there was a greater risk of cataracts with CY-TBI and alopecia with BU-CY. Overall and disease-free survivals were similar in patients with CML, whereas there was a trend for improved disease-free survival with CY-TBI in AML patients. Thus the preparative regimen can be tailored to the primary disease and to the HLA compatibility.

Nonmyeloablative Preparative Regimens

❺ *A nonmyeloablative preparative regimen is less toxic than a myeloablative regimen in hopes of being able to offer the benefits of an allogeneic HCT to more patients. A nonmyeloablative HCT is based on the concept of donor immune response having a graft-versus-tumor effect.*

Because of the severe regimen-related toxicity of a myeloablative preparative regimen, the use of HCT traditionally was limited to younger patients with minimal comorbidities. Most patients diagnosed with cancer are elderly, and thus myeloablative HCT could not be offered to a substantial portion of cancer patients.[47] The concept of donor immune response having a GVT effect gave rise to the theory that a strongly immunosuppressive but not myeloablative preparative regimen [i.e., a nonmyeloablative transplant (NMT)] may result in a state of chimerism in which the recipient and donor are coexisting.[48] The toxicity and efficacy of NMT are being evaluated in patients with nonmalignant conditions, such as congenital immunodeficiency, who are not eligible for a myeloablative HCT.[49]

A nonmyeloablative preparative regimen allows for development of mixed chimerism (defined as 5% to 95% peripheral donor T cells) between the host and recipient to allow for a GVT effect as the primary form of therapy (Fig. 95–1) Chimerism is

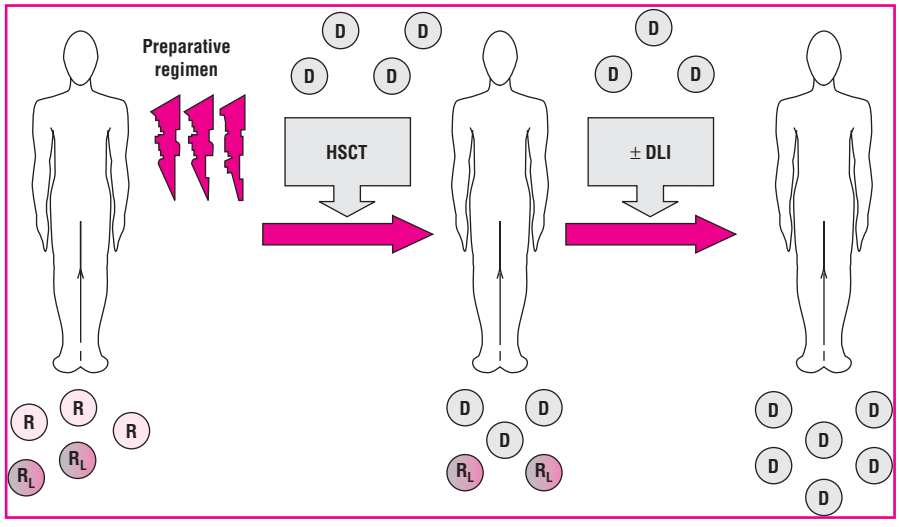

FIGURE 95–1. Schema for nonmyeloablative transplantation. Recipients (R) receive a nonmyeloablative preparative regimen and an allogeneic HCT. Intially, mixed chimerism is present with the coexistence of donor (D) cells and recipient-derived normal and leukemia/lymphoa (R_L) cells. Donor-derived T cells mediate a graft-verus-host hematopoietic effect that eradicates residual recipient-derived normal and malignant hematopoietic cells. Donor lymophycyte infusions (DLI) may be administered to enhance graft-versus-tumor effects. (Adapted from Champlin R, Khouri I, Anderlini P, et al. Nonmyeloablative preparative regimens for allogeneic hematopoietic transplantation: Biology and current indications. Oncology 2003; 17: 94–100.)

assessed within peripheral blood T cells and granulocytes and bone marrow using conventional (e.g., using sex chromosomes for opposite-sex donors) and molecular (e.g., variable number of tandem repeats) methods for same-sex donors.[50]

The nonmyeloablative preparative regimen does not completely eliminate host normal and malignant cells. Donor cells eradicate residual host hematopoiesis, and the GVT effects generally occur after the development of full donor T-cell chimerism.[51] After engraftment, mixed chimerism should be present and is shown by the presence of both donor- and recipient-derived cells. Autologous recovery should occur promptly if the graft is rejected. The intensity of immunosuppression required for engraftment depends on the immunocompetence of the recipient and the histocompatibility and composition of the HCT.[52] More intensive regimens that are required for engraftment in the setting of unrelated-donor- or HLA-mismatched-related HCT recently have been termed *reduced-intensity myeloablative transplants.*[52] After chimerism develops, donor-lymphocyte infusion can be administered safely in patients without GVHD to eradicate malignant cells.

Nonmyeloablative preparative regimens typically consist of a purine analog (e.g., fludarabine) in combination with an alkylating agent or low-dose TBI.[49,53] Adverse effects are decreased because of the lower-intensity preparative regimen, thus making HCT available to patients who in the past were not healthy or young enough to receive a myeloablative preparative regimen. The risk of GVHD remains with NMT; the GVHD prophylaxis regimens are reviewed in the GVHD section below. Presently, NMT is not indicated as first-line therapy for any malignant or nonmalignant conditions. NMT is being evaluated for cancers sensitive to a GVT effect (e.g., CML and AML), in older patients, or for those with comorbidities who would not be able to tolerate a myeloablative HCT.[52,54]

Toxicities and Management of Preparative Regimens

Myelosuppression is a frequent dose-limiting toxicity for antineoplastics when administered in the conventional doses used to treat cancer. However, because myelosuppression is circumvented with hematopoietic rescue in the case of patients receiving HCT, the dose-limiting toxicities of these myeloablative preparative regimens are nonhematologic and vary with the preparative regimen used. Most patients undergoing HCT experience toxicities commonly associated with chemotherapy (e.g., alopecia, mucositis, nausea and vomiting, and infertility), albeit these toxicities are magnified in the HCT population.

Busulfan Seizures

Seizures have been reported in both adult and pediatric patients receiving high-dose busulfan for HCT preparative regimens. Anticonvulsants are used to minimize the risk of seizures. Anticonvulsants are begun shortly before busulfan, with the loading dose completed at least 6 hours prior to the first busulfan dose. Oral loading and maintenance regimens generally are sufficient because target phenytoin concentrations of 10 to 20 mcg/mL (40–79 μmol/L) can be achieved by the peak time of seizure risk. If patients are experiencing significant vomiting or have difficulty maintaining therapeutic phenytoin concentrations, intravenous (IV) phenytoin should be substituted. Benzodiazepines such as lorazepam or clonazepam also have been used for seizure prophylaxis during high-dose busulfan therapy before HCT.[55] Antiseizure medications usually are discontinued 24 to 48 hours after administration of the last dose of busulfan. Seizures still can occur despite the use of prophylactic anticonvulsants and usually do not result in permanent neurologic deficits.

Adaptive Dosing of Busulfan

The considerable interpatient variability in the clearance of both oral and IV busulfan, along with the identified concentration-effect relationships, has led to the adaptive dosing of busulfan. Adjusting the oral busulfan dose to achieve a target concentration minimizes the toxicities of the BU-CY regimen, particularly hepatic sinusoidal obstruction syndrome (SOS, formerly referred to as *veno-occlusive disease*),[56] while improving engraftment and relapse rates. Complete reviews of these relationships after oral busulfan administration are available elsewhere.[57,58] An intravenous busulfan product, Busulfex®, was approved by the FDA in February 1999 in combination with cyclophosphamide as a preparative regimen prior to allogeneic HCT for CML. Recent data with Busulfex® in combination with either cyclophosphamide or fludarabine suggest that therapeutic drug monitoring may be needed.[59] Pharmacokinetic data are also represented as area under the plasma concentration time curve (*AUC*) or C_{SS}; data are easily converted to C_{SS} ($C_{SS} = AUC \div$ dosing interval). One also must pay close attention to the units used in these studies. Results are expressed as micromolar-minutes or nanograms per milliliter; an *AUC* of 1500 mcM · minute is roughly equivalent to a C_{SS} of 1025 ng/mL in those receiving busulfan every 6 hours.

Hemorrhagic Cystitis

High-dose cyclophosphamide causes moderate to severe hemorrhagic cystitis; acrolein, a metabolite of cyclophosphamide, is the putative bladder toxin. Preventive measures to lower the risk of hemorrhagic cystitis include vigorous hydration, continuous bladder irrigation, and/or concomitant use of the uroprotectant mesna. The American Society of Clinical Oncology (ASCO) Guidelines for the Use of Chemotherapy and Radiotherapy Protectants recommends the use of mesna plus saline diuresis or forced saline diuresis to lower the incidence of urothelial toxicity with high-dose cyclophosphamide

in the setting of HCT.[60] The optimal mesna dose with high-dose cyclophosphamide in preparation for myeloablative HCT is unknown. A number of different regimens have been used, including intermittent bolus dosing (mesna dose 20% to 40% of cyclophosphamide dose administered for three or four doses) or continuous-infusion regimens (mesna 80% to 160% of cyclophosphamide dose). Mesna should be continued for 24 to 48 hours after the last cyclophosphamide dose such that mesna is present within the bladder to donate free thiol groups at the same time as the urotoxic metabolite acrolein.

Chemotherapy-Induced Gastrointestinal Effects

Preparative regimens for myeloablative HCT result in other end-organ toxicities, such as renal failure, and idiopathic pneumonia syndrome. In addition, recipients of myeloablative preparative regimens are at risk for severe gastrointestinal (GI) toxicity, specifically chemotherapy-induced nausea and vomiting (CINV) and mucositis. CINV can be due to administration of highly emetogenic chemotherapy over several days, TBI, and also poor control of CINV prior to HCT. Thus patients who are undergoing a myeloablative HCT should be treated with a corticosteroid plus a serotonin antagonist, with higher doses of serotonin antagonists potentially being needed in this patient population.[61]

Virtually all patients receiving a myeloablative preparative regimen experience severe mucositis owing to its effects on rapidly dividing cells of the oral epithelium. Recently, the FDA approved palifermin—a recombinant human form of keratinocyte growth factor that specifically acts on epithelial cells. In recipients of an autologous HCT, palifermin lowered the incidence and average duration of severe oral mucositis.[62] Patients still may require parenteral opioid analgesics for pain relief[63] owing to mucositis and total parenteral nutrition to prevent the development of nutritional deficiencies.

Sinusoidal Obstruction Syndrome (SOS)

Hepatic SOS is a life-threatening complication that may occur secondary to preparative regimens or radiation.[44,64] The pathogenesis of SOS is not understood completely, although several mechanisms have been proposed. The key event appears to be endothelial damage caused by the preparative regimen. The primary site of the toxic injury is the sinusoidal endothelial cells; the endothelial damage initiates the coagulation cascade, induces thrombosis of the hepatic venules, and eventually leads to fibrous obliteration of the affected venules.[44]

The clinical manifestations of SOS are hyperbilirubinemia, jaundice, fluid retention, weight gain, and right upper quadrant abdominal pain.[44] To make a clinical diagnosis of SOS, these features must occur in the absence of other causes of posttransplant liver failure, including GVHD, viral hepatitis, fungal abscesses, or drug reactions. A clinical diagnosis can be confirmed histologically via liver biopsy.

Patients with mild SOS have an excellent prognosis, whereas those with more severe disease [i.e., bilirubin greater than 20 mg/dL (342 μmol/L) or weight gain greater than 15%] have a high mortality rate.[44] Risk factors for SOS include a mismatched or unrelated graft, cyclophosphamide administration, increased transaminases prior to HCT, and a history of hepatitis.[65] Interpatient variability in the metabolism and clearance of the chemotherapy (i.e., busulfan and cyclophosphamide) used within the preparative regimen also may be associated with a poor outcome, although the relationships vary within the various preparative regimens.[57,66] The association of SOS with busulfan concentrations is discussed in the section on adaptive dosing of busulfan. Preliminary data suggest that IV busulfan may be associated with a lower risk of SOS, although more data are needed.[67] Because its use has been associated with a lower incidence of SOS, single-agent ursodiol (600 mg PO daily) is recommended for SOS prophylaxis.[44]

The mainstay of treatment for established SOS is supportive care aimed at sodium restriction, increasing intravascular volume, decreasing extracellular fluid accumulation, and minimizing factors that contribute to or exacerbate hepatotoxicity and encephalopathy. Defibrotide has shown promising results in the treatment of SOS.[44]

Myelosuppression and Hematopoietic Growth Factor (HGF) Use

HGFs may be used prior to an HCT to mobilize PBPCs during the period of aplasia after an autologous HCT to hasten recovery and in cases where the patient fails to engraft.[19]

Autologous HCT is associated with profound aplasia owing to the myeloablative preparative regimen. Aplasia typically lasts 7 to 14 days after an autologous PBPC transplant. During this period of aplasia, patients are at high risk for complications such as bleeding and infection. Filgrastim and sargramostim exert their effects by stimulating the proliferation of committed progenitor cells, and once engraftment occurs, hematopoietic recovery may be accelerated. The anatomic source of hematopoietic cells predicts the degree of benefit, with the greatest benefit when bone marrow is the graft source. With autologous PBPC transplant, the effect of HGF on neutrophil recovery is variable.

The use of HGF after allogeneic HCT—whether from bone marrow or PBPC grafts—is controversial.[68] The limited amount of data with GM-CSF in this setting suggest increased adverse effects,[69] whereas data with G-CSF have shown more rapid neutrophil but slower platelet engraftment in those receiving grafts from bone marrow or PBPCs.[70] The effects of post-HCT use of G-CSF on acute and chronic GVHD have been conflicting, with either no effect or increases in both the incidence of acute and chronic GVHD and treatment-related mortality.[70] Thus there is little reason to treat allogeneic bone marrow transplant with G-CSF as prophylaxis after HCT.

Graft Failure

A delicate balance between host and donor effector cells is necessary, and residual host-versus-graft effects may lead to graft rejection. The incidence of graft rejection is higher in patients with aplastic anemia and those undergoing HCT with histoincompatible marrow or T-cell-depleted marrow.[2] Graft rejection is uncommon in leukemia patients receiving myeloablative preparative regimens with a histocompatible allogeneic donor.

Therapeutic options for the treatment of graft rejection or graft failure are limited. A second HCT is the most definitive therapy, although the toxicities are formidable.[45] Graft rejection is best managed with immunosuppressants such as antithymocyte globulin. Primary graft failure occasionally can be treated successfully using hematopoietic growth factors, although patients who received purged autografts are less likely to respond.

Graft-Versus-Host Disease (GVHD)

❸ *GVHD is caused by the activation of donor lymphocytes, leading to immune damage to the skin, gut, and liver in the recipient.* Immune-mediated destruction of tissues, a hallmark of GVHD, disrupts the integrity of protective mucosal barriers and thus provides an environment that favors the establishment of opportunistic infections. ❸ *An immunosuppressive regimen is administered to prevent GVHD in recipients of an allogeneic graft; this regimen is based on the type of preparative regimen and the source of the graft.* The combination of GVHD and infectious complications is a leading cause of mortality for allogeneic HCT patients. GVHD is divided into two forms (i.e., acute and chronic) based on clinical manifestations. Traditionally, the boundary between acute and chronic GVHD was set at 100 days after HCT; however, more recent definitions hinge on different clinical symptoms rather than the time of onset.[71]

Acute Graft-versus-Host Disease

The degree of histocompatibility between donor and recipient is the most important factor associated with the development of acute GVHD. The pathophysiology for acute GVHD is a multistep phenomenon, including (1) the development of an inflammatory milieu that results from host tissue damage induced by the preparative regimen, (2) both recipient and donor antigen-presenting cells and inflammatory cytokines triggering activation of donor-derived T cells, and (3) the activated donor T cells mediate cytotoxicity through a variety of mechanisms, which leads to tissue damage characteristic of acute GVHD.[72]

Clinically relevant grade II to IV acute GVHD occurs in 20% to 50% of HLA-matched sibling grafts and 50% to 80% of HLA-mismatched sibling or HLA-identical unrelated donors[44] (Fig. 95–2.) Other factors that increase the risk of acute GVHD include increasing recipient or donor age (older than 20 years), female donor to a male recipient, and previous recipient infections with herpesvirus.[44] T-cell depletion and receipt of an UCB graft lower the risk of acute GVHD.[2]

Clinical Presentation of Acute GVHD

Acute GVHD usually is not evident until the time of engraftment, when donor lymphoid elements begin to proliferate. The primary targets of immune-mediated destruction of host tissue by donor lymphocytes in acute GVHD are the skin, liver, and GI tract.[44] A diffuse maculopapular rash on the face, truck, face, extremities, palms, soles, and ears is the usual sign of acute GVHD of the skin. In more severe cases, it can

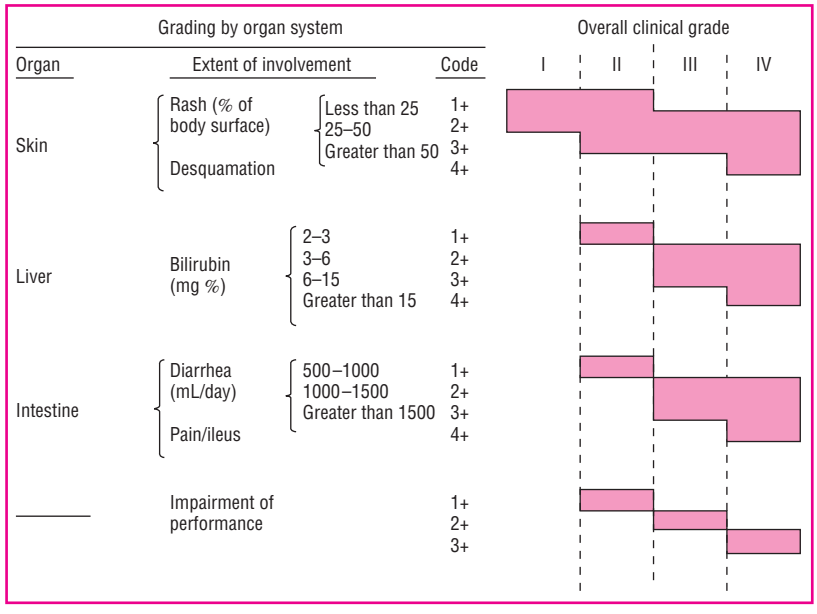

FIGURE 95–2. Clinical grading of acute GVHD. The left panel summarizes the grading of one organ system; the right panel shows the overall clinical grade. With grade I, only the skin can be involved. With more extensive involvement of the skin or involvement of liver and intestinal tract and impairment of the clinical performance status, either alone or in any combination, the severity grade advances from II to IV. (From Perkins JB, Yee GC. Hematopoietic stem cell transplantation. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 2552.)

progress to a generalized total-body erythroderma, bullous formation, and skin desquamation.[44] Acute GVHD of the GI track may present as persistent nausea and anorexia; watery or bloody diarrhea also occurs, which can result in electrolyte abnormalities, dehydration, or ileus in severe cases. [44] Clinical manifestations of liver GVHD include elevated bilirubin, alkaline phosphatase, and hepatic transaminases, which can progress to fulminant hepatic failure.[44] Acute GVHD must be distinguished accurately from other causes of skin, liver, or GI toxicity in the HCT patient (e.g., a maculopapular rash may be due to an allergic reaction to antibiotics). A staging system based on clinical criteria is used to grade acute GVHD. The severity of organ involvement is scored on an ordinal scale from 0 (no symptoms) to IV (severe symptoms), and then an overall grade is established based on the number and extent of involved organs.

Immunosuppressive Prophylaxis of Acute GVHD

GVHD is a leading cause of morbidity and mortality after allogeneic HCT, and thus efforts have focused on preventing acute GVHD. The donor graft and preparative regimen influence the prophylactic regimen for acute GVHD, with two approaches having been taken. One approach involves T-cell depletion, which was discussed more fully in the section on T-cell depletion earlier. The more common method is to use two-drug immunosuppressive therapy that typically consists of a calcineurin inhibitor (i.e., cyclosporine or tacrolimus) with methotrexate after myeloablative HCT and a calcineurin inhibitor with mycophenolate mofetil after nonmyeloablative HCT.

After myeloablative conditioning, acute GVHD rates have been similar or lower with triple-drug regimens, but infectious complications are higher, and overall survival is similar to that with two-drug regimens.[73,74] With the two-drug regimen, a short-course methotrexate (e.g., to day +11) is used and thus can delay engraftment, increase the incidence and severity of mucositis, and cause LFT elevations. The methotrexate dose is reduced in the setting of renal or liver impairment. The calcineurin inhibitors (i.e., cyclosporine and tacrolimus) should be initiated before donor cell infusion (e.g., day –1) when used for GVHD prophylaxis. This schedule is recommended because of the known mechanism of action of cyclosporine, which entails blocking the proliferation of cytotoxic T cells by inhibiting production of T-helper-cell-derived interleukin 2 (IL-2). Administering cyclosporine before the donor cell infusion allows inhibition of IL-2 secretion to occur before a rejection response has been initiated. Studies comparing cyclosporine and tacrolimus in combination with methotrexate have shown that tacrolimus administration is associated with a lower incidence of grade II to IV acute GVHD and a similar incidence of chronic GVHD but variable effects on overall survival.[75–77] Because of the mucosal toxicity to myeloablative preparative regimens, the calcineurin inhibitors are administered intravenously until the GI toxicity from a myeloablative preparative regimen has resolved (e.g., for 7–21 days).[78] Most centers use a 1:2 to 1:3 ratio for conversion of IV to oral cyclosporine with the Neoral formulation; the ratio for tacrolimus conversion from IV to oral is often 1:4. Different conversion ratios for IV to oral regimens may be used when patients are receiving concomitant medications that affect cytochrome P-450 3A or p-glycoprotein, which are involved in the metabolism and transport of the calcineurin inhibitors (e.g., itraconazole).

Prophylaxis of acute GVHD for nonmyeloablative preparative regimens is varied, but a calcineurin inhibitor with either methotrexate or mycophenolate mofetil is used.[6] To date, trials evaluating the optimal acute GVHD prophylaxis regimen have not been conducted.

Adaptive Dosing of the Calcineurin Inhibitors

Most HCT centers have their own standardized approach to dose adjust the calcineurin inhibitors cyclosporine and tacrolimus to target concentration ranges. Cyclosporine trough concentrations are associated with the acute GVHD and nephrotoxicity. Cyclosporine trough concentrations usually are maintained between 150 to 400 ng/mL (125–333 nmol/L) in patients undergoing allogeneic HCT. Tacrolimus trough concentrations are targeted to a range of 10 to 20 ng/mL (10–20 mcg/L).[79] Dosage adjustments to either calcineurin inhibitor also should be made for elevated serum creatinine (SrCr) regardless of their serum concentrations. Nephrotoxicity can occur despite low or normal concentrations of the calcineurin inhibitor cyclosporine and may be a consequence of other drug- or disease-related factors known to influence the development of nephrotoxicity (e.g., genetic risk factors, concurrent use of other nephrotoxic agents, and sepsis). Careful monitoring for drug interactions via cytochrome P-450 3A4 and p-glycoprotein is also warranted.[79] The calcineurin inhibitor doses are adjusted based on serum drug levels and the SrCr concentration. Their dose is escalated when serum concentrations are below the lower limits of normal because this is associated with GVHD.[80] Common adverse effects to these agents include neurotoxicity, hypertension, and/or nephrotoxicity (which may lead to an impaired clearance of methotrexate).

Tapering schedules for the calcineurin inhibitors after myeloablative HCT varies widely. In patients without GVHD, the calcineurin inhibitor doses usually are stable to day +50 and then are tapered slowly with the intent of discontinuing all immunosuppressive agents by 6 months after HCT. By this time, immunologic tolerance has developed, and patients no longer require immunosuppressive therapy. There is a paucity of information regarding the optimal duration of GVHD prophylaxis after nonmyeloablative HCT, with recent data suggesting that a 2-month duration of cyclosporine with a 4-month taper lowers the rate of severe acute GVHD.[81]

Treatment of Acute Graft-Versus-Host Disease

The most effective way to treat GVHD is to prevent its development. Corticosteroids, usually in combination with a calcineurin inhibitor, are the first-line therapy for treatment of established acute GVHD.[72] Corticosteroids indirectly halt the progression of immune-mediated destruction of host tissues by blocking macrophage-derived IL-1 secretion. IL-1 is a primary stimulus for T-helper-cell-induced secretion of IL-2, which, in turn, is responsible for stimulating proliferation of cytotoxic T lymphocytes. The recommended dosage of methylprednisolone in this setting is 2 mg/kg per day; there is no advantage to higher corticosteroid doses (i.e., 10 mg/kg per day).[82] A partial or complete response is seen in approximately 50% of patients treated with corticosteroids. Once a clinical improvement occurs, there is no consensus on the optimal method for tapering the corticosteroids.[72] Patients with steroid-refractory acute GVHD have a poor prognosis, and a number of medications are being studied for "salvage" therapy.[72]

Chronic Graft-Versus-Host Disease

Occurring in 20% to 70% of HCT recipients surviving over 100 days, chronic GVHD is the most frequent and serious late complication of allogeneic HCT.[83] Chronic GVHD is the major cause of nonrelapse mortality and morbidity.[7,83] The clinical course of chronic GVHD is multifaceted, involving almost any organ in the body, and its symptoms resemble autoimmune and immunologic disorders (e.g., scleroderma) (Table 95–3). Chronic GVHD symptoms usually present within 3 years of allogeneic HCT and often are preceded by acute GVHD.[71] Traditionally, the boundary between acute and chronic GVHD was set at 100 days after HCT; however, more recent definitions hinge on different clinical symptoms rather than the time of onset.[83] A consensus document regarding the diagnosis and scoring of chronic GVHD has been published recently.[71] The diagnosis of chronic GVHD requires (1) distinction from acute GVHD, (2) presence of at least one diagnostic clinical sign of chronic GVHD or presence

TABLE 95–3. Abbreviated Table of Signs and Symptoms of Chronic GVHD[71,a]

Affected Organ	Diagnostic	Distinctive	Other Features[b]	Common (Seen with Both Acute and Chronic GVHD)
Skin	Poikiloderma Lichen planus-like features Sclerotic features Morphea-like features Lichen sclerosus-like features	Depigmentation	Seat impairment Ichthyosis Keratosis pilaris Hypopigmentation Hypergimentation	Erythema Maculopapular rash Pruritus
Eyes		New onset drug, gritty or painful eyes[c] Cicatrical conjunctivitis Keratoconjunctivitis sicca[c] Confluent areas of punctuate keratopathy decreased tear formation, dry eyes, burning, photophobia	Photophobia Periorbital hyperpigmentation Erythema of the eyeslids with edema	
GI Tract	Esophageal web stricture or stenosis in the upper to middle third of the esophagus[d]		Exocrine Pancreatic insufficiency	Anorexia Nausea Vomiting Diarrhea Weight loss Failure to thrive (infants and children)
Liver				Total bilirubin, alkaline phosphatase greater than 2 times upper limit of normal[d]
Lung	Bronchiolitis obliterans diagnosed with lung biopsy	Bronchiolitis obliterans diagnosed with pulmonary function tests and radiology[c]		Bronchiolitis obliterans organizing pneumonia

[a]Signs and symptoms for nails, scalp and body hair, mouth, genitalia, muscles, fascia, joints, hematopoietic and immune, and other organs are also described by Filipovich et al.
[b]Can be acknowledged as part of chronic GVHD symptomatology if the diagnosis is confirmed.
[c]Diagnosis of chronic GVHD requires biopsy or radiology confirmation (or Chirmer test for eyes).
[d]Infection, drug effects, malignancy, or other causes must be excluded.

of at least one distinctive manifestation confirmed by pertinent biopsy or other relevant tests, and (3) exclusion of other possible diagnoses. The clinical scoring system is categorized by numerical values of 0 to 3, with more severe symptoms receiving a higher number. Subsequently, a global score is calculated by including the number of organs involved and the severity within each affected organ. The global score reflects the clinical effect of chronic GVHD on the patient's functional status and can be used to evaluate whether treatment (i.e., systemic immunosuppression) of chronic GVHD is needed.

Prevention and Treatment of Chronic GVHD

Chronic GVHD is not a continuation of acute GVHD, and separate approaches are needed for its prevention and management.[83] Prevention of chronic GVHD through prolonged use of immunosuppressive medications has been unsuccessful.[83] Thus its prevention is focused on minimization of factors associated with higher rates of chronic GVHD. Several recipient, donor, and transplant factors are relevant. Recipient risk factors that are not modifiable include older age, certain diagnoses (e.g., chronic myeloid leukemia), and lack of an HLA-matched donor. Modifiable factors that may lower the risk of chronic GVHD include selection of a younger donor, avoidance of a multiparous female donor, use of UCB or bone marrow grafts rather than PBPCs, and limitation of CD34+ and T-cell dose infused.[83,84] Development of acute GVHD is a major predictor for chronic GVHD, and 70% to 80% of those with grade II to IV acute GVHD develop chronic GVHD.[83]

Relative to no treatment, survival in those with chronic GVHD is improved by extended corticosteroid therapy; however, multiple long-term adverse effects are associated with the corticosteroids.[83] The prednisone dosage is 1 mg/kg per day administered orally in divided doses for 30 days and then slowly converted to an alternate-day therapy by increasing the "on day" and decreasing the "off day" dose until a total of 2 mg/kg per day on alternate days is administered. Once therapy is initiated, 1 to 2 months may pass before an improvement in clinical symptoms is noted, and therapy usually is continued for 9 to 12 months. Therapy can be tapered slowly after resolution of signs and symptoms of chronic GVHD. If a flare of chronic GVHD occurs during the tapering schedule or after therapy is discontinued, immunosuppressive therapy is restarted. Other potential approaches for patients who are refractory to initial therapy include etanercept, infliximab, mycophenolate mofetil and tacrolimus, tacrolimus alone, extracorporeal photochemotherapy, acitretin, clofazimine, or hydroxychloroquine.[85,86]

When immunosuppressive therapy is administered for long periods, the patient must be monitored closely for chronic toxicity. Blood counts should be monitored routinely in patients on azathioprine because hematologic toxicity resulting in infection and bleeding may occur. Cushingoid effects, aseptic necrosis of the joints, and diabetes can develop with long-term corticosteroid use. Other severe complications include a high incidence of infection with encapsulated organisms and atypical pathogens such as *Pneumocystis jiroveci*, cytomegalovirus (CMV), and varicella-zoster virus (VZV).

Infectious Complications

❾ *Recipients of HCT are at higher risk of bacterial, viral, and fungal infections and usually receive a prophylactic or preemptive regimen to minimize the morbidity and mortality owing to infectious complications.* After myeloablative and nonmyeloablative HCT, opportunistic infections are a major source of morbidity and mortality. There are three periods of infectious risks, early (days 0–30), middle (engraftment to day plus 100), and late (after day plus 100). From days 0 to 30 after HCT, particularly for patients undergoing myeloablative HCT, the primary pathogens are aerobic bacteria, *Candida,* and herpes simplex virus (HSV). Respiratory viruses such as respiratory syncytial virus (RSV), influenza, adenovirus, and parainfluenza virus are recognized increasingly as pathogens causing pneumonia, particularly during community outbreaks of infection with these organisms. To reduce potential exposure of HCT recipients to such respiratory viruses, visitors and staff members with respiratory signs and symptoms of a viral illness may not be allowed direct contact with patients.

The second period of infectious risk occurs after engraftment to posttransplant day +100. Bacterial infections are still of concern, but pathogens such as CMV, adenovirus, and *Aspergillus* are common. A common manifestation of infection is interstitial pneumonitis (IP), which can be caused by CMV, adenovirus, *Aspergillus,* and *P. jiroveci.* Immune suppression from acute GVHD and corticosteroids contributes to the risk of such infections during this period. Therefore, patients undergoing NMT who are receiving corticosteroids to treat GVHD can be expected to have a similar risk for infection as those undergoing myeloablative HCT.[87] Invasive fungal infections over the first year after HCT occur at a similar rate in NMT when compared with historical controls receiving a myeloablative preparative regimen.[88]

During the late period (after day +100), the predominant organisms are the encapsulated bacteria (e.g., *Streptococcus pneumoniae*, *Hemophilus influenzae*, and *Neisseria meningitidis*), fungi, and VZV. The encapsulated organisms commonly cause sinopulmonary infections. The risk of infection during this late period is increased in patients with chronic GVHD as a result of prolonged immunosuppression.

Owing to the morbidity associated with these opportunistic infections in HCT recipients, optimal pharmacotherapy for preventing and treating infections in this patient population is critical. In 2000, the Center for Disease Control and Prevention (CDC) published guidelines for preventing these infections among HCT recipients.[8] These guidelines were constructed from available data by an expert panel from the CDC, the Infectious Disease Society of America, and the American

Society for Blood and Marrow Transplantation. These guidelines provide a comprehensive review of the data regarding prevention of opportunistic infections in HCT recipients. The review below incorporates information from the CDC guidelines and also provides an update on the pharmacotherapy of opportunistic infections for all types of HCTs (i.e., myeloablative autologous, myeloablative allogeneic, and nonmyeloablative allogeneic HCT recipients).

Prevention and Treatment of Bacterial and Fungal Infections

Because of disease-related immunosuppression, intensive preparative regimens, and/or posttransplant immunosuppressive therapy, patients undergoing allogeneic HCT require close monitoring for regimen-related toxicities and intensive supportive care directed toward maintaining an adequate CBC, preventing or treating infection, and providing adequate nutrition. The need to administer chemotherapy, blood products, antibiotics, parenteral nutrition, and adjunctive medications precludes the use of peripheral access sites that require frequent rotation. Placement of a semipermanent double- or triple-lumen central venous catheter (e.g., Hickman, Groshong, Broviac, or Neostar) is necessary. The use of central venous catheters also allows delivery of maximumally concentrated medications into an area of high blood flow, which reduces infusion times and minimizes daily fluid infusion. However, the indwelling IV central catheters put HCT recipients at increased risk for *Staphylococcus* infections.

Between the time of administration of the preparative regimen and successful engraftment, allogeneic myeloablative HCT patients undergo a period of pancytopenia that can last from 2 to 6 weeks. During this time, multiple RBCs and platelet transfusions are needed when the hematocrit is less tham 25% (0.25) and platelets are less than 10,000 or 20,000/mm^3 ($10–20 \times 10^9$/L $10–20 \times 10^3$/μL). Transfusions with multiple blood products place patients at risk for blood product–derived infection (e.g., CMV and hepatitis) and sensitization to foreign leukocyte HLA antigens (i.e., alloimmunization), which can lead to immune-mediated thrombocytopenia. Thus blood product support in the myeloablative allogeneic HCT patient must incorporate strategies that reduce the risk of viral infection and alloimmunization by minimizing the number of pretransplant infusions, use of single-donor (rather than pooled-donor) blood products, irradiating blood products, or filtering blood products with leukocyte-reduction filters. Given the reduced intensity of the preparative regimen, NMT patients may or may not experience neutropenia and generally have reduced requirements for blood products. Many centers perform NMT in the outpatient setting and admit patients to the hospital only if they have complications requiring more intensive management.

The risk of infection in autologous and allogeneic myeloablative HCT patients is minimized through a variety of measures. Private reverse isolation rooms equipped with positive-pressure HEPA filters and adherence to strict handwashing techniques reduce the incidence of bacterial and fungal infections.[8] To reduce exposure to exogenous sources of bacteria, immunosuppressed-patient (low-microbial) diets are used, and plants or flowers are not allowed in the patient's room. Chemotherapy-induced mucosal damage serves as a portal of entry for many organisms (e.g., *Streptococcus viridans*, aerobic gram-negative bacteria, and fungi) into the bloodstream. The mouth should be kept clean by using frequent (four to six times daily) mouth rinses with sterile water, normal saline, or sodium bicarbonate.[8] Brushing or flossing teeth is avoided during periods of thrombocytopenia and neutropenia. In the first 30-days after HCT, those undergoing a nonmyeloablative preparative regimen have a significantly reduced incidence of mucositis, along with reduced bacteremia and fewer episodes of infection attributable to mucositis, relative to those receiving a myeloablative preparative regimen.

The risk of infection is also reduced by aggressive use of antibacterial, antifungal, and antiviral therapy both prophylactically and for the treatment of documented infection. Antibiotics with a broad gram-negative spectrum may be instituted prophylactically on the day of donor cell infusion (i.e., day 0), once the patient becomes neutropenic, or empirically after the patient is neutropenic and experiences a first fever. The antibacterial prophylactic regimens vary substantially among HCT centers. Some HCT centers use prophylactic fluoroquinolone (e.g., ciprofloxacin) on admission for HCT and then switch to a broad-spectrum IV antibiotic (e.g., ceftazidime) when the patient experiences his or her first neutropenic fever. Although fluoroquinolones reduce the incidence of gram-negative bacteremia, they do not affect the number of days with fever or mortality.[8] Concerns with quinolone use in the prophylactic setting during HCT include the emergence of resistant organisms and an increased risk for streptococcal infection.[8] Prophylactic antibiotics with activity against *Streptococcus* (e.g., penicillin and vancomycin) have been studied, but their use is not recommended owing to a lack of efficacy in preventing streptococcal infections and concern over antibiotic-resistant bacteria.[8,89]

Broad-spectrum IV antibiotics should be initiated or added at the time of the first neutropenic fever under the treatment guidelines endorsed by the Infectious Disease Society of America for management of fever of unknown origin in the neutropenic host.[89]

Prevention of Herpes Simplex Virus (HSV) and Varicella-Zoster Virus (VZV)

Patients who are HSV- or VZV-seronegative prior to HCT rarely develop primary HSV or VZV infection; therefore, prophylactic antivirals are not warranted. Patients who are HSV-antibody-seropositive before HCT are at high risk for reactivation of their

HSV infection. Acyclovir is highly effective in preventing HSV reactivation, and thus prophylactic acyclovir is used commonly in HSV-seropositive patients who are undergoing an allogeneic or autologous HCT.[8] In the setting of HSV prophylaxis, dosing regimens for prophylactic acyclovir vary widely, and most centers discontinue acyclovior at the time of hematopoietic recovery.[8] Valacyclovir, a prodrug of acyclovir with improved bioavailability, may allow for adequate serum concentrations to prevent HSV in patients with mucositis or gastrointestinal GVHD.[90] Typically, valacyclovir is administered as 500 mg orally once or twice daily in the prophylactic setting.

In those with a history of VZV infection, VZV disease occurs in 30% of allogeneic HCT recipients.[91] The appropriate duration of VZV prophylaxis is controversial.[8] Although VZV infections are reduced by prophylactic acyclovir (800 mg twice daily), administered from 1 to 2 months until 1 year after HCT, the risk of VZV persists in those on continued immune suppression.[91]

Prevention and Preemptive Therapy of Cytomegalovirus (CMV) Disease

After allogeneic HCT, CMV disease is common and has high morbidity and mortality rates. Allogeneic patients are at greater risk than autologous recipients primarily because the latter more efficiently reconstitute their immune system after transplantation. However, autologous HCT recipients who are CMV-seropositive before HCT are at risk of CMV infection, and prophylaxis should be considered in a select minority of patients.[8] Two CMV syndromes can occur. CMV infection usually is asymptomatic and develops when CMV replication occurs primarily in body fluids such as the blood (viremia), bronchoalveolar fluid, or urine (viruria). CMV disease is symptomatic and occurs when the virus invades an organ or tissue. Pneumonia and gastritis are the most common types of CMV disease after allogeneic HCT. The presence of a CMV infection substantially increases the risk for developing invasive CMV disease. Strategies to prevent CMV infection have resulted in dramatic reductions in the incidence of CMV disease.

Primary CMV can be prevented with CMV seromatching, which includes transplanting PBPCs or bone marrow from CMV-seronegative donors and infusing CMV-negative blood products to CMV-negative recipients. Antivirals are essential in those who are CMV-seropositive or have a CMV-seropositive graft, with two available approaches to minimize the morbidity associated with CMV. The first is universal prophylaxis, in which ganciclovir is begun at the time of engraftment and is continued until approximately day +100. Second is preemptive therapy, also called *risk-adjusted therapy,* for which ganciclovir is selectively administered based on detection of CMV reactivation.

Preemptive therapy is the most commonly used strategy for preventing CMV disease after allogeneic HCT because ganciclovir is used only in patients at highest risk for developing CMV disease. This approach minimizes administration of ganciclovir, thus lowering the risk of ganciclovir-induced neutropenia with its subsequent increased risk of invasive bacterial and fungal infections or interruptions of ganciclovir and/or filgrastim administration to maintain adequate neutrophil counts. Preemptive therapy hinges on the ability to detect early reactivation of CMV using shell vial cultures, assays of blood for CMV antigens (such as pp65), or viral nucleic acids using polymerase chain reaction (PCR).[92] Antigenemia-based preemptive therapy has similar efficacy in preventing CMV disease as universal ganciclovir prophylaxis, and preemptive therapy also has been associated with a significant reduction in CMV mortality. Preemptive strategies typically use an induction course of ganciclovir 5 mg/kg IV every 12 hours for 7 to 14 days, followed by a maintenance course of 5 mg/kg IV daily until 2 or 3 weeks after the last positive antigenemia result or until day +100 after HCT.[8] Oral valganciclovir is an orally bioavailable prodrug of ganciclovir that is converted to ganciclovir in vivo after intestinal absorption.[93] Foscarnet may be given as an alternate to ganciclovir to prevent CMV disease, although its use is complicated by nephrotoxicity and electrolyte wasting.

CMV infection and disease in patients undergoing NMT appears to have a different temporal pattern than in patients receiving myeloablative preparative regimens. The onset of CMV antigenemia was similar between the groups, but patients undergoing NMT are at increased risk for developing late CMV disease (greater than 100 days after transplantation) compared with their myeloablative counterparts. For this reason, it is recommended that NMT patients receive preemptive antiviral therapy and be monitored for the development of CMV antigenemia for 1 year after transplantation.[87]

Fungal Infections

Prevention of Fungal Infections Prophylactic fluconazole (400 mg/day) until day +75 after allogeneic HCT decreases the incidence of systemic fungal infection and death compared with placebo.[94] The widespread use of fluconazole (400 mg/day) prophylaxis since the early 1990s has led to a significant decline in the morbidity and mortality associated with invasive candidiasis in BMT recipients. However, invasive aspergillosis (IA) and fluconazole-resistant *Candida* species, such as *C. krusei* and *C. glabrata,* have increased markedly in incidence.[95] Itraconazole, another azole antifungal agent, has better in vitro activity against fluconazole-resistant fungi (e.g., *Aspergillus* and some *Candida* spp.) and was more effective than fluconazole for long-term prophylaxis of invasive fungal infections after allogeneic HCT.[96] Itraconazole was associated with more frequent GI side effects (e.g., nausea and vomiting), and its concomitant use with cyclophosphamide is associated with increased exposure to toxic cyclophosphamide metabolites and increased hepato- and

nephrotoxicity, presumably via inhibition of cytochrome P-450 by itraconazole.[96,97] Prophylactic itraconazole should be initiated after cyclophosphamide administration, its plasma concentrations are maintained greater than 500 ng/mL for effective prophylaxis, and patient education should be provided regarding the importance of compliance with the unpleasant-tasting itraconazole solution.[94]

Risk Factors for Invasive Mold Infections Invasive mold infections (e.g., *Aspergillus* spp., *Fusarium* spp., Zygomycetes, and *Scedosporium* spp.) are an increasing cause of morbidity and death after allogeneic and autologous HCT. In HCT recipients, risk factors for invasive fungal infections include previous history of invasive aspergillosis; recipient factors, including age greater than 40 years, CMV seropositivity, type of cell transplant (i.e., UCB or donor-recipient HLA mismatch, and T-cell-depleted grafting); treatment factors (e.g., a fludarabine-based preparative regimen); and transplant complications (e.g., prolonged neutropenia, graft failure, and higher-grade GVHD).[98] Infections with *Aspergillus* species are the most common mold infections, with an annual incidence of invasive aspergillosis (IA) of 10.5% among allogeneic and 5.3% among autologous HCT recipients.[99]

Treatment of Invasive Aspergillosis Early diagnosis and initiation of appropriate therapy may reduce the high mortality of IA. Outcomes also depend on recovery of the recipient's immune system and reduction of immune suppression. Diagnosis is difficult with the use of computed tomographic (CT) scans and cultures. Research is ongoing to evaluate the benefit of using non-culture-based methods, such as galactomannan, which is a component of the fungal cell wall that can be detected by ELISA.[100] Invasive procedures to diagnosis IA can be avoided by determining a patient's likelihood of having IA with the use of a galactomannan assay in combination with CT scans and the known risk factors for IA.[100]

Practice guidelines are available for the treatment of fungal infections in HCT patients.[101] Available mold-active agents include itraconazole, voriconazole, caspofungin, and amphotericin B formulations. Conventional amphotericin B (c-AmB) at a minimum dose of 1 mg/kg per day traditionally has been the "gold standard" antifungal therapy for any IA infection. Most patients respond to single-agent c-AmB; however, 65% of responders eventually die of their infection. Significant toxicity occurs with c-AmB administration, with nephrotoxicity being the most troublesome side effect. Altered renal function occurs in up to 80% of patients receiving c-Amb, particularly in those with additional risk factors for nephrotoxicity (e.g., concomitant aminoglycosides and cyclosporine). Infusion-related reactions (e.g., fever, chills, rigors, hypotension, and hypoxia), electrolyte wasting, nausea, and anemia are additional toxicities of c-Amb. Acetaminophen, diphenhydramine, meperidine, and/or hydrocortisone are administered before each c-Amb dose to ameliorate these infusion-related events with variable success. Electrolyte wasting, especially potassium and magnesium, secondary to c-Amb can be significant and persist well beyond discontinuation of the drug. Most patients require daily potassium and magnesium supplementation, particularly if they require prolonged amphotericin therapy.

Lipid analogs of amphotericin B were developed with the specific intent of reducing nephrotoxicity. These include amphotericin B lipid complex (Abelcet®, ABLC), liposomal amphotericin B (Ambisome®, L-Amb), and amphotericin B colloidal dispersion (Amphotec®, ABCD).[100] Overall, studies of single-agent liposomal formulations of amphotericin B for patients with IA who have failed or are intolerant to c-Amb therapy reveal response rates in the range of 23% to 71% regardless of the agent used. However, no randomized studies have evaluated ABLC and L-Amb for IA treatment, whereas ABCD has similar efficacy, less renal toxicity, but greater infusion reactions than c-Amb.[100] Notably, their high cost relative to c-Amb limits widespread use of the liposomal products.

Select azole antifungals (e.g., itraconazole, voriconazole, and posaconazole) and the echinocandins are available for IA treatment. For initial therapy of IA, voriconazole had higher response and survival rates than c-AMB.[102] An advantage of voriconazole is its 96% oral bioavailability, making use of this oral drug an attractive and less expensive alternative. The dose of voriconazole was 6 mg/kg IV every 12 hours for two doses, followed by 4 mg/kg IV every 12 hours for at least 7 days, at which time oral voriconazole 200 mg every 12 hours could be administered. Common toxicities reported with voriconazole include infusion-related, transient visual disturbances (i.e., blurred vision, altered color perception, photophobia, and visual hallucinations), skin reactions (i.e., rash, pruritus, and photosensitivity), elevations in hepatic transaminases and alkaline phosphatase, nausea, and headache.[102] In addition, voriconazole increases the serum concentrations of medications cleared by cytochrome P-450 2C9, 2C19, and 3A4 (e.g., cyclophosphamide and calcineurin inhibitors); concomitant voriconazole-sirolimus should be avoided.[103]

In patients who have failed initial therapy (i.e., salvage), liposomal amphotericin products, itraconazole, or the echinocandin caspofungin can be used. Itraconazole has a response rate of approximately 40%.[100] Oral itraconazole exhibits erratic absorption; the IV formulation is suspended in cyclodextrin, which is eliminated renally, and thus IV itraconazole should be avoided in patients with a creatinine clearance of less than 30 mL/minute (0.29 mL/s · m^2).[103] Itraconazole also has negative inotropic cardiac effects and increases the serum concentrations of medications (e.g., cyclophosphamide, etoposide, calcineurin inhibitors, and sirolimus).

The echinocandins have a unique target for their antifungal activity—specifically, β-1,3-glucan synthase, an enzyme that produces an important component of the fungal wall. Caspofungin is currently the only product of this class that is FDA approved; it is indicated for treatment of IA refractory

to alternate therapy. Caspofungin is absorbed poorly and is available only as an IV formulation.[103] Most common adverse effects include mild to moderate infusion reactions and headache, with a smaller number of patients experiencing dermatologic reactions related to histamine release (e.g., flushing, erythema, and wheals). Caspofungin therapy has been associated with elevations in hepatic transaminases in patients receiving concomitant cyclosporine, and this combination should be used with caution.[103]

There is an increasing amount of data regarding combination therapy with newly available triazoles, echinocandins, and polyenes in patients with fungal infections. Given the overall poor prognosis of IA in HCT recipients, many practitioners are treating patients with combination therapy known to be synergistic in vitro in order to maximize the chance of response.

The optimal duration of appropriate antifungal therapy for treating IA is individualized to the reconstitution of the patient's immune system and his or her response to antifungal treatment. Most clinicians will continue aggressive antifungal therapy until the infection has stabilized radiographically and may continue with less aggressive "maintenance" therapy (e.g., oral voriconazole) until immunosuppression is lessened or completed. In general, it is not uncommon to require several months of antifungal therapy to treat IA.

Pneumocystis jiroveci

After allogeneic HCT, prophylaxis for *P. jiroveci* (formerly *P. carinii*) pneumonia (PCP) is used because *Pneumocystis* is a common infection with a high mortality rate if left untreated. The optimal prophylactic regimen in this setting is unclear, with most centers using cotrimoxazole for 6 to 12 months after HCT.[8] Dapsone and aerosolized pentamidine are alternatives for patients who are allergic to sulfa drugs or who do not tolerate cotrimoxazole. Because PCP most often occurs after engraftment, cotrimoxazole usually is begun after neutrophil recovery because of its myelosuppressive effects. Patients receiving prophylactic cotrimoxazole should be monitored closely for rash and unexplained neutropenia or thrombocytopenia. Cotrimoxazole usually is avoided on days of methotrexate administration because the sulfonamides can displace methotrexate from plasma binding sites and decrease renal methotrexate clearance, resulting in higher methotrexate concentrations. Autologous HCT patients do not receive posttransplant immunosuppression, and thus their risk of developing PCP is lower.[8] Thus PCP prophylaxis is used often after autologous HCT in patients with a hematologic malignancy.

Issues of Survivorship after HCT

The number of long-term HCT survivors is increasing as 5-year disease-free survival rates improve. Since nonmyeloablative preparative regimens were developed over the past decade, the late effects reported in HCT survivors describe those resulting from myeloablative preparative regimens.[44,104] HCT recipients—with either an autologous or an allogeneic graft—have higher mortality than the general population.[105,106] ⑩ *Long-term survivors of HCT should be monitored closely, particularly for infections and secondary malignant neoplasms.*

HCT survivors are at higher risk for secondary malignant neoplasms.[104] Long-term impairment of end-organ function, including kidney, liver, and lungs, may be due to the preparative regimen, infectious diseases (e.g., hepatitis C), infection complications (either autologous or allogeneic grafts), and posttransplant immunosuppression (allogeneic grafts only).[105] Many HCT recipients experience endocrine dysfunction, such as hypothyroidism from total-body irradiation, adrenal insufficiency from long-term corticosteroids to treat GVHD, and infertility from radiation and/or high doses of alkylating agents in myeloablative preparative regimens.[105] Osteopenia has been found in over half of HCT recipients, most likely from gonadal dysfunction and/or corticosteroid administration.[105]

Close monitoring of HCT recipients for infections is necessary because recovery of immune function is slow, sometimes requiring over 2 years, even in the absence of immunosupressants.[104] Fevers should be assessed and treated rapidly to minimize the likelihood of a fatal infection. HCT recipients—both autologous and allogeneic—lose protective antibodies to vaccine-preventable diseases; the CDC and the European Group for Bone Marrow Transplantation have issued recommendations for reimmunization for HCT recipients.[107]

HCT survivors should be monitored routinely for signs of relapse and, if an allogeneic graft was used, chronic GVHD. They should be advised regarding revaccination and obtaining prompt medical care for fevers or signs of infection. Routine evaluations of organ function (i.e., renal, hepatic, thyroid, and ovarian) and osteopenia should occur and the appropriate management strategies started if necessary.

Patient Encounter 2

AS is a 65-year-old woman with relapsed acute myelogenous leukemia. PMH is significant for type II diabetes and renal insufficiency (CrCl 20 mL/minute). She is day +1 from a nonmyeloablative HCT with fludarabine (30 mg/m^2 per day IV for 3 days) and total-body irradiation preparative regimen and a graft from a full HLA-matched sibling.

- What preventative measures are needed for the complications of HCT?
- How would you monitor AS for GVHD?
- What would you recommend for treatment of GVHD?

OUTCOME EVALUATION

To monitor for the effectiveness of the HCT, monitor for symptoms and signs of the disease that is being treated by HCT. For example, the monitoring plan for a patient with CML would be to monitor disease response by PCR of the *BCR-ABL* transcript. The actual clinical outcome monitored, along with the frequency of monitoring, is based on the underlying disease.

Monitor for nonhematologic toxicity of the preparative regimen during its administration. Monitor these symptoms at least daily, with more frequent monitoring if the patient is experiencing these nonhematologic effects. The goal is to prevent or minimize these adverse effects. Specifically,

- *Busulfan:* Seizures, busulfan concentrations if being used with the BU-CY preparative regimen, number of vomiting episodes, nausea by patient self-report
- *Cyclophosphamide:* Electrocardiogram during IV administration, RBCs in urine, frequency of urination, pain on urination, urinary output, number of vomiting episodes, nausea by patient self-report
- *Etoposide:* Blood pressure, respiratory rate, serum pH, serum bicarbonate with arterial blood gases, and evaluation of anion gap if necessary
- *Total-body irradiation:* Number of vomiting episodes, nausea by patient self-report, sudden weight changes (SOS), total bilirubin

Until the patient has achieved engraftment, monitor the patient for the engraftment with at least daily CBCs with differentials; these tests may be needed more often if the patient is critically ill or had a prior low hemoglobin.

Until engraftment has occurred, monitor the patient's temperature every 4 to 8 hours for signs of infection. Also guide monitoring signs of focal point of infection based on clinical symptoms. For example, if the patient develops shortness of breath, then imaging of the lungs should occur to assess pulmonary infection. Monitor for the toxicity of prophylaxis and/or treatment of bacterial, fungal, or viral infections.

Monitor for acute nonhematologic toxicity to the preparative regimen to approximately day +30. Specifically,

- Monitor the inside of the mouth and assess the patient's mouth pain for signs and symptoms of mucositis.
- Monitor weight and skin color daily to observe sudden weight changes suggesting SOS. Obtain a total bilirubin determination at least twice weekly or more frequently if SOS is suspected based on weight change.

Monitor for signs of acute GVHD at least daily until engraftment and more often if GVHD is suspected or diagnosed. The patient and his or her caregivers should be educated regarding the signs and symptoms to self-monitor for GVHD. The signs and symptoms for acute GVHD that occur between day +0 and day +100 are rash, nausea, diarrhea, jaundice, elevated liver function tests, and elevated bilirubin.

Patient Care and Monitoring

1. Assess the patient regarding the indication for HCT, the type of preparative regimen, and the type of donor. Determine the the nonhematologic toxicity of the preparative regimen, the expected timing of engraftment after the graft is infused, along with the need for GVHD prophylaxis.
2. Determine the supportive care needs during administration of the preparative regimen, including use of indwelling central venous catheters, blood product support, and pharmacologic management of chemotherapy-induced nausea and vomiting (CINV), mucositis, and pain.
3. After the graft is infused, monitor CBC with differential at least daily to evaluate engraftment. Allogeneic HCT patients experience an initial period of pancytopenia followed by a more prolonged period of immunosuppression, which substantially increases the risk of bacterial, fungal, viral, and other opportunistic infections.
4. Counsel the patient regarding adherence to prophylactic antibiotic, antifungal, and antiviral regimens. Evaluate the patient for infection and adverse drug reactions to antibiotics, antifungals, and antivirals. Ensure that the patient is appropriately immunized after recovery from HCT.
5. Counsel the patient regarding adherence to GVHD prophylaxis and treatment. Monitor and manage for adverse drug reactions.

ABBREVIATIONS

CMV:	cytomegalovirus
DLI:	donor lymphocyte infusion
GVHD:	graft-versus-host disease
HLA:	human leukocyte antigen
HCT:	hematopoietic cell transplantation
HSV:	herpes simplex virus
IA:	invasive aspergillosis
NMT:	nonmyeloablative transplant
PCP:	*Pneumocystis jiroveci* pneumonia (formerly *Pneumocystis carinii*)
SOS:	sinusoidal obstruction syndrome
VZV:	varicella-zoster virus

96 Oncologic Emergencies

Brad L. Stanford

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Describe the impact of various oncologic emergencies on the prognosis of patients with cancer.
2. Discuss the causes of various oncologic emergencies in relation to their underlying cancer types.
3. Identify risk factors for oncologic emergencies in relation to prevention and treatment options.
4. Recognize typical presenting signs and symptoms of oncologic emergencies.
5. Outline an appropriate prevention strategy for various oncologic emergencies.
6. Recommend optimal nonpharmacologic and pharmacologic management strategies for patients with oncologic emergencies.
7. Prepare a monitoring plan to evaluate the efficacy and toxicity of pharmacotherapy for oncologic emergencies.

Key Concepts

❶ A risk assessment should be performed at presentation of febrile neutropenia to identify low-risk patients for potential outpatient treatment. Patients who do not meet low-risk criteria should be hospitalized for immediate parenteral administration of broad-spectrum antibacterials before culture results are obtained.

❷ The success of the treatment of febrile neutropenia hinges on the adequate recovery of the absolute neutrophil count and either optimal antimicrobial coverage of identified organisms or empirical coverage of unidentified organisms.

❸ The primary goal of treatment of superior vena cava (SVC) syndrome is to relieve obstruction of the superior vena cava by treating the underlying malignancy.

❹ Since patients with spinal metastases generally are incurable, the primary goal of treatment of spinal cord compression is palliation. The most important prognostic factor for patients presenting with spinal cord compression is the underlying neurologic status.

❺ The goals of treatment of brain metastases are to manage symptoms by reducing cerebral edema, treat the underlying malignancy both locally and systemically, and improve survival.

❻ The use of effective prevention strategies can decrease the incidence of hemorrhagic cystitis to less than 5% in patients receiving cyclophosphamide or ifosfamide. There are three methods to reduce the risk: administration of mesna, hyperhydration, and bladder irrigation with catheterization.

❼ The primary goal of treatment for hypercalcemia is to control the underlying malignancy. Therapies directed at lowering the calcium level are temporary measures that are useful until anticancer therapy begins to work.

❽ Therapeutic options for the treatment of hypercalcemia should be directed toward the level of corrected serum calcium and the presence of symptoms. Adequate treatment of mild or asymptomatic hypercalcemia may be achieved on an outpatient basis with nonpharmacologic measures. Moderate to severe or symptomatic hypercalcemia almost always requires pharmacologic intervention.

❾ The primary goals of management of tumor lysis syndrome are (1) prevention of renal failure and (2) prevention of electrolyte imbalances. Thus the best treatment for tumor lysis syndrome is prophylaxis to enable delivery of cytotoxic therapy for the underlying malignancy.

❿ Chemotherapy extravasation may be avoided in many cases by the use of successful prevention strategies. The most important preventative measure is proper patient education.

Patients with cancer are at risk for life-threatening events from the malignancy itself or various treatments for their cancer. These events traditionally have been defined as oncologic emergencies. Although some of these conditions are not imminently life-threatening (e.g., chemotherapy extravasation), they do require rapid assessment and treatment.

Oncologic emergencies may best be subdivided according to the following systems of origin:

- Hematologic
- Cardiovascular
- Neurologic
- Urologic
- Metabolic
- Miscellaneous

The onset of oncologic emergencies affecting these systems may herald the onset of an undiagnosed malignancy or progression/relapse of a preexisting malignancy. Prompt recognition and optimal management of patients with various oncologic emergencies can decrease morbidity significantly and potentially save lives. Pharmacists and other midlevel practitioners may play a key role in this area.

HEMATOLOGIC COMPLICATIONS

Febrile Neutropenia

Febrile neutropenia is a common adverse effect of the administration of cytotoxic chemotherapy. The mortality rate owing to infectious complications currently remains between 5% and 10%; therefore, febrile neutropenia is considered a true oncologic emergency. Patients frequently require hospitalization for prompt administration of broad-spectrum antibiotics that are critical to avoid morbidity and mortality.

Epidemiology and Etiology

The microorganisms responsible for infections in neutropenic patients have changed significantly in the last 50 years. From the 1960s through the mid-1980s, gram-negative organisms were the most common bacteria isolated. This pattern shifted to the gram-positive organisms in the late 1980s, which remain the most common isolates. Recent data indicate that gram-positive organisms account for 62% to 76% of all bloodstream infections.[1] The causes of this change are attributed to the widespread use of central venous catheters and more aggressive chemotherapy regimens, as well as the use of prophylactic antibiotics with relatively poor gram-positive coverage (quinolones). Commonly isolated pathogens are shown in Table 96–1. Although gram-negative infections are less common, they cause the majority of infections in sites other than the blood and are particularly virulent. It should be noted that isolates vary considerably between institutions; thus attention to institutional isolation patterns is prudent.

Fungal infections due to *Candida* spp. (especially *C. albicans*) have emerged as significant pathogens, especially in patients with hematologic malignancies and those undergoing bone marrow transplantation. In addition, *Aspergillus* spp. are important pathogens in patients with prolonged and severe neutropenia.

Patient Encounter 1, Part 1

BR is a 62-year-old woman who was recently diagnosed with stage IV large B-cell lymphoma. Her bone marrow is positive for lymphoma, and she has type II diabetes and hypertension.

- What risk factors for febrile neutropenia does this patient have?
- What signs and symptoms of infection would you counsel this patient to watch for following treatment?

TABLE 96–1. Commonly Isolated Pathogens in Patients with Febrile Neutropenia

Type of Organism	Comments
Bacteria	
Gram-positive organisms	Most common isolates in febrile neutropenia
Coagulase-negative staphylococci (i.e., *St. epidermidis*)	Between 70% and 90% resistance to methicillin; indolent course with low mortality
Staphylococcus aureus	Some centers report greater than 50% resistance to methicillin
Enterococcus spp.	Resistance to vancomycin greater than or equal to 30%
Viridans streptococci	Increasing resistance to penicillin; result of fluoroquinolone prophylaxis; associated with mucositis
Gram-negative organisms	Infections rapidly fatal
Pseudomonas aeruginosa	High mortality; increasing resistance to quinolones
Escherichia coli	Increased incidence of beta-lactamase producing strains
Klebsiella spp.	Increased incidence of beta-lactamase producing strains
Enterobacter spp.	Occur primarily after prolonged neutropenia (greater than 1 week)
Fungi	
Yeasts	
Candida albicans	Increasing incidence (approximately 10%); high mortality
Non-*albicans Candida* (*C. krusei, C. glabrata*)	Resistant to fluconazole; high mortality
Molds	Resistant to fluconazole; high mortality
Aspergillus spp.	Pulmonary infection common
Fusarium spp.	Emerging pathogen
Scedosporium spp.	Emerging pathogen

Data from refs. 2 and 3.

Pathophysiology

The neutrophils are the primary defense mechanism against bacterial and fungal infection. Most infections in neutropenic patients are a result of organisms contained in endogenous flora, both on the skin and within the gastrointestinal (GI) tract. These organisms are provided access to the bloodstream through breakdowns in host defense barriers (i.e., **mucositis** and use of central venous catheters). Mucositis in particular is a significant risk factor for sepsis and is increasingly more common owing to the widespread use of aggressive chemotherapy regimens.[4]

Neutropenia is defined as an absolute neutrophil count (ANC) of less than $0.5 \times 10^3/\mu L$ ($0.5 \times 10^9/L$) cells or an ANC of less than $1.0 \times 10^3/\mu L$ ($1.0 \times 10^9/L$) cells with a predicted decrease to less than $0.5 \times 10^3/\mu L$ ($0.5 \times 10^9/L$) cells. The ANC is calculated by multiplying the total white blood cell (WBC) count by the percentage of neutrophils (segmented neutrophils plus bands). *Fever* is defined as a single oral temperature of 38.3°C (101°F) or greater or a temperature of 38.0°C (100.4°F) or greater for at least 1 hour. The combination of these two factors defines febrile neutropenia.[5] The risk of infection during the period of neutropenia depends primarily on two factors:

- The duration of the neutropenia [time period of ANC less than $0.5\ 10^3/\mu L$ ($0.5 \times 10^9/L$)]
- The severity of the neutropenia [lowest ANC level reached (nadir)]

A multitude of other risk factors for febrile neutropenia have been identified (Table 96–2). Many of these are also risk factors for poor outcome in patients who experience febrile neutropenia.

TABLE 96–2. Risk Factors for Febrile Neutropenia

Patient-Related	Therapy-Related
Age greater than or equal to 60 years	History of prior extensive chemotherapy
Poor **performance status**	Planned full **dose intensity** of chemotherapy
Bone marrow involvement by tumor	High-dose chemotherapy (i.e. bone marrow transplant)
Poor nutritional status	
Hematologic malignancy	
Elevated LDH	
Decreased hemoglobin level	
Baseline or first-cycle low neutrophil counts	
History of previous febrile neutropenia	
Uncontrolled or advanced stage cancer	

LDH, lactate dehydrogenase.
Data from ref. 6.

TABLE 96–3. Multinational Association for Supportive Care in Cancer (MASCC) Risk Index for Identifying Low-Risk Patients with Febrile Neutropenia[7]

Characteristic	Score
Extent of illness[a]	
No symptoms	5
Mild symptoms	5
Moderate symptoms	3
No hypotension	5
No chronic obstructive pulmonary disease	4
Solid tumor or no fungal infection	4
No dehydration	3
Outpatient onset of fever	3
Age less than 60 years[b]	2

Note: A risk index score of 21 or greater indicates that the patient is likely to be at low risk for complication and morbidity.
[a]Choose one item only.
[b]Does not apply to patients 16 years of age and younger.

It is clear that patients with febrile neutropenia represent a heterogeneous group. Some patients are at lower risk and potentially could be treated as outpatients, thereby avoiding the risk and cost of hospitalization. The Multinational Association for Supportive Care in Cancer (MASCC) has validated a risk-assessment tool that assigns a risk score to patients presenting with febrile neutropenia[7] (Table 96–3). Patients with a risk-index score of 21 or greater are identified as low risk and are candidates for outpatient therapy (discussed under "Treatment").

Clinical Presentation and Diagnosis

General

- Only 50% of patients with febrile neutropenia have a clinically documented infection.
- Only 25% of patients with febrile neutropenia have a microbiologically documented infection.

Signs and Symptoms

- Fever is typically the only sign of infection, although septic patients may have chills.
- Infected catheter sites may be erythematous and tender to the touch.

Laboratory Tests

- Complete blood count (CBC) with differential
- Blood cultures × 2 from *each* access site (peripheral and central), urinalysis, urine culture, chest x-ray, sputum cultures

Other Diagnostic Tests

Detailed physical examination of oral mucosa, sinuses, skin, catheter access sites, and perineal area (no rectal examination owing to risk of bacteremia)

Patient Encounter 1, Part 2

BR arrives at the clinic to receive her first dose of R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone) at full doses.

- What preventative measures should be taken to decrease her risk of febrile neutropenia?
- What specific agent(s) would you consider for prophylactic use in this patient?

Prevention

Three primary modalities for preventing infection in patients who are expected to become neutropenic have been used, the first of which is the cheapest and simplest:

- Careful hand washing
- Prophylactic antibiotics
- Colony-stimulating factors

The advantages and disadvantages of these strategies will be discussed individually in the following sections.

Hand Washing

As discussed previously, most infections in neutropenic patients are a result of endogenous flora; however, prevention of further acquisition of environmental pathogens is also important. Patients who are or will become neutropenic should practice careful hand washing, and contact with people who neglect hand washing should be avoided. In addition, ingestion of fresh fruits and vegetables as well as nonprocessed dairy products, should be avoided during the neutropenic period.

Prophylactic Antibiotics

Routine antibacterial prophylaxis is controversial and has been attempted primarily with sulfamethoxazole-trimethoprim (SMZ-TMP) and quinolones. SMZ-TMP offers improved prophylaxis for gram-positive organisms compared with quinolones, whereas quinolones are more effective prophylaxis against gram-negative infections. The 2002 Infectious Diseases Society of America (IDSA) guidelines for the use of antimicrobial agents in cancer do not recommend the use of these agents for routine prophylaxis.[5] Reasons for this recommendation include the lack of a clear benefit on mortality rates and concerns regarding increasing antibiotic resistance. One exception is that SMZ-TMP is recommended for prophylaxis of *Pneumocystis jiroveci* pneumonitis (PCP) in all at-risk patients (i.e., bone marrow transplant recipients and AIDS patients) regardless of the presence of neutropenia.

Two recent meta-analyses add fuel to this controversial area.[8,9] Decreases in infection-related mortality and gram-negative bacteremia were demonstrated with the use of quinolones, but overall adverse events were higher, and most of the studies were conducted in patients with hematologic malignancies (an inherently high-risk group). Therefore, the use of prophylactic quinolones in patients with hematologic malignancies is reasonable, but pay particular attention to changes in local patterns of resistance if widely implemented.

Colony-Stimulating Factors

The colony-stimulating factors (CSFs) stimulate the maturation and differentiation of neutrophil precursors. Three agents are currently approved for use in the United States (Table 96–4). The prophylactic use of these agents decreases days of hospitalization and use of empirical antibiotics by shortening the duration of neutropenia [defined as an ANC of less than $0.5 \times 10^3/\mu L$ ($0.5 \times 10^9/L$)]. There is little to no effect on the depth of neutrophil nadir. A recent meta-analysis found that the use of prophylactic granulocyte colony-stimulating factor (either filgrastim or peg-filgrastim) resulted in a 46% risk reduction of febrile neutropenia and a 48% risk reduction in infectious mortality, although absolute differences were small (3.3% versus 1.7%).[10] It is critical to note that patients who receive these agents still may experience febrile neutropenia despite the risk reduction.

The primary limitation of the use of these agents is cost. Clinical practice guidelines for the use of CSFs have been developed by the National Comprehensive Care Network (NCCN).[11] These guidelines recommend the use of CSFs beginning with the first cycle (primary prophylaxis) of chemotherapy when the risk of febrile neutropenia is approximately 20% or more. This is the point where the use of CSFs is cost-effective when balanced against the cost of hospitalization and antimicrobials. *Secondary prophylaxis* refers to the subsequent prophylactic use of a CSF after a patient has had a prior episode of febrile neutropenia. This strategy should be used especially when the chemotherapy is being given in patients with the intention of cure (e.g., non-Hodgkin's lymphoma and early breast cancer). In this circumstance, administration of full doses of chemotherapy on time without delays has been shown to improve outcome.

Although generally well tolerated, CSFs may cause bone pain in around 25% of patients. This may be managed with acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs), although attention to the platelet count is warranted with the use of NSAIDs. Sargramostim in particular may result

Patient Encounter 1, Part 3

BR presents to the clinic approximately 8 days after her second cycle of R-CHOP with a temperature of 101.2°F (38.4°C). Her CBC reveals a WBC count of $0.84 \times 10^3/\mu L$ ($0.84 \times 10^9/L$) with 10% (0.10) neutrophils and 15% (0.15) bands.

- What is BR's absolute neutrophil count?
- What treatment goals do you have for BR?
- Construct a treatment plan for this patient with specific monitoring criteria for therapy adjustment.

TABLE 96–4. Overview of Colony-Stimulating Factors[11]

Agent	Effector Cell(s)	Dosage	Common Adverse Effects	Comments
Filgrastim Neupogen® GCSF	Neutrophil	5 mcg/kg per day SQ or IV *or* round to 300- or 480-mcg vial size	Bone pain (approximately 25%)	Begin 1–3 days after chemotherapy
Pegfilgrastim Neulasta®	Neutrophil	6 mg SQ one time	Bone pain (approximately 25%)	Once per cycle dosing Administer 1–3 days after chemotherapy
Sargramostim Leukine® GMCSF	Neutrophil, Eosinophil, Macrophage	250 mcg/m^2 per day SQ or IV *or* round to 250- or 500-mcg vial size	First-dose effect (hypotension, flushing) Low-grade fever Bone pain Injection-site skin reaction	Indicated for use following induction chemotherapy in older patients with AML Limited experience and lack of FDA approval for prevention of febrile neutropenia

GCSF, granulocyte colony stimulating factor; GMCSF, granulocyte-macrophage colony stimulating factor; SQ, subcutaneous; IV, intravenous; AML, acute myeloid leukemia.

in low-grade fever and myalgias, perhaps as a result of its wider pattern of effector cell stimulation.

Treatment

Desired Outcomes

Since rapid death may occur with certain infections in neutropenic patients, prompt and emergent treatment is indicated. The primary goal is to prevent morbidity and mortality during the neutropenic period. This is accomplished by effectively treating subclinical infections or established infections.

General Approach to Treatment

❶ *A risk assessment should be performed at presentation of febrile neutropenia to identify low-risk patients for potential outpatient treatment* (see Table 96–3). *Patients who do not meet low-risk criteria should be hospitalized for parenteral administration of broad-spectrum antibacterials.* The IDSA has published evidence-based guidelines for the management of febrile neutropenia[5,12] (Fig. 96–1). The choice of initial antimicrobial agent(s) depends on the following factors:

- Drug allergies
- Concurrent renal dysfunction or use of nephrotoxic agents
- Use of prophylactic antibiotics
- Institutional susceptibility patterns
- Cost

❶ *The administration of empirical therapy should begin immediately after cultures are taken. Therapy should not be withheld until after culture results are obtained.*

As illustrated in Fig. 96–1, specific criteria exist for the addition of vancomycin for coverage of resistant gram-positive organisms or agents for coverage of fungal infections. Additional agents are necessary in the setting of continued fever or declining clinical status in neutropenic patients. In general, all empirical therapy is continued until recovery of the ANC to levels above $0.5 \times 10^3/\mu L$ ($0.5 \times 10^9/L$) in patients with negative cultures. If a specific etiology is identified, appropriate therapy should be continued until 7 days after neutropenia resolves. Specific regimens with recommended dosages are summarized in Table 96–5.

Pharmacologic Therapy

There are two primary choices for the initial management of high-risk febrile neutropenia: monotherapy and dual therapy (see Fig. 96–1). Both regimens have been shown to be equivalent in randomized studies and meta-analyses. Monotherapy avoids the nephrotoxicity of the aminoglycosides and is potentially less expensive but lacks significant gram-positive coverage and may increase selection of resistant organisms. Dual therapy provides synergistic activity, decreased resistance, and permits dual coverage of *Pseudomonas aeruginosa* but requires therapeutic monitoring for aminoglycosides.

Vancomycin adds broad-spectrum gram-positive coverage, but increasing emergence of vancomycin-resistant organisms (e.g., *Enterococcus* spp.) prompts conservative use. Thus vancomycin should be included as part of the initial therapy only in the following cases:

- Severe mucositis
- Quinolone prophylaxis
- Hypotension
- Colonization with resistant gram-positive organisms (e.g., methicillin-resistant *Staphylococcus aureus*)
- Evidence of central venous catheter infection

Vancomycin may be added to the empirical regimen after 3 to 5 days in persistently febrile patients or if cultures reveal gram-positive organisms. Vancomycin should be changed if the gram-positive organism is susceptible to other antibacterials or discontinued in patients with persistent fever after 3 days with negative cultures.

Empirical antifungal agents typically are added in persistently febrile patients after 5 to 7 days, especially if continued

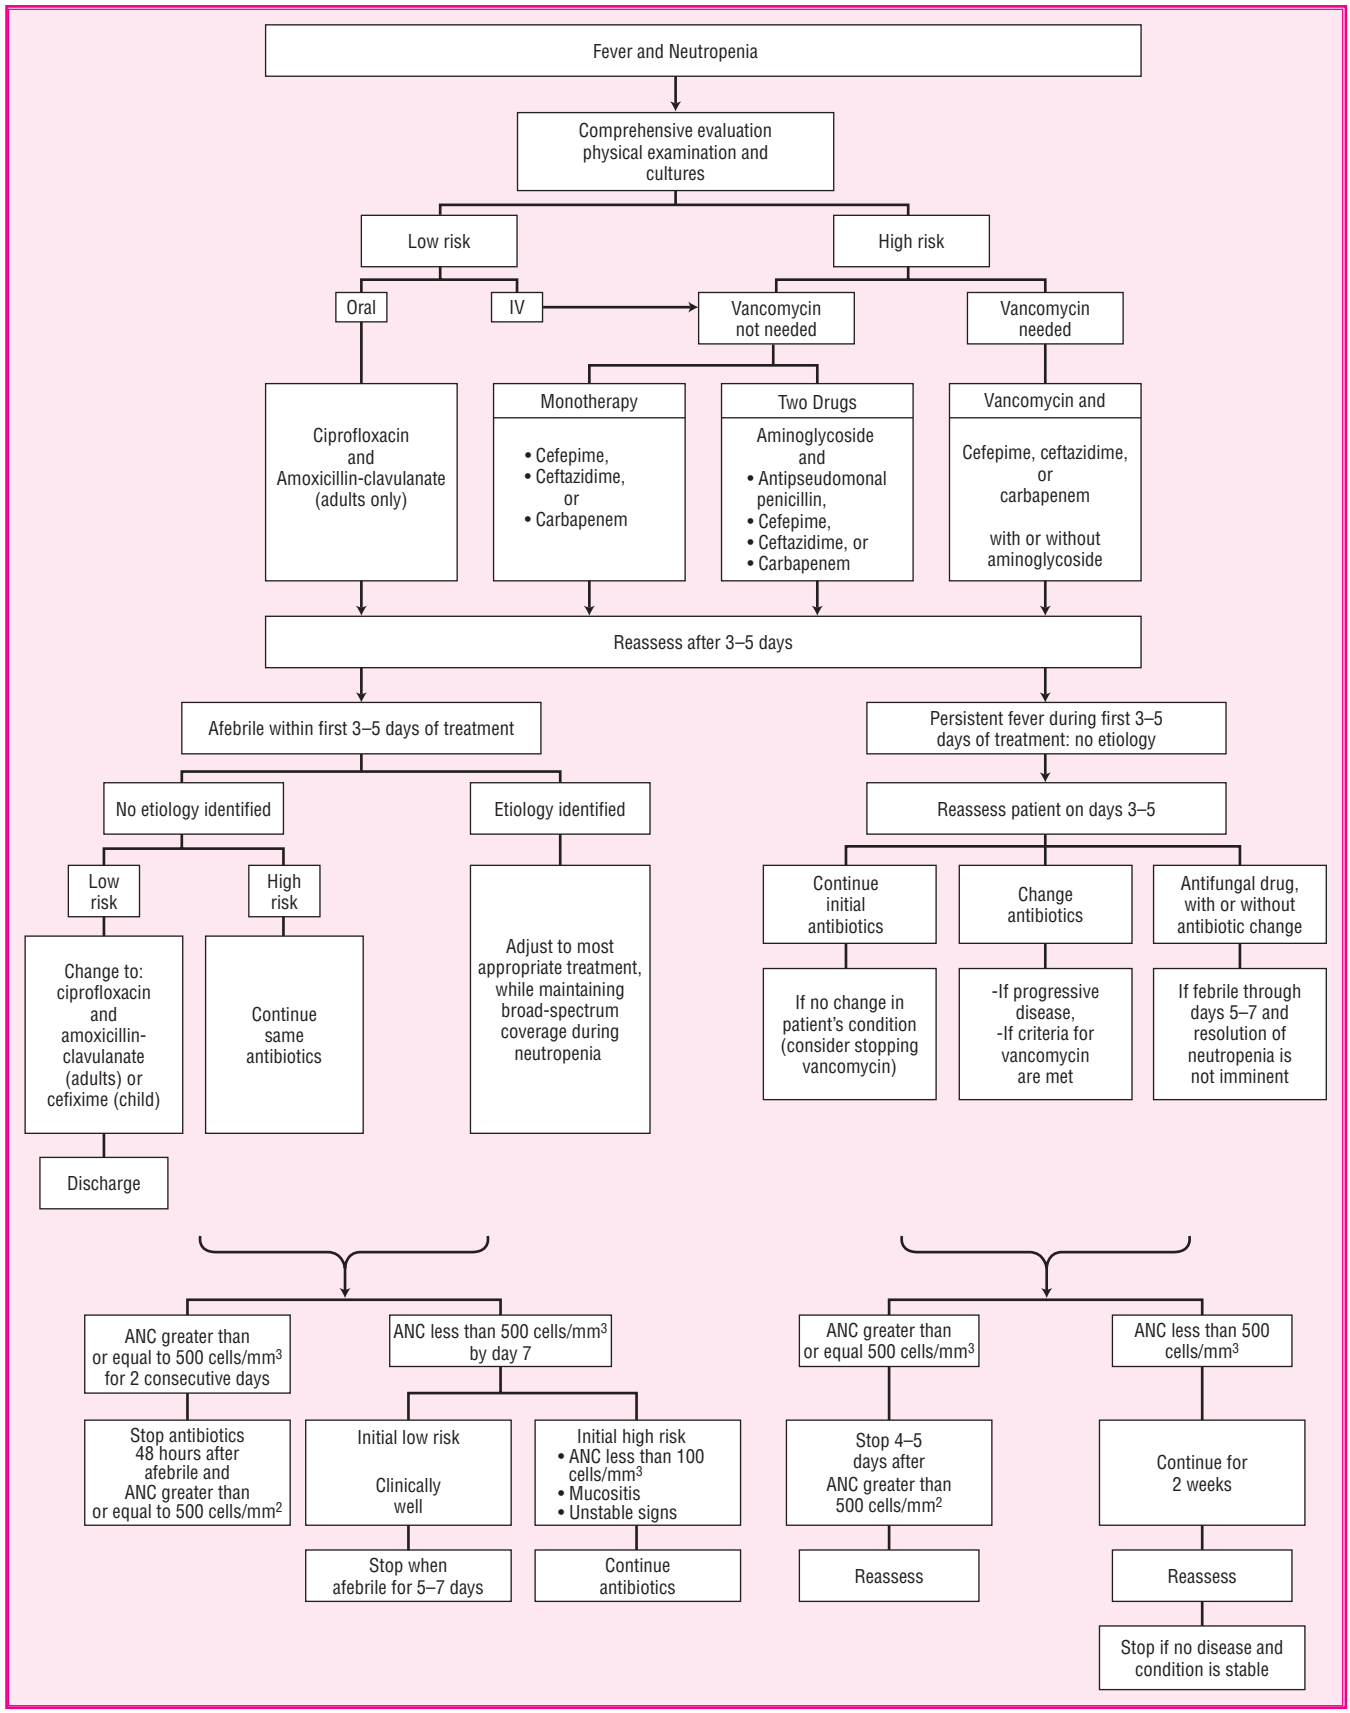

FIGURE 96–1. Management of febrile episodes in neutropenic cancer patients.[5,12]

TABLE 96–5. Dosing Guidelines for Empirical Antimicrobial Agents in Febrile Neutropenia

Regimen Type	Agents and Dosing[a]	Comments
Antibacterial		
β-Lactam monotherapy	Cefepime 2 g IV every 8 hours Ceftazidime 2 g IV every 8 hours Imipenem 500 mg IV every 6 hours Meropenem 1g IV every 8 hours Piperacillin tazobactam 4.5 g IV every 8 hours	Although piperacillin-tazobactam is not recommended in the IDSA guidelines, recent data demonstrate equivalence to other monotherapy and dual-therapy regimens.
Dual therapy with antipseudomonal β-lactam plus aminoglycoside	Cefepime, ceftazidime, imipenem, meropenem, piperacillin-tazobactam (above dosages), ticarcillin–clavulanic acid 3.1 g IV every 6 hours and gentamicin or tobramycin	Gentamicin or tobramycin 2 mg/kg loading dose followed by doses adjusted by serum concentrations; once-daily dosing of aminoglycosides may be used.
Empirical regimens containing vancomycin	Cefepime, ceftazidime, imipenem, meropenem (above dosages) and vancomycin 0.5–1 g every 6–12 hours with or without aminoglycoside	Vancomycin dosages may be adjusted based on serum levels.
Dual therapy containing fluoroquinolone	Ciprofloxacin 400 mg IV every 8 hours and piperacillin-tazobactam, ceftazidime (above dosages)	Cannot be used in patients who receive fluoroquinolone prophylaxis.
Low-risk oral regimen	Ciprofloxacin 750 mg PO every 12 hours and amoxicillin-clavulanate 500–875 mg PO every 12 hours	For patients with MASCC score of 21 or greater not receiving fluoroquinolone prophylaxis.
Antifungal		
Amphotericin B deoxycholate	0.5–1 mg/kg IV daily	Premedication with acetaminophen and diphenhydramine; 500 mL normal saline boluses before and after.
Liposomal amphotericin B	3 mg/kg IV daily	Lower incidence of nephrotoxicity and infusion reactions; more expensive.
Caspofungin	70 mg/kg IV loading dose on day 1 followed by 50 mg/kg IV daily	Dosage adjustment in hepatic dysfunction.
Voriconazole	6 mg/kg IV loading dose every 12 hours on day 1 followed by 4 mg/kg PO/IV every 12 hours	Dosage adjustment in hepatic dysfunction; IV formulation contraindicated if creatinine clearance less than 50 mL/minute; multiple drug interactions.

[a]Dosing for adult patients.
IV, intravenous; PO, by mouth.

neutropenia is expected. Amphotericin B historically has been the drug of choice owing to its broad-spectrum activity against both yeast (*Candida* spp.) and mold (*Aspergillus* spp.) infections. Because frequent toxicity (e.g., nephrotoxicity and infusion reactions) limits the use of amphotericin B, less toxic alternatives have been studied. Lipid formulations of amphotericin provide decreased toxicity, and liposomal amphotericin B (AmBisome®) has been shown to be equivalent to conventional amphotericin B as empirical therapy but is significantly more expensive. The role of voriconazole is unclear at this time; however, caspofungin has been shown to be equivalent with less toxicity than liposomal amphotericin B in a randomized trial and is approved by the Food and Drug Administration (FDA) for this indication.[13] Itraconazole also has been used in some institutions, but its use is complicated by poor bioavailability of oral preparations and numerous drug interactions.

As stated earlier, low-risk patients fulfilling the MASCC criteria (see Table 96–3) may be treated empirically as an outpatient with a regimen combining amoxicillin–clavulanic acid and ciprofloxacin. Clindamycin is a reasonable alternative for penicillin-allergic patients.

The CSFs should not be used routinely for treatment of febrile neutropenia in conjunction with antimicrobial therapy.[5] However, the use of CSFs in certain high-risk patients with hypotension, documented fungal infection, pneumonia, or sepsis is reasonable. A recent meta-analysis demonstrated that hospitalization and neutrophil recovery are shortened and that infection-related mortality is marginally improved.[14] As with prophylactic use of these agents, cost considerations limit their use to high-risk patients.

Outcome Evaluation

❷ *The success of the treatment of febrile neutropenia depends on the adequate recovery of the ANC and either optimal antimicrobial coverage of identified organisms or empirical coverage of unidentified organisms.* Monitor the CBC with differential and T_{max} (maximum temperature during previous 24 hours) daily. Assess renal and hepatic function at least twice weekly,

Patient Care and Monitoring

1. Counsel patients receiving cytotoxic chemotherapy to report fever promptly. Provide patients with a diet to use during the neutropenic period. Counsel patients to avoid close contact with sick friends and relatives, and remind the patient and caregivers of the importance of hand washing.
2. If febrile neutropenia occurs, patient history is important:
   - What chemotherapy did the patient receive and when? Is the ANC on the way down (before nadir) or on the way up (after nadir)? Was the patient receiving prophylactic antibiotics, prophylactic filgrastim, or sargramostim or received prophylactic pegfilgrastim?
   - Did the patient have previous episodes of febrile neutropenia? What were the previous culture results to determine colonization status?
3. Assess the patient daily for any new signs or symptoms of infection. Evaluate the patient for adverse drug reactions, drug allergies, and drug interactions. Have all antibiotics been dose adjusted for renal or hepatic dysfunction?
4. For patients receiving oral antibiotics either prophylactically or as treatment of febrile neutropenia, counsel them that initial or persistent fever should be reported promptly and that compliance with the regimen is critical. Patients also should have easy access to medical care and adequate caregiver support. Provide information on drug interactions and adverse effects.

especially in patients receiving nephrotoxic agents. Vital signs should be taken every 4 hours. Follow up on blood and urine culture results daily because many cultures do not become positive for several days. Assess the patient daily for pain that may indicate an infectious source. Conduct daily physical examination of common sites of infection. Repeat cultures and chest x-ray in persistently febrile patients, and culture developing sources of infection (e.g., stool cultures for diarrhea).

CARDIOVASCULAR COMPLICATIONS

Superior Vena Cava Syndrome (SVCS)

Superior vena cava syndrome (SVCS) is a relatively rare complication of underlying cancer, although nonmalignant causes also may occur in patients with cancer. SVCS is rarely immediately life-threatening, except in patients with airway compromise and/or laryngeal or cerebral edema. However, rapid recognition of typical presenting symptoms facilitates referral for tissue diagnosis (if unknown) and treatment.

Epidemiology and Etiology

SVCS occurs in around 15,000 patients per year, of which approximately 90% are caused by malignancy. Specific cancers associated most commonly with SVCS are listed in Table 96–6. Lung cancer is the most frequent cause, of which small cell lung cancer (SCLC) is the most frequent sub-type associated with SVCS. This is thought to be due its predilection for the central and **perihilar** areas of the lung. Interestingly, right-sided lung cancers are four times more likely than left-sided lesions to cause SVCS. Mediastinal masses from lymphomas are the second most common cause.

The most common nonmalignant etiology of SVCS is catheter-related thrombosis primarily owing to the increasing use of central access devices. Other causes include benign teratoma, tuberculosis, silicosis, and sarcoidosis.

Pathophysiology

The superior vena cava (SVC) is the primary drainage vein for blood return from the head, neck, and upper extremities. It is a relatively thin-walled vein that is particularly vulnerable to obstruction from adjacent tumor invasion or thrombosis. The obstruction leads to elevated venous pressure, although collateral veins partially compensate. This is one reason for the relatively slow onset of the classic symptoms of SVCS. In fact, 75% of patients have signs and symptoms for more than 1 week before seeking medical attention.[15]

Treatment

Desired Outcomes

❸ *The primary goal of treatment of SVCS is to relieve the obstruction of the SVC by treating the underlying malignancy.* In the case of SVCS caused by thrombosis, the goal is to dissolve the thrombus and prevent further clot formation. Resolution of the obstruction will rapidly relieve symptoms and restore normal SVC function. The final goal of therapy is to avoid potentially fatal complications of SVCS, such as cerebral edema from rapid increases in intracranial pressure and intracranial thrombosis or bleeding.

TABLE 96–6. Tumors Most Commonly Associated with Superior Vena Cava Syndrome

Cause	Frequency (%)
Lung cancer	65–80
Lymphoma	10
Mediastinal tumors	10
Germ cell tumors	
Thymoma	
Metastatic solid tumors	5–10
Breast cancer	

Data from ref. 15.

Clinical Presentation and Diagnosis

General

- Presentation depends on the degree of SVC obstruction.
- Almost complete obstruction is necessary to demonstrate classic symptoms.

Signs and Symptoms

- Facial, neck, and upper extremity edema; dyspnea; cough, dilated upper extremity veins; and orthopnea are most common.
- Less common—hoarseness, dysphagia, dizziness, headache, lethargy, chest pain
- Patients with elevated intracranial pressure may have mental status changes.
- Patients with airway obstruction may have shortness of breath.

Diagnostic Tests

Tissue biopsy to determine underlying cause (if unknown), chest x-ray, computed tomographic (CT) scan, bronchoscopy, and mediastinoscopy

General Approach to Treatment

Since most SVCSs are not immediately life-threatening, a tissue diagnosis (if unknown) to specifically identify the underlying malignancy is critical because treatment approaches vary considerably according to tumor histology. Thus therapy typically can be withheld until a tissue diagnosis is established. While biopsy results are pending, supportive measures such as head elevation, diuretics, corticosteroids, and supplemental oxygen may be used.

Nonpharmacologic Therapy

Radiation therapy is the treatment of choice for chemotherapy-resistant tumors such as non–small cell lung cancer (NSCLC) or in chemotherapy-refractory patients with SVCS. Between 70% and 90% of patients will experience relief of symptoms. Radiation therapy also may be combined with chemotherapy for chemotherapy-sensitive tumors such as SCLC and lymphoma. In the rare emergency situations of airway obstruction or elevated intracranial pressure, empirical radiotherapy prior to tissue diagnosis should be used. In most patients, symptoms resolve within 1 to 3 weeks.

Surgical options for the management of SVCS include stent placement and surgical bypass. SVC stenting may provide longer-term relief of symptoms than radiotherapy; thus it is used often in the palliative-care setting when chemotherapy has failed.[16] One disadvantage of SVC stenting is the need for anticoagulation, especially in patients at high risk for thrombosis. The role of surgical bypass is limited to patients with complete SVC obstruction or patients who are refractory to chemotherapy and radiotherapy; thus it is rarely indicated.

Pharmacologic Therapy

Cytotoxic chemotherapy is the treatment of choice for chemotherapy-sensitive tumors such as SCLC and lymphoma. As indicated earlier, chemotherapy also may be combined with radiotherapy, especially in patients with lymphoma who have bulky mediastinal lymphadenopathy.

Corticosteroids play a key role in the management of SVCS, particularly in cases of lymphoma, because these tumors inherently respond to corticosteroid therapy. They are also helpful in the setting of respiratory compromise. Corticosteroids benefit patients who are receiving radiation therapy by reducing local radiation-induced inflammation and increased intracranial pressure. Dexamethasone 4 mg intravenously or by mouth every 6 hours is a frequently used regimen. The dosage should be tapered on completion of radiation therapy or resolution of symptoms.

The role of diuretics in the management of SVCS is controversial. While patients may derive symptomatic relief from edema, complications such as dehydration and reduced venous blood flow may exacerbate the condition. If diuretics are used, furosemide is used most frequently with diligent monitoring of the patient's fluid status and blood pressure.

In the case of thrombosis-related SVCS, anticoagulation is controversial because there is a lack of survival benefit. However, thrombolytics (e.g., alteplase) and anticoagulation with heparin and warfarin may be beneficial in patients with thrombosis owing to indwelling catheters if it is used within 7 days of onset of symptoms, although catheter removal may be required.

Outcome Evaluation

The major measure of outcome of treatment of SVCS is the relief of symptoms, regardless of the therapy used. SVC stenting provides rapid relief of symptoms within 1 to 7 days of stent placement.[15] Patients who receive chemotherapy and/or radiotherapy generally will experience symptom relief within 1 to 2 weeks. Monitor the patient for relief of symptoms by

- Daily physical assessment of signs and symptoms
- Daily monitoring of fluid status
- For corticosteroid use, serum glucose, insomnia, fluid retention, GI upset, mental status changes, signs and symptoms of infection daily

Repeat CT scans of the chest after the first cycle of chemotherapy, surgical stenting, or radiotherapy to assess tumor response.

NEUROLOGIC COMPLICATIONS

Spinal Cord Compression

Although not typically life-threatening, spinal cord compression is a true oncologic emergency because delays in treatment by mere hours may lead to permanent neurologic dysfunction. It is therefore incumbent on practitioners to

Patient Care and Monitoring

1. Does the patient have a known cancer at presentation? Assess the patient's symptoms at presentation to determine the need for emergent treatment versus disease-specific treatment following tissue diagnosis.
2. Review biopsy results to determine optimal chemotherapy and/or radiation regimen.
3. For patients receiving corticosteroids, monitor for adverse effects and drug interactions. Does the patient need GI prophylaxis for long-term treatment? Slowly taper once symptoms improve and/or radiation is completed.
4. Evaluate the patient for drug interactions, allergies, and adverse effects with chemotherapy and/or corticosteroid therapy.

quickly recognize the signs and symptoms to facilitate rapid management strategies.

Epidemiology and Etiology

Around 20,000 cancer patients experience spinal cord compression in the United States every year, most of which involves the thoracic spine (approximately 70%). Cancers that inherently metastasize to bone (e.g., breast, prostate, and lung) are the most frequent etiologies identified. Most spinal cord compression occurs in patients with a known malignancy; however, 8% to 34% occurs as the initial presentation of cancer, especially in patients with non-Hodgkin's lymphoma, multiple myeloma, and lung cancer.[17]

Clinical Presentation and Diagnosis

General

- Once neurologic deficits appear, progression to irreversible paralysis may occur within hours to days.
- Around 10% to 38% of patients present with multiple sites of spinal involvement.

Signs and Symptoms

- Back pain is present in more than 90% of patients.
  - Initially localized and increases in intensity over several weeks
  - Aggravated by movement, supine positioning, coughing, sneezing, neck flexion, straight-leg raise, Valsalva maneuver, and palpation of spine
- Sensory deficit
  - Cervical spine compression may lead to quadriplegia
  - Thoracic spine compression may lead to paraplegia
  - Upper lumbar spine compression may lead to bowel and bladder dysfunction (constipation and urinary retention) and abnormal extensor plantar reflexes
- Weakness

Diagnostic Tests

- Magnetic resonance imaging (MRI) with gadolinium enhancement is the "gold standard."
- X-rays may be helpful to identify bone abnormalities.

Pathophysiology

The spinal cord emerges from the brain stem at the base of the skull and terminates at the second lumbar vertebra. The thoracic spine is most vulnerable to cord compression because of natural kyphosis and because the width of the thoracic spinal canal is the smallest among the vertebrae. Most spinal cord compression is due to adjacent vertebral metastases that compress the spinal cord or from pathologic compression fracture of the vertebra. This results in significant edema and inflammation in the affected area.

Treatment

Desired Outcome

❶ *Since patients with spinal metastases generally are incurable, the primary goal of treatment of spinal cord compression is palliation. The most important prognostic factor for patients presenting with spinal cord compression is the underlying neurologic status.* Only around 10% of patients who present with paralysis are able to ambulate following treatment, whereas 98% of ambulatory and 60% of nonambulatory patients are able to ambulate after treatment.[17] Therefore, the goals of treatment are recovery of normal neurologic function, local tumor control, pain control, and stabilization of the spine. Therapeutic options depend primarily on the following factors:

- Underlying malignancy
- Prior therapies
- Stability of the spine at presentation
- Overall patient prognosis

Nonpharmacologic Therapy

Radiation therapy generally is considered to be the treatment of choice for most patients. Exceptions to this include patients with prior radiation to the treatment site and patients with inherently radioresistant tumors (e.g., melanoma and renal cell carcinoma). The radiation field should include two vertebral bodies above and below the involved area.

Surgery for spinal cord compression typically involves either **laminectomy** for posterior lesions or decompression with fixation. Surgery is the treatment of choice for the following patients: (1) those with an unstable spine requiring

stabilization, (2) those with immediately impending sphincter dysfunction requiring rapid spinal decompression, (3) those who do not respond to or have received their maximum dose of radiotherapy, and (4) those with direct compression of the spinal cord owing to spinal bony fragments.[17] Recent evidence suggests that surgery followed by radiation therapy may be superior to radiotherapy alone in terms of increased ambulation time after treatment, maintenance of continence, and rates of nonambulatory patients becoming ambulatory.[18] Surgery also is useful for establishing a tissue diagnosis in cases of unknown malignancy. Overall, the risks and benefits of surgery must be weighed against the expected prognosis of the patient in light of the significant rehabilitation required after surgery.

Pharmacologic Therapy

Corticosteroids play a key role in the management of spinal cord compression. Dexamethasone is used most frequently to reduce edema, inhibit inflammation, and delay onset of neurologic complications. Dexamethasone has been shown to improve ambulation in combination with radiation as compared with radiation alone.[19] Significant controversy exists regarding the optimal dosing of dexamethasone. Loading doses of 10 to 100 mg followed by 4 to 24 mg four times daily have been used. Higher doses may be used in cases of rapidly progressing symptoms, but adverse effects including GI bleeding and psychosis are more severe. Steroids should be continued during radiation therapy and then tapered appropriately.

Pain management is also of critical importance in patients with spinal cord compression. While dexamethasone will provide some benefit, opioid analgesics also should be used and titrated rapidly to achieve adequate pain control.

Outcome Evaluation

Patients who receive definitive treatment with radiation and/or surgery generally derive benefit within days. Monitor patients for

- Improved symptoms of sensory loss using physical examination every 4 hours until symptoms improve and then daily
- Improved autonomic system function, including urine and bowel control, every 4 hours until symptoms improve and then daily
- Improved pain control using detailed pain assessment every 2 to 4 hours during initial titration and then daily thereafter
- For corticosteroid use, serum glucose, insomnia, fluid retention, GI upset, mental status changes, and signs and symptoms of infection daily

Complications of Brain Metastases

Brain metastases are among the most feared complications of cancer and generally carry a poor prognosis. One serious consequence of brain metastases is elevated intracranial pressure, which can rapidly lead to fatal intracranial herniation and death. Rapid identification of the signs and symptoms of brain metastases is critical to improve long-term outcome and avoid mortality.

Epidemiology and Etiology

Brain metastasis is the most common neurologic complication seen in patients with cancer. Approximately 170,000 patients develop brain metastases in the United States each year.[20] Many malignancies are frequently associated with brain metastases (Table 96–7). While melanoma is the tumor type most likely to metastasize to the brain, brain metastases owing to lung and breast cancers are seen more often because they are among the most common cancers. In addition, brain metastasis may be diagnosed at the same time as the primary malignancy in around 20% of cases.[22] Around 80% of brain metastases occur in the cerebral hemispheres, 15% in the cerebellum, and 5% in the brain stem.

Pathophysiology

A delicate balance of normal pressure is maintained in the brain and spinal cord by brain, blood, and cerebrospinal fluid (CSF) volume. Since the brain is contained within a confined space (skull), any foreign mass contained within that space causes adverse sequelae. This results in either destruction or displacement of normal brain tissue with associated edema. Most brain metastases occur through hematogenous spread of the primary tumor, and around 80% of patients will have multiple sites of metastases within the brain.

Patient Care and Monitoring

1. Does the patient have a known cancer at presentation? Determine the need for surgery to make the tissue diagnosis, and treat the compression.
2. What is the neurologic status of the patient at presentation? A detailed physical examination and history are keys to determine long-term outcome.
3. For patients receiving corticosteroids, monitor for adverse effects and drug interactions. Does the patient need GI prophylaxis for long-term treatment? Slowly taper once symptoms improve and/or radiation is completed.
4. Provide patient education regarding when to take medications and the importance of compliance, and promptly report symptoms of recurrence.
5. Refer patient to physical therapy for rehabilitation to help regain optimal neurosensory function.

TABLE 96–7. Cancers Most Frequently Associated with Brain Metastases

Type of Cancer	Frequency (%)
Lung cancer	18–64
Breast cancer	2–21
Melanoma	4–16
Colorectal cancer	2–11
Hematologic malignancies (i.e., leukemia)	Approximately 10 (primarily owing to leptomeningeal spread)

Data from ref. 21.

Treatment

Desired Outcomes

Therapeutic modalities used for the management of brain metastases may be divided into symptomatic management and definitive management. ❺ *The goals of treatment of brain metastases are to manage symptoms by reducing cerebral edema, treat the underlying malignancy both locally and systemically, and improve survival.*

General Approach to Treatment

Patients with brain metastases have a poor prognosis. Untreated patients generally have a median survival of 1 month. The choice of treatment depends primarily on the status of the patient's underlying malignancy and the number and sites of brain metastases. The primary definitive treatments for brain metastases are surgery and radiation therapy. Pharmacologic modalities are used primarily to control symptoms, although cytotoxic chemotherapy plays a limited role in the management.

Clinical Presentation and Diagnosis

General

- Almost all patients with brain metastases are symptomatic.
- New cerebral neurologic symptoms in a cancer patient should initiate evaluation for brain metastases.
- Other causes of brain lesions, including hemorrhage, infection, and infarction, should be ruled out.

Signs and Symptoms

- Mental status changes (most common) leads to loss of consciousness, irritability, confusion
- Hemiparesis, aphasia, **papilledema**, weakness, seizure, nausea and vomiting
- Headache may be of gradual onset or sudden in the case of hemorrhage.

Diagnostic Tests

- MRI with contrast enhancement is the "gold standard."
- CT scans may be used in patients with pacemakers but may miss small metastases.

Nonpharmacologic Therapy

Radiation therapy is the treatment of choice for most patients with brain metastases. Most patients receive whole-brain radiation because the majority of brain metastases are multifocal. Another method known as *stereotactic radiosurgery* provides intense focal radiation, typically using a **linear accelerator** or **gamma knife,** in patients who cannot tolerate surgery or have lesions that are surgically inaccessible (e.g., in the brain stem).

Surgery plays a key role in the management of patients with brain metastases, particularly patients whose systemic disease is well controlled and in those with solitary lesions. Surgery also may benefit patients with multiple metastatic sites who have a single dominant lesion with current or impending neurologic sequelae.

In cases of elevated intracranial pressure (ICP) owing to cerebral herniation, mechanical hyperventilation to decrease the arterial P_{CO_2} down to 25 mm Hg (3.33 kPA) acutely decreases ICP by causing cerebral vasoconstriction. Elevation of the patient bed also may quickly reduce the ICP. It should be noted that these strategies only relieve symptoms and that definitive therapy is still required.

Pharmacologic Therapy

Corticosteroids are a mainstay in the management of brain metastases. They reduce edema that typically surrounds sites of metastasis, thereby reducing ICP. A loading dose of dexamethasone 10 mg followed by 4 mg by mouth or intravenously every 6 hours typically is used. Symptom relief may occur shortly after the loading dose, although the maximum benefit may not be seen for several days (after definitive therapy).

Mannitol is an agent that may be used in patients with impending cerebral herniation. Mannitol is an osmotic diuretic that shifts brain osmolarity from the brain to the blood. Doses of 100 g (1–2 g/kg) as an intravenous bolus should be used. Repeated doses typically are not recommended because mannitol may diffuse into damaged brain tissue, leading to rebound increased ICP.[21]

Twenty percent of patients with brain metastases may present with seizures and require anticonvulsant therapy. Phenytoin is the most frequently used agent, with a loading dose of 15 mg/kg followed by 300 mg by mouth daily (titrated to therapeutic levels between 10 and 20 mcg/mL). Diazepam 5 mg intravenously may be used for rapid control of persistent seizures. Prophylactic anticonvulsants have been used frequently, but a recent meta-analysis did not support their use.[23] Thus, because adverse effects and drug interactions are common, the routine use of prophylactic anticonvulsants is not recommended.

Outcome Evaluation

The success of therapy is based on the ability to decrease symptoms, treat the underlying sites of disease within the

brain, and prolong survival. Monitor parameters of symptom improvement by

- Frequent assessment of symptoms (i.e., mental status and sensory and motor function) every 4 hours until symptoms improve and then daily.
- For corticosteroid use, monitor serum glucose, insomnia, fluid retention, GI upset, mental status changes, signs and symptoms of infection daily.

UROLOGIC COMPLICATIONS

Hemorrhagic Cystitis

Hemorrhagic cystitis is defined as acute or insidious bleeding from the lining of the bladder. Although therapy with certain medications is the most common cause, it is also the most preventable. Once it occurs, hemorrhagic cystitis causes significant morbidity and mortality rates of between 2% and 4%. This section will focus on preventative strategies for chemotherapeutic agents, which rely heavily on pharmacotherapeutic approaches.

Epidemiology and Etiology

Numerous etiologies have been linked to hemorrhagic cystitis[24] (Table 96–8). Of these, the oxazaphosphorine alkylating agents (i.e., cyclophosphamide and ifosfamide) are implicated most frequently. Incidence rates vary considerably but generally range between 18% and 40% with ifosfamide and 0.5% and 40% with high-dose cyclophosphamide.[25] Chronic low-dose oral cyclophosphamide, typically as used in autoimmune disorders and chronic lymphocytic leukemia, also is associated infrequently with hemorrhagic cystitis.

Twenty percent of patients receiving pelvic irradiation may experience hemorrhagic cystitis, especially with concurrent cyclophosphamide. Viral infections commonly associated with this condition occur most frequently in bone marrow transplant recipients who also may receive cyclophosphamide.

TABLE 96–8. Primary Causes of Hemorrhagic Cystitis

Pharmacologic	Nonpharmacologic
Cyclophosphamide	Pelvic irradiation
Chronic low doses	Viral infection
High doses used in BMT	Cytomegalovirus
Ifosfamide	Papovavirus
Intravesicular thiotepa	Herpes simplex virus
Chronic oral busulfan	Adenovirus
Anabolic steroids	

BMT, bone marrow transplantation.
Data from ref. 24.

Pathophysiology

Cyclophosphamide- or ifosfamide-induced damage to the bladder wall is caused primarily by their metabolite known as *acrolein*. Acrolein causes sloughing and inflammation of the bladder lining, leading to hemorrhage. This is most common when urine output is low because higher concentrations of acrolein come into contact with the bladder urothelium for longer periods of time.

Patient Care and Monitoring

1. Assess patient symptoms for prompt referral for radiation or surgery.
2. For patients receiving corticosteroids, monitor for adverse effects and drug interactions. Does the patient need GI prophylaxis for long-term treatment? Slowly taper once symptoms improve and/or radiation or surgery is completed.
3. Evaluate the patient for drug interactions, allergies, and adverse effects with phenytoin or corticosteroid therapy.
4. Instruct patients receiving phenytoin about the symptoms of elevated serum concentrations (e.g., nystagmus, blurred vision, dizziness, drowsiness, and lethargy).
5. Provide patient education regarding when to take medications, the importance of compliance, and promptly reporting symptoms of recurrence (e.g., mental status changes and seizures).

Clinical Presentation and Diagnosis

General

Presentation may be mild (microscopic hematuria) or severe (massive hemorrhage) and develops during or shortly after chemotherapy infusion.

Signs and Symptoms

- Suprapubic pain and cramping, urinary urgency and frequency, dysuria and burning, hematuria
- Urinary retention leading to **hydronephrosis** and renal failure may occur if large blood clots obstruct the ureters or bladder outlet.

Laboratory Tests

- Urine dipsticks for blood
- Urinalysis reveals more than three RBCs per high-power field and microscopic hematuria.
- CBC with differential, PT/INR, aPTT, BUN, creatinine.

Prevention

❻ *The use of effective prevention strategies can decrease the incidence of hemorrhagic cystitis to less than 5% in patients receiving cyclophosphamide or ifosfamide. There are three methods to reduce the risk: administration of mesna, hyperhydration, and bladder irrigation with catheterization.* Mesna is the primary method used with ifosfamide, whereas all three strategies are used with cyclophosphamide.

Mesna is a thiol compound that is oxidized rapidly in the bloodstream after administration to dimesna, which is inactive. However, once filtered through the kidneys, dimesna is reduced back to mesna, which binds to acrolein, leading to inactivation and excretion. The American Society of Clinical Oncology (ASCO) has published evidence-based guidelines for the dosing and administration of mesna[25] (Table 96–9). The dose of oral mesna must be double the intravenous dose owing to oral bioavailability of between 40% and 50%. Because the half-life of mesna (approximately 1.2 hours) is much shorter than that of ifosfamide or cyclophosphamide, prolonged administration of mesna beyond the end of the chemotherapy infusion is critical (Fig. 96–2). Patients should receive at least 2 L of intravenous fluids beginning 12 to 24 hours before and ending 24 to 48 hours after the last dose of chemotherapy.

Continuous bladder irrigation by catheterization uses normal saline at 250 to 1000 mL/hour to flush acrolein from the bladder. Hyperhydration with normal saline at 3 L/m^2 per day with intravenous furosemide to maintain urine output greater than 100 mL/hour also has been used with cyclophosphamide. Mesna is equivalent to both strategies in patients receiving high-dose cyclophosphamide and avoids the discomfort and infection risk with catheterization and the intensity of hyperhydration. Thus mesna is the preventative method of choice.

Treatment

Desired Outcome

If hemorrhagic cystitis occurs, the goals of treatment are to decrease exposure to the offending etiology, establish and maintain urine outflow, avoid obstruction and renal compromise, and maintain blood and plasma volume. Restoration of normal bladder function is the ultimate goal following acute treatment.

General Approach to Treatment

The treatment of hemorrhagic cystitis first involves discontinuation of the offending agent. Agents such as anticoagulants and inhibitors of platelet function also should be discontinued. Intravenous fluids should be administered aggressively to irrigate the bladder. Blood and platelet transfusions may be necessary to maintain normal hematologic values. Pain should be managed with opioid analgesics. Local **intravesicular** therapies may be necessary if hematuria does not resolve (Fig. 96–3).

Nonpharmacologic Therapy

A large-diameter multihole urethral catheter should be inserted to facilitate saline lavage and evacuation of blood clots. Surgical removal of blood clots under anesthesia may be required if saline lavage is ineffective. Active bleeding from isolated areas may be cauterized with an electrode or laser. In severe cases that are unresponsive to local or systemic pharmacologic intervention,

TABLE 96–9. ASCO Guidelines for the Use of Mesna with Ifosfamide and High-Dose Cyclophosphamide

Chemotherapy Schedule	Dosing Schedule for Mesna	Comments
Low-dose ifosfamide 2 g/m^2 per day	Oral: 100% of total daily dose of ifosfamide given 20% IV 15 minutes before and 40% PO 2 and 6 hours after start of ifosfamide	Available in 400-mg tablets. Peak urinary thiol concentrations with oral mesna is at 3 hours. If patient vomits within 2 hours of administration, repeat dose orally or intravenously.
Standard-dose ifosfamide 2.5 g/m^2/day	Bolus: 60% of total daily dose of ifosfamide given IV in 20% increments 15 minutes before and 4 and 8 hours after start of ifosfamide Infusion: 60% of total daily dose of ifosfamide given 20% IV 15 minutes before and 40% by continuous infusion during and for 12–24 hours after end of ifosfamide	Peak urinary thiol concentrations with intravenous mesna is at 1 hour. Compatible with ifosfamide and cyclophosphamide by Y-site administration or when admixed in the same bag.
High-dose ifosfamide Greater than 2.5 g/m^2 per day	Lack of evidence for dosing, however higher doses for longer duration recommended based on longer half-life of ifosfamide at high doses	
Standard-dose cyclophosphamide	Use of mesna is not routinely necessary.	
High-dose cyclophosphamide (bone marrow transplant)	Bolus: 40% of cyclophosphamide dose given IV at hours 0, 3, 6, and 9 after cyclophosphamide Infusion: 100% of cyclophosphamide dose given by continuous infusion until 24 hours after cyclophosphamide	Should be combined with saline diuresis (1.5 liters/m^2 per day of normal saline).

ASCO, American Society of Clinical Oncology; IV, intravenously; PO, by mouth.
Data from ref. 25.

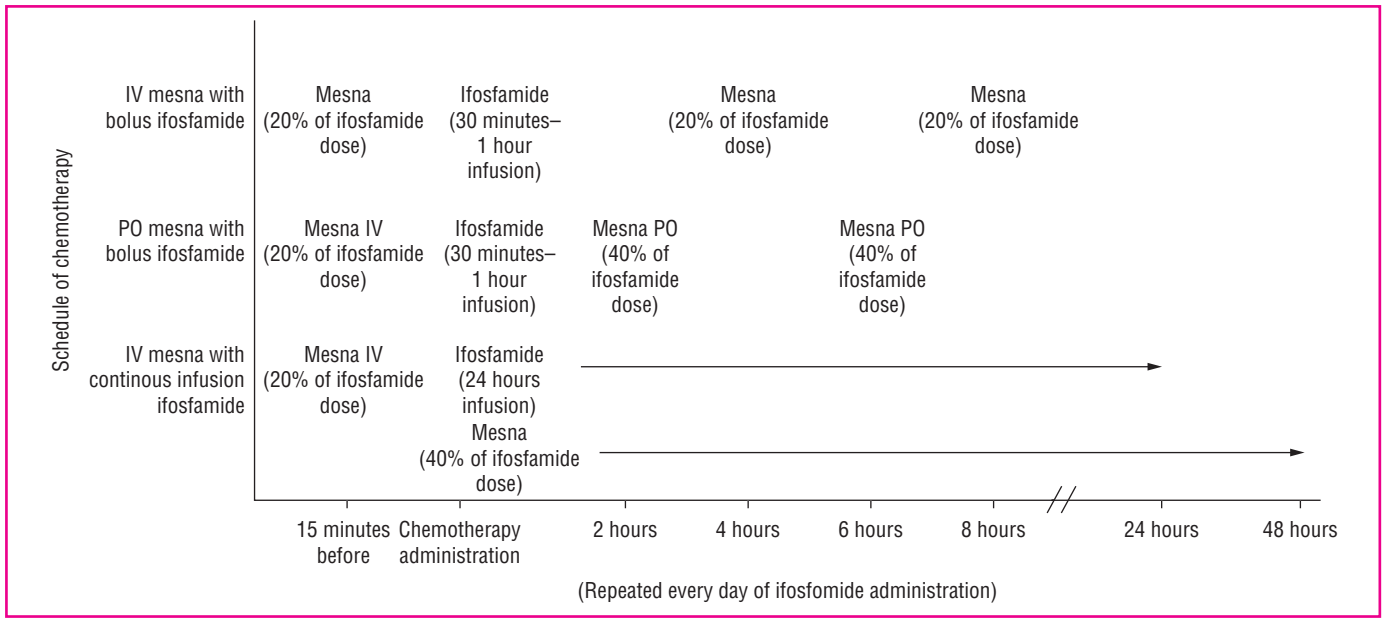

FIGURE 96–2. Examples of mesna administration with ifosfamide. IV, intravenous. PO, by mouth.

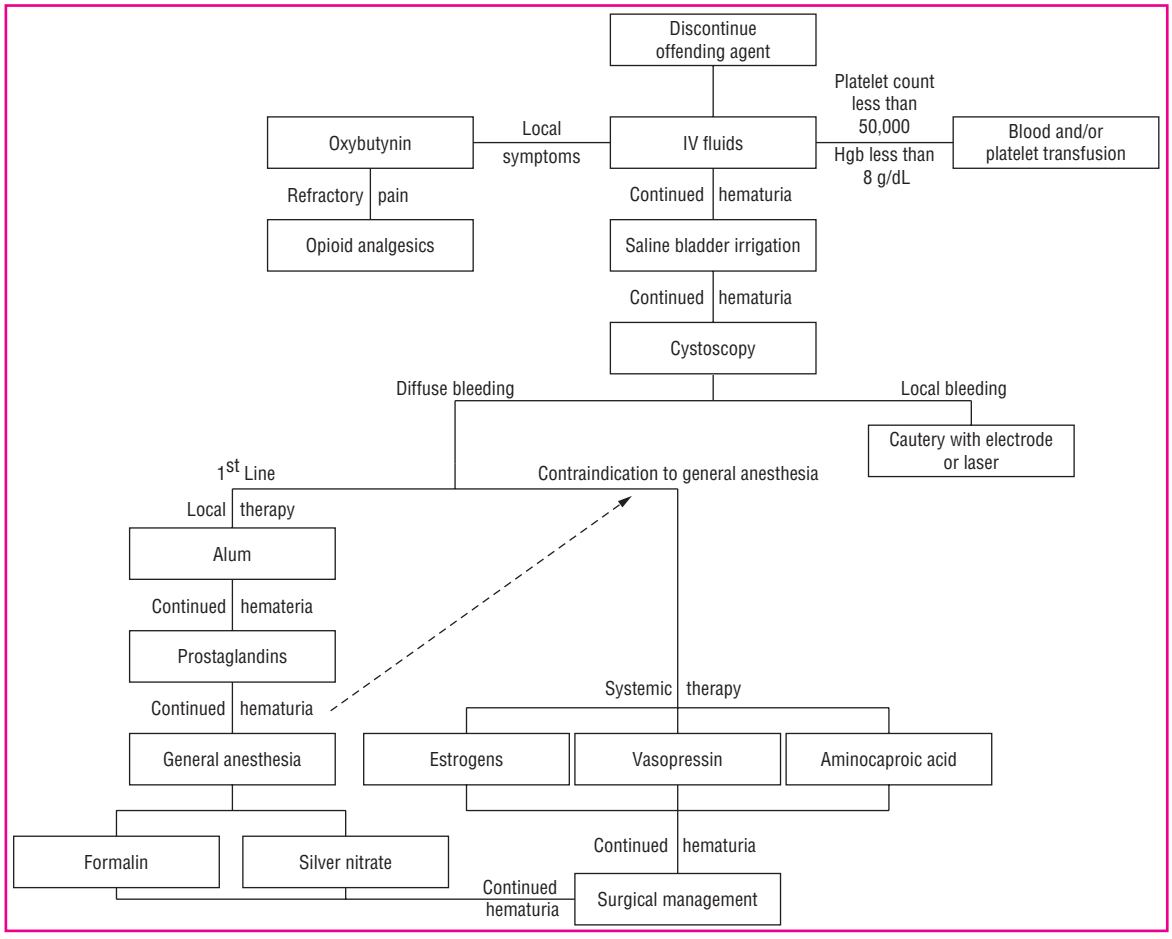

FIGURE 96–3. Treatment of hemorrhagic cystitis. IV, intravenous. (Data from ref. 24.)

Patient Care and Monitoring

1. Assess the patient receiving ifosfamide or cyclophosphamide at least daily for the development of hematuria.
2. Ensure administration of adequate hydration and proper doses of mesna.
3. Counsel the patient receiving oral mesna on the importance of compliance, when to take the doses, and to immediately report any episodes of vomiting for intravenous readministration.
4. Assess the quantity of urinary bleeding, and promptly refer to a urologist for local or surgical management.
5. Patients receiving systemic treatment should be monitored every 4 hours for resolution of hematuria. Promptly refer to urologist for refractory hematuria.
6. Evaluate the patient for drug interactions, allergies, and adverse effects with chemotherapy, mesna, or systemic therapies for management.

urinary diversion with percutaneous **nephrostomy** or surgical removal of the bladder may be required.

Pharmacologic Therapy

Many agents administered either locally or systemically are used in the treatment of hemorrhagic cystitis.[24] Local one-time administration of hemostatic agents such as alum, prostaglandins, silver nitrate, and formalin may be used; however, general anesthesia is required, especially with formalin. Systemic agents including estrogens, vasopressin, and aminocaproic acid may be used in patients who are refractory to local therapy, although they introduce the risk of systemic side effects. These agents should be continued until bleeding stops.

Antispasmodic agents such as oxybutynin 5 mg by mouth two to three times daily may be used for bladder spasms. In patients with refractory pain, opioid analgesics should be titrated to adequate pain control.

Outcome Evaluation

Monitor the patient for resolution of hematuria after each successive therapeutic intervention. Frequency of monitoring is based on the severity of hemorrhaging. Monitor urinary output and serum chemistries (including sodium, potassium, chloride, blood urea nitrogen, and serum creatinine) daily for renal dysfunction. Check the CBC at least daily to monitor hemoglobin and platelet count.

METABOLIC COMPLICATIONS

Hypercalcemia of Malignancy

Hypercalcemia is the most common metabolic abnormality experienced by patients with cancer. Once hypercalcemia occurs, it is associated with a very poor prognosis owing to the frequent association with advanced or metastatic disease.[26]

Epidemiology and Etiology

Hypercalcemia occurs in 10% to 30% of patients with cancer during the course of their disease. The most common tumor types associated with hypercalcemia are breast cancer; squamous cell carcinomas of the head, neck, and lung; and renal cancer. Hematologic malignancies such as multiple myeloma and, rarely, lymphomas are other causes of hypercalcemia.

Pathophysiology

Around 99% of calcium is contained in the bones, whereas the other 1% resides in the extracellular fluid. Of this extracellular calcium, approximately 40% is bound to albumin, and the remainder is in the ionized, physiologically active form. Normal calcium levels are maintained by three primary factors: parathyroid hormone, 1,25-dihydroxyvitamin D, and calcitonin. Parathyroid hormone increases renal tubular calcium resorption and promotes bone resorption. The active form of vitamin D, 1,25-dihydroxyvitamin D, regulates absorption of calcium from the GI tract. Calcitonin serves as an inhibitory factor by suppressing osteoclast activity and stimulating calcium deposition into the bones.

The delicate balance maintained by these factors is altered in patients with cancer by two principal mechanisms: tumor production of **humoral** factors that alter calcium metabolism (humoral hypercalcemia) and local osteolytic activity from bone metastases.[27] Humoral hypercalcemia causes around 80% of all hypercalcemia cases and is mediated primarily by systemic secretion of parathyroid hormone–related protein

Patient Encounter 2, Part 1

LP is a 58-year-old man with newly diagnosed stage IIIA non–small cell lung cancer who presents to the clinic complaining of loss of appetite, excess thirst, nausea and vomiting, and confusion × 2 days. The medication history lists NKDA, hydrochlorothiazide 50 mg by mouth daily for hypertension, and naproxen 500 mg by mouth twice daily for arthritis.

- What risk factors for hypercalcemia are exhibited in this patient?
- Are there any presenting signs or symptoms that are consistent with possible hypercalcemia?

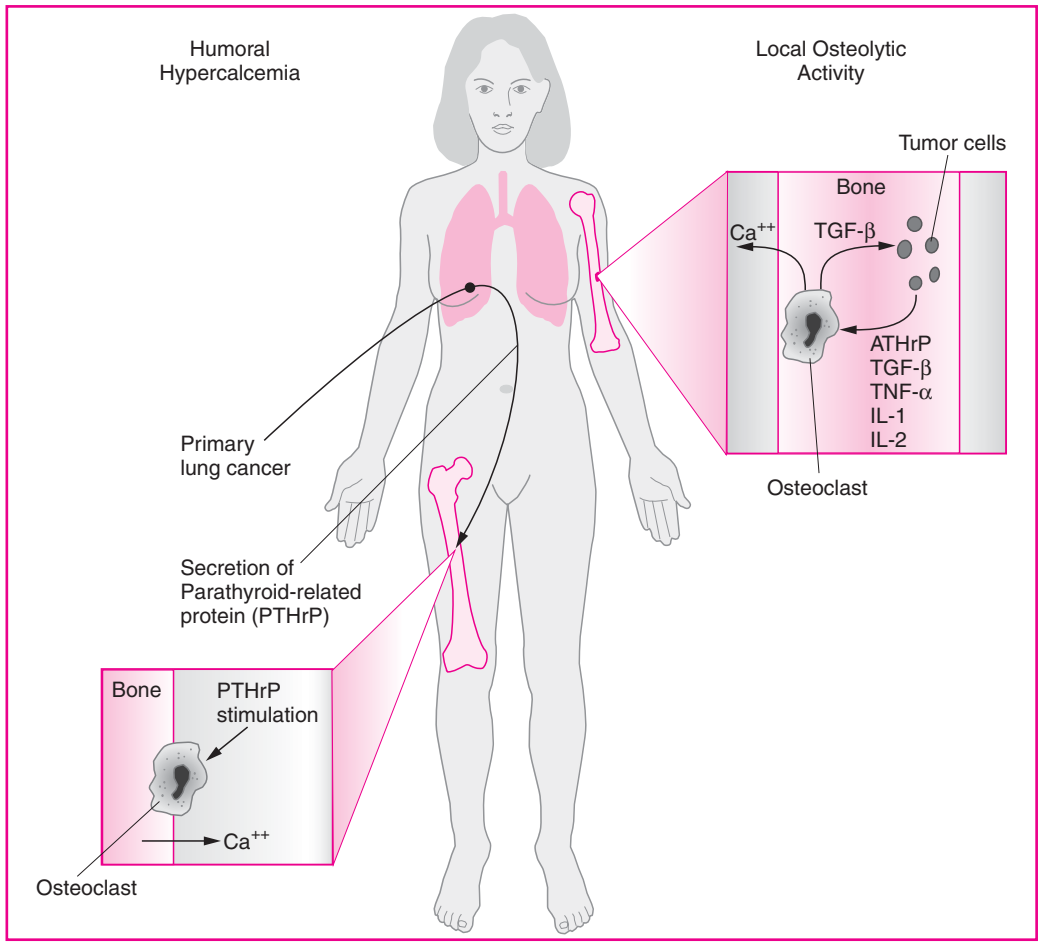

FIGURE 96–4. Pathophysiology of the hypercalcemia of malignancy. PTHrP, parathyroid hormone–related protein; TGF-β, transforming growth factor β; TNF-α, tumor necrosis factor alpha; Ca^{2+}, calcium; IL-1, interleukin 1; IL-2, interleukin 2.

(PTHrP). This protein mimics the action of endogenous parathyroid hormone on bones. Local osteolytic activity causes 20% to 30% of hypercalcemia cases, although local osteolytic activity also may have a humoral component. Local production of various factors directly stimulates osteoclastic bone resorption, which releases growth factors and cytokines (e.g., transforming growth factor β) that are necessary for tumor growth. Thus these metastatic tumors perpetuate their own growth through this mechanism. Calcium is also released by the osteolytic activity, resulting in hypercalcemia (Fig, 96–4).

Clinical Presentation and Diagnosis

General

- Presence of symptoms depends not only on the calcium level but also on the rapidity of onset.
- Normal calcium level is 8.5 to 10.5 g/dL (2.1–2.6 mmol/L) (varies by lab).
- Serum calcium level *must* be corrected for albumin level using the following formula: Corrected calcium = (measured calcium – measured albumin) + 4.

Signs and Symptoms

Five primary organ systems may be affected:

- Gastrointestinal: anorexia, nausea, vomiting, and constipation
- Musculoskeletal: weakness, bone pain, fatigue, and ataxia
- Central nervous system: confusion, headache, lethargy, seizures, and coma
- Genitourinary: polydipsia, polyuria, and renal failure
- Cardiac: bradycardia, ECG abnormalities, and arrhythmias

Laboratory Tests

- Elevated corrected serum calcium level greater than or equal to 10.5 g/dL (2.6 mmol/L), serum albumin, low to normal serum phosphate
- Patient may have elevated BUN and serum creatinine.
- Elevated alkaline phosphatase may indicate bone destruction.
- ECG may indicate prolonged PR interval, shortened QT interval, and widened T wave.

Other Diagnostic Tests

Rule out other causes of hypercalcemia, including primary hyperparathyroidism, hyperthyroidism, vitamin D intoxication, and chronic renal failure.

Patient Encounter 2, Part 2

A chemistry panel is drawn from LP that reveals a serum calcium level of 12.4 g/dL (3.1 mmol/L) and a serum albumin level of 2.6 g/dL (26 g/L). An ECG is done that reveals a prolonged PR interval.

- What is LP's corrected calcium level?
- What treatment plan would you outline to manage LP's hypercalcemia based on the calcium level and his signs and symptoms?
- What changes (if any) would you make to LP's current medication regimen?

A third and less common mechanism is production of 1,25-dihydroxyvitamin D by tumor cells (usually lymphoma), which increases GI absorption of calcium and enhances osteoclastic bone resorption.

Treatment

Desired Outcome

❼ *The primary goal of treatment for hypercalcemia is to control the underlying malignancy. Therapies directed at lowering the calcium level are temporary measures that are useful until anticancer therapy begins to work.* The goals of calcium-lowering therapy are to (1) lower the corrected calcium to normal levels, (2) regain fluid and electrolyte balance, (3) relieve symptoms, and (4) prevent life-threatening complications. Patients who are refractory to available therapies may have calcium-lowering therapy withheld (usually resulting in coma and death), which may be a humane approach.[26]

General Approach to Treatment

❽ *Therapeutic options for the treatment of hypercalcemia should be directed toward the level of corrected serum calcium and the presence of symptoms* (Fig. 96–5). Hypercalcemia may be classified as mild [corrected calcium equal to 10.5–11.9 g/dL (2.6–3 mmol/L)], moderate [12–13.9 g/dL (3–3.5 mmol/L)], and severe [greater than 14 g/dL (3.5 mmol/L)].[26] ❽ *Adequate treatment of mild or asymptomatic hypercalcemia may be achieved on an outpatient basis with nonpharmacologic measures. Moderate to severe or symptomatic hypercalcemia almost always requires pharmacologic intervention.*

Nonpharmacologic Therapy

Calciuric therapy in the form of hydration is a key component of the treatment of hypercalcemia, regardless of severity or presence of symptoms.[28] Mild or asymptomatic patients may be encouraged to increase oral fluid intake (3–4 L/day). Patients with moderate to severe or symptomatic hypercalcemia should receive normal saline at 200 to 500 mL/hour according to dehydration and cardiovascular status. Patients should be encouraged to ambulate as much as possible because immobility enhances

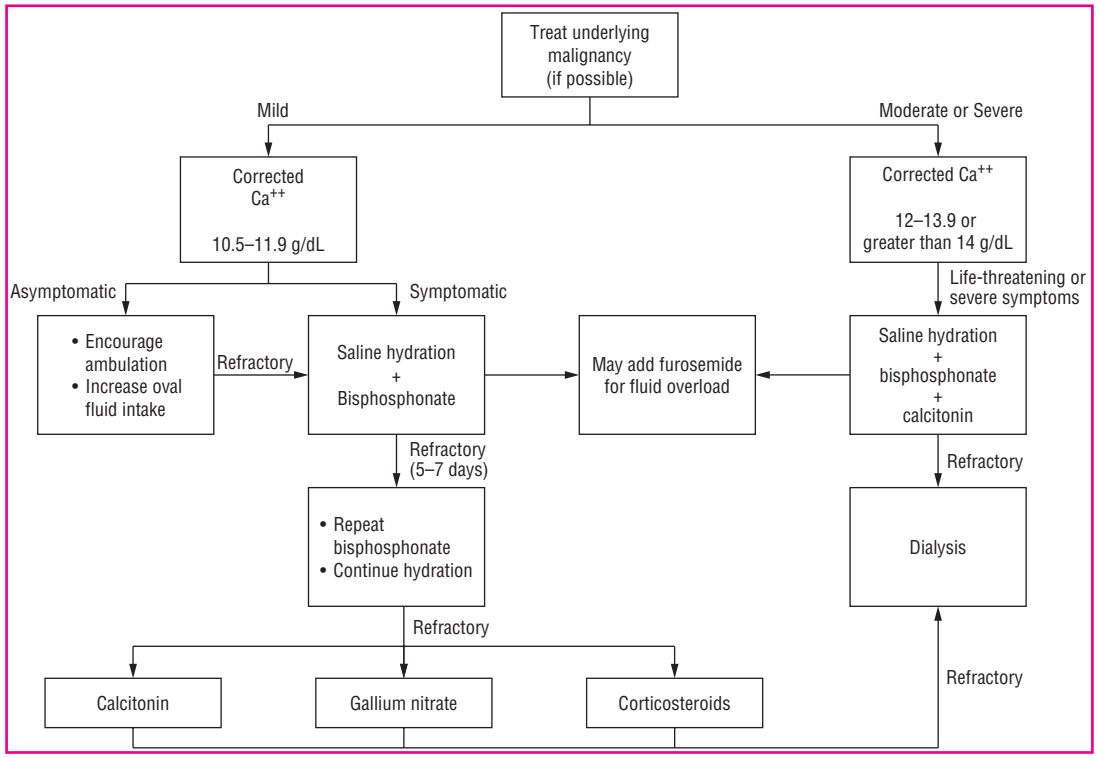

FIGURE 96–5.
Treatment algorithm for the hypercalcemia of malignancy.

bone resorption. Although calcium should be discontinued from parenteral feeding solutions, oral calcium supplementation minimally contributes to hypercalcemia unless it is mediated by vitamin D. In these cases, oral calcium should be discontinued. Finally, agents that may contribute to hypercalcemia (e.g., thiazide diuretics, vitamin D, and lithium) or decrease renal function (e.g., NSAIDs) should be discontinued. Dialysis may be used in refractory cases or in patients who cannot tolerate aggressive saline hydration.

Pharmacologic Therapy

Multiple pharmacologic interventions are available for the treatment of hypercalcemia (Table 96–10). Furosemide 20 to 40 mg/day may be added to hydration once rehydration has been achieved to avoid fluid overload and enhance renal excretion of calcium. Although effective in relieving symptoms, hydration and diuretics are temporary measures that are useful until the onset of antiresorptive therapy; thus hydration and antiresorptive therapy should be initiated simultaneously.

The antiresorptive therapy of choice for hypercalcemia of malignancy is a bisphosphonate. Because of poor oral bioavailability, only intravenous agents should be used. Pamidronate and zoledronic acid are used most commonly and are potent inhibitors of osteoclast activity.[29] The choice of bisphosphonate is a difficult one; zoledronic acid is more efficacious in terms of response rate and longer duration of normocalcemia but is approximately four times more expensive.[30] Regardless of selection, the bisphosphonates should be administered at diagnosis owing to their delayed onset of action.

Calcitonin is the drug of choice in cases of emergent hypercalcemia (e.g., in patients with life-threatening ECG changes, arrhythmias, or CNS effects) owing to its rapid onset of action. Calcitonin inhibits osteoclast activity and decreases renal tubular calcium resorption. Corticosteroids are useful in patients with steroid-responsive malignancies, such as lymphomas or multiple myeloma, and may delay **tachyphylaxis** to calcitonin. Gallium nitrate also was recently reapproved for treatment, although the 5-day administration regimen and risk of nephrotoxicity limit its use.

Outcome Evaluation

The long-term success of therapy for hypercalcemia is determined primarily by the success of treatment of the underlying malignancy. In the short term, monitor patients for relief of

TABLE 96–10. Treatment Options for Hypercalcemia of Malignancy

	Agent	Dosage	Onset	Duration	Reduction in Serum Calcium Concentration	Comments
Calciuric therapy	Intravenous normal saline	200–500 mL/hour	24–48 hours	2–3 days	0.5–2 mg/dL	Avoid fluid overload, monitor electrolytes.
	Furosemide	20–40 mg IV	4 hours	2–3 days	—	Monitor for hypokalemia, dehydration.
Antiresorptive therapy	Pamidronate	60–90 mg IV over 2–24 hours[a]	24–72 hours	3–4 weeks	Greater than 1 mg/dL	Nadir not seen until after 4–7 days; may cause fever, renal dysfunction; pamidronate less expensive.
	Zoledronic acid	4 mg IV over 15 minutes	24–48 hours	4+ weeks	Greater than 1 mg/dL	
	Corticosteroids	Prednisone (or equivalent) 50–100 mg daily	5–7 days	3–4 days	0.5–3 mg/dL	Monitor for hyperglycemia, insomnia, immunosuppression.
	Calcitonin	4–8 IU/kg SQ or IM q6–12 hours	2–4 hours	1–3 days	2–3 mg/dL	Salmon-derived formulation preferred; 1-unit test dose recommended; can be given in renal failure; may cause flushing, nausea.
	Gallium nitrate	100–200 mg/m^2 CIV daily for 5 days	24–48 hours	—	—	Do not administer if creatinine is greater than 2.5 mg/dL (221 µmol/L); may cause renal failure.

[a]60 mg of pamidronate may be used in smaller patients or in those patients with mild hypercalcemia or renal dysfunction. May use longer infusion time in patients with renal dysfunction.
IU, international units; IV, intravenously; SQ, subcutaneously; IM, intramuscularly; CIV, continuous intravenous infusion.
Data from refs. 26 and 28.

Patient Care and Monitoring

1. Determine the status of the patient's underlying malignancy. Has this patient been treated for his or her underlying malignancy? Has the patient received any prior therapy for hypercalcemia? Is calcium-lowering therapy still warranted?
2. Assess the patient's symptoms to determine the need for laboratory studies. Determine if absence of symptoms in the presence of mild hypercalcemia warrants conservative outpatient management.
3. Obtain a complete history of prescription, nonprescription, and natural drug products. Avoid or discontinue agents that increase calcium levels, impair excretion of calcium, or decrease renal function.
4. Determine the need for long-term maintenance therapy with monthly bisphosphonates. Is the patient beginning definitive therapy for a responsive malignancy?
5. Counsel the patient to avoid excessive oral calcium intake in vitamin D–mediated hypercalcemia.
6. Evaluate the patient for adverse drug reactions, allergies, and drug interactions when starting calcium-lowering therapy.

symptoms and restoration of fluid balance. Monitor the serum calcium level, serum albumin, serum blood urea nitrogen (BUN) and creatinine, and electrolytes daily during therapy. Assess the fluid balance by daily ins and outs, weights, and signs of fluid overload. Monitor the ECG in patients with cardiac manifestations until normalized. Repeat doses of bisphosphonate after 5 to 7 days if the patient does not become normocalcemic. Reassess patient status in terms of refractoriness to treatment to determine if treatment should be withheld.

Tumor Lysis Syndrome

Although not as common as hypercalcemia, tumor lysis syndrome may cause significant morbidity and mortality if adequate prophylaxis and treatment are not instituted. Tumor lysis syndrome is the result of rapid destruction of malignant cells with subsequent release of intracellular contents into the circulation.

Patient Encounter 3, Part 1

HT is a 55-year-old man with newly diagnosed acute myeloid leukemia. The patient is asymptomatic at this time. Laboratory results reveal the following significant findings:

- WBC count $39 \times 10^3/\mu L$ ($39 \times 10^9/L$)
- Serum potassium 4.9 mEq/L (4.9 mmol/L)
- Serum phosphorous 4.2 mg/dL (1.4 mmol/L)
- Serum calcium 7.6 mg/dL (1.9 mmol/L)
- Uric acid 9.1 mg/dL (541 µmol/L)

In addition, the patient has a serum creatinine of 1.6 mg/dL (141 µmol/L) and a BUN of 21 mg/dL (7.5 mmol/L). His LDH is normal.

- What risk factors does HT have for tumor lysis syndrome?
- Why is the serum uric acid elevated and renal function decreased?

Epidemiology and Etiology

The overall incidence of tumor lysis syndrome is unknown but has been linked to a number of risk factors[31] (Table 96–11). Tumor lysis syndrome typically occurs in malignancies with high tumor burdens or high proliferative rates. Thus children are affected most frequently because they frequently have aggressive malignancies. Tumor lysis syndrome typically is induced by cancer treatment modalities, including chemotherapy, hormonal therapy, radiation, biologic therapy, and corticosteroids, although some patients may present spontaneously before treatment.

TABLE 96–11. Risk Factors for Tumor Lysis Syndrome

Disease Related
High-risk
Acute lymphoblastic leukemia
High-grade non-Hodgkin's lymphoma (i.e. Burkitt's)
Intermediate risk
Chronic lymphocytic leukemia (especially bulky lymphadenopathy)
Acute myeloid leukemia (especially white blood cell count greater than $50/mm^3$)
Multiple myeloma
Low risk
Low- and intermediate-grade non-Hodgkin's lymphoma
Hodgkin's disease
Chronic myeloid leukemia (blast crisis)
Rare
Breast cancer
Small cell lung cancer
Testicular cancer
Patient Related
Decreased urinary output, dehydration, or renal failure
Preexisting hyperuricemia
Acidic urine
White blood cell count greater than $50 \times 10^3/\mu L$ ($50 \times 10^9/L$)
Lactate dehydrogenase (LDH) levels greater than 1500 IU/L (1500 U/L or 25 uKat/L)
High tumor sensitivity to treatment modalities

IU, international unit.
Data from refs. 31 and 32.

Clinical Presentation and Diagnosis

General

- Patients present primarily with lab abnormalities.
- Normal uric acid is equal to 2 to 8 mg/dL (119–476 µmol/L).
- Most often occurs within 12 to 72 hours of initiation of cytotoxic therapy.

Signs and Symptoms

- Most patients are asymptomatic.
- Patients may develop edema, fluid overload, and oliguria that may progress to anuria with acute renal failure.
- Some patients with hyperuricemia may have nausea, vomiting, and lethargy.
- Hyperkalemia leads to lethargy, muscle weakness, **paresthesia,** ECG changes, bradycardia
- Hypocalcemia leads to muscle cramps, **tetany**, irritability, paresthesias, arrhythmias

Laboratory Tests (Adults)

- Serum uric acid level greater than 8 mg/dL (476 µmol/L)
- Serum potassium greater than 6 mEq/L (6 mmol/L)
- Serum phosphorous greater than 4.5 mg/dL (1.45 mmol/L)
- Serum calcium less than 7 mg/dL (1.75 mmol/L)
- Elevated BUN and creatinine once renal dysfunction develops
- Or a change of greater than 25% from baseline in any of these lab values[32]

Pathophysiology

Patients with tumor lysis syndrome experience a wide range of metabolic abnormalities. The massive cell lysis that occurs leads to the release of intracellular electrolytes, resulting in hyperkalemia and hyperphosphatemia. High concentrations of phosphate bind to calcium, leading to hypocalcemia and calcium phosphate precipitation in the renal tubule. Purine nucleic acids are also released that are subsequently metabolized to uric acid through multiple enzyme-mediated steps (Fig. 96–6). Uric acid is poorly soluble at urinary acidic pH, leading to crystallization in the renal tubule. The precipitation of uric acid and calcium phosphate leads to metabolic acidosis, facilitating further uric acid crystallization. Acute renal failure may be the end result.

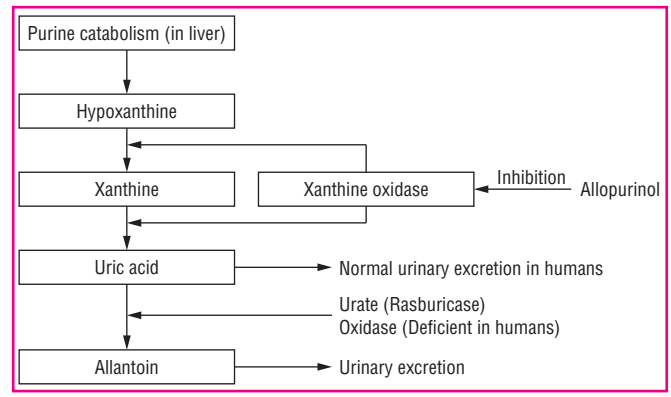

FIGURE 96–6. The role of allopurinol and rasburicase in the enzymatic degradation of purine nucleic acids.

Patient Encounter 3, Part 2

Chemotherapy with 7+3 (cytarabine for 7 days + idarubicin for 3 days) is ordered for HT. You also determine that HT is taking lisinopril 10 mg by mouth daily for hypertension.

- When should tumor lysis syndrome prophylaxis begin for HT?
- What strategies would you use for tumor lysis syndrome prophylaxis for HT?
- If tumor lysis syndrome develops, how would you modify your management approach?

Treatment

Desired Outcomes

❾ *The primary goals of management of tumor lysis syndrome are (1) prevention of renal failure and (2) prevention of electrolyte imbalances. Thus the best treatment for tumor lysis syndrome is prophylaxis to enable delivery of cytotoxic therapy for the underlying malignancy.* For patients who present with or develop tumor lysis syndrome despite prophylaxis, treatment goals include (1) decrease uric acid levels, (2) correct electrolyte imbalances, and (3) prevent compromised renal function. These goals should be achieved in a cost-effective manner.

General Approach to Treatment

Prevention of tumor lysis syndrome generally is achieved by increasing the urine output and preventing accumulation of uric acid. Prophylactic strategies should begin immediately on presentation, preferably 48 hours prior to cytotoxic therapy. Treatment modalities primarily increase uric acid solubility, address electrolyte disturbances, and support renal output.

Nonpharmacologic Therapy

Vigorous intravenous hydration with dextrose 5% in water with half-normal saline at 3 L/m^2 per day to maintain a urine output of 100 mL/m^2 per hour or more is necessary, unless the patient presents with acute renal dysfunction. Alkalinization of the urine to a pH of 7.0 or more with 50 to 100 mEq/L of sodium bicarbonate has been used to promote uric acid solubility for excretion. This measure is controversial because xanthine and hypoxanthine are less soluble at alkaline pH, potentially leading to crystallization, especially during and after allopurinol therapy[32] (see Fig. 96–6). Medications that increase serum

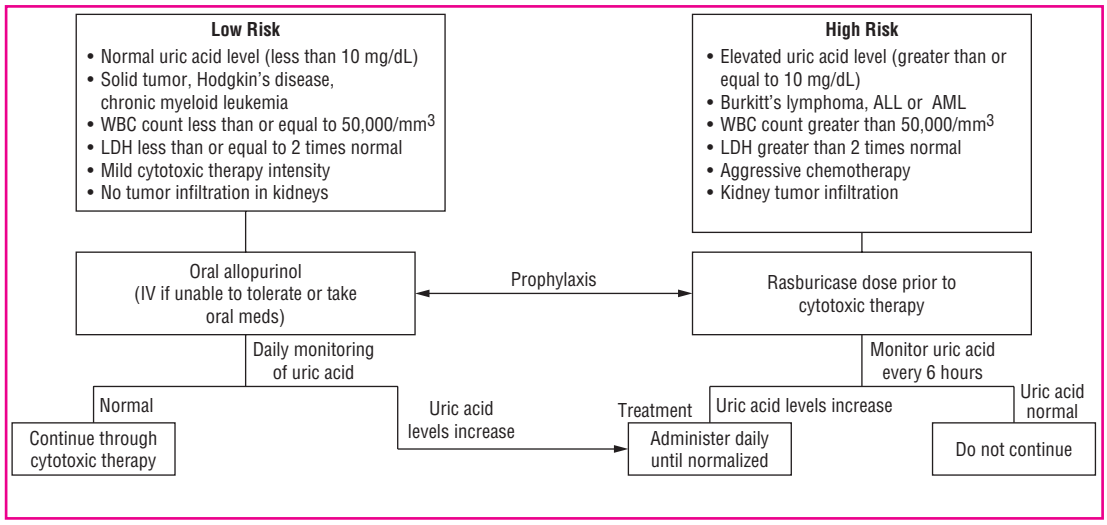

FIGURE 96–7. Prophylaxis and treatment of hyperuricemia associated with tumor lysis syndrome. ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; IV, intravenous. (Data from refs. 32 and 33.)

potassium (e.g., ACE inhibitors and spironolactone) or block tubular resorption of uric acid (e.g., probenecid and thiazides) should be discontinued. Nephrotoxic agents such as amphotericin B or aminoglycosides also should be avoided. Hemodialysis may be required in patients who develop anuria or uncontrolled hyperkalemia, hyperphosphatemia, hypocalcemia, acidosis, or volume overload.

Pharmacologic Therapy

Pharmacologic prevention strategies for tumor lysis syndrome are aimed at low- and high-risk patients (Fig. 96–7). Allopurinol is a xanthine oxidase inhibitor that is used for prevention only because it has no effect on preexisting elevated uric acid. Rasburicase is a recombinant form of urate oxidase that is useful for both prevention and treatment but is extremely expensive (Table 96–12). Although the approved dose is 0.2 mg/kg per day for 5 days, recent studies using abbreviated courses (1–3 days) and/or lower doses (0.05–0.1 mg/kg per day) may be equally efficacious with significantly reduced cost.[32] Since uric acid levels generally fall within 4 hours of the first dose, one dose may be administered with frequent, serial monitoring of the uric acid level for repeat dosing if necessary (see Fig. 96–7). Of note, rasburicase continues to break down uric acid in blood samples drawn from patients. This can be avoided by immediately placing the sample in an ice bath for processing to avoid falsely lowered uric acid levels.

Electrolyte disturbances that develop in patients with tumor lysis syndrome should be managed aggressively to avoid renal failure from hyperphosphatemia and hypocalcemia and cardiac signs from hyperkalemia. One exception pertains to the use of intravenous calcium for hypocalcemia. Adding calcium may cause further calcium phosphate precipitation in the presence of hyperphosphatemia and should be used cautiously.

TABLE 96–12. Comparison of Allopurinol and Rasburicase

Drug	Dosing	2005 AWP[a]	Comments
Oral allopurinol (Zyloprim®)	Adult: 600–800 mg/day in 2–3 divided doses Child: 10 mg/kg per day or 200–300 mg/m^2 per day	$0.48/day (generic)	Adjust dose for renal impairment. Avoid drug interactions (mercaptopurine). Monitor for skin rash.
Intravenous allopurinol (Aloprim®)	Adult: 200–400 mg/m^2 per day Child: 200 mg/m^2 per day	$625–$1250/day	As above. Reserve for patients who cannot tolerate or take oral medications. Maximum dose = 600 mg/day.
Rasburicase (Elitek®)	0.2 mg/kg per day for up to 5 days	$12,000/day	Lower doses and abbreviated schedules may be used to decrease cost (0.05–0.1 mg/kg per day). May rarely cause nausea and vomiting. Contraindicated in patients with G6PD deficiency lead to hemolytic anemia. Rare cases of hypersensitivity and antibody formation.

[a]Normalized for a 70-kg patient or body surface area of 1.73m^2; all costs are estimated and may vary.
G6PD, glucose-6-phosphate dehydrogenase, AWP, average wholesale price.
Data from ref. 34.

Patient Care and Monitoring

1. Assess patient risk factors prior to onset of treatment.
2. Discontinue or avoid medications that affect renal function or contribute to electrolyte abnormalities. Obtain a complete medication history.
3. Evaluate the patient for drug interactions, allergies, and adverse effects of allopurinol or rasburicase.

Outcome Evaluation

The most successful outcome in tumor lysis syndrome is prevention. Monitor the patient who presents with normal lab values every day for serum uric acid, electrolytes (i.e., Na, K, Ca, Mg, Cl, and PO_4), BUN, creatinine, and urine output. Monitor the patient for signs of fluid overload during aggressive hydration. Continue hydration and prophylaxis until 2 to 3 days after cytotoxic therapy. In patients undergoing urinary alkalinization with sodium bicarbonate, assess the urine pH every 6 hours and maintain above 7. For patients who present with or develop signs of tumor lysis syndrome, monitor these parameters every 6 hours until stable. Order an ECG for patients with hyperkalemia, and monitor serially until resolution. Adjust the dose of allopurinol and other renally eliminated medications for patients who develop renal dysfunction. In patients receiving rasburicase, monitor the hemoglobin and hematocrit for signs of hemolytic anemia.

MISCELLANEOUS

Chemotherapy Extravasation

Extravasation generally is defined as leakage of intravenous fluids into the interstitial tissue. It is one of the most feared complications of the administration of cytotoxic chemotherapy. While extravasation does not cause death, significant morbidity may result from local tissue destruction, and immediate management is necessary.

Epidemiology and Etiology

The incidence of chemotherapy extravasation generally is reported to be between 0.5% and 6% of all chemotherapy-related adverse events.[35] A number of risk factors have been identified for chemotherapy extravasation (Table 96–13).

TABLE 96–13. Risk Factors for Chemotherapy Extravasation

Presence of multiple venipunctures (common in cancer patients)
Poor needle insertion technique
Poor catheter location (dorsum of the hand, antecubital fossa)
Inability to communicate symptoms (children, sedated patients, language barrier between patient and nurse)
Presence of peripheral neuropathy
Nurse experience and training
Young age or elderly patients (small or fragile veins)
Gross obesity

Patient Encounter 4, Part 1

JM is a 32-year-old woman who was recently diagnosed with stage IIIB Hodgkin's disease. She comes to the clinic to receive her first dose of ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) chemotherapy. She currently does not have a central access device; therefore, she will receive her chemotherapy via peripheral vein.

- Which chemotherapy agent(s) will JM receive is(are) considered to be vesicants? Irritants? Nonvesicants?
- What techniques and prevention strategies should be employed to decrease the risk of an extravasation?
- What symptoms or signs should you watch for during chemotherapy administration?

Chemotherapy agents generally are classified into three groups: vesicants, irritants, and nonvesicants[36] (Table 96–14). Either vesicants or irritants may cause local symptoms, but vesicants cause local tissue necrosis on extravasation, whereas irritants do not. The degree of tissue injury depends on the concentration and amount of fluid extravasated. It is important to note that some agents are well-known vesicants. For many agents, however, only isolated case reports of tissue necrosis exist. Therefore, it is imperative to use caution when administering any chemotherapeutic agent, especially new or investigational agents that have unknown vesicant properties.

TABLE 96–14. Chemotherapeutic Agents with Vesicant or Irritant Properties

Vesicants	Irritants
Common	
Anthracyclines	Camptothecins
Daunorubicin	Irinotecan
Doxorubicin	Topotecan
Epirubicin	Carmustine
Idarubicin	Cyclophosphamide
Dactinomycin	Dacarbazine
Mechlorethamine	Epipodophyllotoxins
Mitomycin C	Etoposide
Vinca alkaloids	Teniposide
Vincristine	Fluorouracil
Vinblastine	Gemcitabine
Vinorelbine	Ifosfamide
Rare[a]	Melphalan
Cisplatin	Pentostatin
Liposomal doxorubicin	Streptozocin
Mitoxantrone	
Oxaliplatin	
Taxanes	
Docetaxel	
Paclitaxel	

[a]Agents for which there are isolated case reports of local tissue necrosis.
Data from ref. 36.

Clinical Presentation and Diagnosis

General

- Anthracycline, mechlorethamine, and vinca alkaloid extravasations typically cause immediate pain.
- Patients may be asymptomatic at the time of extravasation but may return within days to weeks with signs of tissue damage (particularly with mitomycin C).
- Exposure to ultraviolet light may worsen some lesions.

Signs and Symptoms

- Local pain (burning, tingling, stinging), swelling, erythema, induration
- Lack of blood return
- Ulceration may not develop until after 1 to 2 weeks or longer.

Diagnostic Tests

Usually based on clinical history and presenting symptoms, but tissue biopsy may reveal definitive findings.

Pathophysiology

The mechanism of tissue injury is related to the pharmacodynamic characteristics of the extravasated drug. These agents may be classified into DNA-binding and non-DNA-binding. Examples of DNA-binding agents include the anthracyclines, mechlorethamine, and mitomycin C. These agents first cause cell death through interactions with DNA, then are released into the surrounding tissue, and are taken up by adjacent cells. This repeating cycle is perpetuated by the lipophilic nature of these drugs, resulting in chronic, slow-healing tissue injury owing to long tissue retention. Doxorubicin in particular may remain in tissues for weeks to months.[36]

Non-DNA-binding agents include the vinca alkaloids and etoposide. These agents tend to cause injury in the pattern of a thermal burn and are cleared more easily from interstitial spaces. Thus they are more readily neutralized and tend to have a better healing prognosis.

Prevention

⓾ *Chemotherapy extravasation may be avoided in many cases by the use of successful prevention strategies. The most important preventative measure is proper patient education.* Patients must be instructed to promptly report any local symptoms not only during administration but also days to weeks later. Another key factor is the exclusive use of highly trained personnel who are trained to administer chemotherapeutic drugs. The Oncology Nursing Society has developed guidelines for the administration of vesicant drugs, as summarized in Table 96–15.[37] Although placement of a central venous catheter is recommended, extravasations still may occur owing to dislodged or poorly placed needles or nicked catheters.

TABLE 96–15. Prevention Strategies for Chemotherapy Extravasation[37]

Central venous catheters should be placed for vesicant administration whenever possible, especially in high-risk patients.
Avoid the dorsum of the hand, antecubital fossa, and limbs with significant lymphedema.
Use uncovered plastic cannulas or a butterfly needle for peripheral administration.
Always test the line with intravenous fluids before chemotherapy administration, and observe the site for swelling.
Check for blood return prior to and frequently during administration.
If venipuncture is repeated, should be proximal to prior needle insertion site.
Vesicants given via peripheral vein should be given by intravenous push rather than by infusion to enable immediate cessation and withdrawal of fluids if extravasation occurs.

Treatment

Desired Outcome

Once extravasation occurs, the primary goals of treatment are (1) avoid further tissue damage by using appropriate nonpharmacologic and pharmacologic strategies and (2) promptly refer patients for surgery if required. Optimal pharmacologic and nonpharmacologic treatment of the extravasation will allow the cancer patient to continue with his or her chemotherapy (Table 96–16).

Nonpharmacologic Therapy

If extravasation occurs, the infusion should be stopped immediately, with aspiration of fluid from the site, needle, and tubing as much as possible. The affected limb or area should be elevated (if possible). The site should be documented photographically as well as the time, date, site, patient complaints, and estimated volume of extravasated drug.[36] Both hot and cold packs have been used to manage extravasations, but use of the proper therapy for certain agents is critical. For example, warm compresses have been shown to worsen doxorubicin extravasations, whereas cold packs may exacerbate vinca alkaloid

Patient Encounter 4, Part 2

Despite adequate precautions, midway through her doxorubicin administration, JM complains of intense burning around the catheter site, and the site appears to be swollen and erythematous.

- What nonpharmacologic management strategies should be employed immediately?
- What pharmacologic management strategy would you recommend to manage this potential extravasation?

TABLE 96–16. Management of Chemotherapy Extravasation

Drug	Application of Heating or Cooling	Pharmacologic Antidote	Dose	Comments
Anthracyclines	Cold packs	DMSO 50–99%	Apply 1–2 mL to area of skin twice the size of lesion every 6–8 hours for 7–14 days	Allow to air dry. Do not cover
		Alternative: Dexrazoxane	1000 mg/m^2 IV within 5 hours of extravasation followed by 1000 mg/m^2 on day 2,500 mg/m^2 day 3	Promising new agent; expensive, may not be reimbursed by payors.
Mitomycin C	Cold packs	DMSO 50–99%	As above	
Mechlorethamine	Cold packs	Sodium thiosulfate	Prepare 1/6 M solution by adding 4 mL of 10% solution to 6 mL sterile water; inject 2 mL for each mg of mechlorethamine. Follow with 1 mL SQ (0.1 mL doses clockwise around area); may repeat every 3–4 hours if needed.	Sodium thiosulfate must be diluted prior to administration.
Vinca alkaloids	Hot packs	Hyaluronidase	Inject 1–6 mL of 150 units/mL concentration (150–900 units) through IV line or SQ if removed; may repeat every 3–4 hours if needed	Dilute with normal saline.
Paclitaxel	Cold packs	Hyaluronidase	As above	Hot packs paradoxically shown to worsen lesions in some case reports.

DMSO, dimethylsulfoxide; SQ, subcutaneously; IV, intravenously.
Data from ref. 36.

lesions. Pressure should not be applied to the area because this may facilitate spread. Finally, patients should be referred to a plastic surgeon if pain persists or ulceration develops despite treatment.

Pharmacologic Therapy

Therapeutic modalities to treat extravasation events consist of specific antidotes to halt or decrease the severity of local tissue necrosis. It should be noted that only one-third of extravasation events will lead to local tissue necrosis, and most studies of antidotes are in animal models or isolated case reports. Antidotes either disperse or bind the chemotherapy agent and accelerate the removal of the agent from the tissues. Specific antidotes and their uses are presented in Table 96–16.

Dimethylsulfoxide (DMSO) is the antidote of choice for anthracycline and mitomycin C extravasations. It readily penetrates tissues and increases diffusion in the tissue area. In addition, DMSO is a free-radical scavenger that functions to block this principal mechanism of anthracycline- and mitomycin C–mediated tissue injury. DMSO generally is well tolerated but may cause some mild burning and redness. Dexrazoxane is a free-radical scavenger typically used for cardioprotection from anthracyclines. Promising results have been seen with large-volume extravasations and in a mouse model.[38]

Hyaluronidase is the antidote of choice for vinca alkaloid and high-concentration epipodophyllotoxin extravasations. Hyaluronidase breaks down hyaluronic acid, which functions as "tissue cement." This promotes absorption of the extravasated drug away from the local site. Hyaluronidase also may be used for paclitaxel extravasations, but there are conflicting reports regarding its efficacy.[39] Hyaluronidase should not be used with anthracycline extravasations because enhancement of local spread may occur.

The antidote of choice for mechlorethamine extravasations is sodium thiosulfate. This agent binds alkylating agents, resulting in neutralization to inactive compounds that are then excreted. Sodium thiosulfate also may be effective for high-concentration cisplatin or dacarbazine extravasations.

Outcome Evaluation

The primary outcome is the prevention of extravasation events using proper administration techniques. Instruct patients to promptly report any symptoms of extravasation. If extravasation occurs, select the proper antidote and thermal application for immediate administration. Promptly refer the patient for plastic surgery if pain persists or ulceration develops.

Patient Care and Monitoring

1. On diagnosis, determine the need for administration of chemotherapy with vesicant properties. Refer the patient for surgical placement of a central access device.
2. Ensure proper training and certification of all personnel in institutions who administer chemotherapeutic agents.
3. Educate the patient regarding signs and symptoms of extravasation and instruct to *immediately* relate to caregiver.
4. Educate the patient to report increasing pain promptly, spread of the lesion, or ulceration.
5. Educate the patient regarding proper application of hot or cold packs as well as topical antidotes. Should the area be allowed to air dry or be covered?
6. Evaluate the patient for allergies and adverse effects of pharmacologic antidotes.

ABBREVIATIONS

ACE: angiotensin converting enzyme inhibitor
AIDS: acquired immune deficiency syndrome
ANC: absolute neutrophil count
AWP: average wholesale price
BMT: bone marrow transplantation
BUN: blood urea nitrogen
CBC: complete blood count
CIV: continuous intravenous
CNS: central nervous system

97 Parenteral Nutrition

Michael D. Kraft and Imad F. Btaiche

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. List appropriate indications for the use of parenteral nutrition (PN).
2. Describe the components of PN and their role in nutrition support.
3. Explain the pharmaceutical and compounding issues with PN.
4. Develop a PN prescription and a plan to initiate PN based on patient-specific factors.
5. Describe the etiology and risk factors for substrate intolerance, including hyperglycemia, hypoglycemia, hyperlipidemia, and azotemia, in patients receiving PN.
6. Describe the etiology and risk factors for the refeeding syndrome in patients receiving PN.
7. Describe the etiology and risk factors for liver complications and metabolic bone disease in patients receiving PN.
8. Design a plan to monitor, prevent, and treat PN–associated complications.
9. Design a plan to monitor and correct electrolyte, vitamin, and trace-element abnormalities in patients receiving PN.

Key Concepts

❶ Parenteral nutrition (PN), also called total parenteral nutrition (TPN), is the intravenous administration of fluids, macronutrients, electrolytes, vitamins, and trace elements for the purpose of weight maintenance or gain, to preserve or replete lean body mass and visceral proteins, and to support anabolism and nitrogen balance *when the oral/enteral route is not feasible or adequate.*

❷ Amino acids are provided to preserve or replete lean body mass and visceral proteins and to promote protein anabolism and wound healing.

❸ Dextrose (D-glucose) is the major immediate energy source in PN and is vital for cellular metabolism, body protein preservation, and cellular growth.

❹ Intravenous lipid emulsions are used as an energy source in PN and to prevent or treat essential fatty acid deficiency.

❺ PN should not be used to treat acute fluid abnormalities. Rather, PN should be adjusted to minimize worsening of underlying fluid disturbances.

❻ Electrolytes, vitamins, and trace elements are essential for numerous biochemical and metabolic functions and should be added to PN daily unless otherwise not indicated.

❼ PN can be administered via a small peripheral vein [as peripheral PN (PPN)] or via a larger central vein (as central PN).

❽ PN admixtures can be prepared by mixing all components into one bag [3-in-1 admixture or a total nutrient admixture (TNA)] or by mixing and infusing dextrose, amino acids, and all other components together and infusing intravenous lipid emulsion separately (2-and-1 admixture).

❾ PN is associated with significant complications with both short- and long-term therapy.

❿ Patients receiving PN should have specific laboratory values checked to assess electrolyte status, organ function, and nutritional status, and these parameters should be monitored as indicated clinically.

Maintaining adequate nutritional status, especially during periods of illness and metabolic stress, is an important part of patient care. Malnutrition in hospitalized patients is associated with significant complications, including increased infection risk, poor wound healing, prolonged hospital stay, and increased mortality, especially in surgical and critically ill patients.[1] *Specialized nutrition support* refers to the administration of nutrients via the oral, enteral, or parenteral route for therapeutic purposes.[1] ❶ *Parenteral nutrition (PN), also*

called total parenteral nutrition (TPN), is the intravenous administration of fluids, macronutrients, electrolytes, vitamins, and trace elements for the purpose of weight maintenance or gain, to preserve or replete lean body mass and visceral proteins, and to support anabolism and nitrogen balance when the oral/enteral route is not feasible or adequate. PN is a potentially lifesaving therapy in patients with intestinal failure but also may be associated with significant complications.

DESIRED OUTCOMES AND GOALS

Specialized nutrition support is aimed at meeting nutritional needs, improving energy and protein balance, promoting growth or weight maintenance, and improving healing, particularly in malnourished patients. Goals of providing specialized nutrition support include:

- Weight maintenance (potentially weight gain in malnourished patients and growing children)
- Preservation (or repletion) of lean body mass and visceral proteins
- Support of anabolism and nitrogen balance
- Correction or avoidance of fluid and electrolyte abnormalities
- Correction or avoidance of vitamin and trace element abnormalities
- Avoidance of further nutritional deficiencies

INDICATIONS

Parenteral nutrition can be a lifesaving therapy in patients with intestinal failure, but the oral or enteral route is preferred when providing nutrition support ("when the gut works, use it"). Compared with PN, enteral nutrition generally is associated with fewer infectious complications (e.g., pneumonia, intraabdominal abscess, and catheter-related infections) and potentially improved outcomes.[1–3] However, if used in appropriate patients (i.e., patients with questionable intestinal function or when the intestine cannot be used), PN can be used safely and effectively and may improve nutrient delivery.[4] Indications for PN are listed in Table 97–1.[1]

TABLE 97–1. Indications for Parenteral Nutrition[1,a]

Bowel obstruction
Physical/mechanical (e.g., tumor compressing intestinal lumen)
Functional (e.g., postoperative ileus)
Major small bowel resection (e.g., short bowel syndrome)
Adult patients with less than 100 cm small bowel distal to the ligament of Treitz without a colon
Adult patients with less than 50 cm of small bowel if the colon is intact
Diffuse peritonitis
Gastrointestinal fistulas if enteral nutrition cannot be provided above or below the fistula
Pancreatitis—if patients have failed enteral nutrition beyond the ligament of Treitz or cannot receive enteral nutrition (e.g., due to obstruction)
Severe intractable vomiting
Severe intractable diarrhea
Preoperative nutrition support in patients with moderate to severe malnutrition who cannot tolerate enteral nutrition and in whom surgery can be delayed safely for at least 7 days

[a]When adequate oral or enteral nutrition is not possible for 5–10 days in patients with malnutrition or critical illness or for 7–14 days in most other cases.

PN COMPONENTS

PN should provide a *balanced* nutritional intake, including macronutrients, micronutrients, and fluid. Macronutrients, including amino acids, dextrose, and intravenous lipid emulsions, are important sources of structural and energy-yielding substrates. A balanced PN formulation includes 10% to 20% of total daily calories from amino acids, 50% to 60% of total daily calories from dextrose, and 20% to 30% of total daily calories from intravenous lipid emulsion. Micronutrients, including electrolytes, vitamins, and trace elements, are required to support essential biochemical reactions. Parenteral nutrition also provides a significant source of fluids. Patients require individual adjustments of PN components based on their nutritional requirements, underlying disease state(s), degree of metabolic stress, clinical status, and organ function.

Amino Acids

Amino acids are the building blocks of body proteins. There is no excess storage form of protein in the body, so amino acids are an essential component of the PN admixture. ❷ *Amino acids are provided to preserve or replete lean body mass and visceral proteins and to promote protein anabolism and wound healing.* Amino acids are a source of calories with a caloric value of 4 kcal/g.

Crystalline amino acid bulk solutions are supplied by various manufacturers in various concentrations (e.g., 3.5%, 5%, 7%, 8.5%, 10%, 15%, and 20%). Different formulations are tailored for specific age groups (e.g., adults and infants) and disease states (e.g., renal and liver disease). Specialized formulations for patients with renal failure contain higher proportions of essential amino acids. Formulas for patients with hepatic encephalopathy contain higher amounts of branched-chain and lower amounts of aromatic amino acids. However, these specialized formulations should not be used routinely in clinical practice because their efficacy has not been clearly demonstrated. Crystalline amino acid solutions have an acidic pH (pH ≈ 5–7) and may contain inherent electrolytes (e.g., sodium, potassium, acetate, and phosphate).

Dextrose

❸ *Dextrose (D-glucose) is the major immediate energy source, and it is vital for cellular metabolism, body protein*

Patient Encounter, Part 1

AA is 45-year-old woman admitted to the hospital with chief complaints of fever, abdominal pain, nausea, and vomiting for 2 days. She also reports decreased appetite and decreased oral intake for the past 3 to 4 days. The patient was discharged 2 weeks ago after having a small bowel resection for recurrent bowel obstruction.

MH
Recurrent intestinal **strictures,** intestinal obstructions, type II diabetes mellitus

SH
Small bowel resections (greater than 100 cm of small intestine remaining, colon intact)

FH and SH
Non-contributory

Meds prior to admission
Glipizide XL 5 mg orally daily

PE
Height 168 cm (5 ft, 6 in), weight 60 kg (132 lbs), temperature 38.9°C (102°F), heart rate 98 beats/minute, blood pressure 98/55 mm Hg, respiratory rate 30 breaths/minute, alert and oriented × 3, mucous membranes and skin appear cool and dry, **tachycardic, tachypneic,** lungs clear

Abd: slightly tense, diffuse abdominal pain

Diagnoses
Possible intestinal leak/perforation, diffuse peritonitis, **sepsis,** mild dehydration, and hypovolemic hypotonic hyponatremia

Plan
Admit to the surgical intensive-care unit for resuscitation and treatment.

- Would PN be indicated in this patient?
- What other patient data should be collected to help formulate a PN prescription?

preservation, and cellular growth. Several body tissues depend primarily on dextrose as an energy source, including the central nervous system, red blood cells, and the renal medulla.

Dextrose used in PN compounding typically is provided as a 70% stock solution (70 g/100 mL), although some institutions use a 50% stock solution. The final dextrose concentration in the PN solution typically should not exceed 35%. Hydrous dextrose provides 3.4 kcal/g (14.2 kJ/g). A dextrose infusion rate of 2 mg/kg per minute should be sufficient to suppress gluconeogenesis and prevent protein breakdown in adults.[5] Continuous dextrose infusion rate in adult patients generally should not exceed 4 to 5 mg/kg per minute in most hospitalized patients.[6,7]

Intravenous Lipid Emulsions

❹ *Intravenous lipid emulsions have two main clinical uses: prevent or treat essential fatty acid deficiency and provide an energy source.* Intravenous lipid emulsions currently marketed in the United States consist of long-chain triglycerides. Lipid particles consist of a triglyceride core surrounded by a layer of egg phospholipids (emulsifiers). These particles carry a negative charge on their surface that creates repulsive electrostatic forces between droplets and maintains the stability of the emulsion. Glycerol is added to the emulsion to adjust the tonicity, and water is the solvent. The stability of intravenous lipid emulsions can be affected by several factors. The negative charges on the surface of the lipid particles can be disrupted by cations, especially divalent cations such as calcium and magnesium or iron[8] which can exist in divalent or trivalent form, and possibly by pH changes, particularly acidic pH. Disruption of the negative charges can diminish the repulsive electrostatic forces and impair stability of the lipid emulsion. Lipid particles also can aggregate and form larger particles. **Creaming** of the emulsion occurs when these particles form and migrate to the surface of the emulsion but can be reversed with mild agitation. If these particles continue to aggregate, **coalescence** may occur and destabilize the emulsion. Once an emulsion has coalesced, it should not be infused into a patient because this can result in the formation of fat emboli. If coalescence continues, irreversible separation of the emulsion can occur (**oiling out** or breaking of the emulsion).

Intravenous lipid emulsions differ in their concentration (10%, 20%, and 30%), caloric density, natural source of lipids, and ratio of phospholipids to triglycerides (PL:TG). Table 97–2 shows a comparison of commercially available intravenous lipid emulsions in the United States. The 10%, 20%, and 30% lipid emulsions provide 1.1 kcal/mL (4.6 kJ/mL), 2 kcal/mL (8.4 kJ/mL), and 3 kcal/mL (12.6 kJ/mL) with a PL:TG of 0.12, 0.06 and 0.04 respectively. The lower PL:TG indicates a lower phospholipid content and translates to a better clearance of the 20% and 30% lipid emulsions compared with the 10% lipid emulsion.[9] The 30% lipid emulsion is only approved for infusion in a TNA and should not be infused directly into patients.

Intravenous lipid emulsion particles are hydrolyzed in the bloodstream by the enzyme **lipoprotein lipase** to release free fatty acids and glycerol. Free fatty acids then are be taken up into adipose tissue for storage (triglycerides), oxidized to energy in various tissues (e.g., skeletal muscle), or recycled in the liver to make lipoproteins.

The essential fatty acids in humans are linoleic acid (C-18:2 N-6) and α-linolenic acid (C18:3 N-3). Arachidonic acid (C20:4 N-6) is also essential but can be synthesized from linoleic acid. Administration of 2% to 4% of total daily calories as linoleic acid should be adequate to prevent **essential fatty acid deficiency** in adults (e.g., infusion of 500 mL of 20% intravenous lipid emulsion once weekly).[7] Biochemical evidence of essential fatty acid deficiency can develop in about 2 to 4 weeks in adult patients receiving lipid-free PN, and clinical manifestations generally appear after an additional

TABLE 97–2. Comparison of Intravenous Lipid Emulsions

1 to 2 weeks.[10] Symptoms may include hair loss, thinning of skin, and skin **desquamation.**

Intravenous lipid emulsions are also a source of calories. The typical daily dose in adults is approximately 0.5 to 1 g/kg per day. In the absence of hypertriglyceridemia, substituting a portion of dextrose calories with lipid calories may be beneficial in situations where dextrose infusion may lead to complications (e.g., hyperglycemia). Some examples include patients with diabetes mellitus or pancreatic disease and patients under severe stress (e.g., trauma or burns) who are at risk for hyperglycemia. The maximum of dose of lipid emulsions is 2.5 g/kg per day,[7] or 60% of total daily calories, although doses this high are used rarely in practice.

Complications and safety concerns related to the administration of intravenous lipid emulsions include severe hypertriglyceridemia, infection, **anaphylactic** reactions, and infusion-related reactions. Patients with hypertriglyceridemia, renal dysfunction, hepatic dysfunction, **pancreatitis,** and severe metabolic stress may have reduced lipid clearance and are at high risk of developing hypertriglyceridemia. Patients with hyperglycemia are also at risk of developing hypertriglyceridemia. In general, intravenous lipid emulsions should be withheld in adult patients with a serum triglyceride concentration of 400 mg/dL (4.52 mmol/L) or more and used cautiously in critically ill patients, especially those with sepsis.

Patients without malnutrition who receive PN may have a higher incidence of infectious complications than patients who do not receive PN.[11] However, conflicting data exist on the incidence of infectious complications in patients receiving PN with or without intravenous lipid emulsions. Intravenous lipid emulsions support the growth of common bacterial and fungal pathogens, but bacterial growth is slower in TNAs than in intravenous lipid emulsions alone.[12,13] This may be due to the acidic pH of amino acid solutions and osmolarity of PN formulations. Furthermore, a 0.22-micron bacterial retention filter cannot be used on the infusion line because the average size of lipid particles is approximately 0.5 micron. Therefore, strict aseptic techniques must be used when handling intravenous lipid emulsions to minimize the risk of PN contamination and possible infectious complications. The Centers for Disease Control and Prevention (CDC) recommends that infusion of intravenous lipid emulsions separately from PN be completed within 12 hours of initiation. Because TNAs support microbial growth at a slower rate than intravenous lipid emulsions, the CDC recommends that TNA infusion be completed within 24 hours of initiation.

Patients with allergy to eggs or legumes (e.g., soy beans, broad beans, and lentils) may have cross-sensitivity with intravenous lipid emulsions and are at risk for allergic reactions. Infusion-related adverse effects also may occur with rapid infusion of intravenous lipid emulsions, including fever, chills, headache, palpitations, dyspnea, chest tightness, and nausea. Although these reactions are rare, patients should be monitored for adverse events related to lipid infusion. Extending the infusion time (e.g., 12–24 hours) can minimize infusion-related adverse events and improves lipid clearance. If a 24-hour lipid infusion is used separately from PN, then two lipid containers should be used, with each container infused over 12 hours.

Fluid

❺ *PN generally should not be used to treat acute fluid abnormalities. Rather, PN should be adjusted to minimize worsening of underlying fluid disturbances, taking into account other fluids the patient is receiving.* Daily maintenance fluid requirements for adults can be estimated with the following equation:

$$\text{Total daily maintenance fluid requirements} = 1500\ \text{mL} + \{20\ \text{mL/kg} \times [\text{wt (kg)} - 20]\}^{*}$$

For patients with fluid deficits, it is safer and more cost-effective to correct fluid abnormalities using standard intravenous fluids (e.g., sodium chloride 0.9% in water, dextrose 5% in water, and lactated Ringer's solution). Minimizing fluid volume in PN may be indicated in patients with fluid overload, such as critically ill patients who receive large-volume resuscitation fluids, patients with oliguric (urine output less than 400 mL/day) or anuric (urine output less than 50 mL/day) renal failure, and those with congestive heart failure. It is reasonable to

*For elderly patients (e.g., greater than 60 years old), use 15 mL/kg for every kilogram above 20 kg.

provide total daily fluid requirements (both maintenance needs and abnormal/extrarenal losses) in the PN admixture in patients who depend on long-term PN. However, caution should be exercised when the PN solution is diluted to an extent that may alter the stability and compatibility of a concentrated solution. Diluting a PN admixture may affect the physical and chemical properties of the admixture (e.g., the pH, which could affect lipid emulsion stability and calcium-phosphate compatibility); therefore, stability and compatibility data should be confirmed first.

Electrolytes

❻ *Electrolytes are involved in many metabolic and homeostatic functions, including enzymatic and biochemical reactions, maintenance of cell membrane structure and function, neurotransmission, hormone function, muscle contraction, cardiovascular function, bone composition, and fluid homeostasis.* The causes of electrolyte abnormalities in patients receiving PN may be multifactorial, including altered absorption and distribution; excessive or inadequate intake; altered hormonal, neurologic, and homeostatic mechanisms; altered excretion via gastrointestinal and renal losses; changes in fluid status and fluid shifts; and medications.

Electrolytes that are included routinely in PN admixtures include sodium, potassium, phosphorus (as phosphate), calcium, magnesium, chloride, and acetate. When determining electrolytes in PN admixtures, the patient's renal function always must be taken into account. Typical daily electrolyte maintenance requirements for adults with normal renal function are listed in Table 97–3.

Sodium

Sodium is the most abundant extracellular cation in the body and is the major osmotically active ion in the extracellular fluid. Sodium concentration determines the distribution of water in the extracellular space, and sodium disorders can be caused by many factors. Patients with abnormal gastrointestinal losses (e.g., gastric, **ostomy,** and **fistula** losses) have increased sodium requirements. Patients with fluid overload and hypervolemic hypotonic hyponatremia may require sodium and fluid restriction. Sodium in PN can be provided in the forms of chloride, acetate, and phosphate salts. One millimole (mmol) of sodium phosphate provides 1.33 mEq of elemental sodium. Total sodium concentration in PN should not exceed 154 mmol/L (the equivalent of normal saline). PN is not used to treat sodium disturbances but rather to minimize worsening of any underlying disorders.

Potassium

Potassium is the second most abundant cation in the body and is found primarily in the intracellular fluid. Potassium has many important physiologic functions, including regulation of cell membrane electrical action potential (especially in the myocardium), muscular function, cellular metabolism, and glycogen and protein synthesis. Potassium in PN can be provided as chloride, acetate, and phosphate salts. One millimole of potassium phosphate provides 1.47 mEq of elemental potassium. Generally, the concentration of potassium in peripheral PN (PPN) admixtures should not exceed 80 mEq/L (80 mmol/L). While it is safer to also stick to the 80 mEq/L (80 mmol/L) limit for administration through a central vein, the maximum recommended potassium concentration for infusion via a central vein is 150 mEq/L (150 mmol/L).[14] Patients with abnormal potassium losses (e.g., loop or thiazide diuretic therapy) may have higher requirements, and patients with renal failure may require potassium restriction.

Phosphorus and Calcium

Phosphorus and calcium are essential electrolytes involved in many physiologic processes and biochemical reactions.

TABLE 97–3. Approximate Daily Maintenance Electrolyte Requirements for Adults[7]

Electrolyte	Approximate Daily Maintenance Requirements	Electrolyte Salts Used in PN
Sodium	1–2 mEq/kg	Chloride, acetate, phosphate
Potassium	1–2 mEq/kg	Chloride, acetate, phosphate
Phosphorus	20–40 mmol	Sodium phosphate, potassium phosphate
Calcium	10–15 mEq	Gluconate
Magnesium	8–20 mEq	Sulfate
Chloride	[a]	Sodium, potassium
Acetate	[a]	Sodium, potassium
Conversions	1 mmol potassium phosphate = 1.47 mEq potassium 1 mmol sodium phosphate = 1.33 mEq sodium	

[a]As needed to maintain acid-base balance; linked to amounts of sodium and potassium provided (as chloride and acetate salts).

Phosphorus is provided as sodium or potassium phosphate in PN. Approximately 10 to 15 mmol of phosphate are needed per 1000 kilocalories to maintain normal serum phosphorus concentrations (provided the patient is well nourished and has normal renal function).[15] Patients with renal insufficiency may require phosphorus restriction.

The Food and Drug Administration (FDA) published a safety alert in 1994 in response to two deaths associated with calcium-phosphate precipitation in PN.[16] Autopsy reports from these patients revealed diffuse **microvascular pulmonary emboli** containing calcium-phosphate precipitates. Because calcium and phosphate can bind and precipitate in solution, caution must be exercised when mixing these two electrolytes in PN admixtures. Several factors can affect calcium-phosphate solubility, including

- *pH.* Largely affected by the final amino acid concentration, to a lesser extent by the dextrose concentration (unless the final amino acid concentration is very low); the lower the solution pH, the less chance there is for precipitation; monobasic phosphates predominate at low pH, leaving fewer free dibasic phosphates for precipitation with divalent calcium; monobasic calcium phosphate is more soluble than dibasic calcium phosphate.
- *Amino acid concentration.* Primary factor that affects pH of the PN admixture; the higher the concentration of amino acids, the higher is the amount of calcium and phosphate that can remain in solution (phosphate likely binds with amino acids and less is available to bind with calcium), therefore lowering the risk of calcium-phosphate precipitation.
- *Calcium salt.* Calcium gluconate is the preferred salt in PN because it is has a low dissociation in solution with lesser free calcium available at a given time to bind phosphate (as opposed to calcium chloride, which dissociates rapidly in solution).
- *Time.* More calcium and phosphate will dissociate over time, increasing the risk for calcium-phosphate precipitation.
- *Temperature.* As temperature increases, more calcium and phosphate dissociate and increase the risk of calcium-phosphate precipitation.
- *Order of mixing.* Calcium and phosphate should be separated when mixing PN admixtures (e.g., add phosphate first, then all other PN components, and then add calcium last); if calcium is added before all other components are in the bag, including lipid emulsion, then the volume in the bag at the time calcium is added must be used to determine the maximum calcium that can be added.

Magnesium

Magnesium is the second most abundant intracellular cation. Magnesium serves as an essential cofactor for numerous enzymes and in many biochemical reactions, including reactions involving adenosine triphosphate (ATP).[17] Magnesium disorders can be multifactorial and can be related to renal function, disease state, and medication therapy. Magnesium in PN typically is provided as magnesium sulfate (1 g magnesium sulfate = 8.1 mEq of elemental magnesium).

Chloride and Acetate

Concentration limits for chloride and acetate in PN typically are linked to limitations for sodium and potassium. The usual ratio of chloride:acetate in PN is about 1:1 to 1.5:1. Chloride and acetate primarily play a role in acid-base balance. Acetate is converted to bicarbonate at a 1:1 molar ratio. This conversion appears to occur mostly outside the liver. Bicarbonate *never* should be added to or coinfused with PN solutions. This can lead to the release of carbon dioxide and potentially result in the formation of calcium or magnesium carbonate (very insoluble salts).

Vitamins

❻ *The water-soluble and fat-soluble vitamins in the parenteral multivitamin mix are essential cofactors for numerous biochemical reactions and metabolic processes. Parenteral multivitamins are added daily to the PN.* Patients with chronic renal failure are at risk for vitamin A accumulation and potential toxicity. Serum vitamin A concentrations should be measured in patients with renal failure when vitamin A accumulation is a concern. Previously, vitamin K was administered either daily or once weekly because intravenous multivitamin formulations did not contain vitamin K. However, manufacturers have reformulated their parenteral multivitamin products to provide 150 mcg of vitamin K in accordance with FDA recommendations. There is a parenteral multivitamin formulation available without vitamin K (e.g., for patients who require warfarin therapy), but standard compounding of PN formulations should include a parenteral multivitamin that contains vitamin K unless otherwise clinically indicated.

Trace Elements

❻ *Trace elements are essential cofactors for numerous biochemical processes. Trace elements that are added routinely to PN include zinc, selenium, copper, manganese, and chromium.* There are various commercial parenteral trace element formulations that can be added to PN admixtures (e.g., MTE-5®). Zinc is important for wound healing, and patients with high-output fistulas, diarrhea, burns, and large open wounds may require additional zinc supplementation. Patients may lose as much as 12 to 17 mg zinc per liter of gastrointestinal (GI) output (e.g., from diarrhea or enterocutaneous fistula losses); however, others have demonstrated that 12 mg/day may be adequate to maintain these patients in positive zinc balance.[18] Patients with chronic diarrhea, malabsorption, and short-gut syndrome may have increased selenium losses and may require additional selenium supplementation. Patients with severe **cholestasis** should have copper and manganese

restricted to avoid their accumulation and toxicity because both elements undergo biliary elimination. Chromium is an important cofactor for glucose metabolism, and patients with chromium deficiency may exhibit glucose intolerance; however, this is a rare cause of hyperglycemia. Monitor trace-element concentrations regularly, deficiency or toxicity especially in patients at risk for.

PN Additives

Heparin

Heparin (0.5–1 unit/mL) may be added to PN admixtures for three reasons:

- To maintain catheter patency
- To reduce **thrombophlebitis**
- To enhance lipid particle clearance by acting as a cofactor for the lipoprotein lipase enzyme

The benefit and necessity of adding heparin to PN are unclear. There are also concerns about the stability/compatibility of intravenous lipid emulsions with heparin added at concentrations above 1 unit/mL. Heparin should be omitted in patients with active bleeding, **thrombocytopenia,** heparin-induced thrombocytopenia (HIT), or heparin allergy.

Regular Insulin

Regular insulin may be added to PN admixtures for glycemic control. The dose of insulin depends on the severity of hyperglycemia and daily insulin requirements. Generally, once the patient is receiving PN at goal, about 70% of the total insulin administered over the previous 24 hours as sliding scale (or continuous infusion) can be added to the next PN admixture. The insulin dose should be adjusted based on frequent capillary blood glucose evaluation. Caution should be used when insulin is added to PN to avoid hypoglycemia. Adding insulin to PN rather than administering as a continuous intravenous infusion does not provide the flexibility of frequent titration of the insulin dose to the desired target blood glucose concentration. As such, severe uncontrolled hyperglycemia is best treated with a continuous insulin infusion.

Histamine-2-Receptor Antagonists

Intravenous histamine-2-receptor antagonists such as ranitidine, famotidine, and cimetidine are compatible with PN and can be added to the daily PN for prevention of stress-related mucosal damage and peptic ulcer disease. This provides a continuous acid suppression and reduces nursing time by avoiding intermittent scheduled infusions.

Human Albumin

Human albumin is a colloid used as a plasma volume expander and is *not* a source of nutrition. Albumin should be administered separately from PN because it may be incompatible and may increase microbial growth and infectious risk when mixed in the PN admixture.

Iron Dextran

Iron-deficiency anemia in chronic PN patients may be due to underlying clinical conditions and the lack of iron supplementation in PN. Parenteral iron therapy becomes necessary in iron-deficient patients who cannot absorb or tolerate oral iron. Parenteral iron should be used with caution owing to infusion-related adverse effects. A test dose of 25 mg of iron dextran should be administered first, and the patient should be monitored for adverse effects for at least 60 minutes. Intravenous iron dextran then may be added to lipid-free PN at a daily dose of 100 mg until the total iron dose is given. Iron dextran is not compatible with intravenous lipid emulsions at therapeutic doses and can cause oiling out of the emulsion. Other parenteral iron formulations (e.g., iron sucrose and ferric gluconate) have not been evaluated for compounding in PN and should not be added to PN formulations.

NUTRITION ASSESSMENT AND NUTRITIONAL REQUIREMENTS

The first step before delivering specialized nutrition support is to perform a nutritional assessment and determine nutrient requirements based on the patient's nutritional status and clinical conditions. Collect subjective and objective data to determine a patient's level of nutrition, to identify patients with malnutrition or at risk for malnutrition, and to identify risk factors that may put a patient at risk for nutrition-related problems.[1] A nutrition assessment should include:[1,19]

- Patient history
- Physical assessment including height, weight, ideal body weight (IBW), and recent weight loss (intentional or unintentional)
- Physical examination of the musculoskeletal system (e.g., biceps, triceps, quadriceps, temporalis, deltoid, and interosseus muscles) for loss of muscle mass, and examination of the skin and mucous membranes for abnormalities (e.g., noting dry or flaky skin, bruising, edema, ascites, poorly healing wounds) and loss of subcutaneous fat
- Changes in eating habits and/or changes in GI function
- Presence and severity of underlying disease(s)
- Serum proteins (i.e., albumin concentration) because hypoalbuminemia at baseline or prior to hospitalization may be indicative of malnutrition and associated with poor outcome

There are several approaches and methods to conducting a nutrition assessment, but one approach that has been validated is the Subjective Global Assessment (SGA).[1] Application of the SGA requires gathering the data just listed and assessing these parameters (i.e., weight change, change in diet, GI symptoms, functional capacity, and physical examination)

TABLE 97–4. Estimating Daily Nutritional Requirements in Adults[1,7,19]

Determining Energy Expenditure	
Harris-Benedict equations[a]	Men: BEE = 66.42 + 13.75 (W) + 5 (H) – 6.78 (A) Women: BEE = 655.1 + 9.65 (W) + 1.85 (H) – 4.68 (A) W = weight in kg, H = height in cm, A = age in years Energy expenditure then should be multiplied by a stress factor to estimate the total energy expenditure (TEE): Bed rest ≈ 1.2 × BEE Ambulatory ≈ 1.3 × BEE Anabolic ≈ 1.5 × BEE Energy requirements should also be increased ~ 12% with each degree of fever above 37°C (98.6°F).
Energy expenditure per body weight (i.e., kcal/kg)[a]	Range of ~ 20–35 kcal/kg per day Maintenance ~ 20–25 kcal/kg per day Repletion/postoperative wound healing/critical illness/sepsis/ ~ 25–30 kcal/kg per day Anabolic//trauma/burns ~ 30–35 kcal/kg per day

Determining Protein Requirements

Patient Clinical Condition	Daily Protein Requirements[b]
Maintenance/non-stressed	0.8–1 g/kg
Repletion	1.3–1.5 g/kg
Trauma, sepsis, critical illness	1.5–2 g/kg
Burns	1.5–2.5 g/kg
Hepatic failure with encephalopathy	0.5–1 g/kg
Renal failure predialysis	0.6–0.8 g/kg
Renal failure receiving intermittent hemodialysis (IHD)	1.1–1.3 g/kg
Renal failure receiving continuous ambulatory peritoneal dialysis (CAPD)	1.2–1.3 g/kg
Renal failure receiving continuous renal replacement therapy (CRRT)	1.5–2.5 g/kg

[a]Use AdjBW in significantly obese patients.
[b]Protein requirements based on ideal body weight (IBW); use AdjBW in obese patients.

and then assigning a subjective rating (A = well nourished; B = moderately malnourished or suspected of being malnourished; C = severely malnourished).[19]

After performing a nutrition assessment, estimate the patient's daily caloric and protein needs (Table 97–4). Indirect calorimetry involves measuring oxygen consumption and carbon dioxide production to determine the daily energy expenditure (EE). This is a valuable method to determine energy requirements, but it is technically very difficult, requires expensive equipment and trained personnel to use, and therefore is not feasible in all institutions. Over 200 separate equations have been developed to determine EE for adults, but the Harris-Benedict equations are some of the most widely used. These equations take into account a patient's sex, weight, height, and age to determine basal EE (BEE), and then a "stress factor" can be applied to estimate the daily total EE (TEE). Alternatively, EE can be estimated based on EE per body weight (i.e., kilocalories per kilogram). However, dry weight or admission weight should be used, and this estimation may not be appropriate in patients who are obese or in elderly patients. There is debate over the best method to use for patients who are obese (e.g., over 130% of IBW), but it is reasonable to use an adjusted body weight (AdjBW) in order to avoid overfeeding:

$$\text{AdjBW} = \text{IBW} + [0.25 \times (\text{actual weight} - \text{IBW})]$$

Protein requirements must be based on the patient's nutrition assessment and appropriate amounts provided (based on IBW or AdjBW for obese patients) to facilitate anabolism and wound healing, and avoid adverse effects (e.g., azotemia and uremia).

PREPARING THE PN PRESCRIPTION: ADMINISTRATION, COMPOUNDING, AND PHARMACEUTICAL ISSUES

After performing a nutrition assessment and estimating nutritional requirements, determine the optimal route to provide specialized nutrition support (e.g., oral, enteral, or parenteral). If PN is deemed necessary, venous access (i.e., peripheral or central; see below) for PN infusion must be obtained. Finally, formulate a PN prescription, and administer PN according to proper safety guidelines.

Route of PN Administration: Peripheral Versus Central Vein Infusion

❼ *PN can be administered via a smaller peripheral vein (e.g., cephalic or basilic vein) or via a larger central vein (e.g., superior vena cava).* Peripheral PN (PPN) is infused via a peripheral vein and generally is reserved for short-term administration (up to 7 days) when central venous access is not available. PN formulations are hypertonic, and infusion via a peripheral vein can cause thrombophlebitis. Factors that increase the risk of **phlebitis** include high solution osmolarity, extreme pH, rapid infusion rate, vein properties, catheter material, and infusion time via the same vein.[20] The osmolarity of PPN admixtures should be limited to 900 mOsm/L or less to minimize the risk of phlebitis. The approximate osmolarity of a PN admixture can be calculated from the osmolarities of individual components:

- Amino acids = 10 mOsm/g (or 100 mOsm/1% final concentration in PN)
- Dextrose = 5 mOsm/g (or 50 mOsm/1% final concentration in PN)
- Sodium (chloride, acetate, and phosphate) = 2 mOsm/mEq
- Potassium (chloride, acetate, and phosphate) = 2 mOsm/mEq
- Calcium gluconate = 1.4 mOsm/mEq
- Magnesium sulfate = 1 mOsm/mEq

PPN admixtures should be coinfused with intravenous lipid emulsion when using the 2-and-1 PN because this may decrease the risk of phlebitis. Infectious and mechanical complications may be lower with PPN compared with central venous PN administration. However, because of the risk of phlebitis and osmolarity limit, PPN admixtures have low macronutrient concentrations and therefore require large fluid volumes to meet a patient's nutritional requirements. Given these limitations, every effort should be made to obtain central venous access and initiate central PN when it is unlikely a patient will tolerate enteral or oral nutrition within 5 to 7 days.

Central PN refers to the administration of PN via a large central vein, and the catheter tip must be positioned in the vena cava. Central PN allows the infusion of a highly concentrated, hypertonic nutrient admixture. The typical osmolarity of a central PN admixture is about 1500 to 2000 mOsm/L. Central veins have much higher blood flow, and the PN admixture is diluted rapidly on infusion, so phlebitis is usually not a concern. Patients who require PN administration for longer periods of time (greater than 7 days) should receive central PN. One limitation of central PN is the need for placement of a central venous catheter and an x-ray to confirm placement of the catheter tip. Central venous catheter placement may be associated with complications, including **pneumothorax,** arterial injury, **air embolus,** venous thrombosis, infection, **chylothorax,** and **brachial plexus** injury.[1,20]

Type of PN Formulation: 3-in-1 versus 2-and-1

❽ *PN admixtures can be prepared by mixing all components into one bag, or instead, intravenous lipid emulsion may be infused separately (via a Y-site infusion or through a separate intravenous catheter). When all components are mixed together, this is referred to as a 3-in-1 admixture or a total nutrient admixture (TNA).*[21] *When dextrose, amino acids, and all other components are mixed together without intravenous lipid emulsion, this is referred to as a 2-and-1 admixture.* With a 2-and-1 PN, intravenous lipid emulsion can be infused separately on a daily or intermittent basis. Once lipid emulsion is added, the TNA becomes an emulsion. There are various advantages and disadvantages to using either 3-in-1 or 2-and-1 PN (Table 97–5).

A primary concern when administering PN is safety. The FDA published a safety alert in 1994 in response to two deaths associated with TNA infusion.[16] Autopsy reports from these patients revealed diffuse microvascular pulmonary emboli containing calcium-phosphate precipitates. The FDA provided

TABLE 97–5. Advantages and Disadvantages of Using 3-in-1 (TNA) or 2-and-1 PN Admixtures

	3-in-1 (TNA)	2-and-1
Advantages	Simplified regimen for patient Increased patient compliance at home Decreased labor Decreased costs Decreased risk of contamination (due to less manipulation) Minimize infusion-related reactions from intravenous lipid emulsions Decreased vein irritation (especially with PPN)	Improved stability compared to TNA Increased number of compatible medications Decreased bacterial growth compared to TNA Easier visual inspection Can use 0.22-micron bacterial retention filter Cost savings if unused (i.e. not spiked) intravenous lipid emulsion can be reused
Disadvantages	Decreased stability compared to 2-in-1 PN Cannot use 0.22-micron bacterial retention filter Increased bacterial growth compared to 2-in-1 PN Visual inspection is difficult Limited compatibility with medications	Increased labor and costs (if intravenous lipid emulsion infused separately) Increased vein irritation, especially if PPN is not coinfused with intravenous lipid emulsion

PPN, peripheral parenteral nutrition; TNA, total nutrient admixture.

recommendations for safe infusion of PN admixtures containing calcium and phosphate:

- A 0.22-micron air-eliminating filter should be used for infusion of non-lipid-containing PN.
- A 1.2-micron in-line filter should be used for the infusion of 3-in-1 PN (i.e., a TNA) because it can remove large and unstable lipid droplets as well as particulate matter.[22]

Another concern is the coinfusion of intravenous medications with PN admixtures. Many intravenous medications have limited compatibility with 3-in-1 formulations but may be coinfused with a 2-and-1 formulation.[23,24] Some medications can be coinfused at the Y-site, few medications can be mixed directly into the PN solution or coinfused with intravenous lipid emulsion, and some cannot be mixed or coinfused with the PN admixture.[23,24] Always consult compatibility data before adding a medication to a PN admixture or coinfusing with PN. Medications that are compatible should be added to PN only if it is reasonable and safe (i.e., based on toxicity profile, pharmacokinetic/pharmacodynamic considerations).

Formulating a PN Admixture and Regimen

After completing a full nutrition assessment (e.g., SGA),[1,19] estimating the patient's daily fluid, calorie, and protein requirements (Table 97–4), and determining if PN is indicated (Table 97–1), develop a PN prescription.

Patient Encounter, Part 2

AA was diagnosed with an intestinal leak at the previous surgical site, diffuse peritonitis, sepsis, mild dehydration, and hypovolemic hypotonic hyponatremia.

Laboratory data

Na =130 mEq/L (130 mmol/L), K = 3.4 mEq/L (3.4 mmol/L), Cl = 104 mEq/L (104 mmol/L), HCO_3 = 21 mEq/L (21 mmol/L), BUN = 14 mg/dL (5 mmol/L), serum creatinine = 0.6 mg/dL (53 µmol/L), blood glucose = 177 mg/dL (9.8 mmol/L), Ca = 3.96 mEq/L (1.98 mmol/L), ionized Ca = 2.34 mEq/L (1.17 mmol/L), Mg = 1.72 mEq/L (0.86 mmol/L), phosphorus = 2.1 mg/dL (0.68 mmol/L), WBC count = 14,400/mm^3 (14×10^9/L), hemoglobin = 11.2 mg/dL (112 g/L or 6.9 mmol/L), hematocrit = 42% (0.42), and platelets = 164,000/mm^3 (164×10^9/L)

AA was taken to the operating room for an **exploratory laparotomy,** repair of the intestinal leak, and small bowel resection. Postoperatively, a nasogastric (NG) tube was placed and drained 800 to 1000 mL/day on postoperative days 1 and 2. The surgeons placed a central venous catheter and wanted to start the patient on central PN given her diagnoses of diffuse peritonitis, intestinal leak, evidence of poor intestinal function (given high NG tube output), and history of recurrent bowel obstructions. Refer to Table 97–6 for recommendations on formulating a goal PN prescription for AA.

Patient Encounter, Part 3

The surgical team plans to initiate the PN prescription you recommended for AA. How should this PN admixture be initiated and titrated to goal?

Day 1: Start at approximately 50% of the goal (i.e., initiate at 40 mL/hour or 960 mL/day) with a maximum of 2 mg/kg per minute of dextrose.

Initiating PN

Exercise caution when initiating PN to avoid hyperglycemia and fluid and electrolyte abnormalities. Once the goal daily volume is determined, infuse the PN admixture over 24 hours. For safety, initiate PN at a lower infusion rate (e.g., ~50% of goal for 24 hours) on day 1 with no more than 150 to 200 g of dextrose per day. Then titrate PN up to goal infusion rate, provided that glycemic control is maintained and the patient does not experience any significant fluid or electrolyte abnormalities. Monitor electrolytes daily and correct as needed, and monitor severely malnourished patients for refeeding syndrome (see "Complications of PN").

Cycling PN

PN should be administered over 24 hours in most hospitalized patients to minimize glucose, fluid, and electrolyte abnormalities. However, administering PN via an intermittent infusion, or *cycling PN*, may be advantageous in certain patients and situations. Cycling PN typically involves administering the same goal PN volume usually over 12 hours rather than over 24 hours. Taper PN to the goal cycle over 2 to 4 days (e.g., 24 hours, then 18 hours the next day, then 14 hours the next day, and then 12 hours the next day). Titrate the PN infusion rate up over 1 to 2 hours to goal rate and then taper down over 1 to 2 hours at the end of the cycle to avoid reactive hypoglycemia. Most home infusion pumps can be programmed to cycle a given PN volume automatically over a given time. However, the pharmacist may have to develop an appropriate PN cycle if the infusion pump cannot be programmed (e.g., in the inpatient setting or in long-term care facilities).

Cyclic PN has the following advantages:

- It helps to limit PN-associated liver cholestasis by avoiding continuous compulsive nutrient overload on the liver.[25]
- It improves the quality of life of patients receiving home PN by allowing the patient time off of PN to engage in normal daily activities.

TABLE 97–6. Patient Encounter, Part 2, Developing a Goal PN Prescription

PN Component	Formulation and Considerations
Fluid	Adjust PN to provide minimal amount of fluid, then take into consideration other fluid sources (e.g., other IV fluids) and adjust to meet daily maintenance fluid needs Safer and more cost-effective to adjust IV fluids rather than PN 1500 mL + (20 mL/kg × 40 kg) = 1500 mL + 800 mL = 2300 mL/day
Goal calorie and protein requirements	Perform a subjective global assessment Take into consideration the patient's current clinical status, diagnoses, medications, etc. Total daily calories ~25–30 kcal/kg per day, or ~1500–1800 kcal/day Protein ~1.5–2 g/kg per day of ideal body weight (~89–118 g protein/day) This patient has sepsis, diffuse peritonitis, and recent surgical procedures, target ~1800 kcal/day and ~110 g protein/day
Intravenous lipid emulsion	Typical intravenous lipid emulsion should provide ~20–30% of total daily calories Can be an alternative source of calories in patients with diabetes or hyperglycemia—consider increasing calories from intravenous lipid emulsion in these patients (e.g., 30% of total daily calories) Total daily goal calories ≈ 1800 kcal/day 1800 kcal/day × 0.3 = 540 kcal/day 540 kcal/day to be provided from intravenous lipid emulsion $\frac{540 \text{ kcal/day}}{2 \text{ kcal/mL}}$ ~ 270 mL of 20% intravenous lipid emulsion/day (11.25 mL/hour × 24 hours, so round to 11 mL/hour) 11 mL/hour × 24 hours = 264 mL/day of 20% intravenous lipid emulsion = 528 kcal/day
Amino acids	Amino acids: goal of ~110 g/day 440 kcal/day (should provide ~10–20% of total daily calories) If using a 10% stock amino acid solution: $110 \text{ g} \times \frac{100 \text{ mL}}{10 \text{g}} = 1100 \text{ mL}$ of 10% stock solution
Dextrose	Dextrose infusion rate should be ~3–4 mg/kg per minute, should comprise ~50–60% of total daily calories Since this patient has type 2 diabetes mellitus, consider a goal of ~3 mg/kg per minute Provide remainder of total daily calories as dextrose: Total daily goal calories ≈ 1800 kcal/day 1800 kcal/day –528 kcal/day (from intravenous lipid emulsion) 1272 kcal/day –440 kcal/day (from amino acids) 832 kcal/day to make up with dextrose. $\frac{832 \text{ kcal/day}}{3.4 \text{ kcal/g}} \approx 245$ g dextrose/day If using a 70% stock dextrose solution: $245 \text{ g} \times \frac{100 \text{ mL}}{70 \text{ g}} = 350 \text{ mL}$ 245 g/day × 3.4 kcal/g ≈ 833 kcal/day As a double-check, convert to mg/kg/minute: 245 g dextrose/day × 1000 mg/1 g × 1 day/1440 minute = 170.1 mg/minute $\frac{170.1 \text{ mg/minute}}{60 \text{ kg}} \approx 2.8$ mg/kg per minute
Final goal PN formulation (if using a 3-in-1 preparation)	Fluid: 264 mL from lipid emulsion, 1100 mL from amino acids, 350 mL from dextrose; assume approximately 100 mL for electrolytes, multivitamin, trace elements, and any additives Total fluid = 264 mL + 1100 mL + 350 mL + 100 mL = 1814 mL/day, or ~ 76 mL/hour Dextrose = 245 g/day (833 kcal/day); or 135 g/L (13.5% final concentration) Amino acids = 110 g/day (440 kcal/day); or 60 g/L (6% final concentration) 20% intravenous lipid emulsion = 264 mL/day (528 kcal/day); or 2.9% final concentration ~ 1801 kcal/day and 110 g amino acids/day ~ 30 kcal/kg/day; ~1.83 g amino acids/kg per day
Electrolytes	Daily doses based on daily maintenance requirements, renal function, gastrointestinal losses, acid-base status, concomitant drug therapy, nutritional and anabolic status Patient has hyponatremia, hypokalemia, hypomagnesemia, and hypophosphatemia, also has low serum bicarbonate concentration, could be component of metabolic acidosis due to sepsis

(*Continued*)

TABLE 97–6. Patient Encounter, Part 2, Developing a Goal PN Prescription (*Continued*)

PN Component	Formulation and Considerations
Electrolytes (*continued*)	Sodium chloride/acetate ≈ 275 mEq/day initially (or ~154 mEq/L, given that the patient has hypovolemic hypotonic hyponatremia, likely from vomiting and gastric/NG tube losses); may require adjustment as hyponatremia corrects (e.g., change to ~70–80 mEq/L) Potassium chloride/acetate ≈ 90 mEq/day initially (~1.5 mEq/kg/day given the patient has hypokalemia and normal renal function); may require adjustment after serum potassium corrects Assess arterial blood gas measurement (if available) and determine appropriate amounts of chloride and acetate (i.e., consider increasing acetate amount if found with metabolic acidosis) Sodium phosphate ≈ 35–40 mmol/day initially (given the patient has hypophosphatemia and normal renal function); may require adjustment after serum phosphorus corrects Calcium gluconate ≈ 10 mEq/day initially Magnesium sulfate ≈ 10–15 mEq/day initially
Vitamins	Provide standard parenteral multivitamin (containing water- and fat-soluble vitamins) in PN daily; assess for any possible deficiencies, otherwise no indication for additional supplemental vitamins
Trace elements	Provide standard parenteral trace element preparation (containing zinc, copper, manganese, chromium, and selenium) daily in PN Assess patient for any possible adjustments needed (e.g., delete copper and manganese from PN if the patient has evidence of severe cholestasis, supplemental zinc and selenium for any GI or fistula losses) or potential deficiencies
Additives	Consider other medications the patient may be receiving Consider adding histamine-2-receptor antagonist to PN if indicated Consider adding regular insulin to PN if the patient continues to exhibit hyperglycemia and requires exogenous insulin for blood glucose control

Concerns with cycling PN include hyperglycemia with high infusion rates, reactive hypoglycemia, and fluid and electrolyte abnormalities. Reactive hypoglycemia can be minimized by tapering down PN over 1 to 2 hours before disconnecting. Typically, the nadir will occur around 30 to 60 minutes or even a little over an hour after the PN is stopped. Random capillary blood glucose concentrations should be checked 4 hours into the PN cycle (~2 hours after reaching goal rate), 15 to 60 minutes after PN stops, and intermittently during the PN cycle as needed for glycemic control.

Transition to Oral or Enteral Nutrition

The goal is to transition the patient to enteral or oral nutrition and taper off PN as soon as feasible clinically. When initiating enteral or oral nutrition, monitor the patient for glucose, fluid, and electrolyte abnormalities. Perform calorie counts to determine the adequacy of nutrition via the oral or enteral route. When the patient is tolerating more than 50% of total estimated daily calorie and protein requirements via the oral or enteral route, wean PN by about 50%. PN can be stopped once the patient is tolerating more than 75% of total estimated daily calorie and protein requirements via the oral or enteral route, assuming that intestinal absorption is maintained.

AMERICAN SOCIETY FOR PARENTERAL AND ENTERAL NUTRITION SAFE PRACTICES OF PN

Because serious and sometimes fatal adverse events have occurred with inappropriate use of PN, the American Society for Parenteral and Enteral Nutrition (A.S.P.E.N.) has published an updated safe practice guidelines for PN.[7] These practice guidelines provide a tool and reference for health professionals for the safe and efficacious use of PN. The guidelines represent the standards of practice as they relate to PN prescribing, compounding, stability, compatibility, labeling, administration, and quality assurance. Although application of these guidelines is voluntary, pharmacists who handle PN should review these guidelines and apply them as they fit in light of the circumstances of their practice sites and individual patient conditions.

COMPLICATIONS OF PN

❾ *PN therapy is associated with significant complications, both with short- and long-term therapy. Many complications are related to overfeeding (Table 97–7). Metabolic complications include hyperglycemia, hypoglycemia, hyperlipidemia,* ***hypercapnia,*** *electrolyte disturbances, refeeding syndrome, and acid-base*

TABLE 97–7. Consequences of Overfeeding

Source of Overfeeding	Consequences
Dextrose	Hyperglycemia, hypertriglyceridemia, hepatic steatosis, hypercapnia; hyperglycemia may cause fluid and electrolyte disturbances and increased infection risk
Intravenous lipid emulsions	Hypertriglyceridemia, hyperlipidemia, hepatic steatosis
Amino acids	Azotemia
Total calories	Hepatic steatosis, cholestasis, hypercapnia

disturbances. Long-term metabolic complications include liver toxicity, vitamin abnormalities, trace element abnormalities, and metabolic bone disease. Other complications include infectious and mechanical complications that relate to venous catheters.

Hyperglycemia

Hyperglycemia is one of the most common complications associated with PN therapy. The rate of dextrose oxidation may be reduced in patients with stress and hypermetabolism (e.g., surgery, organ failure, and sepsis), patients with diabetes or acute pancreatitis, and patients receiving certain medications (e.g., corticosteroids, **vasopressors,** octreotide, and tacrolimus).[26,27] Uncontrolled hyperglycemia can lead to fluid and electrolyte disturbances, **hyperglycemic hyperosmolar nonketotic syndrome,** hypertriglyceridemia, and increased risk of infection.[28]

Hyperglycemia in critically ill patients may be more a reflection of illness severity than from dextrose infusions, provided that the patient is not being overfed.[29] Critical illness is associated with increased endogenous glucose production (due to increased glycogenolysis and gluconeogenesis) and insulin resistance. Therefore, critically ill patients have lower tolerance for dextrose infusion compared nonstressed patients. In patients with hyperglycemia, it is reasonable to initiate PN with a continuous dextrose infusion rate of approximately 2 mg/kg per minute until glycemic control is achieved and then advance to goal.[5] Dextrose infusion rate typically ranges between approximately 3 and 4 mg/kg per minute but should not exceed 5 mg/kg per minute in the adult stressed patient.[1,6] Adjusted body weight should be used in obese patients rather than actual weight. A portion of calories can be provided with intravenous lipid emulsion rather than dextrose to help decrease hyperglycemia, provided that the patient does not have hypertriglyceridemia or sepsis. Overfeeding (with dextrose and with total calories) always must be avoided.

Hyperglycemia can impair cellular and humoral host defenses and can lead to the development of nosocomial and wound infections.[28] Historically, hyperglycemia has been defined as blood glucose concentrations of more than 200 to 220 mg/dL (11.1–12.21 mmol/L), and concentrations of 150 to 200 mg/dL (8.3–11.1 mmol/L) were considered "acceptable" in critically ill patients. More recent data suggest that tighter glucose control (e.g., 80–110 mg/dL or 4.4–6.1 mmol/L) with intensive insulin therapy may improve patient outcomes and reduce mortality.[30] It also appears that the benefits observed are due to glycemic control rather than to the dose of insulin.[31] Achieving a goal serum glucose concentration of 80 to 110 g/dL (4.4–6.1 mmol/L) may be a challenge while avoiding hypoglycemia. The exact goal range for optimal glucose control and reduction in hyperglycemia-associated complications is still debated, but an upper threshold for serum glucose concentration of 145 mg/dL (8.0 mmol/L) has been suggested as acceptable.[32] The use of regular insulin as a continuous infusion rather than adding insulin to PN may reduce the risk of prolonged hypoglycemia because the insulin drip can be readily titrated as insulin requirements change.

Hypoglycemia

Hypoglycemia can occur in patients when PN is interrupted suddenly (reactive hypoglycemia), especially when patients are treated with insulin or as a result of insulin overdosing in PN.[1] It is essential to prevent hypoglycemia and, if it occurs, to identify and treat it promptly. Reactive hypoglycemia typically is rare and usually can be avoided by tapering PN over 1 to 2 hours before discontinuation rather than abruptly stopping the infusion (especially if the patient is receiving insulin in PN or if the patient is not receiving oral or enteral nutrition). Reactive hypoglycemia generally occurs within 15 to 60 minutes after stopping PN (especially in neonatal patients), although it can occur later than this after discontinuing PN.[1] Capillary blood glucose concentrations should be monitored about 15–60 minutes after stopping PN infusion in order to detect any potential hypoglycemia. If PN is interrupted abruptly (e.g., due to lost intravenous access), infusing dextrose 10% in water at the same rate as PN should prevent hypoglycemia. In patients with poor venous access, reduce the PN infusion rate to half for 1 hour before discontinuing. Another alternative to prevent reactive hypoglycemia is to provide a glucose source via the oral route (by mouth or sublingually) when feasible. Monitor capillary blood glucose concentrations regularly in patients receiving insulin in PN, and adjust insulin doses accordingly.

Hyperlipidemia

Patients receiving intravenous lipid emulsion may be at risk for hyperlipidemia and hypertriglyceridemia. Hyperglycemia can lead to hypertriglyceridemia and is the most common cause of hypertriglyceridemia in patients receiving PN. Hyperlipidemia in patients receiving PN may lead to a reduction in pulmonary gas diffusion and pulmonary vascular resistance (especially in patients with underlying pulmonary and vascular disease).[33] Severe hypertriglyceridemia (especially when serum triglyceride concentrations exceed 1000 mg/dL or 11.3 mmol/L) can precipitate acute pancreatitis.[34] Hypertriglyceridemia may develop as a result of increased fatty acid synthesis due to hyperglycemia or impaired lipid clearance or in patients with history of hyperlipidemia, obesity, diabetes, alcoholism, renal failure, liver failure, multiorgan failure, sepsis, pancreatitis, or as a result of medications (e.g., propofol, corticosteroids, cyclosporine, and sirolimus).[35] Propofol is formulated in a 10% lipid emulsion (which is not cleared as effectively as the 20% or 30% lipid emulsions) and may lead to hypertriglyceridemia. It also has been proposed that propofol could have direct effects on lipid metabolism, given that hypertriglyceridemia associated with propofol infusion has been observed with lipid doses that are lower than those typically given in PN.[35,36]

A higher PL:TG ratio in the 10% lipid emulsion has been proposed to cause the appearance of the abnormal lipoprotein X particles [rich in phospholipids (~60%) and cholesterol (~25%), small amounts of triglycerides] in the blood.[9,35] Lipoprotein X

may compete with lipid particles for metabolism by lipoprotein lipase. Therefore, intravenous lipid emulsions with a lower PL:TG ratio (i.e., 20% or 30% lipid emulsions) have improved clearance compared with emulsions with a higher PL:TG ratio (i.e., 10% lipid emulsion)[9,35] and should be used, especially in patients with hypertriglyceridemia. Lipid clearance may be improved by newer formulations of mixed medium- and long-chain triglycerides; however, these products are not yet approved for use in the United States.

Monitor serum triglyceride concentrations regularly during PN therapy (e.g., at the initiation of PN, then once or twice per week initially, and thereafter depending on clinical condition). If a patient develops hypertriglyceridemia, identify and correct the underlying cause(s) if possible (e.g., treatment of hyperglycemia or reduction of dextrose and/or lipid dose). Prolonging the infusion of intravenous lipid emulsion (e.g., over 24 hours) may improve clearance; however, this may require hanging two containers daily because each container of lipid emulsion should infuse for only 12 hours based on USP Chapter 797 and infection-control policies and practices. If a patient is receiving propofol, take into account the calories administered from the 10% lipid emulsion in propofol (1.1 kcal/mL or 4.6 kJ/mL). For safety reasons, intravenous lipid emulsion should be withheld in patients receiving propofol. It also should be held when the serum is lipemic or when serum triglyceride concentrations are greater than 400 mg/dL (4.5 mmol/L). When this occurs, restart intravenous lipid emulsions when the serum triglyceride concentration is approximately 200 to 400 mg/dL (2.3–4.5 mmol/L) (or less), and administer only two to three times per week to prevent essential fatty acid deficiency.

Hypercapnia

Hypercapnia (abnormally high concentration of carbon dioxide in the blood) can develop as a result of overfeeding with both dextrose and total calories.[1,37] Excess carbon dioxide production and retention can lead to acute respiratory acidosis. The excess carbon dioxide also will stimulate compensatory mechanisms, resulting in an increase in respiratory rate in order to eliminate the excess carbon dioxide via the lungs. This increase in respiratory workload can cause respiratory insufficiency that may require mechanical ventilation. Reducing total calorie and dextrose intake would result in resolution of hypercapnia if due to overfeeding.

Acid-Base Disturbances

Acid-base disturbances associated with PN usually are related to the patient's underlying condition(s). However, acid-base abnormalities may develop as a result of changes in chloride or acetate concentrations in PN admixtures. Because acetate is converted to bicarbonate in the body, excessive acetate salts in PN can lead to metabolic alkalosis; excessive chloride salts in PN can lead to metabolic acidosis. PN should not be used to treat or correct the underlying disorder. However, adjusting chloride or acetate salts in the PN admixture may help to prevent these acid-base disorders or minimize worsening of any underlying acid-base disorders.

Liver Complications

The incidence of liver complications associated with PN ranges from approximately 7% to 84%, and end-stage liver disease develops in as many as 15% to 40% of adult patients on long-term PN.[35] Patients often develop a mild increase in liver enzymes within 1 to 2 weeks of initiating PN, but this generally resolves when PN is discontinued. Severe liver complications include hepatic steatosis (fat deposition in liver), **steatohepatitis** (a severe form of liver disease characterized by hepatic inflammation that may progress rapidly to liver fibrosis and cirrhosis), cholestasis, and **cholelithiasis.**[35]

Hepatic steatosis usually is a result of excessive administration of carbohydrates and/or lipids, but deficiencies of carnitine, choline, and essential fatty acids also may contribute. Hepatic steatosis can be minimized or reversed by avoiding overfeeding, especially from dextrose and lipids.[35,38] Carnitine is an important amine that transports long-chain triglycerides into the mitochondria for oxidation, but carnitine deficiency in adults is extremely rare and is mostly a problem in premature infants and patients receiving chronic dialysis. Choline is an essential amine required for synthesis of cell membrane components such as phospholipids. Although a true choline deficiency is rare, preliminary studies of choline supplementation to adult patients' PN caused reversal of steatosis.

Cholestasis is a common problem in patients who are dependent on PN. Factors that predispose PN patients to cholestasis include overfeeding, lack of bowel stimulation, bowel rest (decrease in cholecystokinin secretion), long duration of PN, short bowel syndrome, bacterial overgrowth and translocation, and sepsis.[35] Patients may exhibit increased liver transaminases, increase alkaline phosphatase and gamma-glutamyl transferase concentrations, and mainly increased bilirubin concentrations with jaundice. The most sensitive marker of cholestasis is an increased serum conjugated bilirubin concentration of 2 mg/dL (greater than 34.2 μmol/L) or more.[35] Cholestasis generally is reversible if PN is discontinued before permanent liver damage occurs. Serum liver enzyme concentrations may take up to 3 months to return to normal after discontinuing PN. Steps to prevent cholestasis associated with PN include early initiation of enteral or oral feedings (even at a low or "trophic" rate), using a balanced PN formulation, avoiding overfeeding, cyclic PN infusion, and treating and avoiding sepsis.[35] Pharmacologic treatments include ursodeoxycholic acid (ursodiol), which may improve bile flow and reduce the signs and symptoms of cholestasis. However, ursodiol is only available in an oral dosage form, and absorption may be limited in patients with intestinal resections. If other measures are not successful, and bacterial

overgrowth is thought to be contributing to cholestasis, courses of oral metronidazole, oral gentamicin, or oral neomycin have been used to reduce bacterial overgrowth.

Cholelithiasis can develop as a result of decreased gallbladder contractility, especially in the absence of enteral or oral intake. Lack of intestinal stimulation reduces secretion of cholecystokinin, a peptide hormone secreted in the duodenum that induces gallbladder contractility. The best prevention of cholelithiasis is early initiation of enteral or oral feeding, as stated earlier (to stimulate secretion of cholecystokinin, gallbladder contraction and emptying, and intestinal motility).

Monitor liver function tests, including serum aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase, total bilirubin, conjugated bilirubin, unconjugated bilirubin, and gamma-glutamyl transferase at the initiation of PN therapy and regularly thereafter during PN therapy. The frequency of monitoring liver function tests depends on the presence or absence of liver disease. This varies from one to two times weekly in the acute setting to once weekly to once monthly in the stable home PN patient.

Manganese Toxicity

Manganese is a trace element that serves as a coenzyme in multiple biochemical reactions. Manganese usually is supplied in PN admixtures as part of the trace element package in an adult dose of 0.5 mg/day; however, this may be excessive for longer-term PN patients. Manganese accumulation can occur in patients with cholestasis, and the most common toxicity is neurotoxicity, but liver toxicity also may occur.[35] Neurologic symptoms associated with manganese toxicity include headache, somnolence, weakness, confusion, tremor, muscle rigidity, altered gait, and masklike face (a Parkinson's-like syndrome).[35] Conversely, some patients with hypermanganesemia may not exhibit symptoms of toxicity. Periodic measurement of blood manganese concentrations in patients on long-term PN is recommended. Patients with cholestasis receiving PN may require restriction of manganese to prevent accumulation.

Metabolic Bone Disease

Metabolic bone disease is a condition of bone demineralization leading to **osteomalacia, osteopenia,** or **osteoporosis** in patients receiving long-term PN. Metabolic bone disease, to some degree, may occur in as many as 40% to 100% of patients receiving long-term PN.[35] Often patients are asymptomatic, although symptoms can include bone pain, back pain, and fractures. Patients often will have increased serum alkaline phosphatase concentrations, low to normal parathyroid hormone (PTH) concentrations, normal 25-hydroxyvitamin D, low 1,25 dihydroxyvitamin D concentrations, hypercalcemia or hypocalcemia, and hypercalcuria.[39] Because patients may be asymptomatic, diagnosis can be incidental. Radiologic techniques commonly used in diagnosing bone disease include quantitative computed tomography (CT) and bone mineral density.[39]

Factors that can predispose patients to developing metabolic bone disease include deficiencies of phosphorus, calcium, and vitamin D; vitamin D and/or aluminum toxicity; amino acids and hypertonic dextrose infusions; chronic metabolic acidosis; corticosteroid therapy; and lack of mobility.[35,39] Calcium deficiency (due to decreased intake or increased urinary excretion) is one of the major causes of metabolic bone disease in patients receiving PN. Provide adequate calcium and phosphate with PN to improve bone mineralization and help to prevent metabolic bone disease. Administration of amino acids and chronic metabolic acidosis also appear to play an important role. Provide adequate amounts of acetate in PN admixtures to maintain acid-base balance.

Vitamin D toxicity has been suggested as a cause of metabolic bone disease. However, vitamin D deficiency results in bone loss, and data on vitamin D excess and metabolic bone disease remain controversial.

Aluminum toxicity appears to play a role in the development of metabolic bone disease in patients on long-term PN, possibly by impairing calcium bone fixation,[40] inhibiting the conversion of 25-hydroxyvitamin D to the active 1,25-dihydroxyvitamin D, and/or reducing PTH secretion.[35,41] Measure serum aluminum concentrations in PN patients with suspected metabolic bone disease to rule out aluminum toxicity. The FDA has been investigating the issue of aluminum contamination in parenteral products and issued a rule specifying acceptable aluminum concentrations in large-volume parenterals in 2000.[42] The rule further stated that the package insert ("Precautions") for large-volume parenterals used in making PN should indicate that the product contains no more than 25 mcg/L of aluminum and defined a safe upper limit for parenteral aluminum intake at less than 4 to 5 mcg/kg per day. This has required a great amount of effort by manufacturers to meet these limits and requires pharmacy policies for monitoring aluminum concentrations in PN admixtures.

Encourage patients on long-term PN to engage in regular low-intensity exercise. Yearly bone density measurements also should be performed on patients on long-term PN and when metabolic bone disease is suspected.

Refeeding Syndrome

Refeeding syndrome describes the metabolic derangements that occur during nutritional repletion of patients who are starved, underweight, or severely malnourished.[43] Hypophosphatemia and associated complications are the classic signs and symptoms, but refeeding syndrome encompasses a constellation of fluid and electrolyte abnormalities affecting multiple organ systems, including neurologic, cardiac, hematologic, neuromuscular, and pulmonary function. The most severe cases of refeeding syndrome have resulted in cardiac failure, seizures, coma, and death.[43–45] The reintroduction of carbohydrates/glucose drives metabolism back to using glucose as the predominant fuel source. This increases insulin secretion, creates a high demand for

the production of phosphorylated intermediates of glycolysis [e.g., ATP, and **2,3-diphosphoglycerate** (2,3-DPG)], inhibits fat metabolism, and causes an intracellular shift of phosphorus, potassium, and magnesium. These changes, in combination with preexisting low total body stores of phosphorus, potassium, and magnesium and enhanced cellular uptake of phosphorus during anabolic refeeding, result in hypophosphatemia, hypokalemia, and hypomagnesemia. Vitamin deficiencies (e.g., thiamine) also may exist or be precipitated during refeeding. High carbohydrate intake increases the demand for thiamine, an essential cofactor involved in carbohydrate metabolism. This can precipitate thiamine deficiency with its potential complications, including lactic acidosis and neurologic abnormalities,[43,46] as well as myocardial dysfunction and congestive heart failure. Other metabolic alterations that may occur include expansion of the extracellular water compartment, fluid imbalance, and fluid intolerance.

The primary goal is preventing refeeding syndrome when initiating PN in high-risk patients (e.g., patients with prolonged lack of adequate nutritional intake, significant weight loss, or moderate-severe malnutrition). When initiating nutrition support, the rule of thumb to prevent refeeding syndrome is to "start low and go slow." Initiate PN cautiously (e.g., approximately 25% of estimated nutritional needs on day 1), and gradually increase to goal over 3 to 5 days. Correct electrolyte abnormalities (e.g., hypophosphatemia, hypokalemia, and hypomagnesemia) before initiating PN, and provide supplemental phosphate, potassium, and magnesium in or outside of PN (if the patient has normal renal function). Well-nourished patients require 10 to 15 mmol of phosphate per 1000 kcal to avoid hypophosphatemia,[15] but patients with moderate to severe malnutrition who are at risk for refeeding syndrome will require more aggressive supplementation. Doses of intravenous phosphate as aggressive as 0.64 to 1 mmol/kg have been used to treat severe hypophosphatemia (provided the patient has normal renal function).[47,48] Vitamin supplementation also should be provided in addition to the multivitamin provided in PN. Provide supplemental oral or intravenous thiamine 100 mg/day and folic acid 1 mg/day for about a week. In addition, minimize fluid and sodium intake during the first few days of PN (e.g., total fluid of 1000 mL/day or less and sodium of 20 mEq/day or less).[49] Assess patients for fluid balance, signs of edema, fluid overload, and weight gain because any gain of more than 1 kg per week likely represents fluid retention.[49] Monitor patients closely for signs and symptoms of refeeding syndrome. Monitor vital signs (i.e., heart rate, blood pressure, and respiratory rate), mental status, and neurologic and neuromuscular function routinely during the first several days of PN until goal is reached. Monitor pulse oximetry and any electrocardiographic changes when indicated clinically.

Infectious Complications

Patients receiving central PN are at increased risk of developing infectious complications caused by bacterial and fungal pathogens.[1,50] Infections may be related to placement of a central venous catheter, contamination of a central venous catheter or intravenous site (catheter-related infection), and persistent hyperglycemia. Strict aseptic techniques must be used when placing the catheter, along with continuous care of the catheter and infusion site. Catheter-related bloodstream infections are a common complication in long-term PN patients, often requiring hospital admission for parenteral antimicrobial therapy and/or removal of the catheter. Contamination of the PN admixture is possible, although rare if protocols are followed for aseptic preparation of PN admixtures. Lack of use of the intestinal tract also may increase the risk of infection possibly by reducing gut immunity, leading to intestinal bacterial overgrowth and subsequent systemic bacterial translocation.

Mechanical Complications

Mechanical complications of PN are related to catheter placement and the system and equipment used to administer PN. A central venous catheter must be placed by a trained professional, and risks associated with placement include pneumothorax, arterial puncture, bleeding, hematoma formation, venous thrombosis, and air embolism.[1,20] Over time, the catheter may require replacement. Problems with the equipment include malfunctions of the infusion pump, intravenous tubing sets, and filters.

MONITORING PN THERAPY

⑩ When initiating PN, patients should have important baseline laboratory values checked to assess electrolyte status, organ function, and nutritional status (Table 97–8). Baseline laboratory monitoring should include

- Basic metabolic panel (i.e., sodium, potassium, chloride, bicarbonate, blood urea nitrogen, creatinine, glucose, and calcium), phosphorus, and magnesium
- Liver function, including AST, ALT, alkaline phosphatase, lactate dehydrogenase (LDH), total and conjugated bilirubin; a comprehensive metabolic panel can be ordered (i.e., sodium, potassium, chloride, bicarbonate, blood urea nitrogen, creatinine, glucose, calcium, AST, ALT, alkaline phosphatase, albumin, and total bilirubin), but phosphorus, magnesium, and fractionated

Patient Encounter, Part 4

The surgical team plans to initiate PN for AA as you have recommended. Laboratory data were listed previously.

- What other laboratory data or monitoring parameters should be obtained before initiating PN?
- How frequently should you monitor each of the various parameters after initiating PN?
- What potential complications of PN should you monitor for in this patient?

TABLE 97–8. Suggested Frequency of Monitoring Parameters in Hospitalized Patients Receiving Parenteral Nutrition

Parameters	Initial	Daily (Unstable)	2–3 × Weekly (Stable)	Weekly	As Indicated
Blood urea nitrogen, creatinine	X	X	X		
Sodium, potassium, chloride, bicarbonate	X	X	X		
Glucose	X	X	X		
Calcium, phosphorus, magnesium	X	X	X		
Albumin, aspartate aminotransferase (AST), alanine aminotransferase (ALT), lactate dehydrogenase (LDH), alkaline phosphatase, total bilirubin, conjugated bilirubin	X			X	X
Prealbumin	X			X	X (once weekly)
Triglycerides	X			X	X
Red blood cell count, hemoglobin, hematocrit, white blood cell count ± differential, platelets, partial thromboplastin time	X				X
Prothrombin time/INR				X	X
Nitrogen balance					X
Zinc, selenium, chromium, copper, manganese, iron					X
Total iron-binding capacity, ferritin					X
Vitamin concentrations					X
Ammonia					X
Blood cultures					X
Weight	X	X	X		

or conjugated bilirubin are not included on this panel and must be ordered separately.

- Albumin, prealbumin, total protein, triglycerides
- Complete blood count (including hemoglobin, hematocrit, red blood cell count, and white blood cell count), and platelets with differential

⑩ *Thereafter, the preceding parameters and other nutritional parameters should be monitored routinely or as indicated* (Table 97–8). Random capillary blood glucose concentrations also should be monitored every 6 to 8 hours when initiating PN, and regular insulin should be administered to control glucose as needed (either by intermittent administration per sliding scale or as a continuous infusion).

SUMMARY AND CONCLUSION

PN is a specialized method of administering nutrition support but is associated with complications. Enteral nutrition is the preferred route of providing specialized nutrition support. However, PN can be a lifesaving therapy in patients who cannot receive oral or enteral nutrition. Administration of PN is associated with significant adverse effects, and patients must be monitored closely. Patients receiving PN therapy are at risk for metabolic, infectious, and mechanical complications. Optimal design of a PN regimen is essential to minimize the risk of adverse effects and complications, and patients must be monitored closely while receiving PN in order to optimize outcomes.

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Discuss how gut structure and function impact choice of feeding route and outcome of feeding.
2. Evaluate patient specific parameters to determine whether enteral nutrition (EN) is appropriate.
3. Compare clinical efficacy, complications, and costs of enteral nutrition (EN) versus parenteral nutrition (PN).
4. Choose an appropriate method of enteral nutrition (EN) delivery based on patient specific parameters.
5. Estimate kilocalorie and protein requirements of an enteral feeding candidate and design an enteral nutrition (EN) regimen to meet these.
6. Choose an appropriate category of enteral nutrition (EN) product given patient-specific parameters.
7. Formulate a monitoring plan for an enteral nutrition (EN) patient.
8. Select appropriate medication administration techniques for an enteral nutrition (EN) patient.

Key Concepts

❶ Enteral nutrition (EN) is the preferred route if the gut can be used safely in a patient who cannot meet nutritional requirements by oral intake.
❷ Enteral nutrition (EN) is associated with fewer infectious complications than parenteral nutrition (PN).
❸ For patients intolerant of gastric feedings or in whom the risk of aspiration is high, feedings delivered with the tip of the tube past the pylorus into the duodenum or, preferably, the jejunum are preferred.
❹ Standard enteral nutrition (EN) formulas are polymeric formulas; these are appropriate for most patients.
❺ When choosing an enteral nutrition (EN) formula, the patient's fluid status should dictate the caloric density selected.
❻ Clinical trial data supporting the use of specialty formulas in niche populations typically are unconvincing in terms of patient outcomes.
❼ The role of enteral immunonutrition in clinical practice remains controversial.
❽ Gastrointestinal complications are the most common complications of enteral nutrition (EN), limiting the amount of feeding that patients receive.
❾ An important practice to help prevent medication-related occlusion is adequate water flushing of the tube before, between, and after each medication is given through the tube.
❿ Compatibility of medications with an enteral nutrition (EN) formula and, conversely, an enteral nutrition (EN) formula with administered medications is of concern when administering medications through feeding tubes.

Enteral nutrition (EN) is broadly defined as delivery of nutrients via the gastrointestinal (GI) tract. This could include normal oral feeding as well as delivery of nutrients in a liquid form by a tube. Sometimes when the term *enteral nutrition* is used, only tube feedings are included; hence the terms *enteral nutrition* and *tube feedings* are often used synonymously. The bulk of this chapter will include information regarding delivery of feedings via tubes. Formulas for EN usually are delivered in the form of commercially prepared liquid preparations, although some products are produced as powders for reconstitution.

It might be expected that EN via tubes would have been used widely before the development of **parenteral nutrition** (PN); however, this was not actually the case. EN via tubes inserted down the mouth or nose into the stomach and also via rectal tubes was used occasionally in the decades before the development of PN in the 1960s.[1] However, modern techniques for enteral access, both the placement of the tubes themselves and the materials for making pliable, comfortable tubes, had not yet been developed. Before the PN era, the formulas delivered by the tube route often were blenderized foods. The National Aeronautics and Space Administration effort in the United States in the 1960s led to the development of low-residue (monomeric) diets for astronauts. These diets were adapted for use in sick patients requiring EN. Nonvolitional feedings in patients who cannot meet nutritional requirements by oral intake thus include EN and PN; these techniques are collectively known as *specialized nutrition support* (SNS).

GASTROINTESTINAL TRACT STRUCTURE AND FUNCTION

Anatomy and Absorptive Function

With normal volitional feeding, food is ingested via the mouth. Here, the process of breaking down complex foodstuffs into simpler forms that can be absorbed subsequently by the small bowel begins. Solid food is chewed in the mouth, and enzymes begin the digestive process. The trigger for release of many of these substances is the presence of food in specific regions of the GI tract. The food then is swallowed and passes through the esophagus and the esophageal sphincter on its way to the stomach, where additional digestive enzymes and acid further break down the food. The stomach also serves a mixing and grinding function.

The food, now in a liquid form known as *chyme,* passes through the pyloric sphincter into the duodenum, where stomach acid is neutralized. There is wide variation in lengths of the components of the small intestine (i.e., duodenum, jejunum, and ileum) between individuals (Table 98–1). Most absorption of digested carbohydrate and protein occurs within the jejunum. Most fat absorption occurs within the jejunum and ileum. In the small bowel, breakdown of macronutrients (i.e., carbohydrate, protein, and fat) occurs both within the lumen of the gut and at the intestinal mucosal membrane surface. The absorptive units on the intestinal mucosal membrane are infoldings known as *villi.* These villi are made up of epithelial cells called *enterocytes.* Projections (striations) from these enterocytes called *microvilli* greatly increase the surface area of the small bowel and make up what is known as the *brush-border membrane.*

Digestive enzymes secreted by the pancreas play a role in food breakdown. The pancreas secretes large amounts of sodium bicarbonate that neutralize stomach acid. These substances flow from the pancreas through the pancreatic duct. The pancreatic duct typically joins with the hepatic duct to become the common bile duct that empties through the **sphincter of Oddi** into the duodenum. Bile secreted by the liver does not contain digestive enzymes, but bile salts help to emulsify fat and thus facilitate fat absorption. Bile flows through bile ducts into the hepatic duct and common bile duct. Bile is stored in the gallbladder until it is needed in the gut to aid fat digestion, at which time it empties through the cystic duct to the common bile duct to the duodenum. Pathways through which carbohydrate, protein, and fat are digested and absorbed through the small bowel are illustrated in Fig. 98–1.

After absorption in the small bowel, remaining undigested food passes from the ileum through the ileocecal valve to the colon. A major role of the colon is absorption of fluid. Some of the water and sodium absorption achieved by the colon is facilitated by short-chain fatty acids (SFCAs) formed from digestion of certain dietary fibers by colonic bacterial enzymes.

TABLE 98–1. Length of the Small Bowel in Adults

Segment	Length (ft)
Total	12–20
Duodenum	1
Jejunum	5–8
Ileum	7–12

Gut Immune Function

In addition to its roles in digestion and absorption, the gut plays significant immune roles in the body. The distal small bowel and colon host large numbers of bacteria and their endotoxins, and it is important that these organisms not gain access to the internal systems of the body. This function is known globally as the *gut barrier function* and can be divided into several components.[2] Normal flora of the gut comprise one component. The normal flora, particularly some of the anaerobes, help to prevent overgrowth of potential pathogens. A second component of the gut barrier includes mechanical factors. These include an epithelial mucus gel layer that prevents adherence of bacteria and peristalsis of the small bowel that prevents stasis of bacteria. **Gut-associated lymphoid tissue** (GALT), prominent in the small bowel, serves as a local immune system. Secretory immunoglobulin A produced at the mucosal surface prevents bacteria from invading the surface. Bile salts and the **reticuloendothelial system** of the liver are believed to bind bacterial endotoxin and help to clear it from the blood should it be absorbed into the portal circulation.

PATIENT SELECTION

In general, ❶ *if the gut can be used safely in a patient who cannot meet nutritional requirements by oral intake, then EN is the preferred route.* If the gut functions, EN is usually preferred

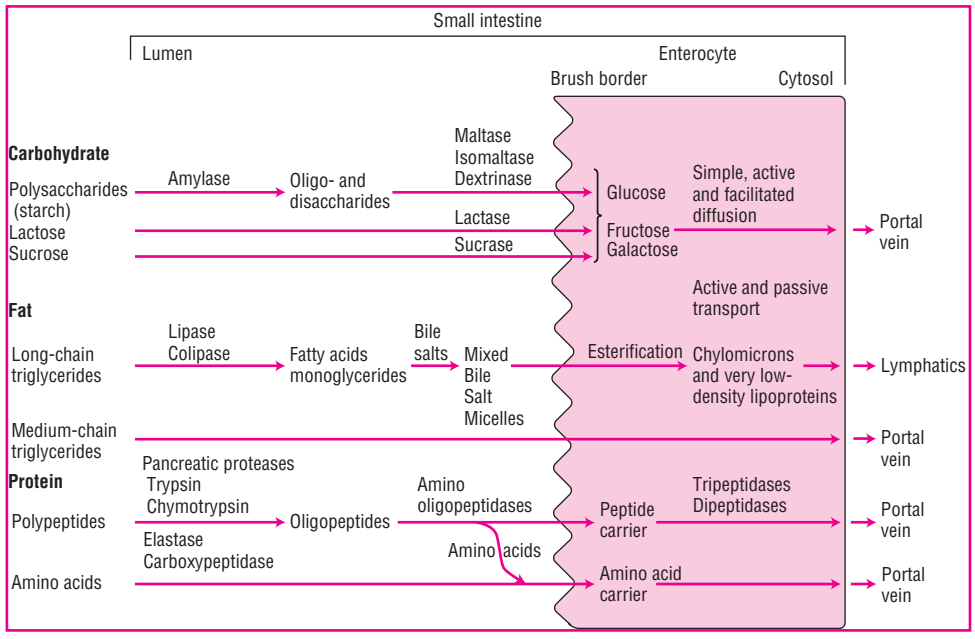

FIGURE 98–1. Schematic representation of carbohydrate, fat, and protein digestion. (From Kumpf VJ, Chessman KH. Enteral nutrition. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 2616.)

over PN. The timing of SNS (either EN or PN) is controversial, but definitive guidelines for these therapies state that SNS should be started when intake has been inadequate for 7 to 14 days or if inadequate oral intake is anticipated to last at least 7 to 14 days.[3] Prior nutritional status of the patient also should be considered. Previously well-nourished patients can better afford not being fed for longer periods of time than those who are previously poorly nourished. Methods for assessing nutritional status and designing SNS regimens are covered in Chapter 97. In general, hospitalized patients require 25 to 35 kcal/kg of body weight per day and 1 to 2 g protein per kilogram of body weight per day.

Indications

Many potential indications for EN exist (Table 98–2). PN was used extensively previously for many of these conditions. Advances in EN technology now allow many patients with these conditions to receive EN. EN is administered in both institutional (e.g., hospital and long-term care facility) and home settings.

Contraindications and Precautions

EN should not be used or should be used with extreme caution in certain conditions (Table 98–3). It is possible to use EN in some patients with these conditions depending on severity of illness, location of the abnormality, and experience of the practitioners delivering care. Controversy surrounds some of these contraindications and precautions. For example, whereas some clinicians will deliberately avoid enteral feedings in the hemodynamically unstable patient for fear of worsening intestinal ischemia, others believe that early feeding may facilitate intestinal perfusion and thus be beneficial.[4–6] Still others might avoid jejunal feedings in this setting but would be comfortable proceeding with cautious gastric feedings.

TABLE 98–2. Potential Indications for Enteral Nutrition

Neoplastic disease	**Gastrointestinal disease**
Chemotherapy	Inflammatory bowel disease
Radiation therapy	Short bowel syndrome
Upper gastrointestinal tumors	Esophageal motility disorder
Cancer cachexia	Pancreatitis
Organ failure	Fistulas
Hepatic	Gastroesophageal reflux disease
Renal	Esophageal atresia
Cardiac cachexia	**Neurologic impairment**
Pulmonary	Comatose state
Bronchopulmonary dysplasia	Cerebrovascular accident
Congenital heart disease	Demyelinating disease
Hypermetabolic states	Severe depression
Closed head injury	Failure to thrive
Burns	Cerebral palsy
Trauma	**Other indications**
Postoperative major surgery	Acquired immune deficiency syndrome
Sepsis	Anorexia nervosa
	Complications during pregnancy
	Geriatric patients with multiple chronic disease
	Organ transplantation
	Inborn errors of metabolism
	Cystic fibrosis
	Extreme prematurity

TABLE 98–3. Contraindications and Precautions for Enteral Nutrition

Severe hemorrhagic pancreatitis
Severe necrotizing pancreatitis
Necrotizing enterocolitis
Diffuse peritonitis
Small bowel obstruction
Paralytic ileus
Severe hemodynamic instability
Enterocutaneous fistulae
Severe diarrhea
Severe malabsorption
Severe gastrointestinal hemorrhage
Intractable vomiting

Enteral Versus Parenteral Feeding

With the advent of the technique of PN by a large central vein in the late 1960s, this modality of feeding quickly became popular. PN was used originally in the patients for whom it was designed (e.g., patients with inflammatory bowel disease or congenital bowel abnormalities), but it also was incorporated quickly into care of other types of patients such as the critically ill. The relative ease of administration of PN, along with the perception that critically ill patients had prolonged high-energy expenditures, led to complications of overfeeding. In the United States, where no intravenous fat emulsion was available commercially for several years during the 1970s, the impact of dextrose overfeeding was observed. Complications included hyperglycemia, carbon dioxide overproduction leading to delays in weaning from mechanical ventilation, and liver abnormalities owing to **hepatic steatosis.**

As complications of PN became evident, the pendulum began to swing toward EN in the late 1980s and early 1990s as clinical studies were published showing better clinical outcomes with EN compared with PN. Some of the potential advantages of EN over PN are included here. First, EN is expected to preserve the gut barrier function better than PN. This, in turn, could prevent **translocation** of bacteria and endotoxin from the gut lumen into the lymphatic system and systemic circulation, thus preventing infections. Studies from the same era support the contention that ❷ *EN is associated with fewer infectious complications than PN.*[7–9] EN is cited frequently as having a better overall safety profile than PN. Whereas PN is associated with more severe complications, such as pneumothorax and catheter sepsis, EN is associated with more nuisance complications, such as GI side effects that may delay or limit the delivery of nutrients. Another major frequently cited advantage of EN over PN is that EN is less expensive. It is true that EN formulas typically are cheaper and less labor-intensive to prepare than PN formulas. However, depending on the method of feeding tube placement, EN costs can mount if the tube must be placed by a radiologist or gastroenterologist rather than a nurse or if the tube must be replaced for some reason.

The arguments in support of EN over PN have been questioned.[10,11] Part of this questioning relates to the question of whether EN is really beneficial compared with PN or whether PN as it has been commonly administered may be detrimental. Overfeeding and hyperglycemia can occur easily with PN administration, and the potential harm of hyperglycemia, especially in the critical-care population, has been demonstrated poignantly in recent years.[12] A large high-profile study published in 1991 demonstrated in a mildly malnourished perioperative population that there were more infectious complications in patients randomized to receive PN compared with those randomized to receive no SNS; there was no difference in noninfectious complications between the two different feeding groups.[13] Only in severely malnourished perioperative patients were fewer noninfectious complications seen with PN feeding; in these patients, no difference in infectious complications was seen between groups. Whether EN truly prevents infections and improves clinical outcomes or whether PN is actually detrimental continues to be debated and is probably highly dependent on the specific patient population. However, at the present time, EN is preferred by most experts over PN when the gut is functional.

ROUTES OF ACCESS[14–16]

There are several access sites for EN (Fig. 98–2). The nasogastric (NG), orogastric (OG), nasoduodenal (ND), and nasojejunal (NJ) routes generally are for short-term use (less than 6 weeks), whereas gastrostomy, **percutaneous endoscopic gastrostomy** (PEG), jejunostomy, and **percutaneous endoscopic jejunostomy** (PEJ) tubes are preferred for longer-term treatment. The esophagostomy/pharyngostomy is used rarely. Both advantages and disadvantages exist for each of the EN routes (Table 98–4).

Gastric Feeding

Gastric feedings are used commonly. They require an intact gag reflex and normal gastric emptying for safety and success. Certain patients, such as those who have suffered head trauma, may not empty their stomachs efficiently and therefore may not be good candidates for gastric feedings. In these patients, it may be impossible to achieve a gastric tube feeding rate to provide adequate nutrients. In addition, pooling of the feeding formula in the stomach could increase the risk of aspiration of feeding into the lungs.

The NG route is used most commonly for short-term (less than 1 month) enteral access. Some institutions prefer the OG route because of less damage to the sinuses; the OG route is also useful in situations such as facial trauma, where nasopharyngeal damage prevents NG feeding. The major advantage of these routes is that the tubes can be placed quickly and inexpensively by the nurse at the bedside.

Gastrostomy tubes, where an incision is made directly through the abdominal wall, are indicated for patients who can tolerate gastric feedings but in whom long-term

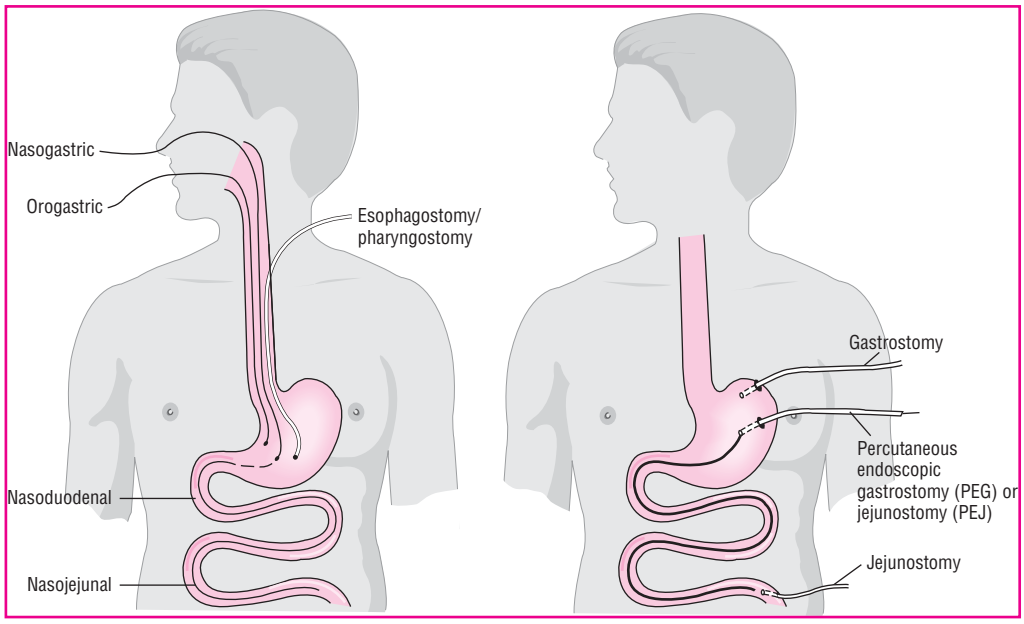

FIGURE 98–2. Access sites for tube feeding. (From Kumpf VJ, Chessman KH. Enteral nutrition. In DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed, New York: McGraw-Hill; 2005: 2619.)

(greater than 1 month) feedings are anticipated. The most commonly placed gastrostomy tubes are PEG tubes placed endoscopically. These tubes also can be placed laparoscopically or during an open procedure by a surgeon. Placement of a gastrostomy tube either endoscopically or surgically is more expensive than bedside OG or NG placement but does result in placement of a larger-bore tube.

An advantage of feeding into the stomach is that the feedings can be delivered in either an intermittent or continuous fashion. This is unlike feedings directly into the small bowel,

TABLE 98–4. Options and Considerations in the Selection of Enteral Access

Access	Indications	Tube Placement Options	Advantages	Disadvantages
Nasogastric or orogastric	Short-term Intact gag reflex Normal gastric emptying	Manually at bedside	Ease of placement Allows for all methods of administration Inexpensive Multiple commercially available tubes and sizes	Potential tube displacement Potential increased aspiration risk
Nasoduodenal or nasojejunal	Short-term Impaired gastric motility or emptying High risk of GER or aspiration	Manually at bedside Fluoroscopically Endoscopically	Potential reduced aspiration risk Allows for early postinjury or postoperative feeding Multiple commercially available tubes and sizes	Manual transpyloric passage requires greater skill Potential tube displacement or clogging Bolus or intermittent feeding not tolerated
Gastrostomy	Long-term Normal gastric emptying	Surgically Endoscopically Radiologically Laparoscopically	Allows for all methods of administration Large-bore tubes less likely to clog Multiple commercially available tubes and sizes Low-profile buttons available	Attendant risks associated with each type of procedure Potential increased aspiration risk Requires stoma site care
Jejunostomy	Long-term Impaired gastric motility or gastric emptying High risk of GER or aspiration	Surgically Endoscopically Radiologically Laparoscopically	Allows for early postinjury or postoperative feeding Potential reduced aspiration risk Multiple commercially available tubes and sizes	Attendant risks associated with each type of procedure Bolus or intermittent feeding not tolerated Requires stoma site care

GER, gastroesophageal reflux.

where continuous feedings must be used. Intermittent feedings into the small bowel result in GI intolerance in most patients.

Postpyloric Feedings

❸ *For patients intolerant of gastric feedings or in whom the risk of aspiration is high, feedings delivered with the tip of the tube past the pylorus into the duodenum or, preferably, the jejunum are preferred.* Feeding in this manner bypasses the problem of poor gastric emptying and adds another barrier (the pyloric sphincter) through which tube feedings must traverse before they are aspirated into the lungs. It should be noted that **postpyloric feedings** do not preclude the possibility of aspiration. In fact, many patients with this complication are not aspirating tube feeding formula but rather their own nasopharyngeal secretions.

ND and NJ feeding tubes can be placed by trained, experienced nurses at the bedside. Although such placements typically take more time than NG or OG placements, this is still an inexpensive method of placement. However, many institutions have not been able to achieve such placements consistently at the bedside. Therefore, in many institutions, ND or NJ placements are done in the radiology suite by a radiologist using fluoroscopy to visualize the advancement of the tube to the appropriate area. This procedure greatly increases the cost of EN therapy. NJ tubes generally are preferred over ND tubes; placement of the tip of the tube distal to the **ligament of Treitz** (located near the junction of the duodenum and the jejunum) may reduce the risk of aspiration further. Alternatively, during a laparotomy, the surgeon can place an ND or NJ tube.

Surgically placed jejunostomy tubes are an option; similar to surgically placed gastrostomy tubes, they are placed through an incision in the abdominal wall, precluding the need for a tube down the nose or mouth. These tubes frequently are placed during laparotomy following abdominal trauma. Alternatively, jejunal access can be obtained by placing a jejunal extension through a PEG tube; the resulting tube is sometimes referred to as a *PEJ tube.* Another option is to place a PEJ tube directly; this technique is a bit more technically difficult than PEG placement and may not be available in some settings.

Patient Encounter, Part 1

A 25-year-old man was involved in a motor vehicle accident in which he suffered several long bone fractures, a ruptured spleen, and a severe closed-head injury. This 5-ft, 10-in man was well nourished and weighed 75 kg before the accident. During the first surgery to repair his abdominal injuries, the surgeon placed a feeding jejunostomy tube. Following surgery, the patient was taken to the intensive-care unit, where he was mechanically ventilated and had an intracranial pressure monitor. He initially required significant amounts of vasopressor agents to maintain his blood pressure. The decision was made to delay dealing with the long bone fractures until he was more stable.

- What would this patient's estimated caloric and protein requirements be?
- What is the potential advantage of using EN rather than PN in this patient?
- Why is a jejunostomy tube a good access route for feeding this patient?
- Would it be prudent to start jejunal feedings immediately after the patient is admitted to the intensive-care unit following his abdominal surgery?

METHODS OF DELIVERY

Enteral feedings are delivered by several different methods. Continuous infusion must be used when duodenal or jejunal feedings are administered. For gastric feedings, bolus or intermittent feedings could be administered instead of continuous feedings. Each method has advantages and disadvantages.

In many hospitals, EN is delivered most commonly as a continuous infusion over 24 hours at a constant rate regulated by an infusion pump. A variation of continuous infusion is cyclic feeding, in which a constant rate is maintained by a pump over a certain number of hours daily. This method of administration is used more commonly in long-term care or home settings. Often EN is administered overnight, giving the patient "freedom" from the infusion pump during the day. This method may not be practical for patients with high nutritional needs because it may be difficult to increase the rate of feedings high enough while maintaining GI tolerance with limited infusion times.

Intermittent feedings are used more commonly in long-term care or home settings largely because they are easier to administer. Patients frequently are started with continuous feedings, transitioned to intermittent feedings given several times a day over about 30 to 45 minutes for each feeding, and eventually changed to bolus feedings, where the feeding is administered several times a day over less than 10 minutes per feeding. An advantage of intermittent feedings is that they may be administered by gravity flow adjusted with a roller clamp, although some institutions may use an infusion pump to administer them. Bolus feedings preclude the need for an infusion set or pump and can be administered using a 60-mL syringe, although, again, in some circumstances an infusion set and pump may be used. Intermittent and bolus feedings often are given in amounts of 240 to 480 mL per feeding, corresponding to one to two cans (8 oz each) of formula.

EN FORMULAS

A number of EN formulas are marketed commercially. Hospitals and long-term care facilities usually limit their formularies of EN formulas, stocking only a limited number of

products. A number of factors should be taken into account when devising a formulary.

Polymeric versus Oligomeric Formulas

One of the major criteria for categorizing various EN products is whether they contain more intact (polymeric) macronutrients or their macronutrient ingredients are present in simpler forms (oligomeric). ❹ *Standard EN formulas are polymeric formulas; these are appropriate for most patients.* Oligomeric formulas should be reserved for patients with GI dysfunction.

Polymeric formulas typically have low osmolality of 300 to 500 mOsm/kg. These formulas also usually supply essential vitamins and minerals in amounts similar to the Adequate Intakes or Recommended Dietary Allowances for these nutrients when the formula is delivered in amounts adequate to meet the macronutrient requirements of most patients. Many polymeric formulas are inexpensive relative to oligomeric formulas. Most polymeric formulas are lactose-free and gluten-free, as are most modern tube feeding products. Products designed to be used as oral supplements generally are polymeric and often have sucrose or other simple sugars added to improve taste.

The oligomeric formulas are also known as *chemically defined formulas.* This class of formulas can be subcategorized based on whether the formula contains all free amino acids (elemental formulas) or peptides (peptide-based) as the protein source. Some of these formulas contain a combination of free amino acids and small peptides. Actually, dipeptides and tripeptides in these formulas are absorbed more efficiently than free amino acids. Oligomeric formulas may be better tolerated than polymeric formulas for patients with defects in GI function and may be particularly useful in patients with severe pancreatic dysfunction or significantly decreased GI surface area (e.g., short bowel syndrome).

Oligomeric formulas typically are more expensive than polymeric formulas and have a higher osmolality because they contain more osmotically active particles. However, the osmolality of these products usually does not exceed 700 mOsm/kg, a value less than that of many oral medications or a regular diet. In the past, there was concern that higher-osmolality EN formulas could cause GI intolerance, particularly diarrhea. This led to dilution of these formulas by half or more with water and gradually increasing both the strength and rate of formula administration. This practice is unnecessary and probably served only to delay attainment of goal nutritional support from tube feedings. Sometimes enteral feedings are diluted to deliver extra water required by the patient; this practice generally is discouraged because of the potential risk of formula contamination. Instead, it is better to give extra water as boluses through the tube. If medications are administered through the feeding tube, generous amounts of water should be used to flush the tube before and after each medication; this practice helps to provide extra fluid to the patient and to prevent problems with occlusion of the feeding tube.

Oligomeric formulas usually are less palatable than polymeric formulas and are not designed for use as oral supplements. Many of the oligomeric formulas provide some fat calories as medium-chain triglycerides (MCTs), which are a fat source that is more readily metabolized by the body than the long-chain triglycerides (LCTs) typically found in polymeric formulas. The MCTs do not require bile salts or pancreatic enzymes for absorption. Some of the elemental formulas contain a very low proportion of fat (less than 10% of total calories), which makes them useful in certain situations where fat needs to be restricted. The carbohydrate source in oligomeric formulas is also less complex than in polymeric formulas, consisting of oligosaccharides rather than hydrolyzed starch.

Fiber Content

Another distinguishing factor of enteral formulas is whether or not a particular formula contains fiber. Both soluble and insoluble fibers may be included in the formula, with insoluble fiber exerting more effect on gut motility by drawing water into the intestine and decreasing transit time, thus preventing constipation. Soluble fiber can help to lower blood cholesterol levels, regulate blood sugar, and prolong gastric emptying. Cellulose gum is an example source of insoluble fiber. Oat fiber and guar gum provide primarily soluble fiber. Soy fiber provides primarily insoluble fiber but also some soluble fiber and is the most commonly used fiber source in tube feeding products. Fiber has been useful for regulating gut motility in some but not all clinical studies; it certainly can be useful in selected patients. Some patients may experience GI discomfort secondary to gas production with the introduction of fiber-containing formulas.

Fructooligosaccharides (FOSs) are a form of fiber receiving increasing attention. These pass through the stomach and small bowel undigested and are fermented by colonic bacteria to the SCFAs butyrate, propionate, and acetate. The SCFAs serve as a major fuel source for colonocytes and facilitate water and sodium reabsorption in the colon.[16] The FOSs fit in the category of substances called *prebiotics* that serve as fermentable substrates for the normal flora of the colon. The SCFAs are not added directly to EN products because they would be absorbed completely before reaching the colon; rather FOSs are added to some formulas, allowing bacterial degradation to form SCFAs.

Caloric Density

Enteral feeding formulas can be categorized based on caloric density. Standard caloric density is 1 to 1.3 kcal/mL. More calorically dense formulas containing 1.5 to 2 kcal/mL are also available and have a higher osmolality. ❺ *When choosing an EN formula, the patient's fluid status should dictate the caloric density selected.* Fluid-overloaded patients may benefit from more calorically dense formulas. It should be recognized that

as the caloric content of a formula increases, the amount of free water decreases. For example, whereas 1 kcal/mL formulas contain about 850 mL of free water per liter of formula, the 2 kcal/mL formulas contain about 710 mL of free water per liter of formula.[17]

Protein Content

The protein content of the EN formula is an important factor in choosing a formula. The standard protein content in EN formulas is up to about 15% of total kilocaloties as protein. High-protein formulas containing up to 25% of total calories as protein are available for highly stressed patients with elevated protein needs, as are low-nitrogen formulas containing less than 10% for use in patients requiring protein restriction. Thus a wide range of protein is available, from about 35 to 85 g/L.

Fat Content

As mentioned earlier, both MCTs and LCTs are used in tube feeding products. Corn, soy, and safflower oils have been the mainstay sources of fat in these products, providing mainly ω-6 polyunsaturated fatty acids (PUFAs). On the other hand, some newer EN products contain higher quantities of ω-3 PUFAs from sources such as fish oil [i.e., docosahexenoic acid (DHA) and eicosapentenoic acid or (EPA)]. Still other formulas contain higher quantities of monounsaturated fatty acids from canola oil and high-oleic safflower or sunflower oils. The essential fatty acid (EFA) content (mainly linoleic acid) of EN formulas is important because EFA deficiency can be induced if at least 1% to 4% of total calories are not supplied as EFA. It is important to note that MCT oil does not contain any EFA.

Specialty Formulas

Specialty formulas designed for use in specific clinical situations generally are much more expensive than standard polymeric formulas. ❻ *Strong clinical trial data supporting use of these specialty formulas in niche populations typically are unconvincing in terms of patient outcomes.*

Stress/Trauma Formulas

Historically, formulas aimed specifically for highly stressed, critically ill patients including those suffering significant trauma and those undergoing major surgical procedures, were enriched with branched-chain amino acids (BCAAs). The rationale for these products was that skeletal muscle BCAAs have been shown to be preferentially used for energy in the setting of critical illness. Thus provision of BCAAs was hoped to limit breakdown of muscle in these patients. Clinical data failed to support or refute the benefit of these formulas unequivocally in terms of clinical outcomes.[17]

The newer generation of enteral feeding formulas marketed for use in these populations covers a broad spectrum of characteristics (Table 98–5). Whereas some are polymeric, others are oligomeric to address the malabsorption that sometimes accompanies high stress. Some of the formulas marketed for use in critical illness are calorically dense (1.5–2 kcal/mL) to

TABLE 98–5. Enteral Feeding Formulas Marketed for Use in High Stress, Pulmonary Disease, and Trauma

Product Name/Manufacturer	kcal/mL	Protein (g/L)	Enriched Ingredients[a]	Selected Specialized Indications

[a]Formula considered enriched if following criteria met: arginine—greater than 10 g/1500 kcal; glutamine—greater than 10 g/1500 kcal; MCT—greater than 30% fat calories; ω-3 fatty acid—ratio of ω-6 to ω-3 less than or equal to 2:1.
CI, critical illness; HS, high stress; PD, pulmonary disease; TR, trauma; EPA, eicosapentenoic acid; GLA, γ-linolenic acid; MCT, medium chain triglycerides

address fluid restrictions sometimes seen in this population, whereas others are less calorically dense. Most of these products contain generous amounts of protein to address the high requirements of highly stressed patients (**nonprotein kilocalories to nitrogen ratios** typically between 75:1 and 125:1). Many of these products contain ingredients purported to increase immune function; the term *immunonutrition* is sometimes attached to these products.

Immune-enhancing ingredients present in some of the enteral feeding products include arginine, glutamine, ω-3 fatty acids, and nucleic acids. Few products contain all of these ingredients (see Table 98–5). Arginine is an important substrate for nitric oxide (NO) synthesis, and small amounts of NO have beneficial effects on immune function under certain conditions.[18] Thus arginine has been purported to have positive influence on lymphocyte and macrophage function. Glutamine is considered to be a conditionally essential amino acid in critical illness. This amino acid is a preferred fuel source for enterocytes of the small bowel. It has been suggested that supplementation with glutamine, either parenterally or enterally, may help to maintain the integrity of the gut mucosa. This might prevent translocation of bacteria and endotoxin from the gut lumen into the lymphatic system and the systemic circulation, although the importance of translocation in humans remains controversial. The ω-3 fatty acids, primarily from fish oils, are included in many immunonutrition products. The metabolites of ω-6 fatty acids include mediators such as prostaglandins, leukotrienes, and thromboxanes that are primarily proinflammatory and increase coagulation. On the other hand, the mediators produced from ω-3 fatty acids predominantly produce anti-inflammatory effects and decrease coagulation. Thus ω-3 fatty acids may help to preserve the antimicrobial capacity of critically ill patients by downregulating inflammation.[18] Finally, there are limited data supporting nucleic acids as immunomodulators. In addition, quantities of antioxidants (particularly vitamin C, vitamin E, and β-carotene) higher than those traditionally found in standard enteral formulas are added to some of the immunonutrition formulas to protect body systems including the immune system from damage by oxygen free radicals.[19] These oxygen free radicals may be produced in high quantities in the setting of injury or infection.

❼ *The role of enteral immunonutrition in clinical practice remains controversial.* A high-profile expert consensus conference held in 2004 concluded that certain populations, particularly malnourished patients undergoing GI surgery and trauma patients, will benefit from this therapy.[20–23] Noteworthy is the fact that this symposium was sponsored by the manufacturer of one of the leading immunonutrition products. Several meta-analyses of the commercial immunonutrition products and/or specific ingredients (e.g., arginine and glutamine) found in these products have been conducted.[24–28] In general, these analyses have found no benefit in terms of mortality from immunonutrition. However, several of them have concluded that infection rates, length of stay, and length of time on a ventilator appear to be decreased with these products. More research will be necessary to further delineate which subpopulations will most likely benefit from these therapies. The best timing (initiation and duration) of delivery also still needs to be determined. There is some concern that supplementation with arginine may be detrimental in septic patients.[28]

Patient Encounter, Part 2

By day 2 postoperatively, the patient's intracranial pressures were improving and he had been weaned off the vasopressor agents. He was still being mechanically ventilated and was requiring an insulin drip at 2 units/hour to keep his blood sugar below 150 mg/dL. He was started on an immune-enhancing enteral formula containing 1.3 kcal/mL and 80 g protein per liter; the beginning rate was 40 mL/hour to be advanced as tolerated to goal rate over 24 to 36 hours.

- What effect would the enteral feeding be expected to have on the patient's blood sugar?
- Is an immune-enhancing formula a good choice for this patient?
- Approximately what should be the goal rate for this patient using this enteral formula?

Pulmonary Formulas

Enteral feeding formulas designed for use in patients with chronic obstructive pulmonary disease or receiving mechanical ventilation contain higher amounts of fat (40%–55% of total kilocalories) than most formulas. The rationale for high fat content is that burning of fat for energy is associated with less carbon dioxide production compared with burning of carbohydrate. Less carbon dioxide production theoretically would be advantageous in patients with retention of this substance and might facilitate weaning from mechanical ventilation. Since part of the market targeted by the manufacturers of these products is mechanically ventilated patients, these products are included in Table 98–5 (e.g., Pulmocare®, Respalor®, Nutrivent®, and Oxepa®). Carbon dioxide retention owing to carbohydrate administration was a problem previously (particularly with PN) when feeding was overzealous. However, at the conservative calorie levels typically administered today, even the standard enteral formulas usually can be given without fear of excess carbon dioxide production.

One formula, Oxepa®, has been studied specifically in critically ill patients with acute respiratory distress syndrome (ARDS).[29] This high-fat formula contains high quantities of the ω-3 fatty acids (EPA) and γ-linolenic acid (GLA). γ-Linolenic

TABLE 98–6. Enteral Feeding Formulas Marketed for Use in Diabetes and Stress-Induced Hyperglycemia

Product Name/ Manufacturer	kcal/mL	% kcal as Fat	% kcal as Carbohydrate	Fiber (g/L)

Diabetisource AC®/Novartis	1.2	44	36	10
Resource Diabetic®/Novartis	1.06	40	36	12.8
Choice DM®/Novartis	1.06	43	40	14.4

acid is metabolized to a prostaglandin with vasodilatory properties. Eicosapentenoic acid (EPA) is converted to prostaglandins and leukotrienes with primarily an anti-inflammatory profile. This formula also contains large quantities of antioxidants. Patients receiving this formula received fewer days of mechanical ventilation and stayed in the intensive-care unit a shorter time than patients receiving a high-fat enteral feeding product as a control.[29] More research should be conducted to confirm the findings of this single study.

Diabetic Formulas

Similar to the pulmonary formulas, formulas designed for the patient with diabetes or stress-induced hyperglycemia are relatively high in fat and low in carbohydrate (Table 98–6). The macronutrient content of these products does not follow the recommendations of the American Diabetes Association for patients with diabetes (lower carbohydrate content and higher fat content than recommended), which could be an issue especially if the formulas are used for more than a couple of weeks. These formulas typically contain fiber (primarily soluble) because it plays some role in glycemic control. They also may contain fructose and monounsaturated fatty acids. Data support improved blood sugar control with use of these formulas in patients with diabetes.[30] There is increasing recognition of the importance of maintenance of euglycemia in various clinical settings including intensive care.[12] Therefore, whether or not a diabetic EN formula is chosen, avoidance of overfeeding and maintenance of good glycemic control with insulin or other hypoglycemic medications are important in these populations.

Renal Formulas

Each of the major manufacturers of EN products markets more than one specialty formula for use in renal failure (Table 98–7). These products uniformly have high caloric density (2 kcal/mL) in light of the need to decrease fluid in this situation. The products vary widely in amounts of nutrients of interest in renal failure patients such as protein, potassium, phosphorus, and magnesium. Products low in protein (20–35 g/L) may be appropriate in chronic renal failure patients not yet receiving dialysis. On the other hand, removal of protein by dialysis, coupled with the hypercatabolic, hypermetabolic condition seen in many patients with acute renal failure, makes use of higher-protein formulas (70–85 g/L) appropriate in these situations. Note that of the products listed in Table 98–7, two manufacturers market a low- and a high-protein product designed for use in renal failure. The potassium, phosphorus, and magnesium contents of EN formulas designed for use in renal failure tend to be lower than in standard formulas because these renally excreted electrolytes can accumulate during renal failure.

Historically, elemental formulas designed for renal failure were enriched with essential amino acids (EAAs) and contained lesser amounts of nonessential amino acids (NEAAs) than standard formulas. Theoretically, EAAs could combine with urea nitrogen in the synthesis of NEAAs, thus leading to a decrease in blood urea nitrogen (BUN). The only situation in which such formulas may be appropriate is in patients with

TABLE 98–7. Enteral Feeding Products Designed for Use in Renal Failure

Product Name/Manufacturer	Protein/L	Characteristics
Renalcal®/Nestle Nutrition	34.4	Enriched with EAAs, arginine, histidine; incomplete[a] formula due to negligible electrolytes and lack of fat soluble vitamins
Nutrirenal®/Nestle Nutrition	70	Complete formula[b] with lower amounts of potassium, phosphate, and magnesium than standard formulas; similar to Nepro®, Novasource Renal®, and Magnacal Renal®

Magnacal Renal®/Novartis	75	Complete formula similar to Nutrirenal®, Nepro®, and Novasource Renal®
Suplena®/Ross	30	Complete formula with low amounts of protein for patients not yet receiving dialysis

[a]Incomplete formula—contains insufficient amounts of one or more essential nutrients.
[b]Complete formula—contains all nutrients in amounts sufficient to meet needs of most patients in a volume equal to or less than that usually administered.

chronic renal failure who are not candidates for dialysis. Even in this setting, the use of these products should be limited to no more than 2 or 3 weeks owing to the risk of increased serum ammonia levels.[3] These EAA-enriched formulas have been supplanted largely by polymeric formulas with a protein content similar to standard EN formulas. The main difference between these products and standard EN formulas is reduced potassium, phosphate, and magnesium concentrations.

Hepatic Formulas

Specialized formulas for patients with hepatic insufficiency are limited in number. These products are enriched with BCAAs while containing a reduced quantity of aromatic amino acids (AAAs) and methionine compared to standard enteral formulas. These changes seek to address the high levels of AAAs and low levels of BCAAs found in the blood of patients with hepatic insufficiency. Theoretically, these products might be helpful for patients with hepatic encephalopathy (HE). One of the mechanisms postulated as a cause of HE is the false neurotransmitter hypothesis. According to this hypothesis, high levels of AAAs in the blood allow large quantities of these amino acids to cross the blood-brain barrier and form false neurotransmitters such as octopamine. Administration of high amounts of BCAAs could competitively inhibit some of the AAAs from crossing the blood-brain barrier, thus decreasing the formation of false neurotransmitters. The hepatic formulas are distinguished from the BCAA-enriched formulas historically used in critical illness and stress by the low AAA content of the hepatic formulas. Although there are some data supporting the use of these specialty products in the treatment of moderate to severe HE, improvement in mortality attributable to them has not been consistent.[3] Therefore, many institutions and clinicians prefer to use less expensive polymeric enteral formulas containing standard protein sources for patients with hepatic insufficiency. The specialty formulas are recommended only for patients with chronic cirrhosis who cannot ingest 1 g protein per kilogram per day without becoming encephalopathic.[3] An example of a specialized hepatic formula is Hepatic-Aid II®, a product that is supplied as a powder for reconstitution and that requires vitamin, mineral, and electrolyte supplementation. A second product is NutriHep®, which is supplied as a liquid formula containing the recommended amounts of key vitamins, minerals, and electrolytes.

MONITORING AND COMPLICATIONS

Although complications of EN generally are considered to be less serious than with PN, some complications nevertheless can be dangerous or can lead to impaired delivery of the desired nutrient load. The complications of EN can be divided into four categories: GI, technical, infectious, and metabolic. The first three of these categories of complications, along with common causes, are listed in Table 98–8. Patients on EN must be monitored for prevention of complications (Table 98–9). Note that monitoring of many of these parameters can become less frequent as the patient's condition stabilizes. Monitoring for efficacy of EN is also important.

GI Complications

❽ *GI complications are the most common complications of EN limiting the amount of feeding that patients receive.* Although diarrhea frequently is blamed on the tube feeding formula or the method of EN administration, other possible causes of diarrhea usually exist (see Table 98–8). Many of these possibilities are related to the fact that, particularly in the inpatient setting, patients receiving EN frequently are some of the sickest patients in the hospital. Along these lines, *Clostridium difficile* colitis must be considered as a possible cause of diarrhea, especially in patients who have been receiving antimicrobial therapy or proton pump inhibitors.[31,32] Antibiotic therapy is one of the major causes of diarrhea in acutely ill patients, including those receiving EN. A medication-related cause of diarrhea that was largely overlooked until the early 1990s is the sorbitol content of medications.[33] Large quantities of this substance present in many oral liquid medications (often considered the dosage form of choice for administration through a feeding tube) can cause diarrhea. Unfortunately, the sorbitol content of many medications is not listed on their labeling, and some manufacturers state that they frequently reformulate these preparations to contain varying amounts of excipients such as sorbitol. Determining the cause of the diarrhea is obviously important to know how to address the problem. Whereas *C. difficile* colitis should be treated with metronidazole, sorbitol- or other medication-induced diarrhea can be addressed by removal of the offending agent. Likewise, diarrhea secondary to malabsorption sometimes can be addressed by changing to an oligomeric EN formula. Antiperistaltic agents such as loperamide may be useful in some cases of diarrhea of noninfectious etiology.

On the other hand, constipation may occur in some patients receiving tube feedings, especially the elderly. Increased provision of fluid or fiber may be useful in attaining bowel regularity. As with diarrhea, constipation may be drug-related, in which case discontinuation or replacement of the offending drug may help to alleviate the problem.

Impaired gastric emptying is another problem seen commonly in EN patients receiving gastric feedings and may be associated with nausea and vomiting. The impaired gastric emptying may be related to a disease process (e.g., diabetic gastroparesis or sequelae to head injury) or to drug therapy, most notably narcotics used for analgesia. Gastric residual checks frequently are measured in patients receiving gastric feedings (see Table 98–9). To accomplish such a check, a syringe is attached to the feeding device, and as much liquid as possible is aspirated into the syringe. Much debate is ongoing as to what constitutes a significant gastric aspirate,

TABLE 98–8. Complications of Tube Feeding

Complication	Causes
Gastrointestinal	
Diarrhea	Drug related
	Antibiotic-induced bacterial overgrowth
	Hyperosmolar medications administered via feeding tubes
	Antacids containing magnesium
	Malabsorption
	Hypoalbuminemia/gut mucosal atrophy
	Pancreatic insufficiency
	Inadequate GIT surface area
	Rapid GIT transit
	Radiation enteritis
	Tube feeding related
	Rapid formula administration
	Formula hyperosmolalty
	Low residue (fiber) content
	Lactose intolerance
	Bacterial contamination
Nausea and vomiting	Gastric dysmotility (surgery, anticholinergic drugs, diabetic gastroparesis)
	Rapid infusion of hyperosmolar formula
Constipation	Dehydration
	Drug induced (anticholinergics)
	Inactivity
	Low residue (fiber) content
	Obstruction/fecal impaction
Abdominal distention/cramping	Too rapid formula administration
Technical	
Occluded feeding tube lumen	Insoluble complexation of enteral formula and medication(s)
	Inadequate flushing of feeding tube
	Undissolved feeding formula
Tube displacement	Self-extubation
	Vomiting or coughing
	Inadequate fixation (jejunostomy)
Aspiration	Improper patient position
	Gastroparesis/atony causing regurgitation
	Feeding tube malpositioned
	Compromised lower esophageal sphincter
	Diminished gag reflex
Peristomal excoriation	Improper skin and tube care
	GIT secretions leaking peristomally
Infectious	
Aspiration pneumonia	Same as technical—aspiration comments
	Prolonged use of large-bore polyvinylchloride tube

From DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 5th ed. New York: McGraw-Hill; 2005: Table 138–14.

with numbers between 100 and 400 mL most commonly defended.[34,35] Approaches to the patient with delayed gastric emptying might include changing to an enteral formula containing less fat because dietary fat is associated with slower gastric emptying. Metoclopramide often is given to patients receiving gastric feedings to facilitate gastric emptying. Erythromcyin is an alternative medication that may be useful in stimulating gastric motility, although it also can be associated with potentially serious drug-drug interactions. Patients with consistently high gastric aspirates are considered to be at higher risk of aspirating feedings into their lungs and should be considered for transition to postpyloric feedings. Postpyloric feedings also may help to relieve the EN-related nausea and vomiting seen in some patients and are preferred for patients without an intact gag reflex. One of the most important practices to help prevent aspiration is elevation of the head of the bed to at least 30 degrees during continuous feedings and during and for 30 to 60 minutes after intermittent and bolus feedings. The practice of adding blue food coloring to tube feeding formulas to help detect aspiration in bronchial or tracheal aspirates has been abandoned largely owing to reports of absorption of this supposedly nonabsorbable substance in patients with sepsis.[36]

TABLE 98–9. Suggested Monitoring for EN Patients to Prevent the Development of Complications

Parameter	During Initiation of EN Therapy	During Stable EN Therapy
Vital signs	Every 4–6 hours	As needed
Clinical assessment		
Weight	Daily	Weekly
Length/height (children)	Weekly–monthly	Monthly
Head circumference (less than 3 y of age)	Weekly–monthly	Monthly
Total intake/output	Daily	As needed
Tube feeding intake	Daily	Daily
Enterostomy tube site assessment	Daily	Daily
GI tolerance		
Stool frequency/volume	Daily	Daily
Abdomen assessment	Daily	Daily
Nausea or vomiting	Daily	Daily
Gastric residual volumes	Every 4–8 hours (varies)	As needed
Tube placement	Prior to starting, then ongoing	Ongoing
Laboratory		
Electrolytes, BUN/S_{cr}, glucose	Daily	As needed
Calcium, magnesium, phosphorus	3–7 times/wk	As needed
Liver function tests	Weekly	As needed
Trace elements, vitamins	Patient-specific	Patient-specific

BUN, blood urea nitrogen; S_{cr}, serum creatinine.

Technical Complications

Technical or mechanical complications are encountered frequently in the patient receiving EN. Tube occlusion most commonly is related to formula occlusion or medication administration through the tube. ❾ *An important practice to help prevent medication-related occlusion is adequate water flushing of the tube before, between, and after each medication is given through the tube.* If intermittent feedings are being used, water flushing after each feeding is recommended. Tube occlusion can increase the cost of EN significantly if the tube has to be removed and replaced. Clearing of the occlusion using water or pancreatic enzymes plus sodium bicarbonate can be attempted, and special devices and kits (e.g., Clog Zapper®) are also available for this purpose.[37]

Tube displacement is a potentially significant complication of EN. This may be seen secondary to an agitated patient pulling at his or her tube, or in some cases the tip of the tube migrates spontaneously. The danger of this complication arises if the tip of the tube is positioned in the tracheobronchial tree and feeding is delivered to this area, potentially leading to pneumonia, pneumothorax, and other problems. The location of the tip of the feeding tube should be confirmed initially by chest radiograph after placement and before use. For ongoing assessment of tube placement, auscultation and measurement of aspirate pH can be used; debate continues as to the best method of monitoring tube placement.

Endoscopic and surgical feeding tubes can be complicated by erosion of the exit site caused by leakage of gastric or intestinal contents onto the skin. This complication must be addressed by good wound care and repair or replacement of the access device. Similarly, NG, ND, and NJ tubes can be complicated by nasopharyngeal irritation or necrosis. This is one of the reasons why such tubes should be considered for short-term use only.

Infectious Complications

Infectious complications of EN include aspiration pneumonia and infections related to delivery of contaminated EN formula. Aspiration is a complication with GI, mechanical, and infectious implications. Although GI infections owing to contamination of enteral formulas have been reported uncommonly, there is ample opportunity for these formulas to be seeded with organisms during the processes of transferring from the can to the delivery bag with ready-to-use formulas and during the process of reconstitution with powdered formulas. The so-called closed systems of delivery, wherein the formulas come from the manufacturer premixed in a delivery bag, should help to decrease the chance of formula contamination.

Metabolic Complications

Metabolic complications of EN most commonly include disorders of fluid and electrolyte homeostasis and hyperglycemia. More severely ill patients require more frequent monitoring than those who are more stable (see Table 98–9). Both dehydration and fluid overload can occur with tube feeding. Careful monitoring of fluid inputs and outputs as well as body weight is important. Dehydration may be due either to excessive fluid

losses or inadequate fluid intake. The trend in the BUN-to-serum-creatinine ratio can be useful in helping to monitor for this complication; a ratio of greater than about 15:1 may be an indicator of dehydration. Attention should be paid to the free-water content of EN formulas; this information usually is included on the product labeling. The free-water content of EN formulas varies from about 65% to 85%, with the percentage of free water typically dropping as the caloric density of the formula rises. If a patient develops dehydration, switching to a less calorically dense formula or using more water flushes with the feeding may be appropriate. Fluid overload is reflected by increases in weight, lower extremity edema, and pulmonary rales and particularly may be a problem in patients with renal or cardiac insufficiency. Use of an EN formula that is more calorically dense (i.e., contains less free water) may be helpful, and diuretic therapy may be necessary. Fluid imbalances often are associated with abnormalities of sodium homeostasis that should be addressed in concert with the fluid imbalance.

Hypokalemia, hypomagnesemia, and hypophosphatemia are some of the most common electrolyte abnormalities in sick, hospitalized patients. These can occur in the context of the so-called refeeding syndrome. This syndrome occurs in chronically malnourished patients when aggressively started on a feeding regime. Although more classically associated with PN, refeeding syndrome can occur with aggressive EN as well. Careful monitoring of these electrolytes, coupled with a feeding regimen that is increased gradually to goal rate over a period of several days to a week, should help to protect the at-risk patient from this potentially harmful complication. Hypokalemia and hypomagnesemia also may be associated with excessive losses through the GI tract or urine and may be associated with various medication therapies, including diuretics. Repletion of these conditions may be accomplished enterally in the nonsymptomatic patient or parenterally if the patient is symptomatic or the abnormality is severe. Enteral repletion with magnesium and phosphate can be associated with diarrhea. Hyperkalemia, hypermagnesemia, and hyperphosphatemia are encountered less commonly and usually are associated with renal insufficiency and decreased excretion. Hyperkalemia also is associated with several medications, including potassium-sparing diuretics and angiotensin-converting enzymes frequently used in hospitalized patients.

Although hyperglycemia is less common with EN than with PN, it can occur nevertheless. Many of the severely ill patients (e.g., septic, highly stressed) receiving EN have a metabolic milieu promoting hyperglycemia. In addition, many of these patients have preexisting or undiagnosed diabetes mellitus. For the intensive-care-unit patient with hyperglycemia receiving continuous EN, an intravenous insulin drip may be the most effective way to achieve the tight glycemic control now generally recommended. Administration of scheduled long-acting insulin is preferred over sliding-scale insulin in patients requiring insulin after they have been stabilized on their enteral feeding regimen. Administration of a higher-fat, lower-carbohydrate EN formula also may be useful in selected patients.

Monitoring for Efficacy/Outcome Evaluation

The most useful physical measurement of efficacy of EN in the long-term patient is typically body weight. Depending on the clinical situation, the goal may be weight gain, weight maintenance, or weight loss. Whereas day-to-day fluctuations in weight generally reflect fluid changes, week-to-week variations are more useful in determining if caloric provision is appropriate.

The amount of EN actually administered is often less than the amount ordered owing to interruptions in therapy for performance of procedures and other daily activities, especially in hospitalized patients. It is imperative to monitor volume of feedings actually received and to make adjustments in rates or amounts of EN as necessary.

Biochemical markers may help the SNS practitioner interpret the adequacy of the EN therapy. Albumin frequently is measured as part of standard metabolic lab panels. However, its long half-life makes this visceral protein less useful for making decisions regarding the adequacy of the nutritional prescription over the short term. Prealbumin, a protein with a much shorter half-life that is expected to increase more rapidly in the setting of sufficient calorie and protein provision, has become the major biochemical monitoring parameter used to determine efficacy of SNS. However, in the acute phase of an illness characterized by a proinflammatory state, proteins known as *acute-phase reactants* are preferentially synthesized. One of these acute-phase reactants commonly measured clinically is C-reactive protein (CRP). Therefore, in some patients with significant illness, prealbumin levels may not rise, even though the patients are receiving the appropriate EN regimen, until the CRP level begins to fall. Collection of urine to measure nitrogen balance also can help to analyze adequacy of caloric and protein provision but must be performed with care to obtain reliable information.

In patients with wounds (e.g., decubitus ulcers), a goal of nutritional therapy is usually to help facilitate wound healing. Therefore, monitoring the status of the wound becomes part of the ongoing nutritional assessment. In debilitated patients, particularly those on long-term EN, measures of functional status such as grip strength and ability to perform activities of daily living become important parts of the assessment of nutritional adequacy.

MEDICATION ADMINISTRATION IN PATIENTS RECEIVING EN

Medication Administration Through Feeding Tubes

If a patient receiving EN is alert and can swallow oral medications, then the medications should be given by mouth. However, many patients are not able to receive their medications by this

route, and the feeding tube may be considered as a route of delivery of some medications. Although used widely, the effects of medication administration through feeding tubes on the delivery of both the drug and the EN formula nutrients have been inadequately studied, and many important questions remain to be answered.[38]

⑩ *Compatibility of medication with an EN formula and, conversely, an EN formula with administered medication is of concern when administering medications through feeding tubes.* An important technical complication of EN is tube occlusion, which is related most commonly to medication administration through the tube. Not only must compatibility of the medication and the EN formula be considered, but interactions between these components and the feeding tube itself also must be considered. Since either medication or EN formula or some combination thereof can physically stick to the tube itself, strict protocols for flushing the tube before, between, and after administration of medications are important. The best fluid for flushing feeding tubes is warm water. Although carbonated beverages and fruit juices have been used commonly in the past, these are no longer recommended and should be avoided because the sugar in these products may stick to the surface of the feeding tube. Between 10 and 30 mL of water should be used as a flush before and after any medication administration through a feeding tube. Medications should be administered one at a time sequentially rather than being mixed together for simultaneous administration down the tube; about 5 mL of water should be used as a flush between each medication. This should help to prevent interactions between drugs within the feeding tube itself that could lead to tube occlusion.

Different dosage forms each present unique challenges for administration through feeding tubes. Certain solid dosage forms should not be crushed because crushing would cause a significant alteration in the release characteristics of the drug.[39] For example, controlled-release, extended-release, and sustained-release preparations should not be crushed; crushing would allow a quicker release of more drug initially than the original dosage form was designed to deliver. Sublingual dosage forms also should not be crushed. Enteric-coated dosage forms generally are designed to protect acid-labile medications from stomach acid; when these dosage forms reach the small bowel with its higher pH, the drug then is released into an environment in which it is more stable. Alternatively, enteric-coated dosage forms protect the stomach from medications that could cause irritation. Thus, crushing of the enteric coating for delivery down a gastric feeding tube defeats the purpose of the dosage form and could lead to decreased efficacy or increased adverse events with the medication.

Medications available commercially as compressed tablets can be crushed for administration through feeding tubes. After such a tablet is crushed into a fine powder, it should be mixed with 10 to 30 mL of fluid (usually warm water) for administration through the tube. A powdered dosage form inside a hard-gelatin capsule similarly can be poured out and mixed with water for administration through feeding tubes. Soft-gelatin capsules can be dissolved in warm water for administration through a tube. Some enteric-coated and delayed-release microencapsulated products can be opened, and the individually coated particles can be administered through the tube without crushing if the tube has a large enough diameter.

If a liquid dosage form of a medication exists, it would seem rational to use this dosage form for administration through a feeding tube. Although such a decision may decrease the potential for tube clogging, it may in some instances decrease tolerability of the medication administration. Sorbitol is an excipient found in many liquid medications in amounts sufficient to cause diarrhea. If diarrhea secondary to sorbitol in a liquid medication is suspected in a patient on EN, contact with the manufacturer to ascertain sorbitol content may be necessary.

Another potential problem with administration of liquid medications through feeding tubes is the high osmolality of some of these products. Dilution of hypertonic medications with 30 to 60 mL of water (depending on the osmolality of the medication and the dosage volume of the undiluted medication) or administration of smaller dosages of the drug more frequently may help to prevent diarrhea. Although administration of intravenous medications through feeding tubes sometimes may be entertained, these dosage forms frequently are hypertonic and contain excipients that can be problematic when given via the GI tract.

It is generally not recommended to mix medications directly into the EN formula because of concerns that physical incompatibilities between the medications and the formula might lead to tube occlusion. There is some evidence that polymeric formulas are more likely to demonstrate physical incompatibility with medications compared with monomeric formulas, although most of the work in this area has used casein or caseinate-based formulas, and other proteins may act differently.[38] The limited data currently available would indicate that acidic syrups and elixirs may be the worst for causing physical incompatibility when admixed with EN formulas. It has been postulated that this incompatibility is due to changes in the protein structure after exposure to acid or alcohol.[38]

It would seem logical that medications considered to be absorbed to a greater extent in the fasted state either should be given between feedings on an intermittent feeding schedule or the feedings should be held for a period before and after medication administration. However, results of one provocative study with the antihypertensive medication hydralazine indicated that a continuous feeding into the stomach resulted in a situation mimicking fasting in terms of the rate of gastric emptying and the drug's absorption.[38] This issue deserves further study.

The location of the tip of the feeding tube is important when considering medication administration down a feeding tube. This is particularly true if the medication acts locally in the GI tract itself. For example, sucralfate and antacids act locally in the stomach. Therefore, administration of these medications through a duodenal or jejunal tube is not logical. Likewise, for medications such as itraconazole that require acid for best absorption, administration directly into the duodenum or jejunum would be expected to result in suboptimal absorption. Absorption of drugs when administered directly into the small bowel, especially the jejunum, rather than into the stomach is another area where more research would be useful.

Problem Medications

Phenytoin

Certain medications present specific challenges when administered through feeding tubes. The medication falling into this category that has been studied most thoroughly is phenytoin. Most studies have shown significant decreases in phenytoin absorption when the medication was administered enterally to patients receiving EN. Several mechanisms have been proposed for this apparent interaction, but no consensus has been reached. Many institutions have adopted a policy of holding tube feedings for 1 or 2 hours before and after administration of phenytoin to decrease the interaction, although some EN patients subjected to this routine still will require relatively high dosages of phenytoin to achieve therapeutic serum concentrations. Likewise, holding the feeding around medication administration can make meeting nutritional requirements difficult with continuous feedings, especially if the phenytoin is administered several times daily. Diligent monitoring of phenytoin serum concentrations is necessary for the patient on EN also receiving this medication.

Patient Encounter, Part 3

After a week in the intensive-care unit, the patient was transferred to a stepdown unit and was switched to a standard polymeric EN formula. He required 3 weeks of inpatient care owing to complications from his injuries, including seizures and a wound infection. He eventually was transferred to a rehabilitation facility still requiring EN.

- How should the patient be monitored for adequacy of his EN regimen?
- Outline a monitoring plan for tolerance of the EN regimen in the intensive-care unit, stepdown unit, and rehabilitation facility.
- Discuss work-up of the patient if diarrhea occurs while he is receiving tube feedings.
- If the patient requires phenytoin for his seizures, how should this medication be administered?

Patient Care and Monitoring

1. Assess the patient's condition to estimate the amount of time he or she is expected to be unable to eat adequately to meet nutritional requirements. If inadequate intake has occurred or is anticipated for 7 to 14 days, start SNS. The threshold for starting SNS is lower for previously malnourished patients than for previously well-nourished patients.
2. Assess whether the GI tract is functional. If it is not, then PN is the first SNS therapy of choice. If the GI tract is functional and no contraindication to EN exists, then EN is the SNS therapy of choice.
3. Does the patient have any condition precluding gastric feeding? If so, then postpyloric feeding should be started.
4. Choose the appropriate type of enteral access device based on the expected duration of SNS.
5. Choose an appropriate feeding formula based on patient-specific factors. This necessitates assessing the patient's nutritional requirements. Standard polymeric formulas are appropriate for the majority of patients.
6. Choose the method of feeding administration (e.g., intermittent or continuous) based on the type of feeding access (i.e., gastric versus postpyloric) and other patient factors. For example, in a patient with a gastric access, starting with or later transitioning to intermittent feedings may be preferred if it is anticipated that the patient will be discharged still receiving these feedings to a long-term care facility or to home.
7. Develop a plan to include monitoring at appropriate intervals for metabolic, gastrointestinal, technical, and infectious complications.
8. Start the tube feeding at full strength and at a low rate, and increase the rate as tolerated to the goal that will meet the patient's nutritional requirements.
9. Develop a monitoring plan for adequacy of the nutritional regimen.
10. If the patient is to be discharged to home on EN, educate the patient or caregiver on
    - Enteral access device care
    - Feeding delivery
    - Troubleshooting
    - Complications to observe for (e.g., fluid overload, dehydration)

In some cases, use of intravenous phenytoin or another anticonvulsant medication may be prudent.

Warfarin

EN formulas contain vitamin K, which can antagonize the pharmacologic activity of warfarin. The vitamin K content of EN formulas generally has been adjusted down over the past

several decades, resulting in products today that contain amounts of vitamin K unlikely to affect anticoagulation by warfarin significantly. However, inadequate warfarin anticoagulation in EN patients receiving formulas containing minimal vitamin K has been reported. There is some thought that a component of certain tube feedings, perhaps protein, may bind warfarin and result in suboptimal activity of the drug. When tube feedings are started, changed, or discontinued, the international normalized ratio (INR) should be monitored closely.

Fluoroquinolones

Absorption of antimicrobial agents such as fluoroquinolones and tetracyclines that can be bound by divalent and trivalent cations potentially could be compromised by administration with EN formulas containing these cations. The fluoroquinolones (e.g., levofloxacin and ciprofloxacin) have been best studied in this regard, and results of studies are not consistent. Mechanisms for an interaction between fluoroquinolones and EN formulas other than chelation by cations have been postulated.[40] Some institutions hold tube feedings for 30 to 60 minutes or more before and after enteral dosages of fluoroquinolones. Because ciprofloxacin absorption has been shown to be decreased with jejunal administration, this drug probably should not be given by jejunal tube.[41]

SUMMARY AND CONCLUSION

EN is an important method of feeding patients who cannot or should not eat enough to meet their nutrient requirements for a prolonged time. When the GI tract can be used safely, EN is preferred over PN. Various types of enteral access devices are available. Whereas tubes inserted through the nose often are adequate for patients who are expected to receive EN for a short time, more permanent devices (endoscopically or surgically placed) are preferred for longer-term patients. The choice of whether to feed into the stomach or postpylorically is patient-specific. Although numerous EN formulas are available commercially, many of the products are very similar, making a limited formulary feasible. Data supporting many of the specialized types of EN formulas are limited. Although complications of EN tend to be less serious than with PN, the adverse effects encountered can be significant, and diligent ongoing monitoring for them is necessary. Although medications can be administered through feeding tubes, various factors must be taken into account in each individual patient to ensure that this practice is prudent.

ABBREVIATIONS

AAA: aromatic amino acids
BCAA: branched-chain amino acids
DHA: docosahexenoic acid
EAAs: essential amino acids
EFAs: essential fatty acids
EN: enteral nutrition
EPA: eicosapentenoic acid
FOSs: fructooligosaccharides
GALT: gut-associated lymphoid tissue
GI: gastrointestinal
GLA: γ-linolenic acid
HE: hepatic encephalopathy
LCTs: long-chain triglycerides
MCTs: medium-chain triglycerides
NO: nitric oxide
PN: parenteral nutrition
PUFAs: polyunsaturated fatty acids
SCFAs: short-chain fatty acids
SNS: specialized nutrition support

99 Overweight and Obesity

Maqual R. Graham and Cameron C. Lindsey

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Explain the underlying causes of overweight and obesity.
2. Identify parameters used to diagnose obesity and other objective information that indicates the severity of disease.
3. Identify desired therapeutic goals for patients who are overweight or obese.
4. Recommend appropriate nonpharmacologic and pharmacologic therapeutic interventions for overweight or obese patients.
5. Implement a monitoring plan that will assess both the efficacy and safety of therapy initiated.
6. Educate patients about the disease state and associated risks, appropriate lifestyle modifications, drug therapy, and surgical options necessary for effective treatment.

Key Concepts

❶ Body mass index (BMI), waist circumference, comorbidities, and readiness to lose weight are used in the assessment of the overweight or obese patient.

❷ Presence of comorbidities [coronary heart disease (CHD), atherosclerosis, type 2 diabetes mellitus, and sleep apnea] and cardiovascular risk factors (cigarette smoking, hypertension, elevated low-density lipoprotein cholesterol, low high-density lipoprotein cholesterol, impaired fasting glucose, family history of premature CHD, and age) requires identification and aggressive management for overall effective treatment of the overweight or obese patient.

❸ Management is directed at preventing weight gain in patients with a BMI greater than or equal to 25 kg/m^2. Weight loss is indicated for patients with a BMI of 25 to 29.9 kg/m^2 or an elevated waist circumference with two or more comorbidities or for any patient with a BMI of 30 kg/m^2 or greater.

❹ The treatment goals for overweight and obesity are to prevent additional weight gain, reduce and maintain a lower body weight, and control related risks.

❺ Weight maintenance occurs following successful achievement of weight loss.

❻ Treatment of obesity includes lifestyle changes (e.g., dietary modification, enhanced physical activity, and behavioral therapy), pharmacologic treatment, surgical intervention, or a combination of modalities.

❼ Pharmacotherapy, in addition to lifestyle modifications, is reserved for patients with a BMI of 30 kg/m^2 or greater or a BMI of 27 kg/m^2 or greater with other obesity-related risk factors.

❽ Weight likely will be regained if lifestyle changes are not continued indefinitely.

❾ Surgery is warranted when other treatment attempts have failed in severely obese patients (BMI of 40 kg/m^2 or greater or 35 kg/m^2 or greater with other obesity-related risk factors).

Overweight is defined as an excess body weight relative to height. Conversely, *obesity* relates to a condition of excess body fat as assessed by various modalities.[1] ❶ *Body mass index (BMI), waist circumference, comorbidities, and readiness to lose weight are used in the assessment of the overweight or obese patient.* The primary modality in defining overweight and obesity is the **body mass index** (BMI)—a measure of body fat based on height and weight that applies to both adult men and women. The BMI accurately measures body fat when compared with body weight alone.[2] Several surveys were conducted to establish categories of BMI.[3] BMI does not reflect distribution of body fat; therefore, the measurement of **waist circumference** is a more practical method to evaluate abdominal fat before and during weight-loss treatment. Abdominal fat poses a greater

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

health risk over peripheral fat and may be an independent risk predictor when BMI is not elevated significantly.[4,5] Both BMI and waist circumference should be used in the diagnosis and management of weight loss. Evaluation of the patient's risk status involves not only calculation of the BMI and measurement of waist circumference but also determination of comorbidities or the presence of cardiovascular disease (CVD) risk factors.

❷ *Presence of comorbidities [coronary heart disease (CHD), atherosclerosis, type 2 diabetes mellitus, and sleep apnea] and cardiovascular risk factors (cigarette smoking, hypertension, elevated low-density lipoprotein cholesterol, low high-density lipoprotein cholesterol, impaired fasting glucose, family history of premature CHD, and age) requires identification and aggressive management for overall effective treatment of the overweight or obese patient.* Obese patients may be at very high risk for mortality if concomitant risk factors exist; therefore, high-risk patients require aggressive modification of risk factors in addition to obesity treatment.[6]

ETIOLOGY AND EPIDEMIOLOGY

Obesity is a multifactorial, complex disease that occurs following an interaction between genotype and the environment. While the etiology is not known completely, it involves overlapping silos of social, behavioral, and cultural influence; pathophysiology; metabolism; and genetic composition.[7] The majority of overweight or obese individuals are adults, but these diseases are also prevalent in children between 2 and 20 years of age. Over 105 million Americans are overweight or obese, including 9 million children over 6 years of age.[8,9] Overweight children typically mature to overweight adults, but most obese adults were not overweight as children.[10] Overweight and obesity, when present in young adults, therefore may be a better predictor of prevalence.[10] Additionally, adulthood overweight and obesity contribute to an increased risk of death in the presence of hypertension, hyperlipidemia, diabetes mellitus, coronary artery disease (CAD), stroke, sleep apnea, gallbladder disease, osteoarthritis, and certain cancers.[6] Psychosocial functioning also may be hindered because obese patients may be at risk for discrimination if negatively stereotyped.[6] Pediatric obesity is also associated with significant health-related problems and thus is a risk factor for much of the adult morbidity and mortality discussed previously.[11,12] Cardiovascular (e.g., dyslipidemia, hypercholesterolemia, and hypertension), endocrine (e.g., hyperinsulinemia, impaired glucose tolerance, type 2 diabetes mellitus, and menstrual irregularities), and mental (e.g., low self-esteem and depression) health problems exist for obese children and adolescents.[13]

The prevalence of overweight and obesity continues to increase, keeping this disease a major public health concern. Results from the most recent National Health and Nutrition Examination Survey (NHANES) reflect an increased combined prevalence for overweight and obesity among adults from 56% (1988–1994) to 65% (1999–2002).[14] Obesity alone has escalated 7%. Likewise, the number of overweight children and adolescents 6 to 19 years of age has increased by 5% during the same time frame.[14]

PATHOPHYSIOLOGY

While a correlation between body weight in parents and children exists, the specific gene or genes contributing to obesity are unknown.[15] Syndromes where obesity is a major component collectively contribute very little to the incidence of obesity.[16] The key factor in the development of overweight and obesity is the imbalance that occurs between energy intake and energy expenditure. The extent of obesity is determined by the length of time this imbalance has been present. Energy intake is affected by environmental influences, including social, behavioral, and cultural factors, whereas genetic composition and metabolism affect energy expenditure.[17]

Energy Intake

Food intake is regulated by various receptor systems. Direct stimulation of 5-HT_{1A} and noradrenergic α_2-receptors will increase food intake, whereas 5-HT_{2C} and noradrenergic α_1- or β_2-receptor activation decreases food intake. Stimulation of histamine receptor subtypes 1 and 3 and dopamine receptors 1 and 2 result in lower food consumption. Recently, the cannabinoid receptor (CB1), which is a G-protein-coupled receptor in the endocannabinoid system, has been identified and associated with food intake and regulation of energy homeostasis.[18–20] Inhibition of CB1 is shown to decrease the craving for food, resulting in weight loss when coupled with dietary and lifestyle modifications.[21] In addition to receptor-modulated food consumption, higher levels of the protein leptin are associated with decreased food intake.[22] In contrast, elevated levels of neuropeptide Y increase food intake.[22]

It is debatable whether obesity is related to total calorie intake or composition of macronutrients. Of the three macronutrients (i.e., carbohydrate, protein, and fat), fat has received the most attention given its desirable texture and its ability to augment the flavor of other foods. Food high in fat promotes weight gain in comparison with the other macronutrients because fat is more energy-dense. When compared with carbohydrate and protein, more than twice as many calories per gram are contained in fat. In addition, fat is stored more easily by the body compared with protein and carbohydrate.[23]

Energy Expenditure

A person's metabolic rate is the primary determinant of energy expenditure. Metabolic rate is enhanced following food consumption and directly related to the amount and type.[16] Physical inactivity may predispose an individual to overweight

TABLE 99–1. BMI Classification[6]

Underweight	Less than 18.5 kg/m^2
Normal weight	18.5 to 24.9 kg/m^2
Overweight	25 to 29.9 kg/m^2
Obesity (class 1)	30 to 34.9 kg/m^2
Obesity (class 2)	35 to 39.9 kg/m^2
Extreme obesity (class 3)	Greater than or equal to 40 kg/m^2

and obesity. In addition, endocrine-related disorders (e.g., hypothyroidism and Cushing's syndrome) may lower the metabolic rate, further contributing to the development of overweight and obesity.

CLINICAL PRESENTATION AND DIAGNOSIS

Any interaction between a patient and a health care provider presents an opportunity to evaluate the patient's height and weight. From these parameters, the BMI should be determined, as well as waist circumference and the presence of comorbidities or associated risks. ❶ *Body mass index (BMI), waist circumference, comorbidities, and readiness to lose weight are used in the assessment of the overweight or obese patient.* The BMI is calculated using the measured weight in kilograms divided by the height in meters squared (kg/m^2) for all patients regardless of gender. BMI then should be classified according to Table 99–1. When determining waist circumference, place a measuring tape at the top of the right iliac crest and proceed around the abdomen, ensuring that the tape is tight but not constricting the skin. The value is measured following normal expiration.[6] Table 99–2 defines high-risk waist circumference.[6] After obtaining measurable parameters, further assess the patient for the presence of comorbidities and cardiovascular risk factors. ❷ *Presence of comorbidities [coronary heart disease (CHD), atherosclerosis, type 2 diabetes mellitus, and sleep apnea] and cardiovascular risk factors (cigarette smoking, hypertension, elevated low-density lipoprotein cholesterol, low high-density lipoprotein cholesterol, impaired fasting glucose, family history of premature CHD, and age) requires identification and aggressive management for overall effective treatment of the overweight or obese patient.* A patient is at very high absolute risk if diagnosed with CHD or other atherosclerotic diseases, type 2 diabetes mellitus, or sleep apnea or if three or more of the risk factors listed in Table 99–3 are present.[6] Aggressive disease management should be initiated and not limited to weight loss.

TABLE 99–2. High-Risk Waist Circumference[6]

Men	Greater than 40 in (102 cm)
Women	Greater than 35 in (89 cm)

TABLE 99–3. Risk Factors[6,24]

Cigarette smoking
Hypertension (systolic blood pressure greater than or equal to 140 mm Hg or diastolic blood pressure greater than or equal to 90 mm Hg) or current use of blood-pressure-lowering medication(s)
Low-density lipoprotein cholesterol greater than or equal to 160 mg/dL (4.14 mmol/L)
Low-density lipoprotein cholesterol greater than or equal to 130 to 159 mg/dL (3.37 to 4.12 mmol/L) plus two additional risk factors
High-density lipoprotein cholesterol less than 35 mg/dL (0.91 mmol/L)
Impaired fasting glucose [fasting blood glucose 100–125 mg/dL (5.6 to 6.9 mmol/L)]
Family history of premature coronary heart disease (first-degree male relative less than 55 years of age or first-degree female relative less than 65 years of age)
Males greater than or equal to 45
Females greater than or equal to 55

TREATMENT

Desired Outcome

General management of obesity is directed at weight reduction, maintenance of weight loss, and prevention of weight regain. ❹ *The treatment goals for overweight and obesity are to prevent additional weight gain, reduce and maintain a lower body weight, and control related risks.* A 10% weight loss as derived from the patient's current weight is the initial goal of obesity management because favorable outcomes on the negative effects of obesity have been documented.[6,25] Weight loss should occur at a rate of 1 to 2 lb per week, meeting the initial goal within the first 6 months of therapy. Weight then should be maintained [minimal regain of less than 3 kg (6.6 lb) and continued reduction in waist circumference of 1.6 in (4 cm)].

Patient Encounter, Part 1

A 35-year-old woman with a history of hypertension presents to your clinic complaining of low energy and irritability. She reports not following any specific diet because they have all failed in the past. She does admit to eating out frequently. This patient does not exercise because her job and her kids are too demanding. Patient does smoke a half pack of cigarettes per day and consumes low-calorie, caffeinated and alcoholic drinks most days. Her BMI is 32 kg/m^2, and her waist circumference is 38 in (97 cm).

- What classification of overweight and obesity is appropriate for this patient?
- Does she have other risk factors that may contribute to morbidity and/or mortality?
- What additional information do you need to know before creating a treatment plan for this patient?

If weight loss has been achieved and/or maintained for 6 months, further therapy promoting weight loss may be considered. Once maximal weight loss has been attained, any therapy used to promote the weight loss must be sustained in order to prevent weight regain.[6] ❺ *Weight maintenance occurs following successful achievement of weight loss.*

General Approach to Treatment

Since the goals for obesity management are multifactorial, it should be considered a chronic illness where treatment is maintained for life. Any implemented therapy promoting weight loss should focus on behavior modification directed toward both dietary restriction and increased activity in conjunction with the selective use of pharmacologic or surgical intervention. Before initiating therapy, secondary causes of obesity (e.g., hypothyroidism and Cushing's syndrome) must be considered. If no secondary cause exists, the presence of other cardiovascular risk factors and comorbidities must be determined to guide clinical decisions. ❷ *Presence of comorbidities [coronary heart disease (CHD), atherosclerosis, type 2 diabetes mellitus, and sleep apnea) and cardiovascular risk factors (cigarette smoking, hypertension, elevated low-density lipoprotein cholesterol, low high-density lipoprotein cholesterol, impaired fasting glucose, family history of premature CHD, and age] requires identification and aggressive management for overall effective treatment of the overweight or obese patient.* Therapy implemented to minimize associated risk(s) may not enhance weight loss, but weight loss will positively address risk factors. Weight loss should not be initiated in pregnant or lactating patients, decompensated psychiatric patients, or patients in whom reduced caloric intake can exacerbate an acute, serious illness.[6] ❻ *Treatment of obesity includes lifestyle changes (dietary modification, enhanced physical activity, and behavioral therapy), pharmacologic treatment, surgical intervention, or a combination of modalities.*

Nonpharmacologic Therapy

Dietary

A low-calorie diet is essential for weight-loss management in overweight and obese patients. The Step 1 Diet (Table 99–4) is a low-calorie diet (LCD) recommended as part of an obesity education initiative from the National Heart, Lung, and Blood Institute.[6] In general, the Step 1 Diet restricts daily calories to a range of 1000 to 1200 kcal (4184 to 5021 kJ)/day for women weighing less than 165 lb (75 kg) and 1400 to 1600 kcal (5858 to 6694 kJ)/day for all others. However, this daily limit should be considered after assessing a patient's normal daily caloric intake and ensuring that the initial caloric restriction does not exceed 500 to 1000 kcal (2092–4184 kJ)/day. For example, a male patient who consumes 3000 kcal (12.552 kJ)/day should not reduce his daily caloric intake to less than 2000 kcal (8368 kJ)/day when initially implementing a dietary program. Further reduction to the target of 1600 kcal (6694 kJ)/day can be attempted once the patient has reduced calories successfully as initially recommended for a period agreeable by the provider and the patient.[6] Diets too restrictive in calorie reduction are successful initially but fail long term because compliance is difficult to sustain.[26] Therefore, this less aggressive approach promotes gradual weight loss and weight maintenance.

Dietary consumption should be balanced in carbohydrates, protein, and fat. Several diet plans exist that promote weight loss through strict limitation or overabundance of only one macronutrient (e.g., low-fat, low-carbohydrate, or high-protein diets); however, overall energy consumption and expenditure will determine the amount of weight alteration. Consultation with a dietician is recommended when

TABLE 99–4. Low-Calorie Step I Diet[6]

Nutrient	Recommended Intake
Calories[a]	Approximately 500 to 1000 kcal/day (2092 to 4184 kJ/day) reduction from usual intake
Total fat[b]	30% or less of total calories
Saturated fatty acids[c]	8–10% of total calories
Monounsaturated fatty acids	Up to 15% of total calories
Polyunsaturated fatty acids	Up to 10% of total calories
Cholesterol[c]	Less than 300 mg/day
Protein[d]	Approximately 15% of total calories
Carbohydrate[e]	55% or more of total calories
Sodium chloride	No more than 100 mmol/day (approximately 2.4 g of sodium or approximately 6 g of sodium chloride)
Calcium[f]	1000 to 1500 mg/day
Fiber[e]	20 to 30 g/day

[a]A reduction in calories of 500 to 1000 kcal/day (2092 to 4184 kJ/day) will help achieve a weight loss of 1 to 2 lb/week (0.45 to 0.9 kg/week). Alcohol provides unneeded calories and displaces more nutritious foods. Alcohol consumption not only increases the number of calories in a diet but has been associated with obesity in epidemiologic studies as well as in experimental studies. The impact of alcohol calories on a person's overall caloric intake needs to be assessed and appropriately controlled.

[b]Fat-modified foods may provide a helpful strategy for lowering total fat intake but will only be effective if they are also low in calories and if there is no compensation by calories from other foods.

[c]Patients with high blood cholesterol levels may need to use the Step II diet to achieve further reductions in LDL-cholesterol levels; in the Step II diet, saturated fats are reduced to less than 7% of total calories, and cholesterol levels to less than 200 mg/day. All of the other nutrients are the same as in Step I.

[d]Proteins should be derived from plant sources and lean sources of animal protein.

[e]Complex carbohydrates from different vegetables, fruits, and whole grains are good sources of vitamins, minerals, and fiber. A diet rich in soluble fiber, including oat bran, legumes, barley, and most fruits and vegetables, may be effective in reducing blood cholesterol levels. A diet high in all types of fiber may also aid in weight management by promoting satiety at lower levels of calorie and fat intake. Some authorities recommend 20 to 30g of fiber daily, with an upper limit of 35g.

[f]During weight loss, attention should be given to maintaining an adequate intake of vitamins and minerals. Maintenance of the recommended calcium intake of 1000 to 1500 mg/day is especially important for women who may be at risk of osteoporosis.

TABLE 99–5. Examples of Moderate Physical Activity[6]

Common Chores[a,b]	Sporting Activities[a,b]
Washing and waxing a car for 45–60 minutes	Playing volleyball for 45–60 minutes
Washing windows or floors for 45–60 minutes	Playing touch football for 45 minutes
Gardening for 30–45 minutes	Walking 1¾ miles in 35 minutes (20 minute/mile)
Wheeling self in wheelchair for 30–40 minutes	Basketball (shooting baskets) for 30 minutes
Pushing a stroller 1½ miles in 30 minutes	Bicycling 5 miles in 30 minutes
Raking leaves for 30 minutes	Dancing fast (social) for 30 minutes
Walking 2 miles in 30 minutes (15 minute/mile)	Water aerobics for 30 minutes
Shoveling snow for 15 minutes	Swimming laps for 20 minutes
Stairwalking for 15 minutes	Basketball (playing a game) for 15–20 minutes
	Jumping rope for 15 minutes
	Running 1½ miles in 15 minutes (15 minute/mile)

[a]A moderate amount of physical activity is roughly equivalent to physical activity that uses approximately 150 calories of energy per day, or 1000 calories per week.
[b]Some activities can be performed at various intensities; the suggested duration correspond to expected intensity of effort.

implementing a healthy meal plan tailored to the individual's nutritional needs.

Exercise

While diet and exercise contribute to weight loss, combining a low-calorie diet with physical activity results in greater weight loss compared with either therapy alone.[25] Additionally, physical activity can help to prevent weight regain and reduce related cardiovascular risks.[6] Slow titration of both the amount and intensity of physical activity is recommended for most overweight and obese patients.[6] A program that incorporates daily walking is a viable option for most patients (Table 99–5). Consider 10 minutes per day 3 days per week with a target of 30 to 45 minutes most days, if not every day.[6,27] This type and amount of activity equate to a 100 to 200 kcal (418–836 kJ)/day caloric expenditure.[6]

Behavioral

Non-adherence with recommended lifestyle changes may result in unsuccessful weight loss.[6,25] Therefore, eliminating these barriers through behavior modification is necessary to gain maximal benefit from both dietary modification and exercise. Components to successful behavioral modification include, but are not limited to, the following steps:

- Determine the patient's readiness to lose weight and willingness to implement a weight-loss plan.
- Build and nurture the patient-provider partnership.
- Restructure cognitive abilities.
- Set achievable goals.
- Contact the patient frequently.
- Instruct the patient on the importance and technique of self-monitoring.
- Control stimuli that negatively affect weight loss or weight maintenance.
- Reward the patient for any amount of weight loss or avoidance of weight regain.

Pharmacologic Therapy

Pharmacotherapy is not recommended for individuals with a BMI of less than 27 kg/m^2. However, drug therapy, in addition to a healthy lifestyle, is warranted for overweight individuals with other related risks and for obese patients. ❼ *Pharmacotherapy, in addition to lifestyle modification, is reserved for patients with a BMI of 30 kg/m^2 or greater or a BMI of 27 kg/m^2 or greater with other obesity-related risk factors.* Currently available pharmacologic products are classified according to their mechanism of action, which includes the suppression of appetite and the suppression of fat absorption (Table 99–6). Therapy was indicated previously for short-term use; however, as obesity-related risks resurface with weight regain, long-term treatment is recommended to minimize these sequelae. ❽ *Weight likely will be regained if lifestyle changes are not continued indefinitely.* Prolonged use of both fenfluramine and dexfenfluramine monotherapy and fenfluramine and phentermine in combination (Fen-Phen) resulted in cardiac valvular disease.[28] Therefore, only two drugs are currently approved for long-term use in promoting weight loss and preventing weight regain. Sibutramine (Meridia®, Abbott Laboratories) was approved by the Food and Drug Administration (FDA) in 1997, and orlistat (Xenical®, Roche Pharmaceuticals) received FDA approval in 1999. Rimonabant is a new medication entity currently under study in phase III clinical trials.

Sibutramine

Sibutramine and its two active metabolites (M_1 and M_2) exert their effect by inhibiting the reuptake of serotonin, norepinephrine, and dopamine.[29] Appetite becomes suppressed because patients feel a sense of satiety.

The effect of prolonged sibutramine use on morbidity and mortality is unknown. Most studies vary in dose and length, from 1 to 30 mg/day and 3 to 12 months of use, respectively.[29] Weight loss appears proportional to the dose of sibutramine used, with greater weight loss observed using higher doses of sibutramine.[29] In one trial, subjects randomized to placebo lost an average of 1.4 kg compared with an average loss of 2.9 and 5 kg using a 5 and 20 mg/day dose of sibutramine, respectively.[30] Two longer-term studies have documented maximal weight loss following 6 months of sibutramine therapy and sustained weight loss over 12 months of use.[29] Three trials with a study duration of greater than 6 months suggest that

TABLE 99–6. Summary of Approved Pharmacologic Weight-Loss Agents

Drug	Class	Daily Dose	Duration of Therapy
Sibutramine	Noradrenergic/serotonergic agent	5–15 mg	Greater than 3 months[a]
Orlistat	Lipase inhibitor	360 mg	Greater than 3 months[b]
Phentermine	Noradrenergic agent	15–37.5 mg	Up to 6 months
Diethylpropion	Noradrenergic agent	75 mg	Up to 12 months

[a]Efficacy and safety have not been determined beyond 2 years of use.
[b]Efficacy and safety have not been determined beyond 4 years of use.

subjects losing 4 lb within 4 weeks of sibutramine initiation are more likely to achieve long-term weight loss.[29] Conversely, sibutramine may not be effective for patients who do not achieve a weight loss of 4 lb within the initial 4 weeks.

Pediatric use has not been established in patients younger than 16 years of age and thus is not recommended.[29]

Since an increased waist circumference is associated with increased risk for type 2 diabetes mellitus, hyperlipidemia, hypertension, and CVD, a decrease then should reduce risk. A significant dose-related reduction in waist circumference has been reported in 6- and 12-month sibutramine trials.[29] Blood glucose and lipid parameters are not adversely affected, but a small rise in blood pressure and pulse has been observed in clinical trials. On average, the blood pressure increased by 1 to 3 mm Hg, and the heart rate increased by 4 to 5 beats per minute. Larger increases have been observed for both blood pressure and heart rate when higher doses of sibutramine were studied. Sibutramine should be used cautiously in patients with hypertension or other disease states resulting in elevated blood pressure and/or pulse. Sibutramine is not recommended for patients with a history of congestive heart failure, CVD, arrhythmias, or stroke. Blood pressure and heart rate should be measured prior to initiating sibutramine and reassessed at regular intervals. A dose reduction or discontinuation of sibutramine should be considered for patients experiencing a sustained elevation in either blood pressure or heart rate. More common adverse reactions include dry mouth, anorexia, insomnia, constipation, and headache.

Although not evaluated systematically, drugs that exhibit their effect on the central nervous system may interact with sibutramine. Since sibutramine inhibits the reuptake of serotonin, use of this drug in combination with a monoamine oxidase inhibitor (MAOI) can elevate blood levels of serotonin, resulting in a serious, potentially fatal reaction known as the *serotonin syndrome.* This syndrome consists of a collection of symptoms that includes one or more of the following: excitement, hypomania, restlessness, loss of consciousness, confusion, disorientation, anxiety, agitation, motor weakness, **myoclonus,** tremor, **hemiballismus,** hypereflexia, ataxia, dysarthria, incoordination, hyperthermia, shivering, pupillary dilation, diaphoresis, emesis, and tachycardia. Two weeks should elapse between discontinuation of the MAOI (or sibutramine) and initiation of sibutramine (or MAOI) to avoid this potentially serious interaction. Concomitant administration of other serotonergic drugs (e.g., fluoxetine, fluvoxamine, paroxetine, sertraline, and venlafaxine) and sibutramine also should be avoided to eliminate the risk of serotonin syndrome.[29] Co-administration of a decongestant and sibutramine may increase blood pressure or heart rate. Cytochrome P-450 inhibitors, including ketoconazole, erythromycin, and cimetidine, in combination with sibutramine have resulted in increased blood levels of sibutramine; however, the clinical relevance of this is unknown.[29] Highly protein-bound drugs such as warfarin or phenytoin have the potential to interact with sibutramine because it too is highly protein-bound. No data exist to evaluate the extent of this interaction.[29]

Since no human data exist to determine its safe use in pregnant women, sibutramine is not recommended; therefore, women of childbearing potential should use effective methods of contraception while taking sibutramine. Further, sibutramine is not recommended for lactating mothers because its excretion in breast milk is likewise unknown.[29]

Initiate sibutramine at a dose of 10 mg once daily, preferably in the morning without regard to meals. The dose may be increased after 4 weeks to 15 mg once daily if weight-loss goals are not attained. Doses exceeding 15 mg/day are not recommended. For patients intolerant of the 10 mg/day, a dose of 5 mg once a day may be used.[29]

Orlistat

Orlistat promotes and maintains weight loss by acting locally in the gastrointestinal (GI) tract. Orlistat is a chemically synthesized derivative of lipstatin, a natural product of *Streptomyces toxitricini* that inhibits pancreatic and gastric lipases, as well as triglyceride hydrolysis. As a result, undigested triglycerides are not absorbed, causing a caloric deficit and weight loss.[31]

Several studies have reported significant weight loss for patients receiving orlistat 120 mg three times a day compared with placebo.[32,33] Weight maintenance or prevention of weight regain also has been documented with continued orlistat use.[32,34] After 1 year of treatment, 57% of orlistat-treated patients lost at least 5% of their baseline weight.[31] The long-term weight-loss effect on one obesity-related comorbidity was assessed in a large placebo-controlled study. In 3000 obese patients, 21% had impaired glucose tolerance at enrollment.

After 4 years, weight loss was greater and the incidence of new diabetes was lower in patients receiving orlistat.[35]

The effect of orlistat in adolescent patients has been evaluated recently. In a group of 12- to 16-year-old individuals, orlistat (120 mg three times daily) in combination with diet, exercise, and behavior modification exhibited minimal weight increase after 1 year (0.53 kg) compared with placebo-treated patients (3.14 kg). Common adverse reactions observed were fatty or oily stools, oily spotting, oily evacuation, or abdominal pain and/or flatulence with bowel movements. Soft stools, nausea, increased defecation, and fecal incontinence also were noted. Orlistat may be better suited for prevention of weight gain in tolerant adolescents, but more studies are warranted before providing a solid recommendation.[36]

The safety and efficacy of orlistat have not been determined beyond 4 years of use. Minimal systemic effects exist because orlistat acts locally in the GI tract. Thus, common side effects reported include oily spotting, flatus with discharge, fecal urgency, fatty/oily stools, oily evacuation, increased defecation, and fecal incontinence.[31] Other adverse events include bloating, abdominal pain, dyspepsia, nausea, vomiting, diarrhea, and headache.[37]

Orlistat reduces the absorption of fat-soluble vitamins. Daily intake of a multivitamin containing vitamins A, D, E, and K, as well as β-carotene, is recommended. Patients should take the multivitamin 2 hours prior to or after the dose of orlistat.[31] Since availability of vitamin K may decline in patients receiving orlistat therapy, close monitoring of coagulation status should occur with concomitant administration of warfarin.[31] Administration of orlistat in conjunction with cyclosporine can result in decreased cyclosporine plasma levels. To avoid this interaction, cyclosporine should be taken 2 hours preceding or following the dose of orlistat. Additionally, cyclosporine levels should be monitored more frequently.[31]

Pregnant or lactating women should not take orlistat because no data exist to establish safety. Orlistat is contraindicated in patients with chronic malabsorption syndrome or cholestasis.[31]

Initiate orlistat 120 mg three times a day with a well-balanced but reduced-caloric meal containing no more than 30% of calories from fat. Orlistat may be taken during or up to 1 hour after the meal. If a meal is missed or contains little fat, the dose of orlistat may be omitted. Doses above 360 mg/day provide no greater benefit and thus are not recommended.

Rimonabant

Rimonabant is a selective CB1 receptor antagonist that is currently under investigation in phase III trials. CB1 receptors are found in the brain, adipose tissue, the GI tract, pituitary and adrenal glands, sympathetic ganglia, heart, lungs, liver, and bladder.[17,18] Food cravings are diminished following inhibition of this receptor.[19]

A 2-year study is currently being conducted. Results from the first year of this 24-month study have been evaluated. Individuals enrolled are 18 years of age and older with a BMI of greater than 30 kg/m^2 or a BMI greater than 27 kg/m^2 with hypertension or dyslipidemia. Patients are randomized to receive rimonabant 5 mg, rimonabant 20 mg, or placebo. All patients are prescribed a hypocaloric diet. After 1 year, rimonbant showed significant absolute weight reduction compared with placebo (5 mg versus placebo, $p = 0.002$, and 20 mg versus placebo, p less than 0.001). Weight was reduced by 4.8 and 8.6 kg in the 5- and 20-mg rimonabant groups, respectively. Waist circumference decreased by 5.3 and 8.5 cm, respectively, for the two treatment groups. Improvement in blood pressure, lipid concentrations, and insulin resistance has been observed for rimonabant. Adverse events commonly reported include nausea, vomiting, dizziness, arthralgia, headache, anxiety, and diarrhea. Adverse events were more prevalent in the patients taking rimonabant 20 mg compared with those taking rimonabant 5 mg or placebo.[19]

Drug-drug and drug-disease interactions have not been evaluated extensively. One precaution to consider when using rimonabant includes increased GI motility.[19] Increased monitoring of patients with diabetes or hyperlipidemia may be necessary given that decreased insulin resistance, increased glucose tolerance, decreased triglycerides, and increased high-density lipoprotein are observed when CB1 receptors are blocked in adipose tissue.[19]

Phentermine

Phentermine decreases food intake, and hence weight, by increasing norepinephrine and dopamine release in the central nervous system. This drug is indicated for short-term use—no more than a few weeks—in addition to lifestyle modifications in obese patients with a BMI of 30 kg/m^2 or greater or a BMI of 27 kg/m^{2-} or greater in the presence of other risk factors.[38]

A recent meta-analysis evaluated patients at doses of 15 and 30 mg daily. Patients were analyzed for periods of 2 to 24 weeks. The majority of patients enrolled were female, and more than 80% of the patients evaluated received adjunctive modification in lifestyle. An average weight loss of 3.6 kg (7.9 lbs) was demonstrated for patients treated with phentermine compared with placebo. Although modest in amount, this value was statistically significant.[37]

Safety and efficacy have not been determined in pediatric patients.[38]

Common adverse reactions seen with phentermine use include heart palpitations, tachycardia, elevated blood pressure, stimulation, restlessness, dizziness, insomnia, euphoria, dysphoria, tremor, headache, dry mouth, constipation, and diarrhea. Phentermine should be avoided in patients with unstable cardiac status, hypertension, hyperthyroidism, agitated states, or glaucoma. In combination with fenfluramine or dexfenfluramine, pulmonary hypertension and valvular heart disease have been reported. The risk of developing either serious adverse effect cannot be ruled out with use of phentermine alone. Since phentermine is related to the amphetamines, the

potential for abuse is high; thus, this should be kept in mind when selecting this agent as an aid for weight loss.[38]

Phentermine use should be avoided in patients concomitantly receiving or having received an MAOI within the preceding 14 days. Combination therapy with any stimulant or MAOI has the potential for causing hypertensive crisis. Alcohol is not recommended for patients prescribed phentermine.[38]

Since no studies have been conducted in pregnant women, phentermine should be administered only when clearly indicated. Owing to the potential for severe adverse effects in nursing infants, a decision to stop the drug or discontinue nursing must be made.[38]

Phentermine is available as an immediate-release and a sustained-release product. In conjunction with a healthy lifestyle, 30 to 37.5 mg of phentermine is administered once daily, typically before breakfast or 1 to 2 hours following the morning meal. The dosage should be individualized; some patients may be managed adequately at 15 to 18.75 mg daily, whereas a dose of 18.75 mg twice daily may be used to minimize side effects, excluding insomnia. To lessen the risk of insomnia, dosing phentermine in the evening should be avoided. Timed-release preparations of phentermine are not recommended because phentermine's half-life is approximately 20 hours.[39]

Diethylpropion

This sympathomimetic amine exudes similar pharmacologic activity as the amphetamines, resulting in central nervous system stimulation and appetite suppression. This drug is indicated for short-term use in conjunction with a reduced-calorie diet and exercise in obese patients with a BMI of 30 kg/m^2 or greater following failed attempts of diet and exercise alone.[40]

One meta-analysis reviewed patients receiving doses of 75 mg daily during periods of 6 to 52 weeks. Similar to study characteristics for phentermine, the majority of patients enrolled were female, and all patients implemented adjunctive lifestyle modifications. The average additional weight loss observed was 3 kg (6.6 lbs) compared with diet and exercise alone, resulting in a borderline statistically significant difference.[37]

Safety and effectiveness of diethylpropion have not been established in patients under the age of 16; therefore, its use is not recommended.[40]

Use of diethylpropion for a period longer than 3 months is associated with an increased risk for development of pulmonary hypertension. When used as directed, reported common central nervous system adverse effects included overstimulation, restlessness, dizziness, insomnia, euphoria, dysphoria, tremor, headache, jitteriness, anxiety, nervousness, depression, drowsiness, malaise, **mydriasis,** and blurred vision. In addition, diethylpropion can decrease seizure threshold, subsequently increasing a patient's risk for an epileptic event. Other organ systems also can adversely be affected, resulting in tachycardia, elevated blood pressure, palpitations, dry mouth, abdominal discomfort, constipation, diarrhea, nausea, vomiting, impotence or change in libido, gynecomastia, bone marrow suppression, agranulocytosis, and leukopenia. Diethylpropion is contraindicated in patients with pulmonary hypertension, advanced arteriosclerosis, severe hypertension, hyperthyroidism, agitated states, or glaucoma. Since diethylpropion is related to the amphetamines, the potential for abuse is high, and therefore, its use is contraindicated in patients with a history of substance abuse.[40]

As with phentermine, use of diethypropion should be avoided in patients concomitantly receiving or having received an MAOI within the preceding 14 days to prevent hypertensive crisis. Combination with other anorectic agents should be avoided.[40]

Patient Encounter, Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH
- Hypertension for 3 years, currently at goal
- Depression

FH
Father alive at 58 years of age. Mother also alive with a history of obesity and depression.

SH
Registered nurse. Drinks one beer nightly after work. Smokes a half pack of cigarettes per day.

Current Meds
- Irbesartan 150 mg once daily
- Hydrochlorothiazide 25 mg once daily
- Fluoxetine 20 mg once daily

ROS
(+) heartburn, regurgitation; (–) chest pain, nausea, vomiting, diarrhea, change in appetite, SOB, or cough

PE
- **VS:** Blood pressure 120/82, heart rate 82, respiratory rate 16, temperature 37°C (98.6°F)
- **Weight:** 240 lb (109 kg)
- **Height:** 64 in (163 cm)
- **Waist circumference:** 38 in (97 cm)
- **Cardiovascular:** Regular rate and rhythm; no murmurs, rubs, or gallops
- **Abd:** Obese, soft, non-tender, non-distended; (+) bowel sounds
- **Exts:** (–) edema
- **Laboratory:** All values are within normal limits.
- **Electrocardiogram:** No evidence of past ischemia.

- Given this additional information, what is your assessment of this patient?
- Identify your treatment goals for the patient.
- What nonpharmacologic and pharmacologic alternatives are available for this patient?

No adequate studies have been conducted using diethylpropion in pregnant women; therefore, the drug should be used only if the benefit outweighs potential fetal risk. Use with caution in nursing mothers because the drug is excreted in breast milk.[40]

Diethylpropion is available as both an immediate-release and a controlled-release product. In conjunction with a reduced-calorie diet and/or exercise, dose diethylpropion (immediate-release) 25 mg three times a day before meals or 75 mg (controlled-release) once a day, usually midmorning.[40]

Other noradrenergic agents not approved by the Food and Drug Administration (FDA) and subsequently not recommended for weight loss include amphetamine salts (e.g., ephedrine and phenylpropanolamine), methamphetamine, and benzophetamine. Although the selective serotonin reuptake inhibitors (e.g., fluoxetine and sertraline) appear to promote weight loss, further study is warranted given the inconsistent results available to date. Dietary supplements containing ephedra or ephedrine alkaloids are banned from sale following the FDA's final ruling.[41] However, ephedrine is available in over-the-counter and prescription formulations for the treatment of bronchospasm, nasal congestion, hypotension/shock, and cardiac arrhythmias. Herbal products lack consistency in labeling, vary in effect, and present potentially dangerous health risks. Herbal products are not recommended.

Surgical Intervention

Weight-reduction (bariatric) surgery is an option for patients whose BMIs are 40 kg/m^2 or greater or 35 kg/m^2 or greater in the presence of other comorbid conditions and who have failed more conventional approaches to weight loss.[6,42] ❾ *Surgery is warranted when other treatment attempts have failed in severely obese patients (BMI of 40 kg/m^2 or greater or35 kg/m^2 or greater with obesity-related risk factors).* There are two basic surgical techniques: (1) gastric bypass—the full partitioning of the proximal gastric segment into a jejunal loop of the intestine—whereby weight loss is induced through both malabsorption of food and limited gastric capacity, and (2) gastroplasty—incomplete partitioning at the proximal gastric segment with the placement of a gastric outlet stoma of set diameter—which promotes weight loss by limiting gastric capacity.[6,42]

A recent meta-analysis of surgical options for obesity reported that surgical treatment produces a weight loss of 20 to 30 kg (44–66 lbs) that is maintained for 5 to 10 years. Additionally, favorable outcomes for comorbid conditions are observed following surgery. When evaluating the various types of surgery available, pooled data concluded that gastric bypass produces a 10 kg (22 lbs) greater weight loss at 12 and 36 months than gastroplasty procedures. Complications are inherent to any surgical procedure. The more common bariatric surgery complications are respiratory problems, wound formation, wound infections, hernia development, deep venous thrombosis, and pulmonary embolism. No differences were observed in mortality rates among various surgical procedures. Postoperative weight loss is much greater when compared with pharmacologic therapies, but no comparative trials exist.[43]

Candidates for bariatric surgery should be part of an integrated program of health education, diet, exercise, and behavioral modification before and following surgery.[6] Patients must understand and commit to a substantial change in eating patterns to maintain long-term weight reduction.[43]

SPECIAL POPULATION CONSIDERATIONS

Childhood/Adolescent Patients with Obesity

Although the prevalence of overweight and obesity is increasing among children and adolescents, current guidelines do not incorporate treatment recommendations because long-term outcome data are limited. As such, prevention of childhood obesity is a national priority for the National Academies' Institute of Medicine (IOM) and cannot succeed without the engagement of those entities (e.g., family, school, and community) that affect the environment and behavior of American youths. The IOM report establishes steps to confront this epidemic and includes the involvement of the federal, state, and local governments; industry and media; health care professionals; community organizations; state and local schools; and parents and families.[44]

The BMI should be calculated for all children and adolescents yearly to identify excessive weight gain relative to linear growth. Education and encouragement should be provided to parents or caregivers to promote healthy eating patterns and self-regulation of food intake. Examples include support for healthy snack selections and parent (caregiver) modeling of nutritious food consumption. Routine physical activity should be advocated, as well as limiting television viewing and video time to 2 hours daily. If children or adolescent patients are overweight or obese, assessment of obesity-related risk factors also should occur.[13]

Elderly Patients with Obesity

The prevalence of obesity in older adults is increasing; therefore, it should not be surprising that more cardiovascular risk factors are present in this group of individuals. Additionally, obesity is a major predictor of functional limitation and mobility problems in older persons. Age alone should not prejudice the clinician from treating geriatric patients, whereas the benefits of cardiovascular health and functionality should be considered. Treatments should be initiated that minimize adverse effects on bone health and nutritional status and should include dietary and activity modifications.[6]

Patient Encounter, Part 3: Creating a Care Plan

Based on the information presented, create a care plan for this patient's obesity. Your plan should include (1) a statement of the drug-related problems, (2) the goals of therapy, (3) a detailed patient-specific therapeutic plan, and (4) a monitoring plan that would determine if goals are achieved and adverse effects avoided.

OUTCOME EVALUATION

Successful management of overweight and obesity is determined by the ability the treatment plan has to (1) prevent weight gain, (2) reduce and maintain a lower body weight, and (3) decrease the risk of obesity-related comorbidities. Since weight is necessary to calculate the BMI, it, as well as waist circumference, should be determined. Obesity management may encompass more than weight loss or maintenance in the presence of other conditions; other pertinent parameters should be assessed at baseline. The presence of hypertension, type 2 diabetes, hyperlipidemia, CAD, sleep apnea, hypothyroidism, osteoarthritis, gallbladder disease, gout, or cancer should be determined. Blood pressure and heart rate should be measured prior to implementation of any therapy. Certain laboratory parameters also should be assessed. A basic metabolic panel, liver function tests, complete blood count, fasting lipid profile, full thyroid function tests, and other laboratory studies as deemed necessary should be obtained. An electrocardiogram should be performed if recent results are unknown.

The patient should be assessed in 2 to 4 weeks following the implementation of therapy to determine effectiveness of and intolerance to treatment. Monthly visits are encouraged during the first 3 months. More frequent follow-up may be necessary in the presence of other medical conditions. Less frequent follow-up occurs after 6 months of effective weight-loss therapy.

At each follow-up visit, compliance with a healthy lifestyle should be determined, as well as measurement of physical parameters, including weight, blood pressure, and heart rate. Waist circumference should be measured intermittently. A complete assessment also would include identification of adverse drug reactions or drug interactions if weight-loss medications have been initiated.

Once the patient has achieved the recommended weight loss, he or she then enters the weight-maintenance phase, which includes continued contact for education, guidance, and risk-factor assessment. If weight loss is not attained, further assessment is required to determine why the goals of therapy have not been met. The interaction should be directed toward determining the motivation to lose weight, balance between caloric intake and physical activity, adherence to behavioral therapy, and determination of psychological stressors present.

Patient Care and Monitoring

1. Determine if history of BMI greater than 25 kg/m^2. If unavailable or BMI unknown, obtain weight, height, and waist circumference. Calculate the BMI. Assess the patient's willingness to lose weight.
2. If the BMI is greater than 25 kg/m^2 or waist circumference is greater than 35 in (89 cm) for females or 40 in (102 cm) for male patients, determine the presence of risk factors.
3. Prevention of weight gain is recommended in all patients with a BMI of 25 kg/m^2 or greater. Weight loss is indicated for patients with a BMI of 25 to 29.9 kg/m^2 or an elevated waist circumference with two or more risk factors or for any patient with a BMI of 30 kg/m^2 or greater.
4. Educate the patient regarding a healthy lifestyle, one that includes a balance between caloric intake and energy expenditure, as well as suggest methods to modify behavior.
5. If the patient presents with a desire to lose weight, develop treatment goals and weight-loss strategies (e.g., nonpharmacologic, drug therapy, or surgical intervention), including control of associated risks.
6. Close monitoring should follow to assess weight, BMI, waist circumference, and presence of complications related to the treatment plan. If weight-loss goals are not attained, determine reasons for failure.

ABBREVIATIONS

BMI:	body mass index
CAD:	coronary artery disease
CB1:	cannabinoid receptor
CHD:	coronary heart disease

APPENDIX A CONVERSION FACTORS AND ANTHROPOMETRICS*

CONVERSION FACTORS

SI Units

SI (*le Systéme International d'Unités*) units are used in *many* countries to express clinical laboratory and serum drug concentration data. Instead of employing units of mass (such as micrograms), the SI system uses moles (mol) to represent the amount of a substance. A molar solution contains 1 mol (the molecular weight of the substance in grams) of the solute in 1 L of solution. The following formula is used to convert units of mass to moles (mcg/mL to μmol/L or, by substitution of terms, mg/mL to mmol/L or ng/mL to nmol/L).

Micromoles per Liter (μmol/L)

$$\mu\text{mol/L} = \frac{\text{drug concentration (mcg/mL)} \times 1000}{\text{molecular weight of drug (g/mol)}}$$

Milliequivalents

An equivalent weight of a substance is that weight which will combine with or replace 1 g of hydrogen; a milliequivalent is 1/1000 of an equivalent weight.

Milliequivalents per Liter (mEq/L)

$$\text{mEq/L} = \frac{\text{weight of salt (g)} \times \text{valence of ion} \times 1000}{\text{molecular weight of salt}}$$

$$\text{Weight of salt (g)} = \frac{\text{mEq/L} \times \text{molecular weight of salt}}{\text{valence of ion} \times 1000}$$

Approximate Milliequivalents

Weights of Selected Ions

Salt	mEq/g Salt	mg Salt/mEq
Calcium carbonate ($CaCO_3$)	20.0	50.0
Calcium chloride ($CaCl_2 \cdot 2H_2O$)	13.6	73.5
Calcium gluceptate ($Ca[C_7H_{13}O_8]_2$)	4.1	245.2
Calcium gluconate ($Ca[C_6H_{11}O_7]_2 \cdot H_2O$)	4.5	224.1
Calcium lactate ($Ca[C_3H_5O_3]_2 \cdot 5H_2O$)	6.5	154.1
Magnesium gluconate ($Mg[C_6H_{11}O_7]_2 \cdot H_2O$)	4.6	216.3
Magnesium oxide (MgO)	49.6	20.2
Magnesium sulfate ($MgSO_4$)	16.6	60.2
Magnesium sulfate ($MgSO_4 \cdot 7H_2O$)	8.1	123.2
Potassium acetate ($K[C_2H_3O_2]$)	10.2	98.1
Potassium chloride (KCl)	13.4	74.6
Potassium citrate ($K_3[C_6H_5O_7] \cdot H_2O$)	9.2	108.1
Potassium iodide (KI)	6.0	166.0
Sodium acetate ($Na[C_2H_3O_2]$)	12.2	82.0
Sodium acetate ($Na[C_2H_3O_2] \cdot 3H_2O$)	7.3	136.1
Sodium bicarbonate ($NaHCO_3$)	11.9	84.0
Sodium chloride ($NaCl$)	17.1	58.4
Sodium citrate ($Na_3[C_6H_5O_7] \cdot 2H_2O$)	10.2	98.0
Sodium iodide (NaI)	6.7	149.9
Sodium lactate ($Na[C_3H_5O_3]$)	8.9	112.1
Zinc sulfate ($ZnSO_4 \cdot 7H_2O$)	7.0	143.8

Valences and Atomic Weights of Selected Ions

Substance	Electrolyte	Valence	Molecular Weight
Calcium	Ca^{2+}	2	40.1
Chloride	Cl^-	1	35.5
Magnesium	Mg^{2+}	2	24.3
Phosphate (pH = 7.4)	HPO_4^- (80%) $H_2PO_4^-$ (20%)	1.8	96.0[a]
Potassium	K^+	1	39.1
Sodium	Na^+	1	23.0
Sulfate	SO_4^-	2	96.0[a]

[a]The molecular weight of phosphorus only is 31; that of sulfur only is 32.1.

Anion Gap

The anion gap is the concentration of plasma anions not routinely measured by laboratory screening. It is useful in the evaluation of acid-base disorders. The anion gap is greater with increased plasma concentrations of endogenous species (e.g., phosphate, sulfate, lactate, and ketoacids) or exogenous species (e.g., salicylate, penicillin, ethylene glycol, ethanol, and methanol). The formulas for calculating the anion gap are as follows:

$$\text{Anion gap} = (Na^+ + K^+) - (Cl^- + HCO_3^-)$$

or

$$\text{Anion gap} = Na^+ - (Cl^- + HCO_3^-)$$

where the expected normal value for the first equation is 11 to 20 mmol/L, and the expected normal value for the second equation is 7 to 16 mmol/L. Note that there is a variation in the upper and lower limits of the normal range.

Temperature

Fahrenheit to Centigrade: (°F – 32) × 5/9 = °C
Centigrade to Fahrenheit: (°C × 9/5) + 32 = °F
Centigrade to Kelvin: °C + 273 = °K

Calories

1 Calorie = 1 kilocalorie = 1000 calories = 4.184 kilojoules (kJ)
1 kilojoule = 0.239 calories = 0.239 kilocalories = 239 calories

Weights and Measures

Metric Weight Equivalents

1 kilogram (kg) = 1000 grams
1 gram (g) = 1000 milligrams
1 milligram (mg) = 0.001 gram
1 microgram (mcg, µg) = 0.001 milligram
1 nanogram (ng) = 0.001 microgram
1 picogram (pg) = 0.001 nanogram
1 femtogram (fg) = 0.001 picogram

Metric Volume Equivalents

1 liter (L) = 1000 milliliters
1 deciliter (dL) = 100 milliliters
1 milliliter (mL) = 0.001 liter
1 microliter (µL) = 0.001 milliliter
1 nanoliter (nL) = 0.001 microliter
1 picoliter (pL) = 0.001 nanoliter
1 femtoliter (fL) = 0.001 picoliter

Apothecary Weight Equivalents

0.6 milligram = 1/100 grain
0.8 milligram = 1/80 grain
1 milligram = 1/65 grain

Metric Length Equivalents

2.54 cm = 1 inch
30.48 cm = 1 foot
1.6 km = 1 mile

ANTHROPOMETRICS

Creatinine Clearance Formulas

Formulas for Estimating Creatinine Clearance in Patients with Stable Renal Function

Cockroft-Gault Formula

Adults (age 18 years and older)[1]:

$$\text{CrCl (males)} = \frac{(140 - \text{age}) \times \text{weight}}{Cr_s \times 72}$$

$$\text{CrCl (females)} = 0.85 \times \text{above value}^*$$

*Some studies suggest that the predictive accuracy of this formula for women is better *without* the correction factor of 0.85.

where CrCl is creatinine clearance (in mL/minute), Cr_s is serum creatinine (in mg/dL), age is in years, and weight is in kilograms.

Children (age 1 to 18 years)[2]:

$$\text{CrCl} = \frac{0.48 \times \text{height} \times \text{BSA}}{Cr_s \times 1.73}$$

where BSA is body surface area (in m^2), CrCl is creatinine clearance (in mL/minute), Cr_s is serum creatinine (in mg/dL), and height is in centimeters.

Formula for Estimating Creatinine Clearance from a Measured Urine Collection

$$\text{CrCl (mL/minute)} = \frac{U \times V^*}{P \times T}$$

where U is the concentration of creatinine in a urine specimen (in same units as P), V is the volume of urine (in mL), P is the concentration of creatinine in serum at the midpoint of the urine collection period (in same units as U), and T is the time of the urine collection period in minutes (e.g., 6 hours = 360 minutes; 24 hours = 1440 minutes).

*The product of $U \times V$ equals the production of creatinine during the collection period and, at steady state, should equal 20 to 25 mg/kg per day for ideal body weight (IBW) in males and 15 to 20 mg/kg per day for IBW in females. If it is less than this, inadequate urine collection may have occurred, and CrCl will be underestimated.

MDRD Formula for Estimating Glomerular Filtration Rate (from the Modification of Diet in Renal Disease Study)[3]

Conventional calibration MDRD equation [used only with those creatinine methods that have *not* been recalibrated to be traceable to isotope dilution mass spectrometry (IDMS)]

For creatinine in mg/dL:

$$X = 186\ \text{creatinine}^{-1.154} \times \text{age}^{-0.203} \times \text{constant}$$

For creatinine in µmol/L:

$$X = 32788 \times \text{creatinine}^{-1.154} \times \text{age}^{-0.203} \times \text{constant}$$

where X is the glomerular filtration rate (GFR), constant for white males is 1 and for females is 0.742, and constant for African Americans is 1.21. Creatinine levels in µmol/L can be converted to mg/dL by dividing by 88.4.

IDMS-Traceable MDRD Equation (Used Only with Creatinine Methods that Have Been Recalibrated to Be Traceable to IDMS)

For creatinine in mg/dL:

$$X = 175 \times \text{creatinine}^{-1.154} \times \text{age}^{-0.203} \times \text{constant}$$

For creatinine in µmol/L:

$$X = 175 \times (\text{creatinine}/88.4)^{-1.154} \times \text{age}^{-0.203} \times \text{constant}$$

where X is the glomerular filtration rate (GFR), constant for white males is 1 and for females is 0.742, and constant for African Americans is 1.21.

Ideal Body Weight (IBW)

IBW is the weight expected for a nonobese person of a given height. The IBW formulas below and various life insurance tables can be used to estimate IBW. Dosing methods described in the literature may use IBW as a method in dosing obese patients.

Adults (age 18 years and older)[4]:

IBW (males) = 50 + (2.3 × height in inches over 5 ft)
IBW (females) = 45.5 + (2.3 × height in inches over 5 ft)

where IBW is in kilograms.

Children (age 1 to 18 years)[2]:
Under 5 feet tall:

$$\text{IBW} = \frac{\text{height}^2 \times 1.65}{1000}$$

where IBW is in kilograms and height is in centimeters.

Five feet or taller:

IBW (males) = 39 + (2.27 × height in inches over 5 ft)
IBW (females) = 42.2 + (2.27 × height in inches over 5 ft)

where IBW is in kilograms.

APPENDIX B COMMON LABORATORY TESTS

The following table is an alphabetical listing of some common laboratory tests and their reference ranges for adults as measured in plasma or serum (unless otherwise indicated). Reference values differ among laboratories, so readers should refer to the published reference ranges used in each institution. For some tests, both SI units and conventional units are reported.

Laboratory	Conventional Units	Conversion Factor	SI Units
Acid phosphatase			
Male	2–12 units/L	16.7	33–200 nkat/L
Female	0.3–9.2 units/L	16.7	5–154 nkat/L
Activated partial thromboplatin time (aPTT)	25–40 s		
Adrenocorticotropic hormone (ACTH)	15–80 pg/mL or ng/L	0.2202	3.3–17.6 pmol/L
Alanine aminotransferase (ALT, SGPT)	7–53 IU/L	0.01667	0.12–0.88 µkat/L
Albumin	3.5–5.0 g/dL	10	35–50 g/L
Albumin:creatinine ratio (urine)			
Normal	Less than 30 mg/g creatinine		
Microalbuminuria	30–300 mg/g creatinine		
Proteinuria	Greater than 300 mg/g creatinine		
or	or		
Normal			
Male	Less than 2.0 mg/mmol creatinine		
Female	Less than 2.8 mg/mmol creatinine		
Microalbuminuria			
Male	2.0–20 mg/mmol creatinine		
Female	2.8–28 mg/mmol creatinine		
Proteinuria			
Male	Greater than 20 mg/mmol creatinine		
Female	Greater than 28 mg/mmol creatinine		
Aldosterone			
Supine	Less than 16 ng/dL	27.7	Less than 444 pmol/L
Upright	Less than 31 ng/dL	27.7	Less than 860 pmol/L
Alkaline phosphatase			
10–15 years	130–550 IU/L	0.01667	2.17–9.17 µkat/L
16–20 years	70–260 IU/L	0.01667	1.17–4.33 µkat/L
Greater than 20 years	38–126 IU/L	0.01667	0.13–2.10 µkat/L
Alpha-fetoprotein (AFP)	Less than 15 ng/mL	1	Less than 15 mcg/L
$Alpha_1$-antitrypsin	80–200 mg/dL	0.01	0.8–2.0 g/L
Amikacin, therapeutic	15–30 mg/L peak	1.71	25.6–51.3 µmol/L peak
	Less than or equal to 8 mg/L trough		Less than or equal to 13.7 µmol/L trough
Amitriptyline	80–200 ng/ml or mcg/L	3.4	272–680 nmol/L
Ammonia (plasma)	15.33–56.20 mcg NH_3/dL	0.5872	9–33 µmol NH_3/L
Amylase	25–115 IU/L	0.01667	0.42–1.92 µkat/L
Androstenedione	50–250 ng/dL	0.0349	1.7–8.7 nmol/L
Angiotensin-converting enzyme	15–70 units/L	16.67	250–1167 nkat/L
Anion gap	7–16 mEq/L	1	7–16 mmol/L
Anti–double-stranded DNA (anti-ds DNA)	Negative		
Anti-HAV	Negative		
Anti-HBc	Negative		
Anti-HBs	Negative		
Anti-HCV	Negative		
Anti–Sm antibody	Negative		
Antinuclear antibody (ANA)	Negative

Laboratory	Conventional Units	Conversion Factor	SI Units
Apolipoprotein A-1			
Male	95–175 mg/dL	0.01	0.95–1.75 g/L
Female	100–200 mg/dL	0.01	1.0–2.0 g/L
Apolipoprotein B			
Male	50–110 mg/dL	0.01	0.5–1.10 g/L
Female	50–105 mg/dL	0.01	0.5–1.05 g/L
Aspartate aminotransferase (AST, SGOT)	11–47 IU/L	0.01667	0.18–0.78 µkat/L
$Beta_2$-microglobulin	Less than 0.2 mg/dL	10	2 mg/L
Bicarbonate	22–26 mEq/L	1	22–26 mmol/L
Bilirubin			
Total	0.3–1.1 mg/dL	17.1	5.13–18.80 µmol/L
Direct	0–0.3 mg/dL	17.1	0–5.1 µmol/L
Indirect	0.1–1.0 mg/dL	17.1	1.71–17.1 µmol/L
Bleeding time	3–7 minutes		
Blood gases (arterial)			
pH	7.35–7.45	1	7.35–7.45
P_{O_2}	80–105 mm Hg	0.133	10.6–14.0 kPa
P_{CO_2}	35–45 mm Hg	0.133	4.7–6.0 kPa
HCO_3	22–26 mEq/L	1	22–26 mmol/L
O_2 saturation	Greater than or equal to 95%	0.01	0.95
Blood urea nitrogen	8–25 mg/dL	0.357	2.9–8.9 mmol/L
B-type natriuretic peptide (BNP)	0–99 pg/mL	1	0–99 ng/L
BUN-to-creatinine ratio	10:1 to 20:1		
C-peptide	0.51–2.70 ng/mL	330 0.33	170–900 pmol/L or 0.172–0.900 nmol/L
C-reactive protein	Less than 0.8 mg/dL	10	Less than 8 mg/L
CA-125	Less than 35 units/mL	1	Less than 35 kilounits/L
CA 15-3	Less than 30 units/mL	1	Less than 30 kilounits/L
CA 19-9	Less than 37 units/mL	1	Less than 37 kilounits/L
CA 27-29	Less than 38 units/mL	1	Less than 38 kilounits/L
Calcium			
Total	8.6–10.3 mg/dL	0.25	2.15–2.58 mmol/L
	4.3–5.16 mEq/L	0.50	2.15–2.58 mmol/L
Ionized	4.5–5.1 mg/dL	0.25	1.13–1.28 mmol/L
	2.26–2.56 mEq/L	0.50	1.13–1.28 mmol/L
Carbamazepine, therapeutic	4–12 mg/L	4.23	17–51 µmol/L
Carboxyhemoglobin (nonsmoker)	Less than 2%	0.01	Less than 0.02
Carcinoembryonic antigen (CEA)			
Nonsmoker	Less than 2.5 ng/mL	1	Less than 2.5 mcg/L
Smoker	Less than 5 ng/mL		Less than 5 mcg/L
Cardiac troponin I (see troponin I)	Variable ng/mL	1	Variable mcg/L
CD4 lymphocyte count	31–61% of total lymphocytes		
CD8 lymphocyte count	18–39% of total lymphocytes		
Cerebrospinal fluid (CSF)			
Pressure	75–175 mm H_2O		
Glucose	40–70 mg/dL	0.0555	2.2–3.9 mmol/L
Protein	15–45 mg/dL	0.01	0.15–0.45 g/L
WBC	Less than 10/mm^3		
Ceruloplasmin	18–45 mg/dL	10 0.063	180–450 mg/L 1.1–2.8 µmol/L
Chloride	97–110 mEq/L	1	97–110 mmol/L
Cholesterol			
Desirable	Less than 200 mg/dL	0.0259	Less than 5.18 mmol/L
Borderline high	200–239 mg/dL	0.0259	5.18–6.19 mmol/L
High	Greater than or equal to 240 mg/dL	0.0259	Greater than or equal to 6.2 mmol/L
Chorionic gonadotropin (β-hCG)	Less than 5 milliunits/mL	1	Less than 5 units/L
Clozapine	Minimum trough 300–350 ng/mL or mcg/L	3.06	918–1071 nmol/L
CO_2 content	22–30 mEq/L	1	22–30 mmol/L
Complement component 3 (C3)	70–160 mg/dL	0.01	0.7–1.6 g/L
Complement component 4 (C4)	20–40 mg/dL	0.01	0.2–0.4 g/L

Laboratory	Conventional Units	Conversion Factor	SI Units
Copper	70–150 mcg/dL	0.157	11–24 µmol/L
Cortisol (fasting, morning)	5–25 mcg/dL	27.6	138–690 nmol/L
Cortisol (free, urinary)	10–100 mcg/day	2.76	28–276 nmol/day
Creatine kinase			
Male	30–200 IU/L	0.01667	0.50–3.33 µkat/L
Female	20–170 IU/L	0.01667	0.33–2.83 µkat/L
MB fraction	0–7 IU/L	0.01667	0.0–0.12 µkat/L
Creatinine clearance (CrCl) (urine)	85–135 mL/minute/1.73 m^2	0.00963	0.82–1.3 mL/s/m^2
Creatinine			
Male 4–20 years	0.2–1.0 mg/dL	88.4	18–88 µmol/L
Female 4–20 years	0.2–1.0 mg/dL	88.4	18–88 µmol/L
Male (adults)	0.7–1.3 mg/dL	88.4	62–115 µmol/L
Female (adults)	0.6–1.1 mg/dL	88.4	53–97 µmol/L
Cyclosporin			
Renal transplant	100–300 ng/mL or mcg/L	0.832	83–250 nmol/L
Cardiac, liver, or pancreatic transplant	200–350 ng/mL or mcg/L	0.832	166–291 nmol/L
Cryptococcal antigen	Negative		
D-dimers	Less than 250 ng/mL	1	Less than 250 mcg/L
Desipramine	75–300 ng/mL or mcg/L	3.75	281–1125 mmol/L
Dexamethasone suppression test (DST) (overnight)	8:00 am cortisol less than 5 mcg/dL	0.0276	Less than 0.14 µmol/L
DHEAS			
Male	170–670 mcg/dL	0.0271	4.6–18.2 µmol/L
Female			
Premenopausal	50–540 mcg/dL	0.0271	1.4–14.7 µmol/L
Postmenopausal	30–260 mcg/dL	0.0271	0.8–7.1 µmol/L
Digoxin, therapeutic	0.5–1.0 ng/mL or mcg/L	1.28	0.6–1.3 nmol/L
Erythrocyte count (blood) See under red blood cell count			
Erythrocyte sedimentation rate (ESR)			
Westergren			
Male	0–20 mm/hour		
Female	0–30 mm/hour		
Wintrobe			
Male	0–9 mm/hour		
Female	0–15 mm/hour		
Erythropoietin	2–25 mIU/mL	1	2–25 IU/L
Estradiol			
Male	10–36 pg/mL	3.67	37–132 pmol/L
Female	34–170 pg/mL	3.67	125–624 pmol/L
Ethanol, legal intoxication	Greater than or equal to 50–100 mg/dL	0.217	10.9–21.7 mmol/L
	Greater than or equal to 0.05–0.1%	217	
Ethosuccimide, therapeutic	40–100 mg/L or mcg/mL	7.08	283–708 µmol/L
Factor VIII or factor IX			
Severe hemophilia	Less than 1 IU/dL	0.01	Less than 0.01 units/mL
Moderate hemophilia	1–5 IU/dL	0.01	0.01–0.05 units/mL
Mild hemophilia	Greater than 5 IU/dL	0.01	Greater than 0.05 units/mL
Usual adult levels	60–140 IU/dL	0.01	0.60–1.40 units/mL
Ferritin			
Male	20–250 ng/mL	1	20–250 mcg/L
Female	10–150 ng/mL	1	10–150 mcg/L
Fibrin degradation products (FDP)	2–10 mg/L		
Fibrinogen	200–400 mg/dL	0.01	2.0–4.0 g/L
Folate (plasma)	3.1–12.4 ng/mL	2.266	7.0–28.1 nmol/L
Folic acid (RBC)	125–600 ng/mL	2.266	283–1360 nmol/L
Follicle-stimulating hormone (FSH)			
Male	1–7 mIU/mL	1	1–7 IU/L
Female			
Follicular phase	1–9 mIU/mL	1	1–9 IU/L
Midcycle	6–26 mIU/mL	1	6–26 IU/L
Luteal phase	1–9 mIU/mL	1	1–9 IU/L
Postmenopausal	30–118 mIU/mL	1	30–118 IU/L

Laboratory	Conventional Units	Conversion Factor	SI Units
Free thyroxine index (FT_4I)	6.5–12.5		
Gamma glutamyl transferase (GGT)	0–30 IU/L	0.01667	0–0.5 µkat/L
Gastrin (fasting)	0–130 pg/mL	1	0–130 ng/L
Gentamicin, therapeutic	4–10 mg/L peak Less than or equal to 2 mg/L trough	2.09	8.4–21 µmol/L peak Less than or equal to 4.2 µmol/L trough
Globulin	2.3–3.5 g/dL	10	23–35 g/L
Glucose (fasting, plasma)	65–109 mg/dL	0.0555	3.6–6.00 mmol/L
Glucose, two hour postprandial blood (PPBG)	Less than 140 mg/dL	0.0555	Less than 7.8 mmol/L
Granulocyte count	$1.8–6.6 \times 10^3/\mu L$	10^6	$1.8–6.6 \times 10^9/L$
Growth hormone (fasting)			
Male	Less than 5 ng/mL	1	Less than 5 mcg/L
Female	Less than 10 ng/mL	1	Less than 10 mcg/L
Haptoglobin	60–270 mg/dL	0.01	0.6–2.7 g/L
HBeAg	Negative		
HbsAg	Negative		
HBV DNA	Negative		
Hematocrit			
Male	40.7–50.3%	0.01	0.407–0.503
Female	36.1–44.3%	0.01	0.361–0.443
Hemoglobin (blood)			
Male	13.8–17.2 g/dL	10 Alternate SI: 0.62	138–172 g/L 8.56–10.67 mmol/L
Female	12.1–15.1 g/dL	10 Alternate SI: 0.62	121–151 g/L 7.5–9.36 mmol/L
Hemoglobin A1c	4.0–6.0%	0.01	0.04–0.06
Heparin			
Via protamine titration method	0.2–0.4 mcg/mL		
Via anti-factor Xa assay	0.3–0.7 mcg/mL		
High-density lipoprotein (HDL) cholesterol	Greater than 35 mg/dL	0.0259	Greater than 0.91 mmol/L
Homocysteine	3.3–10.4 µmol/L		
Ibuprofen			
Therapeutic	10–50 mcg/mL	4.85	49–243 µmol/L
Toxic	100–700 mcg/mL or more	4.85	485–3395 µmol/L or more
Imipramine, therapeutic	100–300 ng/mL or mcg/L	3.57	357–1071 nmol/L
Immunoglobulin A (IgA)	85–385 mg/dL	0.01	0.85–3.85 g/L
Immunoglobulin G (IgG)	565–1765 mg/dL	0.01	5.65–17.65 g/L
Immunoglobulin M (IgM)	53–375 mg/dL	0.01	0.53–3.75 g/L
Insulin (fasting)	2–20 microunits/mL or milliunits/L	7.175	14.35–143.5 pmol/L
International normalized ratio (INR), therapeutic	2.0–3.0 (2.5–3.5 for some indications)		
Iron			
Male	45–160 mcg/dL	0.179	8.1–31.3 µmol/L
Female	30–160 mcg/dL	0.179	5.4–31.3 µmol/L
Iron binding capacity (total)	220–420 mcg/dL	0.179	39.4–75.2 µmol/L
Iron saturation	15–50%	0.01	0.15–0.50
Lactate (plasma)	0.7–2.1 mEq/L 6.3–18.9 mg/dL	1 0.111	0.7–2.1 mmol/L
Lactate dehydrogenase	100–250 IU/L	0.01667	1.67–4.17 µkat/L
Lead	Less than 25 mcg/dL	0.0483	Less than 1.21 µmol/L
Leukocyte count	$3.8–9.8 \times 10^3/\mu L$	10^6	$3.8–9.8 \times 10^9/L$
Lidocaine, therapeutic	1.5–6.0 mcg/mL or mg/L	4.27	6.4–25.6 µmol/L
Lipase	Less than 100 IU/L	0.01667	1.7 µkat/L
Lithium, therapeutic	0.5–1.25 mEq/L	1	0.5–1.25 mmol/L
Low-density lipoprotein (LDL) cholesterol			
Desirable	Less than 130 mg/dL	0.0259	Less than 3.36 mmol/L
Borderline high risk	130–159 mg/dL	0.0259	3.36–4.11 mmol/L
High risk	Greater than or equal to 160 mg/dL	0.0259	Greater than or equal to 4.13 mmol/L

Laboratory	Conventional Units	Conversion Factor	SI Units
Luteinizing hormone (LH)			
Male	1–8 milliunits/mL	1	1–8 units/L
Female			
Follicular phase	1–12 milliunits/mL	1	1–12 units/L
Midcycle	16–104 milliunits/mL	1	16–104 units/L
Luteal phase	1–12 milliunits/mL	1	1–12 units/L
Postmenopausal	16–66 milliunits/mL	1	16–66 units/L
Lymphocyte count	1.2–3.3 × 10^3/μL	10^6	1.2–3.3 × 10^9/L
Magnesium	1.3–2.2 mEq/L	0.5	0.65–1.10 mmol/L
	1.58–2.68 mg/dL	0.411	0.65–1.10 mmol/L
Mean corpuscular volume	80.0–97.6 μm^3	1	80.0–97.6 fL
Mononuclear cell count	0.2–0.7 × 10^3/μL	10^6	0.2–0.7 × 10^9/L
Nortriptyline, therapeutic	50–150 ng/mL or mcg/L	3.8	190–570 nmol/L
NT-ProBNP (see Pro-BNP)			
Osmolality (serum)	275–300 mOsm/kg	1	275–300 mmol/kg
Osmolality (urine)	250–900 mOsm/kg	1	250–900 mmol/kg
Parathyroid hormone (PTH), intact	10–60 pg/mL or ng/L	0.107	1.1–6.4 pmol/L
Parathyroid hormone (PTH), N-terminal	8–24 pg/mL or ng/L		
Parathyroid hormone (PTH), C-terminal	50–330 pg/mL or ng/L		
Phenobarbital, therapeutic	15–40 mcg/mL or mg/L	4.31	65–172 μmol/L
Phenytoin, therapeutic	10–20 mcg/mL or mg/L	3.96	40–79 μmol/L
Phosphate	2.5–4.5 mg/dL	0.323	0.81–1.45 mmol/L
Platelet count	140–440 × 10^3/μL	10^6	140–440 × 10^9/L
Potassium (plasma)	3.3–4.9 mEq/L	1	3.3–4.9 mmol/L
Prealbumin (adult)	19.5–35.8 mg/dL	10	195–358 mg/L
Primidone, therapeutic	5–12 mcg/mL or mg/L	4.58	23–55 μmol/L
ProBNP	Less than 125 pg/mL or ng/L	0.118	Less than 14.75 pmol/L
Procainamide, therapeutic	4–10 mcg/mL or mg/L	4.23	17–42 μmol/L
Progesterone			
Male	13–97 ng/dL	0.0318	0.4–3.1 nmol/L
Female			
Follicular phase	15–70 ng/dL		0.5–2.2 nmol/L
Luteal phase	200–2500 ng/dL		6.4–79.5 nmol/L
Prolactin	Less than 20 ng/mL	1	Less than 20 mcg/L
Prostate-specific antigen (PSA)	Less than 4 ng/mL	1	Less than 4 mcg/L
Protein, total	6.0–8.0 g/dL	10	60–80 g/L
Prothrombin time (PT)	10–12 seconds		
Quinidine, therapeutic	2–5 mcg/mL or mg/L	3.08	6.2–15.4 μmol/L
Radioactive iodine uptake (RAIU)	Less than 6% in 2 hours		
Red blood cell (RBC) count (blood)			
Male	4–6.2 × 10^6/μL	10^6	4–6.2 × 10^{12}/L
Female	4–6.2 × 10^6/μL	10^6	4–6.2 × 10^{12}/L
Pregnant			
Trimester 1	4–5 × 10^6/μL	10^6	4–5 × 10^{12}/L
Trimester 2	3.2–4.5 × 10^6/μL	10^6	3.2–4.5 × 10^{12}/L
Trimester 3	3–4.9 × 10^6/μL	10^6	3–4.9 × 10^{12}/L
Post partum	3.2–5 × 10^6/μL	10^6	3.2–5 × 10^6/L
Red blood cell distribution width (RDW)	11.5–14.5%	0.01	0.115–0.145
Reticulocyte count			
Male	0.5–1.5% of total RBC count	0.01	0.005–0.015
Female	0.5–2.5% of total RBC count	0.01	0.005–0.025
Retinol-binding protein (RBP)	2.7–7.6 mg/dL	10	27–76 mg/L
Rheumatoid factor (RF) titer	Negative		
Salicylate, therapeutic	150–300 mcg/mL or mg/L	0.00724	1.09–2.17 mmol/L
	15–30 mg/dL	0.0724	
Sodium	135–145 mEq/L	1	135–145 mmol/L
Tacrolimus			
Renal transplant	6–12 ng/mL or mcg/L		
Liver transplant	4–10 ng/mL or mcg/L		
Pancreatic transplant	10–18 ng/mL or mcg/L		
Bone marrow transplant	10–20 ng/mL or mcg/L

Vancomycin, therapeutic trough	20–40 mcg/mL or mg/L peak	0.690	14–28 µmol/L peak
for CNS infections	5–20 mcg/mL or mg/L trough	0.690	3–14 µmol/L trough
	15–20 mcg/mL or mg/L trough	0.690	10–14 µmol/L trough
Vitamin A (retinol)	30–95 mcg/dL	0.0349	1.05–3.32 µmol/L
Vitamin B_{12}	180–1000 pg/mL	0.738	133–738 pmol/L
Vitamin D_3, 1, 25-dihydroxy	20–76 pg/m	2.4	48–182 pmol/L
Vitamin D_3, 25-hydroxy	10–50 ng/mL	2.496	25–125 nmol/L
Vitamin E (alpha tocopherol)	0.5–2.0 mg/dL	23.22	12–46 µmol/L
WBC count	$4–10 \times 10^3$/µL or $4–10 \times 10^3$/mm^3	10^6	$4–10 \times 10^9$/L
WBC differential (peripheral blood)			
Polymorphonuclear neutrophils (PMNs)	50–65%		
Bands	0–5%		
Eosinophils	0–3%		
Basophils	1–3%		
Lymphocytes	25–35%		
Monocytes	2–6%		

(Continued)

Laboratory	Conventional Units	Conversion Factor	SI Units
WBC differential (bone marrow)			
Polymorphonuclear neutrophils (PMNs)	3–11%		
Bands	9–15%		
Metamyelocytes	9–25%		
Myelocytes	8–16%		
Promyelocytes	1–8%		
Myeloblasts	0–5%		
Eosinophils	1–5%		
Basophils	0–1%		
Lymphocytes	11–23%		
Monocytes	0–1%		
Zinc	60–150 mcg/dL	0.153	9.2–23.0 μmol/L

This table is a modification of the Medical Algorithms Project (Chapter 40), unit conversions of the following Excel worksheets: Conversion of Conventional to SI units: Blood Chemistries; Conversion of Conventional to SI units: Urine Chemistries; Conversion of Conventional to SI units: Hematology and Coagulation; and Conversion of Conventional to SI units: Therapeutic Drug Monitoring. Available at www.medal.org/visitor/www%5CInactive% 5Cch40.aspx; accessed November 9, 2005.

Appendix C Common Medical Abbreviations

These are abbreviations used commonly in medical practice both in verbal communication and in the medical record.

A&O	Alert and oriented
A&P	Auscultation and percussion; anterior and posterior; assessment and plans
A&W	Alive and well
AAO	Awake, alert, and oriented
AAO×3	Awake and orientated to time, place, and person
ABC	Absolute band counts; absolute basophil count; apnea, bradycardia, and cytology; aspiration, biopsy, and cytology; artificial beta cells
Abd	Abdomen
ABG	Arterial blood gases
ABO	Blood group system (A, AB, B, and O)
ABP	Arterial blood pressure
ABW	Actual body weight
ABx	Antibiotics
AC	Before meals (*ante cibos*)
ACE	Angiotensin-converting enzyme
ACE-I	Angiotensin-converting enzyme inhibitor
ACLS	Advanced cardiac life support
ACS	Acute coronary syndromes
ACTH	Adrenocorticotropic hormone
AD	Alzheimer's disease; right ear (*auris dextra*)
ADA	American Diabetes Association, adenosine deaminase
ADE	Adverse drug effect (or event)
ADH	Antidiuretic hormone
ADHD	Attention-deficit hyperactivity disorder
ADL	Activities of daily living
ADR	Adverse drug reaction
AF	Atrial fibrillation
AFB	Acid-fast bacillus; aortofemoral bypass; aspirated foreign body
AFEB	Afebrile
AIDS	Acquired immune-deficiency syndrome
AKA	Above-knee amputation; alcoholic ketoacidosis; all known allergies; also known as
ALFT	Abnormal liver function test
ALL	Acute lymphoblastic leukemia; acute lymphocytic leukemia
ALP	Alkaline phosphatase
ALT	Alanine transaminase (SGPT); alanine aminotransferase
AMA	Against medical advice; American Medical Association; antimitochondrial antibody
AMI	Acute myocardial infarction
AML	Acute myelogenous leukemia
Amp	Ampule
ANA	Antinuclear antibody
ANC	Absolute neutrophil count
ANLL	Acute nonlymphocytic leukemia
AODM	Adult-onset diabetes mellitus
A&O×3	Awake and oriented to person, place, and time
A&O×4	Awake and oriented to person, place, time, and situation
AP	Anteroposterior
A&P	Active and present; anterior and posterior; assessment and plans; ausculatation and percussion
APAP	Acetaminophen (acetyl-*p*-aminophenol)
aPTT	Activated partial thromboplastin time
ARC	AIDS-related complex
ARD	Acute respiratory disease; adult respiratory disease; antibiotic removal device; aphakic retinal detachment
ARDS	Adult respiratory distress syndrome
ARF	Acute renal failure; acute respiratory failure; acute rheumatic fever
AROM	Active range of motion
AS	Left ear (*auris sinistra*)
ASA	Aspirin (acetylsalicylic acid)
ASCVD	Arteriosclerotic cardiovascular disease
ASHD	Arteriosclerotic heart disease
AST	Aspartate transaminase (SGOT); aspartate aminotransferase
ATG	Antithymocyte globulin
ATN	Acute tubular necrosis
AU	Each ear (*auris uterque*)
AV	Arteriovenous; atrioventricular; auditory visual
AVR	Aortic valve replacement
BBB	Bundle-branch block, blood-brain barrier
BC	Blood culture
BCOP	Board Certified Oncology Pharmacist
BCP	Birth control pill
BCPP	Board Certified Psychiatric Pharmacist
BCPS	Board Certified Pharmacotherapy Specialist
BE	Barium enema
BID	Twice daily (*bis in die*)
BKA	Below-knee amputation
BM	Bone marrow, bowel movement; an isoenzyme of creatine phospokinase
BMC	Bone marrow cells
BMD	Bone mineral density
BMR	Basal metabolic rate
BMT	Bone marrow transplantation
BP	Blood pressure
BPH	Benign prostatic hyperplasia
bpm	Beats per minute
BR	Bed rest

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

BS	Bowel sounds; breath sounds; blood sugar
BSA	Body surface area
BUN	Blood urea nitrogen
Bx	Biopsy
C&S	Culture and sensitivity
CA	Cancer; calcium
CABG	Coronary artery bypass grafting
CAD	Coronary artery disease
CAH	Chronic active hepatitis
CAM	Complementary and alternative medicine
CAPD	Continuous ambulatory peritoneal dialysis
CBC	Complete blood count
CBD	Common bile duct
CBG	Capillary blood gas; corticosteroid-binding globulin
CC	Chief complaint
CCA	Calcium channel antagonist
CCB	Calcium channel blocker
CCE	Clubbing, cyanosis, edema
CCK	Cholecystokinin
CCU	Coronary care unit
CF	Cystic fibrosis
CFS	Chronic fatigue syndrome
CFU	Colony-forming unit
CHD	Coronary heart disease
CHF	Congestive heart failure; chronic heart failure
CHO	Carbohydrate
CI	Cardiac index
CK	Creatine kinase
CKD	Chronic kidney disease
CLL	Chronic lymphocytic leukemia
CM	Costal margin
CMG	Cystometrogram
CML	Chronic myelogenous leukemia
CMV	Cytomegalovirus
CN	Cranial nerve
CNS	Central nervous system
C/O	Complains of
CO	Cardiac output; carbon monoxide
COLD	Chronic obstructive lung disease
COPD	Chronic obstructive pulmonary disease
CP	Chest pain; cerebral palsy
CPAP	Continuous positive airway pressure
CPK	Creatine phosphokinase (BB, MB, and MM are isoenzymes)
CPP	Cerebral perfusion pressure
CPR	Cardiopulmonary resuscitation
CrCL	Creatinine clearance
CRF	Chronic renal failure; corticotropin-releasing factor
CRH	Corticotropin-releasing hormone
CRI	Chronic renal insufficiency; catheter-related infection
CRNA	Certified Registered Nurse Anesthetist
CRNP	Certified Registered Nurse Practitioner
CRTT	Certified Respiratory Therapy Technician
CSF	Cerebrospinal fluid; colony-stimulating factor
CT	Computed tomography; chest tube
cTnI	Cardiac troponin I
CTZ	Chemoreceptor trigger zone
CV	Cardiovascular
CVA	Cerebrovascular accident
CVC	Central venous catheter
CVP	Central venous pressure
Cx	Culture; cervix
CXR	Chest x-ray
D&C	Dilatation and curettage
D_5W	5% Dextrose in water
DBP	Diastolic blood pressure
D/C	Discontinue; discharge
DCC	Direct-current cardioversion
DI	Diabetes insipidus
DIC	Disseminated intravascular coagulation
Diff	Differential
DJD	Degenerative joint disease
DKA	Diabetic ketoacidosis
dL	Deciliter
DM	Diabetes mellitus
DNA	Deoxyribonucleic acid
DNR	Do not resuscitate
DO	Doctor of Osteopathy
DOA	Dead on arrival; date of admission; duration of action
DOB	Date of birth
DOE	Dyspnea on exertion
DOT	Directly observed therapy
DPGN	Diffuse proliferative glomerulonephritis
DRE	Digital rectal examination
DRG	Diagnosis-related group
DS	Double strength
DTP	Diphtheria-tetanus-pertussis
DTR	Deep-tendon reflex
DVT	Deep-vein thrombosis
Dx	Diagnosis
EBV	Epstein-Barr virus
EC	Enteric-coated
ECG	Electrocardiogram
ECHO	Echocardiogram
ECT	Electroconvulsive therapy
ED	Emergency Department
EEG	Electroencephalogram
EENT	Eyes, ears, nose, throat
EF	Ejection fraction
EGD	Esophagogastroduodenoscopy
EIA	Enzyme immunoassay
EKG	Electrocardiogram
EMG	Electromyogram
EMT	Emergency Medical Technician
Endo	Endotracheal, endoscopy
EOMI	Extraocular movements (or muscles) intact
EPO	Erythropoietin
EPS	Extrapyramidal symptoms
ER	Emergency room
ERCP	Endoscopic retrograde cholangiopancreatography
ERT	Estrogen-replacement therapy
ESLD	End-stage liver disease
ESR	Erythrocyte sedimentation rate
ESRD	End-stage renal disease
ET	Endotracheal
EtOH	Ethanol
FB	Finger-breadth; foreign body

FBS	Fasting blood sugar
FDA	Food and Drug Administration
FEF	Forced expiratory flow rate
FEV_1	Forced expiratory volume in 1 second
FFP	Fresh-frozen plasma
FH	Family history
FiO_2	Fraction of inspired oxygen
FOBT	Fecal occult blood test
FPG	Fasting plasma glucose
FPIA	Fluorescence polarization immunoassay
FSH	Follicle-stimulating hormone
FTA	Fluorescent treponemal antibody
F/U	Follow-up
FUO	Fever of unknown origin
Fx	Fracture
G-CSF	Granulocyte colony-stimulating factor
G6PD	Glucose-6-phosphate dehydrogenase
GB	Gall bladder
GBS	Group B *Streptococcus*; Guillain-Barré syndrome
GC	Gonococcus
GDM	Gestational diabetes mellitus
GE	Gastroesophageal; gastroenterology
GERD	Gastroesophageal reflux disease
GFR	Glomerular filtration rate
GGT	γ-Glutamyl transferase
GGTP	γ-Glutamyl transpeptidase
GI	Gastrointestinal
GM-CSF	Granulocyte-macrophage colony-stimulating factor
GN	Glomerulonephritis; graduate nurse
gr	Grain
GT	Gastrostomy tube
gtt	Drops (*guttae*)
GTT	Glucose tolerance test
GU	Genitourinary
GVHD	Graft-versus-host disease
GVL	Graft-versus-leukemia
Gyn	Gynecology
H&H	Hemoglobin and hematocrit
H&P	History and physical examination
H/A	Headache
HAART	Highly-active antiretroviral therapy
HAMD	Hamilton Rating Scale for Depression
HAV	Hepatitis A virus
Hb, hgb	Hemoglobin
HbA_{1c}	Glycosylated hemoglobin (hemoglobin A_{1c})
HBIG	Hepatitis B immune globulin
HBP	High blood pressure
HBsAg	Hepatitis B surface antigen
HBV	Hepatitis B virus
HC	Hydrocortisone, home care
HCG	Human chorionic gonadotropin
HCO_3	Bicarbonate
Hct	Hematocrit
HCTZ	Hydrochlorothiazide
HCV	Hepatitis C virus
HD	Hodgkin's disease; hemodialysis
HDL	High-density lipoprotein
HEENT	Head, eyes, ears, nose, and throat
HF	Heart failure
H flu	*Hemophilus influenzae*
HGH	Human growth hormone
HH	Hiatal hernia
Hib	*Hemophilus influenzae* type b
HIV	Human immunodeficiency virus
HJR	Hepatojugular reflux
HLA	Human leukocyte antigen; human lymphocyte antigen
HMG-CoA	Hydroxy-methylglutaryl coenzyme A
H/O	History of
HOB	Head of bed
HPA	Hypothalamic-pituitary axis
HPI	History of present illness
HR	Heart rate
HRSD	Hamilton Rating Scale for Depression
HRT	Hormone-replacement therapy
HS	At bedtime (*hora somni*)
HSV	Herpes simplex virus
HTN	Hypertension
Hx	History
I&D	Incision and drainage
I&O	Intake and output
IBD	Inflammatory bowel disease
IBW	Ideal body weight
ICD	Implantable cardioverter defibrillator
ICP	Intracranial pressure
ICS	Intercostal space
ICU	Intensive-care unit
ID	Identification; infectious disease
IDDM	Insulin-dependent diabetes mellitus
IFN	Interferon
Ig	Immunoglobulin
IgA	Immunoglobulin A
IgD	Immunoglobulin D
IHD	Ischemic heart disease
IJ	Internal jugular
IM	Intramuscular; infectious mononucleosis
INH	Isoniazid
INR	International normalized ratio
IOP	Intraocular pressure
IP	Intraperitoneal
IPG	Impedance plethysmography
IPN	Interstitial pneumonia
IRB	Institutional Review Board
ISA	Intrinsic sympathomimetic activity
ISH	Isolated systolic hypertension
IT	Intrathecal
ITP	Idiopathic thrombocytopenic purpura
IU	International unit (this can be a dangerous abbreviation because it may be read as 'IV' for "intravenous")
IUD	Intrauterine device
IV	Intravenous; Roman numeral four; symbol for class 4 controlled substances
IVC	Inferior vena cava; intravenous cholangiogram
IVDA	Intravenous drug abuse
IVF	Intravenous fluids
IVIG	Intravenous immunoglobulin
IVP	Intravenous pyelogram; intravenous push
JODM	Juvenile-onset diabetes mellitus

JRA	Juvenile rheumatoid arthritis
JVD	Jugular venous distension
JVP	Jugular venous pressure
K	Potassium
kcal	Kilocalorie
KCL	Potassium chloride
KOH	Potassium hydroxide
KUB	Kidney, ureter, and bladder
KVO	Keep vein open
L	Liter
LAD	Left anterior descending; left axis deviation
LAO	Left anterior oblique
LBP	Low-back pain
LDH	Lactate dehydrogenase
LDL	Low-density lipoprotein
LE	Lower extremity
LES	Lower esophageal sphincter
LFT	Liver function test
LHRH	Luteinizing hormone–releasing hormone
LLE	Left lower extremity
LLL	Left lower lobe
LLQ	Left lower quadrant (abdomen)
LMP	Last menstrual period
LMWH	Low-molecular-weight heparin
LOS	Length of stay
LP	Lumbar puncture
LPN	Licensed Practical Nurse
LPT	Licensed Physical Therapist
LR	Lactated Ringer's
LS	Lumbosacral
LUE	Left upper extremity
LUL	Left upper lobe
LUQ	Left upper quadrant
LVH	Left ventricular hypertrophy
MAP	Mean arterial pressure
MAR	Medication administration record
MB-CK	A creatine kinase isoenzyme
mcg	Microgram
MCH	Mean corpuscular hemoglobin
MCHC	Mean corpuscular hemoglobin concentration
MCV	Mean corpuscular volume
MD	Medical Doctor
MDI	Metered-dose inhaler
mEq	Milliequivalent
mg	Milligram
MHC	Major histocompatibility complex
MI	Myocardial infarction; mitral insufficiency
MIC	Minimum inhibitory concentration
mL	Milliliter
MM	An isoenzyme of creatine phosphokinase
MMR	Measles-mumps-rubella; midline malignant reticulosis
MOM	Milk of magnesia
MPV	Mean platelet volume
m/r/g	Murmur/rub/gallop
MRI	Magnetic resonance imaging
MRSA	Methicillin-resistant *Staphylococcus aureus*
MRSE	Methicillin-resistant *Staphylococcus epidermitis*
MS	Mental status; mitral stenosis; musculoskeletal; multiple sclerosis; morphine sulfate
MSE	Mental status exam
MSW	Master of Social Work
MTD	Maximum tolerated dose
MTX	Methotrexate
MVA	Motor vehicle accident
MVI	Multivitamin
MVR	Mitral valve replacement; mitral valve regurgitation
MVS	mitral valve stenosis; motor, vascular, and sensory
N&V	Nausea and vomiting
NAD	No acute (or apparent) distress
N/C	Noncontributory; nasal cannula
NG	Nasogastric
NGT	Nasogastric tube; normal glucose tolerance
NIDDM	Non-insulin-dependent diabetes mellitus
NIH	National Institutes of Health
NKA	No known allergies
NKDA	No known drug allergies
NHDA	Nonketotic hyperosmolar acidosis
NL	Normal
NOS	Not otherwise specified
NPN	Nonprotein nitrogen
NPO	Nothing by mouth (*nil per os*)
NS	Normal saline solution (0.9% sodium chloride solution); neurosurgery
NSAID	Nonsteroidal anti-inflammatory drug
NSR	Normal sinus rhythm
NSS	Normal saline solution
NTG	Nitroglycerin
NT/ND	Nontender, nondistended
NVD	Nausea/vomiting/diarrhea; neck vein distension; neovascularization of the disk; neurovesicle dysfunction; no venereal disease; nonvalvular disease
N&V	Nausea and vomiting
O&P	Ova and parasites
OA	Osteoarthritis
OB	Obstetrics
OCD	Obsessive-compulsive disorder
OD	Right eye (*oculus dexter*)
OGT	Oral glucose tolerance test
OPV	Oral poliovirus vaccine
OR	Operating room
OR×1	Oriented to time
OR×2	Oriented to time and place
OR×3	Oriented to time, place, and person
OS	Left eye (*oculus sinister*)
OT	Occupational therapy
OTC	Over the counter
OU	*Oculus uterque* (each eye)
P	Pulse; plan; percussion; pressure
P&A	Percussion and auscultation
P&T	Peak and trough
PA	Physician Assistant; posteroanterior; pulmonary artery
PAC	Premature atrial contraction
$Paco_2$	Arterial carbon dioxide tension
Pao_2	Arterial oxygen tension
PAOP	Pulmonary artery occlusion pressure

PC	After meals (*post cibum*)
PCA	Patient-controlled analgesia
PCI	Percutaneous coronary intervention
PCKD	Polycystic kidney disease
PCN	Penicillin
PCP	*Pneumocystis carinii* pneumonia; phencyclidine
PCWP	Pulmonary capillary wedge pressure
PDE	Paroxysmal dyspnea on exertion
PE	Physical examination; pulmonary embolism
PEEP	Positive end-expiratory pressure
PEFR	Peak expiratory flow rate
PEG	Percutaneous endoscopic gastrostomy; polyethylene glycol
PEARLA	Pupils equal and react to light and accommodation
PERL	Pupils equal, react to light
PERRLA	Pupils equal, round, and reactive to light and accommodation
PERRRLA	Pupils equal, round, regular, and react to light and accommodation
PET	Positron-emission tomography
PFT	Pulmonary function test
pH	Hydrogen ion concentration
PH	Past history; personal history; pinhole; poor health; pubic hair; public health
PHx	Past history
PharmD	Doctor of Pharmacy
PID	Pelvic inflammatory disease
PKU	Phenylketonuria
PMH	Past medical history
PMI	Past medical illness; point of maximal impulse
PMN	Polymorphonuclear leukocyte
PMS	Premenstrual syndrome
PND	Paroxysmal nocturnal dyspnea
PO	By mouth (*per os*)
P_{O_2}	Partial pressure of oxygen
POAG	Primary open-angle glaucoma
POD	Postoperative day
PPBG	Postprandial blood glucose
ppd	Packs per day
PPN	Peripheral parenteral nutrition
pr	Per rectum
PRBC	Packed red blood cells
PRERLA	Pupils round, equal, react to light and accommodation
PRN	When necessary, as needed (*pro re nata*)
PSA	Prostate-specific antigen
PSH	Past surgical history
PST	Paroxysmal supraventricular tachycardia
PSVT	Paroxysmal supraventricular tachycardia
PT	Prothrombin time; physical therapy; patient
PTA	Prior to admission; percutaneous transluminal angioplasty
PTCA	Percutaneous transluminal coronary angioplasty
PTE	Pulmonary thromboembolism
PTH	Parathyroid hormone
PTSD	Posttraumatic stress disorder
PTT	Partial thromboplastin time
PUD	Peptic ulcer disease
PVC	Premature ventricular contraction
PVD	Peripheral vascular disease
PVR	Peripheral vascular resistance
PVT	Paroxysmal ventricular tachycardia
q	Every (*quaque*)
QA	Quality assurance
qd	Every day (*quaque die*)
QI	Quality improvement
qid	Four times daily (*quater in die*)
QNS	Quantity not sufficient
qod	Every other day
QOL	Quality of life
QS	Quantity sufficient
R&M	Routine and microscopic
RA	Rheumatoid arthritis; right atrium
RBC	Red blood cell
RCA	Right coronary artery
RCM	Right costal margin
RDA	Recommended daily allowance
RDS	Respiratory distress syndrome
RDW	Red cell distribution width
REM	Rapid eye movement; recent event memory
RES	Reticuloendothelial system
RF	Rheumatoid factor; renal failure; rheumatic fever
Rh	Rhesus factor in blood
RHD	Rheumatic heart disease
RLE	Right lower extremity
RLL	Right lower lobe
RLQ	Right lower quadrant
RML	Right middle lobe
RN	Registered Nurse
RNA	Ribonucleic acid
R/O	Rule out
ROM	Range of motion
ROS	Review of systems
RPh	Registered Pharmacist
R&R	Rate and rhythm
RR	Respiratory rate; recovery room
RRR	Regular rate and rhythm
RRT	Registered Respiratory Therapist
RSV	Respiratory syncytial virus
RT	Radiation therapy
RUE	Right upper extremity
RUL	Right upper lobe
RUQ	Right upper quadrant
RVH	Right ventricular hypertrophy
S_1	First heart sound
S_2	Second heart sound
S_3	Third heart sound (ventricular gallop)
S_4	Fourth heart sound (atrial gallop)
SA	Sinoatrial
SAD	Seasonal affective disorder
SAH	Subarachnoid hemorrhage
Sa_{O_2}	Arterial oxygen percent saturation
SBE	Subacute bacterial endocarditis
SBFT	Small bowel follow-through
SBGM	Self blood glucose monitoring
SBO	Small bowel obstruction
SBP	Systolic blood pressure
SC	Subcutaneous; subclavian
SCr	Serum creatinine

SEM	Systolic ejection murmur
SG	Specific gravity
SGOT (AST)	Serum glutamic oxaloacetic transaminase (aspartate transaminase)
SGPT (ALT)	Serum glutamic pyruvic transaminase (alanine transaminase)
SH	Social history
SIADH	Syndrome of inappropriate antidiuretic hormone secretion
SIDS	Sudden infant death syndrome
SJS	Stevens-Johnson syndrome
SL	Sublingual
SLE	Systemic lupus erythematosus
SMA-6	Sequential multipler analyzer for sodium, potassium, CO_2, chloride, glucose, and BUN
SMA-7	Sodium, potassium, CO_2, chloride, glucose, BUN, and creatinine
SMA-12	Glucose, BUN, uric acid, calcium, phosporous, total protein, albumin, cholesterol, total bilirubin, alkaline phosphatase, SGOT, and LDH
SMA-23	Includes the entire SMA-12 plus sodium, potassium, CO_2, chloride, direct bilirubin, triglyceride, SGPT, indirect bilirubin, R fraction, and BUN/creatinine ratio
SMBG	Self-monitoring of blood glucose
SNF	Skilled nursing facility
SNS	Sympathetic nervous system
SOB	Shortness of breath; see order book; side of bed
S/P	Status post
SPF	Sun protection factor
SQ	Subcutaneous
SSKI	Saturated solution of potassium iodide
SSRI	Selective serotonin reuptake inhibitor
STAT	Immediately, at once
STD	Sexually transmitted disease
SV	Stroke volume
SVC	Superior vena cava
SVRI	Systemic vascular resistance index
SVR	Supraventricular rhythm; systemic vascular resistance
SVT	Supraventricular tachycardia
SW	Social worker
Sx	Signs
T	Temperature
T&A	Tonsillectomy and adenoidectomy
T&C	Type and crossmatch
TB	Tuberculosis
TBG	Thyroid-binding globulin
TBI	Total-body irradiation, traumatic brain injury
T bili	Total bilirubin
TCA	Tricyclic antidepressant
TCN	Tetracycline
TFT	Thyroid function test
TG	Triglyceride
TIA	Transient ischemic attack
TIBC	Total iron-binding capacity
TID	Three times daily (*ter in die*)
TLC	Therapeutic lifestyle changes
TMJ	Temporomandibular joint
TMP-SMX	Trimethoprim-sulfamethoxazole
TNTC	Too numerous to count
TOD	Target-organ damage
TPN	Total parenteral nutrition
TPR	Temperature, pulse, respiration
T PROT	Total protein
TSH	Thyroid-stimulating hormone
TURP	Transurethral resection of the prostate
Tx	Treat, treatment
UA	Urinalysis, uric acid
UC	Ulcerative colitis
UE	Upper extremity
UGI	Upper gastrointestinal
UOQ	Upper outer quadrant
UPT	Urine pregnancy test
URI	Upper respiratory infection
USP	United States Pharmacopeia
UTI	Urinary tract infection
UV	Ultraviolet
VF	Ventricular fibrillation
VLDL	Very low-density lipoprotein
VO	Verbal order
VOD	Veno-occlusive disease
V_A/Q	Ventilation-perfusion
VRE	Vancomycin-resistant *Enterococcus*
VS	Vital signs
VSS	Vital signs stable
VT	Ventricular tachycardia
VTE	Venous thromboembolism
WA	While awake
WBC	White blood cell (count)
W/C	Wheelchair
WDWN	Well-developed, well-nourished
WHO	World Health Organization
WNL	Within normal limits
W/U	Work-up
yo	Year-old
yr	Year

APPENDIX D GLOSSARY

2,3-Diphosphoglycerate: A compound in red blood cells that affects oxygen binding to and release from hemoglobin.

24-Hour ambulatory pH monitoring: A test that quantifies the amount of acid that refluxes into the esophagus over 24 hours under ambulatory (outpatient) conditions.

β-Lactam allergy: Refers to patients who experience allergic reactions to the β-lactam class of antimicrobials.

β_2 Microglobulin: A low-molecular-weight protein that may be elevated in multiple myeloma.

γ-Aminobutyric acid: An inhibitory amino acid found in the central nervous system.

Ablation: Destruction of part or all of an organ or structure.

Abscess: A purulent (i.e., containing, discharging, or causing the production of pus) collection of fluid separated from surrounding tissue by a wall comprised of inflammatory cells and adjacent organs. It usually contains necrotic debris, bacteria, and inflammatory cells.

Acanthosis: Increased thickness of the prickle cell layer of the skin.

Acanthosis nigricans: A skin condition characterized by dark, thickened velvety patches, especially in the folds of skin in the armpits, groin, and back of the neck that is often associated with insulin resistance. Also may be associated with internal malignancy, endocrine disorders, and obesity.

Acetaldehyde: A by-product of alcohol metabolism.

Acetylcholinesterase: An enzyme responsible for the degradation of acetylcholine.

Achlorhydria: Absence of gastric acid in the stomach.

Acidemia: An increase in the hydrogen ion concentration of the blood or a fall below normal in blood pH.

Acid-fast bacillus: General term for mycobacteria based on staining technique.

Acidosis: A pathologic state that leads to acidemia.

Acromegaly: A pathologic condition characterized by excessive production of growth hormone during adulthood after epiphyseal (long bone) fusions have completed.

Action potential: A rapid change in the polarity of the voltage of a cell membrane from negative to positive and back to negative; a wave of electrical discharge that travels across a cell membrane.

Acute chest syndrome: An acute respiratory complication of sickle-cell disease characterized by chest pain, fever, and pulmonary infiltrates.

Acute coronary syndromes: Ischemic chest discomfort at rest, most often accompanied by ST-segment elevation, ST-segment depression, or T-wave inversion on the 12-lead electrocardiogram. Furthermore, it is caused by plaque rupture and partial or complete occlusion of the coronary artery by thrombus. Acute coronary syndromes include myocardial infarction and unstable angina. Former terms used to describe types of acute coronary syndromes include Q-wave myocardial infarction, non–Q-wave myocardial infarction, and unstable angina.

Acute otitis media: Inflammation of the middle ear accompanied by fluid in the middle ear space and signs or symptoms of an acute ear infection.

Acute renal failure: Sudden loss of the kidney's ability to excrete wastes, concentrate urine, and remove electrolytes.

Acute tubular necrosis: A form of acute renal failure that results from toxic or ischemic (insufficient oxygen) injury to the cells in the proximal tubule of the kidney.

Adenocarcinoma: Malignant tumor originating in glandular tissue.

Adenoma: A nonmalignant tumor of epithelial tissue characterized by glandular structures.

Adenomatous polyposis coli (*APC*) gene: A tumor suppressor gene, acting as a "gatekeeper" to prevent development of tumors. A familial cancer syndrome called FAP, or familial adenomatous polyposis, is caused by mutations in *APC*. Mutation of *APC* also occurs commonly in sporadic cases of colorectal carcinoma.

Adjuvant chemotherapy: Chemotherapy given after the primary cancer treatment, designed to eliminate any remaining cancer cells that are undetectable with the goal of improving survival.

Adjuvant therapy: Therapy that supplements or follows primary therapy to prevent the risk of disease recurrence or manage associated symptoms.

Adrenalectomy: Surgical removal of one or both adrenal glands.

Adrenocorticotropic hormone: A hormone secreted by the anterior pituitary that controls secretion of cortisol from the adrenal glands; also referred to as corticotropin.

Afterload: The force against which a ventricle contracts that is contributed to by the vascular resistance, especially of the arteries, and by the physical characteristics (mass and viscosity) of the blood. Afterload is the overall resistance to blood flow leaving the heart.

Air embolus: An obstruction in a small blood vessel caused by air that is introduced into a blood vessel and carried through the circulation until it lodges in a smaller vessel.

Akathisia: Motor or subjective feelings of restlessness.

Akinesia: Lack of movement.

Alcohol dehydrogenase: An enzyme that degrades ethanol in the gut and liver.

Aldosterone: A hormone produced in and secreted by the zona glomerulosa of the adrenal cortex. Aldosterone acts on the kidneys to reabsorb sodium and excrete potassium. It is also a part of the renin–angiotensin–aldosterone system, which regulates blood pressure and blood volume.

Alkalemia: A decrease in the hydrogen ion concentration of the blood or a rise above normal in blood pH.

Alkalosis: A pathologic state that leads to alkalemia.

Allergen immunotherapy: Treatment for IgE-mediated conditions in which specific allergen extracts are sequentially administered in order to modify or eliminate allergic symptoms.

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

Allergic rhinitis: A highly prevalent, allergen-induced, upper airway inflammatory disease characterized by chronic hyperreactive airway mucosa with periods of acute exacerbations.

Allodynia: A condition in which pain results from a stimulus that does not normally cause pain.

Allogeneic hematopoietic cell transplantation: A transplantation of hematopoietic (blood-forming) bone marrow, peripheral blood, or umbilical cord blood involving one person as a donor and another person as a recipient.

Allograft survival: After an organ transplant procedure, when the transplanted organ continues to have some degree of function, from excellent to poor.

Allograft: Tissue or organ transplanted from a donor of the same species but different genetic makeup; the recipient's immune system must be suppressed to prevent rejection of the allograft (graft).

Allorecognition: Recognition of the foreign antigens present on the transplanted organ or the donor's antigen-presenting cells.

Alopecia: Hair absence or loss.

Alport's syndrome: A hereditary disease that affects kidney function and can also cause hearing and vision disorders.

Amenorrhea: The absence or discontinuation of regular menstrual periods.

Amotivation: Apathy, loss of effectiveness, and diminished capacity or willingness to carry out complex, long-term plans, endure frustration, concentrate for long periods, follow routines, or successfully master new material.

Amylase: A pancreatic enzyme that cleaves starches.

Amyloid: Any of a group of chemically diverse proteins that are composed of linear non-branching aggregated fibrils.

Anaphylactic/anaphylaxis: Immediate, severe, potentially fatal hypersensitivity reaction induced by an antigen.

Anaphylactoid: An anaphylactic-like reaction, similar in signs and symptoms, but not mediated by IgE. A drug causing this reaction produces direct release of inflammatory mediators by a pharmacologic effect.

Anaphylaxis: The immediate, transient kind of immunologic (allergic) reaction characterized by contraction of smooth muscle and dilation of capillaries due to release of pharmacologically active substances (histamine, bradykinin, serotonin, and slow-reacting substance), classically initiated by the combination of antigen (allergen) with mast cell–fixed, cytophilic antibody (chiefly IgE). The reaction can also be initiated by relatively large quantities of serum aggregates (antigen–antibody complexes and others) that seemingly activate complement leading to production of anaphylatoxin.

Anemia: A reduction below normal in the concentration of hemoglobin in the body that results in a decrease of the oxygen-carrying capacity of the blood.

Anemia of chronic kidney disease: A decline in red blood cell production caused by a decrease in erythropoietin production by the progenitor cells of the kidney. As kidney function declines in chronic kidney disease, erythropoietin production also declines, resulting in decreased red blood cell production. Other contributing factors include iron deficiency and decreased red blood cell lifespan, caused by uremia.

Anergy: A reduction or lack of an immune response to a specific antigen.

Aneuploidy: Abnormal number of chromosomes.

Angina pectoris: Severe constricting pain in the chest, often radiating from the precordium to a shoulder (usually left) and down the arm, due to ischemia of heart muscle usually caused by coronary artery disease.

Angioedema: Swelling similar to urticaria (hives), but the swelling occurs beneath the skin instead of on the surface. Angioedema is characterized by deep swelling around the eyes and lips, and sometimes of the hands and feet. If it proceeds rapidly, it can lead to airway obstruction and suffocation, and it should therefore be treated as a medical emergency.

Angiogenesis: The formation of new blood vessels.

Anhedonia: Loss of interest or pleasure in activities previously enjoyed.

Anorexia: Loss of appetite.

Antenatal: Prior to birth.

Anterograde amnesia: A condition in which events that occurred after the onset of amnesia cannot be recalled and new memories cannot be formed.

Antiangiogenic: A substance that prevents the formation of new blood vessels.

Anticoagulant: Any substance that inhibits, suppresses, or delays the formation of blood clots. These substances occur naturally and regulate the clotting cascade. Several anticoagulants have been identified in a variety of animal tissues and have been commercially developed for therapeutic use.

Antimicrobial prophylaxis: Antibiotics given to prevent an infection.

Antiproteinase: A substance that inhibits the enzymatic activity of a proteinase.

Antrectomy: Surgical excision of the wall of the antrum, the region of the stomach that produces the hormone gastrin.

APACHE II: Acute Physiology and Chronic Health Evaluation II; a severity of disease classification system using a point score based on initial values of 12 routine physiologic measurements, age, and previous health status; used to provide a general measure of disease severity.

Aphakic: Absence of a lens in the eye.

Aphasia: Impairment of language affecting the ability to speak and understand speech.

Aphthous ulcer: A small superficial area of ulceration within the gastrointestinal mucosa, typically found in the oral cavity.

Apoptosis: Programmed cell death, a normal process in which cells perish in an orderly, highly controlled manner to control an organism's development.

Arcuate scotoma: An arc-shaped area of blindness in the field of vision.

Arterial hypotension: Systolic blood pressure less than 90 mm Hg or an acute fall of greater than 40 mm Hg from baseline.

Arthrocentesis: Puncture and aspiration of fluid from a joint.

Arthroconidia: A specialized spore-like form found in soil that is the propagating infectious form of coccidioidomycoses.

Arthus reaction: Local inflammatory response due to deposition of immune complexes in tissues.

Articular: Related to a joint or joints.

Ascites: Abnormal accumulation of serous fluid in the spaces between tissues and organs in the peritoneal cavity of the abdomen.

Asterixis: Abnormal posture and movements that may occur in advanced liver disease and a few other circumstances.

Asymptomatic bacteriuria: Bacteria present in the urine in a patient without signs or symptoms of a urinary tract infection.

Atelectasis: Decreased or absent air in a partial or entire lung, with resulting loss of lung volume.
Atherosclerosis: A disease process of the arteries involving fatty plaque formation and inflammation in the vascular wall.
Atopic: Related to a genetically determined hypersensitivity to environmental allergens; allergic.
Atopy: A genetic predisposition to develop type I hypersensitivity reactions against common environmental antigens; commonly seen in patients with allergic rhinitis, asthma, and atopic dermatitis.
Atresia: Congenital absence of a normal opening or normally patent lumen.
Atrial natriuretic peptide: A type of peptide, 28 amino acids in length, secreted by the atria of the heart when atrial pressure and stretch are increased.
Attenuate: To render less virulent; to reduce or diminish.
Autograft: A tissue or organ grafted into a new position in or on the body of the same individual.
Autologous hematopoietic cell transplantation: Infusion of a patient's own hematopoietic (blood-forming) cells that rescue the recipient from otherwise dose-limiting hematopoietic toxicity of chemotherapy and radiotherapy.
Autologous: Transplantation using one's own tissues or cells.
Automaticity: Ability of a cardiac fiber or tissue to spontaneously initiate depolarizations.
Autonomic nervous system: Parasympathetic and sympathetic nerves that control involuntary actions in the body.
Azoospermic: Having no living spermatozoa in the semen, or failure of spermatogenesis.
Azotemia: An excess of urea and other nitrogenous wastes in the blood as a result of kidney insufficiency.

Bacille Calmette-Guérin (BCG): A vaccine prepared from a living attenuated strain of tubercle bacilli and used to vaccinate human beings against tuberculosis or treat some types of cancer.
Bacteriuria: Bacteria in the urine evidenced either by urine culture or wet prep evaluation of gross urine under high powered field.
Barium enema: A diagnostic test using x-ray examination to view the lower gastrointestinal tract (colon and rectum) after oral ingestion of barium sulfate, a chalky liquid contrast medium.
Basal ganglia: Clusters of nerve cells deep in the brain that coordinate normal movement.
Bence Jones proteins: Light chain immunoglobulins found in the urine.
Benign prostatic hyperplasia: A benign condition wherein the overgrowth of prostate tissue may impede the flow of urine.
Bilateral: On both sides of the body.
Bilateral salpingo-oophorectomy: Surgical excision (removal) of both ovaries.
Bile acids: The organic acids in bile; contains sodium glycocholate and sodium taurocholate, cholesterol, biliverdin and bilirubin, mucus, fat, lecithin, and cells and cellular debris.
Bile: The yellowish-brown or green fluid secreted by the liver and discharged into the duodenum where it aids in the emulsification of fats, increases peristalsis, and retards putrefaction.
Biliary sludge: A deposit of tiny stones or crystals made up of cholesterol, calcium bilirubinate, and other calcium salts. The cholesterol and calcium bilirubinate crystals in biliary sludge can lead to gallstone formation.
Biopsy: Removal and pathologic examination of specimens in the form of small pieces of tissue from the living body.
Blastospore: A fungal spore produced by budding.
Blood dyscrasias: Any abnormality in blood or bone marrow cellular components such as low white blood cells, red blood cells, or platelets.
Blood urea nitrogen (BUN): A waste product in the blood produced from the breakdown of dietary proteins. The kidneys filter blood to remove urea and maintain homeostasis. A decline in kidney function results in an increase in BUN.
Body mass index: A calculation used to correct weight changes for height and is a direct calculation regardless of gender. It is the result of the weight in kilograms divided by the height in meters squared.
Bone remodeling: The constant process of bone turnover involving bone resorption followed by bone formation.
Bouchard's nodes: Bony outgrowths on the proximal interphalangeal joints due to osteoarthritis.
Brachial plexus: The collection of nerves that arises from the spine at the base of the neck from nerves that supply parts of the shoulder, arm, forearm, and hand.
Brachytherapy: A procedure in which radioactive material, sealed in needles, seeds, wires, or catheters, is placed directly into or near a tumor. Also called internal radiation, implant radiation, or interstitial radiation therapy.
Bradykinesia: Slow movement.
Brain abscess: A localized collection of pus inside the brain.
Bronchiectasis: Chronic dilation of bronchi or bronchioles as a result of inflammatory disease or obstruction associated with heavy sputum; or a chronic condition of one or more bronchi or bronchioles marked by irreversible dilatation and destruction of the bronchial walls.
Bronchoalveolar lavage: Washing out of the lungs with saline or mucolytic agents for diagnostic or therapeutic purposes.
Bronchoscopy: An examination used for inspection of the interior of the tracheobronchial tree.
Brudzinski's sign: A physical sign associated with meningitis, in which flexion of the hips and knees occurs when the neck is flexed by bringing the chin to the chest.
Bullectomy: Surgical removal of one or more bullae (air spaces in the lung measuring more than 1 cm in diameter in the distended state).
Bursa: The fluid-filled sac near the joint where tendons and muscles pass over bone.
Bursitis: An inflammation of the bursa.

Cachectic: Relating to or having the symptoms of cachexia.
Cachexia: Weight loss, wasting of muscle, loss of appetite, and general debility.
Capillary leak: Abnormally high permeability of the capillaries that allows fluid to flow excessively from the capillaries to the interstitial space.
Carcinoembryonic antigen: A protein normally seen during fetal development. When carcinoembryonic antigen is elevated in adults it suggests the presence of colorectal and other cancers. The normal level in nonsmokers is about less than 2.5 ng/mL, but it can be elevated in smokers and other nonmalignant conditions such as pancreatitis.
Carcinogenesis: The process that leads to development of cancer. Carcinogenesis may be a matter of induction by chemical, physical, or biological agents, of neoplasms that are usually not observed, an earlier induction of neoplasms that are usually observed, and/or the induction of more neoplasms than are usually found.

Carcinoma: A malignant growth that arises from epithelium, found in skin or the lining of body organs. Carcinomas tend to infiltrate into adjacent tissue and spread to distant organs; or a cancerous tumor of the epithelial tissue of an organ.

Carcinoma in situ: The earliest stage of a cancer; also referred to as "noninvasive cancer." The cancer has not yet grown through the membranes surrounding the affected organ or invaded other tissues and organs.

Carcinomatosis: Condition of having widespread dissemination of carcinoma (cancer) in the body.

Cardiac cachexia: Physical wasting with loss of weight and muscle mass caused by cardiac disease; a wasting syndrome that causes weakness and a loss of weight, fat, and muscle.

Cardiac index: Cardiac output (see below) normalized for body surface area (cardiac index = cardiac output/body surface area).

Cardiac output: The volume of blood ejected from the left side of the heart per unit of time [cardiac output (L/minute) = stroke volume × heart rate].

Cardiac remodeling: Genome expression resulting in molecular, cellular, and interstitial changes and manifested clinically as changes in size, shape, and function of the heart resulting from cardiac load or injury.

Carotid: The two main arteries in the neck.

Caseating granulomas: A mass or nodule of chronically inflamed tissue with granulations, usually associated with an infective process.

Cataplexy: A sudden attack of muscle weakness with retention of clear consciousness that follows a strong emotional stimulus (e.g., elation, surprise, or anger); a characteristic symptom of narcolepsy.

Causalgia: Persistent burning pain, allodynia, and hyperpathia following a traumatic nerve lesion.

Cavitary lesions: The formation of cavities in an organ or tissue especially in disease.

Central pain: Pain that results from a lesion or dysfunction in the central nervous system.

Cephalgia: Head pain; headache.

Cervicitis: Inflammation of the cervix.

Chemoprevention: The use of drugs, vitamins, or other agents to reduce the risk of or delay the development or recurrence of cancer.

Chemoreceptor trigger zone: Located in the area postrema of the fourth ventricle of the brain, it is exposed to cerebrospinal fluid and blood and is easily stimulated by circulating toxins to induce nausea and vomiting.

Chemosis: Edema of the bulbar conjunctiva, forming a swelling around the cornea.

Cheyne-Stokes respiration: Pattern of breathing with gradual increase in depth and sometimes in rate to a maximum, followed by a decrease resulting in apnea. The cycles ordinarily are 30 seconds to 2 minutes in duration, with 5 to 30 seconds of apnea.

Chimeric: Composed of parts from different origins.

Chloasma: Melasma characterized by irregularly shaped brown patches on the face and other areas of the skin, often seen during pregnancy or associated with use of oral contraceptives.

Chlorpromazine equivalents: Approximate dose equivalent of a first-generation antipsychotic to 100 mg of chlorpromazine (relative potency).

Cholecystitis: Inflammation or infection of the gallbladder; chronic cholecystitis is associated with gallstones.

Cholelithiasis: Formation of stones in the gallbladder (gallstones).

Cholestasis: Reduced or lack of flow of bile, or obstruction of bile flow.

Cholesteatoma: A mass of keratinized epithelial cells and cholesterol resembling a tumor that forms in the middle ear or mastoid region.

Chorea: A type of dyskinesia with rhythmic dance-like movement. The increase in motor activity may be associated with fidgeting, twitching, or flinging movements.

Choroidal neovascular membranes: Development of abnormal blood vessels in and under the retina.

Chronic kidney disease: A progressive, irreversible decline in kidney function that occurs over a period of several months to years.

Chronotropic: Affecting pulse rate, or referring to changes in heart rate.

Churg-Strauss syndrome: A systemic necrotizing vasculitis with prominent lung involvement including severe asthma and eosinophilia.

Chvostek's sign: The physical sign noted when a tap on the patient's facial nerve adjacent to the ear produces a brief contraction of the upper lip, nose, or side of the face.

Chylothorax: The presence of lymphatic fluid (chyle) in the pleural cavity.

Circadian: Pertaining to events that occur with a cycle of about 24 hours.

Circadian rhythm: 24-Hour cycles of behavior and physiology that are generated by endogenous biological clocks (pacemakers).

Circulatory shock: A life-threatening condition wherein the circulatory system is unable to deliver enough oxygen and metabolic substrates to meet the demands of tissues and adequately clear metabolic waste products from those tissues.

Cirrhosis: Widespread disruption of normal liver structure by fibrosis and the formation of regenerative nodules that is caused by any of various chronic progressive conditions affecting the liver.

Class switching: Change in the isotype of antibody produced after a B cell has encountered an antigen.

Clinical cure: Resolution of signs and symptoms of a disease.

Closed comedo: A plugged follicle of sebum, keratinocytes, and bacteria that remains beneath the surface of the skin; also referred to as a "whitehead."

Clotting cascade: A series of enzymatic reactions by clotting factors leading to the formation of a blood clot. The clotting cascade is initiated by several thrombogenic substances. Each reaction in the cascade is triggered by the preceding one, and the effect is amplified by positive feedback loops.

Clotting factor: Plasma proteins found in the blood that are essential to the formation of blood clots; clotting factors circulate in inactive forms, but are activated by their predecessor in the clotting cascade or a thrombogenic substance. Each clotting factor is designated by a Roman numeral (e.g., factor VII) and by the letter "a" when activated (e.g., factor VIIa).

Clubbing: Proliferation of soft tissues, especially in the nail bed, which results in thickening and widening of finger and toe extremities.

Clue cells: Vaginal epithelial cells that, when coated with bacteria, appear with fuzzy, irregular borders under microscopic examination.

Coalescence: Fusion of smaller lipid emulsion particles forming larger particles, resulting in destabilization of the emulsion.

Cognitive function: Executive function and mental processing such as understanding, perception, reasoning, language, and awareness. Executive function involves a long list of skills, but they can

be divided into four categories: organization, self-regulation, attention, and problem solving. For example, a patient may have trouble thinking quickly, making decisions, and planning and prioritizing tasks. These functions can be evaluated by various neuropsychological tests.

Coitus: Sexual intercourse.

Coliforms: Gram-negative organisms that commonly inhabit the intestines of humans and other vertebrates (e.g., *Escherichia coli*).

Colloids: Resuscitation fluids that restore and/or increase the intravascular oncotic pressure.

Colon cancer: A disease in which cells in the lining of the colon become malignant and proliferate without control. Often referred to as colorectal cancer to include cells of the rectum.

Colonoscopy: Visual examination of the colon using a lighted, lens-equipped, flexible tube (colonoscope) inserted into the rectum.

Colony-forming units: The number of microorganisms that form colonies when cultured; indicates the number of viable microorganisms in a sample.

Comedolytic: An agent that is able to break up or destroy a comedo.

Comorbidities: Multiple disease states occurring concurrently in one patient.

Complementary and alternative medicines: A group of practices and products that are not presently considered to be part of conventional medicine, including alternative medical systems (e.g., homeopathic medicine and naturopathic medicine), mind-body interventions (e.g., meditation and mental healing), biologically-based therapies (e.g., dietary supplements, vitamins, herbs, and other natural products), manipulative body-based methods (e.g., acupuncture and massage), and energy therapies (e.g., therapeutic touch and bioelectromagnetic-based therapies).

Complicated urinary tract infection (UTI): Generally used to describe a UTI in a patient who has a structural or functional abnormality or an indwelling foreign body such as a urinary catheter.

Computed tomography (CT) scan: A series of x-ray scans taken from different angles and then compiled by computer to show a cross-section of a body part of interest; a method of body imaging that uses x-ray technology to create cross-sectional images of a person's body.

Computed tomography: Radiographic imaging of anatomic information from a cross-sectional plane of the body.

Concreteness: Inability to think in abstract terms. It may be a primary developmental defect or secondary to organic mental disorder or schizophrenia.

Congenital adrenal hyperplasia: A rare inherited condition resulting from a deficiency in cortisol and aldosterone synthesis with resulting excess androgen production. The clinical presentation depends on the variant of the condition, but it typically manifests as abnormalities in sexual development and/or adrenal insufficiency.

Conidia: Propagating form (spores) of filamentous fungi that are released into soil and air currents. Inhalation of spores is the most common route of infections for endemic fungi and invasive molds.

Conjunctival injection: Erythema of the conjunctiva.

Conjunctivitis medicamentosa: A contact allergy to a topical medication.

Conjunctivitis: Inflammation of the conjunctiva.

Contiguous: Describes two structures that are in close contact, or located next to each other.

Continuous positive airway pressure: Therapy delivered using a nasal mask to improve the patency of the upper airway by maintaining sufficient air pressure to alleviate sleep-disordered breathing.

Contralateral: Pertaining to the opposite side of the body.

Copulation: Sexual union of male and female; coitus; sexual intercourse; also, conjugation between two cells that do not fuse but separate after mutual fertilization.

Cor pulmonale: Right-sided heart failure, usually due to structural lung disease (e.g., pulmonary fibrosis or emphysema).

Corneal arcus: Accumulation of lipid on the cornea.

Coronary artery bypass graft surgery: Thoracic surgery whereby parts of a saphenous vein from a leg or internal mammary artery from the arm are placed as conduits to restore blood flow between the aorta and one or more coronary arteries to "bypass" the coronary artery stenosis (occlusion).

Corpus luteum: The small yellow endocrine structure that develops within a ruptured ovarian follicle and secretes progesterone and estrogen.

Corticotropin-releasing hormone: A hormone released by the hypothalamus that stimulates release of adrenocorticotropic hormone by the anterior pituitary gland.

Cortisol: An adrenal gland hormone responsible for maintaining homeostasis of carbohydrate, protein, and fat metabolism.

Cosyntropin: A synthetic version of adrenocorticotropic hormone.

C-reactive protein: A nonspecific inflammatory marker that may be elevated in osteomyelitis as well as other infections and inflammatory diseases; represents a specific protein produced by the liver during times of inflammation.

Creaming: Aggregation of lipid emulsion particles that then migrate to the surface of the emulsion that can be reversed with mild agitation.

Creatine kinase, creatine kinase myocardial band: Creatine kinase (CK) enzymes are found in many isoforms, with varying concentrations depending on the type of tissue. Creatine kinase is a general term used to describe the nonspecific total release of all types of CK, including that found in skeletal muscle (MM), brain (BB) and heart (MB). CK MB is released into the blood from necrotic myocytes in response to infarction and is a useful laboratory test for diagnosing myocardial infarction. If the total CK is elevated, then the relative index (RI), or fraction of the total that is composed of CK MB, is calculated as follows: RI = (CK MB/CK total) × 100. An RI greater than 2 is typically diagnostic of infarction.

Creatinine: A waste product in the blood produced from the breakdown of protein by-products generated by muscle in the body or ingested in the diet. The kidneys filter blood to remove creatinine and maintain homeostasis. A decline in kidney function results in an increase in creatinine.

Creatinine clearance: The rate at which creatinine is filtered across the glomerulus; an estimate of glomerular filtration rate.

Crescendo: Rapidly increasing symptoms.

Cretinism: Obsolete term for congenital hypothyroidism.

Cross allergenicity: Sensitivity to one drug that results in reaction to a different drug with a similar chemical structure.

Crossover design: A clinical trial design in which patients receive, in sequence, the treatment (or the control), and then after a specified time, receive the opposite arm of the trial. This allows patients to serve as their own controls. Randomization should be

used to determine the order in which a patient receives the treatment and control.

Cryoprecipitate: Component of blood obtained by freezing and thawing plasma that is rich in clotting factors. One unit of cryoprecipitate derived from a unit of whole blood contains a volume of 10 to 20 mL, 80 to 100 units of factor VIII which consists of both the procoagulant activity and the von Willebrand factor, 150 to 250 mg of fibrinogen, 50 to 100 units of factor XIII, and 50 to 60 mg of fibronectin.

Crypt abscess: Neutrophilic infiltration of the intestinal glands (crypts of Lieberkühn); a characteristic finding in patients with ulcerative colitis.

Crystalloids: Resuscitation fluids that are composed of dissolved electrolytes.

Cyanosis: A dark blue or purple discoloration of the skin and mucous membranes due to deficient oxygenation of the blood.

Cyclic citrullinated peptide: A circular peptide (a ring of amino acids) containing the amino acid citrulline. Autoantibodies directed against cyclic citrullinated peptide provide the basis for a test of importance in rheumatoid arthritis.

Cyclooxygenase: Enzymes responsible for metabolizing arachidonic acid to prostaglandins.

Cyst: An abnormal membranous sac within the body that contains liquid or partially solid material.

Cystitis: Cystitis refers to the syndrome associated with a urinary tract infection involving dysuria, frequency, urgency, and occasional suprapubic tenderness.

Cystocele: Hernial protrusion of the bladder, usually through the vaginal wall.

Cytogenetic analysis: Laboratory identification of chromosomes to detect mutational defects.

Cytokines: Regulatory proteins, such as interleukins and lymphokines, that are released by cells of the immune system and act as intercellular mediators in the generation of an immune response.

Cytomegalovirus (CMV) disease: The term used when patients who are already infected with CMV present with classic symptoms that resemble a viral infection and may include fever, malaise, arthralgias, and others.

Cytomegalovirus (CMV) infection: The term used when a patient has anti-CMV antibodies in the blood, when CMV antigens are detected in infected cells, or when the virus is isolated from a culture.

Dactylitis ("hand-foot syndrome"): Diffuse swelling of the hands and/or feet often associated with pain and tenderness.

Deep vein thrombosis: A disorder of thrombus (blood clot) formation causing obstruction of a deep vein in the leg, pelvis, or abdomen.

Dementia: An organic mental disorder characterized by a general loss of intellectual abilities involving impairment in memory, judgment, and abstract thinking, as well as changes in personality.

Denervation: Loss of nerve impulse input, such as by severing a nerve during surgery or nerve impulse blockade farther up the nerve chain.

Dermatophyte: Any microscopic fungus that grows on the skin, scalp, and nails; a microscopic fungus that grows on the skin or mucosa but does not invade deeper tissues.

Desensitization: A method to reduce or eliminate an individual's negative reaction to a substance or stimulus.

Desquamation: Peeling or shedding of the epidermis (superficial layer of the skin) in scales or flakes.

Detrusor muscle: Smooth muscle of the bladder body. When the detrusor muscle contracts, the bladder is emptied of urine.

Detumescence: Reduction or lessening of a swelling, especially the restoration of a swollen organ or body part to normal size; the return of the penis to a flaccid state after an erection.

Diabetes insipidus: Polyuria due to the failure of renal tubules to reabsorb water in response to antidiuretic hormone.

Diabetes mellitus: A group of chronic metabolic disorders characterized by hyperglycemia and associated with long-term microvascular, macrovascular, and neuropathic complications.

Diabetic ketoacidosis: A reversible but life-threatening short-term complication primarily seen in patients with type 1 diabetes caused by the relative or absolute lack of insulin that results in marked ketosis and acidosis.

Diarrhea: Excessive and frequent evacuation of watery feces.

Diarthrodial joint: A joint in which the opposing bony surfaces are covered with a layer of hyaline cartilage and in which some degree of free movement is possible.

Diastolic dysfunction: Abnormal filling of the ventricles during diastole.

Digital rectal examination: Procedure in which the health care professional inserts a gloved finger into the rectum to examine the rectum and the prostate gland for signs of cancer.

Direct current cardioversion: The process of administering a synchronized electrical shock to the chest to simultaneously depolarize all of the myocardial cells, resulting in restoration of normal sinus rhythm.

Directly observed therapy: A treatment method in which patients are under direct observation when they take their medication or receive their treatment. This method is designed to reduce the risk of treatment interruption and to ensure patient adherence.

Disease-free survival: Length of time after treatment during which no disease is found.

Disseminated idiopathic skeletal hyperostosis: Excessive bone formation at skeletal sites subject to stress, generally where tendons and ligaments attach to bone.

Disulfiram-like reaction: Adverse reaction associated with alcohol use manifested by severe nausea, vomiting, and abdominal pain.

DNA mismatch repair genes: Genes that identify and correct errors in DNA base pairs during DNA replication. Mutations in the mismatch repair genes can lead to cancer by allowing abnormal cells to continue to grow.

Dose intensity: Delivery of a predetermined dose per unit of time (e.g., $mg/m^2/wk$).

Down-regulation: The process of reducing or suppressing a response to a stimulus.

Drug of choice: The optimal drug for any given disease state.

Drusen: Tiny yellow or white deposits in the retina.

Ductus arteriosus: The structure that shunts fetal blood flow away from the undeveloped fetal lungs.

Duodenum: The beginning portion of the small intestine, starting at the lower end of the stomach and extending to the jejunum.

Dysarthria: A speech disorder due to weakness or incoordination of speech muscles; speech is slow, weak, and imprecise.

Dysentery: An illness involving severe diarrhea that is often associated with blood in the stool.

Dysesthesias: An unpleasant abnormal sensation.

Dysgeusia: Unpleasant taste in the mouth.
Dyskinesia: Abnormal involuntary movements, which include dystonia, chorea, and akathisia.
Dysmenorrhea: Crampy pelvic pain occurring with or just prior to menses. Primary dysmenorrhea implies pain in the setting of normal pelvic anatomy, whereas secondary dysmenorrhea is due to underlying pelvic pathology.
Dyspareunia: Painful or difficult sexual intercourse.
Dysphagia: Painful or difficult swallowing, accompanied by a sensation of food being stuck in passage.
Dysphonia: Impairment of the voice or difficulty speaking.
Dysphoria: A feeling of general unwellness and discontent.
Dysplasia: Abnormal change in size, shape, or organization of cells in a tissue.
Dyspnea: Difficulty in breathing, often associated with lung or heart disease, and resulting in shortness of breath.
Dyssynergic defecation: A lack of coordination between the pelvic floor muscles and the anal sphincter.
Dystonia: A type of dyskinesia. The movement is slow and twisting. It may be associated with painful muscle contractions or spasms.
Dysuria: Painful urination.

Eburnation: Degeneration of bone into a hard, dense mass with a smooth surface; may occur at articular surfaces of bones in osteoarthritis.
Ecchymoses: Passage of blood from ruptured blood vessels into subcutaneous tissue, causing purple discoloration of the skin.
Ectopic pregnancy: Presence of a fertilized ovum outside the uterine cavity.
Effector cells: Cells that become active in response to initiation of the immune response.
Eisenmenger's syndrome: A congenital heart defect with an abnormal connection between systemic circulation and lung circulation.
Ejection fraction: The fraction of the volume present at the end of diastole that is pushed into the aorta during systole.
Electrocardiogram: A noninvasive method of recording the electrical activity of the heart.
Electroconvulsive therapy: Administration of electric current to the brain through electrodes placed on the head in order to induce seizure activity in the brain, used in the treatment of certain mental disorders.
Electroencephalography: The recording of brain waves via electrodes placed on the scalp or cortex.
Embolism: The sudden blockage of a vessel caused by a blood clot or foreign material that has been brought to the site by the flow of blood.
Embolization: The process by which a blood clot or foreign material dislodges from its site of origin, flows in the blood, and blocks a distant vessel.
Emesis: Vomiting.
Empiric antimicrobial therapy: Antimicrobial therapy given prior to the availability of microbiologic culture results.
Empyema: Pus in the pleural cavity, usually secondary to infection in the lung.
Encephalitis: Acute inflammation of the brain tissue.
Endarterectomy: Excision of the inner lining of an artery occluded by atherosclerotic plaque.
Endogenous: Originating from or produced by metabolic synthesis in the body.
Endometritis: Inflammation of the membrane lining the uterus.
Endoscopic retrograde cholangiopancreatography: A procedure that combines the use of an endoscope with x-rays to examine the ducts that drain the liver, gallbladder, and pancreas.
Endoscopy: A procedure used to evaluate the interior surfaces of an organ by inserting a small scope into the body; through it, one can directly examine almost any part of the intestinal tract. Biopsies can be obtained, polyps removed, and clear images obtained.
Endothelial cells: A single layer of cells surrounding the lumen of arteries.
End-stage liver disease: Liver failure that is usually accompanied by complications such as ascites or hepatic encephalopathy.
Enteral nutrition: Delivery of nutrients via the gastrointestinal tract, either by mouth or by feeding tube.
Enterobacteriaceae: A family of enteric gram-negative bacilli (e.g., *Escherichia coli* or *Klebsiella pneumoniae*).
Enterocytes: Cells lining the small intestine.
Enuresis: Involuntary urination, usually occurring at night or during sleep.
Enzyme-linked immunosorbent assay (ELISA): A biochemical technique used to detect the presence of an antibody or antigen in a sample. The technique uses two antibodies. The first is specific to the antigen and the second is coupled to an enzyme. The second antibody will cause a chromogenic or fluorogenic substrate to produce a signal. Because the ELISA can be used to evaluate the presence of either an antibody or an antigen in a sample, it is useful for both determining serum antibody concentrations (e.g., with human immunodeficiency virus or West Nile virus) and detecting the presence of an antigen.
Epilepsy: A neurologic disorder characterized by recurring motor, sensory, or psychic malfunction with or without loss of consciousness or convulsive seizures.
Erectile dysfunction: The inability to achieve or maintain an erection sufficient for sexual intercourse.
Erythema multiforme: A rash characterized by papular (small raised bumps) or vesicular lesions (blisters), and reddening or discoloration of the skin, often in concentric zones around the lesion.
Erythematous: Flushing of the skin caused by dilation of the capillaries. It is often a sign of inflammation and infection.
Erythrocyte sedimentation rate (ESR): A nonspecific inflammatory marker that may be elevated in some infections and inflammatory diseases; specifically, the ESR is obtained from a blood sample by measuring the distance that red blood cells precipitate after 1 hour.
Erythropoiesis-stimulating agents: Agents developed by recombinant DNA technology that have the same biologic activity as endogenous erythropoietin to stimulate erythropoiesis (red blood cell production) in the bone marrow.
Erythropoietin: A hormone primarily produced by the progenitor cells of the kidney that stimulates red blood cell production in the bone marrow. Lack of this hormone leads to anemia.
Esophageal stricture: Narrowing of the esophageal lumen. Esophageal strictures are usually benign and caused by acid refluxing into the lower esophagus.
Esophageal varices: Dilated blood vessels in the esophagus.
Esophagitis: Inflammation of the esophagus caused by frequent regurgitation of acid and peptic juices from the stomach. The main symptoms are heartburn, regurgitation of bitter fluid, and sometimes difficulty in swallowing. Complications of esophagitis

include narrowing (stricture) of the esophageal lumen, ulcerations, and hemorrhage.

Essential fatty acid deficiency: Deficiency of linoleic acid, linolenic acid, and/or arachidonic acid, characterized by hair loss, thinning of skin, and skin desquamation. Long-chain fatty acids include trienes (containing three double-bonds [e.g., 5,8,11-eicosatrienoic acid, or Mead acid; trienoic acids) and tetraenes (containing four double-bonds [e.g., arachidonic acid]). Biochemical evidence of essential fatty acid deficiency includes a triene:tetraene ratio greater than 0.4 and low linoleic or arachidonic acid plasma concentrations.

Euthymia: Normal mood.

Euthyroid: State of normal thyroid function or hormone activity.

Event-free survival: The length of time after treatment that a person remains free of certain negative events.

Evoked potential testing: A procedure in which sensory nerve pathways are stimulated and the time lapse to electrical response in the corresponding area of the brain is measured.

Exanthem: Eruption of the skin.

Exfoliative dermatitis: Widespread dermatitis characterized by scaling and shedding of the skin and usually accompanied by redness. Also called pityriasis rubra.

Exogenous: Originating outside a body organ or part of the body.

Exophthalmos: Abnormal protrusion of the eyeball; seen in Graves' disease.

Exploratory laparotomy: Surgical incision into the abdominal cavity, performed to examine the abdominal organs and cavity in search of an abnormality and diagnosis.

External beam radiotherapy: Treatment by radiation emitted from a source located at a distance from the body; also called beam therapy and external beam therapy.

Extra-abdominal: Refers to operations taking place outside the abdominal cavity.

Extrapyramidal symptoms (EPS): Adverse effects of medications such as antipsychotics. EPS include dystonia (involuntary muscle contractions), tardive dyskinesia (repetitive, involuntary movements), parkinsonian symptoms (akinesia and tremors), and akathisia (motor restlessness or anxiety).

Extravasation: Movement of fluid from inside a blood vessel into the surrounding tissues; for example, leakage or infiltration of a vesicant chemotherapy agent into local tissue.

Fabry's disease: An x-linked recessive lipid storage disease with an accumulation of the glycosphingolipid.

Facultative anaerobe: An organism that makes adenosine triphosphate by aerobic respiration if oxygen is present, but switches to fermentation under anaerobic conditions.

Facultative: Biologically capable but not restricted to a particular function or mode of life (e.g., survival within macrophages).

Failure to thrive: Below-average growth due to a medical condition. A pronounced lack of growth in a child because of inadequate absorption of nutrients or a serious heart or kidney condition, resulting in below-average height and weight.

Familial adenomatous polyposis: An inherited condition in which numerous polyps form, mainly in the epithelium of the large intestine. While these polyps start out benign, malignant transformation into colon cancer occurs 100% of the time when not treated.

Felty's syndrome: An extra-articular manifestation of rheumatoid arthritis associated with splenomegaly and neutropenia.

Festination: Walking with short, rapid, shuffling steps.

Fetal growth restriction: Diminished fetal growth that often leads to low birth weight.

Fibrin: An insoluble protein that is one of the principal ingredients of a blood clot. Fibrin strands bind to one another to form a fibrin mesh. The fibrin mesh often traps platelets and other blood cells.

Fibrinolysis: A normal ongoing process that dissolves fibrin and results in the removal of small blood clots; hydrolysis of fibrin.

Fibroadenoma: A benign neoplasm derived from glandular epithelium that commonly occurs in breast tissue.

Fistula: Abnormal connection between two internal organs (e.g., arteriovenous fistula, which is a connection between an artery and a vein), or between an internal organ and the exterior or skin (e.g., enterocutaneous fistula, which is a connection between the intestine and the skin).

Flame hemorrhage: Bleeding into the sclera in a pattern similar to a fork or flame. May be associated with bacterial endocarditis.

Flank pain: Pain in the side of the trunk between the right or left upper abdomen and the back (costovertebral angle).

Flight of ideas: A nearly continuous flow of rapid speech and thought that jumps from topic to topic, usually with topics loosely connected.

Flow cytometry: A method of measuring the number of cells in a sample, the percentage of live cells in a sample, and certain characteristics of cells, such as size, shape, and the presence of tumor markers on the cell surface. The cells are stained with a light-sensitive dye, placed in a fluid, and passed in a stream before a laser or other type of light. The measurements are based on how the light-sensitive dye reacts to the light.

Foam cell: Lipid-laden white blood cells.

Fragility fracture: A fracture resulting from a fall from standing height or lesser trauma.

Frank-Starling mechanism: The ability of the heart to change its force of contraction and therefore stroke volume in response to changes in venous return.

Fremitus: A sensation felt by a hand placed on a part of the body (as the chest) that vibrates during speech.

Fresh frozen plasma: Plasma that is frozen within hours after donation to preserve clotting factors.

Friable: Easily crumbled, pulverized, or reduced to powder.

Frontotemporal: Located to the front or side of the head.

Fructooligosaccharides: Polymers of fructose that reach the colon undigested and are broken down there to short-chain fatty acids by bacterial enzymes.

Functional bowel disease: A condition characterized by gastrointestinal symptoms in the absence of a demonstrated pathologic condition.

Galactorrhea: Inappropriate breast milk production.

Gallstone (cholelithiasis): A solid formation in the gallbladder or bile duct composed of cholesterol and bile salts.

Gamma knife: A device that uses multiple converging beams of gamma radiation from cobalt-60 to highly focus radiation on small tumors within the brain.

Gastric bypass: A surgical procedure for weight loss that elicits its effectiveness through malabsorption and volume limitation. The procedure involves full partitioning of the proximal gastric segment into a jejunal loop.

Gastritis: Acute or chronic inflammation of the lining of the stomach.

Gastroenteritis: Inflammation of the gastrointestinal tract causing nausea, vomiting, diarrhea, and fever.

Gastroesophageal reflux disease: Symptoms or mucosal damage that result from abnormal reflux of gastric contents into the esophagus.

Gastroparesis: Partial or mild paralysis of the stomach.

Gastroplasty: A surgical procedure for weight loss that elicits its effectiveness through gastric volume limitation. The procedure involves partial partitioning at the proximal gastric segment with the placement of a gastric outlet stoma of fixed diameter.

Gastroschisis: Rare congenital fissure of the abdominal wall.

Gastrostomy: Operative placement of a new opening into the stomach, usually associated with feeding tube placement.

Geniculate nucleus: The portion of the brain that processes visual information from the optic nerve and relays it to the cerebral cortex.

Genotype: The genetic constitution of an individual.

Gigantism: A condition of abnormal size or overgrowth of the entire body or of any of its parts.

Glasgow Coma Scale (GCS): A scale for evaluating level of consciousness after central nervous system injury (evaluates eye opening and verbal and motor responsiveness).

Glomerular filtration rate (GFR): The volume of plasma that is filtered by the glomerulus per unit time, usually expressed as mL/minute or mL/minute/1.73 m^2, which adjusts the value for body surface area. GFR is the primary index used to describe overall renal function.

Glomerulonephritis: Glomerular lesions that are characterized by inflammation of the capillary loops of the glomerulus. These lesions are generally caused by immunologic, vascular, or other idiopathic diseases. Glomerulonephritis can lead to high blood pressure and loss of kidney function.

Gluconeogenesis: Formation of glucose from precursors other than carbohydrates (especially by the liver and kidney) using amino acids from proteins, glycerol from fats, or lactate produced by muscle during anaerobic glycolysis.

Glutamate: An excitatory amino acid found in the central nervous system.

Glycogenolysis: The process by which glycogen is broken down to glucose in body tissues.

Glycosuria: The presence of abnormal amounts of glucose in the urine.

Goiter: A nonmalignant enlargement of the thyroid gland, visible as a swelling at the front of the neck, that is often associated with iodine deficiency.

Gonioscopy: Examination of the anterior chamber angle of the eye. A gonioprism or Goldman lens is used to perform gonioscopic evaluation.

Goodpasture's syndrome: A rare autoimmune disease that can affect the lungs and kidneys.

Gout: A group of disorders of purine metabolism, manifested by various combinations of hyperuricemia; recurrent acute inflammatory arthritis induced by crystals of monosodium urate monohydrate; tophaceous deposits of monosodium urate monohydrate crystals in and around the joints of the extremities, which may lead to crippling destruction of joints; and uric acid urolithiasis.

Graft-versus-host disease: Failure of a recipient's body to accept a transplanted tissue or organ as the result of immunologic incompatibility; immunologic resistance to foreign tissue.

Graft-versus-tumor effect: Cytotoxic T lymphocytes in the donor stem cells have anti-cancer activity.

Grandiosity: Exaggerated sense of self-importance, ideas, plans, or abilities.

Granuloma: A small nodular delimited aggregation of mononuclear inflammatory cells, or such a collection of modified macrophages usually surrounded by a rim of lymphocytes. Generally denotes a chronic, cell-mediated immune response.

Gummatous: A tumor of rubbery consistency that is characteristic of the tertiary stage of syphilis.

Gut-associated lymphoid tissue (GALT): Lymphoid tissue, including Peyer's patches, found in the gut that is important for providing localized immunity against pathogens.

Haptenation: The process by which a drug, usually of low molecular weight, is bound to a carrier protein or cell and becomes immunogenic.

Heberden's nodes: Small bony growths found on the terminal phalanges of the fingers in patients with osteoarthritis.

Hematochezia: The presence of visible bright red blood in the stool.

Hematogenous: Spread through the blood.

Hematopoietic cell transplantation: Infusion of hematopoietic cells from a donor after administration of a combination of chemotherapy and/or radiation.

Hematuria: Blood in the urine.

Hemiballismus: A rare movement disorder that can be life-threatening. Patients with hemiballismus have a dismal prognosis, with physical exhaustion, injuries, and medical complications often leading to death.

Hemiparesis: Weakness or slight paralysis involving one side of the body.

Hemisensory deficit: Loss of sensation on one side of the body.

Hemithorax: One side of the chest.

Hemolytic uremic syndrome: A syndrome characterized by microangiopathic hemolytic anemia, acute renal failure, and a low platelet count (thrombocytopenia).

Hemoptysis: The expectoration of blood or blood-tinged sputum from the larynx, trachea, bronchi, or lungs.

Hemorrhagic conversion: Conversion of an ischemic stroke into a hemorrhagic stroke.

Hemostasis: Cessation of bleeding through natural (clot formation or constriction of blood vessels), artificial (compression or ligation), or surgical means.

Heparin-induced thrombocytopenia: A clinical syndrome of IgG antibody production against the heparin-platelet factor 4 complex occurring in approximately 1% to 5% of patients exposed to either heparin or low-molecular-weight heparin. Heparin-induced thrombocytopenia results in excess production of thrombin, platelet aggregation, and thrombocytopenia (due to platelet clumping), often leading to venous and arterial thrombosis, amputation of extremities, and death.

Hepatic encephalopathy: Change in mental or neurologic status secondary to progressive liver disease; or confusion and disorientation that a patient with advanced liver disease experiences due to accumulation of ammonia.

Hepatic steatosis: Fatty infiltration of the liver.

Hepatocytes: The basic functional cells of the liver.

Hepatojugular reflex: A physical sign evidenced by distention of the jugular vein with application of pressure on the abdomen over the liver.

Hepatosplenomegaly: Enlargement of the liver and spleen.

Hepatotoxicity: Toxicity to the liver causing damage to liver cells.
Herniation: A protrusion through an abnormal bodily opening.
Heterozygous: Having different alleles at a gene locus.
Hirschsprung's disease: A disease of the small intestine that causes constipation (bowel movements are difficult).
Hirsutism: Excess body hair.
HIV genotype: A type of resistance testing for human immunodeficiency virus (HIV) in which a patient's blood sample is obtained, their HIV RNA is sequenced, and mutations that have developed that may confer resistance to antiretrovirals are reported.
HIV phenotype: A type of resistance testing for human immunodeficiency virus (HIV) in which a patient's blood sample is obtained, and the patient's HIV genes that encode for reverse transcriptase and protease are removed and placed in an HIV viral vector. This viral vector is replicated in a cell culture system with varying concentrations of antiretrovirals. A drug concentration–viral inhibition curve is developed and the concentration needed to inhibit 50% of the patient's virus is reported. This is used to predict resistance versus susceptibility.
HIV virtual phenotype: A database of matching human immunodeficiency virus (HIV) genotypes and phenotypes is developed. When an HIV genotype for a patient is obtained, the database is used to predict the patient's phenotype based on their actual genotype using matches that occur in the database.
Homozygous: Having identical alleles at a gene locus.
Hot flashes: A feeling of warmth that is commonly accompanied by skin flushing and mild to severe perspiration.
Hypothalamic–pituitary–adrenal (HPA) axis: A neuroendocrine feedback loop that controls response to stress.
Human chorionic gonadotropin: A hormone secreted by the placenta that is used to aid in the determination of pregnancy.
Human leukocyte antigens (HLA): Groups of genes found on the major histocompatibility complex, which contain cell-surface antigen-presenting proteins. The body uses HLA to distinguish between self-cells and non–self-cells.
Humoral: Relating to products secreted into the blood or body fluids.
Hydramnios: Excess amniotic fluid.
Hydronephrosis: Distention of the pelvis and kidney with urine resulting from obstruction of the ureter.
Hyperalgesia: An increased pain response to a stimulus that normally causes pain.
Hyperbilirubinemia: Abnormally high concentrations of the bile pigment bilirubin in the bloodstream. Hyperbilirubinemia is defined as a total serum bilirubin level greater than 5 mg/dL.
Hypercalcemia: Excessive calcium concentration in the blood.
Hypercalciuria: Excessive amount of calcium in the urine.
Hypercapnia: Abnormally high concentration of carbon dioxide in the blood.
Hypercoagulable state: A disorder or state of excessive or frequent thrombus formation; also known as thrombophilia.
Hyperemesis gravidarum: A rare disorder of severe and persistent nausea and vomiting during pregnancy that can result in dehydration, malnutrition, weight loss, and hospitalization.
Hyperemic: Denotes an increased amount of blood in a part of the body.
Hyperglycemia: Abnormally high blood glucose concentration.
Hyperglycemic hyperosmolar nonketotic syndrome: Severe increase in serum glucose concentration without the production of ketones, leading to an increase in serum osmolality and symptoms such as increased thirst, urination, weakness, fatigue, confusion, and in severe cases convulsions and/or coma.
Hyperinsulinemia: High concentration of insulin in the blood.
Hyperopia: Farsightedness.
Hyperosmolar hyperglycemic state: A potentially fatal short-term complication most commonly seen in older patients with type 2 diabetes caused by an insufficiency of insulin action that leads to alterations of osmolality and hyperglycemia, but without the ketosis and acidosis seen in diabetic ketoacidosis.
Hyperpathia: A painful syndrome characterized by increased reaction to a stimulus, especially a repetitive stimulus, as well as an increased threshold.
Hyperpigmentation: A common darkening of the skin which occurs when an excess of melanin forms deposits in the skin.
Hyperplasia: An increase in the number of cells within a tissue leading to an increase in tissue or organ size.
Hyperprolactinemia: Elevated serum prolactin characterized by prolactin serum concentrations greater than 20 ng/mL (20 mcg/L) in men or 25 ng/mL (25 mcg/L) in women.
Hyperthyroidism: State caused by excess production of thyroid hormone.
Hypertrichosis: Excessive growth of hair.
Hyperuricemia: Elevated serum uric acid concentration, defined as a level greater than 7.0 mg/dL.
Hypochlorhydria: Hypoacidity; decreased hydrochloric acid secretion by the stomach.
Hypocretin: A wakefulness-promoting hypothalamic neuropeptide, a deficiency of which is involved in the pathophysiology of narcolepsy.
Hypogammaglobulinemia: Reduced levels of antibodies.
Hypoglycemia: Abnormal decrease in blood glucose below the normal range.
Hypogonadism: A condition resulting from or characterized by abnormally decreased functional activity of the gonads, with retardation of growth and sexual development; or reduced or absent secretion of hormones from the sex glands resulting in low testosterone levels in men.
Hypomania: Abnormal mood elevation that does not meet the criteria for mania.
Hypopituitarism: A clinical disorder characterized by complete or partial deficiency in pituitary hormone production.
Hypothyroidism: State caused by inadequate production of thyroid hormone.
Hypovolemic shock: A shock state characterized by an inadequate intravascular volume to meet the oxygen and metabolic needs of the body.
Hypoxemia: Deficient oxygenation of the blood.
Hypoxia: A pathologic condition in which the body (generalized hypoxia) or region of the body (tissue hypoxia) is deprived of adequate oxygen supply (partial arterial oxygen pressure less than 80 mm Hg). Hypoxia in which there is complete deprivation of the oxygen supply is referred to as anoxia.
Hysterectomy: Excision of the uterus.

Immune reconstitution syndrome: A syndrome characterized by fever and worsening of clinical symptoms of opportunistic infections or new symptoms occurring within weeks after starting antiretroviral therapy. This has been described for mycobacterial infections (*Mycobacterium avium* complex and *Mycobacterium tuberculosis*), *Pneumocystis jiroveci* pneumonia, toxoplasmosis,

hepatitis B and C viruses, cytomegalovirus infection, varicella-zoster virus infection, cryptococcal infection, and progressive multifocal leukoencephalopathy.

Immunocompromised: A condition in which the immune system is not functioning normally. This condition is seen in the very young, the very old, human immunodeficiency virus–infected individuals, and in transplant patients. An immunocompromised person is susceptible to opportunistic infections.

Immunogenicity: The property that gives a substance the ability to provoke an immune response.

Immunoglobulin G index: The ratio of immunoglobulin G to protein in the serum or cerebrospinal fluid.

Immunophenotype: The process of identification and quantitation of cellular antigens through fluorochrome-labeled monoclonal antibodies.

Implantable cardioverter-defibrillator (ICD): A device implanted into the heart transvenously with a generator implanted subcutaneously in the pectoral area that provides internal electrical cardioversion of ventricular tachycardia or defibrillation of ventricular fibrillation.

Index patient: The patient originally diagnosed with a disease.

Indirect immunofluorescence assay (IFA): A laboratory test used to detect antibodies in serum or other body fluid. The specific antibodies are labeled with a compound that will make them glow a fluorescent green color when observed microscopically under ultraviolet light.

Induration: An increase in the fibrous elements in tissue commonly associated with inflammation and marked by loss of elasticity.

Infarction: The formation of an infarct, an area of tissue death due to a local lack of oxygen.

Infective endocarditis: Historically referred to as bacterial endocarditis, this is an infection, either acute or subacute, that primarily affects the heart valves, but may extend into other surrounding areas of the heart.

Inotropic: Relating to or influencing the force of muscular contractions, usually referring to changes in the contractile state of the heart.

Insensate: Devoid of sensation or feeling.

Insulin-like growth factor-I: An anabolic peptide that acts as a direct stimulator of cell proliferation and growth in all body cells.

Insulin secretagogue: A substance or medication that stimulates insulin secretion from the pancreas.

Insulin sensitizer: A substance that increases the action of insulin in peripheral tissues by reducing the effects of insulin resistance.

International Normalized Ratio (INR): The ratio of the patient's clotting time to the clinical laboratory's mean reference value; normalized by raising it to the International Sensitivity Index (ISI) power to account for differences in thromboplastin reagents. Therefore, INR = (patient's prothrombin time/laboratory's mean normal prothrombin time)$_{ISI}$.

Intima: The inner layer of the wall of an artery or vein.

Intra-abdominal: Within the abdominal cavity.

Intra-articular: In the hollow space within joints.

Intrapartum: During labor and delivery.

Intraperitoneal: Within the peritoneal cavity.

Intrathecal: Drug administration into the cerebrospinal fluid of the spinal cord.

Intravenous pyelogram: Radiograph of the urinary tract, including the kidney, ureters, urinary bladder, and urethra; radiographic contrast media that is filtered 100% by the glomerulus is given intravenously. Timed x-rays are taken after administration of the contrast media to assess anatomy and function of the organs in the urinary tract.

Intussusception: The folding of one part of the intestine into the lumen of an immediately adjoining part; or the enfolding of one segment of the intestine within another.

Iontophoresis: Introduction of a medication into tissue through use of an electric current.

Ipsilateral: Pertaining to the same side of the body.

Iron hematoxylin: Stain or dye to identify cell nuclei or identifiable characteristics of an organism.

Janeway lesion: A finding of endocarditis wherein there are nonraised and nonpainful linear lines on the palms of the hands or soles of the feet.

Jarisch-Herxheimer reaction: A reaction to antibiotic therapy commonly seen in secondary syphilis wherein the patient develops a skin rash and temperature.

Jejunum: The section of the small intestine between the duodenum and the ileum.

Jejunostomy: Operative placement of a new opening into the jejunum, usually associated with feeding tube placement.

Karyotypic: Number, size, and structure of cell chromosomes.

Kegel exercises: Specific exercises that strengthen the pelvic floor muscles and help to prevent and treat stress incontinence.

Keratinocyte: The epidermal cell that synthesizes keratin, making up 95% of all epidermal cells; commonly called "skin cells."

Keratitis: Infection of the cornea.

Keratoconjunctivitis sicca: Dryness of conjunctiva and cornea; a component of Sjögren's syndrome.

Keratotic: Pertaining to any horny growth such as a wart or callus.

Kernig's sign: Sign associated with meningitis, in which reflex contraction or spasm of the hamstring muscle occurs when extending the lower leg at an angle greater than 90° to the body.

Ketosis: An abnormal increase of ketone bodies present in conditions of reduced or disturbed carbohydrate metabolism.

Koebner phenomenon: The occurrence of psoriatic lesions due to skin trauma.

Korotkoff sounds: The noise heard over an artery by auscultation when pressure over the artery is reduced below the systolic arterial pressure.

Kyphosis: Abnormal curvature of the spine resulting in protrusion of the upper back; hunchback.

Lactic acidosis: A condition caused by build-up of lactic acid in the body. It leads to acidification of the blood (acidosis), and is a form of metabolic acidosis.

Lactose intolerance: Inability of the body to digest lactose.

Lagophthalmos: Poor closure of the upper eyelid.

Lamina cribrosa: A series of perforated sheets of connective tissue that the optic nerve passes through as it exits the eye.

Laminectomy: Excision of the posterior arch of a vertebra to relieve pressure on the spinal cord.

Laparoscopy: A type of surgical procedure in which a small incision is made, usually in the navel. A viewing tube (laparoscope) which has a small camera on the eyepiece is inserted, allowing examination of the abdominal and pelvic organs using a video

monitor connected to the tube. Other small incisions can be made to insert instruments to perform procedures. This procedure is less invasive than regular open abdominal surgery (laparotomy).

Laparotomy: Surgical opening of the abdominal cavity.

Lentigines: Plural of lentigo, which is a small, flat, tan to dark brown or black, macular melanosis on the skin that looks like a freckle but is histologically distinct. Lentigines do not darken on exposure to sunlight, freckles do.

Leukemoid reaction: An elevated white blood cell count that is a physiologic response to stress or infection (as opposed to a primary blood malignancy, such as leukemia).

Leukocytoclastic: The breaking up of white blood cells.

Leukocytosis: Elevation of the white blood cell count above the normal range.

Leukopenia: A reduction in the circulating white blood cell count; also a condition in which the number of circulating white blood cells is abnormally low due to decreased production of new cells, possibly in conjunction with medication toxicities.

Leukostasis: Abnormal intravascular leukocyte aggregation and clumping seen in leukemia patients. The brain and the lungs are the two most frequent organs involved.

Lewy bodies: Abnormal masses inside some nerve cells. They occur in a variety of locations, and their structure and composition vary depending on location.

Lhermitte's sign: Paresthesias radiating down the back of the extremities with neck flexion; also tingling or shock-like sensation passing down the trunk when the neck is flexed.

Libido: Conscious or unconscious sexual desire.

Ligament of Treitz: Suspensory muscle of the duodenum; the tissue that connects the duodenum to the diaphragm.

Linea nigra: Common physical finding during pregnancy, which manifests as a dark line on the skin running from the navel to the pubis.

Linear accelerator: A device that uses microwave technology to accelerate electrons in a highly focused beam to deliver targeted radiation to tumor sites.

Lipase: A pancreatic enzyme that cleaves lipids.

Lipolysis: The splitting up (hydrolysis) or chemical decomposition of fat.

Lipophilic: Having an affinity for fatty substances.

Lipoprotein lipase: Enzyme located in the capillary endothelium involved in the breakdown of intravenous lipid emulsion particles.

Locus ceruleus: Nucleus of norepinephrine-containing neurons located in the brain stem that are responsible for physiologic response to stress and panic.

Lower urinary tract infection (UTI): Includes infections of the bladder, urethra, and (in men) prostate and epididymis.

Luteolysis: The structural and functional degradation of the corpus luteum that occurs at the end of the luteal phase in the absence of pregnancy; caused by the hormones prostaglandin-2α and oxytocin. Communication between the corpus luteum and uterine endometrium is necessary for luteolysis.

Lymphadenectomy: Surgical excision of lymph nodes.

Lymphadenitis: Inflammation of the lymph nodes, which become swollen, painful, and tender.

Lymphatic system: The tissues and organs that produce, store, and carry white blood cells that fight infection and disease. This system includes the bone marrow, spleen, thymus, and lymph nodes and a network of thin tubes that carry lymph and white blood cells.

Lymphoproliferative: Of or related to the growth of lymphoid tissue.

Maceration: The softening or breaking down of a solid by leaving it immersed in a liquid.

Macrophages: Large scavenger cells present in connective tissue and many major organs that remove bacteria.

Macula: An oval, yellow-pigmented area on the central retina containing color-sensitive rods and the central point of sharpest vision.

Maculopapular: Describes a rash that contains both macules and papules. A macule is a flat discolored area of the skin, and a papule is a small raised bump. A maculopapular rash is usually a large area that is red and has small, confluent bumps.

Magnetic resonance imaging (MRI): Method of body imaging that uses a magnetic field and radio waves to create cross-sectional images of one's body, which provides detailed pictures of organs and tissues.

Manometry: Measurement of pressures within organs of the body. Manometry is often used to indicate muscular activity in motile tubes such as the esophagus.

Mastalgia: Tenderness of the breast.

Matrix metalloproteinases: Zinc-dependent enzymes capable of degrading extracellular matrix proteins, including connective tissue.

Mean arterial blood pressure: A calculated measure of arterial blood pressure; mean arterial blood pressure = (2 × diastolic blood pressure + systolic blood pressure)/3.

Meatal stenosis: Narrowing of the urethral opening at the tip of the penis.

Meconium: The first intestinal discharge or "stool" of a newborn infant, usually green in color and consisting of epithelial cells, mucus, and bile.

Media: The middle layer of the wall of an artery or vein.

Mediastinitis: Inflammation of the midline partition of the chest cavity.

Mediastinum: The space in the thoracic cavity between the pleural sacs and behind the sternum.

Medullary cystic disease: A hereditary kidney disorder characterized by gradual and progressive loss of kidney function because of cysts in the kidney medulla.

Melanosis: Excessive pigmentation of the skin due to a disturbance in melanin pigmentation; also called melanism.

Melasma: Facial pigmentation found across the upper cheeks, nose, and forehead.

Menarche: The onset of menstrual periods, usually occurring between the ages of 10 and 17.

Meninges: Group of three membranes (dura mater, pia mater, arachnoid) surrounding the brain and spinal cord.

Meningitis: An acute inflammation of the membranes surrounding the brain or spinal cord (meninges) and the cerebrospinal fluid in contact with these membranes.

Menopause: Permanent cessation of menstruation following the loss of ovarian follicular activity.

Menorrhagia: Menstrual blood loss of greater than 80 mL per cycle; a more practical definition is heavy menstrual flow associated with problems of containment of flow, unpredictably heavy flow days, or other associated symptoms.

Mesocortical: A neural pathway that connects the ventral tegmentum to the cortex, particularly the frontal lobes. It is one of the major dopamine pathways in the brain.

Mesothelioma: A rare benign or malignant tumor affecting the lining of the chest or abdomen. Exposure to asbestos fibers is the most common risk factor for mesothelioma.

Metabolic acidosis: An acid-base disorder caused by overproduction or accumulation of acid (often lactic acid; see lactic acidosis) or a deficit of base (i.e., bicarbonate).

Metabolic alkalosis: Increased alkalinity of body fluids caused by excessive alkali (usually bicarbonate) intake or excessive acid loss (e.g., from vomiting).

Metalloproteinase: A family of protein-hydrolyzing endopeptidases that contain zinc ions as part of the active structure.

Metastasis: The migration of cancer cells from the original tumor site through the blood and lymph vessels to produce cancers in other tissues.

Micelle: A microscopic particle of digested fat and cholesterol.

Microalbuminuria: Presence of small quantities of urine albumin (a urine albumin test measures the amount of protein in urine); the presence of a small amount of albumin (30 to 300 mg/day) in the urine, which is an early sign of chronic kidney disease.

Micrographia: Small handwriting, often seen in patients with Parkinson's disease.

Microvascular pulmonary emboli: An obstruction in the small blood vessels in the lung caused by material (e.g., blood clot, fat, air, and foreign body) that is carried through the circulation until it lodges in another small vessel.

Micturition: Voiding; urination.

Migraineur: A person who suffers from migraine headaches.

Minimum bactericidal concentration: The lowest concentration of antibiotic that will eliminate 3 logs or 99.9% of bacteria.

Minimum inhibitory concentration: The lowest concentration of a drug that will visually inhibit the growth of a microorganism.

Miosis: Pupillary constriction.

Mixed acid-base disorder: More than one of the following disorders occurring simultaneously: acidosis (metabolic or respiratory) and alkalosis (metabolic or respiratory).

Mixed mood episodes: Symptoms of mania and depression occurring simultaneously or in close juxtaposition.

Molds: Multicellular filamentous fungi that asexually reproduce by formation of reproductive hyphae that release conidia into the environment.

Monocytes: A leukocyte that protects against blood-borne pathogens which rapidly moves to sites of infection in tissues. Monocytes consist of 3% to 8% of the leukocytes in the blood. In tissues, monocytes mature into different types of macrophages at different anatomic locations. Their main function is phagocytosis of foreign material, cellular debris, and pathogens that are not effectively controlled by neutrophils.

Monoparesis: Slight or incomplete paralysis affecting a single extremity or part of one.

Monosodium urate: A crystallized form of uric acid that can deposit in joints leading to an inflammatory reaction and the symptoms of gout.

Morphology: The science of structure and form of cells without regard to function.

Motor tics: Sudden, involuntary muscle movements (e.g., spasms).

Mucositis: Inflammation of mucous membranes, typically within the oral and esophageal mucosa. Mucositis is usually associated with certain chemotherapy agents and radiation therapy involving mucosal areas.

Mucous colitis: A condition of the mucous membrane of the colon characterized by pain, constipation, or diarrhea (sometimes alternating), and passage of mucus or mucous shreds.

Multidrug resistant tuberculosis (TB): The presence of at least 1% of *Mycobacterium* strains in a bacterial population or culture that are resistant to at least isoniazid and rifampin.

Multiparity: Condition of having given birth to multiple children.

Multiple organ dysfunction syndrome: Relatively simultaneous failure of more than one organ, regardless of etiology.

Mydriasis: Pupillary dilation.

Myelin: A protein and phospholipid sheath that surrounds the axons of certain neurons. Myelinated nerves conduct impulses more rapidly than nonmyelinated nerves.

Myelodysplastic syndrome: A diverse collection of hematologic conditions united by ineffective production of some or all of the blood cells.

Myeloproliferative disorder: A group of diseases of the bone marrow in which excess cells, usually lymphocytes, are produced.

Myelosuppression: A condition in which bone marrow activity is decreased, resulting in fewer red blood cells, white blood cells, and platelets. Myelosuppression is a side effect of some cancer treatments.

Myocardial contractility: The force of contraction of the heart during systole.

Myocarditis: Inflammation of the muscular wall of the heart.

Myoclonus: A sudden, involuntary jerking of a muscle or group of muscles.

Myoglobinuria: The presence of myoglobin in urine.

Myopathy: Any disease of the muscle causing weakness, pain, and tenderness.

Myringotomy: A surgical incision in the tympanic membrane to relieve pressure and drain fluid from the middle ear.

Myxedema: Advanced hypothyroidism characterized by a relatively firm edema of subcutaneous tissue, subnormal body temperature, dryness and loss of hair, hoarseness, and muscle weakness.

Nasal polyposis: Presence of several polyps (benign growths) in the nasal cavity.

Nasal scotoma: An area of blindness in the nasal portion of peripheral vision.

Nascent: Immature; beginning.

Nasolacrimal occlusion: The closing of the tear duct by application of manual pressure to decrease systemic absorption of a drug.

Nausea: A feeling of sickness or discomfort in the stomach that may come with an urge to vomit.

Necrotizing fasciitis: A severe soft-tissue infection involving the superficial fascia.

Nelson's syndrome: A condition characterized by the aggressive growth of a pituitary tumor and hyperpigmentation of the skin.

Neoadjuvant therapy: Therapy given prior to the primary treatment. In cancer, it is usually given prior to surgery to make the surgical procedure easier to perform.

Neovascularization: New blood vessel formation (vascularization) especially in abnormal quantity (as in some conditions of the retina) or in abnormal tissue (as a tumor).

Nephrolithiasis: A condition marked by the presence of renal calculi (stones) in the kidney or urinary system.

Nephron: The working unit of the kidney that filters blood to remove fluid, toxins, and drugs. Each kidney contains approximately 1 million nephrons.

Nephrostomy: Insertion of a catheter through the skin into the renal pelvis to bypass ureteral obstruction and facilitate urine drainage.

Neuralgia: Pain that extends along the course of one or more nerves.
Neural tube defects: Birth defect resulting from improper development of the central nervous system.
Neuritic (senile) plaques: Microscopic lesions composed of fragmented axon terminals and dendrites surrounding a core of amyloid seen in the cerebral cortex in Alzheimer's disease.
Neuritis: Inflammation of a nerve.
Neurofibrillary tangles: Intracellular knots or clumps of neurofibrils seen in the cerebral cortex in Alzheimer's disease.
Neuroimaging: Radiologic studies of the brain, usually referring to computed tomography (CT) or magnetic resonance imaging (MRI).
Neurologic focality: Symptomatic sensory or motor deficits that point to specific lesions or dysfunction in the brain.
Neuropathic pain: Pain resulting from a lesion or dysfunction of the nervous system.
Neuropathy: An abnormal and usually degenerative state of the nervous system or nerves.
Neurotransmitter: Chemical intermediary in the nervous system that facilitates transmission of impulses across synapses.
Neutralizing antibodies: Antibodies that develop in response to a therapeutic agent that decrease the efficacy of the agent.
Nuclear factor-κB: Nuclear factor-kappa B (NF-κB) is a transcription factor that regulates cytokine production.
Nociceptors: Receptors for pain caused by injury from physical stimuli (mechanical, electrical, or thermal) or chemical stimuli (toxins). Nociceptors are located in the skin, muscles, and in the walls of the viscera.
Nocturia: Urination at night, especially if excessive.
Nocturnal polysomnography: Visual and electrophysiologic assessment of human sleep minimally composed of electroencephalogram, electrooculogram, and electromyogram that allows determination of sleep stage, breathing events, and muscle movements.
Nodules: Subcutaneous knobby tissue mass over bony prominences or extensor surfaces.
Nonbacterial thrombotic endocarditis: Endocarditis caused by noninfectious vegetations.
Nonnucleoside reverse transcriptase inhibitor (NNRTI): A noncompetitive inhibitor of the viral reverse transcriptase enzyme that binds to the active site of the enzyme itself, rather than by terminating the enzymatic product. NNRTIs are only active against human immunodeficiency virus-1.
Nonpolyposis: Absence of polyps.
Nonprotein kcal:nitrogen ratio: Ratio of carbohydrate plus fat calories in a volume compared to the grams of nitrogen (calculated as number of grams of protein divided by 6.25).
Non-REM sleep: A state of usually dreamless sleep that occurs regularly during a normal period of sleep with intervening periods of rapid eye movement (REM) sleep and that consists of four distinct substages and low levels of autonomic physiologic activity.
Non–ST-segment elevation: A type of myocardial infarction (MI) that is limited to the subendocardial myocardium and is smaller and less extensive than an ST-segment MI. There is usually no pathologic Q-wave on the electrocardiogram in non–ST-segment elevation.
Normal flora: Normal colonizing bacteria of a human host.
Normochromic: Being normal in color; referring especially to red blood cells.
Normocytic: Normal size, especially referring to red blood cells.
Nosocomial infection: An infection acquired within the health care system. Generally, symptoms of infection must occur after at least 48 hours of care to be considered nosocomial.
Nuchal rigidity: Severe neck stiffness usually associated with meningitis; inability to touch chin to chest.
Nuclear medicine scans: Method of body imaging that uses a radioactive tracer material (e.g., technetium and gallium) to produce body images. For example, bone scans detect uptake and cellular activity in areas of inflammation.
Nucleoside reverse transcriptase inhibitor (NRTI)/nucleotide reverse transcriptase inhibitor (NtRI): A modified version of a naturally-occurring nucleoside or nucleotide that prevents human immunodeficiency virus (HIV) replication by interfering with the function of the viral reverse transcriptase enzyme. The nucleoside/nucleotide analog causes early termination of the proviral DNA chain. For activity, an NRTI requires three phosphorylation steps once inside the cell, whereas an NtRI has a phosphate group attached and needs only two phosphorylation steps inside the cell for activity.
Nucleus: A group of specialized nerve cells or a localized mass of gray matter in the brain or spinal cord.
Nulliparity: The condition of not having borne children.
Nystagmus: Rapid, involuntary eye movements.

Obliterative bronchiolitis: Inflammation of the bronchioles (the small elements of the tracheobronchial tree) characterized by obliteration and/or permanent narrowing of the airways.
Odynophagia: Sensation of pain behind the sternum when swallowing food or fluids.
Oiling out: Continued coalescence of lipid emulsion particles, resulting in irreversible separation of the emulsion (or "breaking" of the emulsion).
Oligoanovulation: The condition of having few or no ovulatory menstrual cycles.
Oligoclonal bands: Two to five bands of immunoglobulins on protein electrophoresis of cerebrospinal fluid.
Oligomenorrhea: Reduced frequency of menses with a time interval between periods more than 40 days but less than 6 months.
Oliguria: Reduced urine output; usually defined as less than 400 mL in 24 hours or less than 0.5 mL/kg/hour.
Omentumectomy: Excision of the double fold of peritoneum attached to the stomach and connecting it with abdominal viscera (omentum).
Oncogene: Family of genes that encodes for proteins involved with cell growth or regulation; Genes that cause transformation of normal cells into cancer cells by promoting uncontrolled cell growth and multiplication leading to tumor formation.
Onychomycosis: Fungal infection of fingernails or toenails.
Oophorectomy: Surgery to remove the ovaries.
Open comedo: A plugged follicle of sebum, keratinocytes, and bacteria that protrudes from the surface of the skin and appears black or brown in color. Also referred to as a "blackhead."
Opsonization: The process by which an antigen is altered so as to become more readily and more efficiently engulfed by phagocytes.
Optic neuritis: Usually monocular central visual acuity loss and ocular/periorbital pain caused by demyelination of the optic nerve.
Orbital and supraorbital: Pertaining to the eye socket and the area directly above it.
Orchiectomy: Surgical removal of the testicles.

Organification: Binding of iodine to tyrosine residues of thyroglobulin.
Orthopnea: Difficulty in breathing that occurs when lying down and is relieved upon changing to an upright position.
Orthostasis: A drop in blood pressure when standing up from sitting or lying down, often causing lightheadedness and dizziness.
Orthotopic: Placing a transplanted organ into the normal anatomic location.
Osler's node: Raised, painful, red lesions found on the finger pulps and soles of the feet; indicative of subacute bacterial endocarditis. Osler's nodes are caused by immune complex deposition.
Osmolality: A measure of the number of osmotically active particles per unit solution, independent of the weight or nature of the particle.
Osmolar gap: The difference between the measured serum osmolality and the calculated serum osmolality.
Osmophobia: A fear of strong odors and unpleasant smells; also called olfactophobia.
Osteoblasts: Cells involved in bone formation during the remodeling process.
Osteoclasts: Cells responsible for bone resorption during the remodeling process.
Osteomalacia: A disease characterized by softening of bones.
Osteonecrosis: Death of bone tissue.
Osteopenia: Reduced bone density or mass.
Osteophytes: Pathologic bony outgrowths, often seen in osteoarthritis.
Osteoporosis: Disease of the bones characterized by a loss of bone density or mass, resulting in brittle, weak bones that are susceptible to fracture (porous bones).
Ostomy: A surgical operation whereby part of the abdominal wall is opened and part of the intestine is connected to the opening for intestinal draining (e.g., colostomy and ileostomy).
Otitis media with effusion: Fluid in the middle ear space with no signs or symptoms of an acute infection.
Ovulation: Periodic ripening and rupture of a mature follicle and the discharge of an ovum from the cortex of the ovary.

Pacemaker: A mass of fibers that possess actual or potential automaticity, which initiates and determines the rate of spontaneous depolarizations.
Pancolitis: Inflammation involving the majority of the colon in patients with inflammatory bowel disease.
Pancreatitis: Inflammation of the pancreas.
Panhypopituitarism: A state in which the secretion of all anterior pituitary hormones is inadequate or absent.
Pannus: Inflamed synovial tissue that invades and destroys articular structures.
Papilledema: Edema of the optic disc typically associated with increased intracranial pressure.
Paracentral scotoma: A blind spot near the center of the visual field.
Parasomnia: Undesirable physical or behavioral phenomena that occur predominantly during sleep (e.g., sleep walking, bruxism, enuresis, sleep talking, and rapid eye movement behavior disorder).
Parenchyma: The essential and distinctive cells or tissue of an organ (as distinguished from its supporting framework).
Parenteral nutrition: Delivery of nutrients via the intravenous route.
Paresthesia: An abnormal touch sensation, such as burning, tingling, or prickling, often in the absence of external stimuli.
Parietooccipital: Located to the top and back of the head.
Paroxysmal: An intermittent occurrence initiating suddenly and spontaneously; may last minutes to hours; terminates suddenly and spontaneously.
Patent ductus arteriosus: Failure of the ductus arteriosus to close, resulting in neonatal hypoxemia.
Peak expiratory flow: The maximum flow rate of air leaving the lungs upon forced exhalation.
Pelvic inflammatory disease (PID): Inflammation of the endometrium, uterine tubes, and pelvic peritoneum. PID is often due to a sexually transmitted infection.
Percutaneous coronary intervention: A minimally invasive procedure whereby access to the coronary arteries is obtained through the femoral artery up the aorta to the coronary os. Contrast media is used to visualize the coronary artery stenosis using a coronary angiogram. A guidewire is used to cross the stenosis and a small balloon is inflated and/or stent is deployed to break up atherosclerotic plaque and restore coronary artery blood flow. The stent is left in place to prevent acute closure and restenosis of the coronary artery. Newer stents are coated with antiproliferative drugs, such as paclitaxel and sirolimus, which further reduce the risk of restenosis of the coronary artery.
Percutaneous endoscopic gastrostomy: Gastric feeding tube placed via endoscopic technique.
Percutaneous endoscopic jejunostomy: Jejunal feeding tube placed via endoscopic technique.
Performance status: A clinical staging of the patient's ability to perform activities of daily life. Oncologists use it in evaluation of a patient's ability to tolerate a contemplated chemotherapy regimen.
Perihilar: The area surrounding the depression in the medial surface of a lung that forms the opening through which the bronchus, blood vessels, and nerves pass.
Perimenopause: The period of time prior to menopause when hormonal and biological changes and physical symptoms begin to occur and usually lasts for 1 year after the last menstrual period. The perimenopausal period may last for an average of 3 to 5 years. Perimenopause is also known as the climacteric.
Perimetry: Measurement of the field of vision.
Peripheral resistance: The sum of resistance to blood flow offered by systemic blood vessels.
Peritonitis: An acute inflammatory reaction of the peritoneal lining to microorganisms or chemical irritation.
Perseveration: Continued involuntary repetition of a response to varied stimuli.
Petechiae: Tiny localized hemorrhages from the small blood vessels just beneath the surface of the skin.
Phagocyte: A cell that engulfs and digests foreign material (e.g., microorganisms) and debris.
Phagocytosis: The process of ingesting and destroying foreign material and debris by phagocytes.
Pharmacogenomics: The science of understanding the correlation between an individual patient's genetic make-up (genotype) and their response to drug treatment.
Pharyngitis: Inflammation and/or infection of the pharynx that causes throat pain.
Phenotype: The expression of the genes present in an individual. This may be directly observable (e.g., eye color) or apparent only

with specific tests (e.g., blood type). Some phenotypes such as the blood groups are completely determined by heredity, while others are readily altered by environmental agents.

Pheochromocytoma: A tumor arising from chromaffin cells, most commonly found in the adrenal medulla. The tumor causes the adrenal medulla to hypersecrete epinephrine and norepinephrine, resulting in hypertension and other signs and symptoms of excessive sympathetic nervous system activity. The tumor is usually benign but may occasionally be cancerous.

Phlebitis: Inflammation of a blood vessel (e.g., vein).

Phonophobia: A fear of or intolerance to sounds, loud noises, and even one's own voice.

Photophobia: An abnormal sensitivity to or intolerance of light.

Phototherapy: The use of ultraviolet light applied to the skin, for example in treating psoriasis or neonatal hyperbilirubinemia.

Plasma cell: A lymphocyte that is a mature antibody-secreting B cell.

Plasmapheresis: A process of separating blood cells from plasma. This process is used to remove monoclonal antibodies from the blood.

Platelet-activating factor: A mediator of platelet aggregation and inflammation that is produced in response to stimuli, such as white blood cells.

Pleocytosis: A transient increase in the number of leukocytes in a body fluid.

Pleuritis: Inflammation of the lining around the lungs.

Plication: A folding or putting together in pleats. Plication is an operation for reducing the size of a hollow organ by taking folds or tucks in its wall.

Pneumatic otoscopy: A diagnostic technique involving visualization of the tympanic membrane for transparency, position, and color, and its response to positive and negative air pressure to assess mobility.

Pneumothorax: The presence of air in the pleural cavity, often causing part of the lung to collapse.

Polycystic kidney disease: A disorder in which clusters of cysts develop within the kidneys.

Polycythemia: A condition in which there is a net increase in the total circulating erythrocyte (red blood cell) mass of the body.

Polydipsia: Excessive thirst.

Polymerase chain reaction (PCR): Laboratory technique involving amplification of small amounts of DNA or RNA. PCR is commonly used in medical and biological research labs for a variety of tasks, such as the detection of hereditary diseases, the identification of genetic fingerprints, the diagnosis of infectious diseases, the cloning of genes, and paternity testing.

Polymorphic metabolism: Genetically determined rates of metabolism (fast vs. slow) by selected isozymes of cytochrome P-450 drug-metabolizing enzymes.

Polyp: A growth from a mucous membrane commonly found in organs such as the colon, rectum, and nose.

Polyphagia: Eating excessively large amounts of food at a meal.

Polyradiculitis: Refers to inflammation of multiple spinal nerve roots.

Polyradiculopathy: Disease or injury involving multiple spinal nerve roots.

Polyuria: Excessive excretion of urine.

Portal hypertension: Increased blood pressure within the portal vein that supplies the liver.

Positron emission tomography (PET) scan: A scan that produces images of the body after the injection of a radioactive form of glucose. The scan is often used to detect cancer since tumors use more sugar than normal cells. PET scans may also be used to see how well the tumor is responding to treatment.

Postpyloric feeding: Delivery of nutrients via a tube placed with its tip past the pyloric sphincter separating the stomach from the duodenum.

Postvoid residual urine volume: Amount of urine left in the urinary bladder after the patient has been asked to empty the bladder. Assessed by urethral catheterization or ultrasonography. Normal postvoid residual urine volume should be less than 50 mL. An increased postvoid residual urine volume is consistent with incomplete bladder emptying.

Prediabetes: An asymptomatic but abnormal state that precedes the development of clinically evident diabetes.

Preload: The stretched condition of the heart muscle at the end of diastole just before contraction; volume in the left ventricle at the end of diastole estimated by the pulmonary artery occlusion pressure (also known as the pulmonary artery wedge pressure or pulmonary capillary wedge pressure).

Premenstrual dysphoric disorder: Severe psychiatric mood disorder with marked affective symptoms causing significant interference in work or relationships that is temporally associated with the luteal phase and not caused by an underlying psychiatric disturbance.

Premenstrual syndrome: A constellation of symptoms including mild mood disturbance, and physical symptoms that occur prior to menses, and resolve with initiation of menses.

Preparative regimen: The combination of chemotherapy and/or radiation used immediately prior to allogeneic hematopoietic cell transplantation; also referred to as the conditioning regimen.

Priapism: A prolonged, often painful erection of the penis.

Primary amenorrhea: Absence of menses by age 16 in the presence of normal secondary sexual development; or absence of menses by age 14 in the absence of normal secondary sexual development.

Primary prevention: The removal or reduction of risk factors before the development of disease.

Probiotics: Dietary supplements containing potentially beneficial bacteria that promote health by stimulating optimal mucosal immune responses.

Proctitis: Inflammation confined to the rectum in patients with inflammatory bowel disease.

Prodrome: Early symptom(s) indicating the onset of an attack or a disease.

Progenitor cell: An immature or precursor cell that can divide and give rise to a differentiated cell.

Prolapse: Protrusion of an organ or part of an organ through an opening (e.g., uterine prolapse occurs when the uterus is displaced downward such that the cervix is within the vaginal opening [first-degree], the cervix is outside the opening [second-degree], or the entire uterus is outside the opening [third-degree]).

Proptosis: Forward displacement of the eyeball.

Prostaglandin: Any of a large group of biologically active, carbon-20, unsaturated fatty acids that are produced by the metabolism of arachidonic acid through the cyclooxygenase pathway.

Prostate: An organ in the urogenital tract that surrounds the urethra at the base of the urinary bladder. Prostatic secretions are secreted into the urethra and become part of the ejaculate in males.

Prostatectomy: Removal of all or part of the prostate gland.
Prostate-specific antigen (PSA): a substance secreted by the prostate and normally carried by ducts to the urethra during ejaculation; PSA is used as a screening test for prostate cancer.
Prosthetic-valve endocarditis: Endocarditis that occurs in patients with bioprosthetic or synthetic implanted heart valves.
Protease: Any one of numerous enzymes that hydrolyze proteins.
Protease inhibitor: A drug that acts by inhibiting the viral protease enzyme, which prevents long strands of protein from being cleaved into the smaller proteins the virus requires for assembly.
Proteinase: Any one of numerous enzymes that catalyze the breakdown of proteins; also called protease.
Proteinuria: Abnormally high amount of protein in the urine. Proteinuria is defined as urinary protein excretion of greater than 150 mg per day.
Proteoglycans: Glycosaminoglycans (mucopolysaccharides) bound to protein chains in covalent complexes. Proteoglycans are present in the extracellular matrix of connective tissue.
Proteolysis: The hydrolysis of proteins, usually by enzyme action, into simpler substances.
Proteosome: An enzyme complex that degrades intracellular proteins.
Prothrombin: A clotting factor that is converted to thrombin; also known as factor II.
Prothrombin time (PT): A measure of coagulation representing the amount of time required to form a blood clot after the addition of thromboplastin to the blood sample; PT is also known as Quick's test.
Prothrombotic state: A state of high coagulation of the blood.
Pruritus: Localized or generalized itching due to irritation of sensory nerve endings.
Pseudohyphae: Elongated forms created by replicating yeast that form buds but do not detach from one another.
Pseudophakic: Refers to presence of a lens after cataract extraction.
Pseudopolyp: An area of hypertrophied gastrointestinal mucosa that resembles a polyp and contains nonmalignant cells.
Pulmonary artery catheter: An invasive device used to measure hemodynamic parameters directly, including cardiac output and pulmonary artery occlusion pressure; calculated parameters include stroke volume and systemic vascular resistance.
Pulmonary embolism: A disorder of thrombus formation causing obstruction of a pulmonary artery or one of its branches; may result in pulmonary infarction.
Pulsus paradoxus: Exaggeration of normal variation in the pulse during respiration—the pulse becomes weaker during inhalation and stronger during exhalation; characteristic of constrictive pericarditis or pericardial effusion.
Purified protein derivative (PPD): Material used in the tuberculin skin test, the most common test for exposure to *Mycobacterium tuberculosis.*
Purkinje fibers: Specialized myocardial fibers that conduct impulses from the atrioventricular node to the ventricles.
Purpura: A small hemorrhage in the skin, mucous membrane, or serosal surface.
Purulent: Containing, consisting of, or being pus.
Pyloroplasty: A surgical procedure for enlarging the opening of the stomach to the duodenum.
Pyuria: The presence of white blood cells in the urine, a known marker of inflammatory response to bacterial infection.
Quality of life: Measured by validated scales and patient interviews to determine the effect of therapy on a patient's lifestyle. An improvement in quality of life may be an endpoint in clinical trials.

Radiation nephritis: Kidney injury and impairment of function caused by ionizing radiation.
Radical prostatectomy: Surgical removal of the entire prostate and the seminal vesicles.
Radiofrequency catheter ablation: Procedure during which radiofrequency energy is delivered through a catheter positioned at the atrioventricular node of the heart for the purpose of destroying one pathway of a reentrant circuit.
Raphe nuclei: A bed of serotonin-containing neurons that extends to the hypothalamus, septum, hippocampus, and cingulate gyrus.
Rebound effect: Symptoms reoccur after treatment has been stopped or is no longer effective. In some cases, symptoms can be more pronounced than when symptoms were initially identified.
Rectal prolapse: Sinking of the rectum through the anal sphincter so that it is visible externally.
Recurrence: The occurrence of another episode of illness once recovery has been made from the previous episode.
Reentry: Circular movement of electrical impulses; a mechanism of many arrhythmias.
Refractory periods: The period of time after an impulse is initiated and conducted during which cells cannot be depolarized again.
Regurgitation: A passive process without involvement of the abdominal wall and the diaphragm wherein gastric or esophageal contents move into the mouth.
Relapse: Regression after partial or full recovery from an illness.
Rapid eye movement (REM) sleep: A state of sleep that recurs cyclically several times during a normal period of sleep and is characterized by increased neuronal activity of the forebrain and midbrain, by depressed muscle tone, and especially in humans by dreaming, rapid eye movements, and vascular congestion of the sex organs.
Remission: The resolution or abatement of symptoms of a disease state.
Renal osteodystrophy: Altered bone turnover that results from sustained metabolic conditions that occur in chronic kidney disease, including secondary hyperparathyroidism, hyperphosphatemia, hypocalcemia, and vitamin D deficiency.
Renin–angiotensin–aldosterone system (RAAS): The hormonal system controlled mainly by the kidneys and adrenal glands that regulates blood pressure, blood volume, and electrolyte balance.
Resorption of bone: The process of bone breakdown by osteoclasts.
Respiratory acidosis: Acidosis caused by retention of carbon dioxide due to a respiratory abnormality (e.g., chronic obstructive lung disease).
Respiratory alkalosis: Alkalosis caused by excessive loss of carbon dioxide due to a respiratory abnormality (e.g., hyperventilation).
Respiratory disturbance index: A summary measure that quantifies the number of apneas, hypopneas, and respiratory effort–related arousals per hour of sleep.
Response: Refers to a predefined reduction of symptoms from baseline that generally results in significant functional improvement.
Retching: A process that follows nausea and consists of diaphragm, abdominal wall, and chest wall contractions and spasmodic breathing against a closed glottis.
Reticulocytes: Immature blood cells that mature into erythrocytes.
Reticuloendothelial system: Cells located throughout the body that can phagocytose particulate matter.

Retroperitoneal fibrosis: An accumulation of fibrotic tissues in the retroperitoneum (the anatomic space behind the abdominal cavity). Structures that lie behind the peritoneum are thus termed "retroperitoneal." These structures include kidneys, the bladder, portions of the duodenum, portions of the colon, and the inferior vena cava.

Reye's syndrome: A sudden, sometimes fatal, syndrome characterized by encephalopathy and liver degeneration; it occurs in children after viral infection and may be associated with aspirin use.

Rhabdomyolysis: Destruction of skeletal muscle.

Rheumatic fever: An acute inflammatory disease involving the joints, heart, skin, and other tissues caused by an immune response to streptococcal infection, particularly seen in children.

Rheumatoid factors: Antibodies reactive with the Fc region of immunoglobulin G.

Rhinitis medicamentosa: Inflammation of nasal mucous membranes due to excessive use of topical medication.

Rhinorrhea: Nasal secretions; a runny nose.

Rhinosinusitis: Inflammation of the mucous membranes in the nose and sinuses.

Rhonchi: Abnormal rumbling sounds heard on auscultation of an obstructed airway. They are more prominent during expiration and may clear somewhat on coughing.

Risk factor: Refers to any characteristic of a patient or procedure that increases the chance of a patient experiencing a negative endpoint.

Roth spot: Possible sign of endocarditis where there is localized capillary retinal bleeding.

Rubefacient: An agent applied to the skin that causes local irritation and redness; used to relieve pain by a counterirritant mechanism.

Sarcoidosis: An inflammatory disease characterized by granulomas (masses of chronically inflamed tissues with granulations) that can produce many different symptoms.

Scarlatiniform rash: Bright, scarlet-colored skin eruption that occurs in patches over the entire body with eventual peeling as a result of streptococcal infection.

Scleritis: Inflammation of the outer layer of the eyeball.

Scoliosis: Lateral curvature of the spine.

Secondary amenorrhea: Absence of menses for three cycles or 6 months in a previously menstruating woman.

Secondary hyperparathyroidism: Increased secretion of parathyroid hormone from the parathyroid glands caused by hyperphosphatemia, hypocalcemia, and vitamin D deficiency that result from decreased kidney function. It can lead to bone disease (renal osteodystrophy).

Secondary transmission: Transferring a disease from the primary source to another person.

Sepsis: A syndrome characterized by a systemic inflammatory response (abnormal increases in body temperature, heart rate, respiratory rate, and/or white blood cell concentration) caused by infection.

Serosal: An enclosing serous membrane of the pericardial, pleural, and peritoneal cavities.

Serum ferritin: A complex protein formed in the intestine, containing about 23% iron, the amount of ferritin found in serum is directly related to iron storage in the body.

Serum bactericidal titer: The lowest titer of serum and antibiotic obtained from the patient, usually at the peak or trough of antibiotic administration, that results in a 99.9% kill of bacteria.

Serum inhibitory titer: The lowest titer of serum and antibiotic obtained from the patient, usually at the peak or trough of antibiotic administration, that inhibits bacterial growth.

Serum sickness: A group of symptoms that can be caused by a delayed immune response to certain medications. Arthralgias, fever, malaise, and urticaria may develop, usually 7 to 14 days after exposure to the causative antigen.

Shear stress: A risk factor for pressure ulcers that is generated when the head of a patient's bed is elevated, causing deeper blood vessels to crimp, which leads to ischemia.

Shock: A condition wherein the principal function of the circulatory system to supply oxygen and vital metabolic substrates to cells throughout the body as well as removal of metabolic waste products is compromised. The four major shock types are hypovolemic, obstructive, cardiogenic, and distributive.

Sialorrhea: Drooling.

Sickle-cell anemia: An autosomal recessive disorder in which a mutation in the gene for one of the proteins that comprises hemoglobin results in the formation of defective hemoglobin molecules known as hemoglobin S. Individuals who are homozygous for this mutation (possess two genes for hemoglobin S) have red blood cells that change from the normal discoid shape to a sickle shape when the oxygen supply is low. These sickle-shaped cells are easily trapped in capillaries and damaged, resulting in severe anemia.

Sickle-cell syndrome: A group of autosomal recessive genetic disorders characterized by the presence of at least one sickle-hemoglobin gene.

Sickle hemoglobin: A defective form of hemoglobin produced as a result of a single substitution of the amino acid valine for glutamic acid at position 6 of the β-polypeptide chain.

Sick sinus syndrome: Idiopathic sinus node dysfunction leading to symptomatic sinus bradycardia.

Sigmoidoscopy: Visual inspection of the sigmoid colon and rectum with a flexible tube called a sigmoidoscope.

Single nucleotide polymorphisms: Single base-pair changes that are inherited as mendelian traits and might associate with a trait such as susceptibility to disease.

Sjögren's syndrome: An inflammatory disorder of unknown cause that affects the mucous membranes, causing dry mouth, decreased tear production, decreased sense of taste and smell, joint pain, and swollen glands.

Sleep apnea: The temporary cessation of breathing during sleep; can be caused by airway narrowing as a result of soft tissue swelling.

Sleep latency: The amount of time it takes to fall asleep.

Slit lamp biomicroscope: An instrument that allows for the microscopic examination of the cornea, anterior chamber lens, and posterior chamber.

Somatic hypermutation: High frequency of mutation that occurs in the gene segments encoding the variable regions of antibodies during the differentiation of B lymphocytes into antibody-producing plasma cells.

Somatostatin: A growth hormone–inhibiting hormone that stops production of growth hormone from the anterior pituitary.

Somatotrope: Growth hormone producing cells in the anterior pituitary.

Source control: Removal of the primary cause of an infection such as contaminated prosthetic materials (e.g., catheters), necrotic tissue, or drainage of an abscess. Antimicrobials are unlikely to be effective if the process or source that led to the infection is not controlled.

Spasticity: A motor disorder characterized by an increase in muscle tone with exaggerated tendon jerks, resulting from hyperexcitability of the stretch reflex.
Spastic colon: A synonym for irritable bowel syndrome.
Spectrum of activity: A qualitative term that describes the number of different bacterial species that are susceptible to an antimicrobial regimen. Generally, broad-spectrum activity refers to regimens that possess activity against many bacterial species, whereas narrow-spectrum therapy refers to activity against a few bacterial species.
Sphincter of Oddi: A muscular valve separating the common bile duct from the duodenum. The sphincter of Oddi is the structure through which the common bile duct empties bile and pancreatic secretions into the duodenum.
Spinal shock: Shock that occurs as a result of malfunction of the sympathetic nervous system after a spinal cord injury.
Splinter hemorrhage: Linear image under the nail beds caused by local hemorrhage as a result of hand trauma or endocarditis.
Spirometry: Measurement of inhaled and exhaled volumes and flow rates of gas from the lungs. Pulmonary function tests obtained from spirometry are used to aid in the diagnosis of obstructive and restrictive airway diseases.
Splenomegaly: An enlarged spleen.
Spontaneous bacterial peritonitis: Bacterial infection of the peritoneal fluid without an abdominal source.
Sprain: An overstretching of supporting ligaments that results in a partial or complete tear of the ligament.
Sputum cultures: The process of growing living material obtained from sputum (as bacteria or viruses) in prepared nutrient media.
Sputum smears: Lower respiratory tract smear on a microscope slide to determine the presence of organisms.
Status epilepticus: Any seizure lasting more than 30 minutes, with or without a loss of consciousness; having recurrent seizures without regaining consciousness between seizure episodes.
Steatohepatitis: A severe form of liver disease caused by fat deposition in the liver, characterized by hepatic inflammation that may rapidly progress to liver fibrosis and cirrhosis.
Steatorrhea: Excessive loss of fat in stool.
Steatosis: A process of tissue degeneration characterized by deposition of fat globules in cells; also known fatty degeneration.
Stenosis: Narrowing or constriction of the diameter of a bodily passage or orifice.
Stenting: Placement of a stent (a short metal or plastic tube) to allow blood flow through an artery.
Stevens-Johnson syndrome: A severe expression of erythema multiforme (also known as erythema multiforme major). It typically involves the skin and the mucous membranes with the potential for severe morbidity and even death.
Stimulants: Medications that increase physiologic activity in the body by augmenting dopamine and/or norepinephrine.
Stomatitis: Inflammation of mucous membranes in the mouth.
Strain: Damage to the muscle fibers or muscle sheath without tearing of the ligament.
Striae: Linear, atrophic, pinkish or purplish, scar-like lesions that later become white (striae albicantes or lineae albicantes); may occur on the abdomen, breasts, buttocks, and thighs; they are due to weakening of the elastic tissues; commonly called stretch marks.
Stricture: An area of narrowing or constriction of a tubular structure. Strictures may result from long-standing inflammation.
Stroke volume: The amount of blood ejected from the heart during systole.
ST-segment elevation: A type of myocardial infarction (MI) that typically results in an injury that transects the thickness of the myocardial wall. Following an ST-elevation MI, pathologic Q waves are frequently seen on the electrocardiogram, indicating transmural myocardial infarction.
Subchondral: Beneath or below the cartilage.
Substantia nigra: The area in the brain stem that makes dopamine.
Surgical site infection: Refers to an infection resulting from a surgical procedure. May involve the incision or associated tissue and organs.
Synechia: Adhesions or the abnormal attachment of the iris to another structure. Peripheral anterior synechia refers to occurrence of synechia with the trabecular meshwork.
Synovitis: Inflammation of the synovial membrane, especially when a joint is involved.
Synovium: The membrane lining the internal surfaces of the joint.
Systemic vascular resistance: The portion of resistance to blood flow leaving the heart that is determined by vascular tone (constriction or relaxation). Systemic vascular resistance = mean arterial blood pressure/cardiac output.
Systolic dysfunction: An abnormal contraction of the ventricles during systole.

T2-weighted magnetic resonance imaging: A setting of the magnetic resonance imaging machine that shows water as a bright signal.
Tachycardia: An abnormally rapid beating of the heart, defined as a resting heart rate over 100 beats per minute in an average adult.
Tachyphylaxis: Rapidly decreasing response to a drug or other physiologically active agent after a few doses.
Tachypnea: Abnormally rapid respiratory rate.
Tangentiality: Abandoning one's ideational objective in pursuit of thoughts peripheral to the original goal. Used to describe a thought and speech pattern wherein the individual never gets to the point or answers the question.
Tardive dyskinesia: A chronic disorder of the nervous system characterized by involuntary jerky or writhing movements of the face, tongue, jaws, trunk, and limbs, usually developing as a late side effect of prolonged treatment with antipsychotic drugs.
Telangiectasia: Permanent dilation of preexisting small blood vessels (capillaries, arterioles, and venules), usually in the skin or mucous membranes, which presents as a coarse or fine red mark.
Tendinitis: Inflammation of a tendon.
Tenesmus: Straining, especially painful, or ineffectual straining with a bowel movement or straining on defecation.
Tenosynovitis: Inflammation of the tendon sheath.
Teratogen: Any substance that leads to structural or functional abnormality in the fetus, including death.
Teratogenic: Causing malformations in a fetus.
Teratogenicity: The property of causing malformations in the developing fetus.
Teratogenic potential: The ability of an agent to cause harm or malformations to a fetus or embryo. Medications are assigned pregnancy categories based on their teratogenic potential.
Tetany: Hyperexcitability of nerves and muscles characterized by muscular twitching and cramps, laryngospasm with inspiratory stridor, and hyperreflexia.

Therapeutic drug monitoring: The process of using drug concentrations, pharmacokinetic principles, and pharmacodynamic criteria to optimize drug therapy in individual patients.
Thoracentesis: Removal of fluid present in the pleural space; a common procedure to determine the cause of fluid accumulation.
Thought blocking: Speech is halted, often in mid-sentence, and then picked up later, usually at another point in the thought process.
Thrombin: The enzyme formed from prothrombin, which converts fibrinogen to fibrin. It is the principal driving force in the clotting cascade.
Thrombocytopenia: Persistent decrease in the number of blood platelets.
Thrombocytosis: Increased number of platelets in the blood.
Thrombogenesis: The process of forming a blood clot.
Thrombogenic: Relating to thrombogen; causing thrombosis or coagulation of the blood.
Thrombolysis: The process of enzymatically dissolving or breaking apart a blood clot.
Thrombolytic: Breaking up a clot.
Thrombophlebitis: Inflammation of a blood vessel (e.g., vein) associated with the stimulation of clotting and formation of a thrombus (or blood clot).
Thromboplastin: A substance that triggers the coagulation cascade. Tissue factor is a naturally-occurring thromboplastin and is used in the prothrombin time test.
Thrombosis: A condition in which blood changes from a liquid to a solid state and produces a blood clot (thrombus).
Thrombotic thrombocytopenic purpura: Condition characterized by formation of small clots within the circulation resulting in the consumption of platelets and a low platelet count.
Thrombus: An aggregation of fibrin and platelets within a blood vessel. A thrombus often causes vessel obstruction, inflammation, and injury.
Thymoma: A tumor derived from the epithelial or lymphoid elements of the thymus.
Thyroglobulin: A thyroid hormone–containing protein, usually stored in the colloid within the thyroid follicles.
Thyroiditis: Inflammation of the thyroid gland.
Thyroid peroxidase: An enzyme that catalyzes the organification and coupling steps of thyroid hormone synthesis.
Thyrotoxicosis: A state caused by an excess of thyroid hormone.
Tocolytic agents: Medications that can stop labor by slowing down or halting the contractions.
Tonometry: A method of measuring the pressure of the eye by measuring the tone or firmness of its surface.
Tophi: Chalky deposits of sodium urate occurring in gout. Tophi form most often around joints in cartilage, bone, bursae, and subcutaneous tissue and in the external ear, producing a chronic, foreign-body inflammatory response. If untreated, tophi can lead to joint deformity or destruction.
Topoisomerase: An enzyme that uncoils DNA during replication by cutting the DNA. Topoisomerase inhibitors prevent DNA from sealing the cut, which causes DNA strand breakage.
Toxic epidermal necrolysis: A life-threatening skin disorder characterized by blistering and peeling of the top layer of skin.
Toxoid: A toxin of a pathogenic organism treated to destroy its toxicity but leave it capable of inducing antibody formation upon injection.
Tracheal aspiration: Suctioning of secretions from the trachea.
Transaminases: Hepatocellular enzymes that are released into the bloodstream after hepatic damage.
Transesophageal echocardiogram: A procedure used to generate an image of the heart using sound waves, via a probe introduced into the esophagus (rather than the traditional transthoracic view) in order to obtain a better image of the left atrium.
Transferrin saturation: A laboratory test that indicates the amount of transferrin that is bound with iron.
Transient ischemic attack: A focal neurologic deficit lasting less than 24 hours in which symptoms resolve completely.
Transit time: The time it takes for food to travel from mouth to anus.
Translocation: Movement of bacteria and endotoxin from the intestinal lumen through the gut mucosa and into the lymphatic and systemic circulation.
Transmural: Across the wall of an organ or structure.
Transsphenoidal pituitary microsurgery: Surgery through the nasal cavity to access the pituitary gland through the sphenoid bone.
Transvenous pacing: Insertion of a pacemaker into the heart via venous access for the purpose of pacing.
Travelers' diarrhea: An acute infectious diarrhea that afflicts travelers. The disease is characterized by the presence of at least three loose stools within 24 hours that is associated with nausea, vomiting, abdominal pain, fecal urgency, or dysentery.
Treatment-resistant depression: Depression characterized by multiple failed trials of antidepressants and/or electroconvulsive therapy.
Trigeminal nerve: The fifth cranial nerve responsible for pain perception in the head and face.
Trigeminal neuralgia: A disorder of the fifth cranial (trigeminal) nerve characterized by excruciating paroxysms of pain in the face.
Trigeminovascular: Referring to the cranial nerve and its vascular supply responsible for the generation of headache pain.
Troponins T or I: Proteins found predominantly in cardiac muscle that regulate calcium-mediated interaction of actin and myosin; troponins I and T are released into the blood from myocytes at the time of myocardial cell necrosis after infarction. These biochemical markers become elevated and are used in the diagnosis of myocardial infarction.
Trousseau's sign: An indication of latent tetany in which carpal spasm occurs when the upper arm is compressed, as by a tourniquet or a blood pressure cuff.
Trypsin: A proteolytic enzyme formed in the small intestine from trypsinogen.
Tuberoeruptive xanthomas: Small yellow-red raised papules usually presenting on the elbows, knees, back, and buttocks.
Tubulointerstitial: Pertaining to the renal tubules and interstitial tissue.
Tumor suppressor genes: Genes that normally restrain cell growth, but when missing or inactivated by mutation, allow cells to grow uncontrolled and tumors to form.
Turbinate: Any of the scrolled spongy bones of the nasal passage.
Tympanocentesis: Puncture of the tympanic membrane with a needle to aspirate middle ear fluid.
Tympanostomy tube: A small plastic or metal tube inserted in the eardrum to keep the middle ear aerated and improve hearing in patients with chronic middle ear effusion.

Uhthoff's phenomenon: Acute worsening of multiple sclerosis symptoms on exposure to heat because high body temperatures may exceed the capacitance of the demyelinated nerve and conduction may fail.

Ulceration: A suppurative or non-healing lesion on a surface such as skin, cornea, or mucous membrane.
Ultrasound: Noninvasive imaging of organ or tissue to detect fluid, masses, or cyst.
Uncomplicated urinary tract infection (UTI): Generally used to describe a UTI in a patient without structural or functional abnormalities of the urinary tract.
Unilateral: Pertaining to one side.
Upper respiratory tract infection: Sinusitis, bronchitis, or otitis caused by viral or bacterial infections.
Upper urinary tract infection: Typically used to describe infection involving the upper urinary tract, particularly the kidneys.
Uremia: A condition that results from accumulation of metabolic waste products and endogenous toxins in the body resulting from impaired kidney function. Symptoms of uremia include nausea, vomiting, weakness, loss of appetite, and mental confusion.
Urethral stricture: Fibrosis and scarring of the urethra that results in narrowing of the urethral lumen.
Uric acid: A by-product of purine metabolism in mammals, including humans. A high serum uric acid concentration is a major risk factor for gout.
Uricosuric: Pertaining to, characterized by, or promoting renal secretion of uric acid.
Urosepsis: The sepsis syndrome that may be seen in patients with a urinary tract infection.
Urticaria: Itchy, raised, swollen areas on the skin; also known as hives.
Uveitis: An inflammation of the uvea in the eye. Uveal structures include the iris, the ciliary body, and the choroid.

Vagal maneuvers: Maneuvers that stimulate the activity of the parasympathetic nervous system and thereby inhibit atrioventricular nodal conduction. Examples of vagal maneuvers include cough, carotid sinus massage, and Valsalva maneuver.
Vagotomy: A surgical procedure that blocks vagal (cholinergic) stimulation to the stomach.
Valsalva maneuver: A vagal maneuver in which the patient bears down against a closed glottis, as if having a bowel movement.
Variceal bleeding: Gastric or esophageal bleeding from collateral vessels (varices).
Vasculitis: Inflammation of the walls of blood vessels.
Vasopressors: Medications that cause constriction of blood vessels, increase in vascular resistance, and increase in blood pressure.
Ventilation-perfusion ratio (V_A/Q): A comparison of the proportion of lung tissue being ventilated by inhaled air to the rate of oxygenation of pulmonary blood.
Ventricular depolarization: Change in the membrane potential of a ventricular myocyte, resulting in loss of polarization. Under normal conditions, depolarization of ventricular myocytes is followed by ventricular contraction.
Vertigo: Sensation of spinning or feeling out of balance.
Vesicant: A drug that causes significant tissue damage (e.g., necrosis) upon infiltration into soft tissue after intravenous administration.
Virilization: Production or acquisition of virilism, which is a masculine characteristic.
Vital signs: Major physical parameters, including heart rate, blood pressure, respiratory rate, and body temperature.
Volvulus: Abnormal twisting of the intestine causing obstruction.
Vomiting: A reflexive rapid and forceful oral expulsion of upper gastrointestinal contents due to powerful and sustained contractions in the abdominal and thoracic musculature.

Western blot: A method to detect protein in a given sample of tissue homogenate or extract. It uses gel electrophoresis to separate denatured proteins by mass. Some diagnostic applications for the Western blot include Lyme disease, bovine spongiform encephalopathy, and human immunodeficiency virus (HIV) (it is considered the gold standard for HIV diagnostic testing).
Wheeze: A high-pitched whistling sound caused by air moving through narrowed airways. Wheezes are usually heard at the end of expiration, but may be heard during inspiration and expiration in severe acute asthma.
White coat hypertension: A persistently elevated average office blood pressure greater than 140/90 mm Hg (stage 1) in the presence of a health care worker, whereas the patient otherwise has an average daytime ambulatory reading less than 135/85 mm Hg.
Wilms' tumor: A kidney cancer that primarily affects children.
Wilson's disease: A disorder of copper metabolism characterized by cirrhosis of the liver and neurologic manifestations; a potentially fatal genetic disorder that causes the body to retain copper.

Xanthoma: Firm, raised nodules composed of lipid-containing histiocytes.
Xerostomia: Dryness of the mouth resulting from diminished or arrested salivary secretion.

Yeast: Single-celled fungi that reproduce by budding.

ZAP-70 expression: An intracellular tyrosine kinase found in B cells in chronic lymphocytic leukemia.
Zymogen: A proenzyme; the inactive or nearly inactive precursor of an enzyme that is converted into an active enzyme by proteolysis.

in musculoskeletal disorders, 905t, 906
in osteoarthritis, 884t, 888–889
in pain, 498
Capsicum, 154t
in musculoskeletal disorders, 905t, 906
Capsules, administration through feeding tubes, 1525
Captopril
in acute coronary syndromes, 95t
adverse effects of, 19t
dosage of, 19t, 46t, 75t, 95t
in heart failure, 46, 46t
in hypertension, 19t
in ischemic heart disease, 74, 75t
Caput medusae, 326
Carafate, drug interactions of, 1183t
Carbachol
adverse effects of, 920
dosage of, 915t
in glaucoma, 915t, 920
mechanism of action of, 915t
Carbamazepine
adverse effects of, 452, 453t, 599
in alcohol withdrawal, 535
allergic drug reactions, 825
anxiety with, 610t
arrhythmia with, 114t
autoinduction of metabolism of, 450, 450f
in bipolar disorder, 593t, 595t–596t, 598t, 599–602
dosage of, 450, 453t, 593t, 599
drug interactions of, 153t, 458, 458t, 534t, 563, 576t, 599–600, 613t, 675t, 746t, 844t
in epilepsy, 450, 451t, 453t, 457
erectile dysfunction with, 782t
mechanism of action of, 444, 453t, 599
monitoring therapy with, 598t, 599
in oxaliplatin-induced neuropathy, 1351
pharmacokinetics of, 453t, 595t–596t
in pregnancy, 458
in prevention of migraine, 508
teratogenic effects of, 726t
Carbapenems
allergic drug reactions, 822t
in intraabdominal infections, 1133
in meningitis, 1044
in sepsis, 1191–1192, 1191t
in urinary tract infections, 1155t
Carbimazole
in hyperthyroidism, 678–680
mechanism of action of, 678
Carbohydrates
digestion of, 1513f
metabolism of, growth hormone effects on, 704t
Carbon dioxide
blood, 420–424
total venous, 420
Carbon monoxide poisoning, 424t
Carbonic anhydrase inhibitors
in glaucoma, 915t, 919–920
systemic, 919–920
topical, 919
Carboplatin, 1291
adverse effects of, 371, 1291, 1330t, 1392t
in breast cancer, 1320
in cancer therapy, 1291
dosage of, 1330t–1331t, 1381t, 1391t, 1392t
in renal dysfunction, 1300t
emetogenicity of, 302t
in lung cancer, 1330t–1331t, 1331–1334
mechanism of action of, 1284f, 1291
in non-Hodgkin's lymphoma, 1381t
in ovarian cancer, 1389–1392, 1391t, 1392t
pharmacokinetics of, 1291
Carbuncle
clinical presentation in, 1077t
diagnosis of, 1077t
epidemiology of, 1077t

in inflammatory bowel disease, 287t, 289, 291
in multiple sclerosis, 434
in nausea and vomiting, 299t, 301, 303–304
osteoporosis with, 864–865
in transplant recipient, 842
Methylprednisone
dosage of, 1381t
in non-Hodgkin's lymphoma, 1381t
Methyltestosterone, 788
Methylxanthine, respiratory alkalosis with, 427t
Methysergide
adverse effects of, 509
in prevention of migraine, 508t
Metipranolol
dosage of, 915t
in glaucoma, 915t, 918
mechanism of action of, 915t
ocular changes with, 947t
Metoclopramide
adverse effects of, 264, 299t, 301, 474
arrhythmia with, 129t
dosage of, 299t, 728t, 730t
to facilitate gastric emptying, 1522
in gastroparesis, 496t
in GERD, 264, 727, 728t
hyperprolactinemia with, 714t
in lactation enhancement, 730t, 734
in nausea and vomiting, 299t, 301, 303–304, 728t
in pregnancy, 727, 728t, 728t
Metolazone, in heart failure, 44, 55
Metoprolol
in acute coronary syndromes, 94t
adverse effects of, 18t, 40t, 119t
in arrhythmias, 112t
dosage of, 18t, 46t, 77t, 94t
in heart failure, 46t, 48–49
in hypertension, 18t, 23f
in ischemic heart disease, 77, 77t
mechanism of action of, 112t
in prevention of migraine, 508t
Metronidazole
adverse effects of, 276, 1167, 1183t
in amebiasis, 1142
in bacterial vaginosis, 729t, 731–732, 1172
in cellulitis, 1079t
in *Clostridium difficile*-associated diarrhea, 1124
disulfiram-like reaction with, 732
dosage of, 276t, 290t, 729t, 1079t, 1141–1142, 1167, 1172, 1173t, 1182t
drug interactions of, 153t, 1183t
in giardiasis, 1141
in *Helicobacter pylori* eradication, 275–277, 276t, 1382
in inflammatory bowel disease, 288, 290t, 291
in intraabdominal infections, 1133–1134, 1135t
in lactation, 726t, 733
in osteomyelitis, 1179t, 1182t
in pancreatitis, 340t
pancreatitis with, 338t
in PID, 1173t
in pneumonia, 1057
in pregnancy, 729t, 731–733
in sepsis, 1191t, 1192
in surgical prophylaxis, 1233, 1235–1236, 1235t
in trichomoniasis, 729t, 733, 1167
Metyrapone
adverse effects of, 697t
in Cushing's syndrome, 695, 697t
dosage of, 697t
mechanism of action of, 697t
overnight metyrapone test, 689t
Mexican-Americans. *See* Ethnicity
Mexiletine
in arrhythmias, 112t
drug interactions of, 481
mechanism of action of, 112t
Mezlocillin, in intraabdominal infections, 1134
MHC. *See* Major histocompatibility complex
Micafungin
in fungal infections, 846
in invasive candidiasis, 1220
in prevention of invasive candidiasis, 1223
Micelle, 177
Michaelis-Menten metabolism, 449–450
Miconazole
in diaper dermatitis, 971
dosage of, 729t, 730t, 1201t
drug interactions of, 153t, 844t
in nipple candidiasis, 730t, 734
in pregnancy, 729t
in vulvovaginal candidiasis, 729t, 1201t
Microalbuminuria
in chronic kidney disease, 376–377
in diabetes mellitus, 664
in hypertension, 14
Micrococci, normal flora, 1021f
Microdialysis studies, during withdrawal, 528
Micrographia, in Parkinson's disease, 475

Microvascular pulmonary emboli, 1498, 1501–1502
Microvilli, 1512
Microvillous inclusion disease, intestine transplantation in, 831
Micturition, 805
Midazolam
adverse effects of, 466t
dosage of, 465, 466t, 467t, 468, 469t
drug interactions of, 1216
in status epilepticus, 465, 466t, 467t, 468, 469t
Middle cerebral artery embolectomy, in stroke, 167
Midodrine
adverse effects of, 396
in hypotension, 396
Mifepristone
adrenal insufficiency with, 687t
adverse effects of, 698t
in Cushing's syndrome, 698t
dosage of, 698t
mechanism of action of, 698t
Miglitol
adverse effects of, 657
in diabetes mellitus, 655t, 657
dosage of, 655t
Migraine, 488
in adolescents, 509
anxiety with, 610t
with aura, 503–504
without aura, 503–504
chronic, 504
clinical presentation in, 503–504
diagnosis of, 504
epidemiology of, 501–502
etiology of, 502
factors that trigger, 506t
multiple sclerosis and, 432
nausea and vomiting with, 296t
outcome evaluation in, 510
pathophysiology of, 502
patient care and monitoring in, 510–511
in pediatric patients, 509
prevention of, 508–509, 508t
antiepileptic drugs, 508, 508t
β-blockers, 508, 508t
calcium channel blockers, 508, 508t
ergotamine derivatives, 508–509, 508t
in pregnancy, 510
renin-angiotensin antagonists, 508
tricyclic antidepressants, 508, 508t
stroke and, 165t
treatment of, 298, 505–510
ergotamine derivatives, 506
NSAID, 505–506
opioids, 505–506
triptans, 505–506, 507t, 509
Migraineur, 502
Milk-alkali syndrome, 414
Milrinone
adverse effects of, 58
arrhythmia with, 115t
dosage of, 56t, 58
in heart failure, 55t, 56t, 58
hemodynamic effects of, 55t, 56t, 58
Mineral oil
in constipation, 309t, 310
dosage of, 309t
Mineral supplementation, in inflammatory bowel disease, 285–286
Minimum inhibitory concentration, 1024, 1025f, 1093
Minitransplant, 1451
Minocycline
in acne vulgaris, 964, 964t
adverse effects of, 964, 964t
in cellulitis, 1078
in cystic fibrosis, 250–252, 251t
dosage of, 251t, 964t
drug interactions of, 746t
in urinary tract infections, 1155t
Minoxidil
adverse effects of, 20t, 26
dosage of, 20t
in hypertension, 20t, 26

Miosis
  drug-induced, 947t
  in opioid intoxication, 532
Mircette, 745
Mirena, 747
Mirtazapine
  adverse effects of, 575, 575t, 628
  in depression, 581
  dosage of, 577, 577t
  drug interactions of, 575, 576t
  in elderly, 581
  in insomnia, 626
  mechanism of action of, 573t, 574
  pharmacokinetics of, 575t
Miscarriage, 753
Misoprostol
  adverse effects of, 734
  in cervical ripening, 730t, 733–735
  diarrhea with, 312t
  dosage of, 730t
  in prevention of NSAID-induced ulcers, 277–278, 872, 886
  teratogenic effects of, 726t
Mithramycin
  dosage of, 414t
  in hypercalcemia, 414, 414t
Mitomycin C, 1292
  adverse effects of, 1292
  in breast cancer, 1319
  in cancer therapy, 1292
  extravasation of, 1489t, 1490–1491, 1491t
  mechanism of action of, 1284f, 1292
  pharmacokinetics of, 1292
  at site of trabeculectomy, 916
Mitotane
  adverse effects of, 697t
  in Cushing's syndrome, 695, 697t
  dosage of, 697t
  mechanism of action of, 697t
Mitoxantrone, 1289
  in acute myelogenous leukemia, 1409–1410
  adverse effects of, 437t, 438, 1289
  in breast cancer, 1319
  in cancer therapy, 1289
  cardiotoxicity of, 439
  dosage of, 437t, 439, 1289, 1410
  emetogenicity of, 302t
  extravasation of, 1489t
  mechanism of action of, 438, 1284f, 1289
  in multiple sclerosis, 436, 437t, 438, 439t
  pharmacokinetics of, 1289
  pharmacology of, 438

  pathophysiology of, 324–328, 325f
  treatment of, 330–335
    β-blockers, 331–332
Portal venous system, 324f
Posaconazole
  in aspergillosis, 1221t, 1227, 1462
  dosage of, 1221t–1222t
  in fusariosis, 1222t, 1228
  in prevention of invasive candidiasis, 1223
  in zygomycosis, 1229
Positive expiratory pressure, oscillating, in cystic fibrosis, 249
Postgastrectomy state, osteoporosis in, 865
Post-herpetic neuralgia, 488, 490, 498t, 1246
Post-ictal state, 592t
Postoperative nausea and vomiting, 295–296, 298, 301, 303–304
  prevention of, 303–304
  risk factors for, 303
Postpyloric feeding, 1516, 1522
Postthrombotic syndrome, 134, 137, 139, 142, 155
Posttransplant lymphoproliferative disorder, 850
  Epstein-Barr virus and, 850
  treatment of, 850
Posttraumatic stress disorder, 554t
Postural drainage, 249
Postvagotomy syndrome, 296t
Post-void residual urine volume, in benign prostatic hyperplasia, 794, 795t
Potassium
  in extracellular fluid, 408t
  in intracellular fluid, 407, 408t
  for parenteral nutrition, 1497, 1497t
  serum, 410
    normal range for, 408t
  in ventricular action potential, 109, 109f
Potassium acetate
  in hypokalemia, 411
  potassium content in, 411t
Potassium balance, 410–413
  impaired, in chronic kidney disease, 381–382
Potassium bicarbonate
  in hypokalemia, 411
  potassium content in, 411t
Potassium chloride
  GERD with, 259t
  in hypokalemia, 411
  in intraabdominal infections, 1133
  potassium content in, 411t
Potassium citrate, potassium content in, 411t
Potassium gluconate
  in hypokalemia, 411
  potassium content in, 411t
Potassium iodide, in hyperthyroidism, 678
Potassium phosphate, in hypophosphatemia, 415t
Potassium requirement, 410
Potassium restriction, in hyperkalemia, 382
Potassium therapy
  in hypokalemia, 412, 412t
  oral products, 411t
Potassium-sparing diuretics. *See also specific drugs*
  adverse effects of, 22, 381
  hyperkalemia with, 412
  in hypertension, 21–22
Poverty of speech, in schizophrenia, 549
PR interval, 109f, 110
Pramipexole
  adverse effects of, 480–481, 629t
  augmentation of antidepressant therapy with, 578
  dosage of, 479t, 480, 629t
  mechanism of action of, 479t
  in Parkinson's disease, 479t, 480–481, 483
  in restless-legs syndrome, 628, 629t
Pramlintide
  adverse effects of, 661
  in diabetes mellitus, 661, 661t
  dosage of, 661t
  drug interactions of, 661
Pravastatin
  adverse effects of, 187t
  dosage of, 187t
  in hyperlipidemia, 186t, 187t
  in ischemic heart disease, 74
Prazepam, drug interactions of, 533t
Praziquantel
  dosage of, 1144
  in tapeworm infections, 1144
Prazosin
  adverse effects of, 19t
  dosage of, 19t
  drug interactions of, 576t
  in hypertension, 19t, 26
  in muscle cramps, 397
  in urinary incontinence, 812
Prealbumin, in nutritional assessment, 1524
Prebiotics, 1517
Preconception care, 727, 728t
Preconception planning, 725–726
Prediabetes, 644, 649, 652
Prednisolone
  in adrenal insufficiency, 690t
  in asthma, 219t, 221t, 227t
  in cystic fibrosis, 250
  dosage of, 219t, 221t, 227t, 287t
  in inflammatory bowel disease, 287t
  in viral conjunctivitis, 939
Prednisone
  in acute lymphocytic leukemia, 1405t, 1407t
  in adrenal insufficiency, 690t
  adverse effects of, 836t, 1379t

anxiety with, 610t
in asthma, 221t, 225, 227t
in breast cancer, 1310
in cystic fibrosis, 250
dosage of, 221t, 227t, 287t, 289t, 290t, 435, 836t, 842, 894t, 895, 999, 999t, 1378t, 1379t, 1380t, 1381t, 1405t, 1407t, 1459
