Epilepsy is a disorder that afflicts approximately 2 million individuals in the United States, with an age-adjusted prevalence of approximately 4 to 7 cases per 1000 persons.[1] The incidence of epilepsy in the United States is estimated at 35 to 75 cases per 100,000 persons per year, which is similar to that of other developed countries.[2,3] In developing countries, the incidence is higher at 100 to 190 cases per 100,000 persons per year, possibly related to poor health care and prenatal care, increased risk of neurologic trauma, and increased rates of infections. About 8% of the United States' population will experience a seizure during their lifetime. New-onset seizures occur most frequently in infants below 1 year of age and in adults after age 55.[4] However, the largest number of patients suffering from epilepsy is between the ages of 15 and 64 years.

Social Impact

Epilepsy is a disorder with profound impact on a patient's lifestyle. All states limit driving for individuals who have recently had a seizure with impaired consciousness and restrictions vary from state to state.[5] Patients who live in communities without adequate public transportation face major impediments to simple activities of daily life, such as purchasing groceries or getting to a job. Education is also problematic for patients with epilepsy.[6,7] Individuals with persistent seizures have poor school attendance. Fifty percent of patients with epilepsy complain of cognitive difficulties and believe their seizures interfere with learning. Additionally, patients with epilepsy score 50% lower on standardized examinations and have lower graduation rates from high school and college. Transportation and educational difficulties combine with persistent seizures to cause patients with epilepsy to be unemployed or underemployed. Thus, this group of patients faces multiple financial difficulties and often does not have health insurance.

Finally, patients with epilepsy are often dependent upon caregivers to assist with medications, transportation, and ensuring their safety. Caregivers should be informed of the patients' medical needs and how to assist should a seizure occur.

Etiology

For nearly 80% of patients with epilepsy, the underlying etiology is unknown.[8] The most common recognized causes of epilepsy are head trauma and stroke. Developmental and genetic defects are the cause of about 5% of cases of epilepsy. Central nervous system (CNS) tumors, central nervous system infections, and neurodegenerative diseases are other common causes. Other important causes of epilepsy are human immunodeficiency virus infection or neurocysticercosis infection, primarily occurring in Latin America.

Isolated seizures that are not epilepsy can be caused by stroke, central nervous system trauma, central nervous system infections, metabolic disturbances (e.g., hyponatremia and hypoglycemia), and hypoxia. If these underlying causes of seizures are not corrected, they may lead to the development of recurrent seizures or epilepsy. Medications can also cause seizures. Some drugs that are commonly associated with seizures include tramadol, bupropion, theophylline, some antidepressants, some antipsychotics, amphetamines, cocaine, imipenem, lithium, excessive doses of penicillins or cephalosporins, and sympathomimetics or stimulants.

PATHOPHYSIOLOGY

Seizures

Regardless of the underlying etiology, all seizures involve a sudden electrical disturbance of the cerebral cortex. A population of neurons fires rapidly and repetitively for seconds to minutes. Cortical electrical discharges become excessively rapid, rhythmic, and synchronous. This phenomenon is presumably related to an excess of excitatory neurotransmitter action, a failure of inhibitory neurotransmitter action, or a combination of the two. In the individual patient, however, it is usually impossible to identify which neurochemical factors are responsible.

Neurotransmitters

The major excitatory neurotransmitter in the cerebral cortex is glutamate.[9] When glutamate is released from a presynaptic neuron, it attaches to one of several receptor types on the postsynaptic neuron. The result is opening of membrane channels to allow sodium or calcium to flow into the postsynaptic neuron, thus depolarizing it and transmitting the excitatory signal.[10] Many antiepileptic drugs (e.g., phenytoin, carbamazepine, and lamotrigine) work by interfering with this mechanism, either by blocking the release of glutamate or by blocking the sodium or calcium channels, thus preventing excessive excitation.[11] These drugs typically do not block normal neuronal signaling, only the excessively rapid firing characteristic of a seizure. For this reason they do not usually affect normal brain function.

The major inhibitory neurotransmitter in the cerebral cortex is γ-aminobutyric acid (GABA). It attaches to neuronal membranes and opens chloride channels. When chloride flows into the neuron, it becomes hyperpolarized and less excitable. This mechanism is probably critical for shutting off seizure activity by controlling the excessive neuronal firing. Some antiepileptic drugs, primarily barbiturates and benzodiazepines, work by enhancing the action of GABA.

Cortical function is modulated by many other neurotransmitters. However, their role in the pathophysiology of epilepsy and in the action of antiepileptic drugs is not yet well known.

Neuronal Mechanisms

Seizures originate in a group of neurons which do not have normal electrical behavior.[12] Individual neuronal firing is prolonged and repetitive. This long, abnormal depolarization is called a paroxysmal depolarizing shift (PDS).

The excessive electrical discharges can spread to other neurons, either adjacent ones or distant ones connected by fiber tracts. The seizure thus spreads to other areas of the brain, recruiting them into the uncontrolled firing pattern. The neurons involved may not be abnormal themselves, but are diverted from their normal functioning to participate in the wildly excessive discharges. The degree of spread and the location of brain areas involved determine the clinical manifestations of the seizure.

Nearly all seizures stop spontaneously, because after seconds to minutes brain inhibitory mechanisms become strong enough to shut off the abnormal excitation.

Epilepsy

Epilepsy is the tendency to have seizures on a chronic, recurrent basis. This implies that there is a permanent change in cortical function which renders neurons more likely to participate in a seizure discharge. This process is referred to as epileptogenesis, and the exact way in which it occurs is not known. A process thought to be similar to epileptogenesis in humans occurs after prolonged, intermittent electrical stimulation of animal brains and is known as kindling. Epilepsy may develop days, months, or many years after an insult to the cortex. It may be that an originally small group of abnormal neurons causes adjacent or connected neurons to gradually become abnormal as well, by bombarding them over time with frequent, repeated electrical impulses. When the network of abnormal neurons becomes sufficiently large, it becomes capable of sustaining an excessive firing pattern for at least several seconds: a seizure. This hyperexcitable network of neurons is then the seizure focus.

If the change in cortical electrical characteristics is permanent, why don't seizures occur all the time? This is probably because the occurrence of an individual seizure depends upon an interplay of environmental and internal brain factors which from time to time result in loss of the normal mechanisms that contain and control abnormal neuronal firing. Some common factors are sleep loss and fatigue, but it is impossible to determine what sets off a particular seizure in most patients.

In some patients, epilepsy worsens over time, with the seizures becoming more frequent as patients grow older. This does not occur in most patients with epilepsy. In those so affected, it is possible that the seizures themselves may cause some damage to the cortex; loss of neurons, especially inhibitory neurons, has been demonstrated in tissue from seizure foci. Other changes occur in brain areas affected by seizures: reorganization of connections between groups of neurons may strengthen excitatory connections and weaken inhibitory connections, making the occurrence of future seizures more likely. Additionally, epilepsy is associated with an increased mortality rate.[13] For these reasons, an argument can be made for controlling epileptic seizures with medications as early as possible. This may reduce the possibility of permanent changes in brain function, although this hypothesis is unproven.

Genetic Factors

Patients with seizures may be concerned that their children or other family members will inherit epilepsy. This fear is usually unfounded. Patients with acquired causes of seizures, such as head trauma or stroke, will not transmit the problem. There is a group of patients, however, who apparently have epilepsy on a genetic basis. Most of these individuals have primary generalized epilepsy.[14,15] Usually these patients develop seizures during childhood. However, the hereditary tendency is not strong. Complex inheritance patterns are usually seen, indicating the likely involvement of several abnormal genes or other factors for seizures to be clinically expressed in offspring. Thus, most patients can be reassured that their children and siblings are unlikely to develop epilepsy. Increasing numbers of epilepsy syndromes are being identified as being of genetic origin, and once the specific genes are identified it may be possible to target drug therapies more specifically toward individual biochemical defects.

SEIZURE CLASSIFICATION AND PRESENTATION

General Principles

Careful diagnosis and identification of seizure types is essential to proper treatment of epilepsy. Numerous schemes and descriptions of seizures exist, but the International League Against Epilepsy (ILAE) has established the currently accepted standard for classifying epileptic seizures (Fig. 27–1) and epilepsies or epilepsy syndromes (Table 27–1).[16,17] Classification of epileptic seizures is based upon electroencephalographic (EEG) findings combined with the clinical findings or semiology of the seizure events. Clinical presentations of seizures vary widely, depending on the region and amount of brain involved in the seizure.

Primary Generalized Seizures

If the entire cerebral cortex is involved in the seizure from the onset of the seizure, the seizure is classified as primary generalized. The following are types of primary generalized seizures.

- *Tonic-clonic:* Characterized by a sudden loss of consciousness accompanied by tonic extension and rhythmic clonic contractions of all major muscle groups. The duration of the seizure is usually 1 to 3 minutes. These seizures are often described as "grand mal."

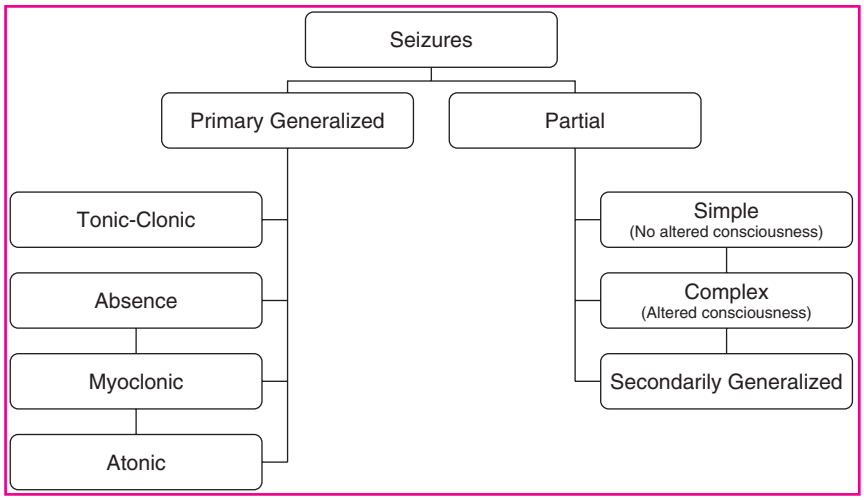

FIGURE 27–1. International League Against Epilepsy classification of epileptic seizures. Data from reference 16.

- *Absence:* Sudden and brief (i.e., several seconds in duration) losses of consciousness without muscle movements. These seizures are often described as daydreaming or blanking out episodes. A common term for these seizures is "petit mal."
- *Myoclonic:* Single and very brief jerks of all major muscle groups. Patients with these may not lose consciousness, due to the seizure lasting less than 3 to 4 seconds. Patients may describe these seizures as shoulder shrugs or spinal chills. Myoclonic seizures may cluster and build into a generalized tonic-clonic seizure.
- *Atonic:* The patient loses consciousness and muscle tone. No muscle movements are typically noted, and the patient will fall when they are not lying down or sitting in a chair. These seizures may be described as "falling out."

TABLE 27–1. International League Against Epilepsy Classification Scheme for Epilepsies and Epilepsy Syndromes

I. Localization-related (focal, local, or partial) epilepsies and epileptic syndromes
  A. Idiopathic with age-related onset
    1. Benign childhood epilepsy with centrotemporal spikes
    2. Childhood epilepsy with occipital paroxysms
  B. Symptomatic
II. Generalized epilepsies and epileptic syndromes
  A. Idiopathic and age-related onset
    1. Benign neonatal epilepsy
    2. Childhood absence epilepsy (pyknolepsy)
    3. Juvenile myoclonic epilepsy (impulsive petit mal)
    4. Juvenile absence epilepsy with generalized tonic-clonic seizure on awakening
  B. Secondary (idiopathic or symptomatic)
    1. West syndrome (infantile spasms)
    2. Lennox-Gastaut syndrome
  C. Symptomatic
    1. Nonspecific etiology (early myoclonic encephalopathy)
    2. Specific syndromes (epileptic seizures that may complicate many diseases, e.g., Ramsay-Hunt syndrome, Unverricht's disease)

Data from reference 17.

Partial Seizures

When the seizure begins in a localized area of the brain, it is defined as partial. There are three types of partial seizures in the current classification system.

- *Simple:* The patient will have a sensation or uncontrolled muscle movement of a portion of their body without an alteration in consciousness. The type of sensation or movement is dependent on the location of seizure in the brain.
- *Complex:* Although the seizure is localized in a specific area of the brain, like a simple partial seizure, this seizure causes an alteration in the patient's level of consciousness.
- *Secondarily generalized:* Seizures that start as a simple or complex partial seizure and spread to involve the entire brain. Patients may report a warning or aura, and these are actually the start of the seizure.

Epilepsy Syndromes

Classification of epilepsies and epilepsy syndromes is helpful in determining appropriate pharmacotherapy. This classification scheme is based on the type of seizures a patient has and an attempt to identify the etiology of the epilepsy or epilepsy syndrome.

- *Idiopathic epilepsies:* These syndromes are thought to be due to genetic alterations, but the underlying etiology is not identified. Neurologic functions are completely normal apart from the occurrence of seizures.
- *Symptomatic epilepsies:* There is an identifiable cause for the seizures, such as trauma or hypoxia.

Clinical Presentation and Diagnosis

General

Typically, health care providers are not able to observe a patient's seizures, and for most types of seizures the patient has no memory of the event. It is important to obtain a careful history from the patient and any individuals who witnessed the seizures.

Common Descriptions of Seizures

The clinical presentation of seizures will vary from patient to patient depending on the portion of brain involved in the seizure. Events will tend to be stereotypical for an individual patient.

Patients who experience seizures may complain of paroxysmal spells of:

- Blanking out spells, lapses in memory, periods of altered consciousness
- Warnings or auras consisting of various sensations or automatic, uncontrolled movements
- Daydreaming
- Jerks, shoulder shrugs, and sudden chills of the spine
- Falling out

Associated Symptoms

- Incontinence, usually of urine
- Tongue biting
- Traumatic injuries, usually associated with falling during a seizure

Diagnosis

Description of events: The patient and any witnesses to the seizures should be carefully interviewed to obtain a full and complete description of typical seizures.

Neurologic examination: Usually, the neurologic physical examination is completely normal. Any neurologic deficits that are identified should be fully investigated, because seizures do not usually cause permanent, detectable neurologic deficits.

Electroencephalogram

A routine EEG can be helpful if epileptiform discharges are seen. However, the EEG may be normal between seizures, and most routine EEGs are not performed during a seizure. Maneuvers such as sleep deprivation, photic stimulation, hyperventilation, or prolonged monitoring can help reveal EEG changes consistent with epilepsy.

Neuroimaging (preferably a magnetic resonance imaging [MRI] scan of the brain): Imaging of the brain is important to rule out obvious causes of seizures such as stroke or tumors. An MRI is also helpful in detecting mesial temporal sclerosis, a finding often associated with mesial temporal lobe epilepsy and predictive of positive surgical outcomes.

Video-EEG monitoring: A procedure consisting of continuous video monitoring of the patient with a simultaneous EEG. Usually a patient is monitored in the hospital for 4 to 5 days. This procedure is used to determine if the patient is truly having seizures, to determine the specific type of seizures the patient is having, and to localize the area of the brain that is the origin for the seizures.

- *Cryptogenic epilepsies:* In these epilepsies the seizures are the result of an underlying neurologic disorder that is often ill-defined or undocumented. Neurologic functions are often abnormal or developmentally delayed in patients with cryptogenic epilepsies.

A complete description of a patient's epilepsy should include the seizure type with the epilepsy or syndrome type (i.e., idiopathic, symptomatic, or cryptogenic).

Commonly encountered epilepsy syndromes are:

- *Juvenile myoclonic epilepsy (JME):* A primary generalized epilepsy syndrome that usually starts in the early to middle teenage years and has a strong familial component. Patients have myoclonic jerks and tonic-clonic seizures and may also have absence seizures.
- *Lennox-Gastaut syndrome (LGS):* Patients with this syndrome have cognitive dysfunction and mental retardation. Their seizures usually consist of a combination of tonic-clonic, absence, atonic, and myoclonic seizures.
- *Mesial temporal lobe epilepsy (MTLE):* A type of epilepsy that consists of partial seizures arising from the mesial temporal lobe of the brain. Often this type of epilepsy is associated with an anatomic change described as hippocampal sclerosis. Patients with this type of epilepsy often have excellent outcomes with surgery for epilepsy.
- *Infantile spasms:* A seizure syndrome that occurs in infants less than 1 year of age. It is characterized by a specific EEG pattern and spasms or jitters and is also known as West's syndrome. Infants with infantile spasms often develop other seizure types and epilepsies later in life.

Other Classifications

The ILAE is proposing a new classification system that improves the description of the seizure type and epilepsy.[18,19] The proposed scheme revolves around five axes:

- Axis 1: description of the seizure event
- Axis 2: epileptic seizure type or types
- Axis 3: any syndrome type
- Axis 4: etiology when known
- Axis 5: degree of impairment by the epilepsy.

This classification system is undergoing final review and should become the standard in the near future.

Diagnosis

❶ Determining a correct and accurate diagnosis is essential prior to any consideration of pharmacotherapy. When a patient complains of paroxysmal, stereotypical spells that may be seizures, it must be determined if the spells are really seizures. Numerous other disorders, including syncope, psychogenic nonepileptic events (i.e., pseudoseizures), anxiety attacks, cardiac arrhythmias, hypoglycemia, transient ischemic

attacks, tics, and complicated migraine headaches, are often mistaken for seizures by patients and caregivers.

A proper diagnostic workup of a patient presenting with seizures should include the following elements:

- Thorough neurologic examination
- Electroencephalogram
- Laboratory tests (CBC, LFT, and serum chemistry)
- Neuroimaging (preferably magnetic resonance imaging)

Patients with epilepsy may have completely normal findings in these assessments. Many of the tests are done to rule out other causes of seizures (e.g., infection or electrolyte imbalance). Often the EEG appears normal between seizures.[20] Several manipulations can be done in an attempt to capture seizure or seizure-like activity on the EEG. These include sleep deprivation, photic stimulation, prolonged (greater than 20 minutes) EEG recording, and 24-hour EEG monitoring with video correlation.

TREATMENT

Desired Outcomes

The ultimate outcome goal for any patient with epilepsy is elimination of all seizures without any adverse effects of the treatment. An effective treatment plan would allow the patient to pursue a normal lifestyle with complete control of seizures. Specifically, the treatment should enable the patient to drive, perform well in school, hold a reasonable job, and function effectively in the family and community. However, due to the intractability of the seizures or sensitivity to antiepileptic drugs (AEDs), many patients are not able to achieve these outcomes. In these cases, the goal of therapy is to provide a tolerable balance between reduced seizure severity and/or frequency and medication adverse effects that optimizes the individual's ability to have a lifestyle as nearly normal as possible.

General Approach to Treatment

❷ Once it is concluded that the patient has seizures, the type of seizure and epilepsy syndrome, if any, must be determined. Proper identification and classification of the seizure type is most helpful in selecting appropriate pharmacotherapy. Without an accurate classification of the seizure type, it is possible to select a medication that is ineffective or even harmful to the patient.

❸ Additionally, the risk of a subsequent seizure must be determined. If there is an underlying treatable cause, such as hyponatremia or a CNS infection, the risks of another seizure and the development of epilepsy are very small. In these cases, the only pharmacotherapy that is necessary is to correct the underlying problem and possibly short-term use of an AED. Risk factors for repeated seizures in patients without an underlying disorder include:

- Structural CNS lesion
- Abnormal EEG
- Partial seizure type
- Positive family history
- Postictal motor paralysis[21]

If no risk factors are present, the risk of another seizure is 10% to 15%. However, if two or more risk factors are present, the risk of another seizure is 100%.

When sufficient evidence is available to determine that the patient has real seizures and is at risk for another seizure, pharmacotherapy is usually started (Fig. 27–2). The patient should be in agreement with the plan, be willing to take the medication, and be able to monitor seizure frequency and adverse drug effects in some way. Design of an appropriate pharmacotherapeutic plan is based on the patient's seizure type, the common adverse-effect profile of possible AEDs, and economic factors (e.g., cost of the drug, insurance formulary, and ability to pay). Other patient factors such as gender, concomitant drugs, age, and lifestyle also need to be considered.

Nonpharmacologic Treatment

Several nonpharmacologic treatments for epilepsy are available. For some patients, surgery is the treatment approach with the greatest probability of achieving a seizure-free state.[22] The most common surgical approach for epilepsy is temporal lobectomy. When the seizure focus can be localized and it is in a region of the brain that is not too close to critical areas, such as those responsible for speech or muscle control, surgical removal of the focus can result in 80% to 90% of patients becoming seizure-free. According to a National Institutes of Health Consensus Conference, three criteria should be met for patients to be candidates for surgery.[23] These criteria are a definite diagnosis of epilepsy, failure of adequate drug therapies, and definition of the electroclinical syndrome (i.e., localization of the seizure focus in the brain). Other surgical procedures, that are less likely to make a patient seizure-free, include corpus callosotomy and extra-temporal lesion removal.

Vagal nerve stimulation is another nonpharmacologic approach to treating seizures.[24] In this treatment, a unit that generates an intermittent electrical current is placed under the skin in the chest. A wire is tunneled under the skin to the left vagus nerve in the neck. The unit generates a small electrical current that stimulates the vagus nerve every 5 minutes. Additional stimulations can be initiated by the patient swiping a magnet over the device located in the chest. This treatment approach is essentially equivalent in efficacy to starting a new medication, but the precise mechanism for its effect has not been elucidated. Approximately 25% to 50% of patients who have a vagal nerve stimulator placed will experience at least a 50% reduction in seizure frequency. However, fewer than 10% become seizure-free. Adverse effects include hoarseness, swallowing difficulties, tingling or vibration in the neck, infection

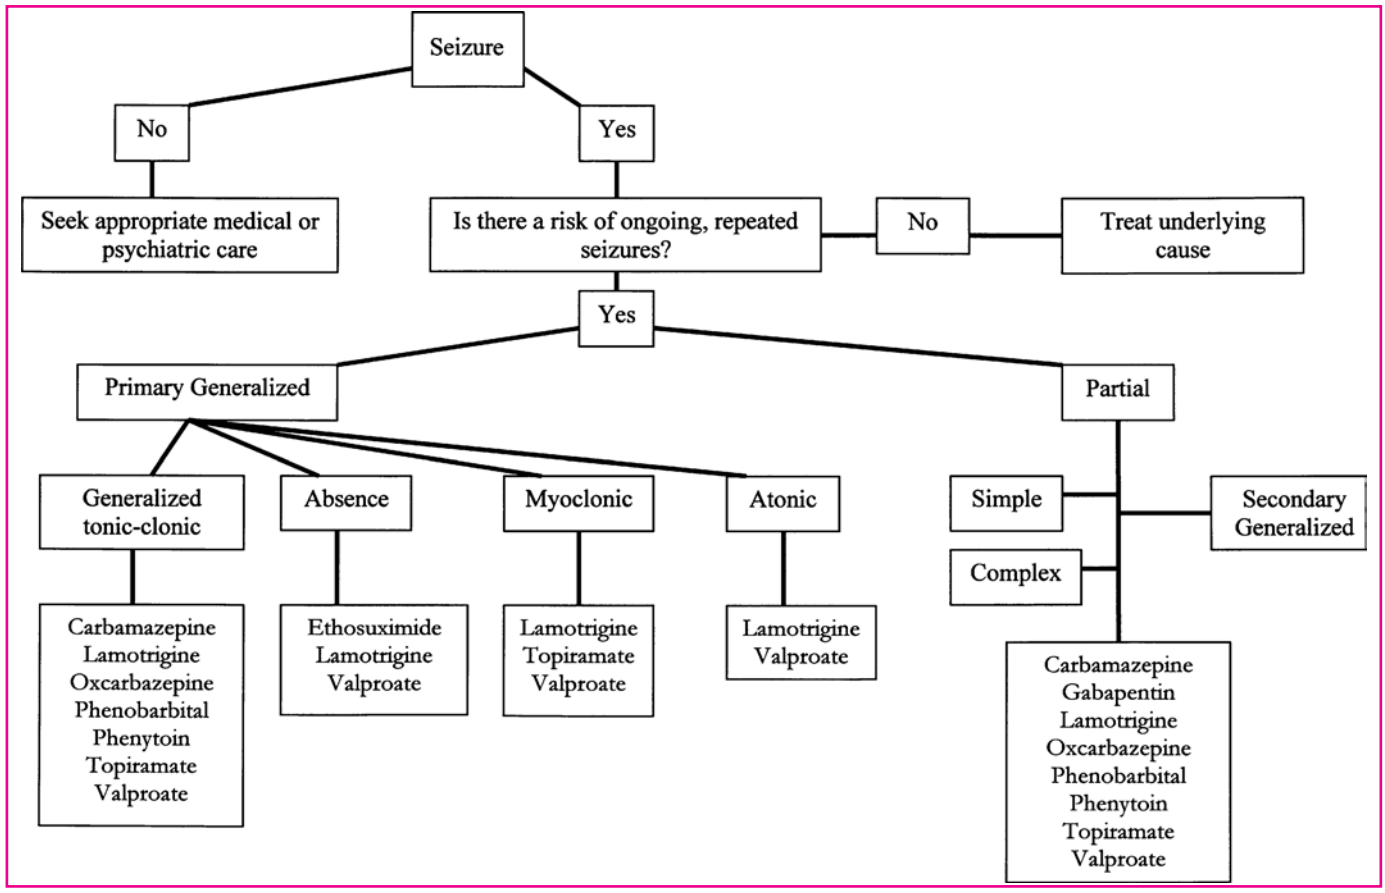

FIGURE 27–2. Treatment algorithm for management of seizure disorders.

or bleeding due to surgery, and rarely laryngeal spasms. Vagal nerve stimulation is usually reserved for patients who do not respond to several drugs and are not surgical candidates.

One of the oldest nonpharmacologic treatments is the ketogenic diet.[25] Modern use of the diet was started in the 1920s. This diet produces a ketoacidotic state through the elimination of nearly all carbohydrates. To initiate the diet, patients undergo 24 to 48 hours of fasting until ketones are detected in the urine. The diet consisting of dietary fats (e.g., butter, heavy cream, and fatty meats) and protein with no added sugar is started. Daily urinalysis for ketones is performed to ensure that the patient remains in ketosis. Any inadvertent consumption of sugar results in the need to reinitiate the diet. Pharmacists have an important role in maintaining the diet, by determining the sugar or carbohydrate content of medications the patient is taking. This diet is typically used only in children with difficult-to-control seizures. In certain patients the diet can be extremely effective, resulting in complete seizure control and reduction of AEDs. However, it is hard to maintain a ketotic state, and palatability of the diet is a concern. Additionally, there are concerns about growth retardation in children and hypercholesterolemia with prolonged use of the diet.

Pharmacologic Therapy

Special Considerations

❹ Use of the AEDs presents some unique challenges, some of which relate to their pharmacokinetic properties, which need to be clearly understood.[26]

Michaelis-Menten Metabolism

Phenytoin metabolism is capacity-limited, meaning the maximum capacity of hepatic enzymes to metabolize the drug is reached within the normal dosage range. This is defined as Michaelis-Menten metabolism or Michaelis-Menten pharmacokinetics. The clinical significance is that small changes in doses result in disproportionate and large changes in serum concentrations. The patient is at risk of sudden toxicity if too large a dose increase is made, or a breakthrough seizure may occur if too large a reduction in dose is made. Due to individual differences in metabolism, each patient follows a different curve in the relationship between dose and serum concentrations. These differences can be defined only by careful use of serum concentration and dosing data. There are numerous schemes for determining appropriate dosage adjustments of

phenytoin, and these are discussed in pharmacokinetics textbooks. For routine clinical practice, dosage adjustments for adults with normal protein binding of phenytoin and a steady-state serum concentration can be made using the following plan.

- For serum concentrations less than 7 mcg/mL (28 μmol/L) the total daily dose is increased by 100 mg.
- For serum concentrations of 7 to 12 mcg/mL (28–48 μmol/L) the total daily dose is increased by 50 mg.
- For serum concentrations greater than 12 mcg/mL (48 μmol/L) the total daily dose is increased by no more than 30 mg.[27]

Protein Binding

Some AEDs, especially phenytoin and valproate, are highly bound to plasma proteins. When interpreting a reported concentration for these drugs, it is important to remember that the value represents the total (i.e., bound and unbound) concentration in the blood. Because of differences in the metabolism of these drugs, the clinical effects of altered protein binding are different for different drugs.

Normally, 88% to 92% of phenytoin is bound to plasma protein, leaving 8% to 12% unbound. The unbound component is able to leave the blood to produce the clinical effect in the CNS, produce dose-related side effects in the CNS and at other sites, distribute to other peripheral sites, and be metabolized. Certain patient groups are known to have decreased protein binding, resulting in an increased percentage of drug that is unbound. These patient groups include:

- Those with renal failure
- Those with hypoalbuminemia
- Neonates
- Pregnant women
- Those taking multiple highly protein-bound drugs
- Patients in critical care

Due to the Michaelis-Menten metabolism of phenytoin, alterations in its protein binding will result in increased severity of dose-related adverse effects. In patients with suspected changes in protein binding, it is useful to measure unbound phenytoin concentrations.

When valproate protein binding is altered, the risk for severe dose-related adverse effects is much less compared to phenytoin. Michaelis-Menten metabolism is not a factor with valproate, so hepatic enzymes are able to efficiently metabolize the additional unbound portion.

Autoinduction

Carbamazepine is a potent inducer of hepatic microsomal enzymes. Not only does it increase the rate of metabolism for many other drugs, it increases the rate of its own metabolism. Hepatic enzymes become maximally induced over several weeks, necessitating a small initial dose of carbamazepine that is increased over time to compensate for the enzyme induction (Fig. 27–3). Most dosage regimens for carbamazepine call for a starting dose that is 25% to 30% of the typical maintenance dose of 15 mg/kg per day. The dosage is increased weekly until the target maintenance dose is achieved within 3 to 4 weeks. Titration of the carbamazepine dose lessens the risk for severe dose-related adverse effects when carbamazepine is first started.

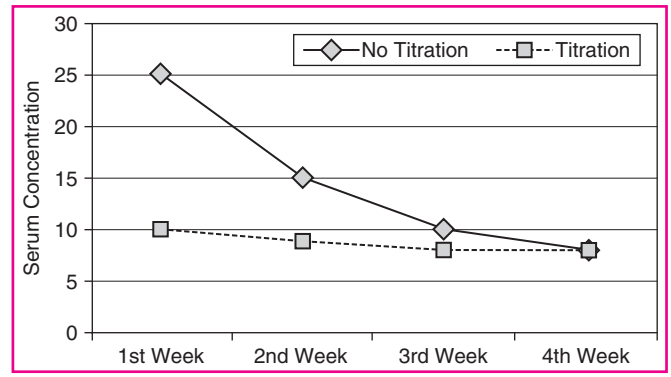

FIGURE 27–3. Serum concentrations of carbamazepine in the presence and absence of appropriate dose titration. Carbamazepine induces its own metabolism, so maintenance dose requirements are much greater than starting doses. To avoid excessive adverse effects, starting doses should be 25% to 30% of the target maintenance doses and increased gradually to the target maintenance dose, usually over 3 to 4 weeks.

Drug Selection and Seizure Type

The key to selecting effective pharmacotherapy is to base the decision on the seizure type. Several consensus treatment guidelines from the Scottish Intercollegiate Guidelines Network, the National Institute for Clinical Excellence in the United Kingdom, and the American Academy of Neurology all use determination of seizure type as the basis for selection of pharmacotherapy (Table 27–2).[28–30] While the guidelines make recommendations for specific drugs to be used in certain seizure types, the consensus recommendations utilize only data available from the medical literature. In many cases, a recommendation is not made, because there are no published data on which to make an evidence-based decision. Therefore, a drug may not currently be recommended for a seizure type simply because it has not been studied for that seizure type. Absence of a recommendation should not be taken to mean that the drug is ineffective for a specific seizure type.

Outside of the evidence-based guidelines, other pharmacologic treatments are commonly used or avoided. For initial treatment of absence seizures, ethosuximide and valproate are commonly used, not only in the United Kingdom, but also in the United States. Zonisamide may be also used for initial treatment of absence and myoclonic seizures. In absence and myoclonic seizures, carbamazepine, oxcarbazepine, gabapentin, tiagabine, and pregabalin should be avoided, as they have been associated with an exacerbation of these types of seizures.

TABLE 27–2. Evidence-Based Guidelines for Initial Monotherapy Treatment of Epilepsy

Seizure Type	American Academy of Neurology	Scottish Intercollegiate Guidelines Network	United Kingdom National Institute for Clinical Excellence
Primary generalized tonic-clonic	Carbamazepine[a] Lamotrigine[a] Oxcarbazepine[a] Phenobarbital[a] Phenytoin[a] Topiramate[a] Valproate[a]	Lamotrigine Valproate	Carbamazepine Lamotrigine Topiramate Valproate *Second-line:* Clobazam[b] Levetiracetam Oxcarbazepine
Absence	Lamotrigine (children)	Ethosuximide Lamotrigine Valproate	Ethosuximide Lamotrigine Valproate *Second-line:* Clobazam[b] Clonazepam Topiramate
Myoclonic	Not mentioned	Lamotrigine Valproate	Valproate Topiramate (children with severe myoclonic epilepsy of infancy) *Second-line:* Clobazam[b] Clonazepam Lamotrigine Levetiracetam Piracetam[b] Topiramate
Tonic	Not mentioned	Not mentioned	Lamotrigine Valproate *Second-line:* Clobazam[b] Clonazepam Levetiracetam Topiramate
Atonic	Not mentioned	Not mentioned	Lamotrigine Valproate *Second-line:* Clobazam[b] Clonazepam Levetiracetam Topiramate
Partial with or without secondary generalization	Carbamazepine Gabapentin Lamotrigine Oxcarbazepine Phenobarbital Phenytoin Topiramate Valproate	Phenytoin Carbamazepine Valproate Lamotrigine Oxcarbazepine	Carbamazepine Lamotrigine Oxcarbazepine Valproate Topiramate *Second-line:* Clobazam[b] Gabapentin Levetiracetam Phenytoin Tiagabine

Data from references 27, 28, 29, 30.

Patient Encounter 1, New-Onset Seizures

AG, a 20-year-old male college student, is seen by his physician 4 days after an apparent seizure during finals week. According to his roommate, he suddenly fell to the floor and had a generalized tonic-clonic seizure. This seizure lasted for 1 to 2 minutes. The patient was incontinent for urine during the seizure. He was sleepy and confused when the paramedics arrived 10 minutes later. Due to final examinations he reports being sleep-deprived. His physical exam is completely normal and no focal neurologic deficits were observed.

- What diagnostic tests should be done at this time?
- Should these tests be performed prior to starting medications?
- His MRI is normal, and focal epileptiform activity originating from his left temporal lobe is observed on the EEG.
- Should an AED be started at this point?
- If you decide to treat, what drug and dose would you use?
- How should that drug be monitored?

Three months later he has another seizure, but this time it is characterized by a rising feeling in his stomach followed by confused speech, lip smacking, repetitive movements of his right hand, and unresponsiveness. This episode lasts for 2 to 3 minutes, and it takes 15 minutes for his speech to return to normal.

- If he is receiving an AED, should a second AED be started at this time?
- What tests and evaluations should you do before starting a second AED?
- If a second drug is started, what drug and dose would you use?

Refractory seizure (i.e., unresponsive to at least two first-line AEDs) treatment is somewhat different. According to the American Academy of Neurology (AAN) Practice Parameter, topiramate is useful as monotherapy for primary generalized tonic-clonic seizures, and there is insufficient evidence to make any recommendation regarding gabapentin, lamotrigine, oxcarbazepine, tiagabine, levetiracetam, or zonisamide.[31] Combinations of drugs are not addressed by the AAN, but may be useful in patients with difficult-to-control primary generalized seizures. This practice parameter also gives the highest recommendation to oxcarbazepine and topiramate as monotherapy in patients with refractory partial epilepsy. Additionally, lamotrigine is noted to be effective as monotherapy for refractory partial seizures, but was associated with a high dropout rate in the clinical trials. All AEDs, except ethosuximide, are effective in combination therapy for partial seizures.

Complications of Pharmacotherapy

❺ Adverse effects of AEDs are frequently dose-limiting or can cause a drug to be discontinued. Two types of adverse effects occur with AEDs: dose-related (Table 27–3) and idiosyncratic. Concentration-related adverse effects happen with increasing frequency and severity as the dose or concentration of a drug is increased. For many AEDs, common concentration-related adverse effects include sedation, ataxia, and diplopia. When selecting an AED, these adverse effects should be carefully considered and used as one of the selection criteria. ❻ For example, if a patient has a job that requires mental alertness, it is best to choose an AED that is less likely to cause sedation (e.g., lamotrigine).

Idiosyncratic adverse effects are not dose- or concentration-related and will almost always result in the AED being discontinued. Rash, hepatotoxicity, and hematologic toxicities are the most common idiosyncratic reactions seen with AEDs. Because many of these adverse effects are life-threatening or potentially life-threatening, the AED should be discontinued immediately when the reaction is observed. Carbamazepine, phenytoin, phenobarbital, valproate, lamotrigine, oxcarbazepine, and felbamate are most likely to cause these types of reactions. Many of these reactions are thought to occur primarily on an immunologic basis, which raises the possibility of cross-reactivity. This is especially true for carbamazepine, phenytoin, phenobarbital, and oxcarbazepine, for which 15% to 25% of patients who have an idiosyncratic reaction to one drug will have a similar reaction to the other drugs.

Chronic Adverse Reactions

Because AEDs are administered for long periods of time, adverse effects due to prolonged drug exposure are of concern. Some chronic adverse effects that have been associated with AEDs include peripheral neuropathy and cerebellar atrophy. Other chronic adverse effects are extensions of acute adverse effects, for example weight gain.

One chronic adverse effect that is of concern is osteoporosis.[32,33] Carbamazepine, phenytoin, phenobarbital, oxcarbazepine, and valproate have all been shown to decrease bone mineral density, even after only 6 months of treatment. Data on the relationship between other AEDs and osteoporosis are not currently available. Multiple studies have shown the risk of osteoporosis due to chronic AED use to be similar to the risk with chronic use of corticosteroids. Patients taking carbamazepine, phenytoin, phenobarbital, or valproate for longer than 6 months should take supplemental calcium and vitamin D. Additionally, routine monitoring for osteoporosis should be performed every 2 years, and patients should be instructed on ways to protect themselves from fractures.

Practical Issues

Comorbid Disease States

Patients with epilepsy often have comorbid disease states. Disorders such as chronic headaches and asthma are frequent problems. For patients who also have asthma, care must be taken to identify drug interactions between AEDs

TABLE 27–3. Characteristics of Common Antiepileptic Drugs

Drug	Mechanism of Action	Dose	Pharmacokinetic Parameters	Usual Serum Concentration Range	Dose-Related Adverse Effects	Idiosyncratic Adverse Effects
Carbamazepine	Modulate sodium channels	*Loading dose:* Not recommended due to excessive dose-related toxicity *Maintenance dose:* Titrate dosage to target over 3–4 weeks Adults: 10–20 mg/kg per day as a divided dose Children: 20–30 mg/kg per day as a divided dose	*Half-life:* 10–25 hours with chronic dosing *Apparent volume of distribution:* 0.8–1.9 L/kg *Protein binding:* 67–81% *Primary elimination route:* Hepatic	4–12 mcg/mL (17–51 µmol/L)	Diplopia, drowsiness, nausea, sedation	Aplastic anemia, hyponatremia, leukopenia, osteoporosis, rash
Clonazepam	Enhance GABA activity	*Loading dose:* Not recommended due to increased adverse effects *Maintenance dose:* Initiate at 0.5 mg one to three times daily, titrate dose to effectiveness usually 3–5 mg daily in 2 to 3 divided doses	*Half-life:* 30–40 hours *Apparent volume of distribution:* 3.2 L/kg *Protein binding:* 47–80% *Primary elimination route:* Hepatic	Not established	Ataxia, memory impairment, sedation, slowed thinking	
Ethosuximide	Modulate calcium channels	*Loading dose:* Not recommended due to increased adverse effects *Maintenance dose:* Initiate at 250 mg twice daily and titrate to 500–1000 mg twice daily	*Half-life:* 60 hours 60 hours *Apparent volume of distribution:* 0.6–0.7 L/kg *Protein binding:* None *Primary elimination route:* Hepatic	40–100 mcg/mL (283–708 µmol/L)	Ataxia, sedation	Hepatotoxicity, neutropenia, rash
Felbamate	Inhibit glutamate activity	*Loading dose:* Not recommended due to increased adverse effects *Maintenance dose:* 1200–3600 mg/day in 3–4 divided doses	*Half-life:* Monotherapy: 20 hours Concurrent enzyme inducers: 11–16 hours *Apparent volume of distribution:* 0.7–0.8 L/kg *Protein binding:* 25–35% *Primary elimination route:* Hepatic	Not established	Anxiety, insomnia, nausea	Anorexia, aplastic anemia, headache, hepatotoxicity, weight loss

(*Continued*)

TABLE 27–3. Characteristics of Common Antiepileptic Drugs *(Continued)*

Drug	Mechanism of Action	Dose	Pharmacokinetic Parameters	Usual Serum Concentration Range	Dose-Related Adverse Effects	Idiosyncratic Adverse Effects
Gabapentin	Modulate calcium channels and enhance GABA activity	*Loading dose:* Not recommended due to short half-life *Maintenance dose:* 900–3600 mg/day in 3–4 divided doses (doses up to 10,000 mg/day have been tolerated)	*Half-life:* 5–7 hours (proportional to creatinine clearance) *Apparent volume of distribution:* 0.6–0.8 L/kg *Protein binding:* less than 10% *Primary elimination route:* Renal	Not established	Drowsiness, sedation	Peripheral edema, weight gain
Lamotrigine	Modulate sodium channels	*Loading dose:* Not recommended due to increased risk of rash *Maintenance dose:* 150–800 mg/day in 2–3 divided doses. Doses should be initiated and titrated according to the manufacturer's recommendations to reduce the risk of rash	*Half-life:* Monotherapy: 24 hours Concurrent enzyme inducers: 12–15 hours Concurrent enzyme inhibitors: 55–60 hours *Apparent volume of distribution:* 1.1 L/kg *Protein binding:* 55% *Primary elimination route:* Hepatic	Not established	Ataxia, drowsiness, headache, insomnia, sedation	Rash
Levetiracetam	Unknown	*Loading dose:* Not recommended due to excessive adverse effects *Maintenance dose:* 1000–3000 mg/day. Start at 1000 mg/day and titrate upward as indicated by response	*Half-life:* 6–8 hours *Apparent volume of distribution:* 0.5–0.7 L/kg *Protein binding:* less than 10% *Primary elimination route:* 70% renal 30% hepatic	Not established	Somnolence, dizziness	Depression
Oxcarbazepine	Modulate sodium channels	*Loading dose:* Not recommended due to excessive adverse effects *Maintenance dose:* 600–1200 mg/day. Start at 300 mg twice daily and titrate upward as indicated by response	*Half-life:* Parent drug ~2 hours; 10-monohydroxy metabolite ~9 hours *Apparent volume of distribution:* 0.5–0.7 L/kg *Protein binding:* 40% *Primary elimination route:* Hepatic	Not established	Diplopia, dizziness, somnolence	Hyponatremia, 25–30% cross sensitivity in patients with hypersensitivity to carbamazepine

Phenobarbital	Modulate sodium channels	*Loading dose:* 10–20 mg/kg as single or divided intravenous infusions or orally in divided doses over 24–48 hours *Maintenance dose:* Adults: 1–4 mg/kg per day, as a single or divided dose Children: 3–6 mg/kg per day, as divided dose Neonates: 1–3 mg/kg per day, as divided dose	*Half–life:* Adults: 49–120 hours Children: 37–73 hours Neonates: ~115 hours *Volume of distribution:* 0.7–1 L/kg *Protein binding:* ~50% *Primary elimination route:* Hepatic	15–40 mcg/mL (65–172 µmol/L)	Ataxia, drowsiness, sedation	Attention deficit, cognitive impairment, hyperactivity, osteoporosis, passive-aggressive behavior
Phenytoin	Modulate sodium channels	*Loading dose:* Adults: 15–20 mg/kg single intravenous dose or divided oral dose Infants less than 3 months: 10–15 mg/kg single intravenous dose Neonates: 15–20 mg/kg single intravenous dose *Maintenance dose:* Adults: 5–7 mg/kg per day, as single or divided dose Children: 6–15 mg/kg per day, as divided dose Neonates: 3–8 mg/kg per day, as divided dose	*Half-life:* Follows capacity-limited or Michaelis-Menten pharmacokinetics Half-life increases as the dose and serum concentration increases *Volume of distribution:* Adults: 0.7 L/kg Children: 0.8 L/kg Neonates: 1.2 L/kg *Protein binding:* Adults, children: 88–92% Neonates: 65% *Primary elimination route:* Hepatic	10–20 mcg/mL (40–79 µmol/L) total concentration 1–2 mcg/mL (4–8 µmol/L) unbound concentration	Ataxia, diplopia, drowsiness, sedation	Anemia, gingival hyperplasia, hirsutism, lymphadenopathy, osteoporosis, rash
Pregabalin	Modulate calcium channels	*Loading dose:* Not recommended due to increased adverse effects *Maintenance dose:* Initiate at 150 mg/day in 2–3 divided doses and titrate to a maximum dose of 600 mg/day	*Half-life:* 6.3 hours, proportional to creatinine clearance *Apparent volume of distribution:* 0.5 L/kg *Protein binding:* Negligible *Primary elimination route:* *Renal*	Not established	Ataxia, blurred vision, dizziness, dry mouth, somnolence	Edema, weight gain
Tiagabine	Enhance GABA activity	*Loading dose:* Not recommended due to excessive adverse effects *Maintenance dose:* 32–56 mg/day in four divided doses Doses should be titrated upward over 6 weeks, starting at 4 mg/day	*Half-life:* Monotherapy: 7–9 hours Concurrent enzyme inducers: 2.5–4.5 hours *Apparent volume of distribution:* 0.6–0.8 L/kg *Protein binding:* 96% *Primary elimination route:* Hepatic	Not established	Dizziness, somnolence, irritability, slowed thinking	

(*Continued*)

TABLE 27–3. Characteristics of Common Antiepileptic Drugs (*Continued*)

Drug	Mechanism of Action	Dose	Pharmacokinetic Parameters	Usual Serum Concentration Range	Dose-Related Adverse Effects	Idiosyncratic Adverse Effects
Topiramate	Modulate sodium channels; inhibit glutamate activity; enhance GABA activity	*Loading dose:* Not recommended due to excessive adverse effects *Maintenance dose:* 100–400 mg/day in 2–3 divided doses Doses should be started at 25–50 mg/day and gradually titrated upward over 3–6 weeks to avoid excessive adverse effects	*Half-life:* Monotherapy: 21 hours Concurrent enzyme inducers: 11–16 hours *Apparent volume of distribution:* 0.55–0.8 L/kg *Protein binding:* 13–17% *Primary elimination route:* 60% renal 40% hepatic	Not established	Ataxia, dizziness, drowsiness, slowed thinking	Acute glaucoma, metabolic acidosis, oligohidrosis, paresthesias, renal calculi, weight loss
Valproic acid/ divalproex sodium	Modulate sodium channels	*Loading dose:* 20–40 mg/kg *Maintenance dose:* Adults: 15–45 mg/kg per day in 2–4 divided doses Children: 5–60 mg/kg per day in 2–4 divided doses	*Half-life:* Adults: 8–15 hours Children: 4–15 hours Infants less than 2 months: 65 hours *Volume of distribution:* 0.1–0.5 L/kg *Protein binding:* 90% (decreases with increasing serum concentrations) *Primary elimination route:* Hepatic	50–100 mcg/mL (346–693 µmol/L); children may require concentrations up to 150 mcg/mL (1040 µmol/L)	Drowsiness, nausea, sedation, tremor	Hepatotoxicity, osteoporosis, pancreatitis, weight gain
Zonisamide	Modulate sodium and calcium channels	*Loading dose:* Not recommended due to excessive adverse effects *Maintenance dose:* 100–600 mg/day; start at 100 mg/day and titrate upward as indicated by response	*Half-life:* ~63 hours *Apparent volume of distribution:* 1.45 L/kg *Protein binding:* 40% *Primary elimination route:* Hepatic	Not established	Dizziness, somnolence	Metabolic acidosis, oligohidrosis, paresthesias, renal calculi

GABA, γ-aminobutyric acid.
Data from references 25, 35, 36, 37, 38.

and medications used for asthma. These interactions may necessitate close monitoring for changes in efficacy or increased toxicity, and dosage changes of other drugs may be necessary when an AED is added or removed. Patients with chronic headaches need special attention in the selection of an AED. Agents known to prevent headache (e.g., valproate and topiramate) may be preferred among several choices, and agents associated with increased headaches (e.g., lamotrigine and felbamate) may be a secondary or tertiary alternative.

Depression is a common problem in patients with epilepsy, with approximately 30% having symptoms of major depression at some point.[34] Patients with epilepsy should be routinely assessed for signs of depression, and treatment should be initiated if necessary. Certain AEDs may exacerbate depression, for example levetiracetam and phenytoin. Other AEDs (e.g., lamotrigine, carbamazepine, and oxcarbazepine) may be useful in treating depression. Changes in mood can be precipitated by addition or discontinuation of an AED. If treatment for depression is necessary, caution should be exercised in choosing an agent that does not increase seizure frequency and does not interact with AEDs.

Switching Drugs

❼ Changing from one AED to another can be a complex process. If the first drug is stopped too abruptly breakthrough seizures may occur. Stopping or adding a drug can introduce various problems with drug interactions which should be considered in any regimen change. Typically the new drug is started at a low initial dose and gradually increased over several weeks. Once the new drug is at a minimally effective dose, the drug to be discontinued is gradually tapered while the dose of the new drug continues to be increased to the target dose. During a transition between drugs, patients should be cautioned about the possibility of increased seizures or adverse reactions.

Patient Encounter 2, Switching a Patient to a Different Antiepileptic Drug

BC, a 22-year-old woman, was diagnosed 2 years ago with juvenile myoclonic epilepsy. She has been treated with valproate 1500 mg/day. Since starting valproate she has gained 45 pounds (20.5 kg), continues to have occasional myoclonic jerks, had a generalized tonic-clonic seizure 3 months ago, and is sexually active. Additionally, she complains of easily falling asleep during the day. Due to adverse effects, poor seizure control, and the risk of birth defects with valproate, the decision is made to switch to a different antiepileptic drug.

- What drug would be the optimal alternative drug for this patient?
- How should the new drug be started and the valproate discontinued?
- What instructions should be given to the patient regarding the switch to another drug?

Stopping Therapy

❽ Epilepsy is generally considered to be a lifelong disorder that requires ongoing treatment. However, many patients who are seizure-free may desire to discontinue their medications.[35] Patients who become seizure-free following surgery for their epilepsy may have medications slowly tapered starting 1 to 2 years after their surgery. Many patients will choose to stay on at least one medication following successful surgery to ensure that they remain seizure-free. Five criteria must be met before considering the discontinuation of AEDs.[36] They are:

- No seizures for 2 to 5 years
- Normal neurologic examination
- Normal intelligence quotient
- Single type of partial or generalized seizure
- Normal EEG with treatment

Individuals who fulfill all of these criteria have a 61% chance of remaining seizure-free after AEDs are discontinued. Additionally, there is a direct relationship between the duration of seizure freedom while taking medications and the chance of being seizure-free after medications are withdrawn. Withdrawal of AEDs is done slowly, usually with a tapering dose over at least 3 months.

Dosing

Dosing of AEDs is determined by general guidelines and response of the patient. Serum concentrations may be helpful in benchmarking a specific response. Therapeutic ranges that are often quoted are broad guidelines for dosing, but should never replace careful evaluation of the patient's response. It is not unusual for a patient to be well managed with serum concentrations or doses outside the typical ranges.

Patient Encounter 3, Discontinuing Antiepileptic Drug Therapy

The consultant pharmacist is reviewing the care of AN, who is a 79-year-old male resident of a long-term care facility. According to his records, he has received phenytoin and phenobarbital ever since suffering a stroke 12 years ago. There is no record of a seizure in his chart, and the nursing staff has not observed a seizure since he arrived at the facility 2 years ago. His family recalls that he had 1 seizure around the time of his stroke, but has not had any more seizures.

- Can his antiepileptic medications be discontinued?
- What additional information would be helpful to determine the possibility of discontinuing his antiepileptic drugs?
- If the antiepileptic drugs are stopped, how should they be discontinued?

Drug Interactions

AEDs are associated with many different drug interactions.[37–39] These interactions are primarily in relation to absorption, metabolism, and protein binding. Tube feedings and antacids are known to reduce the absorption of phenytoin and carbamazepine. Phenytoin, carbamazepine, and phenobarbital are potent inducers of various cytochrome P-450 (CYP450) isoenzymes, increasing the clearance of other drugs metabolized through these pathways (Table 27–4). In contrast, valproate is a CYP450 isoenzyme inhibitor and reduces the clearance of some drugs. Phenytoin and valproate are highly protein-bound and can be displaced when taken concurrently with other highly protein-bound drugs. For example, when phenytoin and valproate are taken together, there may be increased dose-related adverse effects within several hours of dosing. This can be avoided by staggering doses or giving smaller doses more frequently during the day. Whenever a change in a medication regimen occurs, drug interactions should be considered and appropriate adjustments in dose made.

Special Populations

❾ Children and women present special challenges in the management of epilepsy and use of AEDs. In children, developmental changes occur rapidly, and metabolic rates are greater than those seen in adults. When treating a child it is imperative to control seizures as quickly as possible to avoid interference with development of the brain and cognition. Antiepileptic drug doses are increased rapidly, and frequent changes in the regimen are made to maximize control of seizures. Due to the rapid metabolic rates seen in children, doses of AEDs are typically higher on a milligram-per-kilogram basis compared to those for adults, and serum concentrations are used more extensively to help ensure an adequate trial of a drug has been given.

For women, the treatment of epilepsy poses challenges, including teratogenicity, interactions between AEDs and hormonal contraceptives, and reduced fertility.[40,41] Recommendations for managing women of child-bearing potential and who are pregnant have been developed (Table 27–5). Several AEDs have been implicated in causing both minor and serious birth defects.[42] Of special concern are neural tube defects (e.g., spina bifida, microcephaly, and anencephaly), associated most commonly with valproate and possibly carbamazepine. All women of child-bearing potential who have epilepsy should be taking 1 to 4 mg daily of supplemental folic acid to reduce the risk of these defects. Even with drugs like valproate, more than 90% of pregnancies will produce a completely normal infant. Therefore, use of valproate is not contraindicated in women who may become pregnant, but it may be

TABLE 27–4. Common Drug Interactions with Antiepileptic Drug[36–38]

Enzyme	Substrate	Common Inducers	Common Inhibitors
CYP1A2	Carbamazepine	Carbamazepine Phenytoin Phenobarbital Rifampin	Cimetidine Ciprofloxacin Erythromycin Clarithromycin
CYP2C9	Phenobarbital[a] Phenytoin[a] Carbamazepine Valproate	Carbamazepine Phenytoin Phenobarbital Rifampin	Amiodarone Cimetidine Fluconazole Valproate
CYP2C19	Phenobarbital Phenytoin Valproate		Felbamate Ticlopidine Topiramate Zonisamide
CYP2D6	Zonisamide	Carbamazepine	
CYP3A4	Carbamazepine[a] Tiagabine[a] Zonisamide[a]	Carbamazepine Phenytoin Phenobarbital Rifampin	Amiodarone Erythromycin Propoxyphene Ketoconazole
Uridine diphosphate glucuronyl-transferase	Lamotrigine[a] Carbamazepine	Lamotrigine Phenobarbital Phenytoin	Valproate

[a]Primary route of metabolism.
CYP450, cytochrome P-450 isoenzyme.
Data from references 36, 37, 38.

TABLE 27–5. Management of Antiepileptic Drugs during Pregnancy

Give supplemental folic acid, 1–4 mg daily, to all women of child-bearing potential
Use monotherapy whenever possible
Use the lowest doses that control seizures
Continue pharmacotherapy that best controls seizures prior to pregnancy
Monitor antiepileptic drug serum concentrations at the start of pregnancy and monthly thereafter
Adjust antiepileptic drug doses to maintain baseline serum concentrations
Administer supplemental vitamin K during the eighth month of pregnancy to women receiving enzyme-inducing antiepileptic drugs
Monitor postpartum antiepileptic drug serum concentrations to guide adjustments of drug doses

advisable to start alternative AEDs, if appropriate, in women of child-bearing potential.

As noted above, many of the AEDs induce hepatic microsomal enzyme systems and thus reduce the effectiveness of hormonal contraceptives. Women taking AEDs that may reduce the effectiveness of hormonal contraceptives should be encouraged to also use other forms of birth control. Due to induction or inhibition of sex hormone metabolism and changes in binding of hormones to sex hormone binding globulin, some AEDs may reduce fertility. For example, valproate has been associated with a drug-induced polycystic ovarian syndrome. Women who experience difficulties with fertility should seek the advice of health care professionals with expertise in fertility.

Outcome Evaluation

Efficacy

- Seizure counts are the only reasonable and standard way to evaluate efficacy of treatment.
- Encourage patients to keep a seizure calendar that notes the time and day seizures occur and the type of seizure. Comparisons can then be made on a monthly basis to determine the level of seizure control.

Toxicity

- Monitor toxicity of AEDs at every clinic visit.
- Question patients about common adverse effects of the AEDs they are receiving. Weigh the impact of acute adverse effects against the extent of seizure control achieved. If it is determined that the adverse effects negatively impact a patient more than the extent of seizure control obtained benefits the patient, adjust the therapeutic regimen. Continuously monitor chronic adverse effects of AEDs.

Patient Encounter 4, Hormonal Contraceptives and Interactions with Antiepileptic Drugs

LJ, a 25-year-old-woman with complex partial seizures, presents a prescription to the pharmacy for a triphasic oral contraceptive containing ethinyl estradiol and norgestimate. A review of her medication profile shows that she is taking carbamazepine extended-release 1200 mg/day. Her last refill for this prescription was 2 weeks ago. She reports that she has not had a seizure for a year and that she just became engaged. She is planning to be married in 4 months.

- Is there an interaction between carbamazepine and the oral contraceptive?
- If so, what is the mechanism and clinical outcome of the interaction?
- If there is an interaction, how should it be managed?
- What AEDs interact with hormonal contraceptives?
- What are the clinical implications of these interactions? How should they be managed?

Patient Care and Monitoring

1. *Monitor the patient's seizure frequency and characteristics.* The only objective measure ofefficacy of AEDs is a count of seizure frequency. Ask patients to keep seizure calendars, noting the numbers and types of seizures that occur and have them bring the calendars to clinic at every visit for analysis and documentation of seizure frequency.
2. *Monitor for acute and chronic adverse effects of AEDs.* Acute adverse effects are best detected by a thorough neurologic examination at clinic visits. Instruct patients to report sedation, ataxia, rash, or other problems immediately. Monitor for chronic adverse effects including a loss of bone mineral density, which should be measured every 2 years in patients taking phenytoin, phenobarbital, carbamazepine, and valproate.
3. *Monitor for comorbid disease states at each clinic visit.* Evaluate for depression at every clinic visit.
4. *Take measures to ensure compliance with medications and access to care.* Compliance with medication regimens is a common problem for patients with epilepsy. Patients should be asked at every visit how they are taking their medications and if they missed any doses. Identify barriers to care, such as financial issues or transportation problems.
5. *Instruct patients, family members, and caregivers on first aid for seizures.* First aid for seizures consists primarily of keeping the patients from hurting themselves. They should be placed on the floor, if possible, and their heads cushioned. First responders to a seizure should never attempt to restrain them or force an item into their mouth. If a seizure lasts longer than 5 to 10 minutes, emergency medical assistance should be called.

28 Status Epilepticus

Gretchen M. Brophy and Eljim P. Tesoro

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Discuss the pathophysiology of status epilepticus.
2. Explain the urgency of diagnosis and treatment of status epilepticus.
3. Recognize the signs and symptoms of status epilepticus.
4. Identify the treatment options available for termination of status epilepticus.
5. Formulate an initial treatment strategy for a patient in generalized convulsive status epilepticus.
6. Compare the pharmacotherapeutic options for refractory status epilepticus.
7. Describe adverse drug events associated with the pharmacotherapy of status epilepticus.
8. Recommend monitoring parameters for a patient in status epilepticus.

Key Concepts

❶ Status epilepticus is a neurologic emergency that can lead to permanent brain damage or death.

❷ Status epilepticus can be defined as any seizure lasting more than 30 minutes, with or without a loss of consciousness; or having recurrent seizures without regaining consciousness between seizure episodes. However, this definition does not provide any guidance for treatment strategies in the clinical setting where interventions begin within a few minutes of seizure onset. A more practical definition to guide treatment would be continuous seizure activity lasting more than 5 minutes or two or more seizures without complete recovery of consciousness.

❸ It is important to evaluate for possible etiologies of status epilepticus and treat any underlying causes in order to optimize seizure control.

❹ The goal of therapy is to arrest physical and electroencephalographic evidence of seizures, prevent recurrence of seizures, and minimize adverse drug events.

❺ The first-line treatment for status epilepticus is intravenous benzodiazepines. Diazepam, lorazepam, or midazolam may be used to rapidly control clinical signs of seizures. Lorazepam is currently considered the first-line agent by most clinicians.

❻ Antiepileptic drugs are used to prevent the recurrence of seizures. Intravenous phenytoin (or fosphenytoin) and phenobarbital are administered after benzodiazepines are given.

❼ Refractory status epilepticus is seizure activity that is not controlled by first-line and second-line therapies, including benzodiazepines and antiepileptic drugs.

❽ Midazolam, propofol, and pentobarbital infusions can be used for refractory status epilepticus but may require intensive monitoring and supportive care.

❶ ***Status epilepticus*** *(SE) is a neurologic emergency that can lead to permanent brain damage or death.* ❷ *SE can be defined as any seizure lasting more than 30 minutes, with or without a loss of consciousness; or having recurrent seizures without regaining consciousness between seizure episodes.*[1] *However, this definition does not provide any guidance for treatment strategies in the clinical setting where interventions begin within a few minutes of seizure onset.* ❷ *A more practical definition to guide treatment would be continuous seizures lasting more than 5 minutes or two or more seizures without complete recovery of consciousness.*[2] Refractory status epilepticus (RSE) can be defined as seizure activity that does not respond to first-line antiepileptic therapy.[3]

SE can present as non-convulsive status epilepticus (NCSE) or generalized convulsive status epilepticus (GCSE). NCSE is characterized by a persistent state of impaired consciousness and/or motor or sensory seizures without impaired consciousness. For patients with NCSE, **electroencephalography** (EEG) is the key to diagnosis. GCSE is characterized by full body motor seizures and involves the entire brain. This chapter will focus on GCSE, which is the most common type of SE and is associated with the greatest risk of neurologic and physical damage.

Patient Encounter, Part 1

CH, a 42-year-old man, comes into the emergency department after his sister discovered him seizing at home. He has a history of hypertension, diabetes, epilepsy, and rheumatoid arthritis. His medications include hydrochlorothiazide, glyburide, phenytoin, and aspirin. He smokes one pack per day, drinks heavily on the weekends, and has a history of cocaine use. Upon further discussion with his sister, you discover that he stopped taking his phenytoin 4 days ago due to failure to obtain a refill from his doctor. He is currently unarousable since his last seizure 10 minutes ago.

- What initial assessments should be performed?
- What are some possible etiologies for his seizure?
- What interventions need to be performed at this time?

EPIDEMIOLOGY AND ETIOLOGY

There are an estimated 150,000 cases of SE each year in the United States, with approximately 55,000 associated deaths, and an estimated annual direct cost for inpatient admissions of $4 billion.[4,5] Status epilepticus occurs more frequently in African-Americans, children, and the elderly. Additional attention should be given to elderly individuals with SE, as other underlying disease states may complicate therapy and worsen prognosis.[6]

❸ *It is important to understand the underlying cause of SE, as this will guide the course of treatment, potentially shortening the duration of SE and improve outcomes.* The causes of SE can be categorized as acute or chronic. Acute changes that cause SE include metabolic disturbances; central nervous system (CNS) disorders, infections, or injuries; **hypoxia**; drug toxicity; or acute illness. Chronic processes that cause SE include preexisting **epilepsy**, chronic alcohol abuse, CNS tumors, and strokes.[3] In individuals diagnosed with epilepsy, the common causes of SE are anticonvulsant withdrawal or subtherapeutic anticonvulsant levels. Patients with SE due to chronic processes generally respond well to antiepileptic drug (AED) therapy.

PATHOPHYSIOLOGY

Status epilepticus occurs because the brain fails to stop an isolated seizure. The exact reason for this failure is unknown and probably involves many mechanisms. A seizure is likely to occur due to a mismatch of excitatory and inhibitory neurotransmitters in the brain. The primary excitatory neurotransmitter in the brain is **glutamate**. Glutamate stimulates postsynaptic N-methyl-D-aspartate (NMDA) receptors in the brain, causing an influx of calcium into the cells and depolarization of the neuron. Sustained depolarization may maintain SE and eventually cause neuronal injury and death.[7] The primary inhibitory neurotransmitter, **γ-aminobutyric acid** (GABA), opposes the excitatory response by stimulating $GABA_A$ receptors. $GABA_A$-receptor stimulation enhances the chloride inhibitory currents, producing hyperpolarization and inhibition of the postsynaptic cell membrane. The inhibitory ability of GABA is diminished as the duration of seizures increases. This may be due to a mechanistic shift in the functional properties of the $GABA_A$ receptors which causes a decrease in response to GABA-receptor agonists.[8,9] Seizure activity lasting more than 30 minutes can cause cerebral injury and neuronal loss in the hippocampal, cortical, and thalamic regions. These neurologic sequelae are related to the excessive electrical activity and alterations in cerebral metabolic demand. The clinical impact of the $GABA_A$-receptor changes on treatment response and the worsening degree of neuronal injury with prolongation of seizure activity highlights the urgency of rapid control of SE.

There are several systemic changes that occur during the course of SE. These changes can be divided into two phases. Phase I occurs during the first 30 minutes of seizure activity, and phase II occurs after 30 minutes of seizure activity.[10]

Phase I

During phase I, each seizure causes a sharp increase in autonomic activity with increases in epinephrine, norepinephrine, and steroid plasma concentrations, resulting in hypertension, tachycardia, hyperglycemia, hyperthermia, sweating, and salivation. Cerebral blood flow is also increased to preserve the oxygen supply to the brain during this period of high metabolic demand. Increases in sympathetic and parasympathetic stimulation with muscle hypoxia can lead to ventricular arrhythmias, severe acidosis, and rhabdomyolysis. These, in turn, could lead to hypotension, shock, hyperkalemia, and acute tubular necrosis.

Phase II

After approximately 30 minutes of continuous seizure activity, the patient enters phase II and there is loss of cerebral autoregulation, decreased cerebral blood flow, increased intracranial pressure, and systemic hypotension. Metabolic demand is still high; however, the body is no longer able to compensate. The systemic changes that may occur during this phase include hypoglycemia, hyperthermia, respiratory failure, hypoxia, respiratory and metabolic acidosis, hyperkalemia, hyponatremia, and uremia. It is important to note that during prolonged seizure activity, motor activity may not be clinically noticeable, but the electrical seizures may still persist. This is referred to as subclinical seizure activity and needs to be recognized and treated aggressively.

CLINICAL PRESENTATION AND DIAGNOSIS

History

❸ When a patient presents with seizures, a thorough history is needed to determine the type and duration of the seizure

Clinical Presentation of Status Epilepticus

General
The patient may present with or without clinically noticeable seizure activity.

Symptoms
- Impaired consciousness ranging from lethargy to coma
- Disorientation after cessation of GCSE
- Pain from associated injuries (e.g., tongue lacerations, dislocated shoulder, head trauma, facial trauma)

Signs

Phase I:	**Phase II (greater than 30 minutes of SE):**
Generalized convulsions	Respiratory failure with pulmonary edema
Hypertension, tachycardia	Cardiac failure (arrhythmias, shock)
Fever and sweating	Hypotension
Muscle contractions, spasms	Hyperthermia
Respiratory compromise	Rhabdomyolysis and multiorgan failure
Incontinence	

Laboratory Tests
- Hyperglycemia (phase I) and hypoglycemia (phase II) can occur
- Hyponatremia, hypernatremia, hyperkalemia, hypocalcemia, hypomagnesemia, and hypoglycemia can cause SE
- The white blood cell (WBC) count may slightly increase
- Abnormal arterial blood gases (ABGs) due to hypoxia and respiratory or metabolic acidosis
- Elevated serum creatinine will be present in renal failure patients
- Myoglobinuria can occur in patients with continuous seizures

Diagnostic Tests
Electroencephalography (EEG) will show seizure activity

activity. This will help guide therapy and identify which laboratory and diagnostic testing need to be conducted urgently. A diagnosis of status epilepticus will be made when a patient with a history of repeated seizures and impaired consciousness has a seizure witnessed by a health care professional.

Physical Examination

Upon admission and control of seizure activity, a neurologic exam should be conducted to evaluate level of consciousness (coma, lethargy, and somnolence), motor function and reflexes (rhythmic contractions, rigidity, spasms, and posturing), and pupillary response. A physical exam to identify secondary injuries from the SE should also be conducted.

Clinical Symptoms

Patients with SE usually present with generalized, convulsive tonic-clonic seizure activity that is unresponsive to initial AED treatment. They may also be hypertensive, tachycardic, febrile, and diaphoretic; however, these symptoms will resolve soon after the seizure is terminated. A loss of bowel or bladder function, respiratory compromise, and **nystagmus** may also be observed. When seizure activity is sustained for more than approximately 30 to 60 minutes, muscle contractions may no longer be visible, but the patient remains in SE. Twitching of the face, hands, or feet may be seen in these comatose patients with prolonged seizures.

Laboratory Parameters

❸ *It is important to obtain a serum chemistry profile to help identify the underlying cause of SE.* Abnormalities that can cause seizures include hypoglycemia, hyponatremia, hypernatremia, hypomagnesemia, hypocalcemia, and renal failure. In a febrile patient with an elevated WBC count, an active infection should be ruled out or treated appropriately. Cultures from the blood, cerebrospinal fluid (CSF), respiratory tract, and urine should be obtained once the seizures are controlled. Computed tomography (CT) or magnetic resonance imaging (MRI) can be done to rule out CNS abscesses, bleeding, or tumors, all of which may be a source for seizure activity. A blood alcohol level and urine toxicology screen for drugs of abuse should also be conducted to determine if a chronic alcoholic is having alcohol withdrawal seizures or if illicit drug use or a drug overdose could be the underlying cause of SE. Also,

drug levels should be obtained in a drug overdose situation to rule out toxicity as a cause of SE. ❸ *Knowing the source of SE will help to guide the initial antiepileptic therapy and increase the probability of halting seizure activity.*

In patients with a history of AED use, a baseline serum concentration may be useful to determine if the drug concentration is below the desired range and if a loading dose is needed. Albumin levels, renal function tests, and liver function tests can also be helpful when assessing antiepileptic therapy.

Hypoxia and respiratory or metabolic acidosis are common in patients with SE. Therefore, pulse oximetry and ABG measurements are useful to assess the patient's respiratory status and determine if airway protection or supplemental oxygen is needed. Metabolic acidosis typically corrects on its own after seizure activity stops, so pharmacologic treatment is not required.

Patient Encounter, Part 2

Physical exam and laboratory studies reveal the following additional information about CH.

PE

VS: blood pressure 148/87 mm Hg, pulse 115 beats per minute, respiratory rate 23/minute, temperature 39.0°C (102.2°F), Ht 180 cm (5′11″), Wt 80 kg (176 lbs)
CNS: Unresponsive, unarousable
CV: Sinus tachycardia; normal S_1, S_2; no murmurs, rubs, gallops
Pulm: Tachypneic; oxygen saturation 92% on room air; no rhonchi, wheezes, rales
Abd: Firm, non-tender, non-distended; (+) bowel sounds; no hepatosplenomegaly
Exts: Rhythmic tonic-clonic movements of all extremities
GU: Incontinent of urine and stool
HEENT: Persistent upward gaze

Labs

Sodium 130 mEq/L (130 mmol/L), WBC $12 \times 10^3/mm^3$ ($12 \times 10^9/L$)

Phenytoin 2.1 mcg/mL (8.3 µmol/L), albumin 3.5 g/dL (35 g/L)

Potassium 3.5 mEq/L (3.5 mmol/L), hemoglobin 14 g/dL (140 g/L or 8.7 mmol/L)

Chloride 100 mEq/L (100 mmol/L), hematocrit 42% (0.42 volume fraction)

Carbon dioxide 12 mEq/L (12 mmol/L), platelets $235 \times 10^3/mm^3$ ($235 \times 10^9/L$)

Blood urea nitrogen 10 mg/dL (3.6 mmol/L), prothrombin time 12 seconds

Serum creatinine 0.9 mg/dL (80 µmol/L), International Normalized Ratio 1.1

Glucose 189 mg/dL (10.5 mmol/L), activated partial thromboplastin time 28 seconds

- Identify your goals of therapy for this patient.
- What therapies must be instituted next?

Diagnostic Tests

The only way to determine if a comatose patient has SE is by EEG. EEG monitoring should be used for patients who remain unconscious after initial antiepileptic treatment, and for those who received a long-acting paralytic agent or require prolonged therapy for RSE. Treatment should never be delayed while awaiting EEG results. An electrocardiogram (ECG) should be obtained to rule out cardiac dysfunction when hypotension or an abnormal heart rate is observed.

TREATMENT

Desired Outcomes

❹ *The goals of treatment of status epilepticus include the cessation of any seizure activity, both clinical and subclinical, and the prevention of further seizures. Ideally, this is accomplished through directed pharmacotherapy with minimization of any side effects or adverse reactions. Complications of SE should also be treated.*

General Approach

The initial approach to SE involves first removing the patient from harmful surroundings and ensuring a safe airway to prevent respiratory collapse or aspiration. Benzodiazepines are the first medications administered, as they are the drugs of choice to stop acute seizure activity, followed by the initiation of an antiepileptic agent. Medications are typically given intravenously (IV) for immediate onset of action, but if no IV access is available, certain medications may be given intramuscularly (IM), rectally, buccally, or via an endotracheal tube. Once the seizures stop, clinicians must identify and treat the underlying cause of the seizures, such as toxins, hypoglycemia, or trauma. Patients with known seizure disorders should be evaluated for abrupt cessation of their medications or for history of non-compliance.

Nonpharmacologic Treatment

Non-drug interventions may include administration of oxygen or intubation for mechanical ventilation in cases of hypoxemia or body cooling for febrile seizures. All patients should receive glucose in case of hypoglycemia-induced SE. In patients with a history of alcohol abuse, thiamine 100 mg should be given prior to the administration of any glucose-containing solutions to prevent encephalopathy. Specialists in neurology or epileptology should be consulted as appropriate. Admission to an emergency department or intensive care unit (ICU) will allow appropriate monitoring during the seizure and in the postictal period.

Pharmacologic Treatment

Initial Treatment

Benzodiazepines

❺ *Initial drug therapy begins with the administration of an intravenous benzodiazepine since they are most effective in aborting seizure activity. Intravenous bolus doses of diazepam, lorazepam, and midazolam have all been used in status epilepticus because of their rapid effects at inhibiting GABA receptors in the CNS. Diazepam and lorazepam have historically been the more commonly used agents; however, most clinicians currently use lorazepam as the first-line agent.* When treating patients who are taking chronic benzodiazepines, clinicians should consider higher doses to overcome the effects of tolerance. Diazepam and lorazepam should be diluted with normal saline in a 1:1 ratio before parenteral administration via peripheral veins to avoid venous irritation from the propylene glycol diluent in the formulation.

Diazepam Being extremely **lipophilic**, diazepam penetrates quickly into the CNS, but can rapidly redistribute into body fat and muscle. This results in a faster decline in CNS levels and early recurrence of seizures. It is dosed at 5 to 10 mg (or 0.15 mg/kg) and infused no faster than 5 mg/minute. Repeated doses can be given every 5 minutes until seizure activity stops or toxicities are seen (e.g., respiratory depression). Diazepam can also be administered as a rectal suppository, making it possible for non-medical personnel to provide rapid therapy for seizures that develop at home or in public areas.[11] The adult dose is 10 mg given rectally and this dose may be repeated once if necessary. Diazepam is erratically absorbed via the intramuscular route; therefore, IM administration is not recommended.

Lorazepam Less lipophilic than diazepam, lorazepam has a longer redistribution half-life, resulting in longer duration of action and a decrease in the need for repeated doses. Both lorazepam and diazepam are effective in stopping seizures,[12] but lorazepam is currently the preferred agent due to its longer duration of action. Lorazepam is given as a single IV dose of 0.1 mg/kg (maximum dose is 4 mg) with a maximum rate of infusion of 2 mg/minute. It can be re-dosed every 10 to 15 minutes (up to a maximum cumulative dose of 8 mg) until seizure activity stops or side effects such as respiratory depression occur. It should not be given IM since it has slow and unpredictable absorption via the IM route.

Midazolam Midazolam is water-soluble and can be administered intravenously, intramuscularly,[13] buccally,[14,15] and nasally.[16,17] At physiologic pH, it becomes more lipophilic and can diffuse into the CNS. Compared to diazepam and lorazepam, it has fewer effects on the respiratory and cardiovascular systems. Its short half-life requires that it be re-dosed frequently or administered as a continuous infusion. Midazolam can be given at 0.2 mg/kg either intravenously or intramuscularly as a single dose.[18] The liquid or injectable formulation can be given buccally or intranasally (0.3 mg/kg) when IV access cannot be secured. Nasal administration in SE can be hindered by rapid breathing and increased nasal secretions.

Anticonvulsants

❻ Once the first dose of benzodiazepine is given, an antiepileptic drug must be started to prevent further seizures from occurring. AEDs must not be given as first-line therapy since they must be infused relatively slowly to avoid adverse effects, delaying their onset of action.

Once the loading dose of the AED is administered, it is important to remember to initiate maintenance doses to ensure that therapeutic levels are sustained. Chronic and idiosyncratic side effects as well as potential drug interactions should be considered if the patient will continue AED therapy indefinitely. All drug therapy should be adjusted for any hepatic or renal disease states. Table 28–1 summarizes the drug doses used in SE, and Table 28–2 provides an example of an algorithm for the treatment of patients in SE. Published studies comparing these treatment strategies are summarized in Table 28–3.

Phenytoin The most widely used antiepileptic agent is phenytoin, which is administered IV as a loading dose (for patients previously not on phenytoin) of 15 to 20 mg/kg. The loading dose must be modified in those patients who are taking phenytoin and have subtherapeutic levels in order to avoid toxic serum concentrations. The loading dose is infused no faster than 50 mg/minute due to potential risks of hypotension or arrhythmias. Continuous monitoring of ECG and blood pressure is recommended. Maintenance dosing can be started 12 hours after the loading dose. Phenytoin should not be infused with other medications because of stability concerns (it is soluble in propylene glycol and compatible only in 0.9% sodium chloride solutions). It should not be given via the IM route due to its alkaline nature. **Extravasation** of the drug can cause local discoloration, edema, pain, and sometimes necrosis (purple glove syndrome). Although phenytoin comes in a variety of enteral preparations, oral loading is not recommended in SE due to the delay in absorption.

Fosphenytoin Fosphenytoin is a water-soluble, phospho-ester prodrug of phenytoin that is rapidly converted to phenytoin in the body. It is compatible with most IV solutions and is well tolerated as an IM injection, even with the large volumes associated with loading doses (20 to 30 mL).[19] It is dosed in phenytoin equivalents (PE), and it can be infused three times as fast as phenytoin, up to 150 mg PE/minute. The loading dose for patients not taking phenytoin is 15 to 20 mg PE/kg. It can be an advantage to use IM fosphenytoin when IV access cannot be obtained immediately and in patients with poor venous access. Although it has fewer cardiovascular side

TABLE 28–1. Parenteral Medications Used in Status Epilepticus in Adults

Drug Name (Brand Name)	Loading Dose	Administration Rate	Therapeutic Level	Side Effects	Comments
Diazepam (Valium)	0.15 mg/kg	5 mg/minute (IVP)	N/A	Hypotension, respiratory depression	Rapid redistribution rate; can be given rectally
Lorazepam (Ativan)	0.1 mg/kg	2 mg/minute (IVP)	N/A	Hypotension, respiratory depression	May be longer-acting than diazepam
Midazolam (Versed)	0.2 mg/kg	2 mg/minute (IVP)	N/A	Sedation	Can also be given IM, buccally, intranasally; expensive
Phenytoin (Dilantin)	15–20 mg/kg	Up to 50 mg/minute	10–20 mcg/mL (39.6–79.2 µmol/L)	Arrhythmias, hypotension,	Hypotension, especially in elderly
Fosphenytoin (Cerebyx)	15–20 mg PE/kg	Up to 150 mg PE/minute	10–20 mcg/mL	Paresthesias, hypotension	Can be given IM; less CV side effects than phenytoin; expensive
Phenobarbital (Luminal)	20 mg/kg	50–100 mg/minute	15–40 mcg/mL (64.7–172.4 µmol/L)	Hypotension, sedation, respiratory depression	Long-acting
Valproate sodium (Depacon)	15–20 mg/kg (up to 40 mg/kg)	3–6 mg/kg per minute	50–150 mcg/mL (346.5–1039.5 µmol/L)		Less CV side effects than phenytoin
Propofol (Diprivan)	1–2 mg/kg	Approximately 40 mg every 10 seconds	N/A (typically titrated to EEG)	Hypotension, respiratory depression	Requires mechanical intubation; high lipid load (increased calories); propofol infusion syndrome
Pentobarbital (Nembutal)	10–15 mg/kg	Up to 50 mg/minute	10–20 mcg/mL (typically titrated to EEG)	Hypotension, respiratory depression, cardiac depression, infection, ileus	Requires mechanical intubation, pressors, hemodynamic monitoring

CV, cardiovascular; EEG, electroencephalogram; IM, intramuscular; IVP, intravenous push; N/A, not applicable; PE, phenytoin equivalents.

effects than phenytoin, clinicians should still continuously monitor blood pressure, ECG, and heart rate. Maintenance doses are begun 12 hours after the loading dose. A common side effect is **paresthesias**, especially around the lips and in the groin, which typically resolve within a few minutes and should not necessitate stopping the infusion. If a post-load serum level is desired, it should be obtained 2 hours after an IV load or 4 hours after an IM load. Fosphenytoin is more expensive than phenytoin, making it difficult to justify its use in many institutions.[20]

Phenobarbital If phenytoin or fosphenytoin fails to prevent seizure recurrence, phenobarbital can be administered. However, emerging evidence suggests that phenobarbital may not be effective if SE persists after giving benzodiazepines and phenytoin. This may be due to the progressive resistance of the $GABA_A$ receptor, at which the barbiturates also act.[21] It is dosed as an IV load of 15 to 20 mg/kg with a maximum rate of administration of 100 mg/minute. Adverse reactions of phenobarbital include sedation, hypotension, and respiratory depression; therefore, patients who receive a rapid IV loading dose of phenobarbital should have hemodynamic monitoring and be mechanically ventilated. Its long half-life makes it a popular agent for both acute treatment and chronic maintenance therapy.

Valproate Sodium Valproate sodium is an older AED that was released as an intravenous preparation (Depacon®) in 1996. Although it is not FDA-approved for SE, its use has been documented in various types of SE including generalized tonic-clonic, myoclonic, and non-convulsive SE.[22,23] Reports indicate

Patient Encounter, Part 3

Treatment Failure

It has been forty-five minutes since CH's arrival, and he has been given lorazepam 4 mg twice and loaded with 1500 mg of phenytoin. He received another 400 mg dose of phenytoin 15 minutes ago, but is still unarousable. His jerking movements have slowed down, but his temperature is now 39.9°C (103.8°F), and his blood pressure has dropped to 124/62 mm Hg. His oxygen saturation is 91% on 4 L oxygen via nasal cannula. Bilateral crackles are heard upon auscultation of his lungs. A CT scan of his head is obtained which shows no evidence of hemorrhage, tumor, or mass effect.

TABLE 28–3. Randomized, Prospective Trials Comparing Treatments for Status Epilepticus in Adults

Study	Treatment	Outcome	Adverse Events	Comments
Leppik (1983)[44]		Seizure control		Onset did not differ between two groups
	Diazepam 10 mg	76%	12%	
	Lorazepam 4 mg	89%	13%	
Shaner (1988)[45]		Time spent in SE	Incidence of intubation, hypotension, and arrhythmias similar in both groups	Unblinded study
Goal: Time to seizure control	Diazepam + phenytoin	9 minutes		
	Phenobarbital +/– phenytoin	5 minutes		
Treiman (1998)[46]		Seizure control	Resp/cardiac events	Patients with subtle GCSE fared worse than patients with overt GCSE
Goal: Seizure control within 20 minutes and no recurrence within 60 minutes	Diazepam 0.15 mg/kg + phenytoin 18 mg/kg	55.8%	2.1–31.6%	
	Lorazepam 0.1 mg/kg	64.9%	7.2–25.8%	
	Phenobarbital 15 mg/kg	58.2%	3.3–34.1%	
	Phenytoin 18 mg/kg	43.6%	6.9–27%	
Alldredge (2001)[47]		Seizure control	Resp/cardiac events	Higher doses used in hospital for SE
Goal: Seizure control on arrival to ED	Lorazepam 2 mg	59.1%	10.6%	
	Diazepam 5 mg	42.6%	10.3%	
	Placebo	21.1%	22.5%	
Misra (2006)[48]		Seizure control	Resp/cardiac events	As second line agent, valproate controlled more seizures than phenytoin (79% vs 25%)
Goal: Seizure control after infusion	Sodium valproate 30 mg/kg	66%	4%/0%	
	Phenytoin 18 mg/kg	42%	14%/14%	

ED, emergency department; GCSE, generalized convulsive status epilepticus; SE, status epilepticus.

a good response rate (80%) and a relatively benign side-effect profile compared to phenytoin and phenobarbital. It can be considered when the use of phenytoin and phenobarbital are precluded due to allergies or intolerance. Valproate sodium can be loaded intravenously at 15 to 20 mg/kg and infused at a rate of up to 3 mg/kg per minute. Higher doses (up to 30 to 40 mg/kg) have also been used to attain serum levels of 100 to 150 mcg/mL in less responsive cases of SE.[24]

Treatment of Refractory Status Epilepticus

❼ *Seizure activity that does not respond to benzodiazepines (first-line) and antiepileptics (second-line) or persists beyond 60 minutes in duration can be considered refractory status epilepticus (RSE).*[25] It can occur in up to 30% of patients with SE and has a mortality rate approaching 50%. Patients in RSE are unlikely to return to their baseline state, even if the seizures are eventually controlled. As RSE progresses, clinical signs may become subtle, and in certain patients, an EEG is required to detect ongoing seizure activity. ❶ *Even patients without clinical signs of seizing are at risk for brain damage or even death.*

The optimal therapy for RSE has not been determined. Clinicians must aggressively investigate and treat possible causes including infection, tumors, drugs or toxins, metabolic disorders, liver failure, or fever.[26] In general, patients with RSE are managed in an ICU where hemodynamic and respiratory support are available and frequent monitoring can be performed. Continuous EEG monitoring is desirable to document cessation of seizure activity, but treatment should not be delayed if continuous EEG monitoring is not immediately available or while waiting for results. ❽ *Treatment of RSE consists of continuous intravenous infusions of benzodiazepines (midazolam), anesthetic agents (propofol), or barbiturates (pentobarbital) to suppress all clinical and electrographic evidence of seizures.*[27] These agents are typically titrated to achieve "burst suppression" on the EEG, although no strong evidence exists to support this as the universal goal.[28] Any AEDs that were started before treatment for RSE should be continued and their serum levels optimized in order to minimize any breakthrough or withdrawal seizures. Patients should be intubated and mechanically ventilated before initiating these treatment strategies for RSE. Consultation with a neurologist or epileptologist is highly recommended in these cases.

Midazolam

A loading dose of 0.2 mg/kg (repeated up to a maximum of 2 mg/kg) followed by a continuous infusion of 0.05 to 2 mg/kg per hour is recommended in RSE.[29–31] The dose must be adjusted during prolonged infusions, especially in patients with renal impairment, as the active metabolite can accumulate.[32] Breakthrough seizures are common with midazolam infusions and usually respond to a bolus and a 20% increase in the rate. Despite this, tachyphylaxis can occur and the patient should be switched to another agent if seizure activity continues.

Propofol

The anesthetic agent propofol can be started with loading doses of 1 mg/kg repeated every 3 to 5 minutes until a clinical

response is achieved, after which the infusion can be initiated at 2 to 4 mg/kg per hour. Propofol can cause hypotension, especially with loading doses. Long-term, high-dose (greater than 5 mg/kg per hour) propofol infusions are associated with rhabdomyolysis, acidosis, and cardiac arrhythmias (propofol infusion syndrome), especially in children.[33] Propofol has a very short serum half-life and should be tapered off slowly to avoid withdrawal seizures. High-dose propofol infusions can also provide a considerable amount of calories (1 kcal/mL of the 1% solution) over time, so other sources of nutrition may have to be adjusted accordingly.

Pentobarbital

Barbiturate infusions have been reported to be highly successful in treating RSE,[34] but their side effects are considerable. They can cause significant hypotension, myocardial and respiratory depression, ileus, and infection (especially gram-positive organisms). As a result, patients often require mechanical ventilation, intravenous **vasopressor** therapy, invasive hemodynamic monitoring, and total parenteral nutrition while undergoing "barbiturate coma." On the other hand, barbiturates are beneficial if elevated intracranial pressure (ICP) is present, as they are effective in decreasing ICP.

Pentobarbital is commonly loaded at a dose of 10 to 15 mg/kg over 1 to 2 hours, followed by a continuous infusion of 0.5 to 4 mg/kg per hour. Therapy can be tapered off after 12 to 24 hours of seizure control as evident on the EEG.[35] One meta-analysis reported a lower incidence of treatment failure with pentobarbital (3%) when compared to midazolam (21%) or propofol (20%), although the risk of hypotension requiring vasopressor therapy was higher when pentobarbital was used.[36] This relative efficacy for pentobarbital must be considered together with its complications when determining which agent to use. Patients who fail midazolam and/or propofol infusions should be switched over to pentobarbital therapy.

Other Agents

Ketamine,[37] topiramate, and inhaled anesthetics are newer modalities that have been used to treat RSE. Ketamine is an NMDA receptor antagonist that has been given orally[38] and intravenously[39] for RSE in children. Topiramate is a newer oral antiepileptic agent with multiple mechanisms of action that may have some benefit in RSE. The dose in adults ranges from 300 to 1600 mg/day.[41] Children have also been administered topiramate at a starting dose of 2 to 3 mg/kg per day and titrated to a maintenance dose of 5 to 6 mg/kg per day.[41] The inhaled anesthetics, desflurane and isoflurane,[42] are normally delivered in an operating room, and require special equipment for administration in an ICU. Future studies will determine their place in therapy.

Special Populations

Certain patient populations require special considerations due to their altered metabolism, unique volume of distribution, or increased risk for side effects.[43] Although many of these patients are excluded from clinical trials in SE, the standard algorithm for SE still applies for these patients in terms of immediate care, assessment, and drugs (see Table 28–2).

Pediatrics

The treatment approach of SE in children is similar to that in adults with a few exceptions (Table 28–4). The doses are also weight-based but are typically higher than those used in adults due to higher clearance by the liver. It may be difficult to rapidly obtain IV access in children, so alternate methods of

TABLE 28–4. Drugs Used in Pediatric Status Epilepticus

Drug	Dose	Comments
Diazepam (Valium injection, Diastat rectal gel)	IV: 0.2–0.3 mg/kg over 2–5 minutes	Maximum dose in children less than 5 y: 5 mg Maximum dose in children greater than 5 y: 15 mg
	PR: 2–5 years: 0.5 mg/kg 6–11 years: 0.3 mg/kg greater than 12 years: 0.2 mg/kg	A second rectal dose can be given 4–12 hours after the first dose if necessary
Lorazepam (Ativan)	0.05–0.1 mg/kg IV over 2–4 minutes	May redose twice in 10–15 minutes if necessary
Midazolam (Versed)	0.2 mg/kg IV bolus followed by 0.05–0.6 mg/kg per hour continuous infusion	Bolus dose may also be given intranasally, buccally, or intramuscularly
Phenytoin (Dilantin)	15–20 mg/kg IV at 1–3 mg/kg per minute *max*	
Fosphenytoin (Cerebyx)	15–20 mg PE/kg IV at 3 mg/kg per minute *max*	Dose can be given intramuscularly
Phenobarbital (Luminal)	15–20 mg/kg IV at 100 mg/minute *max*	
Valproate sodium (Depacon)	15–20 mg/kg IV at 1.5–3 mg/kg per minute	May have fewer cardiovascular side effects than other agents
Propofol (Diprivan)		Not recommended due to adverse events (e.g., rhabdomyolysis)
Pentobarbital (Nembutal)	10–15 mg/kg IV over 1–2 hours followed by continuous infusion at 1 mg/kg per hour	Titrated to EEG

PR, per rectum; EEG, electroencephalograph; IV, intravenous; PE phenytoin equivalent.

drug administration have been studied, including intranasal, buccal, rectal, and IM.

Geriatrics

The elderly are prone to injury and toxicity from multiple concomitant disease states and polypharmacy. Seizures in the elderly can easily arise from metabolic disorders, drug interactions, or even incorrect dosing of medications in patients with impaired renal and hepatic function and decreased protein binding. Clinicians treating elderly patients presenting with SE should investigate drug- and disease state–induced causes, since treating these etiologies alone may terminate seizures. Acute treatment with benzodiazepines and AEDs is no different in the elderly, but elderly patients may have a more pronounced reaction to these medications in terms of their sedative and cardiorespiratory side effects. Phenytoin and fosphenytoin loading doses should be carefully calculated in the elderly, as their weights may be overestimated, and they may not tolerate the commonly ordered 1-g dose. They should also be infused at slower rates to minimize hypotension and arrhythmias. Phenobarbital may cause respiratory depression earlier in the elderly, especially after benzodiazepines are administered. Clinicians should consider using smaller doses and should evaluate these patients for renal and hepatic insufficiency if repeated doses are to be given.

Pregnancy

The main concern in the treatment of pregnant females in SE is the safety of the fetus which is at risk of hypoxia during periods of prolonged seizures. Although many of the agents used in SE are **teratogenic**, clinicians should still use them as acute measures to stop the seizures and consider alternative agents as maintenance therapy. The volume of distribution and clearance of many drugs are typically increased during pregnancy, and this should be considered when calculating doses.

OUTCOME EVALUATION

❹ *The success of treatment is measured by the early termination of seizures, without adverse drug effects or brain injury.* Therefore, it is essential to start pharmacologic treatment as soon as possible. First-line treatment for SE should halt seizure activity within minutes of administration. In patients who are unarousable following treatment, an EEG should be done to rule out continued excessive electrical brain activity and confirm termination of seizures. A physical exam and evaluation of the patient's laboratory results can help determine if the cause or complications of seizure activity are being appropriately treated.

Once seizure activity has ceased and the patient has stabilized, review the patient's therapeutic regimen. Evaluate and monitor the serum trough concentrations of AEDs with defined target ranges to determine patient-specific therapeutic ranges. If there is a known cause of SE, simplify the treatment regimen once the underlying cause has been treated. In patients with RSE on multiple AEDs, slowly decrease the dose of one drug at a time while continuing to evaluate the patient for seizure activity. Base the titration schedule on the half-life of the drug and individual patient response. The optimal treatment regimen is one that uses the least medications to prevent seizure recurrence and does not cause adverse drug reactions.

Continue to monitor AED serum trough concentrations approximately every 3 to 5 days until the AEDs have reached steady-state concentrations. Give additional loading doses or hold doses as needed to maintain trough concentrations in the patient's therapeutic range. Be sure to evaluate the time the sample was drawn to assure it is a trough level.

Frequently monitor the patient for signs of drug toxicity and seizures until the patient's drug concentrations have stabilized. Drug interactions are likely when patients are on more than one AED; therefore, closely evaluate the patient's entire medication profile, and change medications or doses to minimize the interaction, if possible.

Patient Care and Monitoring

1. Obtain a seizure history from the patient or family members, including precipitating factors and duration of seizure activity.
2. Identify the underlying cause of the seizures and correct the cause, if possible. Does the patient have any laboratory abnormalities? Is there a positive toxicology screen for alcohol or drugs?
3. Obtain a thorough history of non-prescription, prescription, and alternative or herbal drug use. Determine adherence with the medication regimen and whether barriers to care exist. Does the patient have the financial ability and transportation to obtain their prescriptions?
4. Assess the AED serum concentration and adjust therapy as needed for agents with a defined therapeutic range (e.g., phenytoin, carbamazepine, valproic acid, and phenobarbital). Drug levels can also be used to determine adherence to medication regimens for agents that do not have defined ranges.
5. Evaluate the patient for adverse drug reactions, IV site extravasation and allergic reactions. What alternative AEDs should be used if a drug allergy is identified?
6. Determine whether there are any drug interactions with the patient's current or home medication regimens. Do you need to adjust the dose of any medications for toxic or subtherapeutic concentrations from the drug interaction?
7. Maintain adequate cardiovascular support, nutrition, and electrolyte and glucose serum concentrations to prevent recurrence of seizure activity.
8. Continue to evaluate the patient for seizure activity and adjust therapy as needed to control seizures and optimize quality of life.

ABBREVIATIONS

ABG:	arterial blood gas
AED:	antiepileptic drug
CNS:	central nervous system
CSF:	cerebrospinal fluid
CT:	computerized tomography
ECG:	electrocardiogram
EEG:	electroencephalography

29 Parkinson's Disease

Mary L. Wagner

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Explain the etiology of Parkinson's disease.
2. Explain the pathologic and biochemical changes in patients with Parkinson's disease.
3. Identify motor and non-motor symptoms of Parkinson's disease as well as symptoms that indicate disease progression.
4. Explain the desired therapeutic goals for patients with Parkinson's disease.
5. Recommend lifestyle modifications and pharmacotherapy interventions for treating motor symptoms of patients with Parkinson's disease.
6. Recommend drug and non-drug interventions for treating the non-motor symptoms of patients with Parkinson's disease.
7. Develop a monitoring plan to assess effectiveness and adverse effects of nonpharmacologic therapy and pharmacotherapy for Parkinson's disease.
8. Educate patients about the disease state, appropriate lifestyle modifications, and drug therapy required for effective treatment.

Key Concepts

❶ Patients with Parkinson's disease display both motor and non-motor symptoms. The non-motor symptoms may precede the motor symptoms.

❷ The most useful diagnostic tool is the clinical history, including both presenting symptoms and associated risk factors. The Unified Parkinson's Disease Rating Scale (UPDRS) is used to define the degree of disability.

❸ The goals of treatment are to maintain patient independence, activities of daily living (ADL), and quality of life (QOL) by alleviating the patient's symptoms, minimizing the development of response fluctuations, and limiting medication-related adverse effects.

❹ The treatment of Parkinson's disease is categorized into three phases:

- Lifestyle changes, nutrition, and exercise
- Pharmacologic intervention, primarily with drugs that enhance dopamine concentrations
- Surgical treatments for those who fail pharmacologic interventions

❺ The best time to initiate dopaminergic therapy is controversial and patient-specific. Generally, medication is started when the patient's physical impairment affects quality of life.

❻ Medication schedules should be individualized. The doses are divided throughout the day to maximize on and minimize off periods.

❼ The treatment of non-motor symptoms should be based on whether they are worse during an off state or if they could be related to other neurotransmitter dysfunction.

❽ As the disease progresses, most patients develop response fluctuations. Treatment is based on optimizing the pharmacokinetic and pharmacodynamic properties of Parkinson's disease medications.

❾ Patient monitoring should involve a regular systematic evaluation of efficacy and adverse events, referral to appropriate specialists, and patient education.

Parkinson's disease (PD) is a slow, progressive, neurodegenerative disease of the extrapyramidal motor system. Dopamine neurons in the substantia nigra are primarily affected, and degeneration of these neurons causes a disruption in the ability

Patient Encounter, Part 1

MW, a 65-year-old man with a 2-year history of mild depression comes for an initial visit to evaluate his symptoms of tremor and slowness. The tremor started in his right hand about 6 months ago, and he does not remember how long he has been slower at completing his tasks. His wife reports that for the last 4 months he has been slower and that he kicks her while they are sleeping.

- Identify the motor and non-motor symptoms of Parkinson's disease.
- What additional information would you collect before creating this patient's treatment plan?

to generate body movements. There is no cure for PD and treatment is aimed at controlling symptoms and slowing disease progression.

EPIDEMIOLOGY AND ETIOLOGY

PD affects approximately one million Americans (1% of people over 60 years of age). The average age of onset is 60 years of age, and PD is fairly uncommon in those under age 40. The etiology of PD is unknown, but genetic predisposition, environmental factors, or combinations of these have been proposed to explain why nerve cells in the substantia nigra deteriorate. About 15% of patients with PD have a first-degree relative with the disease. The pathogenesis of cell death (neuron degeneration) may be due to oxidative stress, mitochondrial dysfunction, increased concentrations of excitotoxic amino acids and inflammatory cytokines, immune system disorders, trophic factor deficiency, signal-mediated apoptosis, and environmental factors. Conditions that may promote oxidative stress include increased monoamine oxidase B metabolism or decreased glutathione clearance of free radicals which can promote cell dysfunction and death. Environmental toxins include 1-methyl-4-phenyl-1-2-5-6-tetrahydropyridine (MPTP), carbon monoxide, manganese, methanol, hydrogen sulfide, petrochemicals and pesticides, but they have never been clearly proven as causative. Drugs that deplete central dopamine, such as some antipsychotics, amoxapine, antinausea drugs (i.e., prochlorpromazine) and metoclopramide, worsen Parkinson's symptoms.[1,2,3]

Pathology studies of patients with PD indicated that there is a loss of pigmented cells in the substantia nigra that make and store dopamine. When patients are diagnosed with PD, they have lost 50% to 60% of their dopamine neurons in the substantia nigra, and the remaining neurons may not function well, as they have lost about 80% of their activity in the striatum. There may be cortical **Lewy bodies** along with Lewy neurites seen in microscopic samples from the medial temporal, limbic, and frontal areas of the brain, gastrointestinal tract, and peripheral autonomic nervous system that may explain some of the non-motor symptoms of PD.[2–4]

PATHOPHYSIOLOGY

The extrapyramidal motor system controls muscle movement through a system of pathways and nerve tracts that connect the cerebral cortex, basal ganglia, thalamus, cerebellum, reticular formation, and spinal neurons. Patients with PD lose dopamine neurons in the **substantia nigra**, which is located in the midbrain within the brain stem. The substantia

Clinical Presentation of Parkinson's Disease

❶ *Patients with PD display both motor and non-motor symptoms. The non-motor symptoms may precede the motor symptoms.*

Motor Symptoms (TRAP)[7]

T = Tremor at rest ("pill rolling")
R = Rigidity (stiffness and cogwheel rigidity)
A = **Akinesia or bradykinesia**
P = Postural instability and gate abnormalities

Non-motor Symptoms (SOAP)

S = Sleep disturbances (insomnia, rapid eye movement sleep behavioral disorder, restless legs syndrome)
O = Other miscellaneous symptoms (problems with nausea, fatigue, speech, pain, **dysesthesias**, vision, seborrhea)
A = Autonomic symptoms (drooling, constipation, sexual dysfunction, urinary problems, sweating, orthostatic hypotension, dysphagia)
P = Psychological symptoms (anxiety, psychosis, cognitive impairment, depression)

Response Fluctuations (MAD)

M = motor fluctuations (delayed peak, wearing off, random off, freezing)
A = **akathisia**
D = **dyskinesias** (chorea, dystonia, diphasic dyskinesia)

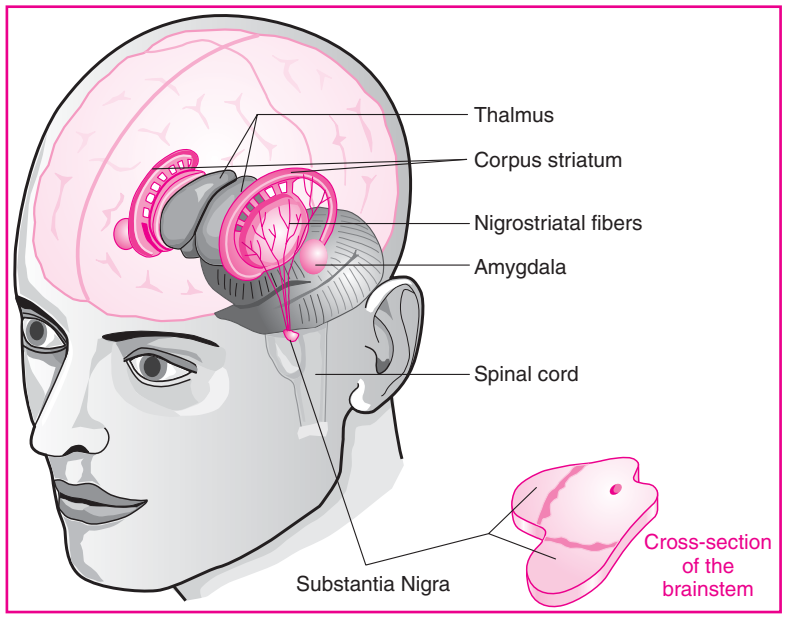

FIGURE 29–1. Anatomy of the extrapyramidal system. The extrapyramidal motor system controls muscle movement through a system of pathways and nerve tracts that connect the cerebral cortex, basal ganglia, thalamus, cerebellum, reticular formation, and spinal neurons. Patients with Parkinson's disease have a loss of dopamine neurons in the substantia nigra in the brain stem that leads to depletion of dopamine in the corpus striatum. The corpus striatum is made up of the caudate nucleus and the lentiform nuclei that are made up of the putamen and the globus pallidus.

nigra sends nerve fibers up to the corpus striatum, which is part of the **basal ganglia** in the cerebrum. The corpus striatum is made up of the caudate **nucleus** and the lentiform nuclei that consist of the pallidum (globus pallidus) and putamen (Fig. 29–1). As dopamine neurons die, dopamine-relayed messages cannot communicate to other motor centers of the brain and patients develop motor symptoms. A variety of chemicals are active in the basal ganglia including acetylcholine, histamine, glutamate, serotonin, dopamine, norepinephrine, epinephrine, γ-aminobutyric acid (GABA), enkephalins, substance P, and adenosine. Some of these neurotransmitters also decrease in concentration as other brain regions degenerate resulting in degeneration of norepinephrine neurons in the locus ceruleus and acetylcholine neurons in the nucleus basalis as well as selected neurons of the dorsal motor nucleus of the vagus, spinal cord, and peripheral autonomic system. Decreases in these neurotransmitters may explain some of the non-motor symptoms of PD.[3] For example, loss of dopamine and norepinephrine neurons in the limbic system has been associated with depression and anxiety, and neuron loss in the hippocampus and amygdala of the limbic system is associated with cognitive impairment.[5,6]

CLINICAL PRESENTATION AND DIAGNOSIS

As the onset of PD is insidious, patients are likely to rationalize other causes for their symptoms. A thorough patient history including past and present medications, family history, environmental exposure, and a detailed description of symptom onset is essential in making an accurate diagnosis. Patients feel slowed down or trapped in their body unable to move. The tremor of PD occurs during rest and disappears with purposeful movement. Tremor usually affects the hands or feet, but may occur in other body parts such as in the lip and chin. The hand tremor can appear as if the patient is rolling a pill between their fingers. Patients describe rigidity as stiffness. Upon physical exam, it feels like uniform resistance as the muscles seem to be in a constant state of increased tone. It is defined as cogwheel rigidity when the examiner extends or flexes the patient's extremities and feels as if they are rhythmically hitting a series of teeth on the rim of a wheel, or a gear that is meshing with another gear with teeth. Bradykinesia is noted when there is hesitancy in movement initiation, slowness in movement performance, or rapid fatiguing during movement. Patients may have a decrease in automatic movements, such as blinking, a decrease in facial expressions (often termed masked facies), or a decrease in arm swing while walking. Postural instability is a result of the loss of reflexes necessary to maintain balance when standing or ambulating. Patients may report a feeling of unsteadiness. Gait abnormalities may be evidenced by shuffling, leg dragging, **festination**, propulsion, retropulsion, or freezing. Rigidity and bradykinesia may make handwriting difficult as evidenced by **micrographia**.[2,8]

Non-motor Symptoms

Non-motor symptoms are due to multiple neurotransmitter abnormalities throughout the brain, and some symptoms may be aggravated by PD medications. Sleep disturbance can affect more than 70% of PD patients and includes insomnia, sleep

fragmentation, rapid eye movement sleep behavioral disorder (RBD), vivid dreams, nightmares, night terrors, hallucinations, restless legs syndrome (RLS), and sleep walking. Speech problems may be exhibited as a decrease in normal volume, slurring, monotone speech, rapid speech, or stammering. Visual problems such as reading problems, double vision, perceptual changes, decreased blink, burning eyes, or itchy eyes are the result of impaired function of the muscles that move the eyeball and decreased retinal dopamine.[7–11]

As the autonomic system is disturbed in patients with PD, orthostatic hypotension and gastrointestinal, urinary, sexual, and dermatologic symptoms are common. Patients with orthostatic hypotension may experience dizziness, lightheadedness, or fainting upon standing. Gastrointestinal symptoms include constipation and **dysphagia** due to a slowing of the automatic pattern of contraction and relaxation of the throat muscles. These swallowing difficulties may lead to weight loss, **sialorrhea**, and aspiration. Genitourinary symptoms include urinary incontinence, urgency, and frequency related to overactivity of the bladder emptying reflex. Symptoms may be worse at night, causing nocturia. Sexual dysfunction includes decreased libido, erectile dysfunction, and delayed ejaculation. Skin symptoms include sweating, and intolerance to heat and cold.[7,8,11,12]

Psychological symptoms may be exaggerated during the patient's off periods and include psychosis, dementia, impaired **cognitive function**, depression, and anxiety. Psychosis can occur in nearly 30% of PD patients and is exhibited as vivid dreams, hallucinations (usually visual), paranoia, and delusions. Hallucinations may be more common when the patient is in dim light, falling asleep, or awakening. Dementia occurs in 20% to 44% of patients, and is described as problems with cognitive function. Depression occurs in 30% to 70% of PD patients and may appear as apathy, psychomotor slowing, memory problems, irritability, or sadness. It may be associated with agitation and sleep disturbances. Some features of PD, such as the decreased facial expression and bradykinesia, may make the diagnosis of depression more difficult. Anxiety may present as panic attacks, phobia, or generalized anxiety and occurs in 30% of patients. Anxiety was noted in 66% of patients with motor fluctuations and is often comorbid with depression.[7–9,11,13,14]

Response Fluctuations

Response fluctuations occur with disease progression as the patient's dopamine reserves are depleted in the brain and as a complication of PD treatment. Motor fluctuations include delayed peak response, early wearing off, random unpredictable on-off, and freezing. Dyskinesias include **chorea**, **dystonia**, and diphasic dyskinesia. Wearing off can be visualized by imagining the therapeutic window of dopamine narrowing over time. The therapeutic window is defined as the minimum effective concentration of dopamine required to control PD symptoms (on without dyskinesia) and the maximum concentration before experiencing side effects from too much dopamine (on with dyskinesia). Early in the disease, a dose of levodopa is administered and the plasma concentrations are supplemented by the brain's supply of dopamine. Thus, although the plasma half-life of levodopa is 1.5 to 2 hours, the therapeutic effect lasts about 5 hours, and the patient experiences no dopamine side effects. As the disease progresses over time, the therapeutic window narrows because the brain can no longer supplement each levodopa dose with additional dopamine. Thus, during advanced disease, each dose lasts 2 to 3 hours and patients experience dopamine side effects in order to be in an on state.[15–16]

❷ *The most useful diagnostic tool is the clinical history, including both presenting symptoms and associated risk factors. The UPDRS is used to define the degree of disability in motor and some non-motor symptoms.*

Patient Encounter, Part 2: The Medical History, Physical Exam, and Diagnostic Tests

Chief Complaint
MW complains of stiffness, slow movements, and mild tremor that worsens his handwriting

PMH
Depression for 2 years

SH
After owning a dry cleaning store for 40 years, he is thinking about retiring because he does not enjoy visiting with the customers anymore; he does not smoke or drink alcohol

Meds
Fluoxetine 10 mg every morning for 2 years
Gen: Pessimistic attitude, apathetic, looks older than stated age, slow movements, thin

PE
VS: Blood pressure: sitting 130/80 mm Hg, standing 110/80 mm Hg (with orthostatic symptoms); pulse 78 beats per minute, respiratory rate 16/minute, Wt 65 kg (143 lbs)
CV: RRR, normal S_1, S_2; no murmurs, rubs, gallops
Abd: Soft, non-tender, non-distended; (+) bowel sounds, no hepatosplenomegaly
Skin: Scalp itchy, oily, and flaky silverish scales
Exts: Tremor in right hand and foot while sitting, cogwheel rigidity in right elbow
Neuro: Steady gait, sensory function intact, alert, normal mental status, UPDRS = 10 while "on"

Labs
Within normal limits

- Assess the patient's condition.
- Identify treatment goals for the patient.
- Describe nonpharmacologic and pharmacologic treatments that are available for the patient.

The patient's degree of disability should be evaluated by using the UPDRS which has six parts. The scale combines patient history and a physical examination that is performed on both sides of the body, as symptoms may appear asymmetric in early disease. It evaluates mentation, behavior, and mood (Part 1); activities of daily living (ADL, Part 2); PD motor symptoms (Part 3); complications of therapy (Part 4); modified Hoehn and Yahr stage of disease (Part 5); and Schwab and England ADL (Part 6). The modified Hoehn and Yahr staging scale defines eight stages of PD ranging from no symptoms to wheelchair or bed bound. A copy of the exam can be obtained at http://www.mdvu.org/pdf/updrs.pdf.[17]

TREATMENT

Desired Outcomes

❸ *The goals of treatment are to maintain patient independence, ADL, and QOL by alleviating the patient's symptoms, minimizing the development of response fluctuations, and limiting medication-related adverse effects.*

General Approach to Treatment

❹ *The treatment of PD is categorized into three phases:*

- *Lifestyle changes, nutrition, and exercise*
- *Pharmacologic intervention, primarily with drugs that enhance dopamine concentrations*
- *Surgical treatments for those who fail pharmacologic interventions*

The initial therapeutic modality selected depends in part on the patient's age, risk of psychiatric adverse effects, and degree of physical impairment. The current approach to treatment is to delay medication therapy until the symptoms begin to interfere with the patient's ability to function or impact their QOL.

Nonpharmacologic Therapy

Lifestyle Modifications

Lifestyle modifications should be started early and continued throughout treatment because they may improve ADL, gait, balance, and mental health. The most common interventions include maintaining good nutrition, physical condition, and social interactions. Patients should avoid medications that block central dopamine, as they may worsen PD.[1,18] A multidisciplinary approach using the expertise of nutritionists, speech therapists, physical therapists, occupational therapists, and social workers may optimize care but may not be covered by insurance. Patients should maintain regular visits with their optometrist or ophthalmologist and their dentist. The dentist should be informed that the patient has PD, as PD medications that decrease saliva flow may increase the risk of dental caries.

Dietary modification can improve constipation, nausea, erratic drug absorption, and minimize the risk of aspiration and weight loss. Patients should eat a balanced diet and take a daily multivitamin if they do not eat well. Nutritionists can help with meal selection, products to boost calories, and suggestions for arranging the proper protein content of meals so as not to interfere with medication absorption. Speech therapy may improve swallowing, articulation, and the force of speech. The therapist can perform swallowing studies that assess the patient's risk of aspiration.

An exercise program and increased activity during the day should minimize daytime sleepiness, possibly improve sleep at night, and may be neuroprotective. Maintaining a daily routine that allows patients to remain as independent as possible is of psychological and physical importance. Stretching, strengthening, and balance training should be encouraged, as well as programs that enhance cardiovascular fitness. Therapists can teach patients skills that would improve motion and reduce the risk of falling. Patient's PD symptoms improve with physical therapy and return to baseline when physical therapy is stopped.[1,8,19]

Occupational therapy may improve confidence and ability to stay active. Therapists can provide information about adaptive equipment for the home, specialized clothing, and personal training that can maximize a patient's independence, safety, and ADLs. They can help improve handwriting and train patients to use special computer programs that enhance communication.

Maintaining social interactions helps overall well being; thus, patients should resist the temptation to withdraw from activities. Maintaining good communication with a spouse regarding sexual issues may prevent conflicts, and clinicians should remind patients of this. Social workers help patients and their families cope with their condition and handle problems related to disease progression. They can provide family counseling and help arrange for special community assistance programs.

Surgery

Surgical treatment is for patients with persistent and disabling motor fluctuations despite maximizing medications. Patients need an intact cognition as determined by neuropsychological testing. Surgical procedures include ablative lesioning such as pallidotomy or thalamotomy, and deep brain stimulation. Pallidotomy helps mostly tremors and drug-induced dyskinesia, whereas thalamotomy is beneficial to tremor only. Deep brain stimulation has become the surgery of choice, as it is less traumatic and may be individualized to treat patient-specific symptoms. It involves the implantation of a high-frequency device that provides electrical stimulation of the globus pallidus and subthalamic nucleus. Patients can expect a 40% to 75% decrease in symptoms.[2,20,21]

Pharmacologic Therapy

❺ *The best time to initiate dopaminergic therapy is controversial and patient-specific. Generally, medication is started when the patient's physical impairment affects QOL.*

❻ *Medication schedules should be individualized. The doses should be divided throughout the day to maximize on and minimize off periods.*

Pharmacologic options include anticholinergic drugs, amantadine, MAO inhibitors, dopamine agonists, levodopa/carbidopa, and catechol-o-methyltransferase (COMT) inhibitors. Medications help relieve symptoms, improve QOL, and may lengthen life expectancy, but they are not curative, as treated PD patients still die earlier than controls.[1] Medications primarily work by enhancing the concentration of dopamine in the brain. Knowing how dopamine is metabolized and how drugs affect dopamine metabolism is important in understanding the pharmacology of PD medications (Fig. 29–2). Which medication to select for initial therapy is also controversial, but the American Academy of Neurology and the Movement Disorder Society determined that it is reasonable to start with levodopa or a dopamine agonist. Starting treatment with a dopamine agonist rather than levodopa may help to delay the onset of dyskinesias and the on/off fluctuations commonly seen with long-term levodopa use. The use of a dopamine agonist in preference to levodopa/carbidopa may result in less motor benefit and greater risk of hallucinations or somnolence. Levodopa results in greater motor improvement and should be used as initial therapy in the elderly (greater than 75 years of age) and in those with cognitive impairment. There is no preference for using controlled-release over immediate-release levodopa as initial therapy. There are insufficient data to recommend initiating treatment with both levodopa and a dopamine agonist. Initiating treatment with anticholinergic medications, amantadine, or selegiline are only for patients who have mild symptoms, as they are not as effective as dopamine agonists.[1,22,23]

Medications should be started at the lowest dose and increased gradually based on the patient's symptoms (Table 29–1). When interviewing patients, ask the following questions for each scheduled dose before adjusting the dose or timing of medications:

- When did the dose start to work and how long did it last?
- How did you feel just before the dose, and during the dosing period?

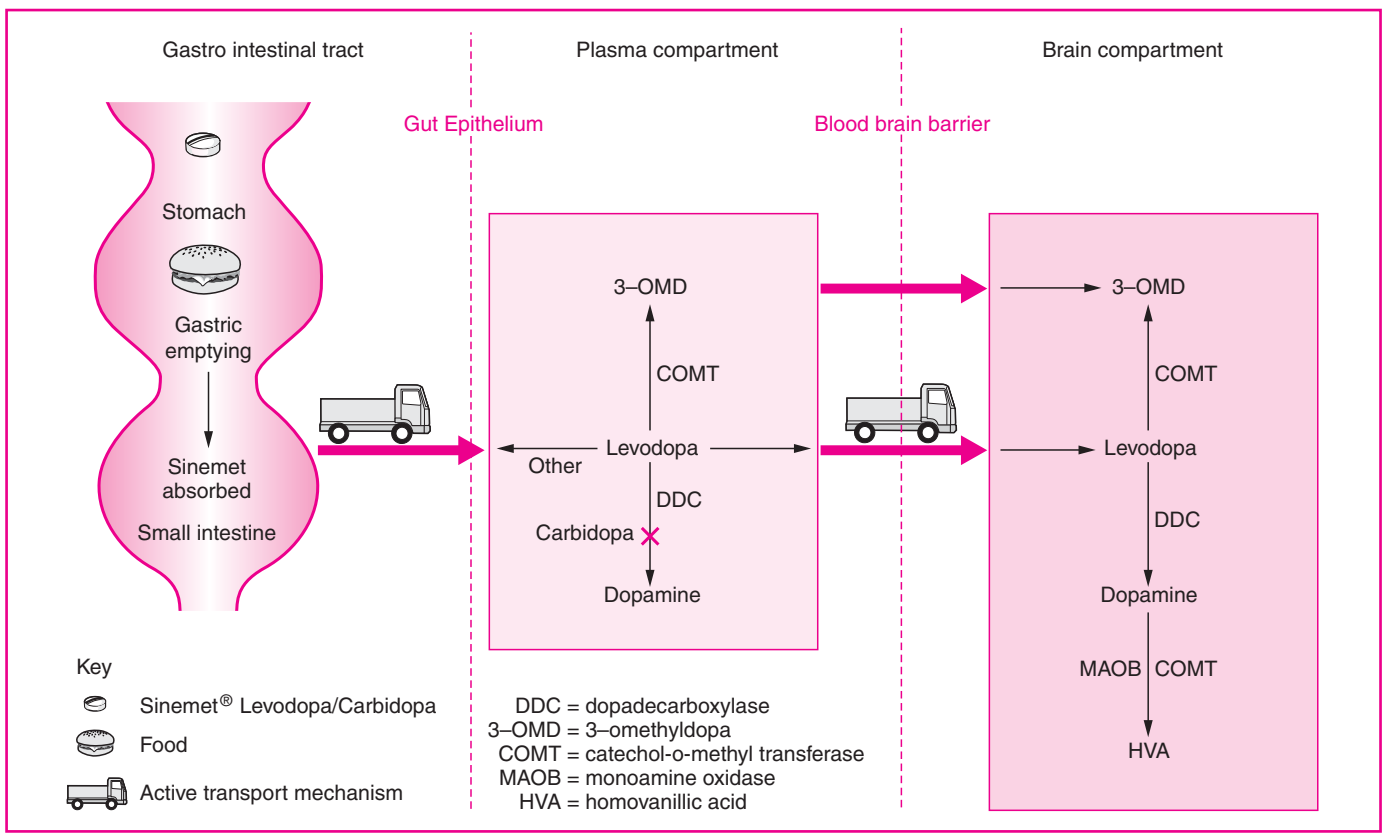

FIGURE 29–2. Levodopa absorption and metabolism. Levodopa is absorbed in the small intestine and is distributed into the plasma and brain compartments by an active transport mechanism. Levodopa is metabolized by dopa decarboxylase, monoamine oxidase, and catechol-O-methyltransferase. Carbidopa does not cross the blood–brain barrier. Large, neutral amino acids in food compete with levodopa for intestinal absorption (transport across gut endothelium to plasma). They also compete for transport across the brain (plasma compartment to brain compartment). Food and anticholinergics delay gastric emptying resulting in levodopa degradation in the stomach and a decreased amount of levodopa absorbed. If the interaction becomes a problem, administer levodopa 30 minutes before or 60 minutes after meals.

TABLE 29–1. Mechanism of Action and Dosing of Medications to Treat Parkinson's Disease[1,2,16,25,29,31,36]

Generic Name (Trade Name)	Mechanism of Action and Receptor Specificity	Dosing
Levodopa (Larodopa®, Dopar®) Carbidopa (Lodosyn®)	LD metabolized to DA CD blocks peripheral conversion of LD to DA and increases LD CNS penetration	Start with Sinemet® $^1/_2$ tab (100 mg LD, 25 mg CD) twice daily for 1 week, then $^1/_2$ tab three times daily; then, increase by $^1/_2$ tab daily every week; usual MD is 300–2000 mg daily; since the duration of LD is 2 to 3 hours, patients may require doses every 2 hours
Levodopa/Carbidopa (Sinemet®) (Parcopa™ with phenylalanine) (Sinemet CR®)	Standard, immediate-release LD Rapid-dissolving LD Controlled-release LD	Sinemet CR: Start with 1 tab (100 mg LD, 25 mg CD) two or three times daily; as symptoms increase, use 200 mg LD tab 2–4 times daily; usual MD is 200–2200 mg daily
Apomorphine (Apokyn®)	Activate postsynaptic D1 and D2 DA receptors	Start an antiemetic for 3 days, then give apomorphine 2 mg SC injection (1 mg if outpatient) while monitoring blood pressure; then increase by 1 to 2 mg every 2 or more hours; usual MD is 2–6 mg 3–5 times daily for off periods
Pergolide (Permax®)	Activate postsynaptic D1 and D2 DA receptors	Start with 0.05 mg daily and increase by 0.05–0.15 mg daily every few days over several weeks to a usual MD of 0.5–1 mg three times daily (maximum 5 mg daily)
Bromocriptine (Parlodel®)	Activate postsynaptic D2 and blocks D1 DA receptors	Start with 1.25 mg daily at bedtime, then 1.25 mg twice daily; on week 2, increase to 2.5 mg twice daily, then increase by 2.5 mg daily every 2–4 weeks up to 15–45 mg daily divided 2–3 times daily
Pramipexole (Mirapex®)	Activate postsynaptic D2 DA receptors	Start with 0.125 mg three times daily; increase about weekly by 0.375–0.75 mg/day to a MD of 0.5–1.5 mg three times daily; dosage reduction needed in patients with creatinine clearance less than 60 mL/minute
Ropinirole (Requip®)	Activate postsynaptic D2 DA receptors	Start with 0.25 mg three times daily; increase about weekly by 0.75–1.5 mg daily to a MD dose of 3–8 mg three times daily
Selegiline (Eldepryl®)	Blocks MAO_B metabolism and presynaptic reuptake of DA in the brain	Start with 5 mg in the morning; if symptoms continue, add 5 mg at noon; 5 mg daily may be as clinically effective as 10 mg daily with fewer side effects
(Zelapar® with phenylalanine)	Rapid-dissolving selegiline	Start with 1.25 mg every morning before breakfast; if symptoms continue after 6 weeks, increase dose to 2.5 mg every morning. Avoid food or liquid for 5 minutes before or after the dose
Rasagaline (Azilect®)	Blocks MAO_B metabolism	Start with 0.5 mg daily if symptoms continue, increase to 1 mg daily
Tolcapone (Tasmar®)	Peripherally blocks COMT metabolism of DA; some central activity	Start with 100 mg with first Sinemet® dose once daily; if symptoms continue, increase to 2 and then 3 times daily, then to 200 mg each dose; usual MD is 100 three times daily to minimize risk of side-effects
Entacapone (Comtan®)	Peripherally blocks COMT metabolism of DA	Take a 200-mg tab with each Sinemet® dose up to 8 tabs daily; usual MD is 200 mg 3–4 times daily; decrease dose by 50% with hepatic impairment
CD/LD/Entacapone (Stalevo®)	See CD, LD, and entacapone	Usual MD is 300–1200 mg LD daily; the largest strength tab contains 150 mg LD and 200 mg entacapone; patients requiring larger LD doses will need additional LD medication; titrate as with LD
Amantadine (Symmetrel®)	NMDA-receptor antagonist that blocks glutamate transmission, promotes DA release, and blocks Ach	Start with 100 mg daily at breakfast; after 1 week, add 100 mg daily in the early afternoon; decrease dose as creatinine clearance decreases less than
Anticholinergics (various, including trihexyphenidyl, benztropine)	Block Ach, decrease Ach: DA ratio	80 mL/minute

Ach, acetylcholine; CNS, central nervous system; CD, carbidopa; COMT, catechol-O-methyltransferase; D1, a class of dopamine receptors which includes D_1 and D_5 subtypes; D2, a class of dopamine receptors which includes D_2, D_3, and D_4 subtypes; DA, dopamine; LD, levodopa; MAO, monoamine oxidase; MD, maintenance dose; NMDA, N-methyl-D-aspartate.

If the dose did not last long enough, consider adding another dose each day, higher individual doses, an additional agent, or changing to a longer-acting dosage form. If the patient experiences side effects related to excessive dopamine concentrations (i.e., dyskinesia), consider decreasing the dose, increasing the time interval between doses, or decreasing the use of concomitant medications that augment dopamine concentrations. A sample diary for monitoring symptoms can be found at www.sinemetcr.com/cross_site/DiaryChart.shtml.

Anticholinergics

Anticholinergics may minimize resting tremor and drooling, but they are not as good as other agents in controlling rigidity, bradykinesia, and gait problems. Anticholinergics should be discontinued gradually to avoid withdrawal effects or worsening of PD symptoms. Side effects of anticholinergics include dry mouth (decreased saliva), blurred vision, constipation, cognitive impairment (forgetfulness, confusion, and hallucinations), urinary retention, orthostatic hypotension, temperature sensitivity, and sedation. They are usually avoided or used with caution in patients older than 70 years of age because of an increased risk of cognitive impairment. Use of anticholinergics is associated with an increased incidence of amyloid plaques and neurofibrillary tangles in patients with PD that may translate to an increased risk of Alzheimer's disease.[1,2,7,8,24–27]

Amantadine

Amantadine improves PD symptoms in mildly affected patients and reduces motor fluctuations in patients with more advanced disease. Amantadine may minimize or delay the development of motor complications, as levodopa's pulsatile stimulation of dopamine receptors is associated with N-methyl-D-aspartate receptor changes and resultant motor complications. Patients who develop tolerance to amantadine's effects may benefit from a drug holiday. Doses need to be reduced in patients with renal impairment. When stopping amantadine, gradually discontinue the drug to minimize potential withdrawal effects. Side effects include nausea, dizziness, livedo reticularis (purple mottling of the skin), peripheral edema, orthostatic hypotension, hallucinations, restlessness, and anticholinergic effects (confusion and sedation). Its stimulant action may worsen insomnia, so amantadine should not be dosed in the evening. It should be avoided in the elderly who cannot tolerate its anticholinergic effects. It should be used cautiously with memantine, as there may be an increased risk of psychosis.[1,2,7,8,16,18,22,24–26,28]

MAO_B Inhibitors

MAO_B inhibitors include selegiline and rasagaline. They may provide mild symptomatic benefit for those patients who choose to delay dopaminergic medications. Combining selegiline or rasagaline with levodopa in early treatment may delay motor complications. In patients with advanced disease, they decrease off time and improve wearing-off symptoms in patients with motor fluctuations.

Side effects of selegiline include nausea, confusion, hallucinations, headache, jitteriness, and orthostatic hypotension. Selegiline is metabolized to amphetamines which may cause insomnia, and should not be dosed in the afternoon or evening. Doses are limited to 10 mg daily, as MAO_B selectivity may be lost at higher doses increasing the risk of adverse effects and drug interactions. Rasagaline is not metabolized to amphetamine; thus, there is less risk of insomnia, and it may be neuroprotective. Treatment-limiting side effects in clinical trials included diarrhea, weight loss, hallucinations, and rash. The MAO_B selectivity of rasagaline in humans and sensitivity to tyramine has not been well defined. Therefore, the manufacturer recommends that patients restrict the intake of tyramine-containing foods and medications that contain amines. Dyskinesias can be minimized by decreasing the levodopa dose when adding either of these agents. Patients should avoid or use these medications cautiously with narcotic analgesics, antidepressants, or sympathomimetic amines (cold and weight loss products). Drugs that inhibit CYP1A2, such as ciprofloxacin, will increase serum rasagaline concentrations.[1,2,7,8,16,18,22,25]

Dopamine Agonists

Dopamine agonists are useful as initial therapy, as they can delay the need to start levodopa and can decrease the risk of developing motor fluctuations by two- to threefold during the first 4 to 5 years of treatment. After a few years, dopamine agonists inadequately control the patient's symptoms and levodopa needs to be started. In advanced disease, dopamine agonists can be added to levodopa because they have a longer duration of action, minimize fluctuations in dopamine blood concentrations, decrease off-time, improve wearing-off symptoms, allow a reduction in levodopa dose, and improve ADLs.[1–3,16,22,23,26]

Dopamine agonists include the ergot derivatives (pergolide, bromocriptine, and cabergoline) and the non-ergot derivatives (rotigotine, pramipexole, ropinirole, and apomorphine). Rotigotine is an investigational once-daily skin patch. Generally, all are equally effective except bromocriptine, which is the least effective. There are five subtypes of dopamine receptors that are divided into two classes called D1 (D_1 and D_5 subtypes) and D2 (D_2, D_3, and D_4 subtypes). Receptor selectivity may result in subtle differences between the products, as pramipexole is thought to have an antidepressant effect because it has greater D_3 receptor affinity. Ropinirole and pergolide may also have higher D_3 specificity, but less than pramipexole. Pergolide and apomorphine are also D1 agonists which may optimize their effect. Cabergoline, a very long-acting agonist, is effective for PD, but it is approved for hyperprolactinemia instead of PD. If patients fail one dopamine agonist, another can be tried. Although not well established, it appears that bromocriptine 30 mg, ropinirole 15 mg, pramipexole 4.5 mg, and pergolide 3 mg are equivalent and can be a guide when switching agents.[16,25,29]

Common side effects include nausea, vomiting, sedation (highest with apomorphine), pedal edema, orthostatic hypotension (highest with pramipexole and cabergoline), and

psychiatric effects that are greater than with levodopa (nightmares, confusion, and hallucinations). Obsessive-compulsive behaviors such as pathologically excessive gambling, shopping, sexual desire, or eating may occur. Reducing or eliminating the agonist will usually resolve the problem.[26,30,31] Ergot side effects are uncommon but include painful reddish discoloration of the skin over the shins and pleuropulmonary, retroperitoneal, and cardiac fibrosis.[1,16,25]

In addition, pergolide, and possibly other ergot dopamine agonists, may cause a thickening and restriction in cardiac valves in 33% of patients. As of March 2007, the manufacturers of pergolide voluntarily withdrew their drug from the market because of this risk. It may remain available under an Investigational New Drug Application. It is hypothesized that ergot derivatives stimulate 5-HT_{2B} serotonin receptors that promote fibrotic lesions. While there are no specific guidelines, many specialists obtain a baseline echocardiogram when starting pergolide, or get one as soon as possible if the patient is already receiving pergolide. If there are no specific abnormalities of concern, the echocardiogram should be repeated yearly while the patient receives pergolide. If valvular regurgitation is detected, and determined to be significant by the cardiologist, pergolide should be discontinued. The risk is greater in patients receiving doses higher than 5 mg/day.[1,2,29,32]

Excessive daytime sleepiness occurs in 15% to 20% of PD patients and can be aggravated by all dopaminergic drugs. Sleep attacks without warning may occur in up to 6% of patients. Patients at greatest risk of sleep attacks are those with an Epworth Sleepiness Scale score more than 10 (http://jama.amaassn.org/cgi/content/full/287/4/455/TABLEJOC10367T1), long duration of PD, and those taking dopamine agonists with levodopa. Sleepiness may also be due to the pathology of PD or co-existing conditions such as sleep disturbances or depression.[10,11,32–34] Adding modafinil (100 to 200 mg twice daily) or possibly selegiline can improve alertness.[35] Patients who are still driving need to be aware of this potentially dangerous effect. Occupational therapists can evaluate the patient's driving ability by using a simulated driver's test.

All dopamine agonists are metabolized by the liver except pramipexole, which is eliminated unchanged in the urine by active tubular secretion and requires dose reduction in renal insufficiency (creatinine clearance less than 60 mL/minute). Drug interactions may occur if it is given concurrently with other agents that are eliminated by active tubular secretion, such as procainamide, trimethoprim, and cimetidine. Ropinirole is metabolized by cytochrome P-450 oxidation in the liver and subject to drug-drug interactions with drugs that induce or inhibit CYP1A2 such as ciprofloxacin, fluvoxamine, and mexiletine.[31]

Apomorphine is approved for acute off episodes in patients with advanced stages of PD. The onset of effect is within 10 to 20 minutes and the duration of effect is about 60 minutes. It requires premedication with an antiemetic because it causes nausea and vomiting. Antiemetics that block central dopamine worsen the symptoms of PD, and 5-HT_3 antagonists, such as ondansetron, can aggravate PD-related hypotension. Trimethobenzamide (300 mg three times daily) should be started 3 days prior to starting apomorphine and continued for 2 months or until tolerance to the nausea develops. It should be used with caution in patients receiving antihypertensives or drugs that increase the QT interval. Patients who are allergic to sulfites may be allergic to apomorphine.[36]

Levodopa/Carbidopa

Levodopa, a dopamine precursor, is the most effective agent for PD. Patients experience a 40% to 50% improvement in motor function. It is absorbed in the small intestine and peaks in the plasma in 30 to 120 minutes. A stomach with excess acid, food, or anticholinergic medications will delay gastric emptying time and decrease the amount of levodopa absorbed. Antacids decrease stomach acidity and improve levodopa absorption. Levodopa requires active transport by a large, neutral amino acid transporter protein from the small intestine into the plasma and from the plasma across the blood–brain barrier into the brain (Fig. 29–2). Levodopa competes with other amino acids, such as those contained in food, for this transport mechanism. Thus, in advanced disease, adjusting the timing of protein-rich meals in relationship to levodopa doses may be helpful. Levodopa also binds to iron supplements and administration of these should be spaced by at least 2 hours from the levodopa dose.[1,8,16,25]

The controlled-release (CR) formulation is more slowly absorbed and longer acting than immediate-release tablets. Patients need to increase the total daily dose by 30%, as it is not as bioavailable as the immediate-release levodopa/carbidopa. The CR formulation has a delayed onset (45 to 60 minutes) compared to the standard formulation (15 to 30 minutes). Thus, patients may also need to take immediate-release tablets or even a liquid formulation when they want a quicker onset of effect, such as with the first morning dose.[1,8,25]

Carbidopa, a dopa-decarboxylase inhibitor, is added to the levodopa in order to decrease the peripheral conversion of levodopa to dopamine. It does not cross the blood–brain barrier and does not interfere with levodopa conversion in the brain. Concomitant administration of carbidopa and levodopa allows for lower levodopa doses and minimizes levodopa peripheral side effects such as nausea, vomiting, anorexia, and hypotension. For most patients, at least 75 to 100 mg daily of carbidopa is required to adequately block dopamine decarboxylase in the peripheral metabolism of levodopa in most patients. Taking extra carbidopa may reduce nausea related to initiating levodopa.[8,16]

Side effects include dyskinesias, orthostatic hypotension, dizziness, nausea, insomnia, sleep attacks, pathologic gambling, discoloration of urine/sweat, and psychiatric effects (confusion, hallucinations, nightmares, and altered behavior). Dyskinesias caused by adding other PD drugs to levodopa may be improved by decreasing the levodopa dose. Motor complications occur in about 40% of patients within 4 to 6 years of starting levodopa.[1,8,24,25,37]

Patients with severe dyskinesias and off periods may achieve more constant blood concentrations (lower peak and higher trough concentrations) by taking a liquid formulation of levodopa with carbidopa. Each day patients make a 1 mg/mL levodopa

solution made with water and ascorbic acid or with a carbonated beverage, which allows patients to take a precisely adjusted dose every 30 to 90 minutes.[25,38]

COMT Inhibitors

Catechol-O-methyltransferase inhibitors are used in conjunction with levodopa/carbidopa. They minimize peak and trough levodopa fluctuations by prolonging the half-life and area under the curve of levodopa. They may allow for a decrease in daily levodopa doses while increasing on time, decreasing wearing off, and improving ADLs in patients with motor fluctuations. Some clinicians believe that a COMT inhibitor should be added when levodopa is first introduced in an effort to promote more continuous dopamine stimulation, potentially minimizing long-term complications associated with the more pulsatile effect of intermittent levodopa administration. However, starting multiple drugs at the same time increases the risk of side effects. Side effects include diarrhea, nausea, vomiting, anorexia, dyskinesias, urine discoloration, daytime sleepiness, sleep attacks, orthostatic hypotension, and hallucinations. Dyskinesias should improve with a decrease in the levodopa dose.[24,25,29]

Tolcapone has been associated with several cases of severe liver failure, including fatalities, and has been removed from the market in some countries. Thus, it should only be used in patients who cannot take or do not respond to entacapone. Serum alanine aminotransferase and aspartate aminotransferase concentrations should be monitored at baseline, then every 2 to 4 weeks for 6 months, and then periodically for the remainder of therapy. Patients who fail to show symptomatic benefit after 3 weeks should discontinue tolcapone. Entacapone has not been associated with liver damage, so monitoring of liver enzymes is not currently recommended.[24,25,29]

Herbs and Supplements

Clinicians should ask patients if they take any herbs and supplements, as they may not volunteer this information. The most common herbs and supplements that patients ask about are vitamins, melatonin, valerian, and coenzyme Q_{10}. There is very little support for using creatinine, gingko, ginseng, green tea, ginger, yohimbine, and St John's wort in patients with PD. Patients should be cautioned that supplements and herbs are not well controlled by the FDA and may not contain the amounts indicated on the label. Melatonin and valerian may improve insomnia, but they are not commonly used because there is insufficient information in PD patients.[39]

There is usually no need to supplement with specific vitamins. Patients should be encouraged to eat a well balanced diet and should also take a multivitamin and mineral supplement. Some clinicians recommend vitamins C and E for their antioxidant properties; however, no significant improvements have been shown compared to placebo. Encourage patients to eat a diet rich in vitamin C and E (i.e., bright colored fruits and vegetables, nuts, and whole grains). Metabolism of levodopa may cause elevated homocysteine concentrations that may be associated with an increased risk of vascular disease, dementia, and depression. Administering levodopa with a COMT inhibitor may minimize the increase in homocysteine. Vitamin B is involved in maintaining normal homocysteine concentrations; thus, PD patients may have a greater requirement of B vitamins than patients not receiving levodopa. Eating foods rich in B vitamins (i.e., wheat germ, beans, and whole grains) and taking a multivitamin should be sufficient; however, B vitamin supplements may be warranted in patients with elevated homocysteine concentrations. Excess pyridoxine (vitamin B_6) may decrease the effect of levodopa, so limit doses to less than 50 mg per day.[8,40,41]

Coenzyme Q_{10} is an antioxidant essential for mitochondrial function. A dose of 1200 mg daily was associated with a slower decline in UPDRS scores than patients not receiving coenzyme Q_{10}. Lower doses were no better than placebo, but the drug continues to be studied in doses up to 2400 mg daily. Many formulations contain vitamin E, and patients should not exceed recommended daily allowances of this vitamin, as bleeding times may be prolonged.[42,43]

Treatment of Non-motor Symptoms

❼ *The treatment of nonmotor symptoms should be based on whether they are worse during an off state or if they could be related to other neurotransmitter dysfunction.*

The treatment of non-motor symptoms, such as psychological conditions, sleep disorders, and autonomic dysfunction, should include both pharmacologic and nonpharmacologic approaches. Patients should be given suggestions for maintaining ADLs, a positive self-image, family communication, and a safe environment.

Psychological Symptoms

Patients should report vivid dreams or nightmares, as these may herald psychosis. Neuropsychometric testing may be a helpful diagnostic tool. Other potential causes of psychosis, dementia, or depression, such as infections, metabolic changes, or toxic exposures should be ruled out. Psychological symptoms may be alleviated by the presence of a night light or correction of vision and hearing deficits. PD therapy should be adjusted to decrease off periods when depression and anxiety may be more likely to occur. Low-efficacy PD medications should be gradually decreased and stopped in patients with psychosis. Patients should be encouraged to participate in tasks that improve cognition, such as puzzles or reading. Some patients and their families may benefit from professional counseling. Some antidepressants may be used for anxiety, panic, or depression. Low-dose quetiapine (12.5 to 200 mg) or clozapine (6.25 to 150 mg) at bedtime can improve psychosis although clozapine requires at least monthly blood monitoring for agranulocytosis. Dementia symptoms may improve with acetylcholinesterase inhibitor or memantine. Electroconvulsive therapy can be considered in patients who fail medications.[2,7–9,11,13,14,44,45]

Sleep Problems

Sleep problems and fatigue are common in PD and may be due to medications, uncontrolled PD symptoms, or many other medical and psychological causes. The patient's bed partner can provide useful information on the patient's quality of sleep. Patients may benefit from instruction on good sleep hygiene, adjustment of therapy to control nighttime PD symptoms, or cognitive behavioral therapy. Referral to a sleep specialist may be necessary. Amantadine and selegiline may worsen insomnia, selegiline and tricyclic antidepressants may worsen RBD, and some antidepressants and antipsychotics may worsen RLS. Short-acting benzodiazepines and sedating antidepressants are used for short periods to help insomnia. Ramelteon may prove beneficial in patients with circadian sleep disorders. Pramipexole, melatonin, and clonazepam are recommended for RBD. In addition to dopaminergic medications, iron, gabapentin, and opioids are recommended for RLS. A nighttime dose of a COMT inhibitor may also help RLS. Benzodiazepines may increase the risk of falling. Iron may decrease the absorption of levodopa and increase constipation.[2,10,11,44,45]

Autonomic and Other Problems

Drooling may be accompanied by speech problems and dysphagia. Anticholinergics, botulinum toxin injections, and sublingual atropine can decrease drooling. A speech therapist can perform a swallowing study to assess the risk of aspiration, and a nutritionist can help optimize diet. Patients at high risk of aspiration or poor nutrition may require placement of a percutaneous endoscopic gastrostomy tube. Nausea can be improved by having patients take their PD medications with meals or pharmacologic therapy (domperidone from Canada or trimethobenzamide). Sexual dysfunction or urinary problems may need a urologic evaluation. Improvement of PD therapy to increase on time, removal of drugs that decrease sexual response, and pharmacologic therapy (sildenafil or yohimbine) may be helpful to treat sexual dysfunction. Patients with urinary frequency may find a bedside urinal along with a decrease in evening fluids helpful. Improvement in PD control can also benefit, but worsening symptoms may require catheterization or pharmacologic measures (oxybutynin, tolterodine, propantheline, imipramine, hyoscyamine, or nocturnal intranasal desmopressin). Anticholinergic drugs could cause urinary retention as well as constipation. Constipation can be helped with increased fluid and fiber-rich diet intake and physical activity. Patients should avoid cathartic laxatives and use stool softeners, osmotic or bulk-forming laxatives, glycerin suppositories, or enemas. Dyskinesia-related sweating may respond to PD therapy adjustment or β-blockers. Orthostasis may respond to removal of offending drugs (tricyclic antidepressants, PD medications, alcohol, and antihypertensives) increasing carbidopa doses, or addition of salt or fluids to the diet, compression stockings, fludrocortisone, indomethacin, or mitodrine. Seborrhea usually responds to over-the-counter dandruff shampoos or topical steroids.[2,7,8,11,12,44,45]

Treatment of Response Fluctuations

As the disease progresses, most patients develop response fluctuations. Management of these is based on optimizing the pharmacokinetic and pharmacodynamic properties of PD medications.

Treatment includes adjusting or adding medications to maximize the patient's on time, minimize the time on with dyskinesia, and minimize off time (Table 29–2). Use various

TABLE 29–2. Management of Motor Complications in Advanced Disease[2,15,16,44–46]

I. Motor Fluctuations
- A. Suboptimal or delayed peak response
  1. Take Sinemet® on an empty stomach
  2. Use rapid-dissolving tablet (Parcopa™), crush Sinemet®, or make liquid Sinemet®
  3. Decrease dietary protein around the dose that is delayed
  4. Substitute standard Sinemet® for some of the Sinemet CR®
- B. Optimal peak but early wearing off
  1. Decrease dose and increase frequency of standard Sinemet®
  2. Substitute Sinemet CR® for some of the standard Sinemet®
  3. Add other PD medications (dopamine agonist, selegiline, amantadine, or COMT inhibitor)
- C. Optimal peak but unpredictable offs
  1. Adjust time with meals and avoid high-protein meals or redistribute the protein in meals
  2. Substitute or add rapid-dissolving tablet form or liquid form of Sinemet®
  3. Rescue with a dopamine agonist (apomorphine) given with domperidone or trimethobenzamide
  4. Sinemet® via intraduodenal tube
  5. Deep brain stimulation procedure
- D. Freezing
  1. Gait modifications (use visual cues such as walk over lines, tapping, rhythmic commands, rocking; use rolling walker)
  2. Difficult to treat so adjust current medication up or down based on other PD symptoms
  3. Treat anxiety with benzodiazepine

II. Dyskinesias
- A. Peak dose chorea
  1. Decrease risk by lowering Sinemet® dose when adding other PD medications
  2. Smaller doses more frequently (liquid Sinemet®)
  3. Decrease Sinemet® dose and add dopamine agonist
  4. Amantadine
  5. Add propranolol, fluoxetine, buspirone, or clozapine
  6. Deep brain stimulation
- B. Off period dystonia in the early morning (i.e., foot cramping)
  1. Add Sinemet® CR or dopamine agonist at bedtime if having nighttime offs
  2. Morning Sinemet® dose should be immediate-release with or without CR
  3. Selective denervation with botulinum toxin
- C. Diphasic dyskinesia
  1. Avoid controlled-release preparations; consider liquid Sinemet®
  2. Add dopamine agonist, amantadine, or COMT inhibitor
  3. Deep brain stimulation

III. Akathisia
1. Benzodiazepine
2. Propranolol
3. Dopamine agonists
4. Gabapentin

COMT, catechol-O-methyltransferase.

Patient Encounter, Part 3: Creating a Care Plan

Create a care plan for MW that includes:

- The goals of therapy.
- A list of problems and how well each is controlled.
- A therapeutic plan that includes non-drug and drug therapy.
- A protocol for monitoring efficacy and adverse effects.
- A definition of your outcome variables.

dosage plans to minimize suboptimal or delayed peak levodopa concentrations by adding longer-acting medications to minimize wearing off periods, adding or adjusting medications to stop an unpredicted off period, and providing treatments that decrease freezing episodes. It also involves adjusting or adding medications to decrease chorea, dystonia, diphasic dyskinesias, or akathisia. Patients should schedule activities when they are on. Patients can also keep an extra dose of medication with them when they are away from home in case their medication wears off.[2,15,16,44–46]

OUTCOME EVALUATION

Evaluate the clinical outcomes of treatment by using the UPDRS. In addition, periodically ask patients to record the amount of on and off time they have with and without dyskinesias in a diary. There are a variety of scales that can be used to assess QOL, depression, anxiety, and sleep disorders. Patients with PD cannot be cured; but treatment can delay the progression of symptoms and improve QOL. Delaying the patient's admission into a nursing home is a good outcome.

Patient Encounter, Part 4: Evaluation of the Outcomes

At the last visit, MW's fluoxetine was changed to bupropion, pergolide was started and gradually increased to 0.25 mg three times daily, and a dandruff shampoo was started. Since that time his skin condition, attitude, apathy, stiffness, rigidity, handwriting, tremor, slowness, and kicking have improved. The UPDRs score is 5 while "on".

- Do you agree with this therapeutic plan?
- Have therapeutic goals been achieved?
- What additional questions would you ask the patient?

Patient Care and Monitoring

❾ *Patient monitoring should involve a regular systematic evaluation of efficacy and adverse events, referral to appropriate specialists, and patient education.*

1. Determine type of symptoms, frequency, and exacerbating factors. Does the patient have any PD treatment-related complications? Assess the patient's symptoms to determine if therapy should be adjusted or maintained, or if referral for more extensive evaluation is needed.
2. Review any available diagnostic data to determine status, motor ability, dyskinesias, and non-motor symptoms.
3. Obtain a thorough history of prescription, non-prescription, and complementary/alternative medication use. Determine what treatments have been helpful to the patient in the past. Is the patient taking any medications that may increase PD symptoms?
4. Educate the patient about lifestyle modifications that will improve symptoms and sustain independence.
5. Is the patient taking the appropriate dose of PD medication to maximize on time and minimize adverse effects? If not, why?
6. Determine if polytherapy treatment is necessary and/or adequate.
7. Assess improvement in QOL measures.
8. Evaluate the patient for the presence of drug adverse reactions, allergies, and interactions.
9. Recommend a therapeutic regimen that is easy for the patient to follow. Educate the patient on how to use medications, and allow the patient to adjust medications for fluctuations in response.
10. Educate patients regarding PD, including lifestyle modifications and drug therapy, including:
    - When and how to take medications.
    - The potential adverse effects that may occur.
    - Which drugs may interact with therapy (give patients a list).
    - Warning signs to report to the physician.
    - Where they can obtain further information such as books and Web sites (e.g., http://www.apdaparkinson.org; http://www.parkinson.org)
11. Refer patients to a local PD support group where they can obtain educational materials as well as empathy and social support from fellow PD patients. Support groups that include patients with advanced disease may upset patients with early disease; therefore, the advantages and disadvantages of attending should be explained to the patient.

ABBREVIATIONS

ADL: activities of daily living
COMT: catechol-O-methyltransferase
CR: controlled-release
GABA: γ-aminobutyric acid
MAO: monoamine oxidase
MPTP: 1-methyl-4-phenyl-1-2-5-6-tetrahydropyridine
NMDA: N-methyl-D-aspartate
PD: Parkinson's disease
RBD: rapid eye movement sleep behavioral disorder
RLS: restless legs syndrome
UPDRS: Unified Parkinson's Disease Rating Scale

30 Pain Management

Christine K. O'Neil

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Identify characteristics of the types of pain: nociceptive, inflammatory, neuropathic, and functional.
2. Explain the mechanisms involved in pain transmission.
3. Select an appropriate method of pain assessment.
4. Recommend an appropriate choice of analgesic, dose, and monitoring plan for a patient based on type and severity of pain and other patient-specific parameters.
5. Perform calculations involving equianalgesic doses, conversion of one opioid to another, rescue doses, and conversion to a continuous infusion.
6. Educate patients and caregivers about effective pain management, dealing with chronic pain, and the use of nonpharmacologic measures.

Key Concepts

❶ Pain is an unpleasant subjective experience that is the net effect of a complex interaction of the ascending and descending nervous systems involving biochemical, physiologic, psychological, and neocortical processes.
❷ Following initial assessment of pain, reassessment should be done as needed based on medication choice and the clinical situation.
❸ Effective treatment involves an evaluation of the cause, duration, and intensity of the pain and selection of an appropriate treatment modality for the pain situation.
❹ Whenever possible, the least potent oral analgesic should be selected.
❺ Equianalgesic doses should be used when converting from one opioid to another.

Pain is defined by the International Association for the Study of Pain (IASP) as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[1] ❶ *Pain is an unpleasant subjective experience that is the net effect of a complex interaction of the ascending and descending nervous systems involving biochemical, physiologic, psychological, and neocortical processes.* Pain can affect all areas of a person's life including sleep, thought, emotion, and activities of daily living. Since there are no reliable objective markers for pain, the patients are the only ones to describe the intensity and quality of their pain.

Pain is the most common symptom prompting patients to seek medical attention and is reported by more than 80% of individuals who visit their primary care provider.[1] Despite the frequency of pain symptoms, individuals often do not obtain satisfactory relief of pain. This has led to recent initiatives in health care to make pain the fifth vital sign, thus making pain assessment equally important as obtaining a patient's temperature, pulse, blood pressure, and respiratory rate.

EPIDEMIOLOGY AND ETIOLOGY

Prevalence of Pain

Most people experience pain at some time in their lives, and pain is a symptom of a variety of diseases. For some, pain may be mild to moderate, intermittent, easily managed, and has minimal effect on daily activities. For others, pain may be chronic, severe or disabling, all consuming, and be treatment resistant. Thus, identifying the exact prevalence of pain is a difficult task. According to the American Pain Foundation, more than 50 million people in the United States suffer from

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

chronic pain, and an additional 25 million experience acute pain from injury or surgery.[2] About 20% of adults, mostly women and the elderly, experience chronic pain such as back pain, headache, and joint pain.

Prevalence rates for a variety of different types of pain have been described. The annual incidence of moderate-intensity back pain is 10% to 15% in the adult population with a point prevalence of 15% to 30%.[3] Migraine affects more than 25 million Americans, and 90% of Americans report some other types of headaches (e.g., tension or sinus) each year.[4] Pain resulting from fibromyalgia affects 4 million Americans.[5] Cancer is commonly associated with both acute and chronic pain, and about 70% of those diagnosed with cancer will experience significant pain.[6]

The prevalence of **neuropathic pain** is unknown because of the lack of epidemiologic studies. Current estimates suggest that approximately 1.5% of the population in the United States may be affected by neuropathic pain.[7] However, this figure is probably an underestimate and will likely increase due to the increase in disorders associated with neuropathic pain in the ever-growing older population. Approximately 25% to 50% of all pain clinic visits are related to neuropathic pain.[8] Central neuropathic pain is estimated to occur in 2% to 8% of all stroke patients.[9]

The elderly, defined as people 65 years of age and over, bear a significant burden of pain, and pain continues to be underrecognized and undertreated in this population. The prevalence of pain in people over the 60 years of age is twice that in those younger than 60 years of age.[10] Studies suggest that 25% to 50% of community-dwelling elderly suffer pain. Pain is quite common among nursing home residents. It is estimated that pain in 45% to 80% of nursing home patients contributes to functional impairment and a decreased quality of life.[11]

The financial impact of pain is considered to be significant. The National Institute for Occupational Safety and Health (NIOSH) estimated that the cost of low back pain alone was between $50 billion and $100 billion per year.[12] The American Productivity Audit of the United States workforce, conducted from 2001 to 2002, revealed that the cost of lost productivity due to arthritis, back pain, headache, and other musculoskeletal pain was approximately $ 80 billion per year.[13]

The Undertreatment of Pain

Despite the growing emphasis on pain management, pain often remains undertreated and continues to be a problem in hospitals, long-term care facilities, and the community. In one series of reports, 50% of seriously ill hospitalized patients reported pain; however, 15% were dissatisfied with pain control, and some remained in pain after hospitalization.[14,15]

Misconceptions about pain management, both from patients and health care providers, are among the most common causes of analgesic failure. Some clinicians may be hesitant to treat pain because they do not believe the patient's reports of pain or feel the patient is exaggerating symptoms in order to obtain medications. Inadequate clinical knowledge of available pain management strategies, including pharmacologic, nonpharmacologic, and alternative therapy options, also often leads to suboptimal pain management. In one survey, approximately three-fourths of physicians cited low competence in pain assessment as the major barrier to effective pain management.[16] Concerns about opiate misuse, abuse, and diversion also contribute to less than optimal pain management and cause providers to exercise caution when prescribing opiates for pain. Misunderstandings about the terms addiction, physical dependence, tolerance, and pseudoaddiction are additional obstacles to optimal pain management.

Patients may present barriers to pain management by not reporting pain symptoms because of fear of becoming addicted or because of cultural beliefs. Elderly patients may not report pain for a variety of reasons including belief that pain is something they must live with, fear of consequences (e.g., hospitalization or loss of independence), or fear that the pain may be forecasting impending illness, inability to understand terminology used by health care providers, or a belief that showing pain is unacceptable behavior.

PATHOPHYSIOLOGY

Types of Pain

Several distinct types of pain have been described: nociceptive, inflammatory, neuropathic, and functional.[17] **Nociceptive pain** is a transient pain in response to a noxious stimulus at nociceptors that are located in cutaneous tissue, bone, muscle, connective tissue, vessels, and viscera. Nociceptors may be classified as thermal, chemical, or mechanical. The nociceptive system extends from the receptors in the periphery to the spinal cord, brain stem, and to the cerebral cortex where pain sensation is perceived. This system is a key physiologic function that prevents further tissue damage due to the body's autonomic withdrawal reflex. When tissue damage occurs despite the nociceptive defense system, inflammatory pain ensues. The body now changes focus from protecting against painful stimuli to protecting the injured tissue. The inflammatory response contributes to pain hypersensitivity that serves to prevent contact or movement of the injured part until healing is complete, thus reducing further damage.

Neuropathic pain is defined as spontaneous pain and hypersensitivity to pain associated with damage to or pathologic changes in the peripheral nervous system as in painful diabetic peripheral neuropathy (DPN), acquired immunodeficiency syndrome (AIDS), polyneuropathy, post-herpetic neuralgia (PHN); or pain originating in the central nervous system (CNS), that which occurs with spinal cord injury, multiple sclerosis, and stroke. Functional pain, a relatively newer concept, is pain sensitivity due to an abnormal processing or function of the central nervous system in response to normal stimuli. Several conditions considered to have this abnormal sensitivity or hyperresponsiveness include fibromyalgia and irritable bowel syndrome.

Mechanisms of Pain

Pain Transmission

The mechanisms of nociceptive pain are well-defined and provide a foundation for the understanding of other types of pain.[18] Following **nociceptor** stimulation, tissue injury causes the release of substances (bradykinin, serotonin, potassium, histamine, prostaglandins, and substance P) that may further sensitize and/or activate nociceptors. Nociceptor activation produces action potentials (transduction) that are transmitted along myelinated A-δ fibers and unmyelinated C fibers to the spinal cord. The A-δ fibers are responsible for first, fast, sharp pain and release excitatory amino acids that activate α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors in the dorsal horn. The C fibers produce secondary pain which is described as dull, aching, burning, and diffuse. These nerve fibers synapse in the dorsal horn of the spinal cord, where several neurotransmitters are released including glutamate, substance P, and calcitonin gene-related peptide. Transmission of pain signals continues along the spinal cord to the thalamus, which serves as the pain relay center, and eventually to the cortical regions of the brain where pain is perceived.

Pain Modulation

Modulation of pain (inhibition of nociceptive impulses) can occur by a number of processes. Based on the gate control theory, pain modulation may occur at the level of the dorsal horn.[19] Since the brain can process only a limited number of signals at one time, other sensory stimuli at nociceptors may alter pain perception. This theory supports the effectiveness of counterirritants and transcutaneous electrical nerve stimulation (TENS) in pain management. Pain modulation may result through several other complex processes. The endogenous opiate system consists of endorphins (enkephalins, dynorphins, and β-endorphins) that interact with μ, δ, and κ receptors throughout the CNS to inhibit pain impulses and alter perception. The CNS also includes inhibitory descending pathways from the brain that can attenuate pain transmission in the dorsal horn. Neurotransmitters involved in this descending system include endogenous opioids, serotonin, norepinephrine, γ-aminobutyric acid (GABA) and neurotensin. The perception of pain involves not only nociceptive stimulation but physiologic and emotional input that contributes to the perception of pain. Consequently, cognitive behavioral treatments such as distraction, relaxation, and guided imagery can reduce pain perception by altering pain processing in the cortex.

Peripheral Sensitization, Central Sensitization, and Wind-Up

Under normal conditions, a balance generally exists between excitatory and inhibitory neurotransmission. Changes in this balance can occur both peripherally and centrally resulting in exaggerated responses and sensitization such as that observed in inflammatory, neuropathic, or functional chronic pain. Pain in these settings may occur spontaneously without any stimulus or may be evoked by a stimulus. Evoked pain may arise from a stimulus that normally does not cause pain (**allodynia**) such as a light touch in neuropathic pain. **Hyperalgesia**, an exaggerated and/or prolonged pain response to a stimulus that normally causes pain, can also occur as a result of increased sensitivity in the CNS.

During normal pain transmission, the AMPA receptors are activated, but the N-methyl-D-aspartate (NMDA) receptor is blocked by magnesium.[16] Repeated nerve depolarization causes release of the magnesium block allowing the influx of calcium and sodium and results in excessive excitability and amplification of signals. Continued input from C fibers and subsequent increases in substance P and glutamate causes the activation of the NMDA receptor, a process referred to as wind-up. Wind-up increases the number and responsiveness of neurons in the dorsal horn irrespective of the input from the periphery. Recruitment of neurons not normally involved in pain transmission or spread occurs leading to allodynia, hyperalgesia, and spread to uninjured tissues.[20] The wind-up phenomenon supports the observation that untreated acute pain can lead to chronic pain and the belief that pain processes are plastic and not static.

CLINICAL PRESENTATION AND DIAGNOSIS

Classification of Pain

Pain has always been described as a symptom. However, recent advances in the understanding of neural mechanisms have demonstrated that unrelieved pain may lead to changes in the nervous system known as neural plasticity. Since these changes reflect a process that influences a physiologic response, pain, particularly chronic pain, may be considered a disease unto itself.

Pain can be divided into two broad categories: acute and chronic or persistent pain. Acute pain is also referred to as adaptive pain since it serves to protect the individual from further injury or promote healing.[17] However, chronic pain has been called maladaptive, a pathologic function of the nervous system or pain as a disease.

Acute Pain

Acute pain is pain that occurs as a result of injury or surgery and is usually self-limited, subsiding when the injury heals. Untreated acute pain can produce physiologic symptoms including tachypnea, tachycardia, and increased sympathetic nervous system activity, such as pallor, diaphoresis, and pupil dilation. Furthermore, poorly treated pain can cause psychological stress and compromise the immune system due to the release of endogenous corticosteroids. This situation accompanied by decreased range of motion and decreased lung capacity can delay recovery from the initial injury. Somatic acute pain arises from injury to skin, bone, joint, muscle, and connective tissue, and it is generally localized to the site of injury.

Visceral pain involves injury to nerves on internal organs (e.g., intestines or liver) and can present as diffuse, poorly differentiated, and often referred pain. Acute pain should be treated aggressively, even before the diagnosis is established, except in conditions of head or abdominal injury where pain may assist in the differential diagnosis.

Chronic Pain

Chronic pain persists beyond the expected normal time for healing and serves no useful physiologic purpose. Chronic pain may be nociceptive, inflammatory, neuropathic, or functional in origin; however, all forms share some common characteristics. Chronic pain can be episodic or continuous, or both. Physiologic responses observed in acute pain are often absent in chronic pain; however, other symptoms may predominate. There are four main effects of chronic pain, and these include: 1) effects on physical function, 2) psychological changes, 3) social consequences, and 4) societal consequences. Effects of chronic pain on physical function include impaired activities of daily living and sleep disturbances. Psychological components of chronic pain may include depression, anxiety, anger, and loss of self-esteem. As a result of physical and psychological changes, social consequences may ensue such as changes in relationships with friends and family, intimacy, and isolation. On a societal level, chronic pain contributes to increased health care costs, disability, and lost productivity. Management of chronic pain should be multimodal and may involve cognitive interventions, physical manipulations, pharmacologic agents, surgical intervention, and regional or spinal anesthesia.

Chronic Malignant Pain

Chronic malignant pain is associated with a progressive disease that is usually life-threatening such as cancer, AIDS, progressive neurologic diseases, end-stage organ failure, and dementia.[21] The goal is pain alleviation and prevention, often through a systematic and stepwise approach. Tolerance, dependence, and addiction are often not a concern due to the terminal nature of the illness.

Chronic Non-malignant Pain

Pain not associated with a life-threatening disease and lasting longer than 6 months beyond the healing period is referred to as chronic non-malignant pain. Pain associated with low back pain, osteoarthritis, previous bone fractures, peripheral vascular disease, genitourinary infection, rheumatoid arthritis, and coronary heart disease is considered non-malignant. The numerous causes of this type of chronic pain make treatment complex and involves a multidisciplinary approach. Treatment is initially conservative but may involve the use of more potent analgesics including opiates in psychologically healthy patients.[22]

Neuropathic Pain

Neuropathic pain may be considered to be a type of chronic non-malignant pain involving disease of the central and peripheral nervous systems. Neuropathic pain may be broadly categorized as peripheral or central in nature. Examples of neuropathic pain include PHN, which is pain associated with acute herpetic neuralgia or an acute shingles outbreak. Peripheral or polyneuropathic pain is associated with the distal polyneuropathies of diabetes, human immunodeficiency virus (HIV), and chemotherapeutic agents. Types of **central pain** include central stroke pain, trigeminal neuralgia, and a complex of syndromes known as complex regional pain syndrome (CRPS). Complex regional pain syndrome includes both reflex sympathetic dystrophy and **causalgia**, both of which are neuropathic pain associated with abnormal functioning of the autonomic nervous system. One of the newest categories of neuropathic pain is neuropathic low back pain.

The symptoms of neuropathic pain are characterized as tingling, burning, shooting, stabbing, electric shock–like quality, or radiating pain. The patient may describe either a constant dull throbbing or burning pain, or an intermittent pain that is stabbing or shooting. Frequent damage to the peripheral nerves may be referred to the body region innervated by those nerves.

Traditionally neuropathic pain has been difficult to treat and involves a variety of therapeutic modalities. Rational choice of treatment options may be accomplished through evaluation of the neuropathy and its relationship to peripheral or central nerve damage. Targeting the mechanistic points in the pain pathway is another rationale for treating neuropathic pain. For example, certain opioids, such as methadone, are characterized by NMDA receptor antagonist activity and are effective in treating pain. Anticonvulsant drugs are able to block sodium channels in the peripheral afferent nerve fibers. Agents such as tricyclic antidepressants, bupropion, and venlafaxine block the release of monoamines targeting dorsal horn inhibitory mechanisms.

Clinical Presentation of Pain

General

Patients may be in acute distress (acute pain) or have no signs or symptoms of suffering (chronic pain).

Symptoms

Pain is described based on the following characteristics: onset, duration, location, quality, severity, and intensity. Other symptoms may include anxiety, depression, fatigue, anger, fear, and insomnia.

Signs

Acute pain may cause hypertension, tachycardia, diaphoresis, mydriasis, and pallor.

Diagnosis

The patient is the only person who can describe the intensity and quality of their pain. There are no laboratory tests that can diagnose pain.

Pain Assessment

Effective pain management begins with a thorough and accurate assessment of the patient. Even though pain is a common presenting complaint, lack of regular assessment and reassessment of pain remains a problem and contributes to the undertreatment of pain.[23]

Pain Assessment Guidelines and Regulations for Specific Practice Settings

Screening for pain should be a part of a routine assessment, and this has led several organizations such as the Veterans Health Administration (VHA) and the American Pain Society (APS) to declare pain the fifth vital sign. Many states have adopted a bill of rights for patients in pain. In 2001, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) incorporated pain as the fifth vital sign in its accreditation standards. [24] According to the JCAHO, patients have a right to appropriate assessment and management of their pain and education regarding their pain. ❷ *Following initial assessment of pain, reassessment should be done as needed based on medication choice and the clinical situation.*

Methods of Pain Assessment

A patient-oriented approach to pain is essential, and methods do not differ greatly from those used in other medical conditions. A comprehensive history (medical, family, and psychological) and physical exam are necessary to evaluate underlying disease processes for the source of pain and other factors contributing to the pain.[20] A thorough assessment of the characteristics of the pain should be completed including questions about the pain (onset, duration, location, quality, severity, and intensity), pain relief efforts, and efficacy and side effects of current and past treatments for pain. A common mnemonic for pain assessment is PQRST (Palliative/Provocative, Quality, Radiation, Severity, and Temporal).[25] Some clinicians have suggested the addition of U (you) to this mnemonic.[26] During the pain interview, the impact of the pain on the patient's functional status, behavior, and psychological states should also be assessed. Evaluation of psychological status is especially important in patients with chronic pain since depression and affective disorders may be common comorbid conditions. A history of drug and alcohol use should be elicited due to the potential for addiction in patients who may require opiates or other pain medications with a potential for abuse. Other conditions such as renal or hepatic dysfunction, diabetes, and conditions that affect bowel function can influence therapy choices and goals. A discussion of the patient's expectations and goals with respect to pain management (level of pain relief, functional status, and quality of life) should also be part of any pain interview.

Pain Assessment Tools

Pain, particularly acute pain, may be accompanied by physiologic signs and symptoms, and there are no reliable objective markers for pain. Many tools have been designed for assessing the severity of pain including rating scales and multidimensional pain assessment tools.

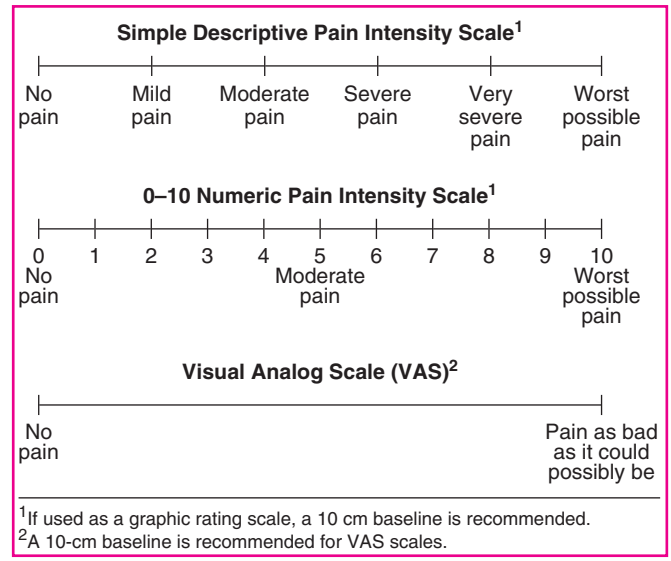

FIGURE 30–1. Pain rating scales.[27]

Rating scales provide a simple way to classify the intensity of pain, and should be selected based on the patient's ability to communicate (Fig. 30–1).[27] Numeric scales are widely used and ask patients to rate their pain on a scale of 0 to 10, with 0 indicating no pain and 10 being the worst pain possible. Using this type of scale, 1 to 3 is considered mild pain, 4 to 6 is moderate pain, and 8 to 10 is severe pain. The visual analog scale (VAS) is similar to the numerical scale in that it requires patients to place a mark on a 10-cm line where one end is no pain, and the worst possible pain is on the other end. For patients who have difficulty assigning a number to their pain, a categorical scale may be an option to communicate the intensity of the pain experience. Examples of this include a simple descriptive list of words and the Wong-Baker FACES of Pain Rating Scale.[28]

Multidimensional assessment tools obtain information about the pain and impact on quality of life, but are often more time-consuming to complete. Examples of these types of tools include the Initial Pain Assessment Tool, Brief Pain Inventory, McGill Pain Questionnaire, the Neuropathic Pain Scale, and the Oswestry Disability Index.[29–33]

Pain Assessment in Challenging Populations

Children Pain interviews may be conducted with children as young as 3 or 4 years of age; however, communication may be limited by vocabulary.[34] Terms familiar to children such as "hurt," "owie," or "boo boo" may be used to describe pain. The VAS is best used with children older than 7 years of age. Other scales based on numbers of objects (e.g., poker chips), increasing color intensity, or faces of pain may be helpful for children between 4 and 7 years of age. In children younger than 3 to 4 years of age, behavioral or physiologic measures, such as pulse or respiratory rate, may be more appropriate. Pain assessment in newborns and infants relies on behavioral observation for such clues as vocalizations (crying and fussing), facial expressions,

body movements (flailing of limbs and pulling legs in), withdrawal, and change in eating and sleeping habits.[35] Preschool children experiencing pain may become clingy, lose motor and verbal skills, and start to deny pain because treatment may be linked to discomfort or punishment. School-age children may exhibit aggressiveness, nightmares, anxiety, and withdrawal when in pain, while adolescents may respond to pain with oppositional behavior and depression.

Elderly Most of the previously discussed pain scales can be used in older persons that are cognitively intact or with mild dementia. The pain thermometer and FACES of pain have been studied in older persons. In persons with moderate to severe dementia or those who are nonverbal, observation of pain behaviors, such as guarding or grimacing, provides an alternative for pain assessment. The Pain Assessment in Advanced Dementia (PAINAD) tool may be used to quantify signs of pain and involves observing the older adult for 15 minutes for breathing, negative vocalizations, facial expression, body language, and consolability.[36] Regardless of which pain assessment tool is used, the practitioner should first determine if the patient understands the concept of the scale to ensure reliability of the instrument.

Patient Encounter, Part 1

HPI
BA is a 58-year-old male recently diagnosed with lung cancer. Following surgery he was placed on morphine patient-controlled analgesia (PCA). He has been using 120 mg of morphine/24 hours with adequate pain control.

PMH
Hypertension × 18 years

FH
Non-contributory

SH
Lives with wife; has four grown children; smoked 2 packs of cigarettes per day × 40 years (quit with diagnosis of lung cancer)

Meds
Hydrochlorothiazide 25 mg every day

Pain assessment: Patient rates pain as 8 on a scale of 1 to 10.

- The physician would like to convert him to a combination preparation of oxycodone and acetaminophen. What dosing regimen would you suggest?
- Six months later, BA's pain is controlled with the escalating doses of the combination product; however, he has reached the maximum dose of acetaminophen. What would you suggest at this time?

TREATMENT

General Approach to Treatment

❸ *Effective treatment involves an evaluation of the cause, duration, and intensity of the pain and selection of an appropriate treatment modality for the pain situation.* Depending on the type of pain, treatment may involve pharmacologic or nonpharmacologic therapy or both. General principles for the pharmacologic management of pain are listed in the section on patient care and monitoring. Two common approaches to the selection of treatment are based on severity of pain and the mechanism responsible for the pain (Fig. 30–2). Clinical practice guidelines for pain management are available from the APS, the Agency for Healthcare Research and Quality (AHRQ), the American Geriatrics Society (AGS), and the American Society of Anesthesiologists (ASA).

Selection of Agent Based on Severity of Pain

❹ *Whenever possible, the least potent oral analgesic should be selected.*

Guidelines for the selection of therapeutic agents based on pain intensity are derived from the World Health Organization (WHO) analgesic ladder for the management of cancer pain (Table 30–1).[37] Mild to moderate pain is generally treated with non-opioid analgesics. Combinations of medium-potency opioids and acetaminophen or non-steroidal anti-inflammatory drugs (NSAIDs) are often used for moderate pain. Potent opioids are recommended for severe pain. Throughout this progression adjuvant medications are added as needed to manage side effects and to augment analgesia. While these guidelines can be useful for initial therapy, the clinical situation (type of pain); cost and pharmacokinetic profile of available drugs; and patient-specific factors (age, concomitant illnesses, previous response, and other medications) must also be considered. Pain medications may also be used in the absence of pain in anticipation of a painful event such as surgery to minimize peripheral and central sensitization.

Mechanistic Approach to Therapy

Current analgesic therapy is aimed at controlling or blunting pain symptoms. However, diverse mechanisms contributing to the various types of pain continue to be further elucidated. An understanding of these new mechanisms of pain transmission may lead to improvement in pain management, as pharmacologic management of pain becomes more mechanism-specific. Use of NSAIDs for inflammatory types of pain is an example of a mechanistic approach. Since several mechanisms of pain often co-exist, a polypharmacy approach seems rational to target each mechanism.

Two current foci in pain management are to identify the mechanisms that are responsible for pain hypersensitivity and to prevent this initial hypersensitivity. Therefore, the goal of pain therapy is to reduce peripheral sensitization and subsequent central stimulation and amplification associated with wind-up, spread, and central sensitization.[17]

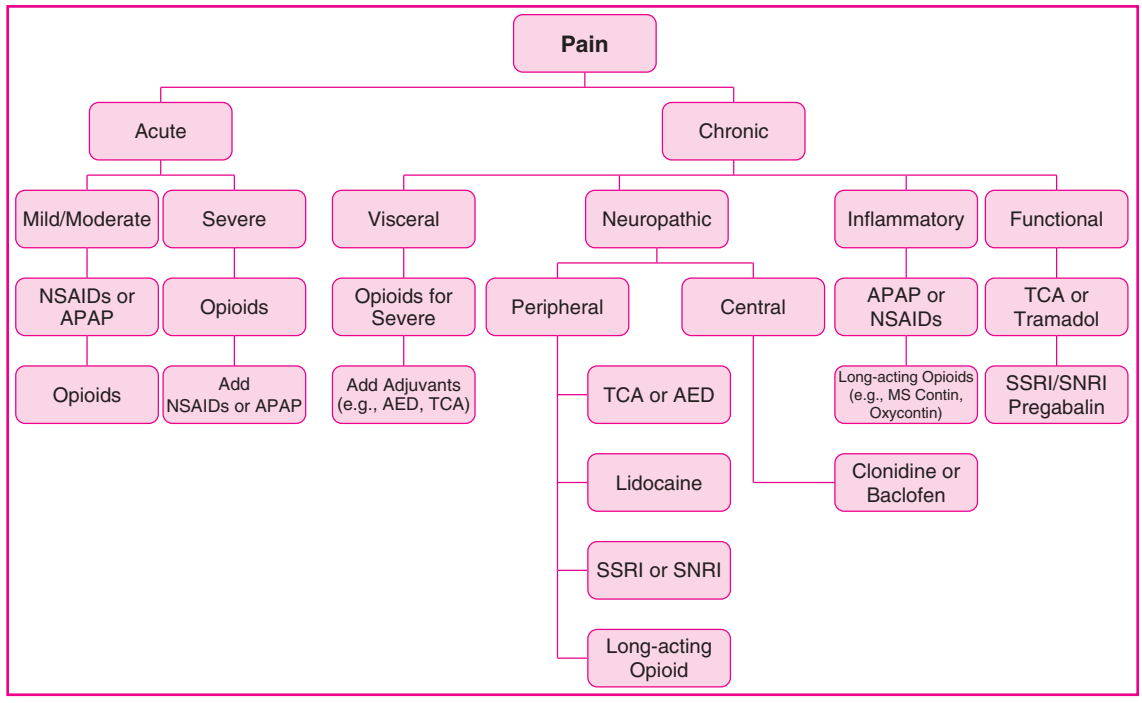

FIGURE 30–2. Pain algorithm. AED, antiepileptic drug; APAP, acetaminophen; NSAID, non-steroidal antiinflammatory drug; SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

Nonpharmacologic Therapy

Nonpharmacologic therapies (psychological interventions and physical therapy) may be used in both acute and chronic pain. Psychological interventions can reduce pain as well as the anxiety, depression, fear, and anger associated with pain. Psychological interventions helpful in management of acute pain are imagery (picturing oneself in a safe, peaceful place) and distraction (listening to music or focusing on breathing). Chronic pain patients may benefit from relaxation, biofeedback, cognitive-behavioral therapy, psychotherapy, support groups, and spiritual counseling. Biofeedback teaches patients to control physiologic responses to pain and has been effective in headache and chronic low back pain. Cognitive therapy encourages patients to monitor their perceptions of pain, reducing stress and negativism. Psychotherapy is very useful for patients with chronic pain, and it can also assist in treatment of psychiatric comorbidities and help patients to deal with terminal illnesses.[38] The patient should be educated about what to expect regarding pain and its treatment whether pain is acute (i.e., preoperative explanations of

TABLE 30–1. Selection of Analgesics Based on Intensity of Pain[37]

Pain Intensity	Corresponding Numerical Rating	WHO Therapeutic Recommendations	Examples of Initial Therapy	Comments
Mild	1–3/10	Non-opioid analgesic; regular scheduled dosing	Acetaminophen 1000 mg every 6 hours; Ibuprofen 600 mg every 6 hours	Consider adding an adjunct or using an alternate regimen if pain is not reduced in 1–2 days
Moderate	4–6/10	Add an opioid to the non-opioid for moderate pain; regular scheduled dosing	Acetaminophen 325 mg + codeine 60 mg every 4 hours; Acetaminophen 325 mg + oxycodone 5 mg every 4 hours	Consider step-up therapy if pain is not relieved by greater than or equal to 2 or more different drugs
Severe	7–10/10	Switch to a high-potency opioid; regular scheduled dosing	Morphine 10 mg every 4 hours; Hydromorphone 4 mg every 4 hours	

WHO, World Health Organization.

expected postsurgical pain) or chronic (patient and family education in hospice care).

Physical therapy is an essential part of many types of pain situations. Treatment modalities include heat, cold, water, ultrasound therapy, TENS, massage, and therapeutic exercise. Heat and cold therapy are utilized in a variety of musculoskeletal conditions (muscle spasms, low back pain, fibromyalgia, sprains, and strains). Heating modalities include local hot packs, paraffin wrap, hydrotherapy, and deep-heating methods (ultrasound). Cold treatments may be delivered via cold packs, ice massage, cold water immersion, or coolant sprays. TENS therapy is based on the theory that electrical stimulation of a nerve in a particular area can block pain impulses originating from that area. TENS is also believed to release endogenous endorphins and enkephalins. Massage therapy is used to relieve muscle tension and stiffness and is also felt to increase endogenous endorphins. Therapeutic exercise improves not only strength, endurance, and range of motion, but also provides cardiovascular, psychological, and other health benefits.

Pharmacologic Therapy

Non-opioid Analgesics

Acetaminophen

Acetaminophen, an analgesic and antipyretic, is often selected as initial therapy for mild to moderate pain and is considered first-line in several pain situations such as low back pain and osteoarthritis.[39] Mechanistically, acetaminophen is believed to inhibit prostaglandin synthesis in the CNS and block pain impulses in the periphery. Acetaminophen is well-tolerated at usual doses and has few clinically significant drug interactions except causing increased hypoprothrombinemic response to warfarin in patients receiving acetaminophen doses of more than 2000 mg per day. The maximum recommended dose for patients with normal renal and hepatic function is 4000 mg per day. Hepatotoxicity has been reported with excessive use and overdose and the risk of this adverse effect increases in those with hepatitis or chronic alcohol use, as well as those who binge drink or are in a fasting state. Regular chronic use of acetaminophen has been associated with chronic renal failure, but reports are conflicting. For these reasons, the maximum dose should be reduced by 50% to 75% in patients with renal dysfunction or hepatic disease and in those who engage in excessive alcohol use.

Aspirin and Other Salicylates

Aspirin, non-acetylated salicylates, and other NSAIDs have analgesic, antipyretic, and anti-inflammatory actions. These agents inhibit cyclooxygenase (COX-1 and COX-2) enzymes, thereby preventing prostaglandin synthesis, which results in reduced nociceptor sensitization and an increased pain threshold. NSAIDs are the preferred agents for mild to moderate pain in situations that are mediated by prostaglandins (e.g., rheumatoid arthritis and osteoarthritis, menstrual cramps, and postsurgical pain) and in the management of pain from bone metastasis, but they are of minimal use in neuropathic pain.

Aspirin is effective for mild to moderate pain; however, the risk of gastrointestinal irritation and bleeding limits frequent use of this drug for pain management. Direct effects of aspirin on the gastrointestinal mucosa and irreversible platelet inhibition contribute to this risk which can occur even at low doses. Hypersensitivity reactions are also possible and may occur in 25% of patients with co-exsiting asthma, nasal polyps, or chronic urticaria. Of additional concern is the potential for cross-sensitivity of other NSAIDs in this group of patients. Non-acetylated salicylates (choline magnesium salicylate and sodium salicylate) have a reduced risk of gastrointestinal effects and platelet inhibition and may be used in aspirin-sensitive patients. Diflunisal, a salicylic acid derivative, is associated with fewer gastrointestinal (GI) complaints compared to aspirin, but platelet inhibition does increase the risk of GI bleeding.

Non-steroidal Anti-Inflammatory Drugs

NSAIDs provide analgesia equal to or better than that of aspirin or acetaminophen combined with codeine, and they are very effective for inflammatory pain and pain associated with bone metastasis.[18] These agents may be classified by their chemical structures (fenamates, acetic acids, propionic acids, pyranocarboxylic acids, pyrrolizine carboxylic acids, and COX-2 inhibitors). While only some members of this class have approval for treatment of pain, it is likely that all of them have similar analgesic effects. All members of this class appear to be equally effective, but there is great intrapatient variability in response. After an adequate trial of 2 to 3 weeks with a particular agent, it is reasonable to switch to another member of the class. NSAIDs demonstrate a flat dose-response curve, with higher doses producing no greater efficacy than moderate doses, but resulting in an increased incidence of adverse effects (gastrointestinal irritation, hepatic dysfunction, renal insufficiency, platelet inhibition, sodium retention, and CNS dysfunction).

Patients at increased risk of NSAID-induced gastrointestinal adverse effects (e.g., dyspepsia, peptic ulcer formation, and bleeding) include the elderly, those with peptic ulcer disease, coagulopathy, and patients receiving high doses of concurrent corticosteroids. Nephrotoxicity is more common in the elderly, patients with creatinine clearance values less than 50 mL/minute, and those with volume depletion or on diuretic therapy. NSAIDs should be used with caution in patients with reduced cardiac output due to sodium retention and in patients receiving antihypertensives, warfarin, and lithium.

NSAIDs are classified as non-selective (they inhibit COX-1 and COX-2) or selective (they inhibit only COX-2) based on degree of cyclooxygenase inhibition. COX-2 inhibition is responsible for anti-inflammatory effects, while COX-1 inhibition contributes to increased GI and renal toxicity associated with non-selective agents. Since the antiplatelet effect of non-selective NSAIDs is reversible, concurrent use may reduce the

cardioprotective effect of aspirin due to competitive inhibition of COX-1. For this reason, administration of aspirin prior to the NSAID is recommended.[40] The cardiovascular safety of the COX-2 inhibitors has been questioned due to increased risk of myocardial infarction and stroke seen in several trials.[41–43] The Food and Drug Administration (FDA) Committees on Arthritis and Drug Safety and Risk Management convened in February 2005 to evaluate the published studies and manufacturer information about the cardiovascular adverse events associated with COX-2 inhibitors.[44] As a follow-up to the committee's recommendations, the FDA took regulatory action in April 2005, announcing that the increased risk of cardiovascular events was likely a class effect of NSAIDs. A boxed warning highlighting the potential for increased risk of cardiovascular events and GI bleeding is now required for all prescription non-selective NSAIDs and celecoxib. Stronger warnings about these adverse events are also required on non-prescription NSAIDs. As a result of the data and subsequent events, two members of this class, rofecoxib and valdecoxib, have been withdrawn from the market. Future COX-2 inhibitors and non-selective NSAIDs will likely have to undergo cardiovascular safety studies before receiving FDA approval. When an NSAID is needed in a patient with cardiovascular risk, the benefits of therapy must outweigh the risk and the lowest effective dose of NSAID is recommended.

Opioid Analgesics

Opioids are considered the agents of choice for the treatment of severe acute pain and moderate to severe pain associated with cancer.[45] For chronic pain, their use was once highly controversial; however, use of opioids in chronic pain is now gaining acceptance.[46] Opioids may be classified by their activity at the receptor site, usual pain intensity treated, and duration of action (short- versus long-acting).

Selection and Dosing

The opioids exert their analgesic efficacy by stimulating opioid receptors (μ, κ, and δ) in the CNS. There is a wide variety of potencies among the opioids, with some used for moderate pain (codeine, hydrocodone, tramadol, and partial agonists) and others reserved for severe pain (morphine and hydromorphone). Pure agonists (morphine) bind to μ receptors to produce analgesia that increases with dose without a ceiling effect. Pure agonists are divided into three chemical classes: phenanthrenes or morphine-like, phenylpiperidine or meperidine-like, and diphenylheptane or methadone-like. Partial agonists/antagonists (butorphanol, pentazocine, and nalbuphine) partially stimulate the μ receptor and antagonize the κ receptors. This activity results in reduced analgesic efficacy with a ceiling dose, reduced side effects at the μ receptor, psychotomimetic side effects due to κ antagonism, and possible withdrawal symptoms in patients who are dependent on pure agonists.

Selection of the agent and route depend on individual patient-related factors including severity of pain, individual perceptions, weight, age, opioid tolerance, and concomitant disease (renal or hepatic dysfunction). Since pure agonists are pharmacologically similar, choice of agent may also be guided by pharmacokinetic parameters and other drug characteristics. Hepatic impairment can decrease the metabolism of most opioids, particularly methadone, meperidine, pentazocine,

Patient Encounter, Part 2: Converting to Different Drugs and Adjusting Doses

Two years following his diagnosis of lung cancer, BA has been diagnosed as having bone metastases. Pain has been controlled with the following medications: hydromorphone (Dilaudid) 10 mg IV every hour and levorphanol (Levodromoran) 10 mg orally every 4 hours. He is currently receiving hydrochlorothiazide 25 mg daily, senna two tablets twice daily, and docusate sodium 100 mg twice daily. As the home care pharmacist, you are asked to convert this patient to a morphine infusion.

Morphine equivalents (based on 10 mg parenteral morphine) (Table 30–2):

Hydromorphone 1.5 mg is equivalent to 10 mg of morphine.

Levorphanol 4 mg is equivalent to 10 mg of morphine.

- Based on BA's opioid requirement, recommend an initial infusion rate (in milligrams per hour) of parenteral morphine.
- Which adjuvant therapy could be considered for BA?
- Recommend a monitoring plan for this patient.
- How would you assess pain response?

TABLE 30–2. Equianalgesic Doses of Selected Opioids[26,45,49,51]

	Dose Equianalgesic to 10 mg of Parenteral Morphine (mg)	
Opioid	**Parenteral (mg)**	**Oral (mg)**
Mild-Moderate Pain		
Codeine	120	200
Hydrocodone	N/A	30
Oxycodone	N/A	20
Meperidine (Demerol)	100	400
Propoxyphene (Darvon)	N/A	65–130
Moderate-Severe Pain		
Morphine	10	30
Hydromorphone (Dilaudid)	1.5	7.5
Oxymorphone	1	N/A
Levorphanol	2	4
Fentanyl (Duragesic)	0.1–0.2	N/A[a]
Methadone (Dolophine)	10[b]	3–5[b]

[a]Transdermal: 100 mcg/hour = 2–4 mg/hour of IV morphine.
[b]Dosage calculations when converting from morphine to methadone are not linear. The equianalgesic dose of methadone will decrease progressively as the morphine equivalents increase (Table 30-4).

and propoxyphene. Furthermore, the clearance of meperidine, propoxyphene, and morphine and their metabolites is reduced in renal dysfunction.

Table 30–3 provides a summary of opiate side effects, but several drugs warrant further discussion. Normeperidine, the active metabolite of meperidine, can produce tremors, myoclonus, delirium, and seizures. Due to the potential for accumulation of normeperidine, meperidine should not be used in the elderly, those with renal impairment, in patients using patient-controlled analgesia devices, or for more than 1 to 2 days of continuous dosing with intermittent dosing. Propoxyphene also has an increased risk of seizures and cardiac conduction abnormalities and should be avoided in the elderly. Despite its popularity, propoxyphene has proven to be no more effective than acetaminophen, aspirin, or codeine alone.[18] Methadone is unique among the opiates since it has several mechanisms (μ agonist, NMDA receptor antagonist, and inhibition of reuptake of serotonin and norepinephrine) that makes it an interesting choice for chronic pain. The long half-life of methadone (30 hours) permits extended dosing intervals; however, the potential for accumulation with repeated dosing often results in challenging dose conversions. Tramadol is a synthetic opioid with a dual mechanism of action (μ agonist and inhibition of serotonin and norepinephrine reuptake), and efficacy and safety similar to that of equianalgesic doses of codeine plus acetaminophen. Tramadol has been evaluated in several types of neuropathic pain and may have a place in the treatment of chronic pain. Tramadol is associated with an increased risk of seizures in patients with a seizure disorder, those at risk for seizures, and those taking medications that can lower the seizure threshold. Doses greater than 500 mg have also been associated with seizures. Use of tramadol with other serotonergic drugs [e.g., selective serotonin reuptake inhibitors (SSRIs)] may precipitate serotonin syndrome. While originally thought to be non-habit forming, dependence may occur with tramadol.

TABLE 30–3. Managing Opioid Side Effects[27,45,49]

Adverse Effects	Drug Treatment/Management
Excessive sedation	Reduce dose by 25% or increase dosing interval
Constipation	Casanthranol-docusate 1 cap at bedtime or twice daily; senna 1–2 tabs at bedtime or twice daily; bisacodyl 5–10 mg daily + docusate 100 mg twice daily
Nausea and vomiting	Prevention: hydroxyzine 25–100 mg (PO/IM) every 4–6 hours as needed; diphenhydramine 25–50 mg (PO/IM) every 6 hours as needed; ondansetron 4 mg IV or 16 mg PO Treatment: prochlorperazine 5–10 mg (PO/IM) every 3–4 hours as needed or 25 mg per rectum twice daily; ondansetron 4–8 mg IV every 8 hours as needed
Gastroparesis	Metoclopramide 10 mg (PO/IV) every 6–8 hours
Vertigo	Meclizine 12.5–25 mg PO every 6 hours as needed
Urticaria/itching	Hydroxyzine 25–100 mg (PO/IM) every 4–6 hours as needed; diphenhydramine 25–50 mg (PO/IM) every 6 hours as needed
Respiratory depression	Mild: Reduce dose by 25% Moderate-severe: naloxone 0.4–2 mg IV every 2–3 minutes (up to 10 mg) for complete reversal; 0.1–0.2 mg IV every 2–3 minutes until desired reversal for partial reversal; may need to repeat in 1–2 hours depending on narcotic half-life
CNS irritability	Discontinue opioid; treat with benzodiazepine

CNS, central nervous system; IM, intramuscular; IV, intravenous; PO, orally.

About 70% of individuals will experience significant analgesia from 10 mg/70 kg (154 lbs) of body weight of intravenous morphine or its equivalent.[18] For severe pain in opiate-naïve patients, a usual starting dose is 5 to 10 mg of morphine every 4 hours. In the initial stages of severe pain, medication should be given around the clock. Rescue doses should be made available in doses equivalent to 10% to 20% of the total daily opioid requirement and administered every 2 to 6 hours if needed. Alternatively one-sixth of the total daily dose or one-third of the 12-hourly dose may be used. Doses should be titrated based on the degree of pain. One method involves adjustment of the maintenance dose based on the total 24-hour rescue dose requirement. Utilizing dose escalation, doses should be increased by 50% to 100% or 30% to 50% of the current dose, for those in severe and moderate pain, respectively. Once pain relief is achieved, and if treatment is necessary for more than a few days, conversion to a controlled-release or long-acting opioid should be made with an equal amount of agent. Several sustained-release products are available containing morphine, oxycodone, and fentanyl. Some clinicians will reduce the total daily dose of the long-acting dosage form by 25% when initiating a sustained-release product to reduce the likelihood of oversedation. The dose of a pure agonist is limited only by tolerability to side effects. Tolerance may develop to analgesic effects necessitating increasing doses to achieve the same level of pain relief. Physical dependence will also occur with long-term use of opioids. However, addiction or psychological dependence is unlikely in legitimate pain patients unless there are predisposing risk factors. Pain patients who are undertreated may appear to be drug-seeking (pseudoaddiction); however, effective pain management resolves the behaviors. When opioids are used for chronic pain, use of informed consent for chronic opioid therapy and medication management agreements or pain contracts may be appropriate to monitor the use (prescribing and dispensing) of controlled substances.

Opioids may be administered in a variety of routes including oral (tablet and liquid), sublingual, rectal, transdermal, transmucosal, intravenous, subcutaneous, and intraspinal. While the oral and transdermal routes are most common, the method of administration is based on patient needs (severity of pain) and characteristics (swallowing difficulty and preference). Oral opioids have an onset of effect of 45 minutes, so intravenous or subcutaneous administration may be preferred if more rapid relief is desired. Intramuscular injections are not recommended because of pain at the injection site and wide fluctuations in drug absorption and peak plasma concentrations achieved. More invasive routes of administration such as PCA and intraspinal (epidural and intrathecal) are primarily used postoperatively, but may also be used in refractory chronic pain situations. PCA delivers a self-administered dose via an infusion pump with a preprogrammed dose, minimum dosing interval, and maximum hourly dose. Morphine, fentanyl, and hydromorphone are commonly administered via PCA pumps by the intravenous route, but less frequently by the subcutaneous or epidural route.

Epidural analgesia is frequently used for lower extremity procedures and pain (e.g., knee surgery, labor pain, and some abdominal procedures). Intermittent bolus or continuous infusion of preservative-free opioids (morphine, hydromorphone, or fentanyl) and local anesthetics (bupivacaine) may be used for epidural analgesia. Opiates given by this route may cause pruritus that is relieved by naloxone. Adverse effects including respiratory depression, hypotension, and urinary retention may occur. When epidural routes are used in narcotic-dependent patients, systemic analgesics must also be used to prevent withdrawal since the opioid is not absorbed and remains in the epidural space. Doses of opioids used in epidural analgesia are 10 times less than intravenous doses, and intrathecal doses are 10 times less than epidural doses (i.e., 10 mg of IV morphine is equivalent to 1 mg epidural morphine and 0.1 mg of intrathecally administered morphine).[45]

Combination Analgesics

Combinations of opioids and non-opioids often result in enhanced analgesia and lower dose of each. Combination analgesics are frequently used in moderate pain. However, in severe pain, the non-opioid component reaches maximum dosage, and thus, the usefulness of non-opioids in this situation is limited. Additionally, the combination products are short-acting and often not suitable for chronic therapy. Single agents offer greater dosing flexibility than combination products.

Opioid Allergy

True narcotic allergies are rare and should not be confused with pruritus associated with opiate use. Cross-sensitivity between morphine-like, meperidine-like, and methadone-like agents is unlikely. Therefore, when an individual is allergic to one drug in a chemical class of opioids, it is reasonable to select an agent in another chemical class. For the purpose of drug selection in patients with allergies, mixed antagonists should be treated as morphine-like agents.

Tapering of Opioids

Tapering of opioids may be necessary once the painful situation has resolved in patients receiving doses greater than 160 mg/day of oral morphine (or the equivalent) or in those with prolonged opioid use. In these situations the dose should be reduced by 15% to 20% each day to avoid withdrawal symptoms.

Managing Opioid Side Effects and Drug Interactions

Side effects common to all opioids include sedation, hallucinations, constipation, nausea and vomiting, urinary retention, myoclonus, and respiratory depression. In terms of medication management, the most frequent are sedation, nausea, and constipation. Sedation and nausea are common when initiating therapy and when increasing doses. Nausea can be prevented with a centrally-acting antiemetic (Table 20–3). Sedation usually improves with continued therapy but may become intractable at high doses, and stimulants may be needed. Respiratory depression is a serious adverse effect, and usually occurs after acute administration in opioid-naïve patients. Tolerance to respiratory depression develops rapidly with repeated doses and is rarely a clinically significant problem in pain patients, even those with respiratory impairment. Constipation is a significant adverse effect to which tolerance does not develop, and prophylaxis with stimulant laxatives (e.g., senna or bisacodyl) and stool softeners, such as docusate, is recommended.

Codeine, hydrocodone, morphine, methadone, and oxycodone are substrates of the cytochrome P-450 isoenzyme CYP2D6.[47] Inhibition of CYP2D6 results in decreased analgesia of codeine and hydrocodone due to decreased conversion to the active metabolites (e.g., morphine and hydromorphone, respectively) and increased effects of morphine, methadone, and oxycodone. Methadone is also a substrate of CYP3A4, and its metabolism is increased by phenytoin and decreased by cimetidine. CNS depressants may potentiate the sedative effects of opiates.

Opioid Rotation

Opioid rotation is the switch from one opioid to another to achieve a better balance between analgesia and treatment-limiting adverse effects. This practice is often used when escalating doses (greater than 1 g of morphine per day) become ineffective. In some settings opioid rotation is utilized routinely to prevent the development of analgesic tolerance.[48]

Equianalgesic Dosing of Opioid Analgesics

Conversion from one dosage form to another or from one opioid to another may be necessary in situations such as ineffective pain control, emergence of side effects, change in patient status, and in formulary restrictions. ❺ *Equianalgesic doses should be used when converting from one opioid to another.* Clinicians

should be familiar with the equianalgesic dosing and conversion strategies to avoid analgesic failure. Equianalgesic tables serve as a guide for selection of the dosage of the new opioid, but have limitations, as they are often based on single-dose studies and clinical observations.[32] Opioid potency is compared using a reference standard of 10 mg of parenteral morphine. Switching from one dosage form to another of the same opioid (i.e., IV to PO) is relatively simple. The current total daily dose is calculated and the total of the new dosage form is determined using a ratio of the equianalgesic doses. This result is then adjusted based on the usual dosing frequency of the new form. When converting to a sustained-release form of the same opioid, dosage may be reduced by 25% to avoid initial sedation; however, the specific product literature should also be consulted.

The first step in an opioid rotation is to calculate the patient's total daily dose of opioid based on the regularly scheduled dose and the total amount of rescue dose needed in 24 hours. This total is then converted to morphine dosing equivalents using equianalgesic doses (Table 30–2). The total daily morphine dose is then used to calculate the daily dose of the new opioid using dosing equivalents from an equianalgesic table. Since cross-tolerance may not be complete between opioids, some references suggest that the calculated equianalgesic dose be reduced by 25% to 50%.[49] If the opioid switch is due to uncontrolled pain, a dosage reduction may not be needed. The equianalgesic dose may need to be reduced more in the medically frail and when converting to methadone.[50] Using the commonly cited equianalgesic dose of morphine to methadone (10 mg morphine/10 mg methadone), methadone doses should be reduced by 75% to 80%. However, this ratio is not applicable even in patients tolerant to low doses of morphine.[51] Methadone appears to be much more potent than once believed, and morphine/methadone ratios vary according to the total dose of morphine taken at the time of making the conversion to methadone (Table 30–4).[52,53] Conversion to methadone is a complex process, and several different strategies have been proposed including a switch of the entire dose in one day or a gradual conversion over 3 days.

Adjuvant Agents for Chronic Pain

The role of NSAIDs and opioids in chronic non-malignant pain has been discussed; however, a review of adjuvant agents for chronic pain, particularly neuropathic pain, is warranted. Adjuvant analgesics are drugs that have indications other than pain but are useful as monotherapy or in combination with non-opioids and opioids. Common adjuvants include antiepileptic drugs (AEDs), antidepressants, antiarrhythmic drugs, local anesthetics, topical agents (e.g., capsaicin), and a variety of miscellaneous drugs (e.g., NMDA antagonists, clonidine, and muscle relaxants).

There is little consensus as to the optimal management of neuropathic pain, because much of the evidence for treatment effectiveness consists of anecdotal reports or poorly designed trials. Published guidelines have been suggested for the general management of neuropathic pain.[54] Suggestions for first-line therapy include gabapentin, lidocaine patch, or tricyclic antidepressants (TCAs) (Table 30–5).[54–58] Newer antidepressants, such as the SSRIs, have fewer side effects but appear to be less effective than the TCAs for neuropathic pain. However, serotonin-norepinephrine reuptake inhibitors (SNRIs) (e.g., duloxetine and venlafaxine) have been used successfully for painful DPN.

TABLE 30–4. Methadone Dose Conversions[53]

Total Daily Dose Oral Morphine	Morphine: Methadone Factor
Less than 100 mg	3:1 3 mg morphine: 1 mg methadone
101–300 mg	5:1
301–600 mg	10:1
601–800 mg	12:1
801–1,000 mg	15:1
Greater than 1,000 mg	20:1

Data from reference 53 with permission.

TABLE 30–5. Selected Adjuvant Analgesics and Suggested Dosing[54–58]

Agent	Dosing Guidelines	FDA-Approved Indication
Amitriptyline (Elavil)	10–25 mg at bedtime with weekly increments to a target dose of 25–150 mg of amitriptyline or an equivalent dose of another TCA	
Duloxetine (Cymbalta)	60 mg daily	DPN
Gabapentin (Neurontin)	Initially, 300 mg three times daily up to a maximum of 3600 mg daily, in divided doses[a]	PHN
Pregabalin (Lyrica)	DPN: Initially, 50 mg three times daily; may be increased to 100 mg three times daily within 1 week based on efficacy and tolerability[a] PHN: Initially 75 mg twice daily or 50 mg three times daily; may be increased to 100 mg three times daily within 1 week based on efficacy and tolerability[a]	DPN and PHN
Lidocaine 5% (Lidoderm patch)	Up to three patches may be applied directly over the painful site once daily; patches are applied using a regimen of 12 hours on and 12 hours off	PHN

[a]Dosing for creatinine clearance of 60 mL/minute or greater.
DPN, diabetic peripheral neuropathy; PHN, post-herpetic neuralgia; TCA, tricyclic antidepressant.

A stepwise approach is suggested for managing the patient with neuropathic pain, beginning with the least invasive effective therapeutic choice and proceeding to the rational use of multiple drug regimens. To guide the choice of pharmacologic agents, patients may be identified as candidates for AEDs, TCAs, or opioids based on the presence of peripheral or central nerve pain and description of symptoms (Fig. 30–2). Choice of agent may also depend on dosing frequency and comorbidities. Data on combination therapy are lacking, and the use of combined treatment is empirical based on additive therapeutic benefit. Scheduled medication regimens instead of "as needed" dosing should be employed when treating chronic pain, and the effectiveness of therapy should be reassessed regularly. If patients are managed on a multiple drug regimen and changes are indicated, changing only one drug at a time is suggested. Topical agents (e.g., capsaicin) may be added to a regimen to reduce the oral medication load, particularly if adverse effects are a problem or if pain is not relieved.

Complementary and Alternative Medicine

Complementary and alternative medicine (CAM) is a term used to encompass a variety of therapies (e.g., acupuncture, chiropractic, botanical and non-botanical dietary supplements, and homeopathy) not typically taught in medical and allied health schools. Painful conditions are among the most common reasons individuals seek relief from CAM. In a recent survey, neck pain, joint pain, arthritis, and headache were among the top ten reasons for use of CAM, and low back pain ranked the number one reason for CAM therapies. A variety of dietary supplements have been suggested for painful conditions, such as S-adenosylmethionine (SAM-e), ginger, fish oil, feverfew, γ-linoleic acid, glucosamine, and chondroitin. Of these, glucosamine and chondroitin are the most popular and have the most evidence of efficacy. Glucosamine in doses of 1500 mg/day is effective in reducing pain of osteoarthritis by repair of cartilage and is recommended by the American Pain Society.

OUTCOME EVALUATION

Individualize treatment goals at the beginning of treatment. Utilize information obtained during the pain interview to create goals that are consistent with the patient's expectations. Prevention, reduction, or elimination of pain are important goals for treatment of acute pain. With chronic pain, elimination of pain may not be possible, and goals may focus on improvement or maintenance of functional capacity and quality of life. Thus, for example, pain goals may include "pain scale less than 3," "be able to play a game with grandchildren, " or "be able to knit again." Assess patients periodically, depending on the method of analgesia and pain condition, for achievement of pain goals. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.

Patient Care and Monitoring

1. Identify the source of pain.
2. Assess the level of pain using a pain intensity scale.
3. Base the initial choice of analgesic on the severity and type of pain, as well as on the patient's medical condition and concurrent medications.
4. Use the least potent oral analgesic that provides adequate pain relief and causes the fewest side effects.
5. Titrate the dose to one that achieves an adequate level of pain control.
6. Use a dosing schedule versus as-needed dosing.
7. Assess the patient for analgesic effectiveness and for side effects at each visit or more frequently, depending on the acuity of the patient's condition.
8. Avoid excessive sedation.
9. Adjust the route of administration if the patient is unable to take oral medications.
10. Use equianalgesic doses as a guide when switching opioids.

31 HEADACHE

Leigh Ann Ross and Brendan S. Ross

LEARNING OBJECTIVES

UPON COMPLETION OF THE CHAPTER, THE READER WILL BE ABLE TO:

1. Differentiate among types of headaches based on symptoms and signs.
2. List underlying causes and precipitating factors of different types of headache disorders.
3. Recommend appropriate nonpharmacologic measures for headache treatment and prevention.
4. Based on patient-specific data, determine when pharmacologic therapy is indicated for headache.
5. Propose individualized pharmacologic treatment regimens for the acute and chronic management of headache syndromes.
6. Construct therapeutic and adverse-effect monitoring plans for patients with headache.
7. Discuss pertinent patient education points for patients with headache disorders.

KEY CONCEPTS

❶ Headache may be a primary, or a secondary disorder due to an underlying medical condition.
❷ Primary headaches are classified as migraine, tension-type, or cluster and other trigeminal autonomic cephalalgias.
❸ The pain experienced with headache is likely due to overactivity in the trigeminovascular system of the brain.
❹ Migraine is further classified as migraine with aura and migraine without aura.
❺ The short-term goal of headache therapy is pain relief and a return to normal activities.
❻ The long-term goal of therapy is the prevention of headache recurrence.
❼ Pharmacologic treatment of acute headache should be started early to improve the response to therapy.
❽ Prophylaxis is indicated if headaches are frequent or severe, lead to significant disability, or require the use of pain-relieving medications two or more times per week.
❾ Regimens for headache disorders should be individualized based on the pattern of occurrence, response to therapy, medication tolerability, and comorbid medical conditions.

Headaches are common and have a significant impact on quality of life. ❶ *They can be classified as primary or secondary, causally related to an underlying medical disorder.* Primary headaches are more common and will be the focus of this chapter. Patients may seek evaluation of headache from a variety of health care providers. Therefore, all clinicians must be familiar with the types of headache, their diagnostic criteria, red flags indicating need for urgent intervention or specialist referral, and nonpharmacologic and pharmacologic options for treatment. ❷ *The International Headache Society (IHS) classifies primary headaches as migraine, tension-type, or cluster and other trigeminal autonomic cephalalgias.*[1] Tension-type headaches appear to be more common than migraine, and both are more common in women than in men. Cluster is a less common chronic headache syndrome that affects predominantly men.

EPIDEMIOLOGY OF HEADACHE DISORDERS

Migraine Headache

Migraine is a primary headache disorder that is estimated to affect 10% to 15% of adults in the United States.[2] Less than one-half of headaches meeting the diagnostic criteria for migraine are appropriately diagnosed. Migraine prevalence depends on age and gender. In children less than 12 years of age, migraines are more prevalent in males. After age 12, this

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

prevalence shifts markedly to women. The evolution in this gender difference is brought on by the hormonal changes of **menarche**.[3] Onset typically occurs between the ages of 10 and 30 years, but the prevalence is highest in the age range of 35 to 45 years.[4] Migraines significantly impact patient function, with over one-half of sufferers reporting severe disability requiring bed rest during an attack. The economic burden of migraine due to direct and indirect costs is substantial. Migraines are the leading cause of employee absenteeism and decreased workplace productivity.[5]

Tension-Type Headache

Tension-type headache (TTH) is the most common primary headache disorder. It is often underrepresented in clinical practice, as many patients do not present for care.[6] The term "tension-type headache" is used to describe all headache syndromes in which muscle contraction is the most significant factor in the pathogenesis of pain. The 1-year prevalence of TTH in the population ranges from 30% to 90%.[6] It is more common in adult females. Environmental factors, as opposed to genetic predisposition, play a more central role in their development. Tension-type headaches can be further divided into episodic or chronic; the mean frequency of attacks is 3 days per month in episodic disorders, and chronic TTH is defined as 15 or more attacks in a 1-month period.[7] The estimated prevalence of chronic TTH is less than 5%.[6] Some researchers believe that chronic TTHs represent a continuum of headache severity with migraine headache.[8] When severe headaches are difficult to differentiate clinically, treatment should initially target TTH.

Cluster Headache and Other Trigeminal Autonomic Cephalalgias

Cluster headache disorders are the most uncommon and severe primary headache syndromes.[9] The estimated point prevalence is less than 1%. Unlike migraine and TTH, cluster headaches occur more frequently in men. Onset commonly occurs prior to age 30.[6] A genetic predisposition seems apparent, although affected individuals often provide a history of tobacco use and alcohol abuse.[6] Attacks consist of debilitating, unilateral head pains that occur in series lasting up to months at a time, but that remit over months to years between occurrences. In rare instances, cluster headache can be a chronic disorder without remissions.[4]

ETIOLOGY AND PATHOPHYSIOLOGY OF HEADACHE DISORDERS

Migraine Headache

The mechanism by which headache pain occurs in **migraineurs** is not confirmed, but competing pathoetiologic theories exist: tissue pain generated by vascular reactivity or neuronal imbalance accompanied by **trigeminovascular** system overactivity.[10] The vascular hypothesis suggests that intracerebral vasoconstriction leads to neural ischemia and is followed by reflex extracranial vasodilation and pain. Recent **neuroimaging** evidence and the effectiveness of medications with no vascular properties do not support this theory, and ischemia alone is no longer accepted as the primary cause of migraine distress.[6] A neuronal etiology has emerged as the leading mechanism of the development of migraine.[11] Depressed neuronal electrical activity spreads across the brain, which produces transitory neural dysfunction.[12] ❸ *The pain experienced with headache is likely due to compensatory overactivity in the trigeminovascular system of the brain.* Activation of trigeminal sensory nerves leads to the release of vasoactive peptides [e.g., calcitonin gene-related peptide (CGRP), neurokinin A, and substance P] that produce a sterile inflammatory response around vascular structures in the meninges of the brain, which leads to pain.[11] Continued sensitization of central nervous system sensory neurons can potentiate and intensify headache pain as an attack progresses.[12] Bioamine pathways projecting from the brain stem regulate activity within the trigeminovascular system. Thus, the pathogenesis of migraine may be due to an imbalance in the modulation of nociceptors and blood vessel tone by serotonin and norepinephrine neurons.[13]

Patient Encounter, Part 1

GC, a 28-year-old woman, complains of a "terrible headache that won't go away." She describes the pain as "on one side and throbbing." The pain began yesterday morning and caused her to leave work. She reports a history of similar headaches since the age of 16, but none that lasted this long. In the past, her headaches were relieved with the use of over-the-counter non-steroidal anti-inflammatory drugs (NSAIDs). She often has to take analgesics multiple times per week.

- What type of headache is the patient most likely experiencing?
- What characteristics of the headache support this diagnosis?
- What are possible causes or triggers of headache in this patient?
- What additional information is needed to formulate a treatment plan?

Tension-Type Headaches

The pathophysiologic mechanisms of TTH are not clearly understood. The pain is thought to originate in the myofascial tissues of the head, but central brain processing is believed to be an important modulator of pain perception.[14]

Chronic TTH syndromes may evolve from recurrent episodic headaches as central nociception becomes sensitized.[15]

Cluster Headache and Other Trigeminal Autonomic Cephalalgias

Cluster headache is one of a group of disorders referred to as trigeminal autonomic **cephalalgias**.[16] The **autonomic** dysfunction is characterized by sympathetic underactivity and parasympathetic activation. Similar to migraine, the pain of a cluster headache is believed to be the result of vasoactive peptide release and neurogenic inflammation. The exact cause of trigeminal activation is not clear.[9] A leading hypothesis is that hypothalamic dysfunction, occasioned by diurnal or seasonal changes in neurohumoral balance, are responsible for headache periodicity.[6] Serotonin affects neuronal activity in the hypothalamus and trigeminal system and may play a role in the pathophysiology of cluster headache. The precipitation of cluster headache by high altitude exposure also implicates hypoxemia in the pathogenesis of trigeminal autonomic cephalalgias.[17]

CLINICAL PRESENTATION OF HEADACHES

Migraine Headache

Migraine presents as a recurrent headache that is severe enough to interfere with daily functioning. ❹ *Migraine headaches are classified as migraine with aura and migraine without aura.*[6] The correlating terms of "classic" and "common" migraine are no longer employed. Aura is defined as a transient focal neurologic symptom, which can be positive or negative, and can occur prior to or during an attack.[18] Examples of positive symptoms include the visual perception of flickering lights, spots, or wavy lines; whereas a partial loss of vision is a classic negative symptom of an aura. The International Classification of Headache Disorders (ICHD) outlines diagnostic criteria that differentiate migraine with and without aura.[6] The pain of a migraine headache is typically described as moderate to severe, throbbing, unilateral, and retro-orbital in location. The pain is accompanied by nausea, sensitivity to light and sound, and difficulty concentrating.[19] Untreated migraines can last from 4 to

Patient Encounter: Part 2: Medical History, Physical Exam and Diagnostic Tests

Further evaluation of GC reveals the following:

Past Medical History
- Mild persistent asthma
- Gastroesophageal reflux disease (GERD)
- Generalized anxiety disorder

Family History
- Father living, age 58 years; hypertension, diabetes mellitus, dyslipidemia
- Mother living, age 57 years; chronic daily "sick" headaches
- No siblings
- Paternal grandparents died at ages 58 and 65 years, both of ischemic stroke
- Maternal grandparents, living, ages 73 and 84; hypertension, osteoarthritis

Social History
- Married
- Employed as an account officer in a local bank
- No tobacco use, "social" alcohol intake (1 to 2 glasses of wine on weekends), drinks 3 to 4 caffeinated beverages per day

Medication Profile
- Advair 250/50 mg, 1 inhalation twice daily
- Albuterol 2 inhalations prn for bronchospasm
- Omeprazole 20 mg PO daily
- Sertraline 150 mg PO daily
- Combination ethinyl estradiol/norgestimate oral contraceptive
- Naproxen sodium 220 mg, 2 PO twice daily prn for headache

Review of Systems
- Headache, severe in intensity
- Sensitivity to light
- No chest pain or palpitations
- No shortness of breath or wheezing
- Nauseated, anorectic
- Dizzy, difficulty concentrating

Physical Exam
VS: Blood pressure 138/82 mm Hg, pulse 88 beats per minute, respiratory rate 16/minute, temperature 37.0°C (98.6°F), oral
HEENT: No papilledema, no neck stiffness
CV: RRR, normal S_1, S_2, no murmur, rub, or gallop
Chest: CTA
Abdomen: Benign, bowel sounds positive
Neurologic: Non-focal

Labs
CBC and chemistry panel within normal limits

- What is your assessment of this patient's condition?
- What medical comorbidities or drug therapies may be contributing to her distress?
- Identify treatment goals for this patient.
- What nonpharmacologic options are needed at present, and what options are appropriate in the long term for this patient?
- What pharmacologic therapy would you recommend for this patient in the acute setting?
- Does this patient require long-term pharmacologic prophylaxis against recurrent headaches?

72 hours. Migraines occurring 15 days per month or for 3 months or longer, without the overuse of analgesic medications, are classified as chronic migraines.[6] Severe and debilitating migraine pain lasting greater than 72 hours is termed status migrainosus.[19] Even in the absence of **neurologic focality**, brain imaging is mandated in patients with frequent, severe, and prolonged attacks or headaches that are atypical for a migraineur's stereotyped presentation.[20]

Tension-Type Headache

Tension-type headache pain differs from migraine pain in that it is usually reported to be mild to moderate, non-pulsating, and bilateral.[6] The pain is described by sufferers as a bandlike tightness or pressure around the head. No transient neurologic deficits are noted, and systemic symptoms are rare.[4] Tension-type headaches infrequently disrupt normal activity. Muscle palpation in the **fronto-temporal** and **parieto-occipital** may identify localized tender points.[4] Neuroimaging and laboratory testing are unrevealing, and they are unnecessary if the presentation and clinical history are classic for TTHs.

Cluster Headache

Pain associated with cluster headache differs from migraine and TTH in that it is severe, intermittent, and short in duration.[6] Headaches typically occur at night, but attacks may occur multiple times per day.[9] The pain is usually unilateral, but unlike migraine it is not described as pulsatile.[6] Aura is not a feature, and pain intensity peaks early after onset and may persist for hours.[6] The headache is described as explosive and excruciating. A constellation of features ascribed to parasympathetic overactivity can be seen, such as ipsilateral conjunctival injection, lacrimation, rhinorrhea, and sweating.[9] Unlike migraineurs, cluster headache disorder patients tend to become excited and restless during attacks, rather than seeking quiet and solitude.[16]

Clinical Presentation and Diagnosis of Migraine without Aura

Patients experiencing migraine without aura display the following headache symptoms and characteristics:

Two or more of the following present:

1. Pain interrupts or worsens with physical activity
2. **Unilateral** pain
3. Pulsating pain
4. Moderate to severe pain intensity

Two or more of the following present during headache:

1. Nausea
2. Vomiting
3. **Photophobia**
4. **Phonophobia**
5. **Osmophobia**

Duration: 4 to 72 hours (treated or not treated)
Criteria for diagnosis: Five or more attacks fulfilling the above criteria are necessary for diagnosis
Laboratory assessments that may be helpful in excluding medical comorbidities: Complete blood cell count (CBC), chemistry panel, thyroid function tests, erythrocyte sedimentation rate (ESR)

Clinical Presentation and Diagnosis of Migraine with Aura

Patients experiencing migraine with aura may display the following headache symptoms and characteristics:

One or more of the following present with no motor weakness:

1. Visual symptoms (positive and/or negative; reversible)
2. Sensory symptoms (positive and/or negative; reversible)
3. Dysphasic speech (reversible)
4. Moderate or severe pain intensity

Two or more of the following present:

1. Homonymous visual symptoms and/or unilateral sensory symptoms
2. One aura symptom develops at least 5 minutes prior and/or a second aura symptom develops 5 minutes or more after headache
3. Duration of each symptom 4 to 60 minutes

Criteria for diagnosis: Two or more attacks fulfilling the above criteria are necessary for diagnosis

Clinical Presentation and Diagnosis of Tension-Type Headache

Patients experiencing tension-type headache may display the following headache symptoms and characteristics:

Two or more of the following present:

1. Bilateral pain
2. Non-pulsating pain
3. Mild or moderate pain intensity

Both of the following present:

1. No nausea or vomiting (anorexia possible)
2. Either photophobia or phonophobia (not both)

Duration: 30 minutes to 7 days
Criteria for diagnosis: Ten or more attacks fulfilling the above criteria occurring on average less than 1 day per month are necessary for diagnosis

Clinical Presentation and Diagnosis of Cluster Headache

Patients experiencing cluster headache may display the following headache symptoms and characteristics:

1. Unilateral pain
2. **Orbital**, **supraorbital**, or temporal pain
3. Sharp and stabbing pain

One or more of the following present:

1. Conjunctival injection and/or lacrimation
2. Nasal congestion and/or **rhinorrhea**
3. Eyelid edema

Duration of pain: 2 seconds to 10 minutes
Frequency of attacks: One or more per day more than half of the time
Criteria for diagnosis: Twenty or more attacks fulfilling the above criteria are necessary for diagnosis

TREATMENT OF HEADACHE DISORDERS

Desired Outcomes

❺ *The primary short-term goal of migraine treatment is to achieve rapid pain relief that allows the patient to resume normal activities.*[21] ❻ *The long-term goal of therapy is prevention of headache recurrence and diminution of headache severity. Similarly, the goal of TTH is to lessen headache pain, while the long-term goal is to avoid analgesic dependence.*[22] *The short-term goal in cluster headache therapy is to achieve rapid pain relief.* Prophylactic therapy may be necessary to obtain the intermediate-term outcome of reducing the frequency and severity of headaches within a periodic cluster series, as well as to achieve the long-term goal of delaying or eliminating recurrent periods.[23]

General Approach to Treatment

The most important goal of acute headache management is pain relief. The primary pharmacologic agents used in the acute setting include analgesics and serotonin receptor agonists (triptans).[24] Despite available pharmacologic therapy, most headache patients are not treated adequately and rely on over-the-counter products for pain relief.[25] ❼ *Pharmacologic treatment of acute headache should be started early to abort the intensification of pain and to improve symptomatic response to therapy.* The long-term management of headache syndromes focuses on lifestyle modification and other nonpharmacologic therapeutic options, but if the headaches are severe and frequent, then prophylactic pharmacologic therapy is needed.[26] Several so-called "red flags" have been identified that, if present, warrant urgent physician referral and further diagnostic evaluation (Table 31–1).

TABLE 31–1. Headache Red Flags That, if Present, Warrant Urgent Further Evaluation

New onset, sudden, and/or severe
Onset after 40 years of age
Stereotyped pattern worsens
Systemic signs (e.g., fever, weight loss, accelerated hypertension)
Focal neurologic symptoms (i.e., other than typical visual or sensory aura)
Papilledema
Cough-, exertion-, or Valsalva-triggered headache
Pregnancy or postpartum
Patients with cancer, human immunodeficiency virus, and other infectious and immunodeficiency disorders
Seizures

Nonpharmacologic Therapy

Patient education is key to the successful management of headache disorders. Recording headache frequency, duration, and severity in a "headache diary" provides useful information for the patient regarding headache precipitants and insight for the clinician in selecting appropriate management strategies.[27] To prevent future occurrences, exposure to headache triggers (Table 31–2) should be limited. In the acute setting, environmental control may be able to abort a migraine attack. Many patients benefit from resting in a dark, quiet area.[28] Behavioral interventions, such as biofeedback, relaxation training, and cognitive-behavioral therapy, are effective and can be recommended for headache prevention.[17] Tension-type headaches may also be managed through stress management training.[17] Acupuncture has yielded inconsistent benefits in clinical trials.[22] Cluster headache patients should be advised to moderate alcohol use and curtail tobacco abuse.[23] Emotional distress may compound headache pain through the outward displacement of inner conflicts into somatization. Psychological interventions are urged in such instances, and they should be considered in all headache sufferers resistant to standard medication treatments.[29] All such non-prescription therapies may be useful in augmenting pharmacologic response.

Pharmacologic Therapy

Migraine

Analgesics such as NSAIDs and opioids are the initial pharmacologic option for the acute management of migraine headache. If these prove to be ineffective, then migraine-specific medications, such as triptans, are administered.[30] Early, abortive treatment should be the rule. If orally administered medications are selected, then appropriate larger doses than otherwise needed to produce pain relief are provided due to the enteric stasis and poor drug absorption accompanying migraine attacks.[20] Intranasal, parenteral, and rectal administration can circumvent this complication.

Clinical trial evidence supports many NSAID medications in the acute treatment of migraines with and without aura.[30] The currently marketed cyclooxygenase-2 (COX-2) selective

drugs are not clearly supported for migraine use, but are likely acceptable. Acetaminophen alone, or in proprietary combinations with aspirin, opioids, caffeine, or the barbiturate butalbital are also effective.[28] Although deemed to have a benign adverse-effect profile on gastric mucosal integrity and renal blood flow, overwhelming clinical experience supports the observation that the overuse of acetaminophen may lead to tolerance or dependence clinically manifested as acute withdrawal headaches.[31] These so-called rebound headaches are the result of poor attention to prevention therapies, and thus chronic use of daily analgesics.[32]

The triptans are considered specific therapies in that they target the pathophysiology underlying migraine.[33] They abort headache through beneficial effects on neuronal imbalances.[11] Triptans inhibit neurotransmission in the trigeminal complex and activate serotonin 1b/1d pathways that modulate nociception in the brain stem. They also decrease the release of vasoactive peptides leading to vascular reactivity and pain.[34] Triptans are a welcome addition to the therapeutic armamentarium in that they are available in intranasal, subcutaneous, and oral dosage forms. The marketed agents differ in their dosing and pharmacokinetic properties, but all are effective treatments to abort or diminish migraine headache pain (Table 31–3).[35] Patient response can be variable. If a patient does not respond to one agent, then another is selected before labeling a patient triptan-unresponsive.[36] The initial severity of pain correlates with response, thus, administration should be prompt. Relief is usually experienced within 2 to 4 hours. Treatment delay may lead to decreased analgesia through the development of refractory central pain sensitization. Efficacy tends to be dose-related, though adverse effects are less so.[37] The most common side effects are a sensation of warmth, dizziness, chest fullness, and nausea. Rarely, ischemic vascular events may be precipitated by the vasoconstrictive nature of these drugs.[34] An initial dose under direct practitioner supervision is indicated for patients presumed at cardiovascular risk. Triptans are avoided in patients experiencing migraine associated with neurologic focality, previous stroke, poorly controlled hypertension, or unstable angina. Triptans are relatively contraindicated for routine use in pregnancy.[30] Triptans should not be used with concurrent ergotamine administration.[34]

Ergotamine derivatives produce salutary effects on serotonin receptors similarly to triptans. They also impact adrenergic and dopaminergic receptors. Ergotamine tartrate and dihydroergotamine are the most commonly employed agents.[20] The latter is not available in an oral dosage form. Analgesic onset is within 4 hours, though additional dosing is required if an acceptable response is not appreciated. When dosed parenterally, these drugs are usually provided with an antiemetic, due to their potential to worsen the nausea associated with migraine. Metoclopramide and chlorpromazine are the drugs of choice. Intranasal dihydroergotamine can be self-administered to abort an attack.[20] The outpatient use of subcutaneous ergotamines is limited by the lack of a prefilled syringe form. The same cautions as those for triptans apply to ergot use in patients at risk for vascular events.

The choice of initial therapy for acute migraine attacks is a subject of debate among specialists.[38] Some believe that nonspecific analgesics should be used first-line, while others believe migraine-specific drugs should be the choice for patients with severe pain or a history of significant disability. A stepped-care approach within attacks from less to more specific drugs is usually recommended.[39] Once a history of headache refractory to common analgesics is established, triptans should be utilized as initial therapy. In patients who present to the hospital with intractable pain, intravenous metoclopramide supplemented with dihydroergotamine may be needed. Oral medications in this setting are not utilized, as nausea and vomiting limit their bioavailability. Migraineurs with frequent and severe attacks are candidates for prophylactic treatment.

Tension-Type Headache

Most individuals who experience episodic TTHs will not seek medical attention.[22] Instead, they will find relief with the use of

TABLE 31–3. Comparison of Serotonin Receptor Agonists (Triptans)[59–65]

Medication (Brand Name)	Dosage Forms	Strength (mg)	Usual Dosage (mg)	May Repeat In	Potential Drug Interactions
Almotriptan (Axert)	Oral tablets	6.25, 12.5	6.25–12.5		Ergot derivatives
Eletriptan (Relpax)	Oral tablets	20, 40	20–40		Substrate: CYP3A4, CYP2D6; ergot derivatives
Frovatriptan (Frova)	Oral tablets	2.5	2–5	2 hours	Substrate: CYP1A2; ergot derivatives

widely available over-the-counter analgesics. Acetaminophen products and NSAIDs are commonly utilized. An individual patient may benefit from topical analgesics (e.g., ice packs) or physical manipulation (e.g., massage) during an acute attack, but the evidence supporting nonpharmacologic therapies is inconsistent.[6] Relaxation techniques can often reduce headache frequency and severity. When pain is unrelieved, prescription-strength NSAID use is required or the combination of acetaminophen with an opioid analgesic may be necessary. The frequency of use of these more potent analgesics should be limited to prevent dependency. Use for more than 2 days per week suggests the need for prophylactic therapy.[40] In those sufferers who do not seek expedient medical attention, but rely instead on the frequent use of unprescribed analgesics, medication-overuse headache may supervene. This chronic daily headache syndrome requires physician referral to desensitize patient-initiated analgesic tolerance and dependence.[41]

Cluster Headache

Cluster headache responds to many of the same treatment modalities used in acute migraine; however, initial prophylactic therapy is required to limit the frequency of recurrent headaches within a periodic series. A novel therapy specific to cluster headaches is the administration of high-flow-rate oxygen: 100% at 5 to 10 L/minute by non-rebreather facemask for approximately 15 minutes.[42] If pain is not aborted, then retreatment is indicated. No side effects are seen with short-term oxygen use. If oxygen therapy is not wholly effective, then pharmaceuticals are useful as adjunctive therapy. They are also used when supplemental oxygen is not readily available. The triptan class agents are safe and effective. Intranasal or subcutaneous sumitriptan has demonstrated efficacy in decreasing cluster headache pain.[43] Oral triptans are also effective, but their delayed onset of action may limit their applicability in acute cluster headache treatment.[44] Cluster headache pain is rapid in onset, achieves peak intensity quickly, and is of short duration. Oral agents may have utility in limiting the recurrence of cluster attacks. Intranasal, intramuscular, or intravenous ergotamine agents are an alternative to triptan use.[6] Repeated dosing may break a cluster series. For those patients in whom triptans and ergotamine derivatives are contraindicated due to ischemic vascular disease, octreotide may be helpful to relieve pain.[45] Octreotide is a somatostatin analogue that has a shorter half-life, and it is available for subcutaneous administration. Unlike the other abortive agents, it has no vasoconstrictive effects. The most prominent treatment emergent adverse effect with octreotide use is gastrointestinal upset. Glucocorticoids, provided intravenously and later tapered orally, are also an effective option when cluster headache attacks are not satisfactorily controlled.[9]

Pharmacologic Therapy for Headache Prophylaxis

❽ *Prophylaxis for headache disorders is indicated if significant disability occurs or pain-relieving medications are used two or more times per week.*

Migraine Prophylaxis

Migraine headaches that are severe, frequent, or lead to significant disability will require long-term medication therapy. Prophylactic therapy is also recommended for migraines associated with neurologic focality, as it may prevent permanent sequelae. Although multiple medication classes have garnered Food and Drug Administration (FDA)-labeling for migraine prevention, there is no consensus on the best initial therapy (Table 31–4). The choice of pharmacologic agent should be individually tailored to patient tolerability and medical comorbidities.

The β-blockers propranolol and timolol are FDA-approved for migraine prophylaxis, but other drugs in the class are also as effective.[46] Cautious dosage titration is advised for those patients who do not have other indications for β-blocker use. Rizatriptan interacts with propranolol and thus dosages must be titrated downward, or another triptan chosen for abortive therapy.[36] Comorbid reactive airway disease is a relative contraindication to β-blocker prophylaxis, and patients with cardiac conduction disturbances should be closely monitored. Calcium channel antagonists are often used when patients cannot tolerate β-blockers. They are purported to beneficially impact aura as well as pain. The different calcium channel blockers are variably effective, and none carries an FDA indication. Moreover, even in responsive patients, tachyphylaxis may develop. Recently, renin-angiotensin antagonists have been noted to decrease headache frequency and severity in migraine sufferers.[47] Consensus recommendations for hypertension treatment often advocate multidrug regimens to achieve tight blood pressure control[48]; combination therapy with the agents noted above are ideal for migraineurs with comorbid hypertension.

Low-dose amitriptyline or other tricyclic antidepressants (TCAs) are also of proven efficacy in migraine prevention.[27] Due to sedation, these medications are commonly administered at night. The use of later-generation tricyclic medications (e.g., nortriptyline) or heterocyclic compounds (e.g., trazodone) decreases the dose-limiting adverse effects of TCAs, especially those attributable to their anticholinergic properties (e.g., dry mouth, constipation, and urinary retention). Whether the various selective serotonin reuptake inhibitors (SSRIs) can yield consistent efficacy in the majority of migraineurs is questionable.[21] Although they affect serotonin balance in the brain, their utility may derive from their beneficial impact on mood and anxiety, rather than through serotonergic effects on migraine generation. Concurrent TCA and triptan administration may rarely precipitate the serotonin syndrome, which presents clinically with confusion, gastrointestinal upset, symptomatic blood pressure changes, and muscle rigidity.[20]

The antiepileptics valproic acid and topiramate are approved for migraine prophylaxis. Gabapentin and lamotrigine are anecdotally reported to be efficacious as well. In patients whose migraine headaches are believed to be related to trigeminal neuralgia, carbamazepine is employed as prevention for both disorders. The precise mechanism of benefit of these agents is unclear, but enhancement of γ-aminobutyric acid (GABA) neuroinhibition and modulation of the neuroexcitatory amino acid glutamate is likely.[49] Divalproex sodium doses are gradually titrated to 1000 mg per day; topiramate is titrated to a maximum of 100 mg twice per day. At these doses, serum drug level monitoring is infrequently needed. These medications are as effective as propranolol at reducing the frequency and severity of migraines and are preferred for prevention in patients intolerant to β-blockers.[50] Topiramate is especially useful in metabolic syndrome, diabetes, and dyslipidemic patients, as it is unlikely to lead to the weight gain often seen with valproic acid use. Patients prescribed topiramate should be advised to stay well hydrated to prevent **dysgeusia**, disordered taste, and more seriously, hyperthermia.

Methysergide is an ergotamine derivative that impacts central serotonin balance.[51] It is reserved for use in migraineurs refractory to other agents, due to its significant adverse-effect profile. As an ergot compound, it is a vasoconstrictor that may worsen vascular dilatory reserves and precipitate cardiovascular events or ischemic stroke in those with

TABLE 31–4. Medications for Prophylaxis of Migraines[66–68]

Medication (Brand Name)	Usual Dosage (mg per day)	Main Adverse Effects
Antiepileptics		
Gabapentin (Neurontin)	1200–2400	Paresthesias, dizziness, fatigue, nausea

underlying atherosclerotic disease. Inflammatory fibrosis is a rare, but potentially serious, adverse reaction associated with prolonged use of methysergide. **Retroperitoneal fibrosis**, pulmonary fibrosis, or fibrosis in cardiac tissue can occur. Drug withdrawal usually reverses the condition, so treatment should be interrupted for at least a 3-week interval every 6 months. On occasion, cardiac valvular damage can be irreversible.

Tension-Type Headache Prophylaxis

The prevention of chronic TTHs employs the same pharmacologic strategies as for migraine prophylaxis. Tricyclic antidepressants are a mainstay of chronic therapy. The efficacy of serotonergic agents remains in question. Although there is little need for muscle relaxants (e.g., methocarbamol) in the treatment of acute TTH, they are often provided as a preventive intervention.[6] Combination prophylactic therapies may be needed to wean patients from daily analgesic abuse. Stress reduction techniques augmenting pharmacologic therapies may be particularly effective in this setting. The injection of botulinum toxin into cranial muscles has demonstrated prophylactic efficacy for severe TTHs.[41]

Cluster Headache Prophylaxis

The calcium channel blocker verapamil is the mainstay of cluster attack prevention and chronic prophylaxis.[6] Within an attack period, it is dosed at 240 to 360 mg per day. Higher doses may be necessary to stave off recurrent cluster periods. Beneficial effects may be appreciated after 1 week of treatment, but 4 to 6 weeks is usually needed to fully assess response. Adverse effects include smooth muscle relaxation with the subsequent exacerbation of gastroesophageal reflux and the development of constipation. Caution should be exercised in patients with myocardial disease, as verapamil is an **inotropic** and **chronotropic** cardiac depressant. Pharmacokinetic drug-drug interactions must be considered, as verapamil is a potent inhibitor of oxidative metabolism through cytochrome P-450 (CYP) enzyme 3A4. Eletriptan is a CYP3A4 substrate and should not be concurrently administered.[36] Lithium is another effective therapy to reduce headache frequency in a cluster series and to limit recurrences.[9] The dose administered should be individualized to achieve a low-serum concentration (0.4 to 0.8 mEq/L or mmol/L). Dose adjustments in the setting of renal disease and congestive heart failure are required.[6] Lithium is contraindicated in patients concurrently prescribed thiazide diuretics and angiotensin-converting enzyme inhibitors and angiotensin receptor blockers. Patient persistence with long-term lithium therapy may be hindered by the emergence of tremor, gastrointestinal distress, and lethargy. Verapamil and lithium doses can be lowered when used in combination with ergotamine. If possible, bedtime dosing of these therapies is recommended, given the nocturnal predilection of cluster headache attacks.[16] Methysergide can shorten the course of cluster attacks, but long-term use should be avoided.

Patient Encounter, Part 3: Creating a Care Plan

Based on the information presented, create a care plan for the acute and chronic management of this patient's headache. Your plan should include: (1) a statement of drug-related needs and/or problems, (2) goals of therapy, (3) a patient-specific detailed therapeutic plan, and (4) a plan for clinical follow-up to determine whether goals have been achieved and adverse effects avoided.

SPECIAL POPULATIONS

Migraine Headache in Children and Adolescents

Migraine headaches are common in children, and their prevalence increases in the adolescent years.[2,3] The diagnosis and evaluation of headaches is especially difficult in children, given their decreased ability to articulate symptoms. Treatment presents another challenge to the practitioner, because medications used for headache management in adults have not been fully evaluated for efficacy and safety in children. Consensus panel recommendations identify ibuprofen as effective and acetaminophen as probably effective in the acute treatment of headache in patients over the age of 6.[26] Aspirin use is avoided due to the risk of precipitating **Reye's syndrome**. Antiemetic therapy can be used alone or in combination with analgesics; promethazine is usually prescribed, as it is less prone to cause **extrapyramidal reactions** than other antiemetics. For adolescents over the age of 12, triptans are effective and are beneficial for abortive migraine therapy.[26] Medication prophylaxis for migraines in children and adolescents is understudied. The data are conflicting, and no consensus recommendation for the use of preventive drug therapy exists.[26] Nonpharmacologic interventions and trigger identification and avoidance are advised.

Pregnancy

Headaches are more common in women than in men. Fluctuation in estrogen levels is believed to account for this gender discrepancy.[52] Hence, headaches are common in pregnancy. Tension-type headaches predominate; migraine attacks may increase in frequency, but more usually decrease in frequency during pregnancy.[53] Recommendations for headache care during pregnancy are based on an insufficient evidence base and are largely anecdotal. As headaches are not associated with fetal harm, reflexive pharmacologic therapy should be avoided and drug treatment choices considered carefully. Standard nonpharmacologic therapies are often sufficient. Acetaminophen is safe for the pregnant woman and her fetus.[54] NSAIDs are avoided late in the third trimester to prevent detrimental prostaglandin

alterations leading to premature **ductus arteriosus** closure. Opioids are second-line agents. They are not to be used chronically, as they can lead to dependence in the mother and acute withdrawal in the baby after birth. Centrally-acting antiemetic agents are safe and may be useful as adjunctive agents. Corticosteroids may be needed for intractable headache relief. Prednisone and methylprednisolone are preferred, as they are metabolized in the placenta and do not expose the fetus. In pregnant women with migraine, vasoconstrictive agents such as triptans are relatively contraindicated, even though maternal registry data reveal little **teratogenicity**.[55] Ergot compounds are strictly avoided, as they may precipitate uterine contractions and consequent ischemia leading to hypoxemia in the fetus. Migraine prophylaxis is considered cautiously, as β-blockers and calcium channel antagonists may lead to maternal hypotension and diminished placental blood flow or fetal bradycardia. Antiepileptic drug use in this setting has not been sufficiently studied to allow definitive recommendations.

Some headache disorders are specific to the pregnant state. These include postprocedure headaches and those associated with preeclampsia. The former are the result of dural puncture with cerebrospinal fluid leakage after spinal anesthesia.[56] Puncture headache generally responds to bed rest in the supine position, though analgesics may be needed as well. The latter are seen in the third trimester accompanied by the clinical triad of hypertension, edema, and proteinuria. Preeclamptic headache pain is believed to result from alterations in cerebral blood flow.[57] Headaches experienced in preeclamptic women herald eclampsia, and urgent delivery is indicated. Antihypertensives are administered to prevent intracranial thrombosis or hemorrhage and prophylactic anticonvulsants are provided to prevent eclamptic seizures.

OUTCOME EVALUATION

- Monitor patients for the relief of headache pain and the lack of headache recurrence. Assure that full patient functionality is restored. Note environmental and behavioral triggers; the onset, character, and duration of pain; and associated symptoms and physical findings.
- Assess frequency and severity of headaches to determine the need for prophylactic therapy.
- Monitor patients for adverse effects of abortive therapies used for headache pain relief:
  - Acetaminophen: Monitor patients for analgesic overuse, which may lead to dependence and the precipitation of withdrawal headaches.
  - NSAIDs: Monitor patients for gastrointestinal distress, signs or symptoms of gastrointestinal bleeding, and hypertension and edema that may reflect renal dysfunction. Monitor CBC and serum creatinine as clinically indicated.
  - Opiates: Monitor patients for sedation and depressed cognition. Address constipation with use of stimulant laxatives.
  - Serotonin receptor agonists (triptans): Monitor patients for flushing, palpitations, chest pain, and shortness of breath. Recommend electrocardiography if symptoms persist.
  - Ergotamine derivatives: Monitor cardiovascular complications as for serotonergic agents.
- If prophylactic medications are required, monitor patients for short- and long-term adverse effects:
  - Antiepileptics: Monitor patients for dizziness, fatigue, nausea, and paresthesias. Assess changes in weight at quarterly intervals.
  - β-Blockers: Monitor patients for bradycardia (heart rate less than 60 bpm), symptomatic hypotension (blood pressure less than 90/60 mm Hg), and easy fatigability.
  - Calcium channel blockers: Monitor for cardiovascular effects similarly to β-blockers. If dihydropyridine calcium channel blockers are employed, assess for dependent edema. Consider withdrawal if GERD or constipation responds poorly to therapy.
  - Tricyclic antidepressants: Monitor for change in vision, sedation, dry mouth, gastrointestinal upset, and orthostatic dizziness.

Patient Care and Monitoring

❾ *Regimens for headache disorders should be individualized based on headache type, pattern of occurrence, response to therapy, medication tolerability, and comorbid medical conditions.*

1. Assess the patient complaint to yield a detailed description of headache: precipitating factors; presence or absence of prodromal symptoms; location, intensity, and duration of pain; changes in sensory acuity; and neurologic alterations.
2. Determine if immediate referral for emergency or specialist care is necessary.
3. Obtain a thorough history of non-prescription and prescription drug use and complementary and alternative therapies utilized, as well as identifying medication allergies.
4. Identify the presence of drug-drug interactions that may guide therapeutic decision making in regard to selecting acute and prophylactic headache treatments.
5. Obtain a complete medical and social history, identifying any potential drug-disease interactions or social factors that may influence treatment choices.
6. Obtain a family medical history, focusing on headache or mental health disorders in first-degree relatives.
7. Complete a review of systems and physical examination to identify causes or complications of headache.

(*Continued*)

8. Determine the type of headache disorder and rule out acute complications.
9. Recommend appropriate pharmacologic therapy to abort headache based on type, patient characteristics, current medication profile, and comorbid conditions.
10. Educate the patient on administration, maximum dosage, and anticipated adverse effects of the prescribed medication.
11. Recommend appropriate nonpharmacologic therapy to abort headache and to prevent future headaches.
12. Determine if the patient is a candidate for prophylactic pharmacologic therapy.
13. Recommend appropriate pharmacologic treatment for prevention of future headaches.
14. Assess response to therapy indicated by the absence of pain and a return to normal activities. Assess response to prophylactic therapy by improvements in headache frequency and severity.
15. Instruct the patient to keep a headache diary to identify potential causes of headaches and responses to therapy.
16. Provide the patient specific information regarding actions to take if therapy is ineffective or adverse effects develop.
17. Educate the patient on the importance of adherence to the individualized pharmacologic regimen to prevent headache and to diminish pain upon recurrence.
18. Educate the patient on the warning symptoms and signs of headache complications, and when to seek emergency medical attention.

ABBREVIATIONS

CBC: complete blood cell count
CGRP: calcitonin gene-related peptide
COX-2: cyclooxygenase-2
CTA: clear to auscultation
CYP: cytochrome P-450 isoenzyme system
ESR: erythrocyte sedimentation rate
FDA: Food and Drug Administration
GABA: γ-aminobutyric acid
GERD: gastroesophageal reflux disease
ICHD: International Classification of Headache Disorders
IHS: International Headache Society
MAO_A: Monoamine oxidase type A
NSAID: non-steroidal anti-inflammatory drug
SSRI: selective serotonin reuptake inhibitors
TCA: tricyclic antidepressant
TTH: tension-type headache

32 Alzheimer's Disease

Gary M. Levin, Toya M. Bowles, and Megan J. Ehret

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Describe the epidemiology of Alzheimer's disease and its effects on society.
2. Describe the pathophysiology including genetic and environmental factors that may be associated with the disease.
3. Detail the clinical presentation of the typical patient with Alzheimer's disease.
4. Describe the clinical course of the disease and typical patient outcomes.
5. Describe how nonpharmacologic therapy is combined with pharmacologic therapy for patients with Alzheimer's disease.
6. Recognize and recommend treatment options for disease-specific symptoms as well as behavioral/non-cognitive symptoms associated with the disease.
7. Develop an alternative treatment plan for patients with Alzheimer's disease.
8. Educate patients and/or caregivers about the expected outcomes for patients with Alzheimer's disease, and provide contact information for support/advocacy agencies.

Key Concepts

❶ Alzheimer's disease is characterized by progressive cognitive decline including memory loss, disorientation, and impaired judgment and learning.

❷ Pathologic hallmarks of the disease in the brain include **neurofibrillary tangles** and **neuritic plaques** (**senile plaques**) made up of various proteins, which result in a shortage of the neurotransmitter acetylcholine.

❸ A diagnosis can be made only at autopsy; therefore the diagnosis is established following an extensive history and physical examination, and by ruling out other potential causes of dementia.

❹ Treatment is focused on delaying disease progression and preservation of functioning as long as possible.

❺ The current gold standard of treatment for cognitive symptoms includes pharmacologic management with a cholinesterase inhibitor and/or an *N*-methyl-D-aspartate (NMDA) antagonist.

❻ The general approach to treatment of cognitive symptoms includes both pharmacologic and nonpharmacologic management.

❼ Treatment of behavioral symptoms should begin with nonpharmacologic treatments, but may also include antipsychotic agents and/or antidepressants.

❽ Delaying disease progression through pharmacotherapy can reduce the total cost of treating AD and delay nursing home placement.

❶ *Alzheimer's disease (AD) is a non-reversible, progressive dementia manifested by gradual deterioration in cognition and behavioral disturbances.* AD is primarily diagnosed by exclusion of other dementias. There is no single symptom unique to AD; therefore diagnosis relies on a thorough patient history. The exact pathophysiologic mechanism underlying AD is not entirely known, although certain genetic and environmental factors may be associated with the disease. There is currently no cure for AD; however, drug treatment can slow symptom progression over time.

Family members of AD patients are also profoundly affected by the increased dependence of their loved one as the disease progresses. Early education and social support of both the patient and family is also important treatment. The Alzheimer's

TABLE 32–1. Ten Warning Signs of Alzheimer's Disease

1. Memory loss: more than typical forgetfulness without remembering later
2. Difficulty performing familiar everyday tasks (e.g., preparing a meal and grooming)
3. Problems with language: forgetting simple words or substituting unusual words
4. Disorientation to time and place: may forget where they are and/or how they got there
5. Poor or decreased judgment: dress without regard to weather or falling prey to scam artists
6. Problems with abstract thinking: not just difficulty balancing a checkbook, but forgetting what the numbers represent
7. Misplacing things in unusual places: such as placing an iron in a freezer
8. Changes in mood or behavior: rapid mood swings with no apparent reason why
9. Changes in personality: extreme confusion, suspicion, or fearfulness
10. Loss of initiative: passivity and loss of interest in usual activities

Data from reference 1 with permission.

Association has developed a checklist of common symptoms (Table 32–1).[1]

EPIDEMIOLOGY AND ETIOLOGY

AD is the most common type of dementia, affecting approximately 4.5 million Americans in the year 2000.[2] Table 32–2 lists the different classifications of dementia.[3] This chapter will address only dementia of the Alzheimer's type.

The prevalence of AD increases with age and it is most prevalent in persons age 65 years and older. In the year 2000, it was estimated that there were 4.5 million people in the United States with AD. Of those affected, 7% were 65 to 74 years of age, 53% were between 75 and 84 years of age, and 40% were persons over 85 years of age.[2] It is projected that by the year 2050 there will be a three-fold increase in prevalence yielding potentially 13.4 million AD patients due to a population increase in persons over 65 years of age. Additionally, the cost to society due to rising Medicare spending for AD is projected to increase from $62 billion in 2000 to over $1 trillion in 2050. Furthermore, the costs associated with nursing home care alone are projected to increase from $19 billion in 2000 to $118 billion in 2050 (Fig. 32–1).[4,5] The severity of AD also correlates with increasing age and is classified

Patient Encounter, Part 1

A woman arrives at the clinic with her 80-year-old mother, LB, complaining that her mother is becoming increasingly forgetful and confused with old age. The woman complains that her mother sometimes takes her diabetes and hypertension medications at a frequency greater than that prescribed. This has become more frequent in the last 6 months and the mother has been getting very agitated when her daughter confronts her. The woman asks you for a pill organizer and if any of the over-the-counter drugs claiming to help with memory would help her mother.

- What information is suggestive of AD?
- Does the mother have any risk factors for AD?
- How would you approach and address the daughter's question?

TABLE 32–2. Classification of Dementia

Dementia of the Alzheimer's type (early- or late-onset)
With or without behavioral symptoms
Vascular dementia
Uncomplicated, with delirium, with delusions, and with depressed mood
Dementia due to HIV disease
Dementia due to head trauma
Dementia due to Parkinson's disease
Dementia due to Huntington's disease
Dementia due to Pick's disease
Dementia due to Creutzfeldt-Jakob disease
Dementia due to a specific general medical condition (specify)
Dementia that is substance-induced
Dementia due to multiple etiologies
Dementia not otherwise specified

HIV, human immunodeficiency virus.

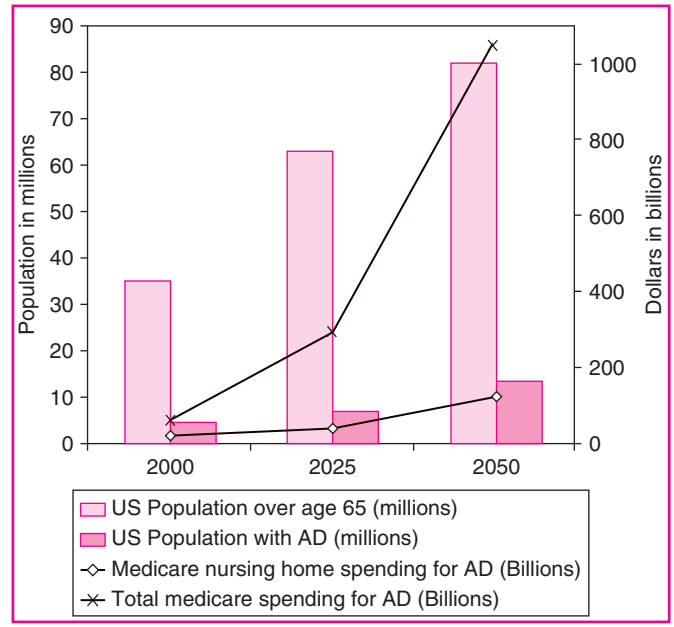

FIGURE 32–1. Projected increases in the population of patients with Alzheimer's disease, Medicare nursing home spending, and total Medicare spending. (Based on data from references 4 and 5.)

as mild, moderate, or severe. Other risk factors associated with AD besides age include family history, female gender, vascular risk factors such as diabetes, hypertension, heart disease, and current smoking.[6,7] However, it is unknown how other factors such as environment contribute and interact with the genetic predisposition for AD.

The mean survival time of persons with AD is reported to be approximately 6 years from the onset of symptoms until death. However, age at diagnosis, severity of AD, and other medical conditions affect survival time.[8] Although AD does not directly cause death, it is associated with an increase in various risk factors which often contribute to death such as senility, sepsis, stroke, pneumonia, dehydration, and decubitus ulcers.

The exact etiology of AD is unknown; however, it has been suggested that genetic factors may contribute to errors in protein synthesis resulting in formation of abnormal proteins involved in the pathogenesis of AD.[9] Early onset, which is defined as AD prior to age 60, accounts for approximately 1% of all AD. This type is usually familial and follows an autosomal dominant pattern in approximately 50% of cases of early-onset AD. Mutations in three genes, presenilin 1 on chromosome 21, **amyloid** precursor protein (APP) on chromosome 21, and presenilin 2 on chromosome 1, lead to an increase in β-A4 peptide fragments of APP which forms neuritic plaques that are the pathologic hallmark of AD.[10]

The genetic basis for the more common late-onset AD appears more complex. Genetic susceptibility is more sporadic and it may be more dependent on environmental factors.[9] The apolipoprotein E (apo E) gene on chromosome 19 has been identified as a strong risk factor for late-onset AD. There are three variants of apo E; however, carriers of two or more of the apo E4 allele have an earlier onset of AD (approximately 6 years earlier) compared with non-carriers.[9] Only 50% of AD patients have the apo E4 allele, thus indicating it is only a susceptibility marker.

PATHOPHYSIOLOGY

❷ *The pathologic hallmarks of the disease in the brain include neurofibrillary tangles and neuritic plaques made up of various proteins, which result in a shortage of the neurotransmitter acetylcholine.* These are primarily located in brain regions involved in learning, memory, and emotional behaviors such as the cerebral cortex, hippocampus, basal forebrain, and amygdala.[11]

Tangles

Neurofibrillary tangles are intracellular and consist of abnormally phosphorylated tau protein which is involved in microtubule assembly. Tangles interfere with neuronal function resulting in cell damage, and their presence has been correlated with the severity of **dementia**.[12] Unfortunately, these tangles are insoluble even after the cell dies, and they cannot be removed once established. The neurons that provide most of the cholinergic innervation to the cortex are most prominently affected.[13] Therefore, prevention is the key to targeted therapy of these tangles.

Plaques

Neuritic or senile plaques are extracellular protein deposits of fibrils and amorphous aggregates of β-amyloid protein.[11] This formed protein is central to the pathogenesis of AD. The β-amyloid protein is present in a non-toxic, soluble form in human brains. In AD, conformational changes occur that render it insoluble and cause it to deposit into amorphous diffuse plaques associated with dystrophic neuritis.[14] Over time, these deposits become compacted into plaques and the β-amyloid protein becomes fibrillar and neurotoxic. Inflammation occurs secondary to clusters of astrocytes and microglia surrounding these plaques.

Acetylcholine

The neurotransmitter acetylcholine (Ach) is responsible for transmitting messages between certain nerve cells in the brain. In AD, the plaques and tangles damage these pathways, leading to a shortage of Ach, resulting in learning and memory impairment.[15] The loss of Ach activity correlates with the severity of AD. The basis of pharmacologic treatment of AD has been to improve cholinergic neurotransmission in the brain. **Acetylcholinesterase** is the enzyme that degrades Ach in the synaptic cleft. Blocking this enzyme leads to an increased level of Ach with a goal of stabilizing neurotransmission.[16] In the United States, the four cholinesterase inhibitors approved for the treatment of AD are tacrine, donepezil, rivastigmine, and galantamine.

Glutamate

Glutamate is the primary excitatory neurotransmitter in the central nervous system (CNS) involved in memory, learning, and neuronal plasticity. It acts by providing information from one brain area to another and affects cognition through facilitation of connections with cholinergic neurons in the cerebral cortex and basal forebrain.[17] In AD, one type of glutamate receptor, *N*-methyl-D-aspartate (NMDA), is less prevalent than normal. There also appears to be overactivation of unregulated glutamate signaling. This results in a rise in calcium ions that induces secondary cascades which lead to neuronal death and an increased production of APP.[16] The increased production of APP is associated with higher rates of plaque development and hyperphosphorylation of tau protein.[18] The drug memantine is a non-competitive NMDA

antagonist which targets this pathophysiologic mechanism.[19] Memantine is presently the only agent in this class that is approved for the treatment of AD.

Cholesterol

Increased cholesterol concentrations have been associated with AD. The cholesterol increases β-amyloid protein synthesis which can lead to plaque formation.[16] Also, the apo E4 allele is thought to be involved in cholesterol metabolism and is associated with higher cholesterol levels.[16]

Estrogen

Estrogen appears to have properties that protect against memory loss associated with normal aging. It has been suggested that estrogen may block β-amyloid protein production and even trigger nerve growth in cholinergic nerve terminals.[20,21] Estrogen is also an antioxidant and helps prevent oxidative cell damage.[20] It is important to note, however, that the Women's Health Initiative Memory Study reported that hormone replacement with either estrogen alone or estrogen plus medroxyprogesterone resulted in negative effects on memory.[22]

Clinical Presentation of Alzheimer's Disease

General

The diagnosis of AD relies on thorough mental status testing and neuropsychological tests, medical and psychiatric history, neurologic exam, interview of caregivers and family members, and laboratory and imaging data to support the diagnosis and exclude other causes.

Signs and Symptoms

- Cognitive: memory loss, problems with language, disorientation to time and place, poor or decreased judgment, problems with learning and abstract thinking, misplacing things
- Non-cognitive: changes in mood or behavior, changes in personality, or loss of initiative
- Functional: difficulty performing familiar tasks

Laboratory Tests

- Magnetic resonance imaging (MRI) or computed tomography (CT) is used to measure changes in brain size and volume and rule out stroke, brain tumor, or a cerebral edema.
- Tests to exclude possible causes of dementia include a depression screen, vitamin B_{12} deficiency, thyroid function tests [thyroid-stimulating hormone (TSH) and free triiodothyronine and thyroxine], complete blood cell count, and chemistry panel.[21]
- Other diagnostic tests to consider for differential diagnosis: erythrocyte sedimentation rate, urinalysis, toxicology, chest x-ray, heavy metal screen, HIV testing, cerebrospinal fluid (CSF) examination, electroencephalography, and neuropsychological tests such as the Folstein Mini Mental Status Exam.

CLINICAL PRESENTATION AND DIAGNOSIS

❸ *Diagnosing AD relies on a thorough medical and psychological history, mental status testing, and laboratory data to exclude other possible causes. There are no biological markers other than those pathophysiologic changes found at autopsy that can confirm AD.* The American Academy of Neurology has adopted practice guidelines for the diagnosis and management of AD.[23] The diagnostic criteria are based on the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) (Table 32–3)[24] or the National Institute of Neurological and Communicative Diseases and Stroke/Alzheimer's Disease and Related Disorders Association (NINCDS-ADRDA). These diagnostic criteria are 85% to 90% accurate in diagnosing AD.[24]

AD is a progressive disease, which over time affects multiple areas of cognition. The symptoms of AD can be divided into cognitive symptoms, non-cognitive symptoms (i.e., behavioral), and functional symptoms for assessment and treatment purposes. Table 32–4 describes the stages of cognitive decline.[25,26]

TABLE 32–3. Diagnostic Criteria for Alzheimer's Disease Based on DSM-IV-TR

Dementia of the Alzheimer's type
A. The development of multiple cognitive deficits manifested by both
  (1) memory impairment (impaired ability to learn new information or to recall previously learned information)
  (2) one or more of the following cognitive disturbances:
    (a) aphasia (language disturbance)
    (b) apraxia (impaired ability to carry out motor activities despite intact motor function)
    (c) agnosia (failure to recognize or identify objects despite intact sensory function)
    (d) disturbance in executive functioning (i.e., planning, organizing, sequencing, abstracting)
B. The cognitive deficits in criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning.
C. The course is characterized by gradual onset and continuing cognitive decline.
D. The cognitive deficits in criteria A1 and A2 are not due to any of the following:
  (1) other central nervous system conditions that cause progressive deficits in memory and cognition
  (2) systemic conditions that are known to cause dementia
  (3) substance-induced conditions
E. The deficits do not occur exclusively during the course of delirium.
F. The disturbance is not better accounted for by another **Axis I** disorder.

Data from American Psychiatric Association with permission.[3]

TABLE 32–4. Stages of Cognitive Decline

Stage	Clinical Attribute	Pathology and Clinical Picture
Stage 1	No cognitive impairment	No memory problems and no impairment is evident to a health care professional.
Stage 2	Very mild decline	Lapses of memory; forgetting familiar names or locations of personal objects (e.g., keys or glasses); problems not evident to friends, family, coworkers, or health care professionals.
Stage 3	Mild cognitive decline	Friends, family, and coworkers begin to notice deficiencies; problems with names or words become evident; performance issues become evident; retention of reading material declines; losing valuable objects; decline in planning and organizational abilities.
Stage 4	Moderate cognitive decline (mild or early-stage AD)	Medical interview detects clear-cut deficiencies; decreased knowledge of current events; impaired ability to perform difficult mathematical problems (e.g., serial 7's); decreased ability to perform complex tasks (managing finances); decreased recall of personal history; individuals may become withdrawn and subdued.
Stage 5	Moderately severe cognitive decline (moderate AD)	Major gaps in memory appear and assistance with day-to-day activities is necessary; inability to recall details such as current address and telephone number may begin; difficulty with orientation to place and time; less challenging mathematical problems may become difficult (e.g., serial 4's or 2's); can still recall their own name and those of spouse and children.
Stage 6	Severe cognitive decline (moderately severe AD)	Significant personality and behavioral symptoms may emerge (delusions, suspiciousness, hallucinations, compulsions) and extensive help with ADLs become necessary (e.g., toileting); loss of awareness of recent experiences and surroundings; may still recall their own name, but recall of other personal history is decreasing; need help in getting dressed properly; disruptions of sleep/wake cycle occur; increase in urinary and fecal incontinence; wandering and getting lost becomes common.
Stage 7	Very severe cognitive decline (severe AD)	Final stage of illness; loss of ability to respond to surroundings; inability to speak and control movement; help is required for eating, walking, and toileting; movements become abnormal and rigid and swallowing is impaired.

AD, Alzheimer's disease; ADLs, activities of daily living.
Data from Alzheimer's Association[25] and Reisberg B with permission.[26]

TREATMENT

Desired and Expected Outcomes

Although there are currently five agents approved for the treatment of Alzheimer's disease, none of these agents are curative or are known to directly reverse the disease process. ❹ *Consequently, the primary outcome of treatment of Alzheimer's disease is to symptomatically treat the cognitive symptoms of the patient and preserve the patient's functioning for as long as possible.* Secondary goals include treating psychiatric and behavioral symptoms that may occur during the course of the disease.

General Approach to Treatment

❺ *The current gold standard of treatment for cognitive symptoms includes pharmacologic management with a cholinesterase (ChE) inhibitor and/or an NMDA antagonist.* There are currently four ChE inhibitors available on the United States market: tacrine, rivastigmine, galantamine, and donepezil. The use of tacrine is limited due to its propensity for hepatotoxicity and difficult titration schedule. Psychiatric and behavioral symptoms that occur during the course of the disease should be treated as they occur.

Essential elements in the treatment of AD include education, communication, and planning with the family/caregiver of the patient. Treatment options, legal and financial decisions, and course of the illness need to be discussed with the patient and family members. In this regard, the clinician's emphasis should be on helping to maintain a therapeutic living environment while minimizing the burden of care resulting from the disease.

Nonpharmacologic Treatment

Treatment of Alzheimer's disease involves both pharmacologic and nonpharmacologic methods, because this disease can be devastating to both the patient and the family. Upon the initial diagnosis, the patient and family should be counseled on the course of the illness, prognosis, available treatments, legal decisions, and quality-of-life issues. The life of a patient with Alzheimer's disease must become progressively more simple and structured as the disease progresses, and the caregiver must learn to keep requests and demands on the patient simple. The family of the patient will need to be prepared to face changes in life that will occur as the disease becomes worse. Basic principles in the treatment of patients with AD include:

- Using a gentle, calm approach to the patient
- Giving reassurance when needed
- Empathizing with the patient's concerns
- Using distraction and redirection

Patient Encounter, Part 2: The Medical History, Physical Exam, and Diagnostic Tests

HPI
LB has seen a neurologist to address her cognitive decline and behavioral issues and is at the clinic for follow-up after obtaining her assessments and labs.

PMH
- Diabetes mellitus since age 55; it was well controlled until last year when it worsened because of increased confusion of when to take her medication
- Hypertension treated for 20 years and well controlled; has been hypotensive on a few occasions recently during physicals
- Insomnia which is getting worse

FH
Father died of myocardial infarction at age 76; mother died of breast cancer at age 79

SH
Lives alone; denies drinking alcohol or smoking

Meds
- Hydrochlorothiazide 25 mg PO once daily
- Losartan 50 mg PO twice daily
- Metformin 1000 mg PO twice daily
- Lorazepam 1 mg PO at bedtime

ROS
(+)weight loss of 12 lb (5.5 kg); (–) N/V/D, change in appetite, heartburn, chest pain, or shortness of breath

PE
VS: blood pressure 128/62 mm Hg supine, pulse 77 beats per minute, respiratory rate 15/minutes, temperature 37°C (98.6°F)
Gen: Poorly-groomed, thin woman looks stated age
Neuro: Folstein Mini Mental Status Exam score 16/30; disoriented to month, date, and day of week, clinic name and floor; poor registration with impaired attention and short-term memory; recalled 0 out of 3 items; good language skills but problems with commands
CT Scan: Mild to moderate generalized cerebral atrophy

- Based on the new information, what is your assessment of the patient?
- What nonpharmacologic and pharmacologic interventions could be recommended?
- What are the short-term and long-term treatment goals?

- Maintaining daily routines
- Providing a safe environment
- Providing daytime activities
- Avoiding overstimulation
- Using familiar decorative items in the living area
- Bringing abrupt declines in function and the appearance of new symptoms to professional attention

Preparation in the early stages of the illness will lessen caregiver stress as the disease progresses.

Conventional Pharmacologic Treatment for Cognitive Symptoms

Cholinesterase Inhibitors (Donepezil, Rivastigmine, and Galantamine)

❺ *The ChE inhibitors all have the indication for the treatment of mild to moderate dementia of the Alzheimer's type.* Guidelines for the treatment of AD were written before the approval of memantine and recommend the use of ChE inhibitors as a valuable treatment for AD.[27–29] None of the ChE inhibitors have been compared in head-to-head studies, so the decision to use one over another is based on differences in mechanisms of action, adverse reactions, and titration schedules.

Treatment should begin as early as possible in patients with a diagnosis of AD.[30] Figure 32–2 provides a recommended treatment algorithm for AD.[31] Patients should be switched to another ChE inhibitor from their initial ChE inhibitor if they show an initial lack of efficacy; initially respond to treatment, but lose clinical benefit; or experience safety/tolerability issues. This switch should not be attempted until the patient has been on a maximally tolerated dose for a period of 3 to 6 months. The switch should also be based on realistic expectations of the patient and/or caregiver.[32] ChE inhibitor therapy should be discontinued in patients who experience poor tolerance or compliance, who show a lack of clinical improvement after 3 to 6 months at optimal dosing, who continue to deteriorate at the pretreatment rate, or who demonstrate dramatic clinical deterioration following initiation of treatment.[33]

Donepezil

❺ *Donepezil is a piperidine cholinesterase inhibitor, which reversibly and non-competitively inhibits centrally active acetylcholinesterase.*[34] This specificity is claimed to result in fewer peripheral side effects as compared to the other ChE inhibitors.

Donepezil is approved for the treatment of mild to moderate dementia of the Alzheimer's type at a dose of 5 mg/day. This dose should be increased to 10 mg/day if needed after 4 to 6 weeks. Table 32–5 describes the dosing strategies for all of the approved agents for Alzheimer's disease.[34–38]

Adverse reactions with donepezil include nausea, vomiting, and diarrhea. These are typical cholinergic side effects to expect with all of the cholinesterase inhibitors. Table 32–6 compares the major side effects for all of the approved agents for Alzheimer's disease.[34–38]

Only a small number of drug interactions have been reported with donepezil. In vitro studies show a low rate of binding of donepezil to cytochrome P-450 (CYP)3A4 or 2D6. Whether or not donepezil has the potential for enzyme induction is not known. No interactions with theophylline, cimetidine, warfarin, digoxin, or ketoconazole have been documented. In vitro studies show that inhibitors of CYP3A4 and 2D6 have the potential to inhibit the metabolism of donepezil. The clinical relevance of this is unknown. However, monitoring for possible increased peripheral side effects is advised

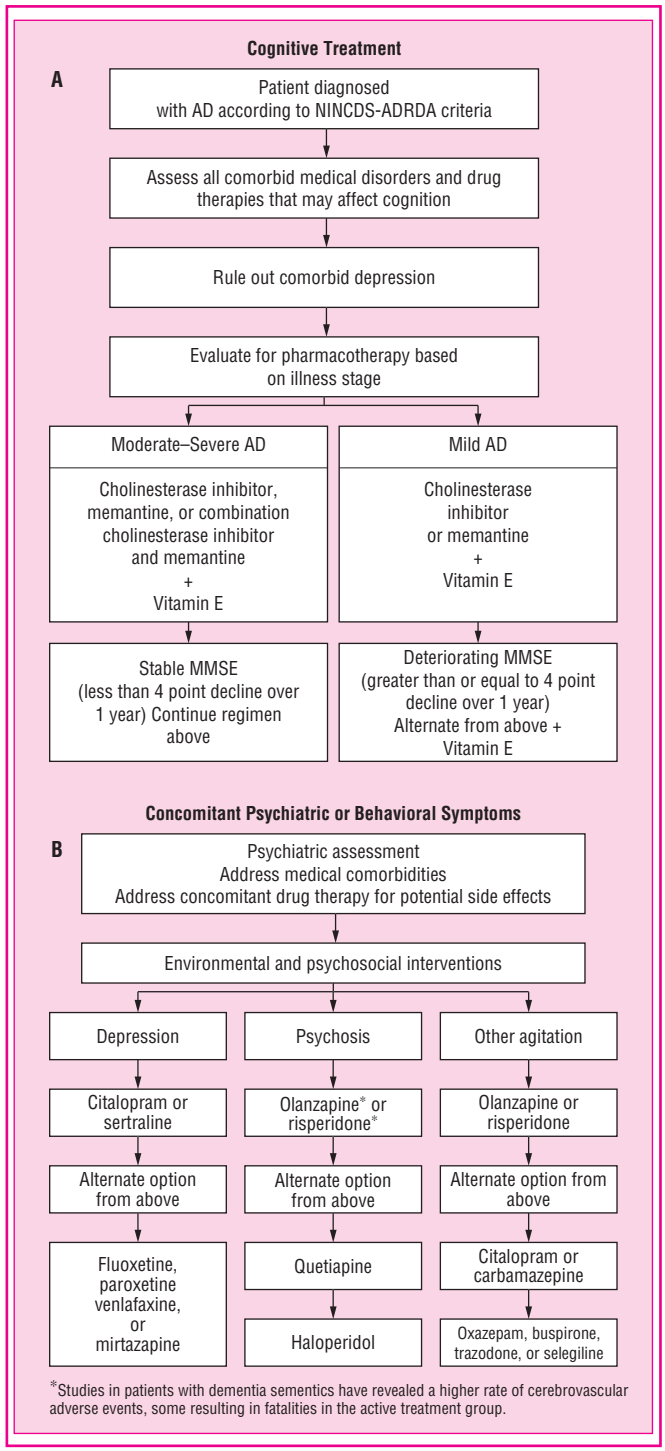

FIGURE 32–2. Treatment algorithm for Alzheimer's disease. *A.* Cognitive treatment. *B.* Treatment of psychiatric or behavioral symptoms. AD, Alzheimer's disease; MMSE, Mini Mental Status Examination; NINCDS-ADRDA National Institute of Neurological and Communicative Disorders and Stroke/Alzheimer's Disease and Related Disorders Association. (From Faulkner JD, Bartlett J, Hicks P. Alzheimer's disease. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 1164, with permission.)

when adding a CYP2D6 or 3A3/4 inhibitor to donepezil treatment. Also, inducers of CYP2D6 and 3A4 could increase the rate of elimination of donepezil.[34]

Rivastigmine

❺ *Rivastigmine has central activity for both the acetylcholinesterase and butyrylcholinesterase enzymes.*[36] Acetylcholinesterase is found in two forms: globular 4 and globular 1. In postmortem studies, globular 4 is significantly depleted, while globular 1 is still abundant. Thus, blocking metabolism of globular 1 may lead to higher concentrations of acetylcholine. Rivastigmine has higher activity at globular 1 than at globular 4. Theoretically this may be advantageous, as rivastigmine prevents the degradation of acetylcholine via the acetylcholinesterase globular 1 over the course of the disease as compared to the other ChE inhibitors.

The dual inhibition of acetylcholinesterase and butyrylcholinesterase may lead to broader efficacy. As acetylcholinesterase activity decreases with disease progression, the acetylcholinesterase-selective agents may lose their effect, while the dual inhibitors may still be effective due to the added inhibition of butyrylcholinesterase. However, this has not been demonstrated clinically.

Rivastigmine is approved for the treatment of mild to moderate dementia of AD at an initial dose of 1.5 mg twice daily; if this dose is tolerated for at least 2 weeks, then the dose can be increased to 3 mg twice daily. Increases to 4.5 mg twice daily and 6 mg twice daily should be attempted only after at least 2 weeks at the previous dose. Tolerability and absorption are improved when the dose is given with food.

Cholinergic side effects (nausea, vomiting, and diarrhea) are common with rivastigmine, but are usually well tolerated if the recommended dosing schedule is followed. If side effects cause intolerance, several doses can be held, then dosing can be restarted at the same or next lower dose. There are no pharmacokinetic drug interactions with drugs metabolized via CYP1A2, 2D6, 3A4/5, 2E1, 2C9, 2C8, or 2C19 expected. Drugs that induce or inhibit CYP450 metabolism are not expected to alter the metabolism of rivastigmine.[36]

Galantamine

❺ *Galantamine is a ChE inhibitor, which elevates acetylcholine in the cerebral cortex by slowing the degradation of acetylcholine.*[37] It also modulates the nicotinic acetylcholine receptors to increase acetylcholine from surviving presynaptic nerve terminals. In addition, it may increase glutamate and serotonin levels. The clinical benefit of action of these additional neurotransmitters is unknown.

Galantamine is approved for the treatment of mild to moderate dementia of Alzheimer's disease. It can be dosed once or twice daily (if using the immediate-release tablet or extended-release capsule). The initial dose is 8 mg daily (or 4 mg twice daily) for 4 weeks. If tolerated the dose can be increased if needed to 16 mg daily (or 8 mg twice daily) for at

TABLE 32–5. Dosing Strategies for Cognitive Agents

	Tacrine	Donepezil	Rivastigmine	Galantamine	Memantine
Starting dose	10 mg four times daily	5 mg daily	1.5 mg twice daily	4 mg twice daily or 8 mg daily	5 mg daily
Maintenance dose	20–40 mg four times daily	5–10 mg daily	3–6 mg twice daily	8–12 mg twice daily or 16–24 mg daily	10 mg twice daily
Time between dose adjustments	4–6 weeks	4–6 weeks	2 weeks	4 weeks	1 week

Data from product Information for tacrine, donepezil, rivastigmine, galantamine, and memantine.[34–38]

least 4 weeks. Again, if this dose is tolerated, the dose can be increased if needed to 24 mg daily (or 12 mg twice daily).

The adverse reactions associated with galantamine are similar to that observed with the ChE inhibitors (e.g., nausea, vomiting, and diarrhea).

CYP3A4 and 2D6 are the major enzymes involved in the metabolism of galantamine. Pharmacokinetic studies with inhibitors of this system have resulted in increased galantamine concentrations or reductions in clearance. Similarly to donepezil, if inhibitors are given concurrently with galantamine, monitoring for increased cholinergic side effects should be done. Studies with inducers of these enzymes have not been completed.[37]

NMDA Receptor Antagonist

Memantine

❺ *Memantine is a non-competitive antagonist of the N-methyl-D-aspartate (NMDA) type of glutamate receptors, which are located ubiquitously throughout the brain.* It regulates activity throughout the brain by controlling the amount of calcium that enters the nerve cell, a process essential for establishing an environment required for information storage. Overstimulation of the NMDA receptor by excessive glutamate allows too much calcium into the cell, disrupting information processing. Blocking NMDA receptors with memantine may protect neurons from the effects of excessive glutamate without disrupting normal neurotransmission.[38]

Memantine is indicated for the treatment of moderate-to-severe dementia of the Alzheimer's type. The initial dose is 5 mg/day with increases to 20 mg/day if needed, with a minimum of 1 week between dosage increases. Doses greater than 5 mg/day should be given in two divided doses. A suggested titration is: 5 mg/day for at least 1 week; 5 mg twice daily for at least 1 week; 15 mg/day (5 mg in the morning and 10 mg in the evening) for at least 1 week; then 10 mg twice daily. If the patient has a creatinine clearance of 5 to 29 mL/minute, then the target dose should be 5 mg twice daily. It is likely to be given as monotherapy, but can be given in combination with ChE inhibitors.

TABLE 32–6. Comparative Common Adverse Effects of AD Medications from Clinical Trial Data[a]

Adverse Event	Tacrine (n = 634)	Donepezil (n = 747)	Rivastigmine (n = 1189)	Galantamine (n = 1040)	Memantine (n = 940)
Elevated liver function tests	29%	NR	NR	NR	NR
Nausea or vomiting	28%	NR	NR	NR	NR
Nausea	NR	11%	47%	24%	NR
Vomiting	NR	5%	31%	13%	3%
Diarrhea	16%	10%	19%	9%	NR
Headache	11%	10%	17%	8%	6%

Weight decrease	3%	3%	3%	7%	NR
Abdominal pain	8%	NR	13%	5%	NR
Agitation	7%	NR	NR	NR	NR
Rhinitis	8%	NR	4%	4%	NR

[a]Caution is urged in making comparisons between drugs based on these data, as different clinical trials often collect adverse event data using different methodologies.
NR, not reported.
Data from Product Information tacrine, donepezil, galantamine, memantine, and rivastigmine.[34–38]

Adverse reactions associated with memantine include: constipation, confusion, dizziness, headache, coughing, and hypertension. These adverse effects are similar to those experienced with ChE inhibitors. Extra monitoring should be done if memantine is given concurrently with a ChE inhibitor.

In vitro studies have shown that memantine produces minimal inhibition of CYP450 enzymes CYP1A2, 2A6, 2C9, 2D6, 2E1, and 3A4. These data indicate that no pharmacokinetic interactions with drugs metabolized by these enzymes should be expected.[38]

Non-conventional Pharmacologic Treatment

❻ *Many other non-conventional treatments have been used as adjunctive treatments during the course of Alzheimer's disease.* Vitamin E has often been recommended for use as an adjunctive treatment because of its antioxidant properties.[39] It has potential effectiveness, a favorable side-effect profile, and low cost. The maintenance dose of vitamin E should be titrated to 1000 International Units twice daily. However, a recent meta-analysis suggests that high doses (greater than 400 International Units per day) of vitamin E should be avoided due to an increased all-cause mortality.[40] Estrogen has been investigated for use in AD, but as mentioned previously, was associated with an increased risk of dementia. Non-steroidal anti-inflammatory drugs (NSAIDs) have also been investigated for their place in the therapy of Alzheimer's disease. There is a lack of convincing data and significant adverse effects (gastritis and gastrointestinal bleeds) associated with their use, so they are not recommended for general use in the treatment or prevention of AD at this time.[41] Statins (3-hydroxy-3-methylglutaryl-CoA reductase inhibitors) should be reserved for those patients who have other indications for their use.[42] Ginkgo biloba has also been studied for its potential use in AD. Until this product has more standardized manufacturing and long-term use is investigated, it should be recommended with caution.[43]

Treatment for Behavioral Symptoms

❼ *Treatment of behavioral symptoms should begin with nonpharmacologic treatments, but may also include antipsychotic agents and/or antidepressants.* Nonpharmacologic recommendations for treatment include:[44]

- Music
- Videotapes of family members
- Audio tapes of the voices of caregivers
- Walking and light exercise
- Sensory stimulation and relaxation

The atypical antipsychotics are the preferred agents for the treatment of psychosis (hallucinations, delusions, and suspiciousness) and the disruptive behaviors (agitation and aggression) of Alzheimer's disease. Double-blind, controlled trials support the efficacy of risperidone and olanzapine in reducing the rate of psychosis and agitation.[45–47] Risperidone should be initiated at 0.25 mg/day and titrated in 0.25 to 0.5 mg/day increments to 1 mg/day, with a maximum dose of 2 mg/day.[45,46,48] Olanzapine has been studied with modest results at doses of 5 to 10 mg/day, and 15 mg/day has not shown to be any better than placebo.[47]

In April 2005, the Food and Drug Administration (FDA) issued a statement requesting black-box warnings on all atypical antipsychotics stating that elderly people with dementia-related psychosis treated with an atypical antipsychotic are at an increased risk of death compared to those treated with placebo. Of a total of 17 placebo-controlled trials investigating olanzapine, aripiprazole, quetiapine, and risperidone in elderly demented patients with behavioral disorders, 15 showed a numerical increase in mortality in the drug-treated group compared to the placebo-treated groups (1.6 to 1.7 times increased risk of death). Specific causes for these deaths were heart-related events (heart failure and sudden death) and infections (mostly pneumonia). The atypical antipsychotics are not currently approved for the treatment of elderly patients with dementia-related psychosis.

Differentiating between depression and dementia can be difficult, so symptoms of depression should be documented for several weeks prior to initiating therapy for the treatment of depression with AD. Citalopram and sertraline are recommended as first-line agents because of their efficacy in placebo-controlled trials.[49] Indications for the use of antidepressants include depression characterized by poor appetite, insomnia, hopelessness, anhedonia, withdrawal, suicidal thoughts, and agitation.

Other miscellaneous therapies for AD include benzodiazepines for anxiety, agitation, and aggression. However, their routine use is not advised.[28] Additionally, benzodiazepines have been associated with an increase in falls leading to the potential for hip fractures in the elderly.[50] Buspirone has shown benefit in treating agitation and aggression in a limited number of patients with minimal adverse effects.[51,52] In open-label and controlled studies, selegiline decreased anxiety, depression, and agitation.[53,54] Finally, trazodone has been shown to decrease insomnia, agitation, and dysphoria, and has been used to treat sundowning in Alzheimer's patients. Figure 32–2 also provides a treatment algorithm for the behavioral symptoms of Alzheimer's disease.[31]

PHARMACOECONOMIC CONSIDERATIONS

❽ *Delaying disease progression through pharmacotherapy can reduce the total cost of treating AD and delay nursing home placement.* Studies with donepezil, rivastigmine, and galantamine have predicted decreases in total costs of AD therapy and delayed nursing home placement.[55–58] A placebo-controlled trial with memantine also reported cost savings and a lower

incidence of institutionalization than in the placebo group.[59] Although these studies show a reduced cost of treating AD, the true cost-effectiveness of these therapies has yet to be established. Further prospective pharmacoeconomic trials of longer duration and more comprehensive cost analysis are needed to determine the position of pharmacotherapy in the treatment of Alzheimer's disease.

OUTCOME EVALUATION

- The success of therapy is measured by the degree to which the care plan decreases the pretreatment deterioration rate, preserves the patients' functioning, and treats psychiatric and behavioral symptoms. The primary outcome measure is thus subjective information from the patient and the caregiver, although the MMSE can be a helpful tool for monitoring changes in the severity of illness. There are no physical examination or laboratory parameters that are used to evaluate the success of therapy.
- Once a tolerated agent is found, continue that therapy until poor tolerance or compliance occurs, no clinical improvement is seen with 3 to 6 months of optimal dosing, or the pretreatment deterioration rate continues. Inform the patient and the caregiver that the treatments available for Alzheimer's disease are not curative, but may slow the deterioration rate of the patient.
- Treat behavioral and psychiatric issues as they arise. Consider the patient's choices of nonpharmacologic and pharmacologic options before recommending a treatment. Discontinue the pharmacologic treatments periodically to re-evaluate the need for continued treatment.
- Develop a plan to assess the effectiveness of the cholinesterase inhibitor in slowing the deterioration of the patient after an appropriate interval (3 to 6 months). Assess improvement in quality-of-life measures such as ability to function independently and for slowing of memory deterioration. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions at appropriate intervals. Continue to be a resource for the patient and caregiver throughout the long course of the disease.

SUMMARY

Alzheimer's disease is a progressive deterioration of cognitive abilities, and patients are likely to have behavioral disturbances and personality changes in the later stages of the disease. Additionally, the disease can be extremely taxing on the patient and caregiver and be very costly to both the family members and society. In an effort to help prepare patients and their caregivers for the inevitable, the Alzheimer's Association has developed ten quick tips on "Living with Alzheimer's disease" (Table 32–7).[60] Although there are many resources available for patients, caregivers affected by AD, and health care professionals, the Alzheimer's Association stands out as the organization that can provide many resources as well as facilitate contacts with other organizations. Contact the association at:

Alzheimer's Association
Contact Center: 1.800.272.3900
TDD Access: 1.312.335.8882

E-mail: info@alz.org
National Office: 225 N. Michigan Ave., Fl. 17
Chicago, IL 60601–7633

Patient Care and Monitoring

1. Assess the frequency and duration of the patient's cognitive and non-cognitive symptoms. Could the patient be depressed?
2. Review any available diagnostic data from the medical and psychiatric history including interviews from family, neuropsychological testing, and other labs.
3. Obtain a thorough history of prescription, non-prescription, and natural drug product use. Is the patient taking any medications that could contribute to cognitive changes in the elderly?
4. Educate both the patient and caregivers about lifestyle modification and refer them to support when needed.
5. Monitor pharmacotherapy initiation. Is it titrated correctly?
6. Develop a plan to monitor cognitive response to treatment over time.
7. Routinely assess medication compliance.
8. Educate patient and caregivers on what to expect from pharmacotherapy.
9. Regularly evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug-drug and drug-disease interactions.
10. Be a resource and give continuous support to the patient and caregivers throughout the long course of the disease.

TABLE 32–7. Living with Alzheimer's Disease: Ten Quick Tips

1. Carry with you a book of important notes and photos.
2. Enroll in Alzheimer's Association Safe Return®.
3. Be open to accepting help from others.
4. Keep doing the things you most enjoy.
5. Talk to others who have Alzheimer's.
6. Find ways to laugh as often as you can.
7. Maintain your physical health.
8. Take steps to make your home safe.
9. Extend the time you can live safely in your home with help from your family and friends.
10. Put plans in place now for your future.

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Identify the extent of abuse of and dependence on commonly used drugs in different segments of the United States population.
2. Explain the commonalities of action of abused substances on the reward system in the brain.
3. Identify the typical signs and symptoms of intoxication associated with the use of alcohol, opioids, cocaine/amphetamines, and cannabis, and determine the appropriate treatment measures to produce a desired outcome following episodes of intoxication.
4. Determine when a patient meets criteria for substance dependence.
5. Describe the different approaches to treating drug withdrawal, and identify the circumstances in which each of these different approaches would be most appropriate.
6. Recognize when long-term maintenance therapy is indicated for an opioid addict, and describe how to choose and initiate a maintenance regimen.
7. Determine which nonpharmacologic therapies should be used, either alone or in combination with pharmacologic treatments, to foster a recovery from addiction.
8. Recommend a comprehensive treatment and monitoring program to establish lifestyle changes that help maintain sobriety and prevent relapse.

Key Concepts

❶ Virtually all abused substances appear to activate the same brain reward pathway.

❷ While activation of the reward pathways explains the pleasurable sensations associated with acute substance use, chronic use of abused substances resulting in both addiction and withdrawal may be related to neuroadaptive effects occurring within the brain.

❸ Individuals with a pattern of chronic use of commonly abused substances should be assessed to determine if they meet Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) criteria for substance dependence (addiction).

❹ The treatment goals for acute intoxication of ethanol, cocaine/amphetamines, and opioids include (1) management of psychological manifestations of intoxication, such as aggression, hostility, or psychosis, and (2) management of medical manifestations of intoxication such as respiratory depression, hyperthermia, hypertension, cardiac arrhythmias, or stroke.

❺ The treatment goals for withdrawal from ethanol, cocaine/amphetamines, and opioids include: (1) a determination if pharmacologic treatment of withdrawal symptoms is necessary, (2) management of medical manifestations of withdrawal such as hypertension, seizures, arthralgias, and nausea, and (3) referral to the appropriate program for substance abuse treatment.

❻ To facilitate recovery from addiction it is necessary to utilize a comprehensive biopsychosocial assessment that includes the motivation for change. Pharmacologic treatments are always adjunctive to psychosocial therapy.

❼ While pharmacologic agents may help prevent relapse, psychotherapy should be the core therapeutic intervention. Motivational enhancement therapy (MET), cognitive-behavioral therapy (CBT), 12-step facilitation (TSF), behavioral couples therapy (BCT), community reinforcement approaches, and contingency management are the best-studied forms of psychotherapy in this group of patients.

❽ Certain pharmacologic agents have been helpful in the treatment of withdrawal and in drug maintenance programs.

⑨ A major component of successful treatment of addiction is to continue monitoring the use of medications such as disulfiram, naltrexone, or acamprosate, which are designed to decrease craving or to block the hedonic effects of abused substances. Also, it is important to identify a mechanism for long-term support of sobriety that might be appropriate for a specific individual such as Alcoholics Anonymous, a spiritual group, or professional recovery programs for professionals such as doctors, nurses, and police officers.

Substance abuse and dependence are highly prevalent problems in the United States and in the world. In the United States the use of all substances of abuse has undergone a series of periodic cycles of societal tolerance or condemnation. As an example, cocaine was first isolated from coca leaves in 1860 by a chemistry graduate student in Germany. Its use was advocated by many in the medical establishment until around the mid-1890s when it became evident that chronic use of cocaine might be addictive in some individuals and could be associated with deleterious physiologic effects. Its use decreased following restriction of prescribing and dispensing of cocaine in the early twentieth century. Cocaine continued to be abused by a small segment of the population, but by and large, much of the medical community seemed to forget the earlier cocaine epidemic. By the late 1970s, at least one pharmacology textbook indicated that cocaine was not addictive. Unfortunately, in the 1980s a smokeable formulation of cocaine (crack) became available, and cocaine use again became an epidemic. The cyclic nature of substance abuse is common to many drugs, including heroin and marijuana, in addition to cocaine.

The abused substances covered in this chapter include: nicotine, alcohol, cocaine, amphetamines, cannabis, and opioids. While many more substances can be and have been abused, these drugs are among the most popular.

EPIDEMIOLOGY

In the United States the federal government annually conducts the National Survey on Drug Use and Health, using a sample of persons who are 12 years of age or older to determine the prevalence of licit and illicit drug use.[1] In 2004, 7.9% of the American population (12 years of age and older) had used an illicit drug within the previous month. Fifty percent of the population currently used alcohol, and 6.9% were heavy users. Tobacco use has declined in recent years from a high of 42% in 1965 to a rate of 29.2% in 2004. Unfortunately, use in the younger age groups remains high. In 2004 39.5% of Americans in the 18- to 25-year-old range reported using cigarettes within the previous month. The trends in prevalence of use for eighth, tenth, and twelfth graders are shown in Fig. 33–1. The use of any illicit drug and of marijuana have both decreased since 1999, and this decrease seems to be correlated with an increase in the perceived risk for using marijuana, cigarettes, heroin, and alcohol among 8th graders.[2]

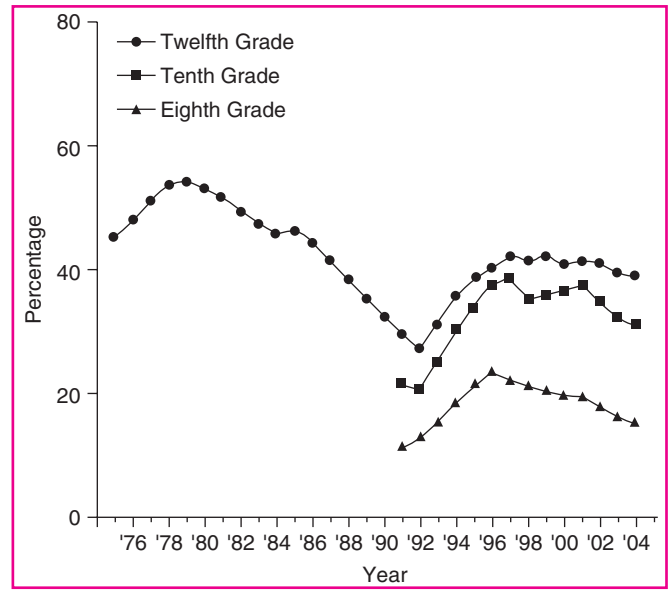

FIGURE 33–1. Trends in illicit drug use in eighth, tenth, and twelfth graders from the Monitoring the Future Survey. Data from reference 2.

While initiation of the use of substances is often in middle and high school, chronic use may be established in young adulthood. The National Alcohol Epidemiologic Survey reported that 16.2% of its 18- to 29-year-old sample met criteria for alcohol abuse or dependence.[3]

The association of substance abuse with emergency department (ED) visits in 21 different metropolitan areas in the United States is reported by the Drug Abuse Warning Network (DAWN). This survey tracks ED visits that are due to a condition induced by or related to drug use. Included in the data are ED visits associated with alcohol, alone and in combination with other substances of abuse, including cocaine, heroin, marijuana, and major stimulants. Figure 33–2 indicates the number of ED visits that are associated with illicit

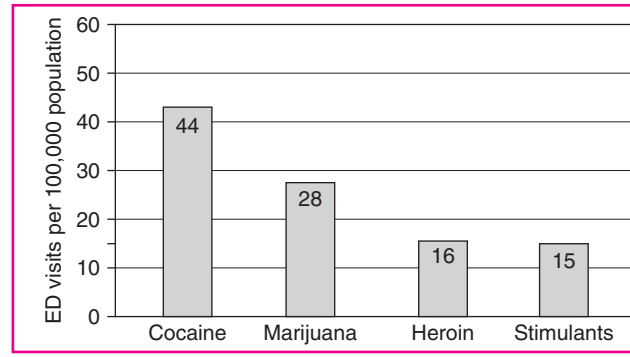

FIGURE 33–2. Emergency department visits associated with illicit drugs for the third and fourth quarters of 2003. Data from reference 4.

drugs per 100,000 people in the population. Abuse of alcohol in combination with other substances ranged from 69 to 75 per 100,000 in each 4-year age subpopulation range from the ages of 18 to 44. The rate dropped to 59 per 100,000 for the 45- to 54-year-old group, and down to 15 for those 55 to 64, and further to 3 per 100,000 population for the 65 and over age group.[4]

The results of these surveys indicate that substance abuse is wide ranging, begins early, and is associated with a considerable number of medical emergencies.

PATHOPHYSIOLOGY

Reward Pathway

Abused drugs generally produce pleasant effects that are desired by the user. However, while most individuals will experience these pleasant effects, not everyone abuses these drugs, and not everyone who abuses them becomes dependent on them. Why some persons abuse drugs while most people do not is a complex area of research. It appears that genetic, environmental, and cultural factors may all interact to predispose some individuals to substance abuse and subsequent dependence. The initial hedonic experiences secondary to use of drugs appear to be primarily due to their ability to activate the primary reward circuits in the brain. These same reward circuits operate under normal circumstances to reinforce certain activities that promote survival, such as food, social affiliation, or sexual activity.

❶ *Virtually all abused substances appear to activate the same brain reward pathway.* Key components of the reward pathway are the dopamine (DA) mesocorticolimbic system that projects from the ventral tegmental area (VTA) and the nucleus accumbens (NA) to the prefrontal cortex, the amygdala, and the olfactory tubercle (Figs. 33–3 and 33–4).[5] Animal studies indicate that ablation of DA neurons in the NA results in decreases in cocaine self-administration. Although many other neurotransmitters can be involved in activation of the reward system, DA appears to be the final common neurotransmitter of this pathway.[6]

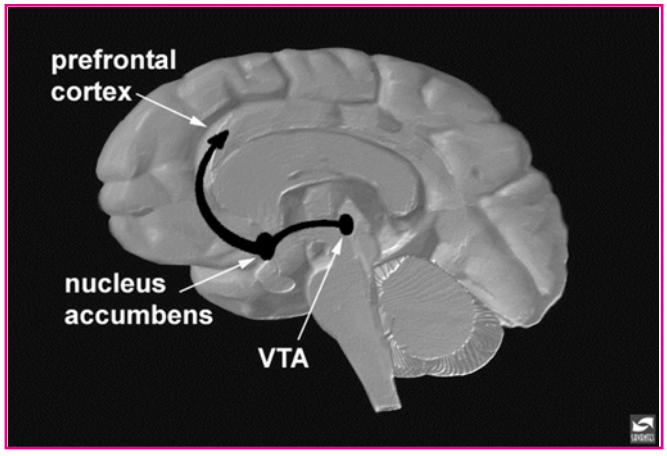

FIGURE 33–3. Location of the dopamine neural tracts associated with the reward system in the brain. Data from reference 5. (From http://www.drugabuse.gov/pubs/Teaching/)

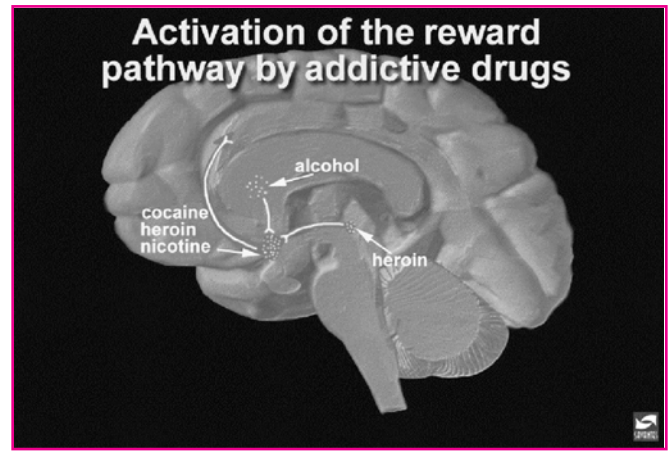

FIGURE 33–4. Where different abused substances interact with the reward system in the brain. Data from reference 5. (From: http://www.drugabuse.gov/pubs/Teaching/)

Cocaine and stimulants, such as amphetamines, probably cause euphoria by blocking the DA reuptake transporter. Additionally, amphetamines also cause the reverse transport of DA into the extracellular space.[6] Although opioids eventually utilize the same circuitry as stimulants, initially they activate μ opioid receptors, in the NA or VTA, which ultimately results in an increase of DA release in the NA. However, reinforcement of opioid use may derive from two mechanisms because in animal studies, when the DA fibers are destroyed, the reinforcing effects of opioids remain.[6] Ethanol probably produces its effects through multiple neurotransmitter pathways. Antagonists of γ-aminobutyric acid (GABA) reverse some of the behavioral effects of ethanol, suggesting that there may be cross-reactivity between benzodiazepines and alcohol, and that alcohol may somehow modulate GABA receptors. Ethanol may activate the DA system indirectly by facilitating the activity of GABA neurons in the pars reticulata, ultimately disinhibiting the VTA DA neurons, resulting in an increase in DA in the NA.[6] There also may be an interaction between serotonin (5-HT) and the reinforcing effects of ethanol, because both 5-HT reuptake inhibitors and 5-HT_{2C} receptor antagonists decrease ethanol intake in animals. However, studies of these drugs that have been conducted in alcohol-dependent humans have not been very promising. Animal studies have indicated that when opioid antagonists are administered to the central nucleus of the amygdala that oral ethanol self-administration will decrease. Studies in humans have noted a modest decrease in alcohol consumption in alcoholics who took a long-acting opioid antagonist (naltrexone) following detoxification. Finally, small doses of ethanol inhibit *N*-methyl-D-aspartate (NMDA) glutamate receptors, and animals

will substitute glutamate receptor antagonists for ethanol, suggesting that they find the effects of the two drugs to be similar. Nicotine also affects the reward pathways by more than one mechanism. In animal studies, either DA antagonists or destruction of DA neurons in the NA decrease nicotine self-administration. Nicotine also interacts with the opioid pathway, because opioid antagonists can precipitate nicotine withdrawal in animals. Finally, marijuana's main active component, tetrahydrocannabinol (THC), binds to cannabinoid-1 (CB_1) receptors resulting in activation of DA neurons in the mesocorticolimbic system. THC also increases the release of DA into the shell of the NA.[6]

Neuronal Adaptation

❷ *While activation of the reward pathways explains the pleasurable sensations associated with acute substance use, chronic use of abused substances resulting in both addiction and withdrawal may be related to neuroadaptive effects occurring within the brain.* Chronic use of drugs of abuse appears to cause a generalized decrease in DA neurotransmission, probably in response to the intermittent increases in DA induced by the frequent use of these drugs. Additionally, with chronic drug use, release of corticotropin-releasing factor (CRF) is increased, indicating an activation of central stress pathways. In vivo microdialysis studies in rats withdrawing from ethanol, cocaine, or THC all showed an increase in extracellular CRF. Also, microinjections of a CRF antagonist into the amygdala reversed some of the anxiogenic behaviors seen during withdrawal.[7]

Two neuroadaptive models have been used to explain how changes in reward function are associated with the development of substance dependence: sensitization and counteradaptation.[7] Sensitization refers to the increased response following repeated intermittent administration of a drug. This is in contrast to the tolerance to drug effects that occurs secondary to continuous exposure to the drug. Sensitization may be akin to the increase in craving a drug after repeated intermittent use of the drug and would facilitate transition from occasional use to compulsive use. Counteradaptation postulates that the initial positive rewarding feelings are followed by the opposing development of tolerance. Since tolerance takes longer to dissipate than the positive rewarding effects, a cycle of escalating drug use ensues. Ultimately, chronic activation of the reward system may result in a depletion of neurotransmitter systems that are overactivated in an effort to maintain response to drugs of abuse. During withdrawal, microdialysis experiments have documented decreases in dopaminergic and serotonergic transmission in the NA. Also seen during alcohol withdrawal are an increase in opioid receptor sensitivity combined with decreased GABAergic and increased NMDA glutamatergic transmission in the accumbens-amygdala pathway. The increase in CRF and concomitant decrease in neuropeptide Y during withdrawal are associated with increases in anxiety and an activation of norepinephrine (NE) pathways, which in turn also activates more CRF release, possibly resulting in an amplification of arousal and stress and maybe even neurotoxic effects if these effects are long-lasting.[7]

With regard to relapse, multiple factors are associated with an increased risk including the availability of the abused drug, an increase in psychological stressors, and a triggering of conditioning factors (cues) such as seeing a white powder or going to a location where drugs were often previously used or obtained. These factors may be acting to trigger residual adaptational changes that occurred in the brain during the period of drug addiction.

OVERALL THEORY OF USE OF PHARMACOLOGIC AGENTS TO TREAT SUBSTANCE ABUSE

Unfortunately, unlike some medical diseases, substance dependence cannot be cured with medications alone. However, we can sometimes alleviate the effects of drug intoxication, attenuate the adverse effects of withdrawal, or use agents that may somewhat decrease craving for, and relapse to, abused substances.

The intoxicating effects of opioids appear to be due to their action as agonists on mu (μ) receptors of the opioid neurotransmitter system. Competitive μ opioid antagonists such as naloxone and naltrexone acutely reverse many of the adverse effects of opioids. To date we do not have specific antagonists for most other abused substances, so rapid pharmacologic reversal of intoxication is usually not possible.

Similarly, reversal of withdrawal syndromes caused by abused substances is not always possible. One pharmacologic solution for reversing a drug withdrawal syndrome, most commonly employed by dependent individuals, is to re-administer the drug that caused the physiologic dependence. The more commonly used clinical method is to administer a medication that has some cross-dependence with the abused drug, but also has fewer of the reinforcing effects and a more predictable pharmacokinetic profile. A good example is the use of benzodiazepines for the withdrawal of ethanol. While benzodiazepines can cause dependence, they are rated as less desirable than ethanol by substance abusers, they cause fewer of the long-term adverse health effects of ethanol, and they are easier to manage medically.

In the case of heroin addiction, maintaining the addict on a regimen of medically managed, orally administered opioids may be preferred over rapidly detoxifying the patient who has a high likelihood of returning to heroin use when extensive strategies for rehabilitation have not been put in place. In order to allow time for psychosocial strategies to help the addicted individual change his or her overall lifestyle, a period of opioid agonist treatment may be indicated. This strategy has been used to maintain addicts on either orally administered μ opioid agonists such as methadone, or partial agonists such as buprenorphine.

No matter which method has been used to facilitate detoxification from the abused substance, addicts have a high risk for reusing substances and manifesting their dependence again. In the long term, the most effective mechanisms for maintaining sobriety are psychosocial strategies rather than pharmacologic ones.

Patient Encounter 1

BB, a 48-year-old man with a history of hypertension, presents to your clinic for follow-up evaluation of his hypertension. You notice that he admits to drinking from one-half to one pint (237–473 mL) of whiskey daily. He says he drinks more on the weekends, but he drinks every day. When you question him about his drinking he says that he doesn't think that it's a problem but admits that his wife has told him he needs to "cut down." He doesn't believe that he is alcohol dependent because on workdays he never drinks before 5 P.M. He admits to having had occasional blackouts.

- What information would suggest that this gentleman might be alcohol dependent?
- What additional information would you need to determine if he meets the criteria for alcohol dependence?

CLINICAL PRESENTATION AND DIAGNOSIS

❸ *Individuals with a pattern of chronic use of commonly abused substances should be assessed to determine if they meet the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) criteria for substance dependence (addiction).*[8] Criteria are not defined for each separate abused substance; rather, a pattern of behavior common to the abuse or dependence of all drugs of abuse is established.

The criteria for abuse indicate an established pattern of using a substance that has resulted in undesirable family, job, or legal consequences, such as recurrent instances of neglecting school, work, or family responsibilities, or being arrested for driving under the influence. However, abuse becomes dependence when tolerance to the drug, withdrawal from the drug, or an inability to discontinue use of the drug is apparent or there is a loss of control over its use or the use has become compulsive. The criteria for substance dependence from the DSM-IV-TR are listed below.

Criteria for Diagnosis of Substance Dependence

A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following, occurring at any time in the same 12-month period:

(1) tolerance, as defined by either of the following:
  (a) a need for markedly increased amounts of the substance to achieve intoxication or desired effect
  (b) markedly diminished effect with continued use of the same amount of the substance
(2) withdrawal, as manifested by either of the following:
  (a) the characteristic withdrawal syndrome for the substance
  (b) the same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms
(3) the substance is often taken in larger amounts or over a longer period than was intended
(4) there is a persistent desire or unsuccessful efforts to cut down or control substance use
(5) a great deal of time is spent in activities necessary to obtain the substance (e.g., visiting multiple doctors or driving long distances), use of the substance (e.g., chain-smoking), or recover from its effects
(6) important social, occupational, or recreational activities are given up or reduced because of substance use
(7) the substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance (e.g., current cocaine use despite recognition of cocaine-induced depression, or continued drinking despite recognition that an ulcer was made worse by alcohol consumption)

specify if:
With Physiological Dependence: evidence of tolerance or withdrawal (i.e., either item 1 or 2 is present); or
Without Physiological Dependence: no evidence of tolerance or withdrawal (i.e., neither item 1 nor 2 is present)
(Reprinted from the Diagnostic and Statistical Manual of Mental Disorders, Copyright 2000, American Psychiatric Association, with permission.)

Intoxication Signs and Symptoms

Euphoria is the one symptom that most drugs of abuse (with the exception of tobacco) have in common. Other signs and symptoms are specific to the particular drug or class of drugs involved. Table 33–1 lists the psychological/behavioral and

Patient Encounter 2

KI, a 27-year-old woman, was admitted to the cardiology unit from the emergency department after she called 911 claiming that she had severe chest pain. Upon arrival in the ED it was noted that her blood pressure was slightly elevated at 143/92 mm Hg, and that she was diaphoretic. She was in otherwise good physical condition, with no previous cardiac history. After a urine toxicology screen was positive for cocaine she admitted that she had smoked several rocks of crack an hour prior to having the chest pain. She said she almost never uses crack, but she's currently really depressed because she has lost her job.

- What are the possible physical signs and symptoms of cocaine use?
- What are the possible psychiatric symptoms associated with cocaine use?

TABLE 33–1. Signs and Symptoms of Drug Intoxication

Drug	Behavioral Effects	Physiologic Effects
Ethanol	Mood lability, inappropriate aggressive or sexual behavior, giddiness or verbally loud, impaired judgment; possibly progressing to somnolence and coma as the blood level increases	*At blood levels of 0.02 g%–0.09 g% (4.34 to 19.5 mmol/L)*: may see some prolonged reaction time and muscular incoordination *At blood levels from 0.1 g%–0.2g% (21.7 to 43.4 mmol/L)*: may see obvious prolonged reaction time, obvious incoordination and ataxia, and mental impairment *At blood levels from 0.2 g% to 0.3g% (43.4 to 65.1 mmol/L)*: marked ataxia, some dysarthria, and possible nausea and vomiting *At blood levels from 0.3 g% to 0.4g% (61.5 to 86.8 mmol/L)*: severe dysarthria, amnesia, and hypothermia *At blood levels from 0.4g%–0.6g% (86.8 to 130.2 mmol/L)*: alcoholic coma often occurs, accompanied by decreased respiration, blood pressure, and body temperature *Blood levels between 0.6 g% and 0.8 g% (130.2 to 173.6 mmol/L)*: are often fatal resulting from respiratory arrest, aspiration of gastric contents, or airway obstruction due to flaccid tongue
Cocaine/ stimulants	Initially, most prominent effect is elated mood, although depression may occur; hypervigilance and anxiety that may progress to panic; with high doses or chronic use, may see impairment of judgment, violence to others or self, paranoia or psychosis with delusions and hallucinations (hallucinations are generally tactile or auditory, rarely visual); an increase in motor activity is common; compulsive or stereotyped behavior (e.g., skin picking) may be seen; severe intoxication may result in a self-limited delirium	*Neurologic*: papillary dilation, headache, tremor, hyperreflexia, muscle twitching, flushing, hyperthermia or cold sweats, seizures, coma, possible cerebral hemorrhage *Cardiovascular*: increased pulse and blood pressure, peripheral vasoconstriction, arrhythmias, myocardial infarction *Gastrointestinal*: nausea and vomiting *Renal*: possible incontinence or renal failure *Neuromuscular*: **rhabdomyolysis**, possibly resulting in renal failure
Opioids	Euphoria and sedation are the most prominent effects; analgesia is also prominent; slurred speech, and impaired memory and attention can be seen along with psychomotor retardation	Nausea and vomiting; respiratory depression that is dose-related and may progress to coma; constipation is very common in chronic users, itching, miosis (pinpoint pupils)
Cannabis	Euphoria or giddiness and increase in appetite may occur; depending on the social setting and the amount ingested, may see panic, paranoia, hallucinations, depersonalization or delirium	*Ocular* effects include conjunctival reddening, a slight miosis, and decreased intraocular pressure *Cardiovascular*: tachycardia and vasodilation combined with orthostatic hypotension in high doses *Neuromuscular*: decreased muscular coordination may be seen; *Gastrointestinal/genitourinary*: dry mouth is common and urinary retention may occur in some persons

Data from references 9, 10, and 11.

physiologic effects of intoxication with ethanol, cocaine and amphetamines, opioids, and cannabis.[9–11]

Withdrawal Signs and Symptoms

Though most abused drugs can cause some degree of physiologic dependence, the severity of withdrawal varies considerably among these drugs. Table 33–2 lists the common withdrawal symptoms seen upon abstinence from drug use.[9–12]

TREATMENT OF INTOXICATION SYNDROMES

❹ *The treatment goals for acute intoxication due to ethanol, cocaine/amphetamines, and opioids include: (1) management of*

TABLE 33–2. Signs and Symptoms of Drug Withdrawal

Drug	Duration	Symptoms
Ethanol	As ethanol level decreases	Vivid dreams, insomnia
	Within 6–24 hours	Tremor, nausea and vomiting, tachycardia (greater than 110 bpm), hypertension (greater than 140/90 mm Hg)
	6–48 hours	Convulsions (usually 1–2 grand mal–type, but they can be more numerous and possibly fatal)
	Days 3–5	Delirium tremens
	Onset at any time	Hallucinations, usually visual
Cocaine/ amphetamine	Immediately following binge	Stimulant craving, accompanied by intense dysphoria, depression, anxiety, agitation
	Within 1–4 hours	Desire for sleep, dysphoria continues
	Days 3–4	Hypersomnia, increased appetite, craving may dissipate slightly, but returns strongly later
Opioids	For shorter-acting opioids (e.g., heroin, morphine, hydrocodone, oxycodone) withdrawal may begin within 6–24 hours following the last dose and last for about 1 week; with longer-action opioids (e.g., methadone) it may take up to 2–4 days for withdrawal to emerge, and it will last longer	*Gastrointestinal*: nausea and vomiting, diarrhea, and dehydration *Neurologic/psychologic*: irritability, restlessness, yawning, tremulousness, and twitching *Cardiovascular*: increase in heart rate, blood pressure *Musculoskeletal*: chills, increased body temperature, piloerection, rhinorrhea *Ocular*: lacrimation and dilated pupils
Nicotine	Within 24 hours of cessation of use	The severity of symptoms reflects the degree and duration of nicotine use; symptoms include anxiety, irritability, frustration, anger, craving, difficulty concentrating, decreased heart rate, and increased appetite
Cannabis	Withdrawal is not usually noticeable, except in heavy, chronic marijuana users; withdrawal occurs within 24 hours, peaks in 2–4 days and resolves in 1–2 weeks	Symptoms are generally mild and reflect the degree and duration of dependence; symptoms include irritability, insomnia, restlessness, anorexia, diaphoresis, diarrhea, and muscle twitches; mild increases in heart rate and blood pressure may also occur

Data from references 9, 10, 11, and 12.

psychological manifestations of intoxication, such as aggression, hostility, or psychosis, and (2) management of medical manifestations of intoxication such as respiratory depression, hyperthermia, hypertension, cardiac arrhythmias, or stroke. In all cases of intoxication associated with a substance use disorder (abuse or dependence), referral to and participation in substance abuse treatment following acute treatment for intoxication is desirable.

Alcohol Intoxication

Most cases of mild to moderate intoxication with alcohol, as well as cases in which blood alcohol levels (BALs) are at the lower limits of legal intoxication (80 to 100 mg%, 0.08 to 0.1% or 17.4 to 21.7 mmol/L), do not require formal treatment. Such intoxications are characterized by mood lability, loud or inappropriate behavior, slurred speech, incoordination, or unsteady gait.

Providing a safe environment and supportive reassurance until the effects of alcohol have worn off is sufficient in most cases. At more severe levels of intoxication, confusion, stupor, coma, and death may be observed. In nontolerant individuals, confusion, depressed consciousness, and vomiting are observed at BALs of 200 to 300 mg% (0.2 to 0.3%, or 43.4 to 65.1 mmol/L); stupor and coma are seen with BALs exceeding 300 to 400 mg% (0.3 to 0.4%, or 65.1 to 86.8 mmol/L). Death may occur at levels of 400 mg% (0.4% or 86.8 mmol/L) or higher from cardiac arrhythmias or respiratory depression. Thus, the most important physiologic goal of treating high levels of intoxication is maintaining cardiopulmonary functioning, including the prevention of aspiration. Accordingly, vital signs must be monitored regularly. Serial BALs at least hourly are strongly recommended, and patients should not be allowed to leave the treatment setting on their own while legally intoxicated (greater than or equal to 80 mg% [0.8% or 17.4 mmol/L]). Initially, BALs may continue to rise if gastrointestinal absorption is still occurring. Otherwise, the BAL generally decreases at a rate of 15 to 20 mg% (0.015 to 0.02% or 3.3 to 4.34 mmol/L) per hour. Although more tolerant individuals may not show the same level of symptoms for a given BAL as non-tolerant individuals, behavioral tolerance and tolerance for vital physiologic functions may differ. Thus, alcoholic patients who are awake and alert at a BAL greater than or equal to 400 mg% (0.4% or 86.8 mmol/L) may still be at risk for cardiopulmonary instability and collapse.

Other causes of confusion, stupor, or coma must be ruled out, because alcohol-intoxicated individuals commonly combine alcohol with other substances, sustain head and other injuries, and have vitamin deficiencies and electrolyte abnormalities. If consciousness is impaired, then thiamine should be given intravenously or intramuscularly at 100 mg daily for at least 3 days. Patients may also develop adverse interactions between alcohol and medications that have been prescribed, including disulfiram. See Table 33–3 for a listing of drug-drug interactions.[13–15] If hypoglycemia is suspected, then thiamine administration should precede administration of glucose-containing fluids to prevent precipitation of an acute Wernicke's syndrome.

Behaviorally, patients may insist on driving, become physically aggressive and agitated, or otherwise become a danger to self or others. Indeed, most suicidal behaviors among alcohol-dependent individuals occur while intoxicated. In such cases, the desired outcomes are appropriate management of medical problems, prevention of harmful behaviors, and stabilization of mood. Less commonly, agitation may require treatment with haloperidol such as 5 to 10 mg by mouth every 2 to 4 hours, or 5 mg either intravenously (IV) or intramuscularly (IM) every 1 to 2 hours. Antipsychotics, however, may lower the seizure threshold and are best avoided. Sedation with benzodiazepines has been used in some cases, but the risk of respiratory depression when mixed with the alcohol already in the patient's system can be dangerous if not fatal.

There are no available medications that can fully reverse the effects of alcohol intoxication. Caffeine and other stimulants can induce arousal and alertness, but they are less effective at reversing the poor judgment and motor incoordination that are vital for complex tasks such as driving. Thus, stimulants are neither indicated nor a viable option to make driving safe. Flumazenil (Romazicon®) reverses the effects of benzodiazepine agonists at GABA receptors, which mediate some of alcohol's effects, but alcohol also acts on many other neurotransmitter systems making flumazenil generally ineffective in reversing alcohol intoxication.

Stimulant Intoxication (Cocaine and Amphetamines)

The desired outcomes of the treatment of stimulant intoxication are appropriate management of medical and psychiatric problems. Medical problems include hyperthermia, hypertension, cardiac arrhythmias, stroke, and seizures. Some medical problems are related to route of administration such as nosebleeds with intranasal administration and infections with intravenous administration. Psychiatric effects include anxiety, irritability, aggression, and psychosis. Psychosis may take the form of tactile hallucinations (such as the sensation of bugs crawling under one's skin, aka formication), visual hallucinations (usually simple geometric shapes), and most commonly auditory hallucinations, as well as paranoia or delusions of grandeur. Cocaine is short-acting, and a single dose of a benzodiazepine sedative-hypnotic may be sufficient treatment for anxiety reactions. Depending on the half-life of the benzodiazepine, one or more sequential doses may be required for amphetamine intoxication. Because stimulants are commonly used in combination with alcohol or opioids, benzodiazepines could increase their sedative and respiratory depressant effects, so a comprehensive drug history and urine drug screen should be obtained. In a small percentage of patients, benzodiazepines can cause paradoxical activation and aggression. Thus, antipsychotics may be needed. Antipsychotics are definitely indicated when psychosis is present, and the psychosis usually responds quite rapidly in the absence of other co-occurring psychiatric disorders.

Opioid Intoxication

The word opioid is used to refer to the overall class including the semi- and fully-synthetic agents, but the word "opiate" only refers to the naturally occurring opioids such as heroin, opium, and morphine.

Patients who are acutely intoxicated with an opioid usually present with **miosis**, euphoria, slow breathing and slow heart rate, low blood pressure, and constipation. Seizures may occur with certain agents such as meperidine (Demerol®). It is critically important to monitor patients carefully to avoid cardiac/respiratory depression and death from an excessive dose of opioids. One strategy is to reverse the intoxication by utilizing naloxone (Narcan®) 0.4 to 2 mg IV every 2 to 3 minutes up to 10 mg. Alternatively, the IM/SC route may be used if IV access is not available. Because naloxone is shorter-acting than most abused opioids, it may need to be readministered at periodic intervals; otherwise the patient could lapse into cardiopulmonary arrest after a symptom-free interval of reversed

TABLE 33–3. Drug Interactions with Abused Drugs or Drugs Used to Treat Drug Abuse

Drug	Interacting Drug	Type of Interaction and Appropriate Action
Amphetamine	Monoamine oxidase inhibitors (phenelzine, tranylcypromine, *possibly linezolid*)	Pharmacodynamic interaction resulting in an increase in blood pressure; possibly resulting in a hypertensive emergency or stroke; avoid this combination.
	Sodium bicarbonate	Sodium bicarbonate increases renal tubular reabsorption of amphetamine, resulting in a prolonged amphetamine elimination half-life; be aware of this combination.
Buprenorphine	There are currently no reported drug interactions with buprenorphine; however, buprenorphine is metabolized primarily by CYP3A4	*Theoretically* buprenorphine metabolism could be inhibited by itraconazole, ketoconazole, grapefruit juice, and erythromycin or any other CYP3A4 inhibitor; the effects may be greater than expected for the dose of buprenorphine being given; may need to decrease buprenorphine dose. Conversely buprenorphine metabolism could by increased by carbamazepine, phenytoin, St. John's wort, efavirenz, and nevirapine, or any other CYP3A4 inducer; the effects may be less than expected; may need to increase buprenorphine dose.
Cigarette smoking	Clozapine	Cigarette smoking induces CYP1A2; increasing the metabolism of clozapine; may need to increase usual clozapine dose when a patient begins to smoke, or decrease clozapine dose if smoking is stopped or nicotine replacement is used instead of smoking.
	Olanzapine	Similar interactions as clozapine; may need to increase the usual olanzapine dose when a patient begins to smoke, or decrease olanzapine dose if smoking is stopped or nicotine replacement is used instead of smoking.
	Theophylline	Theophylline is also a CYP1A2 substrate; may need to increase the usual theophylline dose when a patient begins to smoke, or decrease the theophylline dose if smoking is stopped or nicotine replacement is used instead of smoking.
Clonidine	Amitriptyline, imipramine, desipramine (also likely with nortriptyline, doxepin, protriptyline, and trimipramine)	Pharmacodynamic interaction; clonidine acts as an agonist at α_2-receptors, and these TCAs block this receptor to varying degrees; the result is an increase in blood pressure; either avoid this interaction by choosing another antidepressant or increase the dose of clonidine.
	Cyclosporine	Clonidine may increase cyclosporine blood levels; although only a single case report supports this, it would be prudent to monitor cyclosporine blood levels in a patient receiving clonidine.
	Mirtazapine	This interaction is the same as the one when clonidine is combined with TCAs; however, mirtazapine is a more potent α_2-receptor blocker than the TCAs; avoid this interaction and choose an alternative antidepressant without α_2-blocking effects.
Disulfiram	Benzodiazepines (including alprazolam, chlordiazepoxide, diazepam, flurazepam, halzepam, prazepam, triazolam)	Disulfiram inhibits CYP enzymes 1A2, 2C9, and 3A4; many benzodiazepines are metabolized via these pathways; lorazepam, temazepam, and oxazepam are NOT metabolized via the CYP450 system and are reasonable alternatives. Otherwise, if benzodiazepines are combined with disulfiram the pharmacologic effect may be greater than expected, and the dose of benzodiazepine may need to be lowered.
	Cocaine	Disulfiram decreases the clearance of cocaine from the body; may see increased or prolonged cocaine effects with this combination.
	Isoniazid	The addition of disulfiram to isoniazid therapy has resulted in changes in affect and behavior and decreased coordination; avoid the combination if possible; if they must be given concomitantly, monitor closely.

(*Continued*)

TABLE 33–3. Drug Interactions with Abused Drugs or Drugs Used to Treat Drug Abuse (*Continued*)

Drug	Interacting Drug	Type of Interaction and Appropriate Action
	Phenytoin	Disulfiram decreases the metabolism of phenytoin, resulting in higher phenytoin levels; the dose of phenytoin will need to be reduced; since phenytoin undergoes nonlinear metabolism it is difficult to predict the magnitude of increase in blood levels that could be seen; it is best to avoid this interaction if possible; otherwise, closely monitor phenytoin blood levels.
	Theophylline	Disulfiram inhibits CYP1A2, resulting in an increase in theophylline blood levels; monitor theophylline blood concentration; may need to decrease theophylline dose.
	Warfarin	Disulfiram inhibits several of the enzymes responsible for warfarin metabolism; increased PT/INR have been noted; if disulfiram is added to warfarin therapy, carefully monitor PT/INR; the warfarin dose will probably have to be decreased.
Ethanol	Acetaminophen	Chronic ethanol use increases the risk of hepatotoxicity when acetaminophen is used in high doses; however, acute ingestion of alcohol along with an acetaminophen overdose decreases the toxicity of acetaminophen.
	Cefamandole, cefoperazone, cefotetan, and moxalactam, metronidazole	A disulfiram-type reaction may occur when these anti-infectives are combined with alcohol; the reaction includes flushing, diaphoresis, tachycardia, headache, and increases in blood pressure; avoid alcohol if these drugs are used.
	Isoniazid	Hepatotoxicity is a higher risk when isoniazid is given to those who chronically drink large amounts of alcohol; avoid isoniazid in this group if possible, otherwise monitor LFTs.
	Methotrexate	Hepatotoxicity is a higher risk when methotrexate is given to those who chronically drink large amounts of alcohol; avoid methotrexate in this group if possible; otherwise monitor LFTs.
	Monoamine oxidase inhibitors	Ethanol DOES NOT interact with MAOIs; however, tyramine may be a component of some aged alcoholic drinks, such as red wines or tap beers; if a reaction occurs, hypertension and a pounding headache are the most likely symptoms; usually white wine is fine (in moderation) and most widely available domestic canned beers do not contain significant amounts of tyramine.
Methadone	Carbamazepine	Carbamazepine is an inducer of CYP3A4 and methadone is primarily metabolized via CYP3A4; if carbamazepine is added to a drug regimen containing methadone, the methadone dose will probably need to be adjusted upward to avoid withdrawal.
	Efavirenz	This HIV drug is a CYP3A4 inducer; efavirenz decreases methadone blood levels and has precipitated withdrawal in opioid-dependent individuals; may need to increase methadone dose.
	Fluconazole	Fluconazole is an antifungal agent that moderately inhibits CYP3A4; when added to a drug regimen containing methadone, higher blood levels have been noted; adjustment of methadone dose should be based on clinical judgment, but a decrease of dose may be necessary. *NOTE: Both itraconazole and ketoconazole are more potent inhibitors of CYP3A4, although interactions have not yet been reported, theoretically, they are very likely to occur, resulting in elevated methadone concentrations.*
	Nevirapine	Nervirapine is an HIV drug that is a CYP3A4 inducer; in a small sample, nevirapine caused a 50% reduction in methadone blood levels, resulting in complaints of methadone withdrawal symptoms in patients receiving methadone maintenance; may need to increase methadone dose in patients who have nevirapine added to their drug regimen.
	Phenobarbital	An inducer of many CYP450 enzymes; may result in complaints of withdrawal symptoms in methadone maintenance patients when added to their drug regimen; may need to increase methadone dose.

TABLE 33–3. Drug Interactions with Abused Drugs or Drugs Used to Treat Drug Abuse (*Continued*)

Drug	Interacting Drug	Type of Interaction and Appropriate Action
	Phenytoin	Similar to phenobarbital; may need to increase methadone dose when phenytoin is added to a methadone maintenance drug regimen to avoid withdrawal symptoms.
	St. John's wort	This herbal remedy may induce CYP3A4; the certainty of an interaction probably rests on the specific preparation being used, but caution would dictate that this herbal product should be avoided in those receiving methadone treatment; withdrawal symptoms have been noted in patients taking methadone maintenance who have added St. John's wort to their drug regimen.

CYP. cytochrome P450 isoenzyme; HIV, human immunodeficiency virus; INR, International Normalized Ratio; LFTs, liver function tests; MAOI, monoamine oxidase inhibitor; PT, prothrombin time; TCA, tricyclic antidepressant.
Data from references 13, 14, and 15.

intoxication. In addition, naloxone can induce withdrawal symptoms in opioid-dependent patients, so patients may awaken feeling quite distressed and agitated. It is also critical to secure the airway and ensure breathing. In some cases intubation and manual/ mechanical ventilation may be required. This is a necessary measure to avoid oxygen desaturation leading to brain **hypoxia** or anoxia that may cause brain damage or death.

Overall, intoxication with any of the substances discussed above is evidence of substance abuse and is strongly suggestive of substance dependence. In all cases it is important to strongly emphasize to the patient that this is an issue that needs to be addressed, and that entry into a treatment program could be very beneficial.

TREATMENT OF WITHDRAWAL SYNDROMES

❺ *The treatment goals for withdrawal from ethanol, cocaine/amphetamines, and opioids include: (1) a determination if pharmacologic treatment of withdrawal symptoms is necessary, (2) management of medical manifestations of withdrawal such as hypertension, seizures, arthralgias, and nausea, and (3) referral to the appropriate program for substance abuse treatment.* The desired outcomes in the treatment of withdrawal syndromes are to ensure patient safety, comfort, and successful transition from treatment of withdrawal to treatment of dependence. Referral to specialized treatment for substance dependence is strongly recommended following treatment for withdrawal syndromes, because treatment of withdrawal is not sufficient to prevent relapse to problematic substance use. Achieving a drug-free state by detoxification and then rehabilitation with a focus on total abstinence is the ideal outcome.

Alcohol Withdrawal

There are four different alcohol withdrawal syndromes, which differ in terms of their pharmacologic treatment and need for hospitalization.

Uncomplicated Alcohol Withdrawal

This is the most commonly observed syndrome, and as the name denotes, is not complicated by seizures, delirium tremens (DTs), or hallucinosis. Symptoms are typically rated using a validated scale such as the Clinical Institute Withdrawal Assessment for Alcohol-Revised (CIWA-Ar; Table 33–4).[16] The recommended CIWA-Ar threshold score for treating uncomplicated alcohol withdrawal with medications on an outpatient basis is between 8 and 10. For patients that score greater than or equal to 15, inpatient treatment should be strongly considered. Patients who score 20 or higher on the CIWA-Ar should always be treated with medications. The risks of not treating high-scoring patients with medications are seizures and DTs, and those with a prior history of seizures or DTs have an increased risk for subsequent episodes. Therefore, when a history of seizures or DTs is positive, the lower threshold of 8 is recommended, and hospitalization is safer than outpatient detoxification. There is some evidence for "kindling" during successive episodes of alcohol withdrawal, such that symptom severity and complications increase with additional withdrawal episodes. Thus, some authors recommend routinely using medications when the CIWA-Ar score is in the 8 to 10 range.

Benzodiazepines are the evidence-based treatment of choice for uncomplicated alcohol withdrawal.[17] Barbiturates are not recommended because of their low therapeutic index due to respiratory depression. Some of the anticonvulsants have also been used to treat uncomplicated withdrawal (particularly carbamazepine and sodium valproate). Although anticonvulsants provide an alternative to benzodiazepines, they are not as well studied and are less commonly used. The most commonly employed benzodiazepines are chlordiazepoxide, diazepam, lorazepam, and oxazepam. They differ in three major ways: (1) their pharmacokinetic properties, (2) the available routes for their administration, and (3) the rapidity of their onset of action due to the rate of gastrointestinal absorption and rate of crossing the blood–brain barrier.

Benzodiazepines can be administered using a symptom-triggered approach when withdrawal signs and symptoms are already present.[18] In this approach, medication is administered every hour when the CIWA-Ar is greater than or equal to 8. For the shorter-acting agents, oxazepam (15 to 60 mg orally) or lorazepam (1 to 4 mg orally) is given, and the CIWA-Ar is repeated hourly after each administration during the first 24 hours until the patient is comfortably sedated. Because of

TABLE 33–4. Clinical Institute Withdrawal Assessment for Alcohol-Revised (CIWA-Ar)

Patient Name _____

Date: _____ Time: _____

Pulse: _____ BP: _____

NAUSEA & VOMITING: Ask "Do you feel sick to your stomach? Have you vomited?" Observation.

0 No nausea and no vomiting
1 Mild nausea with no vomiting
2
3
4 Intermittent nausea with dry heaves
5
6
7 Constant nausea, frequent dry heaves and vomiting

TREMOR: Arms extended and fingers spread apart. Observation.

0 No tremor
1 Not visible, but can be felt fingertip to fingertip
2
3
4 Moderate, with patient's arms extended
5
6
7 Severe, even with arms not extended

PAROXYSMAL SWEATS: Observation.

0 No sweat visible
1 Barely perceptible sweating, palms moist
2
3
4 Beads of sweat obvious on forehead
5
6
7 Drenching sweats

ANXIETY: Ask, "Do you feel nervous?" Observation.

0 No anxiety, at ease
1 Mildly anxious
2
3
4 Moderately anxious or guarded, so anxiety is inferred.
5
6
7 Equivalent to acute panic states, as seen in severe delirium or acute schizophrenic reactions

AGITATION: Observation.

0 Normal activity
1 Somewhat more than normal activity
2
3
4 Moderately fidgety and restless
5
6
7 Paces back and forth during most of the interview, or constantly thrashes about

TACTILE DISTURBANCES: Ask "Have you any itching, pins & needles sensations, any burning, any numbness, or do you feel bugs crawling on or under your skin?" Observation.

0 None
1 Very mild itching, pins & needles, burning or numbness
2 Mild itching, pins & needles, burning or numbness
3 Moderate itching, pins & needles, burning or numbness
4 Moderately severe hallucinations
5 Severe hallucinations
6 Extremely severe hallucinations
7 Continuous hallucinations

AUDITORY DISTURBANCES: Ask "Are you more aware of sounds around you? Are they harsh? Do they frighten you? Are you hearing anything that is disturbing to you? Are you hearing things you know are not there?" Observation.

0 Not present
1 Very mild harshness or ability to frighten
2 Mild harshness or ability to frighten
3 Moderate harshness or ability to frighten
4 Moderately severe hallucinations
5 Severe hallucinations
6 Extremely severe hallucinations
7 Continuous hallucinations

VISUAL DISTURBANCES: Ask, "Does the light appear to be too bright? Is the color different? Does it hurt your eyes? Are you seeing anything that is disturbing to you? Are you seeing things you know are not there?" Observation.

0 Not present
1 Very mild sensitivity
2 Mild sensitivity
3 Moderate sensitivity
4 Moderately severe hallucinations
5 Severe hallucinations
6 Extremely severe hallucinations
7 Continuous hallucinations

HEADACHE, FULLNESS IN HEAD: Ask "Does your head feel different? Does it feel like there is a band around your head?" Do not rate dizziness or lightheadedness. Otherwise, rate severity.

0 Not present
1 Very mild
2 Mild
3 Moderate
4 Moderately severe
5 Severe
6 Very severe
7 Extremely severe

ORIENTATION AND CLOUDING OF SENSORIUM: Ask, "What day is this? Where are you? Who am I?" Observation.

0 Oriented and can do serial additions
1 Cannot do serial additions or is uncertain about date
2 Disoriented for date by no more than 2 calendar days
3 Disoriented for date by more than 2 calendar days
4 Disoriented for place and/or person

Total Score: _____

Rater: _____

Maximum Possible Score: 67

Data from reference 16.

their short half-life, dosing on subsequent days may be needed, and the risk of seizures may possibly (although not definitively proven) be higher. For the longer-acting agents, chlordiazepoxide and diazepam, the symptom-triggered approach is used in combination with another technique known as loading. With the loading technique, chlordiazepoxide at doses of 50 to 100 mg or diazepam (10 to 20 mg) is administered orally at 1-hour intervals during the first 24 hours until the patient is comfortably sedated and the CIWA-Ar score is lower than 4. Due to differences in disposition and metabolism, the absolute amount of benzodiazepine required in the first 24 hours will vary, but the majority of patients will respond to about 400 mg of chlordiazepoxide or 60 mg of diazepam. Some may require higher dosages, but it is important to monitor closely for respiratory depression or excessive sedation. Then loading is stopped, and for the next 24 hours the benzodiazepine is used as needed only if the CIWA-Ar score is greater than or equal to 8, although the long half-lives of these drugs and their active metabolites usually provides a natural taper without further drug administration. The loading technique is especially useful in the hospital, where patients can be medically monitored throughout the day. If vital signs are elevated in the absence of high CIWA-Ar scores, then anti-adrenergic drugs like clonidine or propanolol may be used if there are no contraindications (see Chapter 2, Hypertension).

In contrast to chlordiazepoxide and diazepam, lorazepam and oxazepam are not metabolized into active compounds in the liver. Instead, they are excreted by the kidneys following glucuronidation. This is important because many alcohol-dependent patients have compromised liver function. Therefore, when treatment is initiated before the results of blood tests for liver function are known, as is often the case in outpatient clinics, lorazepam and oxazepam may be preferred. Patients with liver disease may still be treated with diazepam and chlordiazepoxide, but at lower doses. This can be accommodated with the loading technique, although hourly dosing with 5 mg of diazepam or 25 mg of chlordiazepoxide may be sufficient.

Oxazepam is available in oral form only, so it is useful only for uncomplicated withdrawal. Other benzodiazepines are available in injectable form and will be further described below. Diazepam and lorazepam are more lipophilic than chlordiazepoxide and oxazepam, resulting in quicker gastrointestinal absorption and passage across the blood–brain barrier, which makes them valuable in an inpatient setting, especially to treat or prevent seizures. However, their faster onset of action may be associated with feeling high, which can be a disadvantage of their use.

Alcohol Withdrawal Seizures

Alcohol withdrawal seizures (AWS) are a medical emergency and should be treated in an inpatient setting. Withdrawal seizures are usually few in number and generalized. The occurrence of focal seizures or status epilepticus may suggest another etiology. Management consists of keeping the airway open and preventing self-injury during convulsions. Benzodiazepines are the treatment of choice. Intravenous (IV) diazepam 5 to 10 mg is preferred to terminate a seizure in progress if IV access is available. The dose may be repeated in 5 minutes if seizures persist. Alternatively, lorazepam 4 mg may be given IM, followed by insertion of an IV line when convulsive movements have subsided. In the event of a recurrent seizure, lorazepam 2 mg IV may be administered if the patient already received IM lorazepam. Intramuscular use of diazepam or chlordiazepoxide should be avoided because of erratic absorption that complicates the timing of subsequent doses and can result in delayed oversedation. IV benzodiazepines may depress respiration, so they should be administered only when and where advanced cardiopulmonary support is readily available. When the patient becomes conscious enough to take medication orally, then treatment may continue using the loading procedure for diazepam or the symptom-triggered technique for lorazepam as described above. Electrolyte imbalances can contribute to seizures and should be corrected if they exist. IV magnesium sulfate should be given in addition to benzodiazepine treatment. Hypomagnesemia can be corrected with magnesium sulfate 1 g every 6 hours IV for the first day of withdrawal, assuming renal function is intact. Oral replenishment of magnesium may be difficult to accomplish due to resultant diarrhea. As with alcohol intoxication, thiamine should be given IV or IM at 100 mg daily for at least 3 days to prevent precipitation of an acute Wernicke's encephalopathy, although some guidelines recommend higher doses (250 mg daily parenterally for 3 to 5 days) for patients with signs of malnutrition or a history of not eating properly.[19] Still higher doses of thiamine (500 mg three times daily parenterally for at least 2 days followed by 250 mg IM or IV daily for 5 days) have been recommended to treat suspected or diagnosed cases of Wernicke's encephalopathy and to prevent the development of Korsakoff's syndrome.[19] In addition, thiamine administration should always precede administration of any dextrose-containing IV fluids.

Alcohol Withdrawal Delirium (Delirium Tremens or DTs)

Deterium tremens is another medical emergency that requires hospitalization in order to prevent mortality. Parenterally administered benzodiazepines are the treatment of choice.[20] A sample regimen consists of diazepam 5 mg IV (at 2.5 mg/minute) every 5 to 10 minutes until "light somnolence" is achieved, referring to a tendency to fall asleep without stimulation or a light stage of sleep from which the patient is easily awakened. If the first two doses of diazepam are not effective, then 10 mg IV every 5 to 10 minutes can be administered for the third and fourth doses. If still not effective, then up to 20 mg IV may be used thereafter. Once a state of light somnolence is induced, then it should be maintained with diazepam 5 to 20 mg IV every 1 hour as needed. Similarly, lorazepam 1 to 4 mg IV every 5 to 10 minutes or lorazepam 1 to 4 mg IM every 30 to 60 minutes may be given to achieve light somnolence, which is then maintained by similar doses every hour as needed. The antipsychotic haloperidol is given only for severe agitation that is

unresponsive to benzodiazepine therapy. The evidence does not support the use of an antipsychotic as a single agent.[20] Haloperidol may be given as 0.5 to 5 mg IV or IM every 30 to 60 minutes as needed or 0.5 to 5 mg orally every 4 hours as needed. The newer-generation antipsychotic agents have not been studied yet for the treatment of DTs. Thiamine should be given according to the same guidelines described above for AWS.

Alcohol Hallucinosis

Alcohol hallucinosis refers to auditory hallucinations that occur during a clear sensorium, which distinguishes it from DTs, during which hallucinations are associated with a reduced clarity of awareness of the environment. Alcohol hallucinosis is generally treated with oral antipsychotics at usual therapeutic dosages for psychosis.

Stimulant Withdrawal (Cocaine Withdrawal and Amphetamine Withdrawal)

Cocaine and amphetamine withdrawal are grouped together because their symptom profiles as described in DSM-IV-TR[8] are identical, and the physiologic basis of their withdrawal syndromes involves the DA neurotransmitter system. Stimulants of this group also include methylphenidate, but not nicotine and caffeine, which have different neurophysiologic mechanisms of action. Although neurophysiologic alterations underlie the syndrome of stimulant withdrawal, its symptoms are manifested psychologically for the most part as a depressed or dysphoric mood. Consequently, the major adverse complication of stimulant withdrawal is profound depression with suicidal thoughts, and the major goal of treatment is to prevent suicide. Other symptoms that are commonly associated with the mood disturbance include fatigue, sleep disturbance, increased appetite, psychomotor retardation or agitation, and/or vivid dreaming, although these symptoms are neither life-threatening nor require pharmacologic treatment. Therefore, unless suicidality warrants hospitalization, stimulant withdrawal can be treated on an outpatient basis with psychological support and reassurance.

A number of medications have been studied to alleviate symptoms of stimulant withdrawal and the intense craving that may accompany it, but inconsistent results across controlled trials preclude any recommendations for their routine use. Patients with stimulant use disorders should be referred to substance abuse treatment because of the high risk for continued use either during or immediately following stimulant withdrawal.

Opioid Withdrawal

Almost no one dies from opioid withdrawal per se; however, underlying medical complications (e.g., hypertension or recent myocardial infarction) increase the risk of death. Therefore, it is important to manage and stabilize any medical issues (i.e., uncontrolled blood pressure or diabetes, among others), and then determine if hospitalization is appropriate. Patients with underlying medical problems should be evaluated for possible triage to an inpatient detoxification program, to be followed up with substance abuse treatment on either the inpatient or outpatient level. Rapid referral to substance abuse treatment will help "seize the moment" and introduce patients to the concept of recovery while they still vividly remember the negative consequences from abusing substances. Withdrawal from opioids is commonly described by patients as resembling "a bad case of the flu" and symptoms include nausea, vomiting, diarrhea, anxiety, headaches, **mydriasis**, **rhinorrhea**, lacrimation, muscle/bone/joint pain, piloerection, yawning, fever, increased heart rate, and hypertension. The use of clinical withdrawal scales such as Clinical Opiate Withdrawal Scale (COWS),[21] provides high interrater reliability and clinical utility since it is an objective measurement of withdrawal severity. See Table 33–5 for a copy of the COWS instrument. The baseline score helps to make the decision to treat pharmacologically or to observe. A score of less than or equal to 5 is considered very mild, and these patients usually do not require pharmacologic intervention, although they benefit from supportive environment and observation. A score of 5 to 12 is considered mild and 13 to 24 is moderate. Patients with scores in these ranges should be managed with a symptom-based approach (Table 33–6) or initiation of buprenorphine induction/detoxification. A score of 25 to 36 is moderately severe, and greater than 36 is considered severe withdrawal. In severe withdrawal either buprenorphine or a full μ agonist is recommended for detoxification. Methadone is the most commonly used full μ agonist, but under current United States law, methadone detoxification requires referral to a federally approved methadone detoxification program. The two possible options for the treatment of opioid withdrawal in regular clinical settings are symptomatic treatment and μ opioid agonists.

Symptomatic treatment focuses on minimizing the withdrawal symptoms to help patients be as comfortable as possible (Tables 33–6 through 33–8). This is combined with the use of methadone or buprenorphine (Suboxone® or Subutex®) to suppress the withdrawal symptoms by providing a μ opioid full or partial agonist in a tapering dose schedule within a controlled environment.

Treatment with a μ opioid agonist is accomplished with either buprenorphine or methadone. Buprenorphine is a partial agonist at the μ opioid receptors that can be used sublingually. It is available in three formulations, two of which are indicated for the treatment of addiction. Buprenorphine plus naloxone (Suboxone®) in ratio of 4:1 (2 mg/0.5 mg or 8 mg:2 mg) is the recommended formulation unless the patient is pregnant or hypersensitive to naloxone, in which case buprenorphine without naloxone (Subutex®) is recommended. Naloxone was added to the Suboxone® formulation to secure Food and Drug Administration (FDA) approval in the United States. Since naloxone is poorly absorbed when used sublingually but blocks opioid receptors if injected, this combination is designed to minimize diversion of the drug to the street for intravenous use. Only 10% of buprenorphine is bioavailable if it is swallowed, but

TABLE 33–5. Clinical Opiate Withdrawal Scale (COWS)

Patient's Name:_____ Date and Time __/__/____:____
Reason for assessment:_____

Resting Pulse Rate: _____beats/minute
Measured after patient is sitting or lying for one minute
0 pulse rate 80 or below
1 pulse rate 81–100
2 pulse rate 101–120
4 pulse rate greater than 120

Sweating: *over past_hour not accounted for by room temperature or patient activity*
0 no report of chills or flushing
1 subjective report of chills or flushing
2 flushed or observable moistness on face
3 beads of sweat on brow or face
4 sweat streaming off face

Restlessness: *observation during assessment*
0 able to sit still
1 reports difficulty sitting still, but is able to do so
3 frequent shifting or extraneous movements of legs/arms
5 unable to sit still for more than a few seconds

Pupil size
0 pupils pinned or normal size for room light
1 pupils possibly larger than normal for room light
2 pupils moderately dilated
5 pupils so dilated that only the rim of the iris is visible

Bone or joint aches: *if patient was having pain. Previously, only the additional component attributed to opiates withdrawal is scored*
0 not present
1 mild diffuse discomfort
2 patient reports severe diffuse aching of joints/muscles
4 patient is rubbing joints or muscles and is unable to sit still because of discomfort

Runny nose or tearing *Not accounted for by cold symptoms or allergies*
0 not present
1 nasal stuffiness or unusually moist eyes
2 nose running or tearing
4 nose constantly running or tears streaming down cheeks

GI Upset: *over last _hour*
0 no GI symptoms
1 stomach cramps
2 nausea or loose stool
3 vomiting or diarrhea
5 multiple episodes of diarrhea or vomiting

Tremor: *observation of outstretched hands*
0 no tremor
1 tremor can be felt, but not observed
2 slight tremor observable
4 gross tremor or muscle twitching

Yawning: *observation during assessment*
0 no yawning
1 yawning once or twice during assessment
2 yawning three or more times during assessment
4 yawning several times/minute

Anxiety or irritability
0 none
1 patient reports increasing irritability or anxiousness
2 patient obviously irritable or anxious
4 patient so irritable or anxious that participation in the assessment is difficult

Gooseflesh skin
0 skin is smooth
3 piloerection of skin can be felt or hairs standing up on arms
5 prominent piloerection

Total Score:_____
The total score is the sum of all 11 items

Initials of person
completing assessment: _____

Data from reference 21.

50% is bioavailable via the sublingual route. An IM/IV preparation of buprenorphine is available in the United States (Buprenex®), and its bioavailability reaches 80% if used IM and100% if used IV. The Buprenex® formulation is indicated only for anesthesia and operative pain use, but not detoxification or maintenance of opioid dependence, due to the high risk for abuse and diversion.

To initiate a buprenorphine induction, a patient has to be suffering moderate or severe withdrawal, and the last opioid use should be at least 12 to 24 hours earlier, depending on the half-life of the particular opioid (the longer the half-life, the longer a clinician should wait before initiating buprenorphine induction). The score on the COWS should be greater than or equal to 5, otherwise buprenorphine likely will induce withdrawal since it has high affinity for μ receptors and it will displace any other μ opioid agonist that is present. Also, buprenorphine should not be used in those taking greater than 60 to 80 mg/day of methadone because buprenorphine would have low efficacy; the methadone dose should be decreased below this amount prior to induction of buprenorphine detoxification. Once

TABLE 33–6. A "Symptoms-Based" Treatment Approach for Opioid Withdrawal

This approach includes the use of any single or a combination of two or more of the following agents, depending on the symptoms reported:

a) Clonidine (Catapres®) 0.1–0.2 mg every 6–8 hours blocks the peripheral response and reduces anxiety (shaking, sweating, and piloerection). Patients may be given as-needed doses, maximum dosage not to exceed 1.2 mg in 24 hours. BP should be monitored prior to each clonidine dose in the clinic. Hold if systolic blood pressure is below 85 or diastolic is below 55 mm Hg.

Advantages and Limitations: Clonidine is a non-narcotic agent that effectively reduces opioid withdrawal. However, lethargy, craving, insomnia, and muscle pains are not as well treated as other withdrawal symptoms, and supplemental medications are often necessary. Patients with low blood pressure may require inpatient treatment. Avoid in pregnant patients; they can be treated with buprenorphine (Subutex®, NOT Suboxone®) or methadone in a government-licensed program.

b) Dicyclomine (Bentyl®) at 20 mg orally every 8–12 hours up to 80 mg per 24 hours as needed for abdominal cramps.

c) Loperamide (Imodium®) 2-mg capsules; use 2 capsules by mouth initially, then 1 capsule by mouth as needed for diarrhea (max dose 4 capsules/day).

d) Trimethobenzamide (Tigan®) suppository 200 mg; one per rectum daily as needed for nausea or vomiting to help with stomach contractions and cramping.

e) Non-steroidal anti-inflammatory or analgesic medications (acetaminophen 500 mg—1 g by mouth every 6 hours or ibuprofen 600 mg by mouth every 8 hours or naproxen 600 mg by mouth) for general pain.

f) Benzodiazepines such as lorazepam (Ativan®) by mouth 1 mg every 6–8 hours or oxazepam (Serax®) 15–30 mg every 6–8 hours to help with anxiety and sleep.

Developed by K. Brower and M. Karam-Hage.

withdrawal is established, buprenorphine can be started at 2 to 4 mg every 2 hours with a maximum recommended dose of 8 mg the first day (Table 33–9). The next day, if the patient is still in withdrawal, the first buprenorphine dose should be the total amount required in the previous 24-hour period. Then the dose can be increased gradually every 2 hours up to a maximum of 16 mg. By the third day the dose can be increased up to 32 mg per day to achieve maximum relief of withdrawal symptoms (see Table 33–9 for a typical induction regimen). Then the dose

TABLE 33–7. Sample Regimen of Clonidine for Withdrawal from All Opioids Except Methadone and Fentanyl (Duragesic®) Patches

Day	Clonidine Oral Dosage
1	0.1 mg four times daily
2	0.1 mg four times daily to 0.2 mg three times daily
3–5	Maintain day 2 dose as tolerated
6+	Decrease dose by 0.1–0.2 mg/day; reduce nighttime dose last

Developed by K. Brower and M. Karam-Hage.

TABLE 33–8. Sample Regimen of Clonidine for Withdrawal from Methadone (Up to 20–30 mg/day) or Equivalent Fentanyl (Duragesic®) Patches

Day	Clonidine Oral Dosage
1	0.1 mg four times daily
2	0.1 mg four times daily to 0.2 mg three times daily
3	0.1 mg four times daily to 0.2 mg four times daily
4–10	Maintain on day 3 dose
11+	Decrease by 0.2 mg/day; reduce nighttime dose last

Developed by K. Brower and M. Karam-Hage.

is tapered down gradually to zero within 1 to 2 weeks (a 25% reduction per day is a general rule of thumb). Methadone, can also be used for opioid detoxification; however, in the United States this can be done only at a federally approved methadone clinic. Methadone detoxification regimens will not be covered here. The reader is referred to the literature for additional information.[22]

General Patient Guidelines for Outpatient Opioid Detoxification

When treating opioid withdrawal with pharmacologic agents, patient safety is the highest priority. The first step is to educate patients about the course of withdrawal. Symptoms peak at around 5 to 7 days and may last up to 2 weeks. Patients also need to be advised regarding the side effects of the drugs used to treat detoxification. For instance, clonidine causes dizziness from low blood pressure, sedation (which may impair driving or operating heavy machinery), and dry mouth. There is also an overdose potential if clonidine is mixed with opioids or other central nervous system (CNS) sedatives or antihypertensives. The risk of these adverse events needs to be balanced with potential benefits. The side effects of buprenorphine include constipation (most commonly), sedation, and headaches. It should also be noted that there is a potential for serious overdose when buprenorphine is mixed with benzodiazepines or other sedative-hypnotics. The risk of

TABLE 33–9. Sample Regimen[a] for Buprenorphine Induction Treatment of Opioid Withdrawal

Day	Buprenorphine Oral Dosage
1	2 mg every 2 hours (max 8 mg on first day)
2	Start by total dose of day 1, with additional 2 mg every 2 hours (max 16 mg)
3	Start by total dose of day 2, with additional 4 mg every 2 hours (max 32 mg)
4–5	Maintain on dose required to alleviate withdrawal symptoms
6+	Decrease dose by 25% each day (or less if patient does not tolerate 25%)

[a]For withdrawal from any opioid including fentanyl (Duragesic®) patches. Data from reference 21.

developing physiologic tolerance to buprenorphine is high if it is used for prolonged periods. In this case buprenorphine should be slowly tapered to discontinuation. However, withdrawal from buprenorphine is easier and less severe than withdrawal from a pure agonist such as methadone.

Successful transition from treatment of withdrawal to treatment of opioid dependence in a rehabilitation setting is the most important challenge for a clinician. Patients often think that all they need is detoxification, but this is not the case because a successful outcome is tied to successful rehabilitation and acquiring recovery skills after detoxification. This goal can be accomplished by either achieving detoxification on site during rehabilitation or by quick and seamless transition of the patient from detoxification to a rehabilitation program. The more time that elapses between the two, the greater the likelihood of failure and return to drug use. This transition is especially important for patients who have engaged in ultra-rapid opioid detoxification using naltrexone or naloxone under conscious sedation. These opioid detoxification regimens are experimental and controversial and they are currently considered to be risky procedures due to several reported deaths mainly due to pulmonary edema.[23]

Nicotine Withdrawal

Smoking cessation counseling should be provided to all smokers, and those interested should be directed and assisted to achieve cessation. Furthermore, it is now a standard of practice for clinicians to screen for smoking and provide all smokers with brief advice and assistance with appropriate medications to quit or provide referral to specialized services when needed.[24]

Symptomatic detoxification from nicotine is achieved with any of the currently available nicotine replacement therapies (NRTs) or a combination thereof.[25] Several CNS neurotransmitters are affected by nicotine including DA, NE, 5-HT, glutamate, GABA, and endogenous opioid peptides. In the brain, nicotine activates nicotinic acetylcholine (nAch) receptors, which are part of the neurotransmitter-gated ion channel family and have crucial neuromodulatory roles in the CNS.[26] Nicotine dependence is assessed using the Fagerström Test for Nicotine Dependence, and a score of greater than or equal to 4 is indicative of physical dependence on nicotine.[27] Nicotine withdrawal can be measured using any of the available scales (e.g., the Wisconsin Scale for Nicotine Withdrawal). In the United States, the FDA does not have the authority to regulate tobacco products; however, it does regulate all NRT formulations. Some of the NRTs are prescription only (Rx), and some are available over the counter (OTC); others are available in both forms. The FDA has approved the following NRTs: polacrilex gum (OTC); patches (16- or 24-hour) (Rx and OTC); nasal spray (Rx); buccal inhaler (puffer) (Rx); flavored gum (OTC); and lozenges (OTC). Table 33–10 shows NRT and other smoking cessation products. Non-nicotine medications that are thought to be helpful for craving and maybe even withdrawal from nicotine include sustained-release bupropion (Zyban® or Wellbutrin-SR®), nortriptyline (Pamelor®), clonidine (Catapres®). The sustained-release form of the antidepressant bupropion was approved by the FDA with a new name (Zyban®) for the treatment of tobacco dependence. It is started 1 to 2 weeks before the quit date. It is begun at 150 mg per day for 3 to 7 days and then increased to 300 mg/day (150 mg twice daily). Bupropion blocks reuptake of DA and NE. Additionally, it acts as a noncompetitive antagonist on a high-affinity nAch receptor. It reduces nicotine reinforcement, withdrawal, and craving.[28] Doubling up the NRTs (i.e., double patch or adding NRTs to each other) is a more effective strategy for certain refractory smokers than either strategy used alone.[29] Studies have also

TABLE 33–10. Pharmacotherapies for Smoking Cessation

Medication	Dose Range and Use
Nicotine patch *Transdermal*	7–22 mg/day (started at 21 mg per day × 2 weeks then 14 mg per day × 2 weeks then 7 mg/day)
Nicotine gum *Buccal*	20–40 mg/day; 2 or 4 mg/piece; one piece every 2 hours up to 10 times/day
Nicotine lozenge *Buccal*	20–40 mg/day; 2–4 mg/lozenge; one lozenge every 2 hours, up to 10 times/day
Nicotine nasal spray *Intranasal*	16–32 mg/day; 1–2 mg/spray, one in each nostril up to 16 times/day
Nicotine vapor inhaler *Buccal*	6–16 mg/day; continuous puffing up to 10 puffs per cartridge maximum of 12 cartridges daily (approx. 120 puffs)
Bupropion *Oral tablets*	Begin at 150 mg/day × 3–7 days then 300 mg/day in twice-per-day dosing
Clonidine *Oral tablets*	0.6–1.2 mg/day, 2–3 times/day
Tricyclic antidepressants Nortriptyline Doxepin	Given by mouth once daily or in two divided doses 75–150 mg/day 150–250 mg/day

Data from reference 25.

suggested that NRTs are safe in certain high-risk patients such as those with cardiac diseases (i.e., post–myocardial infarction) and pregnant smokers, as long as the risk/benefit ratio is favorable.

Second-line pharmacotherapies include nortriptyline and clonidine. Clonidine exhibits modest efficacy in smoking cessation trials, and two meta-analyses that included a total of 13 placebo-controlled clinical trials indicate that it is superior to placebo, with odds ratios of 2.4 (1.7 to 32.8) and 2.0 (1.3 to 3.0).[30] Several tricyclic antidepressants (TCAs), that inhibit the reuptake of NE and 5-HT, such as nortriptyline, might facilitate smoking cessation, either alone or in combination with behavioral treatment. However, TCAs have significant disadvantages, including a significant anticholinergic burden, cardiac side effects, and possible lethality in overdose.[31]

Nonpharmacologic Treatments for Tobacco Cessation

Behavioral treatment delivered by a variety of clinicians (e.g., physician, psychologist, nurse, pharmacist, and dentist) increases abstinence rates. The five A's should be applied by all clinicians:[24]

- Ask if they smoke
- Advise to quit
- Assess motivation for change
- Assist if willing to change
- Arrange for follow-up

The Department of Health and Human Services, in concert with other public health and federal government agencies, has provided general guidelines for smoking cessation[24] (Table 33–11).

There are in excess of 100 studies validating the use of multimodal behavioral therapies for smoking cessation, either alone or in combination with pharmacologic therapies. Multimodal behavioral therapies without pharmacologic agents achieve double the quit rates compared with controls, and the 6-month efficacy ranges between 20% and 25%. Not every smoker requires the same amount of intervention.

One of the possible future directions in smoking cessation is the controversial notion of substituting smokeless tobacco for cigarettes. The idea is based on the premise that the exposure to most carcinogens in tobacco is a result of formation by pyrolysis during the combustion of tobacco. This approach has not been embraced widely by public health and anti-tobacco advocates because certain diseases are more prevalent in users of smokeless tobacco such as gum disease (i.e., gingivitis), and oral (mouth and lip) cancers. Among the different types of smokeless tobacco some products may be safer than others, such as the Swedish Snus® (widely available in Sweden and available OTC in some states in the United States). These contain air dried and processed tobacco that eliminates most nitrosamines that are produced by bacterial fermentation of tobacco and constitute a major group of carcinogenic substances present in tobacco. Other potentially promising developments in different phases of testing[25] include:

- Cannabinoid receptor CB_1-blockers, such as rimonabant (under FDA review)
- A combination of the nicotine antagonist mecamylamine and bupropion (Quitpack®)
- A nicotine partial agonist (Chantix® by Pfizer)
- Nicotine vaccine

TABLE 33–11. General Guidelines on How To Assist if a Patient Wants to Quit Smoking

Start bupropion-SR (Zyban® or Wellbutrin SR®) 1–2 weeks before quit date.
Help patient set a quit date (one of the most important strategies).
Remove all tobacco products the night before the quit date.
Follow-up with patient on the quit date or next day to support self-efficacy.
Provide nicotine replacement: patch, nasal spray or mouth inhaler, gum, or lozenge.
Identify and help educate a support person (best if ex-smoker).
Educate about the high risk for relapse and how to cope with it: "don't quit quitting."

Data from reference 24.

GENERAL APPROACH TO THE TREATMENT OF SUBSTANCE DEPENDENCE

The overall goals in recovery from addiction are the same for all substances and they consist of:

- Developing coping skills: establish a balanced lifestyle between stressors and positive healthy rewards
- Developing a sober social network: this can be through 12-step programs or other mutual self-help resources
- Relapse prevention skills and strategies: the recovering addict should develop a menu of options, a toolbox of coping skills
- Addressing and beginning to process prior histories of interpersonal problems, conflicts, and abuse
- Searching for a spiritual meaning for one's life

All of the above correlate with better long-term outcomes.

❻ *To facilitate recovery from addiction it is necessary to utilize a comprehensive biopsychosocial assessment that includes the motivation for change. Pharmacologic treatments are always adjunctive to psychosocial therapy.* It is important to remember that mere treatment of withdrawal is not sufficient treatment of DSM-IV-TR dependence (addiction), and that medications are always adjunctive to psychosocial therapy. Comorbid psychiatric

conditions such as anxiety, depression, insomnia, pain, and continued smoking should be addressed. All of these conditions increase the risk of relapse to use of drugs. Special precautions are needed when treating dual diagnosis and chronic pain patients with controlled substances.

Nonpharmacologic Therapy

❼ *While pharmacologic agents may help prevent relapse, psychotherapy should be the core therapeutic intervention. Motivational enhancement therapy, cognitive-behavioral therapy, 12-step facilitation, and contingency management are the best-studied forms of psychotherapy in this group of patients.*

Individual Therapy

Traditional psychodynamic therapy in the treatment of addiction often fails; however, the principles of psychodynamic therapy are still valuable and important for a clinician in order to understand the patient and help him or her work through his or her mechanisms of defense, attachment difficulties, processing grief, and coping with internal and external drives.[32] Among the validated and thoroughly studied approaches are the following:

- Enhancing motivation, known as motivational interviewing or *motivational enhancement therapy*, is designed to engage patients with basic principles like expressing empathy, highlighting the discrepancy between patients' ideals and their current behavior, and working within the framework of a specific patient's defenses.
- The development of *coping skills* is designed to help patients cope with life events, daily stressors, and managing painful affects.
- *Cognitive-behavioral therapy* (CBT) has the specific goal of learning relapse prevention techniques such as having a ready "toolbox" to deal with cravings and avoidance of triggers that have led to relapses in the past.
- *Contingency management* consists of providing positive rewards for desirable behavior and setting limits and consequences for undesirable behavior.
- *Improving interpersonal functioning* and enhancing social supports can be accomplished through 12-step facilitation (TSF), or any other mechanism for developing a sober social network.
- Finally, *engaging the spouse or significant other*, as well as the nuclear family, is a very important aspect in the initial stages, as well as in consolidating recovery.

Group Therapy

Group therapy for substance abuse/dependence includes more than three people (ideally 8 to 10) who interact in the same room for 90 to 120 minutes. Group therapy provides patients with the opportunity to bond with others; and the advantages of this can be mutual identification; dealing with shame and guilt; minimizing isolation; and providing peer acceptance and role modeling, realistic feedback, and optimism and hope for the future. The disadvantages are a lack of focus on a particular person's problem, the discussion is not always pertinent to every member, and scheduling times are inflexible. It is also less successful in small communities where people might know each other prior to formation of the group, and/or for people with certain personality disorders such as borderline, schizoid, avoidant, or paranoid.[32]

Pharmacologic Therapy

Maintenance Treatment

❽ *Certain pharmacologic agents have been helpful in the treatment of withdrawal and in drug maintenance programs.* Remaining sober following the treatment of withdrawal is extremely difficult. This is probably related to a complex interaction of biological factors (craving), social factors (lack of employment or lack of a sober social network), and psychological factors (lack of the ability to cope with negative emotions without resorting to drug use). Long-term use of medications to help achieve a reduction in drug craving or to maintain a steady state of legally supervised and predictable drug use may have a better long-term outcome than immediate abstinence. The ultimate goal is always abstinence, but these strategies may allow time to develop new behavioral strategies and a social network within which the patient will be more likely to achieve long-term sobriety.

Alcohol Dependence

Currently the three FDA-approved medications that are indicated to treat alcohol dependence are disulfiram, naltrexone, and acamprosate. Both disulfiram and acamprosate are indicated in patients who have already achieved initial abstinence. Only naltrexone may be initiated without regard to abstinence status.

Disulfiram

Disulfiram works by irreversibly blocking the enzyme aldehyde dehydrogenase, a step in the metabolism of alcohol, resulting in increased blood levels of the toxic metabolite acetaldehyde. As levels of acetaldehyde increase, the patient experiences decreased blood pressure, increased heart rate, chest pain, palpitations, dizziness, flushing, sweating, weakness, nausea and vomiting, headache, shortness of breath, blurred vision, and syncope. These effects are commonly referred to as the disulfiram-ethanol reaction. Their severity increases with the amount of alcohol that is consumed, and they may warrant emergency treatment. Disulfiram is contraindicated in patients who have cardiovascular or cerebrovascular disease, because the hypotensive effects of the disulfiram-alcohol reaction could be fatal in such patients or in combination with antihypertensive medications. Disulfiram is relatively contraindicated in patients with diabetes, hypothyroidism, epilepsy, liver disease, and kidney disease as well as impulsively suicidal patients.

Psychologically, disulfiram works through negative reinforcement, and drinking is avoided to prevent the aversive disulfiram-ethanol reaction. The classic study by Fuller and colleagues demonstrated that the efficacy of disulfiram was compromised by non-compliance.[33] Although that randomized controlled trial is widely cited as a negative study, because no difference between the three groups (disulfiram 250 mg daily, disulfiram 1 mg daily, and a no disulfiram condition) was found for continuous abstinence rates over a 1-year follow-up period, the 250-mg group drank on significantly fewer days (49 days) during that 1-year period than the other groups (75.4 and 86.5 days for the 1-mg disulfiram and no disulfiram groups, respectively). Other controlled trials have demonstrated that disulfiram can be highly effective when procedures for enhancing compliance are employed, such as supervised administration.[34] This may be particularly true when supervised administration is coupled with receiving incentives, such as described above for contingency management techniques, behavioral couples therapy (BCT), and the community reinforcement approach.

The usual starting dose of disulfiram is 250 mg orally per day, and the range is 125 to 500 mg daily. Compared to 250 mg daily, the larger dose is recommended in the absence of a disulfiram-ethanol reaction, and the smaller dose is given when intolerable side effects are experienced. Dosing begins only after the BAL is zero (usually 12 to 24 hours after the last drink) and after the patient understands the consequences of the disulfiram-ethanol reaction. The most common side effects are rash, drowsiness, metallic or garliclike taste, and headache. If drowsiness occurs, the dose may be lowered or given at night. Other adverse effects include optic neuritis and peripheral neuropathy. Because of potential hepatotoxicity with disulfiram including rare cases of fulminant liver failure, estimated at 1 in 25,000 treated patients,[34] baseline liver function tests (LFTs) and periodic monitoring are recommended. If serum levels of alanine aminotransferase (ALT) or aspartate aminotransferase (AST) are greater than three times normal values, then disulfiram should be withheld and the tests repeated every 1 to 2 weeks until they are normal. Once LFTs are within prescribing range, they may be repeated every 1 to 6 months. Although elevated LFTs may signal disulfiram-induced hepatotoxicity, the more likely cause in clinical practice is non-compliance and ethanol-induced hepatotoxicity. Alcohol-dependent patients are also at high risk for viral hepatitis. Another uncommon side effect of disulfiram is psychosis, which has been reported in doses exceeding 500 mg daily, especially in predisposed patients. Nevertheless, alcohol-dependent patients with schizophrenia and other co-occurring mental disorders have received disulfiram at usual therapeutic doses without difficulties.[35]

The disulfiram-ethanol interaction is described above. Depending on the dose of disulfiram, sensitivity to disulfiram, amount of alcohol consumed, and metabolism, patients may be at risk to have an adverse interaction with alcohol for 2 to 14 days after stopping disulfiram (5 days on average) and should be warned accordingly. See Table 33–3 for additional drug-drug interactions with disulfiram.

Naltrexone

Naltrexone is a competitive opioid antagonist, especially at μ opioid receptors, that decreases alcohol intake in both animals and humans. There is evidence that it works by decreasing both craving for alcohol and alcohol-induced euphoria. The large majority of over 15 double-blind randomized controlled trials of naltrexone versus placebo demonstrate its moderate efficacy for decreasing relapse to heavy drinking,[36] but not for increasing rates of total continuous abstinence. The usual therapeutic dose of naltrexone is 50 mg orally per day, with a range from 25 to 100 mg. The 25-mg dose is commonly given initially as a test dose to minimize side effects, especially nausea, and then increased to 50 mg daily as tolerated. An alternative dosing regimen is 100 mg on Mondays, 100 mg on Wednesdays, and 150 mg on Fridays, which is most conducive for patients taking naltrexone under conditions of supervised observation.

Because naltrexone can precipitate withdrawal in patients dependent on opioids, the first dose should be withheld for 7 to 10 days following the last use of opioids and only when the urine drug screen for opioids is negative. Also, naltrexone can be hepatotoxic, albeit not typically at doses less than 250 mg daily. Nevertheless, the same guidelines for monitoring liver function tests as with disulfiram (described above) are recommended. The most common side effects are nausea, headache, fatigue, and nervousness. It is important for patients to carry a pocket warning card or wear a warning bracelet in the event that emergency treatment is needed, because they will be insensitive to opioid analgesia unless toxic doses are administered. Patients need to be warned of the potential for an opioid overdose under two different conditions. First, dosing with opioids to reverse opioid insensitivity (i.e., naltrexone's competitive blockade of opioid receptors) requires very high doses of opioids that can cause respiratory depression and death. Second, chronic antagonist therapy with naltrexone may cause patients to become hypersensitive to opioid drugs after stopping naltrexone, thereby facilitating respiratory depression and death when opioids are used.

Reported predictors of naltrexone efficacy include a family history of alcoholism, early age at onset of drinking problems, high levels of the active metabolite β-naltrexol, and medication adherence.[37] Combining naltrexone with disulfiram had no advantage over either medication alone in one study of alcohol-dependent patients with comorbid psychiatric disorders.[35] Combining naltrexone with acamprosate is discussed below in the section on acamprosate. Combining naltrexone with CBT possibly may have an advantage over combining naltrexone with other psychotherapies.[38] Long-acting intramuscular forms of naltrexone designed for once-monthly administration have been efficacious on some measures of drinking in randomized controlled trials.[39]

Naltrexone can theoretically increase the risk of hepatotoxicity if combined with disulfiram, although in practice this

was not demonstrated.[35] As mentioned above, it can reverse the effects of opioid receptor agonists, rendering them therapeutically ineffective. Finally, somnolence and lethargy have been reported in combination with the antipsychotic thioridazine.

Acamprosate

Acamprosate is an NMDA receptor antagonist that was approved by the FDA in 2004, but it has been available in Europe for nearly 20 years. Alcohol use acutely inhibits NMDA receptors and chronically causes upregulation of NMDA receptors. During alcohol withdrawal and post–acute alcohol withdrawal, increased activity of the NMDA system is caused by upregulation of receptors and the absence of alcohol-related inhibition. Acamprosate is believed to modulate and normalize the NMDA receptor system, although it is ineffective in diminishing acute withdrawal symptoms. It may also have some GABA-enhancing activity.

The efficacy of acamprosate has been extensively reviewed.[40] In contrast to both disulfiram and naltrexone, acamprosate increases continuous abstinence rates in alcohol-dependent patients for periods of 3 to 12 months.[40] Preliminary evidence suggests that combining acamprosate and naltrexone may be more effective than using either one alone, and a large-scale randomized controlled trial to confirm the efficacy of the combination was recently completed and will be published soon.[41] Project COMBINE also compared medical management alone to medical management in combination with a "combined behavior intervention" (consisting of elements from CBT, MET, and TSF). Combining acamprosate with disulfiram may also increase its efficacy.[42]

The therapeutic dose of acamprosate is 666 mg orally three times daily, and it is supplied as a 333 mg tablet. It can be started at the full dose in most patients without titration. It differs from disulfiram and naltrexone in that it is excreted by the kidneys without liver metabolism. Consequently, it is contraindicated in patients with severe renal impairment (creatinine clearance less than or equal to 30 mL/minute), and dose reduction is necessary when the creatinine clearance is between 30 and 50 mL/minute. The most common side effects are gastrointestinal and include nausea and diarrhea. Rates of suicidal thoughts were also increased in patients treated for 1 year with acamprosate (2.4%) versus placebo (0.8%). If necessary the total daily dose may be decreased by 1 to 3 tablets (333–999 mg) per day to alleviate side effects.

Naltrexone can increase blood levels of acamprosate by increasing its absorption, but the clinical significance of this is not known.

Other Agents

Anticonvulsants, especially topiramate, and serotonergic drugs, especially ondansetron, show promise in initial, but well-designed, randomized controlled trials.[43] Further studies are needed. Buspirone is well studied, but results are inconsistent. Finally, a recent meta-analysis of antidepressants to treat alcohol dependence with or without comorbid depression concluded that any beneficial effects were modest at best.[44]

Stimulant Dependence

There are no proven pharmacotherapies for treatment of cocaine or amphetamine dependence. Disulfiram, however, shows some promise in randomized controlled trials for treating cocaine dependence at doses of 250 mg daily, especially in combination with CBT.[45] Its mechanism of action for treating cocaine dependence is not known, but may be due to its inhibition of the dopamine β-hydroxylase enzyme that converts DA to NE in the brain. The resulting increase in DA levels may counter the DA-deficient state that is believed to underlie cocaine withdrawal and craving.

Opioid Dependence

In certain patients who have failed one or more abstinence-based treatments for opioid dependence, maintenance treatment might be the best possible option.

After the conclusion of withdrawal, some patients still don't feel their usual selves for a long time and may relapse to using drugs again, just to "feel normal." Long-term use of opioids results in changes in the brain and the brain might not readily return to its prior homeostasis. Since the goal of treatment is to encourage stability, both in the body and in the patient's life, if an individual is not successful in tapering off of opioids because of a re-emergence of severe withdrawal or a return to opioid use, then maintenance treatment should be considered.

Opioid Agonists

The time-honored opioid agonist treatment for opioid dependence is methadone maintenance, which is beyond the scope of this chapter. In the United States methadone maintenance cannot be provided except in officially designated and approved methadone clinics. The more recent development of the Office-Based Opioid Treatment (OBOT) exclusively utilizes buprenorphine, a partial μ agonist.[21] The effective maintenance dose of buprenorphine (Suboxone®) is usually between 8 and 16 mg per day, with maximum reported efficacy at 64 mg per day. Patients receiving buprenorphine maintenance should sign a treatment contract requiring full compliance, financial responsibility for treatment, adherence to office policies, respectful behavior to staff, agreement to provide random urine samples for drug screens, and patients should bring their bottles for pill counts at every visit. In the event of failure of OBOT, the alternative to buprenorphine maintenance is a referral to an approved methadone clinic where methadone is used at minimal effective doses of 80 mg per day or higher. Under the provisions of the OBOT law physicians may prescribe buprenorphine (Suboxone® or Subutex®) in their office if they meet requirements of expertise in the area of substance abuse or if they receive 8 hours of approved training.[21] In either case a registration with the Drug

Patient Encounter 3

PC, a 19-year-old man, has undergone detoxification of his 3-bags-per-day addiction to heroin. The detoxification regimen began when he had been heroin-free for 24 hours and was undergoing some mild withdrawal symptoms. He was begun on 8 mg daily of sublingual buprenorphine, and the dose of buprenorphine was slowly tapered off during the next 4 weeks. He had begun snorting heroin at about 15 years of age and eventually had progressed to injecting his daily heroin. He dropped out of high school at 17 years of age, prior to graduation, and has never worked, except once in a fast food restaurant for a 2-week period. Since achieving abstinence he has come to realize that he has no legal means of earning a living and he is reluctant to return home to his parents since they have recently divorced. He feels he is worthless and has wasted his life up to now.

- What are the most immediate concerns regarding this young man's newly achieved abstinence?
- How can he be helped to maintain abstinence?
- What are the long-term treatment goals for this young man?

Enforcement Administration (DEA) to obtain a specially designated DEA number is needed after receiving a "waiver."

Opioid Antagonists

Naloxone, naltrexone, and nalmefene (not available yet in the United States for clinical use) can be used to reinforce abstinence. The long-acting naltrexone is especially ideal for health professionals or others who are highly motivated or face major consequences if they do not maintain their abstinence. It is important not to initiate an antagonist until the withdrawal period is over and after 7 to 12 days from the last use of opioid agonists. This is necessary to avoid precipitating more severe withdrawal due to hypersensitive or up-regulated opioid receptors as a result of prior long-term or heavy use of opioid agonists. Naloxone can be used 0.2 to 0.4 mg subcutaneously (naloxone challenge) to test if an individual is indeed abstinent and to make sure it does not induce withdrawal before giving the longer-acting oral naltrexone, although this technique is rarely used in actual practice. Most opioid-dependent patients will be honest about how recently they have used when (1) they understand that severe withdrawal is a consequence of premature naltrexone administration, and (2) a urine test is obtained.

OUTCOME EVALUATION

- To determine immediate treatment outcomes for intoxication and withdrawal syndromes at the individual patient level, evaluate parameters such as blood pressure, heart rate, respirations, and body temperature as well as mental state. Choose from a number of validated and standardized rating scales to monitor the responsiveness of withdrawal syndromes to medical treatment. To determine the overall effectiveness of your health system for the treatment of substance abuse and dependence, you could monitor outcomes using sentinel events such as the rates of cardiopulmonary arrest, seizures, discharges against medical advice, patient violence, and use of physical restraints. The ultimate goal should be to enable the transition of patients to formal substance abuse treatment when indicated, because this is the optimal outcome of treatment for substance-induced intoxications and withdrawals.
- ❾ *A major component of successful treatment of addiction is to continue monitoring the use of medications such as disulfiram, naltrexone, or acamprosate designed to decrease craving or to block the hedonic effects of abused substances. Also, it is important to identify a mechanism for long-term support of sobriety that might be appropriate for a specific individual such as Alcoholics Anonymous, a spiritual group, or professional recovery programs for professionals such as doctors, nurses, and police officers.*
- Important outcome indicators to evaluate postintoxication and/or postwithdrawal treatment of substance abuse and dependence can be divided into three major groups: decreased consumption of substances, decreased problems associated with substance use, and increased psychosocial functioning. Although it is less commonly employed, a quality-of-life scale can help determine how substance abuse/dependence treatment has affected your patients' lives. If you are involved in the cost-justification of services, a cost-benefit analysis could also become important, although this is more often used at the administrative level, rather than the patient care level. In the cases in whom complete abstinence has not been achieved, quantify the consumption of substances using: quantity-frequency measures; rates of abstinence; and time to first relapse as determined by interviews and self-report, and by biological markers such as urine and blood tests. One example of an instrument to measure alcohol-related problems is The Drinker Inventory of Consequences.[46] Another scale that you could use to determine the severity of alcohol-related problems is the Addiction Severity Index, which measures problems associated with any type of substance dependence across a variety of dimensions, including legal, family, psychiatric, medical, and social.[47] If you are concerned about the effects of substance abuse or dependence on cognitive abilities in an older adult, the Mini-Mental State Exam is a commonly used scale. Scores of 26 and higher are generally considered to indicate acceptable cognitive ability with regard to everyday functioning.[48] Quantify overall psychosocial functioning using the Global Assessment of Functioning Scale which is readily accessible in DSM-IV-TR.[8]

Patient Care and Monitoring

1. By evaluating the patient's history and symptoms, determine if substance intoxication or withdrawal are likely.
2. If drug intoxication is a likely scenario:
   - Conduct a physical exam and measure blood pressure, pulse, respiratory rate, and body temperature.
   - In most cases, management of intoxication is supportive. The most important goal is to maintain cardiopulmonary function. If consciousness is impaired, obtain blood chemistries and administer intravenous glucose and thiamine (100 to 250 mg).
   - Cocaine or stimulant intoxication may require administration of a small dose of a short-acting benzodiazepine (e.g., lorazepam 1 to 2 mg) for agitation or severe anxiety. Antipsychotics (e.g., haloperidol 2 to 5 mg) should be used only if psychosis is present. If hyperthermia is present, initiate cooling measures.
   - Observe the patient until the intoxication has resolved [if alcohol, the BAL should be less than 80 mg% (0.08% or 17.4 mmol/L)]. Encourage the patient to consider treatment for substance abuse, especially if this is not the first episode of intoxication.
3. If substance withdrawal is the likely scenario:
   - Determine from which substance or substances the patient is withdrawing.
   - Conduct a physical exam to determine if medical problems are present.
   - If withdrawal is from alcohol, administer the CIWA-Ar to determine withdrawal severity. A score of 8 to 10 denotes relatively mild withdrawal, and the patient can be treated as an outpatient with supportive care only. A score from 11 to 14 can be treated on either an outpatient or inpatient basis, with either supportive care or with benzodiazepines, depending on the presence of underlying medical problems and the prior history of the severity of withdrawal. A score greater than or equal to 15 merits strong consideration of inpatient treatment combined with medications. Those with a score of 20 or greater should always be treated in an inpatient setting with medications.
   - Always treat AWS or DTs in the inpatient setting. The drug of choice for both is a benzodiazepine.
   - Withdrawal from opioids is uncomfortable but unlikely to be fatal unless the patient has underlying medical problems. Administer the COWS to determine the severity of withdrawal. Those with a score of 5 or less require no pharmacologic intervention, while those with scores from 6 to 24 are likely to benefit from either a symptoms-based approach or the initiation of buprenorphine. Those with scores greater than 25 should receive either buprenorphine or an alternative full μ agonist.
4. Withdrawal from nicotine is treated in the outpatient setting. Symptomatic detoxification from nicotine is achieved with any single or combination of NRTs. Additional nonnicotine medications such as bupropion, nortriptyline, and clonidine may be helpful to reduce craving and various other withdrawal symptoms. Including a behavioral therapy component increases abstinence rates when combined with pharmacologic treatment.
5. The overall goals in recovery from addiction are the same for all substances and include improved coping skills and relapse prevention. Methods for accomplishing long-term sobriety include both nonpharmacologic and pharmacologic means.
   - Consider initiation of buprenorphine or methadone maintenance treatment for opioid dependence. In the United States buprenorphine is easier to arrange since physicians can be approved to prescribe buprenorphine following a short course of federally-approved training.
   - Disulfiram (250 mg per day) can be used to promote abstinence from alcohol. Acamprosate and naltrexone can be used to decrease craving for alcohol, but they are not likely to result in complete abstinence from alcohol use.

Deanna L. Kelly and Elaine Weiner

LEARNING OBJECTIVES

UPON COMPLETION OF THE CHAPTER, THE READER WILL BE ABLE TO:

1. Explain the pathophysiologic mechanisms that are thought to underlie schizophrenia.
2. Recognize the signs and symptoms of schizophrenia and be able to distinguish among positive, negative, and cognitive symptoms of the illness.
3. Identify the treatment goals for a patient with schizophrenia.
4. Recommend appropriate antipsychotic medications based on patient-specific data.
5. Compare the side-effect profiles of individual antipsychotics.
6. Describe the components of a monitoring plan to assess the effectiveness and safety of antipsychotic medications.
7. Educate patients and families about schizophrenia, treatments, and the importance of adherence to antipsychotic treatment.

KEY CONCEPTS

❶ Patients presenting with odd behaviors, illogical thought processes, bizarre beliefs, and hallucinations should be assessed for schizophrenia.

❷ A diagnosis of schizophrenia is made clinically, as there are no psychological assessments, brain imaging, or laboratory examinations that confirm the diagnosis.

❸ The goals of treatment are to reduce symptomatology, decrease psychotic relapses, and improve patient functioning and social outcomes.

❹ The cornerstone of treatment is antipsychotic medications. Because most patients with schizophrenia relapse when not medicated, long-term treatment is usually necessary.

❺ Psychosocial support is needed to help improve functional outcomes.

❻ Compared to the older antipsychotics (first-generation antipsychotics), the more recently developed second-generation antipsychotics are associated with a lower risk of motor side effects (tremor, stiffness, restlessness, and dyskinesia); may offer greater benefits for affective, negative, and cognitive symptoms; and may prolong the time to psychotic relapse.

❼ Second-generation antipsychotics as a class are heterogeneous with regard to side-effect profiles. Many second-generation antipsychotics carry an increased risk for weight gain and for the development of glucose and lipid abnormalities; therefore careful monitoring is essential.

❽ Education of the patient and family regarding the benefits and risks of antipsychotic medications and the importance of adherence to their therapeutic regimens must be integrated into pharmacologic management.

In most cases schizophrenia is a chronically debilitating disorder and is likely one of the most devastating of chronic medical illnesses. Conceptually, schizophrenia might better be thought of as a clinical syndrome, comprising several disease entities that manifest with psychotic symptoms, including hallucinations, delusions, and disordered thinking. Commonly, these more flagrant symptoms are accompanied by more insidious ones, including cognitive impairment (abnormalities in thinking, reasoning, attention, memory, and perception), impaired insight and judgment, loss of motivation (avolition), loss of emotional range (restricted affect), and a decrease in spontaneous speech (poverty of speech). The later three symptoms are termed negative symptoms, and when taken together, are frequently called the deficit syndrome. Cognitive impairments and negative symptoms account for much of the poor social and functional outcomes observed in schizophrenia. Schizophrenia is the fourth leading cause of disability among adults and is associated with substantially lower rates of employment, marriage, and

Patient Encounter, Part 1

AG is a 28-year-old single African-American male with an approximately 3-year history of paranoia, increasing use of marijuana and cocaine, and poor work performance. His symptoms seemed to intensify around his being caught taking money from his girlfriend's bank account to buy cocaine. Since then he has become suspicious that the police were watching his movements and that people on the street knew personal information about him. He has left several jobs one after another due to his belief that other employees were sabotaging him and that people were talking behind his back. He occasionally hears his father speaking to him but has not seen him in 10 years. He is sad and hopeless about the state of his life and very guilty about his substance abuse and stealing from his girlfriend. Though supportive of him, the patient's girlfriend is feeling somewhat frustrated by the patient's withdrawal from her and reluctance to socialize to the extent that they had in the past.

- What diagnoses are suggested by this presentation?
- What additional information would help to clarify the diagnosis?

independent living compared to population norms. Approximately 10% of people with schizophrenia die by suicide.[1] However, earlier diagnosis and treatment, as well as advances in research and newer treatment developments, have led to better outcomes for people who suffer from this complex and challenging illness.

EPIDEMIOLOGY AND ETIOLOGY

One percent of the world's population suffers from schizophrenia and symptoms usually first present in late adolescence or early adulthood.[1] While equally prevalent between genders, symptoms generally appear earlier in males, and males have a younger age at first hospitalization (15 to 24 years) compared to females (25 to 34 years). This earlier age of onset leads to a greater disruption in the successful completion of developmental milestones, which may account for the poorer functional outcomes seen in males compared to females. Men are more likely to be treated in the hospital settings and generally account for 60% to 70% of the total inpatient population with this illness. There does not appear to be significant differences in the incidence or prevalence across cultures or among racial or ethnic groups.

The etiology of schizophrenia remains largely unknown, though the evidence strongly supports a genetic basis for the disorder. First-degree relatives of patients with schizophrenia carry a 10% risk of developing the disorder. When both parents have the diagnosis, the risk to their offspring is 40%. For monozygotic twins, the likelihood of one twin developing the illness if the other twin has schizophrenia is about 50%. Many genes have been weakly associated with the development of schizophrenia; however, no clear association exists for any one gene. There is probably no single "schizophrenic gene." Recent data, however, suggest that genes encoding dopamine receptors, serotonin receptors, and the enzyme that metabolizes dopamine, catechol-O-methyltransferase (COMT), may be implicated in the etiology of schizophrenia.[2] Environmental stimuli or triggers along with genetic liability may contribute to the expression of the illness. Some data suggest that intrauterine exposure to viral or bacterial infections may be a risk factor; however, more research is needed in this area.

PATHOPHYSIOLOGY

The oldest theory associated with the pathophysiology of schizophrenia is the dopamine hypothesis, which proposes that psychosis is due to excessive dopamine in the brain. This hypothesis was formed in the late 1950s, following the discovery that chlorpromazine, the first antipsychotic drug, acted as a postsynaptic dopamine antagonist. There is evidence from many pharmacologic challenge studies that drugs that lead to an increase in dopamine (e.g., cocaine and amphetamines) increase psychotic symptoms, while drugs that decrease dopamine (as do all current antipsychotic medications) decrease psychotic symptoms. A wide array of scientific work over the last several decades, including functional magnetic resonance imaging (MRI), positron emission tomography (PET), computed tomography (CT), and studies of dopamine metabolites have revealed a more complicated picture with both hyperdopaminergic, as well as hypodopaminergic brain regions. Hypodopaminergic activity observed in the prefrontal lobe is thought to relate to the core negative symptoms associated with schizophrenia. Thus, a more modern reworking of the dopamine hypothesis is the "dysregulation hypothesis" which takes these findings into account.[3] It is possible, however, that the dopamine abnormalities hypothesized to underlie the etiology of schizophrenia may represent compensatory changes that occur secondary to other pathophysiologic abnormalities intrinsic to the illness. Despite the accumulation of knowledge surrounding dopamine's etiologic relationship to schizophrenia, other neurotransmitter systems have been implicated. Some investigators have suggested that a combined dysfunction of the dopamine and glutamate transmitter systems may better explain the disorder.[4] There has also been a great deal of speculation regarding a role for serotonin receptor antagonism in antipsychotic efficacy,[5] as many second-generation antipsychotics (SGAs) are active at serotonin receptors. Serotonin receptor binding may be important to drug action, possibly by modulating dopamine activity in **mesocortical** pathways. However, a compelling pathophysiologic theory relating to dopamine and serotonin receptor affinities does not yet exist. It is important to note that to date,

Clinical Presentation of Schizophrenia

General

❶ Schizophrenia is a chronic disorder of thought and affect, causing a significant disturbance in the individual's ability to function vocationally and interpersonally. The onset of symptoms in most cases is insidious, usually preceded by a prodromal phase characterized by gradual social withdrawal, diminished interests, changes in appearance and hygiene, changes in cognition, and bizarre or odd behaviors. Despite the tendency of the media to portray a stereotype, the clinical presentation of a person with schizophrenia is extremely varied. Hallmark symptoms include psychotic symptoms, negative symptoms, and cognitive impairments that last for at least 6 months.

Symptoms

Psychotic symptoms: These symptoms are sometimes called positive symptoms, as they are "added on to" a person's normal experience. They may include hallucinations (distortions or exaggeration of perception), delusions (fixed false beliefs), and thought disorder (illogical thought and speech). Hallucinations, most frequently auditory, can also be visual, olfactory, gustatory, and tactile. Auditory hallucinations may be experienced as voices or as thoughts that feel distinct from the person's own thoughts. The content of the hallucinations is variable but often they are threatening or commanding (i.e., commanding the person to perform a particular action). Patients may feel compelled to perform the commanded task or may experience much anxiety when they do not. Delusions frequently involve fixed false beliefs despite invalidating evidence, and may be bizarre in nature. Often they have paranoid themes, which may make the patient suspicious of others. The characteristic thought disorder of schizophrenia includes loosening of associations, **tangentiality**, **thought blocking**, **concreteness**, circumstantiality, and perseveration. Thinking and speech may be incomprehensible and illogical. Subtle disturbances in associative thinking may develop years before disorganized thinking (formal thought disorder).

Negative symptoms: So called because they are qualities "taken away" from the personality, include **i**mpoverished speech and thinking, lack of social drive, flatness of emotional expression, and apathy. Though quite ubiquitous, these symptoms are difficult to evaluate because they occur in a continuum with normality, and can be due to secondary causes, including medication side effects, mood disorder, environmental understimulation, or demoralization. When due to schizophrenia itself, they are termed primary negative symptoms or deficit symptoms. The best strategy for differentiating primary from secondary negative symptoms is to observe for their persistence over time, despite efforts at resolving the other causes. Approximately 10% to 15% of people with schizophrenia may present primarily with negative symptoms; these people may be referred to as having a deficit syndrome.

Cognitive symptoms: Neuropsychological research shows that patients with schizophrenia show abnormalities in the areas of attention, processing speed, verbal and visual memory, working memory, and problem solving. There is a loss of, on average, one standard deviation of preillness IQ, with the average IQ of between 80 and 84.

antipsychotics without any primary or secondary dopamine-modulating properties have been ineffective for the treatment of positive symptoms of schizophrenia.

CLINICAL PRESENTATION AND DIAGNOSIS

People with schizophrenia may appear uncooperative, suspicious, hostile, anxious, or aggressive due to their misinterpretation of reality. They may have poor hygiene and appear unkempt, as psychosis, as well as depressive symptoms, may lead to impaired self-care. Sleep and appetite are often disturbed. People with schizophrenia often have difficulty living independently in the community and have difficulty forming close relationships with others. Additionally, they have problems with initiating or maintaining employment. Rates of illness denial are high, as is non-compliance with medications, particularly early in the course of illness, increasing the risk for relapse and hospitalization. Comorbid medical disorders, such as type 2 diabetes and chronic obstructive pulmonary disease, are prevalent in schizophrenia due to sedentary lifestyles, poor dietary habits leading to obesity, and heavy cigarette smoking. Approximately

85% of people with schizophrenia smoke, and approximately 50% use drugs and alcohol, rates that are much higher than in the general population.[6]

❷ *There is no objective diagnostic or laboratory measure or brain imaging technique to diagnose schizophrenia. Biological markers are being investigated, but currently, the diagnosis is made by ruling out other causes of psychosis and meeting specified diagnostic criteria that are based on symptoms and functioning. Family history of psychiatric disorders is helpful in supporting the diagnosis. The commonly accepted diagnostic criteria for schizophrenia are from the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)*[7] (Table 34–1).

TABLE 34–1. Diagnostic Criteria for Schizophrenia

A. *Characteristic symptoms:* Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated):[a]
- Delusions
- Hallucinations
- Disorganized speech (e.g., frequent derailment/incoherence)
- Grossly disorganized/catatonic behavior
- Negative symptoms (e.g., flat affect, alogia, avolition)

B. *Social/occupational dysfunction:* For a significant portion of the time since the onset of the disturbance, one or more major areas of functioning such as work, interpersonal relations, or self-care are markedly below the level achieved prior to onset (or when onset is in childhood or adolescence, failure to achieve the expected level of interpersonal, academic, or occupational achievement).

C. *Duration:* Continuous signs of disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meet criterion A (i.e., active-phase symptoms), and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of disturbance may be manifested by only negative symptoms, or by two or more symptoms listed in category A present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences).

D. *Ruling out other disorders:*
- Schizoaffective and mood disorder exclusion: Schizoaffective disorder and mood disorder with psychotic features have been ruled out because either (1) no major depressive, manic, or mixed episodes have occurred concurrently with the active-phase symptoms; or (2) if mood episodes have occurred during active-phase symptoms, their total duration has been brief relative to the duration of the active and residual periods.
- Substance/general medical condition exclusion: The disturbance is not due to the direct physiologic effects of a substance (e.g., drug of abuse or medication) or a general medical condition.
- Pervasive developmental disorder: If there is a history of autistic disorder or another pervasive developmental disorder, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations are also present for at least a month (or less if successfully treated).

[a]Only one symptom from category A is required if delusions are bizarre or hallucinations consist of a voice maintaining a running commentary on the person's behavior or thoughts, or two or more voices conversing. Adapted from reference 7 with permission.

COURSE AND PROGNOSIS

The onset of psychosis, whether insidious or acute, is marked by difficulties for patients, families, and clinicians. The severity of symptoms may be denied, and the nature of behavioral disturbances may be misunderstood. Patients may try to keep symptoms hidden from family and friends; they may remove themselves emotionally and geographically from social support networks. The onset of psychosis may be confounded by substance abuse. The gradual development of psychosis, combined with the frequent misunderstanding of symptoms, generally leads to a substantial time period between symptom onset and diagnosis and treatment. While not unequivocal, recent data suggest that people with fewer episodes of acute psychosis and those treated early on in their illness may have a better prognosis. Therefore, the first challenge of optimal therapy is to move treatment initiation closer to the onset of psychosis.

Although the course of schizophrenia is variable, the long-term prognosis for independent function is often poor. The course of illness is marked by intermittent acute psychotic episodes with a downward decline in psychosocial functioning. Over time, a patient may become more withdrawn, bizarre, and non-functional. Complete return to full premorbid functioning is uncommon. Many of the more dramatic and acute symptoms fade with time, but severe residual symptoms may persist. Family and friends often find this illness difficult to interpret and understand. Involvement with the law is fairly common for misdemeanors such as vagrancy, loitering, and disturbing the peace. The overall life expectancy is shortened primarily due to suicide, accidents, and the inability of self-care. The lifetime risk of suicide for people with schizophrenia is about 10%.[8] Persistent compliance with a tolerable drug regimen improves prognosis, though relapse without medication exceeds 50% annually.

TREATMENT

Desired Outcomes

❸ *The goal is for people with schizophrenia to receive, as early in their course as possible, comprehensive treatment designed to achieve functional outcomes. While in the past, the primary treatment goal was to decrease positive symptoms and the associated hostile and aggressive behaviors, newer approaches to treatment have a wider focus, treating not only positive symptoms, but also negative, depressive, and anxious symptoms. The aim is to not only reduce symptomatology and psychotic relapses, but also to improve functional and social outcomes.*[9] It is important to keep in mind that some symptoms respond earlier than others. Combativeness, hostility, sleep disturbances, appetite, and hallucinations may be some of the first symptoms to improve. Improvements in negative symptoms, cognitive functioning, social skills, and judgment generally require a longer period to improve.

Patient Encounter, Part 2

Past Psychiatric History

Though AG describes himself as being depressed "all my life" and remembers that he felt able to read peoples' minds in high school, he denied prior psychiatric treatment until his first hospitalization 2 years ago at the height of his paranoia. At that time, he believed there was a conspiracy against him. He lived in constant fear that his phone was tapped and his home was bugged. He felt he was being watched in public places, and therefore he began avoiding going out. He experienced voices commenting on his behavior and believed the television was talking to him and that shows were about him. At times he felt his "brain was being squeezed" for information, so that his mind was being read. He believed his girlfriend was having affairs, and he could not be reassured. He reported decreased appetite, difficulty sleeping, and suicidal ideation. His toxicology screen and blood alcohol test in the emergency department were negative. In the hospital he was given a diagnosis of major depressive disorder with psychotic features. He was started on olanzapine 10 mg/day for psychosis and fluoxetine 20 mg/day for depression, with some improvement.

Past Medical History

He has no history of medical illness, head trauma, or seizure disorder.

Social History

He grew up in an upper middle class family, completed high school, and entered the Navy where he was discharged dishonorably due to not following rules. He began using alcohol in high school and continued to use other substances intermittently since then. He has held several jobs, the longest for 6 months. He thinks he might apply for disability.

Family Psychiatric History

His father had an alcohol problem.

Mental Status Exam

Appearance: Nicely dressed and groomed. No abnormal movements. Poor eye contact.
Speech: Quiet and somewhat monotonous.
Mood: Nervous.
Affect: Guarded and mildly anxious with restricted range.
Thought content: Adequate historian but with a tendency to leave out detail. Experiences hearing others call his name, and interpreting the car lights coming down his street as meaning people are out to get him. He denies suicidal or homicidal thoughts.
Thought processes: Logical but vague.
Cognition: Grossly intact.
Insight and judgment: Mixed, as he can at times question his thinking, but at other times has full conviction of his beliefs. He is currently taking his medication and cooperating with the evaluation appointments.

- Given this additional information, how was your differential changed?
- What would the goals of outpatient treatment be?
- What pitfalls are likely to occur during outpatient treatment?

Over the past few years, partial recovery and remission have become an increasingly prominent paradigm for conceptualizing the treatment of schizophrenia. In working toward these goals, a range of interventions must be incorporated into long-term treatment strategies, including not only pharmacologic interventions, but psychosocial therapies as well. Current treatment planning is increasingly focused on functional outcomes by providing treatment and recovery-oriented services to people with schizophrenia. Also, newer trends such as evidence-based practice, whereby new information from the published literature gets incorporated into clinicians' prescribing behavior, have led to the use of interventions that promote a remission or recovery attitude.[10] Moreover, recent attempts have been made to address and measure patient satisfaction with treatments and instill hope and optimism in order to attempt to empower patients.

Unfortunately, this new paradigm is in the earliest stages of implementation, and despite these advances and recent treatment improvements, long-term outcomes currently remain poor, and many patients fail to receive comprehensive care.

General Approach to Treatment

A person presenting with the initial episode of psychosis requires a comprehensive assessment and careful diagnosis, as psychosis is not pathognomonic for schizophrenia. The differential diagnosis includes a wide array of neurologic, psychiatric, and general medical conditions (Table 34–2). Often, people present with a short history of psychopathology and cannot recall historical information accurately. This lack of information, along with frequent comorbid substance abuse, medical illnesses, and psychosocial stressors often confound the case. Patients presenting with psychotic symptoms, particularly those in their initial episode, should have a thorough medical and laboratory (electrolytes, blood urea nitrogen, serum creatinine, urinalysis, liver and thyroid function profile, syphilis serology, serum pregnancy test, and urine toxicology) evaluation, including a careful review of systems and a physical exam that includes a neurologic evaluation. At the minimum, in accordance with the American Psychiatric Association Practice Guidelines[11] and the Expert Consensus Guideline Series for Schizophrenia,[12] psychotic patients should have a medical workup at the time of admission to rule out other diagnoses or contributing factors.

❹ *Since early detection and intervention in schizophrenia is important for maximizing outcomes, treatment with antipsychotic medications should begin as soon as psychotic symptoms are recognized. Antipsychotic medications are the cornerstone of therapy for people with schizophrenia, and most patients are on lifelong therapy since non-adherence and discontinuation of antipsychotics are associated with high relapse rates.* If other symptoms are present such as depression and anxiety, these symptoms should also be aggressively treated. Additionally, psychosocial treatments should be used concomitantly to improve patient outcomes.

Nonpharmacologic Therapy

❺ *Psychosocial support is needed to help improve functional outcomes*. Only 30% of patients respond robustly to antipsychotics, another 30% respond partially, and another 30% have a minimal response. Patients who do respond often continue to have residual symptoms such as **amotivation**, isolation, and impaired social functioning, thus limiting their participation in social, vocational, and educational endeavors. Psychosocial interventions are based on the premise that increased psychosocial functioning will lead to improvements in subjective feelings of self-esteem and life satisfaction. However, generalizability from studies in this area are confounded by differences in treatment settings, severity of illness, insurance status of patients, and the presence of comorbid conditions. A few of the best-supported and most promising approaches to psychosocial rehabilitation are social skills training (SST), cognitive-behavioral therapy (CBT), and cognitive remediation (CR). These treatments are used most appropriately as targeted treatments for social and cognitive impairments and not as sole treatments for psychotic symptoms.[13] Most psychosocial studies have been carried out in the United Kingdom, and findings are not yet widely utilized in the United States. Nonetheless, there are substantial data to support that family education and vocational support help to improve long-term functional outcomes.

TABLE 34–2. Disorders That May Present with Psychotic Symptoms

Addison's disease	Huntington's disease
Asperger's disorder	Major depression
Autism	Posttraumatic stress disorder
Bipolar disorder	Sarcoidosis
Cancer	Seizure disorder
Cushing's disease	Substance abuse
Delirium	Syphilis
Dementia	Thyrotoxicosis
Head trauma	Viral encephalitis

Pharmacologic Therapy

There are more choices of antipsychotic medications than ever before. Generally, all people with schizophrenia should be treated with antipsychotics, and adjunctive medications should be used when necessary to treat specific symptoms or comorbid diagnoses. Medications specifically targeting negative symptoms and cognitive deficits are actively being investigated. Because each schizophrenic patient presents differently, each treatment regimen should be individually tailored. After a period of nearly 20 years during which only first-generation antipsychotics (FGAs; typical antipsychotics) were available, six new antipsychotics have been marketed in the United States since 1990. These agents, known as second-generation antipsychotics (SGAs; atypical antipsychotics), include risperidone (Risperdal), olanzapine (Zyprexa), quetiapine (Seroquel), ziprasidone (Geodon), aripiprazole (Abilify), and clozapine (Clozaril). Clozapine, the prototype of this class of medications, is reserved as second-line therapy due to its unusual side-effect profile (see below). ❻ *As a class the SGAs offer greater tolerability, with less risk of* ***extrapyramidal side effects*** *(EPSs) and* ***tardive dyskinesia*** *(TD; see below), and possibly better treatment for mood symptoms, negative symptoms, and cognitive deficits. There are some data to show that they are associated with lower rates of relapse*. Unfortunately, these medications are more expensive than older medications and have similar efficacy for psychotic symptoms, thus pharmacoeconomic cost:benefit profiles provide information essential for designing appropriate therapeutic regimens. The FGAs are currently used in less than 10% of the schizophrenic population, primarily in patients who cannot afford newer medications and those who have responded well and tolerated these medications in the past.

Second-Generation (Atypical) Antipsychotics

While FGAs exert most of their effect through dopamine receptor blockade at the dopamine (D_2) receptor, the SGAs

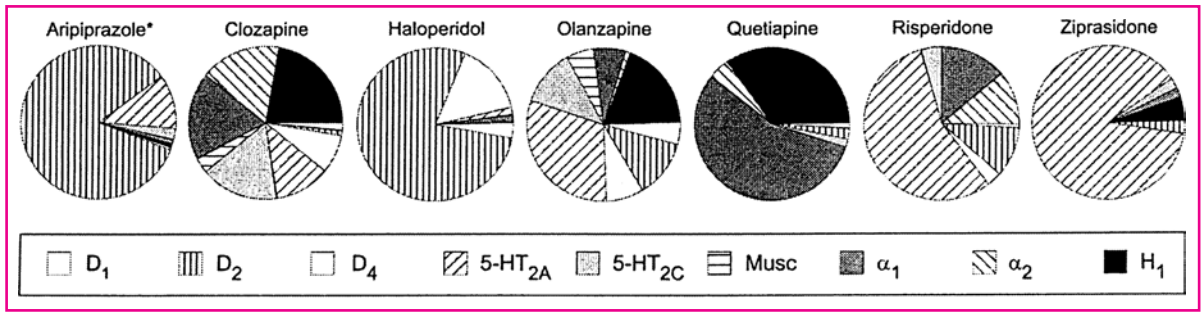

FIGURE 34–1. Profiles for receptor binding of second-generation antipsychotics and haloperidol. [a]Partial agonist activity at D_2 receptors, whereas all others are D_2 antagonists. D, dopamine receptor; H_1, histamine receptor; 5-HT, serotonin receptor; Musc, muscarinic receptor; α_1 and α_2, α_1 and α_2 receptors. (Adapted and reprinted from The Journal of Clinical Psychiatry and Physicians Post Graduate Press. Collaborative Working Group on Clinical Trial Evaluations. J Clin Psychiatry 1998; 59[Suppl 12]:7, and Pharmacologic Treatment of Schizophrenia. Caddo, OK. Professional Communications, Inc, 2003: 52, with permission.)

may work through a more complicated mechanism, as SGAs have greater affinity for serotonin receptors than for dopamine receptors (Fig. 34–1). Despite being very heterogeneous with regard to receptor binding, the overall efficacy among the SGAs is similar.[14] Recently new comparative data among SGAs and FGAs (lower doses) have reported that overall efficacy is similar between groups, which suggests a reevaluation of the place of FGAs in therapy is needed.[14] Only clozapine, however, has demonstrated superior efficacy for some patients (see section below on treatment-resistant patients). An important distinction of the SGAs as a class is their lower propensity to cause EPS and TD. The annual risk of TD is considered to be less than 1.5% per year in adults (less than 54 years old) taking SGAs as compared to approximately a 5%-per-year risk in those taking FGAs.[15] Pharmacologic profiles and side-effect profiles, however, are very different among the agents. Table 34–3 lists the SGA agents, recommended dosing, and dosage forms available. Table 34–4 lists the side-effect profiles of the SGAs and haloperidol. Clozapine is discussed in the section on treatment-resistant patients.

Risperidone

Risperidone, a benzisoxazole derivative, was the first SGA to be marketed following the release of clozapine. It has high binding affinity to both serotonin ($5\text{-}HT_{2A}$) and D_2 receptors and binds to α_1 and α_2 receptors, with very little blockade of cholinergic receptors.[16] Multicenter registry trials found risperidone efficacy to be at least equal to that of haloperidol while producing significantly fewer extrapyramidal symptoms.[17] Risperidone is the only SGA approved for relapse prevention and is associated with significantly lower relapse rates than long-term haloperidol treatment.[18] At clinically effective doses (less than or equal to 6 mg/day), EPSs are low, although higher doses are clearly associated with a greater incidence of EPS. Risperidone is associated with serum prolactin elevations that are similar to or greater than those seen with the FGAs. Elevated prolactin levels can, but

TABLE 34–3. Second-Generation (Atypical) Antipsychotics

Second-Generation Antipsychotic	Usual Target Dose (mg/day)	Maximal Dose Likely to Be Beneficial (mg/day)	Available Dosage Forms
Aripiprazole (Abilify)	15–30	30	• 2-, 5-, 10-, 15-, 20-, and 30-mg tablets • 1 mg/mL oral solution • 10- and 15-mg discmelt orally disintegrating tablets • IM 9.75 mg/1.3 mL
Clozapine (Clozaril)	400	500–800	• 25- and 100-mg tablets • FazaClo (orally disintegrating tablets) 25 and 100 mg
Olanzapine (Zyprexa)	15–20	30-40[a]	• 2.5-, 5-, 7.5-, 10-, 15-, and 20-mg tablets • Zyprexa Zydis (orally disintegrating tablets) 5,10,15, and 20 mg • IM 10–mg vial (after reconsitution, approx. 5 mg/mL)
Quetiapine (Seroquel)	400–600	800–1200[a]	• 25-, 100-, 200-, and 300-mg tablets
Risperidone (Risperdal)	2–4	6	• 0.25-, 0.5-, 1-, 2-, 3-, and 4-mg tablets • 1 mg/mL (30 mL) solution • Risperidal M-tab (orally disintegrating tablets) 0.5, 1, and 2 mg • Risperdal Consta long-acting injectable 25-, 37.5-, and 50-mg vial/kit
Ziprasidone (Geodon)	100–120	160–240[a]	• 20-, 40-, 60-, and 80-mg capsules • IM 20 mg/mL

do not always, lead to clinical symptoms such as hormonal problems (e.g., amenorrhea, galactorrhea, and gynecomastia) or sexual dysfunction. Risperidone is associated with mild to moderate weight gain and mild elevations in lipid and glucose may occur. However, patients chronically treated with other antipsychotics such as olanzapine may have declines in cholesterol and triglyceride levels when changed to risperidone monotherapy.[14]

Olanzapine

Olanzapine has greater affinity for 5-HT_{2A} than for D_2 receptors. In addition, the compound has affinity at the binding sites of D_4, D_3, 5-HT_3, 5-HT_6, α_1-adrenergic, muscarinic ($M_{1–5}$), and histamine (H_1) receptors.[19] Multicenter clinical trials have reported that the effectiveness of olanzapine is at least equal to that of haloperidol for the treatment of positive symptoms[20,21] and equal or superior to haloperidol for the treatment of negative symptoms. The premarketing clinical trials reported no significant differences in efficacy among dosage groups. However, the higher dose range appeared to offer the greatest benefits for both positive and negative symptoms when compared to haloperidol (20 mg). Among the first-line antipsychotic agents, olanzapine is associated with the longest time to treatment discontinuation, a finding that suggests that olanzapine may somewhat differ from the other SGAs in effectiveness.[14] Olanzapine has a low rate of EPS and causes slight, transient prolactin elevations. However, clinically significant weight gain occurs with olanzapine across the dosage range. The degree of weight gain is similar to that seen with clozapine and greater than that observed with the other SGAs. Olanzapine is also associated with hypertriglyceridemia, increased fasting glucose, and new-onset type 2 diabetes (i.e., metabolic syndrome), and among the first-line SGAs, it is associated with the greatest elevations in these metabolic parameters.[14]

Quetiapine

Structurally quetiapine is related to clozapine and olanzapine. Quetiapine has high affinity for 5-HT_{2A} receptors and lower affinity for D_2 and D_1 receptors. This drug has some affinity for α_1, α_2, and H_1 receptors, and very little for muscarinic receptors. The efficacy of quetiapine for psychosis was established in two controlled trials, which found that maximum benefits occurred at 300 mg per day or greater.[22,23] The most effective doses of quetiapine may be higher than 500 mg/day. Quetiapine has not been shown to be superior to haloperidol in any symptom dimension; however, it has beneficial effects for anxious and depressive symptoms. Because of its low D_2 occupancy, motor side effects and prolactin elevations are usually not seen with quetiapine. Sedation may occur but is generally transient. Mild weight gain and minor elevations in triglycerides can occur.

Ziprasidone

Ziprasidone was developed specifically to be a compound that blocks D_2 receptors, but also binds with even greater affinity to central 5-HT_{2A} receptors. As a result, ziprasidone has a binding affinity ratio of 11:1 for 5-HT_{2A}:D_2 receptors. Ziprasidone also has a relatively high affinity for 5-HT_{2C}, 5-HT_{1D}, α_1-adrenergic, and D_1 receptors.[24] Several short-term, placebo-controlled, premarketing clinical trials led to the recommended dose range of 40 to 160 mg daily with food.[25,26] Current dosing suggests that efficacy may be greater at doses over 200 mg/day. Liability for EPS, weight gain, and lipid elevations were very low in the clinical trials. Ziprasidone is associated with some prolongation of the QTc interval in adults. However, drug overdose data and studies of pharmacokinetic interactions have thus far shown little evidence that significant QTc prolongation may occur.

Aripiprazole

Aripiprazole was formulated in the early 1980s to function as a potential dopamine modulator, with both antagonist and agonist activity at the D_2 receptor. It is the first D_2 partial agonist available for the treatment of schizophrenia and is sometimes referred to as a third-generation antipsychotic. This novel mechanism is

Patient Encounter, Part 3

Soon after his discharge from the hospital, AG stopped taking his olanzapine. He had gained a lot of weight, and he didn't believe the medication was helping. He continued to have difficulties maintaining employment and being involved socially. With encouragement from his girlfriend, AG sought treatment again and was started on risperidone 2.5 mg a day. He continued to experience paranoia, still feeling unable to function up to his potential at work, and still tending to be reclusive. A new therapist supported his involvement in Alcoholics Anonymous, and with AG began to question the depression diagnosis. She referred him to a center specializing in schizophrenia where the diagnosis was clarified as schizophrenia, paranoid type, continuous with depressive episode, single episode, alcohol dependence, early full remission; and polysubstance abuse, early full remission.

- List a reason why risperidone was selected as the next antipsychotic choice for AG.
- Describe nonpharmacologic treatment strategies that may be appropriate for AG.
- Discuss a risperidone dosing plan and list side effects AG may experience on this medication.

termed a "dopamine system stabilizer," functioning as an antagonist in a hyperdopaminergic state and as an agonist when in a hypodopaminergic state. Aripiprazole is also a partial agonist at 5-HT_{1A} receptors, an antagonist at 5-HT_{2A} receptors, and also has affinity for D_3 receptors. Additionally, it has a moderate affinity for α_1 and H_1 receptors with no appreciable affinity for the M_1 receptor.[27] The recommended starting dose is 10 to 15 mg daily given without regard to meals. No titration is required, as the starting dose is an effective dose. The recommended dosing range is 10 to 30 mg/day; doses greater than 30 mg have not been systematically evaluated. Doses less than 10 mg/day have not been consistently found to be effective. Side effects are low with sedation and nausea and vomiting occurring the most frequently. Elevations in weight, lipids, and glucose are generally negligible to minor.

First-Generation (Typical) Antipsychotics

First-generation antipsychotics (FGAs), also referred to as conventional, traditional, or typical antipsychotic agents, are high-affinity D_2 receptor antagonists. During chronic treatment, these agents block 65% to 80% of D_2 receptors in the striatum and block dopamine receptors in the other dopamine tracts in the brain as well.[28] Clinical response is generally associated with 60% D_2-receptor blockade, while 70% and 80% are associated with hyperprolactinemia and EPS, respectively. This group of antipsychotics was widely used from the 1950s to the 1990s, until the SGAs began to replace these agents as first-line therapy.

Dosages for these agents are frequently given as **chlorpromazine equivalent** dosages, which are defined as the dosage of any of the FGAs equipotent with 100 mg of chlorpromazine. The target dose recommendation is 400 to 600 chlorpromazine equivalents, unless the patient's history indicates that this dose may result in intolerable side effects. Generally maintenance therapy should provide a dose of 300 to 600 chlorpromazine equivalents for maximum efficacy. Information on dosing and available dosage forms is provided in Table 34–5. All FGAs are equally efficacious in groups of patients when used in equipotent doses. However, individual variation does occur, such that a patient may not respond equally to each antipsychotic. Selection of a particular antipsychotic should be based on patient variables, such as the need to avoid certain side effects

TABLE 34–5. First-Generation (Typical) Antipsychotics

Class	Agent (Brand Name)	Dosage Range (mg/day)	Chlorpromazine Equivalents (mg)	Available Formulations
Butryphenone	Haloperidol (Haldol)	5–30	2	T, LC, I
Dibenzoxazepine	Loxapine (Loxitane)	25–100	10	C
Diphenylbutylpiperidone	Pimozide (Orap)	1–10	1–2	T
Indole	Molindone (Moban)	25–100	10	T
Phenothiazines	Chlorpromazine (Thorazine)	300–800	100	T, LC, I, R
	Fluphenazine (Prolixin)	2–40	2	T, L, I
	Mesoridazine (Serentil)	150–500	50	T, LC
	Perphenazine (Trilafon)	8–64	10	T, LC
	Thioridazine (Mellaril)	300–800	100	T, LC
	Trifluoperazine (Stelazine)	15–30	5	T
Thioxanthenes	Thiothixine (Navane)	5–40	4	C

Low-potency antipsychotics include thioridazine, mesoridazine, and chlorpromazine.
High-potency antipsychotics include haloperidol, fluphenazine, thiothixine, and pimozide.
T, tablet; C, capsule; C-SR, controlled- or sustained-release; I, injection; L, liquid solution, elixir, or suspension; LC, liquid concentrate, R, rectal suppository.

or interactions with concomitant medications. Previous patient or family history of response is also helpful in the selection of a particular agent.

Decanoates

Long-acting, depot preparations are available for two FGAs (fluphenazine decanoate and haloperidol decanoate) in the United States. These compounds are esterified antipsychotics formulated in sesame seed oil for deep intramuscular injection. Because these are long-acting preparations, patients should be exposed to the oral form of the drug first to ensure tolerability. With initial dosing of haloperidol decanoate, oral supplementation may temporarily be necessary, as the drug accumulates over many weeks, not reaching steady state until 4 to 5 dosing intervals have elapsed. The pharmacokinetic profiles of the depot agents are useful parameters for strategic dosing. Patients may be dosed with fluphenazine decanoate on a 1- to 3-week interval, while haloperidol decanoate is usually dosed once a month. Conversion from oral to depot and maintenance dosing recommendations are shown in Table 34–6. Based on these recommendations, a reasonable estimate is that 12.5 mg (0.5 mL) of fluphenazine decanoate given every 2 weeks is approximately equivalent to 10 mg/day of fluphenazine orally. A maintenance haloperidol decanoate dose of 150 mg every 4 weeks is approximately equivalent to 10 mg/day of oral haloperidol. Initial decanoate injections should be preceded by a small test dose.

Side Effects of First-Generation Antipsychotics

FGAs cause a wide range of adverse events, affecting many organ systems. In general, the low-potency agents are less likely to cause EPS than the high-potency agents. Neuroleptic malignant syndrome (NMS), a life-threatening emergency characterized by severe muscular rigidity, autonomic instability, and altered consciousness, can occur uncommonly with all the FGAs. Rapid dose escalation, the use of high-potency FGAs at higher doses, and younger patients are associated with a higher risk of NMS. When NMS is diagnosed or suspected, antipsychotics should be discontinued and supportive and symptomatic treatment begun (e.g., antipyretics, cooling blanket, intravenous fluids, oxygen, monitoring of liver enzymes, and complete blood cell count). Dopamine agonists (i.e., bromocriptine) should be considered in moderate to severe cases. Additionally, dermatologic side effects, photosensitivity, and cataracts may occur with the phenothiazine agents. Sedation is caused from H_1-receptor antagonism, anticholinergic side effects (constipation, blurred vision, dry mouth, and urinary retention) are caused from M_1-receptor antagonism, and α_1-receptor blockade is associated with orthostatic hypotension and tachycardia (Table 34–7.) QTc prolongation may occur with lower-potency FGAs such that thioridazine has a black box warning for QTc prolongation.

The other group of major adverse effects associated with FGAs are EPS and include akathisia (restlessness), dystonia (muscle spasm), and pseudoparkinsonism (akinesia, tremor, and rigidity). These fairly common motor side effects are caused by dopamine antagonism in the nigrostriatal pathways. Akathisia is the most frequently occurring motor side effect, with approximately 20% to 40% of people treated with FGA drugs experiencing an objective or subjective feeling of restlessness. The onset of akathisia is usually 5 to 10 days after the first dose or increase in dosage, but it can occur later. Younger people and those taking high doses of high-potency antipsychotics are at greater risk for the development of akathisia. Acute dystonic reactions are abrupt in onset and are usually seen within 24 to 96 hours after a first dose or increase in dosage. Characteristic signs and symptoms include abnormal positioning or spasm of the muscles of the head, neck, limbs, or trunk. Dystonia may occur in 10% to 20% of patients. Younger patients are at highest risk. Pseudoparkinsonism resembles idiopathic Parkinson's disease, and features may be present in up to 30% to 60% of people treated with FGAs. The onset of symptoms is usually seen within 1 to 2 weeks following initiation of dosing or a dose increase. Risk factors include older age, female gender, high doses, and possibly those with depressive symptoms.[29] Using

TABLE 34–6. First-Generation (Typical) Antipsychotic Dosing of Decanoate Preparations

Drug	Starting Dose	Maintenance Dose	Comments
Haloperidol decanoate	20 × oral haloperidol daily dose; in the elderly use 10–15 × oral haloperidol daily dose Generally 100–450 mg/month Initial dose should not exceed 100 mg regardless of previous dose requirements (if greater than 100 mg give 3–7 days apart)	10–15 × oral haloperidol dose, generally 50–300 mg/month	With initial dosing, oral supplementation may temporarily be necessary; deep IM injection generally with 21-gauge needle; maximum volume per injection site should not exceed 3 mL Available in 5 mg/mL and 100 mg/mL (5-mL vials and 1-mL ampules)
Fluphenazine decanoate	1.2 × oral fluphenazine daily dose, generally 12.5–75 mg/2–3 weeks	Based on starting dose and clinical response Generally 12.5–25 mg dosed every 3–6 weeks	Can be administered IM or SC; 21-gauge needed, must be dry Should not exceed 100 mg; when dosing above 50 mg, should increase in increments of 12.5 mg Available in 25 mg/mL (5-mL vials)

IM, intramuscular, SC, subcutaneous.

decanoate formulations to minimize peak levels may minimize the incidence of EPS.

TD is a movement disorder characterized by abnormal choreiform (rapid, objectively purposeless, irregular, and spontaneous movement) and athetoid (slow and irregular) movements occurring late in onset in relation to initiation of antipsychotic therapy. This adverse effect usually develops over several months or after at least 3 months of cumulative exposure to neuroleptic medications. The estimated average prevalence is 20% with a range of 13% to 36%. The incidence of new cases per treatment year with FGAs is approximately 5%.[30] TD is reversible in one-third to one-half of cases with the cessation of the antipsychotic. When the antipsychotic is tapered or discontinued, there is initially usual worsening of abnormal movements. Risk factors for TD include older age, longer duration of antipsychotic treatment, and higher rates of EPS, substance abuse, and mood disorders.

Treatment Guidelines and Algorithms

Due to the plethora of choices and the rising costs of SGAs, algorithms and treatment/consensus guidelines have been developed for the treatment of schizophrenia. The most widely accepted algorithm in the United States was developed as part of the Texas Implementation of Medication Algorithms (TIMA). A national panel of experts developed this algorithm, most recently updated in 2003.[31] Algorithms go beyond guidelines, providing a framework for clinical decision making at critical decision points. According to the TIMA schizophrenia algorithm, SGAs (except clozapine) should be utilized as first-line treatment. The choice of SGA is guided by consideration of the side-effect profiles and the clinical characteristics of the patient. Treatment should be continued for 4 to 6 weeks in order to assess response. If only partial response or non-response is noted, a trial of a second SGA should be initiated (Fig. 34–2). Other similar guidelines include the American Psychiatric Association Practice Guidelines for schizophrenia,[11] The Expert Consensus Guideline Series,[12] and the Schizophrenia Patient Outcomes Research Team (PORT) Treatment Recommendations.[32]

Treatment Adherence

Medication non-adherence in schizophrenia is common and often associated with symptom relapse.[33] Estimates of non-adherence on FGAs range from approximately 24% to 88% with a mean of approximately 50%.[34] Subjects who are non-compliant have approximately a four-fold greater risk of a relapse than those who are compliant. Adherence to antipsychotic regimens is problematic for many reasons. Neurocognitive deficits and paranoid symptoms may hamper compliance, and identification of non-compliance by caretakers and providers can be challenging. Frequently, there is no obvious connection between non-compliance and symptom exacerbation, as there may be no immediate consequences of missing a dose, and patients may relapse suddenly after only several weeks or months of non-adherence. Side effects from antipsychotics are also a major contributing factor to treatment non-adherence, with 25% to 66% of subjects citing adverse effects as the primary reason for non-adherence.[33] EPS, most notably akathisia, sexual dysfunction, and weight gain are adverse effects that commonly lead to non-adherence.[35] Several factors are associated with non-compliance, including younger age, grandiosity, substance abuse, and deficit symptoms. SGAs may be associated with somewhat better rates of adherence, most likely attributable to a lower incidence of **dysphoria** and EPS; however, rates of medication discontinuation remain high.[14,36] For patients who have relapsed several times due to non-adherence, have a history of dangerous behavior, or risk a significant loss of social/vocational gains when relapsed, treatment with long-acting formulations should be strongly encouraged. Risperidone is currently the only SGA with a long-acting formulation available. It uses a microsphere technology that maintains stable blood levels for about 2 weeks. Dosing is generally 25 to 75 mg every 2 weeks with oral supplementation in the first 3 weeks.

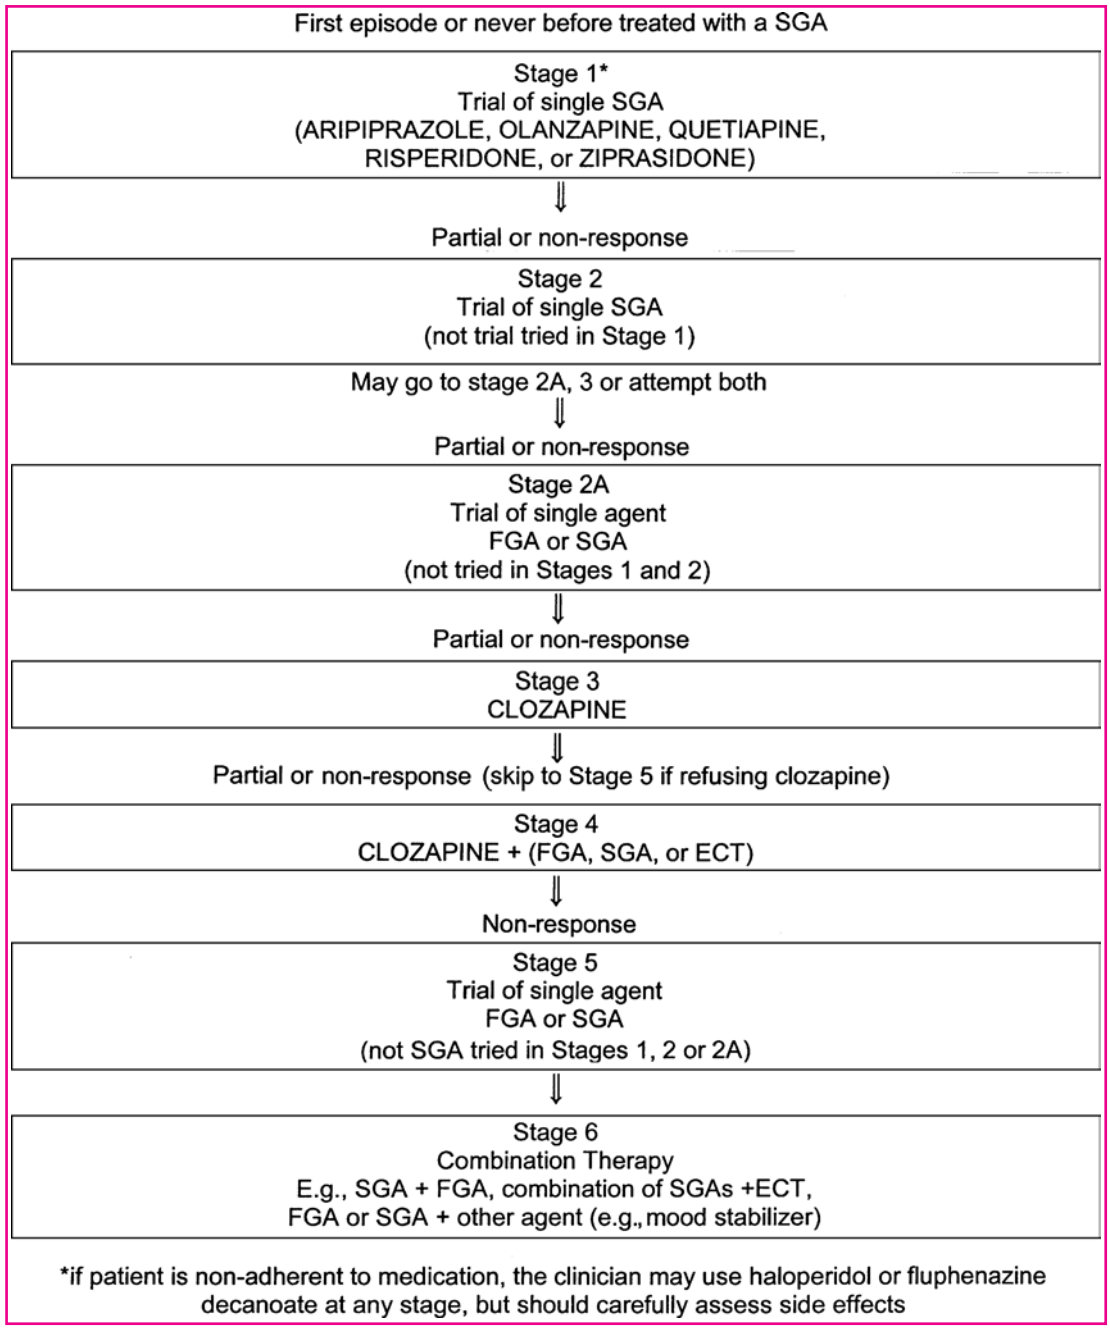

FIGURE 34–2. TIMA algorithm for antipsychotic treatment in schizophrenia. Choice of antipsychotic should be guided by considering the clinical characteristics of the patient and the efficacy and side-effect profiles of the medication. Any stage may be skipped depending on the clinical picture or history of antipsychotic failures. ECT, electroconvulsive therapy; FGA, first-generation antipsychotic; SGA, second-generation antipsychotic. (Adapted from www.dshs.state.tx.us/mhprograms/tmasczman.pdf.)

Patient-Specific Antipsychotic Selection

Patient-specific characteristics may help guide the selection of antipsychotic treatment. Based on expert consensus guidelines, Table 34–8 provides evidence-based suggestions for SGA selection to aid the clinician in individualizing treatment. FGAs continue to have a place in therapy for patients who cannot afford the SGAs or for those who have responded favorably to these agents in the past. Currently, however, SGAs are recommended as first-line therapy.

Special Populations

Adolescents

Epidemiologic data show that 10% to 30% of patients with schizophrenia develop their first psychotic symptoms prior to their eighteenth birthday. Onset between puberty and age of 18 is sometimes classified as early-onset schizophrenia (EOS) or intermediate onset schizophrenia, and those presenting with symptoms before puberty are classified as very early-onset

TABLE 34–8. Suggestions for First-Line Antipsychotic Therapy in Specific Patients

Clinical Condition	First-Line Treatment	Other Options
Diabetes or family history of diabetes	Aripiprazole, quetiapine, ziprasidone	Risperidone
Hyperlipidemia or significant family history of hyperlipidemia	Aripiprazole, ziprasidone	Risperidone, quetiapine
Hypertriglyceridemia or significant family history of elevated triglycerides	Aripiprazole, ziprasidone	Risperidone, quetiapine
Overweight or obese, or concerns about weight	Aripiprazole, ziprasidone	Risperidone, quetiapine
Current sexual dysfunction or concerns about sexual dysfunction	Aripiprazole, quetiapine, clozapine	Olanzapine, ziprasidone
Amenorrhea or problems with menstrual period	Aripiprazole, quetiapine, clozapine	Olanzapine, ziprasidone
Cardiac arrhythmias or current anti-arrhythmic treatment	**NOT** ziprasidone or clozapine	
Suicidal or history of frequent suicide attempts	Clozapine	
Current or past anti-cholinergic side effects	Risperidone, quetiapine, aripiprazole ziprasidone	Olanzapine (low dose)
EPS or severe EPS in the past	Quetiapine, aripiprazole, clozapine	Ziprasidone
Current tardive dyskinesia	Clozapine, quetiapine	Risperidone, olanzapine, ziprasidone
History of non-adherence	Long-acting risperidone	
Difficulty swallowing tablets/capsules	Risperidone or aripiprazole liquid, orally-disintegrating tablets (risperidone, olanzapine, clozapine)	Long-acting risperidone

EPS, extrapyramidal symptoms.
Data from references 11, 12, and 32 and 51.

schizophrenia (VEOS) or as having childhood-onset schizophrenia. The diagnosis of schizophrenia in children and adolescents is often difficult to make, and the differential diagnosis includes pervasive developmental disorders, attention-deficit/hyperactivity disorder, and language or communication disorders. The existence of prominent hallucinations or delusions, however, help make the diagnosis, as they are not a prominent part of the other disorders. Auditory hallucinations are common and occur in approximately 80% of children and adolescents with schizophrenia. Command hallucinations are the most frequently occurring type of hallucination. The content and context of delusions in children and adolescents vary by age. Younger children tend to have delusions that are less complex and fixed. Fifty-four to ninety percent of patients developing schizophrenia before age 18 have premorbid abnormalities such as withdrawal, odd traits, and isolation.[37]

Treatment for psychotic children and adolescents ideally involves an intensive and comprehensive program with a highly structured environment that includes special education and psychoeducation. Day treatment, hospitalization, or long-term residential treatment may be necessary. Pharmacologic treatment is indicated if psychotic symptoms cause significant impairments or interfere with other interventions. Children and adolescents are more vulnerable to EPS, particularly dystonias, than are adults. Due to concerns about EPS and TD, pharmacotherapy in children and adolescents should be initiated with SGAs. Agents with significant sedation and anti-cholinergic side effects are not preferred, as they can cause attention difficulties and cognitive dulling that may interfere with optimal school performance. Compared to adults, children and adolescents tend to gain more weight on these agents. Young patients should be started on lower doses than adults and should be titrated at a slower rate. Side effects should be monitored closely during initiation and throughout maintenance therapy. Informed consent, addressing the rationale for treatment and potential risks and benefits of therapy, should be obtained from the parents or guardians prior to treatment with any antipsychotic medication, and assent should be obtained from the child as well. Standardized clinician ratings such as the Positive and Negative Syndrome Scales derived from the Children's Psychiatric Rating Scale can be helpful in assessing the effects of antipsychotic therapy. Dosing in children and adolescents is initiated lower and titration is slower than in adults.

Elderly

Psychotic symptoms in late life (greater than 65 years of age) are generally a result of an ongoing chronic illness carried over from younger life; however, a small percentage of patients develop psychotic symptoms de novo, defined as late-life schizophrenia. The 6-month prevalence rate of schizophrenia in the elderly is around 1%. However, other illnesses presenting with psychotic symptoms are common in this population, as approximately one-third of patients with Alzheimer's disease, Parkinson's disease, and vascular dementia experience psychotic symptoms. The majority of data for antipsychotic use in the elderly comes from experience treating these other disease states.

Antipsychotics can be safe and effective for the treatment of psychosis in the elderly, if used at lower doses than those commonly used in younger adults. Older adults are particularly vulnerable to the side effects of FGAs. Parkinsonian symptoms

reportedly occur in over 50% of all elderly patients receiving these agents, and the cumulative annual incidence of TD in middle-aged and elderly patients is over 25%. With the SGAs, the risk appears to be approximately 4%.[38] The likelihood of reversing this potentially debilitating condition diminishes with age. Other adverse effects of these agents that are often intolerable in the older population include orthostatic hypotension and anticholinergic effects. For example, orthostasis, estimated to occur in 5% to 30% of geriatric patients, is a major contributing factor to the occurrence of falls that often leads to fractures, injuries, and loss of independence. Low-potency antipsychotics and clozapine are more likely to cause significant drops in orthostatic blood pressure. Antipsychotics may cause or worsen anticholinergic effects including constipation, dry mouth, urinary retention, and cognitive impairment. Cognitive impairment may lead to decreased independence, and a more rapid decline in cognitive functioning may occur in the elderly treated with antipsychotics than the younger adult population. Using lower doses and remaining vigilant to side effects is essential in this population. Recently published data reported a statistically significant increase in mortality rate due to stroke in elderly dementia patients who are treated with SGAs. All SGAs now carry this warning, and patients and families should be informed of this risk prior to treatment with these agents. Dosing in the elderly is initiated lower and titration is slower than in adults. Maximum doses are often one-half of adult doses.

Dually Diagnosed

The prevalence of substance dependence and abuse among persons with schizophrenia is significantly higher than in the general population. Conservative estimates of the proportion of schizophrenic patients abusing alcohol and/or illicit drugs range from one-third to as many as one-half.[39] The most common drugs of abuse are alcohol, cannabis, and cocaine. Although, the reasons for this high comorbidity are unclear, a number of theories have been postulated, including the possibility of a deficiency in the dopamine-mediated brain reward circuit. According to this theory, patients use substances as a way to replete dopamine in the reward centers of the brain. This pleasure-seeking behavior serves in part as the basis for what is termed the self-medication hypothesis, in which patients are described as "self-medicating" with substances sometimes as a way to counter depression, reduce anxiety, or induce sleep. Unfortunately, substance use often worsens the course and complicates the treatment of schizophrenia. Dually-diagnosed patients are more likely to be non-compliant with treatment. Characteristically, they have a poorer response rate to traditional antipsychotics, have more severe psychosis, and have higher rates of relapse and rehospitalization compared to patients who are not abusing substances. Some studies have found that EPS may occur more frequently in substance-abusing patients, and alcohol use is a risk factor for developing TD. There is a growing body of literature indicating that SGAs are effective in this population, and some studies have shown a reduction in the use of drugs and alcohol with SGAs.

Treatment-Resistant Patients

For approximately 20% to 30% of people with schizophrenia, drug treatment is ineffective. A standard definition of treatment resistance includes patients who have persistent positive symptoms despite treatment with at least two different antipsychotics given at adequate doses (at least 600 chlorpromazine equivalents) for an adequate duration (4 to 6 weeks). In addition, patients must have a moderately severe illness as defined by rating instruments, and have a persistence of illness for at least 5 years.[40] These patients are often highly symptomatic and require extensive periods of hospital care.

Clozapine

To date, clozapine remains the only drug with proven and superior efficacy in treatment-resistant patients, and it is currently the only drug approved for the treatment-resistant schizophrenic. Studies have shown a response of approximately 30% to 50% in these well-defined treatment-resistant patients. Clinical trials have consistently found clozapine to be superior to traditional antipsychotics for treatment-refractory patients, and it is efficacious even after non-response to other SGAs and in partially responsive patients. It is often rapidly effective even in those who have had a poor response to other medication for years. Recent studies have demonstrated that it has a beneficial effect for aggression and suicidality, which led to the Food and Drug Administration (FDA) approval for the treatment of suicidal behavior in people with psychosis.[41]

A great deal of interest has been generated in understanding what pharmacologic properties of clozapine contribute to its superior efficacy, but to date this has not been clearly elucidated. Clozapine has a low affinity for D_2 receptors, works also on D_1 receptors, and is a 5-HT_{2A} antagonist. Its unsurpassed efficacy suggests that there is a neuropharmacologic effect associated with clozapine that is to date unique to this agent.

Clozapine's use is limited by its association with the rare but life-threatening risk of agranulocytosis and seizures, as well as common unpleasant side effects including sedation, enuresis, anti-cholinergic effects, weight gain, and hypersalivation. The long-term hematologic monitoring (see monitoring section) required for prevention of agranulocytosis can represent a barrier to both patients and care providers. The optimal plasma level of clozapine is a minimum trough level of 300 to 350 ng/mL (300 to 350 μg/L or 918–1071 nmol/L), usually corresponding to a daily dose of 200 to 400 mg, although dosage must be individualized. According to published guidelines and recommendations, clozapine should be considered after two failed antipsychotic trials.[31] Fewer than 8% of new antipsychotic prescriptions are written for this medication annually in the United States.

Other Strategies

Approximately 30% of patients treated with clozapine will not respond, and another 30% will have only a partial response to the drug. Treatment options with other medications are limited

after clozapine non-response. For these patients, the best evidence points to augmentation using an FGA, SGA, or **electroconvulsive therapy** (ECT). The only available data support the combination of clozapine with risperidone; however, controlled trial results are mixed. Other potential strategies include combining antipsychotics with mood stabilizers (e.g., lithium, lamotrigine, valproate, and topiramate).[31]

Acutely Psychotic Patients

Psychiatric emergencies occur in a variety of settings, including emergency departments, psychiatric units, medical facilities, and outpatient settings. Most psychiatric emergencies require both pharmacologic and psychological interventions. Often, the psychiatrist must make decisions based on limited information and history. Intramuscular (IM) formulations are available for a number of FGAs and two SGAs (ziprasidone and olanzapine). These formulations are safe and effective in treating acute psychosis. These SGAs are now recommended as first-line therapy in agitated schizophrenia patients; however, IM lorazepam with or without concomitant oral (tablets, liquid, or disintegrating tablets) SGAs are also used. High dosing of FGAs, termed rapid neuroleptization, is no longer recommended.

Pregnancy and Lactation

When to use antipsychotics in pregnancy and during lactation remains a complicated decision based on a careful analysis of risks and benefits. Women with schizophrenia have a significantly greater risk for stillbirth, infant death, preterm delivery, low infant birth weight, and infants that are small for gestational age, even in unmedicated patients. Furthermore, women who experience a relapse in psychotic symptoms during pregnancy are at the greatest risk for birth complications.[42] Because risks related to psychotic relapse may be more detrimental than antipsychotic treatment to both mother and baby, antipsychotics are often continued during this period.

Essentially all antipsychotic medications pass through the placenta. The use of these drugs requires critical attention to the timing of the exposure, the dose and duration of use, and fetal susceptibility. When possible, discontinuing antipsychotics for the first trimester is the safest option, as weeks 6 to 10 are the most vulnerable period for organ formation. Generally, monotherapy at the lowest effective dose for the shortest period necessary is the best strategy. High-potency FGAs are associated with a low risk for congenital abnormalities; however, limb defects and dyskinesias have been reported.[43] Low-potency phenothiazine antipsychotics may increase the risk of congenital abnormalities when used in the first trimester. According to the relevant literature published to date, there appears to be little risk associated with the first-line SGAs.[44] However, on the basis of available data, generalization is impossible, and each case and specific antipsychotic should be weighed on an individual basis. While SGAs are excreted in breast milk, most case reports have reported a low frequency of deleterious effects on the infant. Women taking SGAs may have enhanced fertility compared to women taking FGAs, as SGAs (except risperidone) are less likely to cause prolactin elevations leading to anovulation. Therefore, careful discussion with patients, including education about birth control, must occur.

Pharmacokinetics

Pharmacokinetic and pharmacodynamic issues are not generally a major concern with antipsychotic treatment; however, additive side effects may occur with combined treatment, and a few clinically significant drug interactions are notable (Table 34–9). All of the antipsychotics are highly protein-bound; however, protein-binding interactions are generally not clinically significant. Absorption of most antipsychotics is not affected by food, with the exception of ziprasidone, whose absorption is increased by 60% to 70% when given with meals. The absorption of quetiapine may be slightly increased when given with food.

All antipsychotics are metabolized by hepatic microsomal enzymes to water-soluble compounds that are excreted by the kidneys. The most important of the microsomal enzymes are the cytochrome P-450 (CYP450) enzymes, a group of enzymes that play a major role in oxidative drug metabolism. Although over 30 isoenzymes of the CYP450 system have been identified in humans, three play a significant role in the metabolism of antipsychotic medications: CYP4502D6, CYP4501A2, and CYP4503A3/4. Substances that inhibit or induce the function of these enzymes can change antipsychotic blood concentrations. For example cigarette smoking

TABLE 34–9. Metabolism and Drug Interactions with Antipsychotics

Antipsychotic	Major CYP450 Metabolic Enzyme	Other CYP450 Metabolic Pathways	Increase Antipsychotic Concentrations	Decrease Antipsychotic Concentrations
Clozapine	1A2	3A3/4, 2D6, 2C19	Fluvoxamine, ciprofloxacin, paroxetine	Cigarette smoking
Risperidone	2D6	3A3/4		
Olanzapine	1A2	2D6	Fluvoxamine, ciprofloxacin, paroxetine	Cigarette smoking
Quetiapine	3A3/4	2D6	Fluvoxamine, ketoconazole	Carbamazepine
Ziprasidone	3A3/4		Fluvoxamine, ketoconazole	Carbamazepine
Aripiprazole	3A3/4	2D6	Fluvoxamine, ketoconazole	Carbamazepine
Haloperidol	2D6, 3A3/4		Fluvoxamine, fluoxetine, ketoconazole	Carbamazepine
Thioridazine	2D6	1A2	Fluvoxamine	Cigarette smoking
Perphenazine	2D6		Fluvoxamine, fluoxetine, paroxetine	

CYP, cytochrome P-450 isoenzyme.

induces CYP4501A2, and therefore can decrease clozapine and olanzapine plasma concentrations. Table 34–9 lists the primary metabolic enzymes and some potential drug interactions for the antipsychotic medications. Clinicians should assess the clinical impact of the addition or discontinuation of these drugs in individual patients and should make appropriate adjustments when necessary. Unlike the other antipsychotics, ziprasidone is mostly metabolized by aldehyde oxidase, a metabolic system independent of the CYP450 system. Another recent discovery in drug metabolism of antipsychotics and their distribution involves the transmembrane energy-dependent efflux transporter, P-glycoprotein, which may limit a number of drugs from penetrating into the extracellular space.[45] Antipsychotics currently known to use this pathway include perphenazine, haloperidol, fluphenazine, quetiapine, risperidone, and olanzapine.[46]

Due to its propensity to cause prolongation of the QTc interval, the use of ziprasidone with other agents that prolong the QTc interval should be avoided. These other agents include, but are not limited to, anti-arrhythmic medications such as quinidine and sotalol, certain FGAs (chlorpromazine, droperidol, mesoridazine, pimozide, and thioridazine), and certain antibiotics (gatifloxacin, halofantrine, mefloquine, moxifloxacin, and pentamidine). Ziprasidone has not been shown to have clinically significant drug interactions with the CYP4503A3/4 inhibitors regarding increasing the QTc; however, higher doses, especially given with inhibitors of CYP4503A3/4 (e.g., ketoconazole and erythromycin), should be used cautiously. Other risk factors for prolongation of the QTc interval include comorbid diabetes, electrolyte disturbances (e.g., low sodium and potassium serum concentrations), heavy alcohol consumption, female gender, and congenital QTc disorder. Clinicians should also be vigilant to avoid pharmacodynamic interactions with any of the antipsychotics involving additive side effects from combination therapies. Side effects that may be worsened with combination therapies include sedation, hypotension, anti-cholinergic symptoms, and weight gain or metabolic abnormalities.

Adjunct Pharmacologic Treatments

The judicious use of pharmacologic therapies other than antipsychotics may be necessary in the treatment of schizophrenia. Concomitant medications may be indicated for the treatment of motor side effects, anxiety, depression, mood elevation, and possibly refractory psychotic symptoms. Anticholinergic medications (e.g., benztropine, 1 to 2 mg two times daily; trihexyphenidyl, 1 to 3 mg three times daily; and diphenhydramine, 25 to 50 mg two times daily) are used to effectively treat EPS, thereby improving the tolerability of these medications. They are usually prescribed prophylactically with high-D_2-binding agents or in patients at risk for EPS. β-Blockers (e.g., propranolol in doses of 30 to 120 mg/day) are sometimes effective for patients who develop akathisia. In some situations, such as on an inpatient unit, the concomitant use of benzodiazepines (e.g., lorazepam in doses of 1 to 3 mg/day) with the SGAs may be necessary for agitation and insomnia.

Antidepressants may be useful for patients with depressive symptoms that are not due to negative symptomatology or emotional blunting secondary to parkinsonian-type side effects. Sometimes it is necessary for the clinician to treat with an antidepressant to rule out depression, as it is not always possible to differentiate these conditions. Since suicide and depression are interconnected, aggressive treatment is necessary when depression is present. Selective serotonin reuptake inhibitors (SSRIs) are the preferred agents, but may inhibit the CYP450 enzymes, thus raising plasma concentrations of clozapine, olanzapine, and haloperidol. Mood stabilizers, such as lithium and the anticonvulsants, have long been used adjunctively with antipsychotics to treat the affective component of schizoaffective disorder. Valproate is currently the most commonly used mood stabilizer in schizophrenic patients, and its use in conjunction with clozapine may protect against a pre-epileptic condition known as myoclonic jerking. And finally, much research is currently underway to develop better treatments for primary negative symptoms and cognitive impairment; however, no approved treatments are yet available.

OUTCOME EVALUATION

Patient Education

Frequently, patients receive little education about schizophrenia and may not have a good understanding of their diagnosis. Meetings for purposes of medication management offer an opportunity to provide some education on the general illness. Discuss the nature and course of schizophrenia and be prepared to accept that the patient might have a different understanding of the nature of his or her illness. Key points to cover include:

- Involve families in the education and treatment plans, since family psychoeducation may decrease relapse, improve symptomatology, and enhance psychosocial and family outcomes.[47]
- Be clear that there is no cure for schizophrenia and that medications only help to decrease the symptoms.
- Explain common side effects of medications.
- Discuss rare but dangerous side effects which may also occur.
- Stress the importance of medication and treatment adherence for improving long-term outcomes in schizophrenia.

Symptom Monitoring

Develop a good working alliance with the patient. When a solid therapeutic foundation is not formed, patients are frequently reluctant to share their psychotic experiences. Frequently, patients fear that others will interpret their descriptions as "crazy." Alternatively, some care providers have told patients to "keep their beliefs to themselves," as a way to cope with their illness in the community. In these instances, it may take time to gain the patient's trust and to learn enough

about the details of their life experience to explore their more personal experiences. Once a solid working relationship and some knowledge of the patient's psychotic experiences exist, perform a more structured interview. Many assessments are available to more objectively rate positive and negative symptoms, level of function, and life satisfaction. The most commonly used scales include:

- The Positive and Negative Symptom Scale (PANSS)
- The Brief Psychiatric Rating Scale (BPRS)
- The Clinical Global Impression (CGI) scale

Using these scales on a regular basis, particularly when switching medications or changing doses, is a more reliable means of monitoring for improvement. Certainly symptom assessments cannot capture the full range of possible improvements a patient may experience, but they can be useful in deciding whether a medication is having substantial benefit.

Side Effect Monitoring

❼ *Regularly monitor patients for side effects and overall health status while taking antipsychotic medications.*[48,49] *Perform orthostatic blood pressure measurements at the initiation of antipsychotics and throughout treatment. Ask about impaired menstruation, libido, and sexual performance regularly. Encourage patients to have annual eye exams, as several of the antipsychotic medications have been associated with the premature development of cataracts. Check body weight, fasting glucose, glycosylated hemoglobin, and lipid profile at baseline, at 4 months after initiation of medication, and then yearly.*[50] For patients who are at higher risk of developing diabetes and those who gain weight, check body weight more often (Table 34–10). Encourage patients to act proactively against weight gain through healthier eating and exercise. Perform a *baseline electrocardiogram (ECG) for patients with preexisting cardiovascular disease and risk for arrhythmia*. With clozapine therapy there is a risk for the development of agranulocytosis, which is greatest in the first 6 months of treatment. Current guidelines require the monitoring of white blood cell counts (WBC) prior to drug dispensing (Table 34–11).

Commonly used rating scales to monitor for EPS include the Simpson Angus Scale (SAS) and the Extrapyramidal Symptom Rating Scale (ESRS). Akathisia is commonly monitored by the Barnes Akathisia Scale (BAS). The emergence of dyskinesias (writhing or involuntary movements) could represent the emergence of TD. Monitor for TD at least annually, and if FGAs are used patients should be evaluated at each visit. The most commonly used instrument to measure these symptoms is the Abnormal Involuntary Movement Scale (AIMS).

Patient Encounter, Part 4

With his care providers, AG discussed several possible medication choices. Because there had been improvement of auditory hallucinations on risperidone, the initial choice was made to increase the dose to target the ongoing paranoid thinking. AG was seen weekly to monitor for emergence of EPS or akathisia. He was able to tolerate an increase to 4 mg of risperidone daily with improvement in his paranoid thinking. He went on several interviews for jobs and accepted part-time employment at a coffee shop. When he complained of emergence of sexual dysfunction, his prolactin level was determined to be 42 ng/mL (42 µg/L). He discussed risks and benefits of therapy with his clinicians and decided to continue risperidone for now, as he had improved in his ability to work and get out more in the community. He remains interested in having an aripiprazole trial in the future, as he hopes he might more easily lose the weight he gained while taking olanzapine and resume normal sexual functioning. He is no longer taking an antidepressant, and though he has some low days, he does not meet the criteria for diagnosis of depressive episode. He continues to be free of substance abuse, and his girlfriend continues to support his treatment. He still hopes to return to work in his field of expertise someday.

- Based on the information above, create a care plan for this patient's treatment. Your plan should include: (1) a statement of the drug-related concerns and/or problems, (2) the goals of therapy, and (3) a plan for monitoring and follow-up to determine whether the goals have been achieved and adverse effects minimized.

TABLE 34–10. Monitoring Protocol for Patients on Second-Generation (Atypical) Antipsychotics

	Baseline	4 weeks	8 weeks	12 weeks	Quarterly	Annually	Every 5 Years
Personal/family history[a]	X					X	
Weight	X	X	X	X	X		
Waist circumference	X					X	
Blood pressure	X			X		X	
Fasting plasma glucose	X			X		X	
Fasting plasma lipids	X			X			X

TABLE 34–11. Monitoring of White Blood Cell Count and Absolute Neutrophil Count during Clozapine Treatment

	Hematologic Values	Frequency of WBC and ANC Monitoring
Prior to clozapine initiation	Recommended levels: WBC greater than or equal to 3,500/mm^3 and ANC greater than or equal to 2,000/mm^3 No history of a **myeloproliferative disorder** or clozapine-induced agranulocytosis	
Initiation to 6 months	WBC greater than or equal to 3,500/mm^3 and ANC greater than or equal to 2,000/mm^3	Weekly for 6 months
6 to 12 months	WBC greater than or equal to 3,500/mm^3 and ANC greater than or equal to 2,000/mm^3	Every 2 weeks for 6 months
After 12 months of therapy	WBC greater than or equal to 3,500/mm^3 and ANC greater than or equal to 2,000/mm^3	Every 4 weeks
Clozapine discontinuation		Weekly for at least 4 weeks from day of discontinuation
Mild leukopenia or granulocytopenia	3,500/mm^3 greater than WBC greater than or equal to 3,000/mm^3 and/or 2,000/mm^3 greater than ANC greater than or equal to 1,500/mm^3	Twice weekly until returned to recommended levels
Moderate leukopenia or granulocytopenia	3,000/mm^3 greater than WBC greater than or equal to 2,000/mm^3 and/or 1,500/mm^3 greater than ANC greater than or equal to 1,000/mm^3	Interrupt therapy; monitor daily until WBC greater than 3,000/mm^3 and ANC greater than 1,500/mm^3, then twice weekly until back to recommended levels
Severe leukopenia or granulocytopenia or agranulocytosis	WBC less than 2,000/mm^3 and/or ANC less than 1,000/mm^3 ANC less than or equal to 500/mm^3	Discontinue treatment and do not rechallenge; monitor daily until WBC greater than 3,000/mm^3 and ANC greater than 1,500/mm^3, then twice weekly until back to recommended levels

ANC, absolute neutrophil count; WBC, white blood cell.
ANC = Absolute Neutrophil Count, 3500/mm^3 = 3.5 × 10^3/μL or 3.5 × 10^{9}L; 3000/mm^3 = 3 × 10^3/μL or 3 × 10^{9}L; 2000/mm^3 = 2 × 10^3/μL or 2 × 10^{9}L; 1500/mm^3 = 1.5 × 10^3/μL or 1.5 × 10^{9}L; 1000/mm^3 = 1 × 10^3/μL or 1 × 10^{9}L; 500/mm^3 = 0.5 × 10^3/μL or 0.5 × 10^{9}L.

Patient Care and Monitoring

1. Assess the patient's symptoms, review patient and family history, and obtain initial medical evaluation to rule out other causes of psychosis.
2. Periodically review patient data for consistency with diagnostic criteria, and regularly monitor changes in symptomatology.
3. Obtain a thorough history of prescription medication use, and determine what treatments have been helpful in the past, which treatments the patient is currently receiving, and previous side effects experienced.
4. Determine whether the patient is taking an appropriate antipsychotic drug and dose and whether the patient has other symptoms that may need to be treated.
5. Educate the patient, and the family if possible, about the disease state, medication treatments, possible side effects, and goals of treatment.
6. Develop a plan to assess the effectiveness of the current treatment regimen. Also, consider alternative treatments if current treatment is ineffective.
7. Encourage a healthy lifestyle, including eliminating or decreasing substance abuse and cigarette use, as well as appropriate nutritional counseling and exercise suggestions.
8. Determine the role of psychosocial treatments.
9. Evaluate the patient for the presence of adverse drug reactions, drug interactions, and allergies.
10. Monitor the appropriate laboratory measures to prevent or minimize metabolic abnormalities and other side effects.
11. Stress the importance of adherence with the treatment regimen, and maintain treatment even if the patient is feeling well.

35 Major Depressive Disorder

Marshall Cates, Angela Ann Boggs, and Jacqueline Feldman

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Explain the etiology and pathophysiology of major depressive disorder.
2. Identify symptoms and clinical features of major depressive disorder.
3. Differentiate antidepressants according to pharmacologic properties, adverse-effect profiles, pharmacokinetic profiles, drug interaction profiles, and dosing features.
4. Predict adverse-effect profiles of antidepressants based on pharmacology.
5. State the goals of pharmacotherapy in major depressive disorder.
6. Educate patients and caregivers on the proper use of antidepressants.

Key Concepts

❶ Classic views as to the cause of major depressive disorder focus on the monoamine neurotransmitters norepinephrine (NE), serotonin (5-HT), and to a lesser extent, dopamine (DA) in terms of both synaptic concentrations and receptor functioning.

❷ It is not uncommon for a patient to experience only a single major depressive episode, but most patients with major depressive disorder will experience multiple episodes.

❸ One extremely important outcome in the treatment of major depressive disorder is the prevention of suicidal attempts.

❹ Sexual dysfunction is common and challenging to manage and often leads to non-compliance with serotonergic medications.

❺ Each antidepressant has a response rate of approximately 60% to 80%, and no antidepressant medication or class has been reliably shown to be more efficacious than another.

❻ It is widely accepted that it takes approximately 2 to 4 weeks of treatment before improvement is seen in emotional symptoms of depression, such as sadness and anhedonia. Furthermore, it may take as long as 6 to 8 weeks of treatment to see the full effects of antidepressant therapy.

❼ Since the typical major depressive episode lasts 6 months or longer, if antidepressant therapy is interrupted for any reason following the acute phase, the patient may relapse into the depressive episode. When treating the first depressive episode, antidepressants must be given for an additional 4 to 9 months in the continuation phase for the purpose of preventing relapse.

❽ Pediatric patients should be observed closely for suicidality, worsened depression, agitation, irritability, and unusual changes in behavior, especially during the initial few months of therapy or at times of dosage changes. Furthermore, families and caregivers should be advised to monitor patients for such symptoms.

❾ Lack of patient understanding concerning optimal antidepressant drug therapy frequently leads to partial compliance or non-compliance with therapy; thus, the primary purpose of antidepressant counseling is to enhance compliance and improve outcomes.

My spirit is broken,
my days are cut short,
the grave awaits me.
—*Job 17:1*

Contrary to popular belief, major depression is not a fleeting "bad day," is not the result of personal weaknesses or character flaws, and does not respond to volitional efforts simply to feel better. Rather, major depressive disorder (MDD) is a serious medical condition with a biologic foundation, and it responds to biologic and psychological treatments. Individuals who suffer from MDD experience significant and pervasive symptoms that can affect such things as mood, thinking, physical health, work, and relationships. Unfortunately, suicide is often the result of MDD that has not been diagnosed and treated adequately.

Patient Encounter, Part 1

ML, a 28-year-old white woman, comes into your clinic for the first time complaining of decreased sleep, pain, and lack of energy. On interviewing her, you learn that she is also having frequent crying spells and no longer participates in the bowling league, which she used to enjoy every weekend. She fears that she is about to be fired from her job because of numerous sick days and the inability to concentrate on tasks when she is at work, and she claims that she is already under a great deal of financial stress owing to the fact that her husband lost his job several months ago. She states that she has been suffering from these problems for the past two months and is feeling frustrated and hopeless. She admits to drinking about three to four beers per night in order to relax and fall asleep.

- What information is suggestive of MDD?
- What medical or psychiatric issues could be contributing to her symptoms?
- Does she have risk factors for depression?
- What additional information do you need to know before creating a treatment plan for this patient?

Owing to increased awareness of the illness and the advent of newer and safer antidepressant medications, the past two decades have seen improvements in the screening, diagnosis, and treatment of MDD. The willingness of generalist practitioners to involve themselves in the identification and treatment of MDD is noteworthy. To that end, antidepressants have become some of the most commonly prescribed drugs, and they account for 10 of the top 100 prescription drugs dispensed in the United States.[1] Despite recent increases in the treatment of MDD, inadequate treatment remains a serious concern.[2]

EPIDEMIOLOGY

MDD is quite common; lifetime and 12-month prevalence estimates are 16.2% and 6.6%, respectively. Thus, approximately 35 million United States adults will experience MDD in their lifetime.[2] Females are approximately twice as likely as males to experience MDD.[2] Although MDD may begin at any age, the average age at onset is the mid-20s.[3] Interestingly, MDD appears to occur earlier in life in people born in more recent decades.[2] Most patients with MDD also suffer from comorbid psychiatric disorders, especially anxiety disorders and substance-use disorders.[2]

MDD causes serious impairment. According to the World Health Organization (WHO), depression is the leading cause of disability (based on years lived with disability) and the fourth leading contributor to the global burden of disease (based on disability adjusted life years).[4] Those with 12-month MDD reported a mean of about 35 days in the past year in which they were unable to work or carry out usual activities.[2]

ETIOLOGY/PATHOPHYSIOLOGY

The exact cause of MDD remains unknown, but it is probably multifactorial. Biologic, psychological, and social theories abound, and many practitioners suggest that the development of depression often is predicated on the complex synthesis of genetic predisposition, psychological stressors, and biologic pathophysiology. Although knowledge certainly continues to accumulate in this area, there are currently no accepted unifying theories that explain these various factors adequately.

Genetics

The occurrence of MDD shows a familial pattern because first-degree relatives of MDD patients are about three times more likely to develop MDD compared with first-degree relatives of normal control individuals. Adoption studies and twin studies reveal that the familial aggregation of MDD is due to genetic influences.[5]

Life Stress

Depression can occur despite the absence of major life stressors, and conversely, major life stressors do not invariably cause depression. Nevertheless, there is an undeniable association between life stressors and depression, and there appears to be a significant interaction between life stressors and genetic liability in causing depression.[6] Although acute stressors may precipitate depression, chronic stressors have a longer risk period, cause longer episodes, and are more likely to lead to **relapse** and **recurrence.**[6]

Monoamine Neurotransmitter and Receptor Hypotheses

❶ *Classic views as to the cause of MDD focus on the monoamine neurotransmitters norepinephrine (NE), serotonin (5-HT), and to a lesser extent, dopamine (DA) in terms of both synaptic concentrations and receptor functioning.* The monoamine hypothesis asserts that depression is due to a deficiency of monoamine neurotransmitters. The major supporting evidence for this hypothesis is that existing antidepressants increase synaptic monoamine concentrations through various mechanisms (see Pharmacology section). One argument against the monoamine hypothesis is that depressed patients do not consistently exhibit decreased monoamine concentrations. Another problem is that whereas monoamine levels are altered within hours of the introduction of antidepressant therapy, there is a latency period of weeks before the actual antidepressant effect typically is evident.[7–9]

The neurotransmitter receptor hypothesis suggests that depression is related to abnormal functioning of neurotransmitter receptors. In this model, antidepressants presumably exert therapeutic effects by altering receptor sensitivity. In fact,

chronic administration of antidepressants has been shown to cause desensitization, or down-regulation, of β-adrenergic receptors and various 5-HT receptors. Importantly, the time required for changes in receptor sensitivity corresponds to the onset of action of antidepressant therapy.[7–9]

While such models of depression are quite useful in conceptualizing the mechanisms behind antidepressant activity, they are assuredly an oversimplification of the actual pathophysiologic process of the disorder. Depression probably involves a complex dysregulation of monoamine systems, and these systems, in turn, modulate and are modulated by other neurobiologic systems. Thus, the underlying cause of depression may well extend beyond dysfunction of the monoamine system.[10]

Other Neurobiologic Hypotheses

Various other hypotheses have been proposed to help explain the cause of depression. These hypotheses are related to such things as the role of non-monoamine neurotransmitters [e.g., glutamate and gamma-aminobutyric acid (GABA)], neuroendocrine systems (e.g., the hypothalamic-pituitary-adrenal axis), neurosteroids (e.g., allopregnanolone), and neuronal plasticity [e.g., brain-derived neurotrophic factor (BDNF)].[11] Researchers are even starting to gain insight on the intracellular level with findings related to messenger cascades and gene expression.[12]

CLINICAL PRESENTATION AND DIAGNOSIS

The diagnosis of a major depressive episode requires the presence of a certain number of depressive symptoms (five) for a minimum specified duration (2 weeks) that cause clinically significant effects (Table 35–1).[3]

TABLE 35–1. Diagnostic Criteria for Major Depressive Episode[3]

At least five of the following symptoms have been present during the same 2-week period and represent a change from previous functioning:

- Depressed mood[a]
- Markedly diminished interest or pleasure in usual activities[a]
- Increase or decrease in appetite or weight
- Increase or decrease in amount of sleep
- Increase or decrease in psychomotor activity
- Fatigue or loss of energy
- Feelings of worthlessness or guilt
- Diminished ability to think, concentrate, or make decisions
- Recurrent thoughts of death, suicidal ideation, or suicide attempt

The symptoms cause clinically significant distress or impairment in functioning.

The symptoms are not due to the direct physiologic effects of a substance or medical condition.

[a]One of these two symptoms must be present.
With permission.

Clinical Presentation

Patients typically present with a combination of emotional, physical, and cognitive symptoms:

- Emotional
  - Sadness
  - **Anhedonia**
  - Pessimism
  - Feeling of emptiness
  - Irritability
  - Anxiety
  - Worthlessness
  - Thoughts of death/suicidal ideation (SI)
- Physical
  - Disturbed sleep
  - Change in appetite/weight
  - Psychomotor changes
  - Decreased energy
  - Fatigue
  - Bodily aches and pain
- Cognitive
  - Impaired concentration
  - Indecisiveness
  - Poor memory

Occasionally, severely depressed patients also will present with psychotic symptoms:

- Hallucinations
- Delusions

Some patients present with "atypical features" of depression:

- Reactive mood (i.e., mood improves in response to positive events)
- Significant increase in appetite/weight gain
- Hypersomnia
- Heavy feelings in arms or legs
- Sensitivity to interpersonal rejection

HINT: In order to remember the nine diagnostic symptoms for a major depressive episode, learn the following mnemonic: Depression = SIG E CAPS (depression, sleep, interest, guilt, energy, concentration, appetite, psychomotor, suicide).

In turn, the diagnosis of MDD is based on the presence of one or more major depressive episodes during a person's lifetime.[3]

Differential Diagnosis

Major depressive episodes also occur in the context of bipolar disorder. The key difference is that persons with bipolar disorder also experience manic, hypomanic, and/or mixed episodes (see Chap. 36) during the course of their illness, whereas persons with MDD experience only major depressive episodes.[3]

The presence of a significant medical disorder can produce depressive symptoms via either psychological or physiologic mechanisms. Examples include hypothyroidism, anemia, infections, electrolyte disturbances, cardiovascular diseases, neurologic disorders, and many others.[9] Various psychiatric conditions, such as substance-use disorders and anxiety disorders, have been associated with depression as well.[9] The use of central nervous system (CNS) depressants, such as benzodiazepines and narcotics, is associated with increased propensity for depression.[13] Medical drugs that reportedly cause depressive symptoms or depressive-like side effects include corticosteroids, contraceptives, gonadotropin-releasing hormone agonists, interferon-α, interleukin-2, mefloquine, propranolol, and sotalol.[14]

COURSE/PROGNOSIS

Symptoms of a major depressive episode usually develop over days to weeks, but mild depressive and anxiety symptoms may last for weeks to months prior to the onset of the full syndrome. Left untreated, major depressive episodes typically last 6 months or more, but a minority of patients experience chronic episodes that can last for at least 2 years. Approximately two-thirds of patients will recover fully from major depressive episodes and return to usual mood and full functioning, whereas the other third will have partial remission and may continue to experience detrimental effects.[3]

The course of MDD varies markedly from patient to patient. ❷ *It is not uncommon for a patient to experience only a single major depressive episode, but most patients with MDD will experience multiple episodes.* Some patients experience isolated episodes separated by many years, others have clusters of episodes, and still others will suffer more frequent episodes as they age. The number of prior episodes predicts the likelihood of developing subsequent episodes such that by the time a patient experiences a third major depressive episode, there is about a 90% chance that he or she will have a fourth one. MDD is associated with a high mortality rate because about 15% of patients ultimately will commit suicide.[3]

TREATMENT

Desired Outcomes

The obvious goal of therapy for the depressed patient is the resolution of depressive symptoms and a return to **euthymia.** Once symptoms have resolved, then the purpose of ongoing therapy is to prevent relapse and recurrence of depressive symptoms. ❸ *One extremely important outcome in the treatment of MDD is the prevention of suicidal attempts.* Other essential outcomes include improvement of the patient's quality of life, normalization of functioning in areas such as work and relationships, avoidance or minimization of adverse effects, and reduction of health care costs.[15]

Patient Encounter, Part 2: The Medical History, Physical Exam and Diagnostic Tests

The work-up on ML reveals

PMH
- Chronic back pain since motor vehicle accident 3 years ago.

PPH
Non-contributory

FH
- Mother with diabetes mellitus and MDD.
- Father is alive and well with no medical problems.
- Brother is a recovered alcoholic.

SH
Works as a secretary for a construction company. For the past several months has been drinking three to four beers per night. She denies smoking cigarettes or using illicit substances.

Current Meds
- Lo/Ovral 1 tablet every day
- Oxycontin 10-mg tablet twice daily

ROS
- Decreased energy
- Decreased sleep
- All others non-contributory

PE
Height: 5 ft, 2 in (157 cm); weight: 116 lbs (52.7 kg); weight loss of 10 lbs (4.5 kg) over past 2 months

MSE
- Depressed mood
- Decreased concentration
- Thoughts of dying, but no suicidal ideation

Labs
Within normal limits. Pregnancy test negative.

- Given this additional information, what is your assessment of the patient's condition?
- Identify your treatment goals for the patient.
- What non-phamacologic and pharmacologic alternatives are available for this patient?

Nonpharmacologic/Alternative Therapies

Interpersonal therapy and cognitive behavioral therapy are types of psychotherapy that have well-documented efficacy for the treatment of MDD. Psychotherapy alone is an initial treatment option for mild to moderate cases of depression, and it may be useful when combined with pharmacotherapy in the treatment of more severe cases of depression. In fact, the combination of psychotherapy and pharmacotherapy can be more effective than either treatment modality alone in cases of severe or recurrent MDD. Psychotherapy can be especially helpful for patients with significant psychosocial stressors, interpersonal difficulties, or comorbid personality disorders.[16]

Electroconvulsive therapy (ECT) is a highly efficacious treatment for MDD. The **response** rate is about 80% to 90% and even exceeds 50% for patients who have failed pharmacotherapy.[16,17] ECT may be particularly beneficial for MDD that is complicated by psychotic features, severe suicidality, refusal to eat, pregnancy, or contraindication/non-response to pharmacotherapy.[16,17] ECT is typically a very safe treatment alternative, but various cautions do exist, and the chief side effects are confusion and memory impairment.[16]

St. John's wort (*Hypericum perforatum*) is an herbal medication that has shown some efficacy in mild to moderate depression but minimal efficacy for moderate to severe depression.[18] Many patients may believe that herbal medications, being "natural" products, are devoid of adverse effects and drug interactions; however, St. John's wort can cause gastrointestinal irritation, headache, fatigue, and nervousness,[17] and it triggers drug interactions through induction of CYP3A4, as well as other potential mechanisms.[19] The safety and efficacy of St. John's wort combined with standard antidepressant medications remain unknown.[16]

Light therapy is an alternative treatment for depression associated with seasonal (e.g., winter) exacerbations. Possible side effects include eye strain, headache, insomnia, and hypomania.[16,17] Also, potentially vulnerable patients, such as those with photosensitivity or a history of skin cancer, should be evaluated carefully prior to therapy.[16]

Vagus nerve stimulation (VNS) may be used for adult patients with **treatment-resistant depression.** A pulse generator is surgically implanted under the skin of the left chest, and an electrical lead connects the generator to the left vagus nerve. Stimulation of this nerve sends signals to the brain. This therapy is intended to be used along with traditional therapies, such as pharmacotherapy and ECT.[20]

Transcranial magnetic stimulation is a non-invasive and well-tolerated procedure that has shown promise as a novel antidepressant treatment.[21] Some data show that physical exercise may reduce depressive symptoms, but well-controlled studies are needed to clarify its role in the treatment of depression.[18]

Pharmacologic Therapy

Clinical Distinctions

Given that there are now about 25 antidepressant medications, one apparent clinical perplexity is for the clinician to distinguish the various agents. But each antidepressant has its unique blend of characteristics, and in fact, even individual drugs within the same class have important differences.[22]

General Pharmacology

Table 35–2 demonstrates the differing pharmacologic properties of the antidepressant medications,[7–9] whereas Table 35–3 delineates the results of those pharmacologic actions.[7,8] Monoamine oxidase inhibitors (MAOIs) inhibit the enzyme responsible for the intraneuronal breakdown of 5-HT, NE, and DA. Tricyclic antidepressants (TCAs) possess both 5-HT reuptake inhibition (SRI) and NE reuptake inhibition (NRI) properties but unfortunately also block the so-called "dirty receptors", including α_1-adrenergic, histamine-1, and muscarinic cholinergic receptors, which do not contribute to efficacy but do cause problematic adverse effects. The selective serotonin reuptake inhibitors (SSRIs) are classified as such because SRI is the predominant effect. Bupropion is an NE and DA reuptake inhibitor (NDRI). Venlafaxine and duloxetine are 5-HT and NE reuptake inhibitors (SNRIs) but are also weak inhibitors of DA reuptake. Compared with venlafaxine, which has primarily SRI activity, duloxetine has more balanced SRI and NRI activities and has a higher affinity for the reuptake sites. Nefazodone and trazodone are 5-HT antagonists/reuptake inhibitors (SARIs). Their SRI activity is not as pronounced as that of SSRIs, but they potently block 5-HT_{2A} receptors, which allows more 5-HT to interact at postsynaptic 5-HT_{1A} sites. In addition, trazodone blocks histaminergic and

TABLE 35–2. Primary Pharmacologic Actions of Antidepressants[a7–9]

Action	MAOIs	TCAs	SSRIs	Bupropion	Venlafaxine	Duloxetine	Trazodone	Nefazodone	Mirtazapine
Monoamine oxidase inhibition	X

MAOI, monoamine oxidase inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

TABLE 35–3. Efficacy/Adverse-Effect Profiles Based on Pharmacology[7,8]

Pharmacologic Action	Result
Serotonin reuptake inhibition (SRI)	Antidepressant and antianxiety efficacy (via interaction of serotonin at 5HT-1A receptors) Anxiety, insomnia, sexual dysfunction (via interaction of serotonin at 5HT-2A receptors) Anxiety, anorexia (via interaction of serotonin at 5HT-2C receptors) Nausea, GI problems (via interaction of serotonin at 5HT-3 receptors)
Norepinephrine reuptake inhibition (NRI)	Antidepressant efficacy Tremor, tachycardia, sweating, jitteriness, increased blood pressure
Dopamine reuptake inhibition (DRI)	Antidepressant efficacy Euphoria, psychomotor activation, aggravation of psychosis
α_2-Adrenergic receptor blockade	Increase in serotonergic and noradrenergic activity—see actions of SRI and NRI above
Serotonin-2A receptor blockade	Antianxiety efficacy Increased REM sleep, decreased sexual dysfunction
Serotonin-2C receptor blockade	Antianxiety efficacy Increased appetite/weight gain
Serotonin-3 receptor blockade	Antinauseant, decreased GI problems
α_1-Adrenergic receptor blockade	Orthostatic hypotension, dizziness, reflex tachycardia
Histamine-1 receptor blockade	Sedation, weight gain
Muscarinic cholinergic receptor blockade	Dry mouth, blurred vision, constipation, urinary hesitancy, sinus tachycardia, memory problems

α-adrenergic receptors, whereas nefazodone possesses weak NRI and α-adrenergic blocking properties. Finally, mirtazapine is a noradrenergic and specific serotonergic antidepressant (NaSSA). It blocks presynaptic α_2 receptors, both autoreceptors on noradrenergic neurons and heteroreceptors on serotonergic neurons, with resulting increases in NE and 5-HT synaptic concentrations, respectively. Mirtazapine also blocks various postsynaptic serotonergic receptors and histamine-1 receptors.[7–9]

Adverse Effects

The important adverse effects of the various antidepressants are often a function of their underlying pharmacologic profiles[7,8] (Table 35–3). TCAs cause problematic sedative, anticholinergic, and cardiovascular adverse effects owing to their interaction with "dirty receptors." While these adverse effects generally are considered to be common and bothersome, they can be quite serious in certain cases. For example, constipation in its extreme form can lead to paralytic ileus. It is very important to note that TCAs have a quinidine-like effect on the heart, which makes them quite toxic in overdose situations. The average lethal dose in a young adult is only 30 mg/kg, which is typically less than a 1-month's supply of medicine.[7,9,22,23]

The adverse-effect profile of the SSRIs reveals the strong serotonergic influence of these drugs. Sexual dysfunction (e.g., delayed or absent orgasms), CNS stimulation (e.g., nervousness and insomnia), and gastrointestinal disturbances (e.g., nausea and diarrhea) are frequent serotonergic adverse effects.[7,9,22,23] ❹ *Sexual dysfunction is common and challenging to manage and often leads to non-compliance with serotonergic medications.*[24] Various strategies have been used by clinicians to deal with antidepressant-induced sexual dysfunction, including waiting for symptoms to subside, reducing the dosage, permitting periodic "drug holidays," prescribing adjunctive therapy, and switching antidepressants.[25] However, waiting for symptoms to subside usually does not work because sexual dysfunction may very well persist throughout the duration of therapy, and both reducing the dose and using drug holidays have the potential for weakening the therapeutic effects of the medications. Thus, clinicians often prescribe adjunctive therapy, such as dopaminergic drugs (e.g., bupropion or amantadine), 5-HT_2 antagonists (e.g., cyproheptadine and nefazodone), and phosphodiesterase inhibitors (e.g., sildenafil), or simply switch to antidepressants with far less chance of causing these effects, such as bupropion, mirtazapine, and nefazodone.[24,25]

Bupropion causes insomnia, nightmares, decreased appetite, anxiety, and tremors, but the most concerning adverse effect is seizures. Because of the risk for seizures, patients who should not receive the drug include those with a CNS lesion or those with a history of seizures, head trauma, or bulimia. The daily dose of bupropion should not exceed 450 mg/day, and any single dose of the immediate-release formulation should not exceed 150 mg/day Occurrences of insomnia and/or nightmares often respond to moving the last daily dose from bedtime to late afternoon.[7,9,22,23]

The adverse effects of SNRIs look fairly similar to those of SSRIs. Nausea can be particularly troublesome with venlafaxine, which sometimes necessitates using lower starting dosages than usual and giving the medication with food. A dose-related elevation in blood pressure can occur at higher doses, probably owing to the NRI effects. Blood pressure monitoring should be conducted for patients receiving venlafaxine therapy. As a rule, duloxetine should not be prescribed to patients with extensive alcohol use or evidence of chronic liver disease owing to the potential for hepatic injury.[9,22,26,27]

Trazodone routinely causes sedation, which is why it is used far more often as an adjunct with other antidepressants for sleep than as a primary agent for the treatment of depression. Priapism is a rare but serious adverse effect in males who take trazodone. In addition, orthostatic hypotension and dizziness are more common with trazodone than with nefazodone because the latter agent has a weaker effect at α-adrenergic receptors and also has a balancing of adrenergic effects owing

TABLE 35–4. Relative Incidence of Adverse Effects of Various Newer Antidepressants[9,13,28]

Drug	Sedation	Activation	Weight Gain	Weight Loss	GI Upset	Sexual Dysfunction
Bupropion	Min	High	Min	Low	Mod	Min
Citalopram	Min	Min	Min	Min	High	High
Fluoxetine	Min	High	Min	Min	High	High
Mirtazapine	Mod	Min	Low	Min	Min	Min
Nefazodone	Low	Min	Min	Min	Low	Min
Paroxetine	Low	Low	Min	Min	High	High
Sertraline	Min	Mod	Min	Min	High	High
Venlafaxine	Low	Mod	Min	Min	High	High

Min, minimal; mod, moderate.
High greater than Mod greater than Low greater than Min.

to weak NRI activity. Unfortunately, nefazodone has been associated with development of hepatotoxicity, which has led to a black-box warning and a great reduction in its use.[7,9,22,23]

Mirtazapine can cause sedation and weight gain by virtue of blocking histamine-1 receptors. Despite being partially a serotonergic drug, it rarely causes serotonergic-related adverse effects because it blocks the various postsynaptic 5-HT receptors. Although it carries a black-box warning for neutropenia owing to a handful of cases reported during clinical trials, it is questionable whether neutropenia is any more problematic with this agent versus other antidepressants.[9,22,23]

The relative incidence of adverse effects among some of the newer antidepressant agents are shown in Table 35–4.[9,13,28]

Pharmacokinetic Parameters

Pharmacokinetic parameters of the newer antidepressants are shown in Table 35–5.[9,29] Several antidepressants are not very highly protein bound, and the most notable of these is venlafaxine. The elimination half-lives of nefazodone and venlafaxine are relatively short compared with the other agents. Conversely, fluoxetine has a very long half-life (i.e., many days) with chronic dosing, and its active metabolite (norfluoxetine) has an even longer half-life. Owing to the extremely long half-life of fluoxetine and its active metabolite, the clinician must be aware that about 5 weeks are required to either reach steady-state levels or to wash out after discontinuation of therapy. Sertraline and citalopram are the other SSRIs with active metabolites, but these metabolites (desmethylsertraline and desmethylcitalopram, respectively) are only about one-eighth as potent as the parent compounds in terms of SRI activity.

TABLE 35–5. Pharmacokinetic Parameters of Newer Antidepressants

Drug	Protein Binding (%)	Half-Life (hours)	Active Metabolite(s)
Bupropion	84	10–21	Yes
Citalopram	80	33	Yes
Duloxetine	90	9–19	No
Escitalopram	56	27–32	No
Fluoxetine	94	4–6 days with chronic dosing; 4–16 days (active metabolite)	Yes
Fluvoxamine	77	15–26	No
Mirtazapine	85	20–40	No
Nefazodone	99	2–4	Yes
Paroxetine	95	21	No
Sertraline	98	27	Yes
Venlafaxine	27	5	Yes

Drug Interactions

The major drug interactions of antidepressants are shown in Table 35–6.[9,19,30] Antidepressants cause both pharmacodynamic (e.g., additive pharmacologic effects) and pharmacokinetic (e.g., changes in drug levels) interactions with other medications.

The usual pharmacodynamic interactions involve the "dirty receptors" blocked by some antidepressants. Hence especially TCAs can cause significant additive effects with drugs that cause sedation, hypotension, or anticholinergic effects. Similarly, nefazodone and mirtazapine can interact with other drugs that cause hypotensive and sedative effects, respectively. By far the most concerning pharmacodynamic interactions are hypertensive crisis and serotonin syndrome, which are both potentially life-threatening when they occur. Hypertensive crisis is characterized by sharply elevated blood pressure, occipital headache, stiff or sore neck, nausea, vomiting, and sweating. It may result during MAOI therapy if the patient takes a sympathomimetic drug, such as ephedrine, pseudoephedrine, phenylephrine, or phenylpropanolamine, or if the patient consumes foods rich in tyramine, such as tap beers, aged cheeses, fava beans, yeast extracts, liver, dry sausage, sauerkraut, or tofu.[23] There are extensive lists of foods and drinks that are permitted and not permitted during therapy with MAOIs, and these always should be provided to patients for their safety. Furthermore, since many over-the-counter products contain sympathomimetics, patients always

TABLE 35–6. Drug Interactions of Antidepressants[a9,19,30]

Antidepressants	Type of Interaction	Examples of Interacting Drugs
TCAs Trazodone Mirtazapine	Pharmacodynamic—additive sedation	Benzodiazepines Alcohol Antihistamines
TCAs Trazodone	Pharmacodynamic—additive hypotensive effects	Prazosin Antipsychotics
TCAs	Pharmacodynamic—additive anticholinergic effects	Phenothiazines Benztropine

MAOI, monoamine oxidase inhibitor; SARI, serotonin antagonist and reuptake inhibitor; SNRI, serotonin and norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

should be told to consult with their clinician and/or pharmacist prior to using these drugs. Serotonin syndrome is characterized by confusion, restlessness, fever, abnormal muscle movements, hyperreflexia, sweating, diarrhea, and shivering.[31] It may result when a serotonergic agent is added to any serotonergic antidepressant, but the MAOIs are strongly associated with severe cases of serotonin syndrome.[31] Serotonin syndrome is complicated by the general unawareness of clinicians of its diagnosis,[31] as well as the fact that many drugs are not obviously serotonergic in nature, such as dextromethorphan, meperidine, and tramadol.

Several antidepressants, including most of the SSRIs, nefazodone, and duloxetine, are known to inhibit various cytochrome P-450 isoenzymes, thereby elevating plasma levels of substrates for those isoenzymes and thus potentially leading to increased adverse effects or toxicity of those drugs. The propensity to cause these drug interactions will vary with the particular antidepressant and the precise isoenzyme[9,19,30] (Table 35–6).

Dosing

As can be seen in Table 35–7, antidepressants are available in several different dosage forms.[13,16–18,29,32] The extended-release

TABLE 35–7. Dosing of Antidepressants in Adult Patients[13,16–18,29,32]

Generic Name	Brand Name	Generic	Dosage Forms	Initial Dose (mg/day)	Usual Dosage Range (mg/day)	Usual Dosing Schedule
MAOIs						
Phenelzine	Nardil	No	Tablet	15–30	15–90	Twice daily
Tranylcypromine	Parnate	No	Tablet	10–20	30–60	Twice daily
TCAs and Tetracyclics						
Amitriptyline	Elavil[a]	Yes	Tablet	25–50	100–300	Once daily
Amoxapine	Asendin[a]	Yes	Tablet	25–50	100–400	Once to twice daily
Clomipramine	Anafranil	Yes	Capsule	25	100–250	Once daily
Desipramine	Norpramin	Yes	Tablet	25–50	100–300	Once daily
Doxepin	Sinequan	Yes	Capsule, solution	25–50	100–300	Once daily
Imipramine	Tofranil	Yes	Tablet, capsule (PM)	25–50	100–300	Once daily
Maprotiline	Ludiomil[a]	Yes	Tablet	50–75	100–225	Once to twice daily

NaSSA						
Mirtazapine	Remeron	Yes	Tablet, disintegrating tablet (SolTab)	15	15–45	Once daily

[a]Brand name no longer available in the United States.
MAOI, monoamine oxidase inhibitor; NaSSA, noradrenergic and specific serotonergic antidepressant; NDRI, norepinephrine and dopamine reuptake inhibitor; SARI, serotonin antagonist and reuptake inhibitor; SNRI, serotonin and norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

formulations of venlafaxine and bupropion allow for once-daily dosing. The delayed-release capsule of fluoxetine can be given once weekly, which can be started 7 days after the last regular-release capsule or tablet. Liquid dosage forms and disintegrating tablets of various antidepressants are ideal for patients who have difficulty swallowing tablets or capsules or those who otherwise may attempt to "cheek" their medication.

The starting dose is the usual therapeutic dose for most of the SSRIs, duloxetine, and mirtazapine, whereas there is usually need for at least some upward titration of venlafaxine, bupropion, and nefazodone. A particular disadvantage of TCAs is that the customary way of dosing them involves meticulous upward titration from a small starting dose to a wide usual therapeutic dosage range. On the other hand, one advantage is that plasma levels may be used to help guide dosing, especially for those that have well-defined therapeutic plasma level ranges, including nortriptyline (50–150 ng/mL or mcg/L, or 190–570 nmol/L), desipramine (100–160 ng/mL or mcg/L, or 375–600 nmol/L), amitriptyline (75–175 ng/mL or mcg/L, 255–595 nmol/L), and imipramine (greater than 200 ng/mL or mcg/L, or 714 nmol/L).[28]

Efficacy of Pharmacotherapy

❺ *Each antidepressant has a response rate of approximately 60% to 80%, and no antidepressant medication or class has been reliably shown to be more efficacious than another.*[7,22] MAOIs may be the most effective therapy for atypical depression, but MAOI use continues to wane because of problematic adverse effects, dietary restrictions, and possibility of fatal drug interactions.[22,28] There is some evidence that dual-action antidepressants, such as TCAs and SNRIs, may be more effective for inpatients with severe depression than are the single-action drugs such as SSRIs,[22,28] but the more general assertion that multiple mechanisms of action confer efficacy advantages is quite controversial.[33]

Selection of Medication

Figure 35–1 depicts a well-known algorithm for the pharmacologic treatment of non-psychotic MDD—the Texas Medication Algorithm Project.[34] Notable aspects of this algorithm include the preferential use of newer antidepressants in the earlier stages of treatment and sequential trials of antidepressant monotherapy prior to the use of combination therapy (see Managing Partial Response or Non-response). It has been shown that patients undergoing treatment guided by this algorithm fared better than those who received treatment as usual during a 1-year period, as measured by clinician-rated symptoms, self-reported symptoms, and overall mental functioning.[35] Antipsychotic medication should be combined with antidepressant medication in cases of depression with psychotic features.[16]

Various factors must be taken into account when selecting antidepressant therapy for a particular patient. The most reliable predictor of response is the patient's past history of response (e.g., efficacy, side effects, and overall satisfaction) to antidepressants. To a lesser extent, the past history of a first-degree relative's response to antidepressants may be used to predict a patient's response. Adverse-effect profiles should be considered because compliance is influenced greatly by tolerability. In this regard, a frank discussion should occur with the patient in order to determine which adverse effects are acceptable and which are not. The clinician must be careful to contemplate potential drug-drug interactions and disease-state interactions. For instance, a patient with seizure disorder would be an inappropriate candidate for bupropion therapy. The presence of comorbid psychiatric conditions can help the clinician to determine the best antidepressant to choose for a patient. For example, an SSRI can treat both MDD and panic disorder, obviating the need for separate medication therapy. The patient must be willing and able to comply with dosing schedules (e.g., upward titration of TCAs or twice-daily dosing of nefazodone) and special instructions (e.g., diet with MAOI therapy) associated with certain antidepressants. Another patient-specific factor is the potential for accidental or intentional overdosing because certain antidepressants (e.g., TCAs) are quite toxic in those situations. Finally, the patient should be able to comfortably afford the chosen medication or else compliance is at risk.[22]

Time Course of Response

Unfortunately, antidepressants do not produce a clinical response immediately. Improvement in physical symptoms, such as sleep, appetite, and energy, can occur within the first week or so of treatment. Although a recent meta-analysis suggests earlier effects of antidepressant treatment,[36] ❻ *it is widely accepted that it takes approximately 2 to 4 weeks of treatment before improvement is seen in emotional symptoms of depression, such as sadness and anhedonia. Furthermore, it may take as long as 6 to 8 weeks of treatment to see the full effects of antidepressant therapy.*[7,22,23]

Managing Partial Response or Non-response

Approximately one-third of patients with MDD do not respond satisfactorily to their first antidepressant medication.[37] In such cases, the clinician must evaluate the adequacy of antidepressant therapy, including dosage, duration, and patient compliance.[17] Treatment reappraisal also should include verification of the patient's diagnosis and reconsideration of clinical factors that could be impeding successful therapy, such as concurrent medical conditions (e.g., thyroid disorder), comorbid psychiatric conditions (e.g., alcohol abuse), and psychosocial issues (e.g., marital stress).[16]

For patients who have experienced a partial response, extending the medication trial and/or using higher doses within the recommended dosage range of the antidepressant may be helpful.[16] Another option is to employ augmentation therapy, i.e., adding another medication that generally is not used as an antidepressant.[37] Augmenting agents with clear efficacy include lithium and thyroid hormone (e.g., liothyronine), whereas initial enthusiasm has lessened to some extent for the serotonergic drugs buspirone and pindolol owing to negative findings in controlled trials.[38] Efficacy has been suggested for dopaminergic drugs (e.g., pramipexole), psychostimulants (e.g., methylphenidate), and atypical antipsychotics (e.g., olanzapine), whereas various other medications, such as anticonvulsants (e.g., valproic acid), modafanil, and estrogen, have anecdotal evidence to support their use.[38] A third option is to make use of combination therapy, whereby another antidepressant, typically from a different pharmacologic class, is added to the first antidepressant medication. Examples include combining bupropion and SSRIs and combining TCAs and SSRIs.[38,39]

Switching to a different antidepressant is a common strategy for patients who have had no response to initial antidepressant therapy but also is acceptable in cases of partial response.[16] Relative to augmentation/combination, advantages of switching include improved compliance, decreased costs, and less concern over drug interactions, whereas disadvantages include loss of time ("reset the clock") and loss of any improvement seen with the initial drug.[39] When switching from one antidepressant to another, clinicians may choose to stay within the same class (e.g., sertraline to fluoxetine) or go outside of the class (e.g., paroxetine to venlafaxine).[37,39]

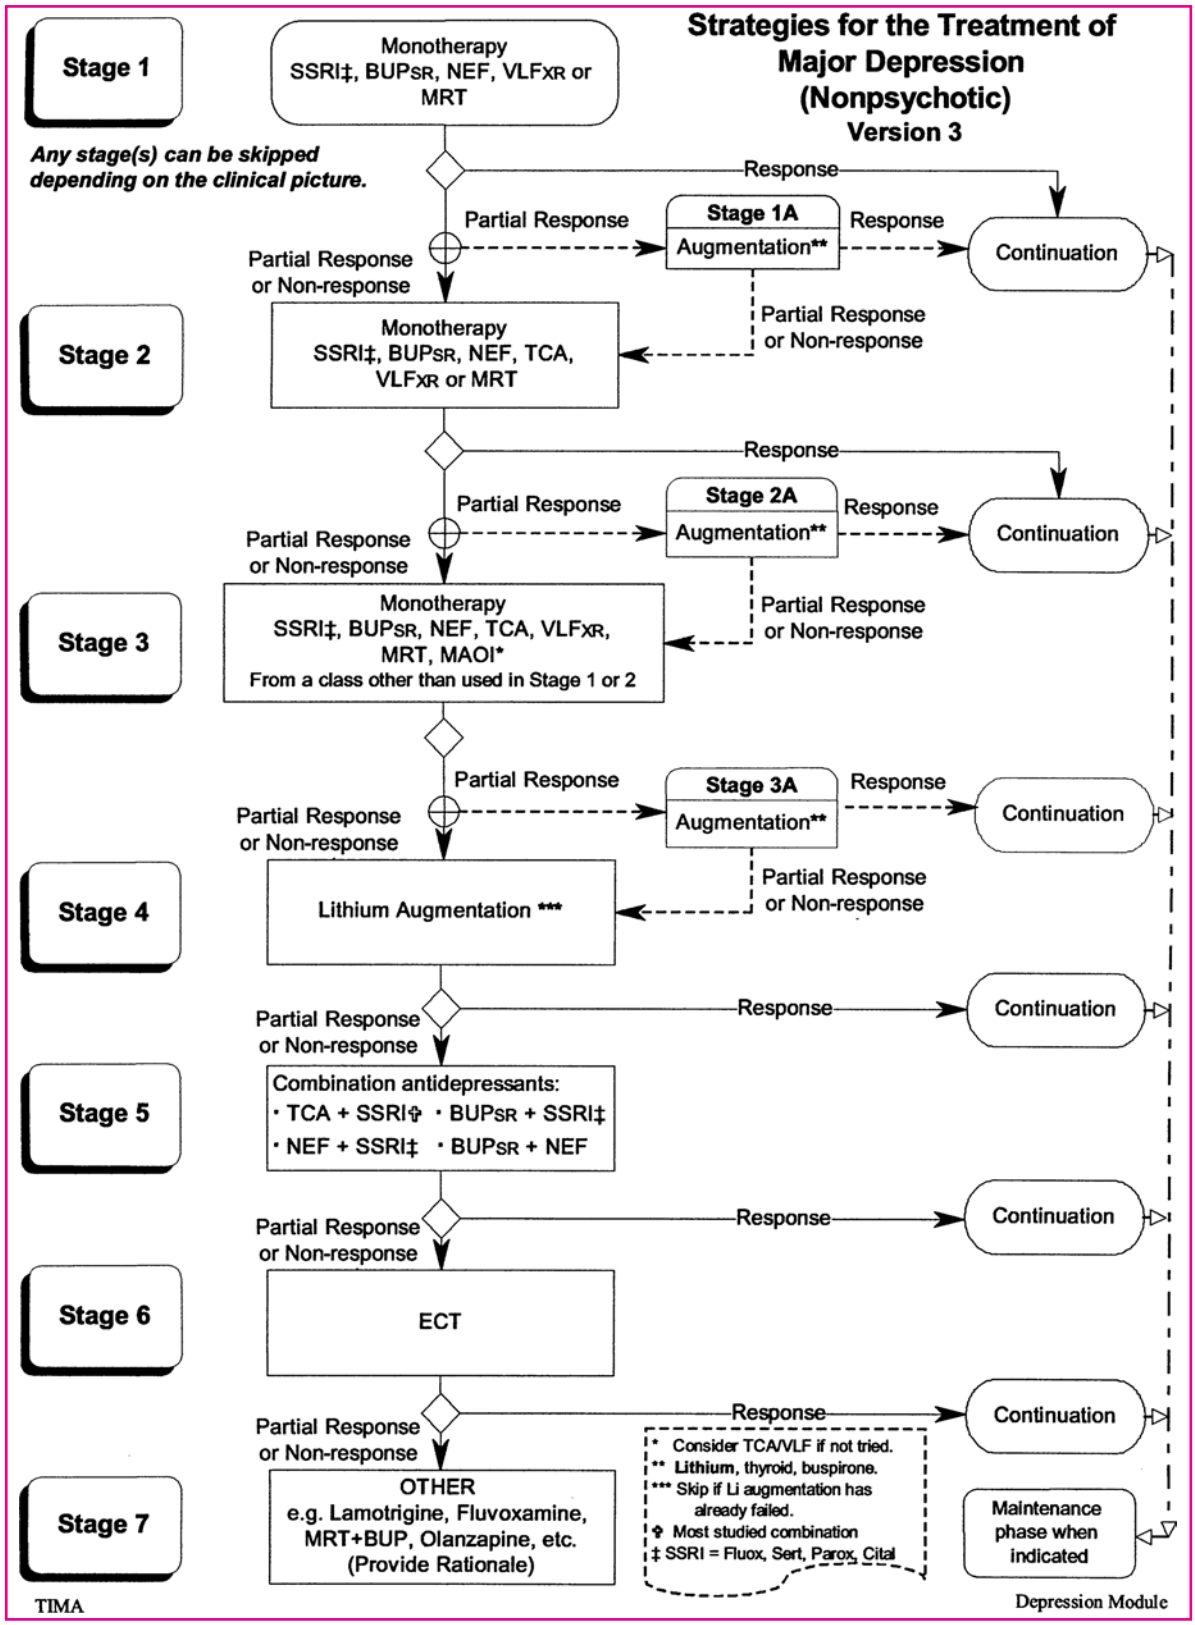

FIGURE 35–1. Strategies for the treatment of non-psychotic major depression.[34] (Used, with permission)

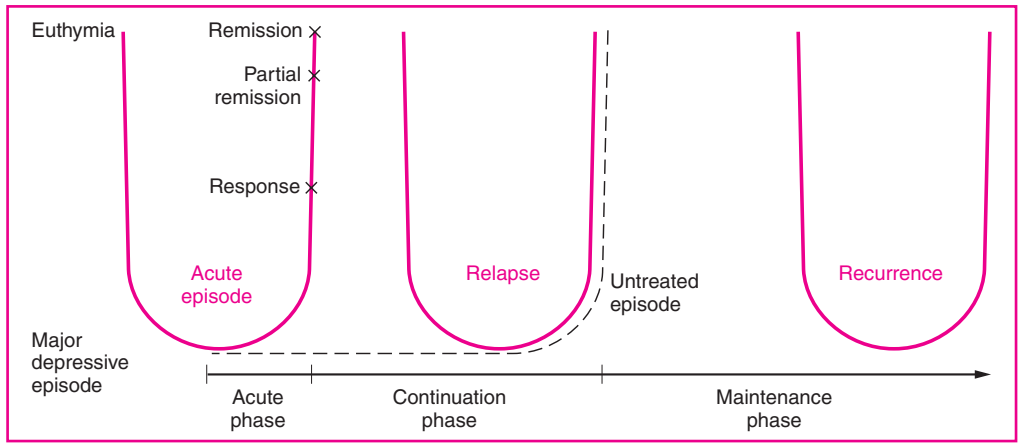

FIGURE 35–2. The course of depression and phases of treatment.[7,8]

Nonpharmacologic interventions in cases of treatment non-response include adding or changing to psychotherapy or initiating ECT.[16]

Duration of Therapy

Treatment of MDD can be conceptualized as a series of three phases: acute, continuation, and maintenance[7,8,16] (Fig. 35–2). During a major depressive episode, a clinician will initiate antidepressant therapy for the purpose of attaining **remission** of symptoms. This acute phase of treatment typically lasts 6 to 12 weeks. ❼ *Since the typical major depressive episode lasts 6 months or longer, if antidepressant therapy is interrupted for any reason following the acute phase, the patient may relapse into the depressive episode. When treating the first depressive episode, antidepressants must be given for an additional 4 to 9 months in the continuation phase for the purpose of preventing relapse.* Maintenance treatment takes place after the normal course of a major depressive episode in order to prevent recurrence, which is the development of future episodes. This phase can last for years, if not for a lifetime. Whereas all patients who suffer a major depressive episode should receive both acute and continuation treatment, not all of them will require maintenance treatment. The reason for this is because not all patients experience multiple major depressive episodes, and even in many cases in which they do, many years may separate the episodes. Therefore, the clinician must consider various factors in determining whether an individual patient requires maintenance treatment. A major factor is the number of prior episodes experienced by the patient. As discussed earlier, the more episodes experienced, the more likely future episodes will occur. This has led many clinicians to adopt the "three strikes and you're on" approach, whereby a patient with a history of three or more major depressive episodes is given lifelong maintenance treatment because of the very high (i.e., 90%) chance of experiencing additional episodes. Other factors to consider are the severity of previous episodes, especially if suicidal attempts were made or psychotic features were present, and patient preference.[16] In general, the dose of the antidepressant required in the acute phase of treatment should be sustained during the continuation and maintenance phases.[16]

Discontinuation of Therapy

When the clinician and patient are ready to attempt discontinuation of therapy, whether at the end of the continuation phase or during the maintenance phase, it is best to do so via gradual taper of the antidepressant. This is done for two reasons. First, almost all antidepressants can produce withdrawal syndromes if discontinued abruptly or tapered too rapidly, especially antidepressants with shorter half-lives (e.g., venlafaxine, paroxetine, and fluvoxamine).[17] These withdrawal syndromes can cause sleep disturbances, anxiety, fatigue, mood changes, malaise, gastrointestinal disturbances, and a host of other symptoms[17] and often are confused with depressive relapse or recurrence.[16] In general, a tapering schedule involving a small dosage decrement (e.g., paroxetine 5 mg) every 3 to 5 days should prevent significant withdrawal symptoms.[17] Second, depressive symptoms may return on taper or discontinuation of the antidepressant. If antidepressant therapy is discontinued abruptly and depressive symptoms return weeks later, then the lag time to onset of action must be observed once the antidepressant is restarted ("reset the clock"); however, if gradual tapering is carried out, then early signs of depression can be countered with a return to the original dosage and a potentially quicker response.[16] Depending on the patient's illness and the clinical circumstances, tapering of the antidepressant can be extended for weeks or even months because of the concern over relapse or recurrence.

Special Considerations

Pregnant/Breast-Feeding Patients

It is a common misconception that pregnancy protects against depression (i.e., the "glow" of pregnancy). Depression actually is quite common in pregnancy, especially for women with a history of recurrent depression. Both maternal and fetal well-being must be taken into account when weighing the benefits and risks of using antidepressant therapy during pregnancy.[40] In general, studies have not demonstrated an increased risk of miscarriage or congenital malformations with antidepressant use,[40] but the prescribing information for paroxetine was changed recently to reflect the findings of epidemiologic studies in which an increased risk of congenital malformations, in particular atrial or ventricular septal defects, was seen in infants born to women taking the drug during the first trimester of pregnancy.[41] Antidepressants have been reported occasionally to cause perinatal sequelae, such as poor neonatal adaptation, respiratory distress, feeding problems, and jitteriness.[40] Data concerning the long-term neurobehavioral effects of in utero antidepressant exposure remain quite limited.[40] Fluoxetine, citalopram, and TCAs have the greatest reproductive safety data and should be considered first-line treatments when pharmacotherapy is indicated.[40]

There will be at least some drug exposure to the infant from nursing mothers taking antidepressant medications. Although there have been rare anecdotal reports of adverse effects (i.e., respiratory depression and seizure-like episodes) in infants exposed to antidepressants through breast milk, no rigorous study has confirmed adverse effects of these drugs, and it is generally accepted that the benefits of breast-feeding outweigh the risks to the infant of antidepressant exposure. However, the decision needs to be made on an individual basis.[42]

Geriatric Patients

It is generally agreed that depression in older adults is underrecognized and undertreated.[43] Although not uncommon in community samples, MDD is particularly prevalent among those living in long-term care facilities.[15,43] Barriers to recognition of geriatric depression include the tendency toward "masked" presentations, i.e., complaints of physical symptoms (e.g., pain and gastrointestinal problems) instead of mood symptoms, the frequent presence of medical illnesses, and the overlap of mood and cognitive symptoms with those of dementia.[15,43] Age-related pharmacokinetic and pharmacodynamic changes cause geriatric patients to be more sensitive to the effects of antidepressant medications.[15] Thus, lower starting doses of antidepressants with slow upward titrations as tolerated are recommended for geriatric patients.[13,16,43] SSRIs are chosen frequently to treat geriatric depression because of their overall favorable adverse-effect profiles and low toxicity, whereas most TCAs are avoided owing to problematic anticholinergic, cardiovascular, and sedative properties.[43] Desipramine and nortriptyline are two TCAs that are more tolerable in terms of these adverse effects and thus may be used in geriatric depression.[43] Other newer antidepressants, such as bupropion, venlafaxine, nefazodone, and mirtazapine, are alternatives for the treatment of geriatric patients as well.[43]

Patient Encounter, Part 3: Creating a Care Plan

Based on the information presented, create a care plan for ML. Your plan should include: (1) a statement of the drug-related needs and/or problems, (2) the goals of therapy, (3) a patient-specific detailed therapeutic plan, and (4) a plan for follow-up to determine whether the goals have been achieved.

Pediatric Patients

Antidepressant medications appear to be useful for certain children and adolescents, particularly those who have severe or psychotic depression, fail psychotherapeutic measures, or experience chronic or recurrent depression. SSRIs generally are considered the initial antidepressants of choice, although comorbid conditions may favor alternative agents. Clinicians should be aware of the possibility of "behavioral activation" with the SSRIs, including such symptoms as impulsivity, silliness, daring conduct, and agitation.[44] Desipramine should be used with caution in this population because of several reports of sudden death, and a baseline and follow-up electrocardiogram (ECG) may be warranted when this medication is used to treat pediatric patients.[9]

The Food and Drug Administration (FDA) has warned that antidepressants increase the risk of suicidality (i.e., suicidal thinking and behavior) in children and adolescents. A large analysis of clinical trials revealed that the risk of such events was 4% for antidepressant medications versus 2% for placebo, although no completed suicides occurred in the trials. Because of this increased risk, antidepressants have black-box warnings concerning the matter, and patient medication guides are required to be distributed with each prescription or refill of antidepressant medications. ❽ *Pediatric patients should be observed closely for suicidality, worsened depression, agitation, irritability, and unusual changes in behavior, especially during the initial few months of therapy or at times of dosage changes. Furthermore, families and caregivers should be advised to monitor patients for such symptoms.*[45]

Suicidal Patients

The FDA is in the process of analyzing data to determine whether there is an increased risk of suicidality in adult patients similar to that seen in pediatric patients (see above). Even though the suicidality risk for adults taking antidepressant medications

TABLE 35–8. Patient Counseling[28,47]

Counseling Point	Clinical Rationale
Mechanism of action—The medication works by affecting certain chemicals in the brain.	Patient may feel that depression is a character weakness or personality flaw instead of a biologic disorder.
Lack of addiction potential—Although the medication affects certain chemicals in the brain, it is not addicting.	Patient may worry that since the antidepressant is psychoactive, it must be addicting.
Need for routine use—The medication will only work if it is taken as prescribed every day.	Patient may try taking the medication on an as-needed basis.
Delayed onset of action—It may take several weeks to see significant improvement in symptoms.	Patient may prematurely discontinue therapy prior to onset of beneficial effects.
Prolonged duration of therapy—The medication should be taken for at least 6 to 12 months; do not discontinue it without consulting with the prescriber.	Patient may prematurely discontinue therapy after symptoms have remitted, which could lead to relapse or recurrence.
Adverse effects—Mention common and expected adverse effects as well as what to do should they occur.	Patient may be more likely to discontinue therapy and distrust the prescriber if adverse effects occur without forewarning.
Avoidance of alcohol/CNS depressants—Use of alcohol or other CNS depressants could cause worsened depression and additive adverse effects with the medicine.	Patient may be unaware of the possible consequences of drinking alcohol or taking other drugs with antidepressants.
Risk of suicidality—Be alert to symptoms of worsening depression and suicidality.	Patient may become suicidal while taking the antidepressant.

Data from references 28 and 47.

is currently unknown, similar monitoring for suicidality and clinical worsening that is mandated for pediatric patients should be followed for adult patients.[46]

The clinician should bear in mind the toxic potential for the various antidepressant medications when patients already have or develop suicidality. The TCAs and MAOIs have narrow therapeutic indices, whereas the SSRIs, SNRIs, nefazodone, and mirtazapine have wide therapeutic indices.[22]

Patient Counseling

Major counseling points and the clinical rationale behind them are outlined in Table 35–8.[28,47] ❾ *Lack of patient understanding concerning optimal antidepressant drug therapy frequently leads to partial compliance or non-compliance with therapy; thus, the primary purpose of antidepressant counseling is to enhance compliance and improve outcomes.*[47]

Recent Developments

The FDA recently approved selegiline (Emsam®) as the first transdermal patch for use in treating MDD.[48] Despite belonging to the MAOI class of antidepressants, the lowest dose of the patch, 6 mg/24 hours, can be used without the usual dietary restrictions associated with MAOI use.[48] Patients receiving the higher doses, 9 and 12 mg/24 hours, should follow the usual dietary restrictions.[48] Patients are advised to change the patch daily. Also, drug labeling advises patients and clinicians about the possibility of increased absorption of medication if the patch is exposed to direct heat.[48] A mild skin reaction at the site of patch placement is a common side effect. As with oral MAOIs, decreased blood pressure and light-headedness are possible.[48]

OUTCOME EVALUATION

- Review the patient's medication profile to ensure that there are no potential/actual pharmacotherapy problems related to dosing, disease-state precautions or contraindications, drug-drug interactions, unnecessary therapeutic duplication, etc.
- Verify the extent of compliance with pharmacotherapy.
- Assess the response to pharmacotherapy, especially with regard to suicidality and those symptoms that cause significant subjective distress and/or functional impairment.
- Determine whether the patient is experiencing adverse effects of pharmacotherapy. Although general questioning (e.g., "Are you having any side effects?") may reveal some problems with therapy, it is better to use direct questioning concerning adverse effects that are most common and/or most problematic (e.g., "Have you noticed any change in your sexual functioning?").
- Provide counseling to enhance patient understanding of MDD and its pharmacotherapy.

Patient Care and Monitoring

1. Assess the patient's severity of symptoms to determine if patient-directed therapy is appropriate or whether a psychiatrist should evaluate the patient.
2. Obtain a thorough history of prescription, nonprescription, natural, and illicit drug product use. Rule out medications or medical disorders that may cause or mimic depressive symptoms.
3. Review *Diagnostic and Statistical Manual of Mental Disorders,* 4th edition, Text Revision (DSM-IV-TR) criteria to determine an appropriate diagnosis.
4. Determine appropriate pharmacologic and psychological treatments (e.g., cognitive-behavioral therapy), including what has been helpful to the patient in the past.
5. Educate patient and/or caretaker about the disease state, lifestyle modifications, and medication therapy.
   - What risk factors are present that could contribute to depression?
   - What lifestyle modifications could be made to improve condition (e.g. exercise)?
   - How should the medication be taken?
   - What potential adverse effects may occur?
   - Which drugs may interact with their therapy?
   - Educate on warning signs and prevention of suicidal and/or homicidal ideation.
6. Develop a plan to assess effectiveness of pharmacologic therapy after 4 weeks of being on a clinically effective dose.
7. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.
8. Assess improvement in quality-of-life measures such as physical, psychological, and social functioning and well-being.
9. If the patient does not respond, determine if the patient is taking the appropriate medication and dose.
10. Recommend changes in therapy if the patient does not respond.
11. Determine long-term maintenance therapy.

ABBREVIATIONS

BDNF:	brain-derived neurotrophic factor
DA:	dopamine
DRI:	dopamine reuptake inhibitor
DSM-IV-TR:	*Diagnostic and Statistical Manual of Mental Disorders.* 4th ed., text revision

36 Bipolar Disorder

Brian L. Crabtree and Martha J. Faulkner

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiologic mechanisms underlying bipolar disorder.
2. Recognize the symptoms of a manic episode and depressive episode in patients with bipolar disorder.
3. Identify common comorbidities of bipolar disorder.
4. Recognize the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision criteria for bipolar disorder as well as the subtypes of bipolar I disorder, bipolar II disorder, and cyclothymic disorder.
5. List the desired therapeutic outcomes for patients with bipolar disorder.
6. Explain the use of drugs as first-line therapy in bipolar disorder, including appropriate dosing, expected therapeutic effects, potential adverse effects, and important drug-drug interactions.
7. Recommend individualized drug therapy for acute treatment and relapse prevention based on patient-specific data.
8. Recommend monitoring methods for assessment of therapeutic and adverse effects of drugs used in the treatment of bipolar disorder.
9. Recommend treatment approaches for special populations of patients with bipolar disorder, including pediatric patients, geriatric patients, and pregnant patients.
10. Educate patients with bipolar disorder about their illness, drug therapy required for effective treatment, and the importance of adherence.

Key Concepts

❶ Patients presenting with depressive or elevated mood features and a history of abnormal or unusual mood swings should be assessed for bipolar disorder.

❷ The diagnosis of bipolar disorder is made based on clinical presentation, a careful diagnostic interview, and review of the history. There are no laboratory examinations, brain imaging studies, or other procedures that confirm the diagnosis.

❸ Goals of treatment are to reduce symptoms, induce remission, prevent relapse, improve patient functioning, and minimize adverse effects of drug therapy.

❹ Psychotherapy is needed to improve functional outcomes.

❺ The primary treatment modality for manic episodes is mood-stabilizing agents, often combined with antipsychotic drugs.

❻ The primary treatment for depressive episodes in bipolar disorder is mood-stabilizing agents, often combined with antidepressant drugs.

❼ The primary treatment for relapse prevention is mood-stabilizing agents.

❽ Education of the patient regarding benefits and risks of drug therapy and the importance of adherence to treatment must be integrated into pharmacologic management.

Bipolar disorder is a mood disorder characterized by one or more episodes of mania or **hypomania**, often with a history of one or more major depressive episodes.[1] It is a chronic illness with a course characterized by relapses and improvements or remissions. Mood episodes can be manic, depressed, or mixed. They can be separated by long periods of stability or can cycle

Patient Encounter, Part 1

MW, a 43-year-old Caucasian female, is a married mother of two boys and is moderately obese. She is wearing a short skirt, low-cut blouse, and heavy makeup, and is somewhat disheveled. She is mildly agitated, speaking rapidly, has fair eye contact, and appears tired and anxious. Her chief complaint: "I am about to get fired from my job, and I can't seem to get any sleep."

- What diagnoses are suggested by this patient's presentation?
- What additional information is needed to clarify the diagnoses?

rapidly. They occur with or without psychosis. Disability and other consequences of bipolar disorder can be devastating to patients, including an increased risk of suicide. Correct diagnosis and treatment are essential as early as possible in the course of the illness to prevent complications and maximize response to treatment. Both pharmacologic and nonpharmacologic treatments are required for maximum benefit.

EPIDEMIOLOGY AND ETIOLOGY

Epidemiology

Bipolar disorders have been categorized into bipolar I disorder, bipolar II disorder, and bipolar disorder, not otherwise specified (NOS). Bipolar I disorder is characterized by one or more manic or **mixed mood episodes**. Bipolar II disorder is characterized by one or more major depressive episodes and at least one hypomanic episode. Hypomania is an abnormally and persistently elevated, expansive, or irritable mood, but not of sufficient severity to cause significant impairment in social or occupational function and does not require hospitalization. Most epidemiologic studies have looked at bipolar disorder of all types (bipolar I and bipolar II), or the bipolar spectrum, which includes all clinical conditions thought to be closely related to bipolar disorder. The lifetime prevalence of bipolar I disorder is estimated to be between 0.3% and 2.4%. The lifetime prevalence of bipolar II disorder ranges from 0.2% to 5%. When including the bipolar spectrum, the lifetime prevalence is between 3% and 6.5%.[1]

Bipolar I disorder affects men and women equally; bipolar II seems to be more common in women. Rapid cycling and mixed mania occur more often in women. Individuals with bipolar disorder commonly have another psychiatric disease with 78% to 85% reporting another Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) diagnosis during their lifetime. The most common comorbid conditions include anxiety, substance abuse, and eating disorders.[2]

The mean age of onset of bipolar disorder is 20, although onset may occur in early childhood to the mid-40s.[1] If the onset of symptoms occurs after 60 years of age, the condition is probably secondary to medical causes. Early onset of bipolar disorder is associated with greater comorbidities, more mood episodes, a greater proportion of days depressed, and greater lifetime risk of suicide attempts, compared to bipolar disorder with a later onset. Substance abuse and anxiety disorders are more common in patients with an early onset. Patients with bipolar disorder also have higher rates of suicidal thinking, suicidal attempts, and completed suicides.

Etiology

The precise etiology of bipolar disorder is unknown. Thought to be genetically based, bipolar disorder is influenced by a variety of factors that may enhance gene expression. These include trauma, environmental factors, anatomic abnormalities, exposure to chemicals or drugs, and others.[3–5] Neurochemical abnormalities in bipolar disorder may be caused by these factors, as discussed further in the pathophysiology section.

PATHOPHYSIOLOGY

Neurochemical

The pathophysiology of bipolar disorder has been poorly understood, but imaging techniques such as positron emission tomography (PET) scans and functional magnetic resonance imaging (fMRI) are now being used to elucidate the cause. Research in the 1970s focused on neurotransmitters such as norepinephrine, dopamine, and serotonin. One hypothesis was that bipolar disorder is caused by an imbalance of cholinergic and catecholaminergic neuronal activity. Serotonin (5-HT) has been suggested to modulate catecholamine activity. Dysregulation of this relationship could cause a mood disturbance.[6] An early theory was that elevation of norepinephrine (NE) and dopamine (DA) caused mania, and a reduction caused depression, but this theory is now considered overly simplistic.[7] Other neurotransmitters are involved and interact with multiple neurochemical and neuroanatomic mechanisms and pathways. The pathophysiology of bipolar disorder has also been hypothesized from the mechanisms of action of lithium and other mood stabilizers. Lithium, valproate, and carbamazepine all have similar effects on neuronal growth that are reversible by inositol, supporting the hypothesis that bipolar disorder is related to inositol depletion.[8]

Genetic

Results of family and twin studies suggest a genetic basis for bipolar disorder.[4] The lifetime risk of bipolar disorder in relatives of a bipolar patient is 40% to 70% for a monozygotic twin and 5% to 10% for another first-degree relative.

Patient Encounter, Part 2: The Medical History, Physical Exam, and Laboratory Exam

The interview reveals the following additional information about MW:

PMH
Para 2, gravida 2

Hx
Sexually transmitted disease (unspecified) as a teen and in her twenties, but has been monogamous since her last marriage in her mid-thirties; she states, "It has not always been easy to stay with my husband"; she feels sexually attracted to many men.

Past Psychiatric Hx
Hospitalized at age 15 for physical aggression towards parents, suicidality, and running away; does not remember if she was placed on medication or if she was given a diagnosis; admits history of sleep disturbance that alternates between hyposomnia and hypersomnia and moodiness, when she shifts from feeling "on top of the world" to very depressed, "like I'm a nobody."

FH
Father was an alcoholic and died in his 50s of cirrhosis; mother is alive and has an anxiety disorder and emphysema; brother was incarcerated for attempted murder and drug trafficking; sister has an anxiety disorder and self-medicates with marijuana

SH
Obtained GED; smokes 2 packs of cigarettes per day; has had multiple jobs and two previous marriages; currently works as a salesperson in an auto parts store; lives with her husband who is a mechanic, and two elementary school–aged sons

Substance Abuse Hx
In late teens into mid-twenties, heavy abuse of stimulants, barbiturates, and alcohol; currently smokes marijuana three times per week and states "it calms me down and helps me sleep"; occasionally drinks on weekends

Meds
Antacids as needed for heartburn, ibuprofen as needed for headache

ROS
(+) Increased energy, irritability, and anger outbursts, racing thoughts, decreased need for sleep; (–) heart palpitations, weight loss, nausea, vomiting, diarrhea

PE
VS: Blood pressure 130/88 mm Hg, pulse 88 beats per minute, respiratory rate 20/minute, temperature 37.0°C (98.6°F)
HEENT: Neck supple; thyroid smooth, symmetrical, non-tender, moveable
CV: RRR, normal S_1, S_2; no murmurs, rubs, gallops, or heaves
Abd: Soft, non-tender, non-distended; (+) bowel sounds, no hepatosplenomegaly

Labs
WNL except + tetrahydrocannabinol (THC).

- Considering this additional information, what is the most likely diagnosis?
- What are the key pieces of information leading you to this conclusion?

Clinical Presentation and Diagnosis[1,3,7]

General
The patient may present in a hypomanic, manic, depressed, or mixed state, and may or may not be in acute distress.

Symptoms
Mood and affect:
- Mood elevation
- Expansive mood
- Irritable mood
- Depression
- Hopelessness
- Suicidality

Physical/behavioral:
- Agitation
- Impulsivity
- Aggression
- Rapid, pressured speech
- Decreased need for sleep
- Insomnia (sometimes for days or weeks)
- Hypersexuality
- Increased physical energy
- Inflated self-esteem, boasting, grandiosity
- Heightened interest in pleasurable activities with high risk of negative consequences (e.g., spending sprees and promiscuity)
- Fatigue
- Hypersomnia

Thought Processes, Content, and Perceptions:
- Racing thoughts, flight of ideas (FOI), distractibility
- Delusions of grandeur; ideas of reference (IOR): persecution, wealth, religion

Psychosocial:
- Substance use
- Disrupted relationships
- Job loss

Laboratory and Other Diagnostic Assessments
❷ *There are no objective laboratory tests or procedures to diagnose bipolar disorder, but such testing can be done to rule out other medical diagnoses.*

- Perform urinalysis, urine toxicology, thyroid function, and white blood cell count in the elderly to rule out urinary tract infection
- A mood disorder questionnaire is completed by the patient that asks about common symptoms of bipolar disorder, problems caused by the symptoms, and family history in a yes-or-no answer format. It is then scored by the clinician.

Suicidality risk is increased in the presence of:

- Substance abuse
- Prior suicide attempts and lethality of attempts
- Access to a means of suicide
- Command hallucinations/psychosis
- Severe anxiety
- Family history of attempted or completed suicide

CLINICAL PRESENTATION AND DIAGNOSIS

Diagnosis of Bipolar Disorder

Bipolar disorder can be conceptualized as a continuum or spectrum of mood disorders and is not comprised solely of bipolar I disorder.[9] They include four subtypes: bipolar I (periods of major depressive, manic, and/or mixed episodes); bipolar II (periods of major depression and hypomania); cyclothymic disorder (periods of hypomanic episodes and depressive episodes that do not meet all criteria for diagnosis of a major depressive episode); and bipolar disorder, NOS. The defining feature of bipolar disorders is one or more manic or hypomanic episodes in addition to depressive episodes that are not caused by any medical condition, substance abuse, or other psychiatric disorder.[1]

Initial and subsequent episodes of bipolar disorder are mostly depressive,[10] although this varies depending on type of bipolar disorder. In males, the initial episode in bipolar I disorder is more likely to be mania, and the number of manic episodes is equal to or greater than depressive episodes.[1] Often misdiagnosed and underdiagnosed, bipolar I and II disorders were correctly diagnosed only 20% of the time, whereas 31% received the misdiagnosis of unipolar depression.[11] It is helpful to utilize a screening tool such as the mood disorder questionnaire.[12]

DSM-IV-TR criteria for the diagnosis of bipolar disorder are summarized in Table 36–1.

Bipolar I Disorder

Bipolar I disorder diagnosis necessitates at least one episode of mania, for at least 1 week or longer, with a persistently elevated, expansive, or irritable mood with related symptoms of decreased need for sleep, excessive energy, racing thoughts, a propensity to be involved in high-risk activities, and excessive talkativeness.[1] Bipolar I depression can be misdiagnosed as major depressive disorder; therefore, it is essential to rule out past episodes of hypomania or mania. If bipolar depression is mistaken for major depressive disorder and the patient is treated with antidepressants, this can precipitate a manic episode or induce rapid cycling of depression and mania.

Bipolar II Disorder

The distinguishing feature of bipolar II disorder is depression with past hypomanic episodes that often are not recalled by the individual as being unusual. Irritability and anger episodes are also common. Collateral information is essential to obtain the entire history (i.e., there cannot have been a prior full manic episode).[1,14]

Cyclothymic Disorder

Cyclothymic disorder is a chronic mood disturbance generally lasting at least 2 years (1 year in children and adolescents) and characterized by mood swings including periods of hypomania and depressive symptoms. Hypomanic symptoms include inflated self-esteem or **grandiosity** (non-delusional), decreased need for sleep, pressure of speech, **flight of ideas**, distractibility, and increased involvement in goal-directed activities, not causing severe impairment in social or occupational functioning or requiring hospitalization. Psychotic features are not found in cyclothymic disorder.[1]

Suicide

Patients with bipolar disorder have a high risk of suicide. Factors that increase that risk are early age at disease onset, high number of depressive episodes, comorbid alcohol abuse, personal history of antidepressant-induced mania, and family history of suicidal behavior.[15] In those with bipolar disorder, 1 of 5 suicide attempts are lethal, in contrast to 1 of 10 to 1 of 20 in the general population.

Differential Diagnosis

Schizophrenia and bipolar disorder often share certain symptoms, including psychosis in some patients. The prominence of mood symptoms and the history of mood episodes distinguish bipolar disorder and schizophrenia. In addition, the psychosis of schizophrenia occurs in the absence of prominent mood symptoms.

Personality disorders are inflexible and maladaptive patterns of behavior that deviate markedly from expectations of society. These patterns are stable over time, pervasive and rigid, and lead to distress or impairment in the individual's life. Onset is in adolescence or early adulthood.[1] Personality disorders and bipolar disorder may be comorbid, and patients with personality disorders may have mood symptoms. The two diagnoses are distinguished, however, by the predominance of mood symptoms and the episodic course of bipolar disorder, in contrast to the stability and persistence of the behavioral patterns of personality disorders.

Delirium is characterized by a disturbance of consciousness and a change in cognition that develops over a short period of time, usually hours or days. The course can fluctuate over the course of the day, usually worsening in the evening. Underlying medical problems such as urinary tract infections in the elderly, substance abuse, or withdrawal symptoms in adults may precipitate delirium.[1]

Dementia is the loss of function in multiple cognitive domains that occurs over a longer period of time, usually months to years. Diagnostic features include memory impairment and at least one of the following: aphasia (deterioration of speech), apraxia (impaired ability to execute motor activities despite intact motor abilities, sensory function, and comprehension of the required task), agnosia (failure to recognize or identify objects despite intact sensory function), or disturbances in executive functioning.[1]

TABLE 36–1. Evaluation and Diagnostic Criteria of Mood Episodes

Diagnostic work-up depends on clinical presentation and findings	• Mental status examination • Psychiatric, medical, and medication history • Physical and neurologic examination • Basic laboratory tests: complete blood count, blood chemistry screen, thyroid function, urinalysis, urine drug screen • Psychological testing • Brain imaging: magnetic resonance imaging and functional scan; alternative: computed tomography scan, positron emission tomography scan • Lumbar puncture • Electroencephalogram

Diagnosis

Episode	Impairment of Functioning or Need for Hospitalization[a]	DSM-IV-TR Criteria[b]
Major depressive	Yes	Greater than 2-week period of either depressed mood or loss of interest or pleasure in normal activities, associated with at least five of the following symptoms: • Depressed, sad mood (adults); may be irritable mood in children • Decreased interest and pleasure in normal activities • Decreased appetite, weight loss • Insomnia or hypersomnia • Psychomotor retardation or agitation • Decreased energy or fatigue • Feeling of guilt or worthlessness • Impaired concentration and decision making • Suicidal thoughts or attempts
Manic	Yes	Greater than 1-week period of abnormal and persistent elevated mood (expansive or irritable), associated with at least three of the following symptoms (four if the mood is only irritable): • Inflated self-esteem (grandiosity) • Decreased need for sleep • Increased talking (pressure of speech) • Racing thoughts (flight of ideas) • Distractible (poor attention) • Increased activity (either socially, at work, or sexually) or increased motor activity or agitation • Excessive involvement in activities that are pleasurable but have a high risk for serious consequences (buying sprees, sexual indiscretions, poor judgment in business ventures)
Hypomanic	No	At least 4 days of abnormal and persistent elevated mood (expansive or irritable); associated with at least three of the following symptoms (four if the mood is only irritable): • Inflated self-esteem (grandiosity) • Decreased need for sleep • Increased talking (pressure of speech) • Racing thoughts (flight of ideas) • Increased activity (either socially, at work, or sexually) or increased motor activity or agitation • Excessive involvement in activities that are pleasurable but have a high risk for serious consequences (buying sprees, sexual indiscretions, poor judgment in business ventures)
Mixed	Yes	Criteria for both a major depressive episode and manic episode (except for duration) occur nearly every day for at least a 1-week period
Rapid cycling	Yes	Greater than 3 major depressive or manic episodes (manic, mixed, or hypomanic) in 12 months

[a]Impairment in social or occupational functioning; need for hospitalization due to potential self-harm, harm to others, or psychotic symptoms.
[b]The disorder is not due to a medical condition (e.g., hypothyroidism) or substance-induced disorder (e.g., antidepressant treatment, medications, electroconvulsive therapy).
From Fankhauser MP, Freeman MP. Bipolar disorder. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 1261, with permission.

Comorbid Psychiatric and Medical Conditions

Psychiatric

Lifetime prevalence rates of psychiatric comorbidity co-existing with bipolar disorder are 42% to 50%.[16] Comorbidities, especially substance abuse, make it difficult to establish a definitive diagnosis and complicate treatment. Comorbidities also place the patient at risk for a poorer outcome, high rates of suicidality, and onset of depression.[2] Psychiatric comorbidities include:

- Personality disorders
- Alcohol and substance abuse or dependence
- Anxiety disorders, including panic disorder, obsessive-compulsive disorder, and social phobia
- Eating disorders
- Attention-deficit/hyperactivity disorder

Medical comorbidities include:

- Migraine
- Multiple sclerosis
- Cushing's syndrome
- Brain tumor
- Head trauma

TREATMENT

Desired Outcomes

❸ *Desired outcomes for the treatment of bipolar disorder are to:*

- Reduce the symptoms of mania
- Reduce the symptoms of bipolar depression
- Prevent the recurrence of a manic or depressive episode
- Avoid or minimize adverse treatment effects
- Promote treatment adherence
- Maintain or improve quality of life and improving function

General Approach to Treatment

Treatment algorithms for manic and depressive episodes of bipolar disorder are included in Table 36–2.

Patient Encounter, Part 3: Creating a Care Plan

Based on all information presented, create a care plan for this patient's bipolar disorder. Your plan should include: (1) a statement of the drug-related needs and/or problems, (2) the goals of therapy, (3) a patient-specific therapeutic plan, and (4) a plan for follow-up to assess therapeutic response and adverse effects.

Although not all patients achieve asymptomatic remission, this is a goal of treatment. The mainstay of drug therapy is mood-stabilizing drugs, summarized below. A person entering treatment for a first mood episode in bipolar disorder must have a complete assessment and careful diagnosis to rule out non-psychiatric causes. A variety of conditions can cause similar symptoms (Table 36–3). Since early and accurate diagnosis is essential to maximizing response to treatment, pharmacologic and nonpharmacologic therapy should begin as soon as possible. Treatment is often lifelong. Comorbid conditions should likewise be addressed aggressively.

Suicidality Risk

Assess for the safety of others and potential for violence. If accompanied by friends or family with whom the patient is living, ask them to remove from the home all guns, caustic chemicals, medications, and objects the person might use to harm self or others. Risk factors for suicide include severity of depression, feelings of hopelessness, comorbid personality disorder, and a history of a previous suicide attempt.[19]

Nonpharmacologic Therapy

❹ *Interpersonal, family, or group therapy with a licensed psychiatric nurse practitioner/clinical nurse specialist, psychologist, social worker, or counselor assists individuals with bipolar disorder to establish and maintain a daily routine and sleep schedule and to improve interpersonal relationships.*[3,20] *These therapies may help treat and protect against manic episodes.*

Cognitive-behavioral therapy (CBT) is a type of psychotherapy that combines cognitive and behavioral theories. It stresses the importance of recognizing patterns of cognition (thought) and how thoughts influence subsequent feelings and behaviors. Other people, situations, and events external to the individual are not seen as the sources of thoughts and behaviors. An advantage of CBT is that patients are taught self-management skills to change their negative thoughts in order to feel and function better, even if external circumstances do not change.

Electroconvulsive therapy (ECT) is the application of prescribed electrical impulses to the brain for the treatment of severe depression, mixed states, psychotic depression, and treatment-refractory mania in patients who are at high risk of suicide. It also may be used in pregnant women who cannot take carbamazepine, lithium, or divalproex.

Psychoeducation for patients, their families, and groups regarding chronicity of bipolar disorders; self-management through sleep hygiene, nutrition, exercise, and stress reduction; and abstinence from alcohol or drugs is critical to the success of supporting the individual in managing bipolar disorder. The development of a crisis intervention plan is essential.

TABLE 36–2. Algorithm and Guidelines for the Acute Treatment of Mood Episodes in Patients with Bipolar I Disorder

Acute Manic or Mixed Episode

General guidelines

- Assess for secondary causes of mania or mixed states (e.g., alcohol or drug use)
- Taper off antidepressants, stimulants, and caffeine if possible
- Treat substance abuse
- Encourage good nutrition (with regular protein and essential fatty acid intake), exercise, adequate sleep, stress reduction, and psychosocial therapy
- Optimize the dose of mood-stabilizing medication(s) before adding on benzodiazepines; if psychotic features are present, add on antipsychotic; ECT used for severe or treatment-resistant manic/mixed episodes or psychotic features

Mild to moderate symptoms of mania or mixed episode

First, initiate and/or optimize mood-stabilizing medication: lithium[a] or valproate[a] or atypical antipsychotic (e.g., olanzapine, quetiapine, risperidone)

Alternative anticonvulsants: carbamazepine, lamotrigine,[b] or oxcarbazepine

Second, if response is inadequate, consider adding a benzodiazepine (lorazepam or clonazepam) for short-term adjunctive treatment of agitation or insomnia if needed

Third, if response is inadequate, consider a two-drug combination:

- Lithium **plus** an anticonvulsant or an atypical antipsychotic
- Anticonvulsant **plus** an anticonvulsant or atypical antipsychotic

Moderate to severe symptoms of mania or mixed episode

First, two-drug combinations: lithium[a] or valproate[a] **plus** an atypical antipsychotic (e.g., olanzapine, quetiapine, risperidone) for short-term adjunctive treatment of psychotic features (e.g., delusions or hallucinations)

Alternative anticonvulsants: carbamazepine, lamotrigine,[b] or oxcarbazepine

Second, if response is inadequate, consider adding a benzodiazepine (lorazepam or clonazepam) for short-term adjunctive treatment of agitation or insomnia if needed; lorazepam is recommended for catatonia

Third, if response is inadequate, consider a three-drug combination:

- Lithium **plus** an anticonvulsant **plus** an atypical antipsychotic
- Anticonvulsant **plus** an anticonvulsant **plus** an atypical antipsychotic

Fourth, if response is inadequate, consider ECT for mania with psychosis or catatonia;[d] or add clozapine for treatment-refractory illness

Fifth, if response is inadequate, consider adding adjunctive therapies[e]

Acute Depressive Episode

General guidelines

- Assess for secondary causes of depression (e.g., alcohol or drug use)
- Taper off antipsychotics, benzodiazepines or sedative-hypnotic agents if possible
- Treat substance abuse
- Encourage good nutrition (with regular protein and essential fatty acid intake), exercise, adequate sleep, stress reduction, and psychosocial therapy
- Optimize the dose of mood stabilizing medication(s) before adding on lithium, lamotrigine, or antidepressant (e.g., bupropion or an SSRI); if psychotic features are present, add on an antipsychotic; ECT used for severe or treatment-resistant depressive episodes or for psychosis or catatonia

Mild to moderate symptoms of depressive episode

First, initiate and/or optimize mood-stabilizing medication: lithium[a] or lamotrigine[b]

Alternative anticonvulsants: carbamazepine, oxcarbazepine, or valproate

Moderate to severe symptoms of depressive episode

First, two-drug combinations: lithium[a] or lamotrigine[b] **plus** an antidepressant[c]; lithium plus lamotrigine

Alternative anticonvulsants: carbamazepine, oxcarbazepine, or valproate

Second, if response is inadequate, consider adding an atypical antipsychotic for short-term adjunctive treatment of psychotic features (e.g., delusions or hallucinations) if needed

Third, if response is inadequate, consider a three-drug combination:

- Lithium **plus** an anticonvulsant **plus** an antidepressant
- Lamotrigine[b] **plus** an anticonvulsant **plus** an antidepressant

Fourth, if response is inadequate, consider ECT for treatment-refractory illness and depression with psychosis or catatonia[d]

Fifth, if response is inadequate, consider adding adjunctive therapies[e]

[a]Utilize standard therapeutic serum concentration ranges; if partial response or breakthrough episode, adjust dose to achieve higher serum concentrations without causing intolerable adverse effects; valproate is preferred over lithium for mixed episodes and rapid cycling; lithium and/or lamotrigine is preferred over valproate for bipolar depression.

[b]Lamotrigine is not approved for the acute treatment of depression, and the dose must be started low and slowly titrated up to decrease adverse effects if used for maintenance therapy of bipolar I disorder. A drug interaction and a severe dermatologic rash may occur when lamotrigine is combined with valproate (i.e., lamotrigine doses must be halved from standard dosing titration).

[c]Antidepressant monotherapy is not recommended for bipolar depression. Bupropion, selective serotonin reuptake inhibitors (SSRIs; e.g., citalopram, escitalopram, or sertraline), and serotonin-norepinephrine reuptake inhibitors (SNRIs; e.g., venlafaxine) have shown good efficacy and fewer adverse effects in the treatment of unipolar depression; monoamine oxidase inhibitors (MAOIs) and tricyclic antidepressants (TCAs) have more adverse effects (e.g., weight gain) and may have a higher risk of causing antidepressant-induced mania; fluoxetine, fluvoxamine, nefazodone, and paroxetine inhibit liver metabolism and should be used with caution in patients on concomitant medications that require cytochrome P450 clearance; paroxetine and venlafaxine have a higher risk for causing a discontinuation syndrome.

[d]Electroconvulsive therapy (ECT) is used for severe mania or depression during pregnancy and for mixed episodes; prior to treatment, anticonvulsants, lithium, and benzodiazepines should be tapered off to maximize therapy and minimize adverse effects.

[e]There are minimal or no efficacy data for some adjunctive (add-on) therapies: α_2-adrenergic agonists, calcium channel blockers, gabapentin, tiagabine, topiramate, and zonisamide; topiramate may have efficacy as an adjunctive agent with standard agents for maintenance therapy, based on initial trials.

Pharmacologic Therapy

❺ *Pharmacotherapy is the cornerstone of acute and maintenance treatment of bipolar disorder. Mood-stabilizing drugs are the usual first-choice treatments and include lithium, divalproex, carbamazepine, and lamotrigine. Atypical antipsychotics other than clozapine are also approved for treatment of acute mania.* Lithium, lamotrigine, olanzapine, and aripiprazole are approved for maintenance therapy. Drugs used with less research support and without Food and Drug Administration (FDA) approval include topiramate and oxcarbazepine. Benzodiazepines are used adjunctively for mania.

❻ *Antidepressants may be used for bipolar depression, but usually along with a mood-stabilizing agent to prevent a mood switch to mania, and only after the patient has failed to respond adequately to optimal mood-stabilizing therapy.*[21] Combinations of two mood-stabilizing drugs or a mood-stabilizing drug and either an antipsychotic or antidepressant drug are common, especially in acute mood episodes.

❼ *Mood-stabilizing drugs are considered the primary pharmacotherapy for relapse prevention.* Olanzapine and aripiprazole are also approved for maintenance therapy.

Table 36–4 includes a summary of current drug therapy for bipolar disorder. An algorithm for treatment of bipolar mania is shown in Table 36–2.

Mood-Stabilizing Drugs

The ideal mood-stabilizing drug has four desired effects: treatment of acute mania, treatment of acute bipolar depression, prevention of manic relapse, and prevention of bipolar depression relapse. All currently approved mood-stabilizing drugs have demonstrated efficacy over placebo for one or more of these effects, but there are differences among them with regard to specific patient populations. Choice of treatment is dictated by individual patient characteristics and history. Few studies have compared mood-stabilizing drugs to each other in systematic clinical trials. Effect sizes across placebo-controlled trials of individual agents are generally similar. Lithium is often considered the first-choice drug for the classic presentation of bipolar disorder. Treatment of childhood bipolar disorder is less well researched. Only lithium is FDA-approved in children and adolescents as young as age 12. Treatment of bipolar disorder during pregnancy is a particular challenge because of the risks of drug exposure in utero.

Lithium

Lithium was the first approved mood-stabilizing drug. It remains a first-line agent and sets the standard for efficacy against which other drugs are usually measured. It has antimanic efficacy, prevents bipolar disorder relapse, and has more modest efficacy for bipolar depression.[22] It remains the only drug supported by multiple controlled trials in mania, depression, and relapse prevention. In most studies, lithium's efficacy is equivalent to that of the anticonvulsant mood-stabilizers and the atypical antipsychotic drugs.[17] It is most effective for patients with few previous episodes, symptom-free interepisode remission, and a family history of bipolar disorder with good response to lithium. Patients with rapid cycling bipolar disorder are less responsive to lithium, however, than to other mood-stabilizing drugs such as divalproex.[26] Additionally, its effect on bipolar depression is less robust than for mania.[27] It may also be less effective in patients with mixed mood episodes (symptoms of mania and depression occurring simultaneously) and in mania secondary to non-psychiatric illness.

Increasing evidence shows an effect of lithium on suicidal behavior that is superior to other mood-stabilizing drugs.[28] Lithium reduces the risk of deliberate self-harm or suicide by about 70%.

Mechanism of Action Lithium's pharmacologic mechanism of action is not well understood and probably involves multiple effects. Possibilities include altered ion transport, increased intraneuronal catecholamine metabolism, neuroprotection or increased brain-derived neurotrophic factor, inhibition of second messenger systems, and reprogramming of gene expression.[29]

TABLE 36–4. Product Formulation, Dosage, and Information, and Clinical Use of Agents Used in the Treatment of Bipolar Disorder[3,22–25]

Generic Name	Brand Names	Formulations	Dosages	Clinical Use
Lithium Salts				
FDA-approved for use in bipolar disorder				
Lithium carbonate	Eskalith Eskalith CR Lithobid Generic	Capsule: 300 mg ER tablet: 450 mg ER tablet: 300 mg Tablet: 300 mg Capsule: 150, 300, 600mg	900–2400 mg/day in 2–4 divided doses, preferably with meals; there is wide variation in the dosage needed to achieve therapeutic response and 12-hour serum lithium concentration (i.e., 0.6–1.2 mEq/L or mmol/L for maintenance therapy and 1.0–1.5 mEq/L or mmol/L for acute mood episodes taken 12 hours after the last dose); single daily dosing is effective and causes fewer adverse renal effects	Monotherapy or in combination with other drugs for the acute treatment of mania and for maintenance treatment
Lithium citrate	Generic	300 mg (8 mEq)/5 mL		
Anticonvulsants				
FDA-approved for use in bipolar disorder				
Carbamazepine	Equetro	Capsule: 100, 200, 300 mg SR; may open capsule but do not crush or chew beads; take with food Tablet: 200 mg	Start at 100–200 mg bid; increase by 200 mg every 3–4 days 200–1800 mg/day in 2–4 divided doses	Monotherapy or in combination with other drugs for the acute treatment of mania or mixed episodes for bipolar I disorder.
	Tegretol	Chewable tablet: 100 mg Suspension: 100 mg/5 mL	Target serum concentration is 4–12 mcg/mL (17–51 µmol/L)	
	Tegretol XR	ER tablet: 100, 200, 400 mg		
	Carbatrol	ER capsule: 200, 300 mg		
Divalproex sodium	Depakote	Enteric-coated, delayed-release tablet: 125, 250, 500 mg Sprinkles: 125 mg	750–3000 mg/day (20–60 mg/kg per day) in 2–3 divided doses for delayed-release divalproex or valproic acid Extended release divalproex may be given once daily at bedtime	Monotherapy or in combination with other drugs for the acute treatment of mania and for maintenance treatment.
	Depakote ER	Extended-release tablet: 250, 500 mg		
Valproic acid	Depakene, generic	Capsules: 250 mg	A loading dose of divalproex (20–30 mg/kg per day) can be given, then 20 mg/kg per day and titrated to a serum concentration of 50–125 mcg/mL (346–866 µmol/L)	
Valproic acid syrup	Depakene, generic	250 mg/5 mL		
Lamotrigine	Lamictal	Tablet: 25, 100, 150, 200 mg	50–400 mg/day in divided doses. Dosage should be slowly increased by following prescribing information; if valproate is added to Lamictal, the Lamictal dosage should be reduced by half	Monotherapy or in combination with other drugs for the long-term maintenance treatment of bipolar depression; may have efficacy for prevention of bipolar depression
Anticonvulsants and Other Drugs Not FDA-Approved for Use in Bipolar Disorder				
Clonazepam	Klonopin	Tablet: 0.5, 1, 2 mg	0.5–20 mg/day in divided doses or one dose at bedtime Dosage should be slowly adjusted up and down according to response and adverse effects	Use in combination with other drugs for the acute treatment of mania or mixed episodes. Use as a short-term adjunctive sedative-hypnotic agent
Lorazepam	Ativan	Tablet: 0.5, 1, 2 mg Oral solution: 2 mg/mL Injection: 2, 4 mg/mL	2–4 mg/day in divided doses or just one dose at bedtime Dosage should be slowly adjusted up and down according to response and adverse effects	

(Continued)

TABLE 36–4. Product Formulation, Dosage, and Information, and Clinical Use of Agents Used in the Treatment of Bipolar Disorder[3,22–25] *(Continued)*

Generic Name	Brand Names	Formulations	Dosages	Clinical Use
Oxcarbazepine	Trileptal	Tablets: 150, 300, 600 mg Suspension: 300 mg/5 mL	300–1200 mg/day in two divided doses Doses should be slowly adjusted up and down according to response and adverse effects (e.g., 150–300 mg twice daily and increase by 300–600 mg/day at weekly intervals)	May cause fewer adverse drug-drug interactions than carbamazepine, but causes more gastrointestinal side effects and hyponatremia Evidence is limited regarding efficacy
Topiramate	Topamax	Tablet: 25, 100, 200 mg Sprinkle capsule: 15, 25 mg	50–200 mg/day in divided doses Dosage should be slowly increased to minimize adverse effects (e.g., 25 mg at bedtime for 1 week, then 25–50 mg/day increments at weekly intervals)	Not recommended for the acute treatment of mania or mixed episodes due to lack of efficacy; used as an adjunctive agent with established mood stabilizers
Atypical Antipsychotics **FDA approved for use in bipolar disorder**				
Aripiprazole	Abilify	Tablets: 5, 10, 15, 20, 30 mg	10–30 mg/day once daily	Use as monotherapy or in combination with lithium or valproate for the acute treatment of mania or mixed states for bipolar I disorder. Olanzapine and aripiprazole are approved for relapse prevention as well as for acute therapy
Olanzapine	Zyprexa	Tablets: 2.5, 5, 7.5, 10, 15, 20 mg	5–20 mg/day in 1 or 2 doses	
	Zyprexa, Zydis	Tablet, orally disintegrating: 5, 10, 15, 20 mg		
Quetiapine	Seroquel	Tablet 25, 100, 200, 300 mg	50–800 mg/day in divided doses or once daily when stabilized	
Risperidone	Risperdal	Tablet: 0.25, 0.5, 1, 2, 3, 4 mg Oral solution: 1 mg/mL	0.5–6 mg/day in 1 or 2 doses	Risperidone microspheres is not approved at present for bipolar disorder
	Risperdal Consta	Long-acting injectable: 25, 37.5, 50 mg		
Ziprasidone	Geodon	Capsule: 20, 40, 60 80 mg	40–160 mg/day in divided doses	

Dosing and Monitoring Lithium is usually initiated at a dosage of 600 to 900 mg per day. Although it is most commonly given in a divided dosage, once-daily dosing is acceptable, especially with sustained-release formulations, and can improve patient adherence and reduce some side effects. It has a narrow therapeutic index, meaning the toxic dosage is not much greater than the therapeutic dosage, and requires regular serum concentration monitoring as a guide to dosage titration and to minimize risk of adverse effects. At least weekly monitoring is recommended until the patient is stabilized, then in decreasing frequency. Well-maintained patients who tolerate lithium without difficulty can be monitored by serum concentration as infrequently as twice yearly. Dosage is titrated to achieve a serum lithium concentration of 0.6 to 1.4 mEq/L (0.6–1.4 mmol/L). Higher serum concentrations are usually required to treat an acute episode than to prevent relapse. However, serum lithium maintained above 0.8 mEq/L (0.8 mmol/L) may be more effective in preventing relapse than lower serum concentrations. The suggested therapeutic serum concentration range is based on a 12-hour post-dose sample collection, usually a morning trough in patients taking more than one dose per day. At least 2 weeks at a suggested therapeutic serum concentration is required for an adequate trial of lithium. Table 36–5 shows pharmacokinetic parameters and desired serum concentrations of mood-stabilizing drugs used for bipolar disorder.

TABLE 36–5. Pharmacokinetics and Therapeutic Serum Concentrations of Lithium and Anticonvulsants Used in the Treatment of Bipolar Disorder

	Lithium	Carbamazepine	Oxcarbazepine	Divalproex (DVPX) Sodium/Valproic Acid (VPA)	Lamotrigine
Gastrointestinal absorption					
Regular release	Rapid: 95–100% within 1–6 hours	Slow and erratic: 85–90%	Slow and complete: 100%	Rapid and complete (VPA)	Rapid: 98%
Syrup/suspension/ solution	Faster rate of absorption: 100%	Faster rate of absorption	Unknown	Faster rate of absorption than tablets	NA
Extended-release/ enteric-coated tablets	Delayed absorption: 60–90%	Delayed absorption: 89% of the suspension; and less than regular-release tablets	NA	Extended-release: 90% of intravenous dose. Delayed-release: 81–90% of intravenous dose Delayed absorption with delayed-release tablets; valproate is rapidlyconverted to VPA in the stomach, then is rapidly and almost completely absorbed from the GI tract	NA
Delay in absorption by food	Yes	No; reports of increased rate of absorption with fatty meals (extended-release capsule)	Unknown	Yes; food slows the rate of absorption but not the extent for DVPX	Bioavailability not affected by food
Time to reach peak serum concentrations	0.5–3 hours (regular-release) 4–12 hours (extended-release) 0.25–1 hours (oral solution)	4.5 hours (regular-release); 1.5 hours (suspension); 3–12 hours (extended-release tablets); 4.1–7.7 hours (extended-release capsules); higher peak concentrations with chewable tablets	4.5 hours (range of 3–13 hours)	1–4 hours (VPA) 3–5 hours (DVPX single dose) 7–14 hours (DVPX extended-release multiple dosing)	1–4 hours
Distribution					
Volume of distribution	Initial: 0.3–0.4 L/kg Steady-state: 0.7–1 L/kg	0.6–2 L/kg (adults)	10-monohydroxy carbazepine (metabolite): 49 L/kg	11 L/1.73 m^2 (total valproate); 92 L/1.73 m^2 (free valproate)	0.9–1.3 L/kg
Crosses the placenta	Yes; pregnancy risk category: D Risk of cardiac defects: 0.1–0.5%	Yes; pregnancy risk category: D	Yes; pregnancy risk category: C	Yes: pregnancy risk category: D Risk of neural tube defects: 1–5%	Yes; pregnancy risk category: C
Crosses into breast milk	Yes: 35–50% of mother's serum concentration; breast-feeding not recommended	Yes: ratio of concentration in breast milk to plasma is 0.4 for drug and 0.5 for epoxide metabolite; considered compatible with breast-feeding	Yes: both drug and active metabolite; breast-feeding not recommended	Yes: considered compatible with breast-feeding	Yes: breast-feeding not recommended
Protein binding	No	75–90%	40% of active metabolite	80–90% (dose dependent)	55%

(Continued)

TABLE 36–5. Pharmacokinetics and Therapeutic Serum Concentrations of Lithium and Anticonvulsants Used in the Treatment of Bipolar Disorder *(Continued)*

	Lithium	Carbamazepine	Oxcarbazepine	Divalproex (DVPX) Sodium/Valproic Acid (VPA)	Lamotrigine
Renal clearance	Yes: 10–40 mL/minute with 90–98% of dose excreted in urine; 80% of lithium that is filtered by the renal glomeruli is reabsorbed	Yes: 1–3% excreted unchanged in urine	Yes: 95% excreted in the urine less than 1% excreted unchanged	Yes: 30–50% excreted as glucuronide conjugate; less than 3% excreted unchanged	Yes: 94% excreted as glucuronide conjugate
Metabolism					
Hepatic metabolism	No	Yes: oxidation and hydroxylation induces liver enzymes to increase its metabolism and other drugs	Yes: oxidation and conjugation	Yes: oxidation and glucuronide conjugation	Yes: glucuronic acid conjugation Induces its own metabolism in normal volunteers
Metabolites	No	Yes: 10, 11-epoxide (active)	Yes: 10-monohydroxy carbazepine (active)	Yes (not active)	No
Kinetics	First-order	First-order after initial enzyme induction phase	First-order	First-order	First-order
Half-life ($t_{1/2}$)	18–27 hours (adult); greater than 36 hours (elderly or patients with renal impairment)	$t_{1/2}$ decreases over time due to autoinduction: 25–65 hours (initial) 12–17 hours (adult multiple dosing) 8–14 hours (children multiple dosing)	2 hours (parent) 9 hours (metabolite)	5–20 hours (adult)	25 hours; increases to 59 hours with concomitant valproic acid therapy
Cytochrome P-450 (CYP450) isoenzyme					
CYP450 substrate	No	2C8 and 3A3/4	Unknown	2C19	Unknown
CYP450 inhibitor	No	No	2C19	2C9, 2D6, and 3A3/4	Unknown
CYP450 inducer	No	1A2, 2C9/10, and 3A3/4	3A3/4	No	Unknown
Therapeutic serum/plasma concentrations					
Obtain blood level 10–12 hours postdose	1–1.5 mEq/L: for adult, acute mania 0.4–0.6 mEq/L: for elderly or medically ill 0.6–1.2 mEq/L: for adult, maintenance	4–12 mcg/mL: for adult, acute mania and maintenance 4–8 mcg/mL: for elderly or medically ill	No established therapeutic range; 12–30 mcg/mL for 10-hydroxy carbazepine based on epilepsy trials	50–125 mcg/mL: adult, acute mania and maintenance 40–75 mcg/mL: elderly or medically ill	No established therapeutic range: 4-20 mcg/mL based on epilepsy trials

NA, not applicable.
From Fankhauser MP, Freeman MP. Bipolar disorder. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 1274–1275, with permission.

It is common for lithium to be combined with other mood-stabilizing drugs or antipsychotic drugs, if necessary, in order to achieve more complete remission of symptoms. Studies indicate that monotherapy is often insufficient to reach this goal.[17]

Adverse Effects The most common adverse effects are gastrointestinal upset, tremor, and polyuria,[30] which are dose-related. Nausea, dyspepsia, and diarrhea can be minimized by coadministration with food, use of sustained-release formulations, and giving smaller doses more frequently to reduce the amount of drug in the gastrointestinal tract at a given time. Tremor is present in up to 50% of patients. In addition to the approaches above, low-dose β-blocker therapy such as propranolol 20 to 60 mg/day often reduces the tremor.

Lithium impairs the kidney's ability to concentrate urine due to its inhibitory effect on vasopressin. This causes an increase in urine volume and frequency and a consequent increase in thirst. Polyuria and polydipsia occur in up to 70% of patients. A severe form of polyuria when urine volume exceeds 3 L/day is known as nephrogenic lithium-induced **diabetes insipidus**. It can be treated with amiloride or hydrochlorothiazide. If the latter is used, the lithium dosage should be reduced by 33% to 50% to account for the drug-drug interaction that could increase serum lithium and cause toxicity. Long-term lithium therapy can cause structural kidney changes such as glomerular sclerosis or tubular atrophy. Once-daily dosing of lithium is less likely to cause renal adverse effects than divided-daily dosing.

Lithium is concentrated in the thyroid gland and can impair thyroid hormone synthesis. Although goiter is uncommon, as many as 30% of patients develop at least transiently elevated thyroid-stimulating hormone values. Lithium-induced hypothyroidism is not usually an indication to discontinue the drug. Patients can be supplemented with levothyroxine if continuation of lithium is desired.[30]

Other common adverse effects include poor concentration, acneiform rash, alopecia, worsening of psoriasis, weight gain, metallic taste, and glucose dysfunction. Lithium causes a benign flattening or inversion of the T wave on the electrocardiogram (ECG). Less commonly, it can cause or worsen arrhythmias. Cardiologic evaluation is recommended for patients with preexisting cardiac disease who are candidates for lithium therapy. A benign leukocytosis is also common.[30]

Lithium and other mood-stabilizing drugs require baseline and routine laboratory monitoring to help determine medical appropriateness for initiation of therapy and monitoring of potential adverse effects. Guidelines for such monitoring are outlined in Table 36–6.

Acute lithium toxicity, which can occur at serum concentrations over 2 mEq/L, can be severe and life-threatening, necessitating emergency medical treatment. Symptoms include worsening of gastrointestinal distress to include severe vomiting and diarrhea; deterioration in motor coordination including a coarse tremor, ataxia, and dysarthria; and impaired cognition. In its most severe form, seizures, cardiac arrhythmias, coma, and kidney damage have been reported. Treatment includes discontinuation of lithium, intravenous fluids to correct fluid and electrolyte imbalance, and osmotic diuresis or hemodialysis. In case of overdose, gastric lavage is indicated. Clinical symptoms can continue well after the serum concentration is lowered, as clearance from the central nervous system is slower than from the serum. Factors predisposing to lithium toxicity include fluid and sodium loss due to hot weather or exercise or drug interactions that increase serum lithium.[30]

Drug Interactions Drug interactions involving lithium are common. Since lithium is not metabolized or protein bound, however, it is not associated with metabolic drug interactions that occur with other mood-stabilizing drugs. Common and significant drug interactions involve thiazide diuretics, nonsteroidal anti-inflammatory drugs (NSAIDs), and angiotensin-converting enzyme inhibitors (ACEIs). If a diuretic must be used with lithium and a thiazide is not required, loop diuretics such as furosemide are less likely to increase lithium retention. The ACEIs can abruptly increase serum lithium with the potential for acute and fatal toxicity, even after months of no effect. This combination is strongly discouraged.[35]

Divalproex Sodium and Valproic Acid

Divalproex sodium is comprised of sodium valproate and valproic acid. The delayed-release and extended-release formulations are converted in the small intestine into valproic acid, which is the systemically absorbed form. It was developed as an antiepileptic drug, but also has efficacy for mood stabilization and migraine headaches. It is FDA-approved for the treatment of the manic phase of bipolar disorder. It is generally equal in efficacy to lithium and some other drugs for bipolar mania. It has particular utility in bipolar disorder patients with rapid cycling, mixed mood features, and substance abuse comorbidity. Although not FDA-approved for relapse prevention, studies support this use, and it is widely prescribed for maintenance therapy. Divalproex can be used as monotherapy or in combination with lithium or an antipsychotic drug.[31]

Mechanism of Action The mechanism of action of divalproex is not well understood. It is known to affect ion transport and enhances the activity of γ-aminobutyric acid. Like lithium, it also has possible neuroprotective effects through enhancement of brain-derived neurotrophic factor.[31]

Dosing and Monitoring Divalproex is often initiated at 500 to 1000 mg per day, but studies indicate a therapeutic serum valproic acid concentration can be reached more quickly through a loading dose approach of 20 to 30 mg/kg per day. Using this approach, patients may respond with a significant reduction in symptoms within the first few days of treatment. The dosage is then titrated according to response, tolerability, and serum concentration. The most often referenced desired serum valproic acid concentration is 50 to 100 mcg/mL (346–693 μmol/L), but

TABLE 36–6. Guidelines for Baseline and Routine Laboratory Tests and Monitoring for Agents Used in the Treatment of Bipolar Disorder

	Baseline: Physical Exam & General Chemistry[a]	Hematologic Tests[c]		Metabolic Tests[b]		Liver Function Tests[d]		Renal Function Tests[e]		Thyroid Function Tests[f]		Serum Electrolytes[g]		Dermatologic[h]	
	Baseline	Baseline	6–12 months	Baseline	6–12 months	Baseline	6–12 months	Baseline	6–12 months	Baseline	6–12 months	Baseline	6–12 months	Baseline	3–6 months
Atypical antipsychotics[i]	X			X	X										
Carbamazepine[j]	X	X	X			X	X	X				X	X	X	X
Lamotrigine[k]	X													X	X
Lithium[l]	X	X	X	X	X			X	X	X	X	X	X	X	X
Oxcarbazepine[m]	X											X	X		
Valproate[n]	X	X	X	X	X	X	X							X	X

[a]Screen for drug abuse and serum pregnancy.
[b]Complete blood cell count (CBC) with differential and platelets.
[c]Fasting glucose, serum lipids, weight.
[d]Lactate dehydrogenase, aspartate aminotransferase, alanine aminotransferase, total bilirubin, alkaline phosphatase.
[e]Serum creatinine, blood urea nitrogen, urinalysis, urine osmolality, specific gravity.
[f]Triiodothyronine, total thyroxine, thyroxine uptake, and thyroid-stimulating hormone.
[g]Serum sodium.
[h]Rashes, hair thinning, alopecia.
[i]Atypical antipsychotics: Monitor for increased appetite with weight gain (primarily in patients with initial low or normal body mass index); monitor closely if rapid or significant weight gain occurs during early therapy; cases of hyperlipidemia and diabetes reported.
[j]Carbamazepine: Manufacturer recommends CBC and platelets (and possibly reticulocyte counts and serum iron) at baseline, and that subsequent monitoring be individualized by the clinician (e.g., CBC, platelet counts, and liver function tests every 2 weeks during the first 2 months of treatment, then every 3 months if normal). Monitor more closely if patient exhibits hematologic or hepatic abnormalities or if the patient is receiving a myelotoxic drug; discontinue if platelets are less than 100,000/mm^3, if white blood cell (WBC) count is less than 3,000/mm^3 or if there is evidence of bone marrow suppression or liver dysfunction. Serum electrolyte levels should be monitored in the elderly or those at risk for hyponatremia. Carbamazepine interferes with some pregnancy tests.
[k]Lamotrigine: If renal or hepatic impairment, monitor closely and adjust dosage according to manufacturer's guidelines. Serious dermatologic reactions have occurred within 2–8 weeks of initiating treatment and are more likely to occur in patients receiving concomitant valproate, with rapid dosage escalation, or using doses exceeding the recommended titration schedule.
[l]Lithium: Obtain baseline electrocardiogram for patients over age 40 or if preexisting cardiac disease (benign, reversible T-wave depression may occur). Renal function tests should be obtained every 2–3 months during the first 6 months, then every 6–12 months; if impaired renal function, monitor 24-hour urine volume and creatinine every 3 months; if urine volume greater than 3 L/day, monitor urinalysis, osmolality, and specific gravity every 3 months. Thyroid function tests should be obtained once or twice during the first 6 months, then every 6–12 months; monitor for signs and symptoms of hypothyroidism; if supplemental thyroid therapy is required, monitor thyroid function tests and adjust thyroid dose every 1–2 months until thyroid function indices are within normal range, then monitor every 3–6 months.
[m]Oxcarbazepine: Hyponatremia (serum sodium concentrations less than 125 mEq/L) has been reported and occurs more frequently during the first 3 months of therapy; serum sodium concentrations should be monitored in patients receiving drugs that lower serum sodium concentrations (e.g., diuretics or drugs that cause inappropriate antidiuretic hormone secretion) or in patients with symptoms of hyponatremia (e.g., confusion, headache, lethargy, and malaise). Hypersensitivity reactions have occurred in approximately 25–30% of patients with a history of carbamazepine hypersensitivity and requires immediate discontinuation.
[n]Valproate: Weight gain reported in patients with low or normal body mass index. Monitor platelets and liver function during first 3–6 months if evidence of increased bruising or bleeding. Monitor closely if patients exhibit hematologic or hepatic abnormalities or in patients receiving drugs that affect coagulation, such as aspirin or warfarin; discontinue if platelets are Less than 100,000/mm^3/L or if prolonged bleeding time. Pancreatitis, hyperammonemic encephalopathy, polycystic ovary syndrome, increased testosterone, and menstrual irregularities have been reported; not recommended during first trimester of pregnancy due to risk of neural tube defects.
From Fankhauser MP, Freeman MP. Bipolar disorder. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 1276, with permission.

it is not unusual for patients to require over 100 mcg/mL (693 μmol/L) for optimal efficacy. Some patients require high-milligram dosages in order to reach a desired serum concentration. The suggested serum concentration range is based on morning sampling, which is a trough value for patients taking divided-daily dosing. Serum concentration monitoring is recommended at least every 2 weeks until stabilized, then less frequently, sometimes as infrequently as twice yearly. The extended-release formulation can be taken once daily, usually at night. In this instance also, a morning blood sampling is recommended. The systemic bioavailability of extended-release divalproex is about 15% less than that of the delayed-release formulation. Patients who have difficulty swallowing large tablets can use the sprinkle formulation. Valproic acid is available in a syrup formulation, which is generally given three or four times per day.[31]

Adverse Effects The most common adverse effects of divalproex are gastrointestinal (loss of appetite, nausea, dyspepsia, and diarrhea), tremor, and drowsiness. Gastrointestinal distress can be reduced by coadministration with food. The delayed-release and extended-release formulations are less likely to cause gastric distress than the immediate-release valproic acid. This is an advantage for divalproex, along with fewer daily doses, which can improve patient adherence to treatment. Dosage reduction can reduce all of the common divalproex side effects. As with lithium, a low-dose β-blocker may alleviate the tremor. Weight gain is also common, occurring in up to 50% of patients on maintenance therapy.[31]

Other adverse effects that are less common include alopecia or a change in hair color or texture. Hair loss can be minimized by supplementation with a vitamin containing selenium and zinc. Polycystic ovarian syndrome associated with increased androgen production has been reported. Thrombocytopenia is not uncommon, and the platelet count should be monitored periodically. It is a dose-related adverse effect and usually asymptomatic, but the drug is usually stopped if the platelet count decreases to less than 100,000/mm^3 (100×10^3/μL or 100×10^9/L). More rare are hepatic toxicity and pancreatitis, which are not always dose-related. Severe gastrointestinal symptoms of hepatic or pancreatic toxicity include vomiting, pain, and loss of appetite. When these occur, the patient should be evaluated for possible hepatitis or pancreatitis. Divalproex has a wide therapeutic index. Acute toxicity for high dosages or overdosage is not life-threatening.[31]

Drug Interactions Drug interactions involving divalproex are common. It is a weak inhibitor of some of the drug-metabolizing liver enzymes and can affect the metabolism of other drugs. These include other antiepileptic drugs and tricyclic antidepressants. The interaction between divalproex and lamotrigine is particularly important. The risk of a dangerous rash due to lamotrigine is increased when given concurrently with divalproex. When lamotrigine is added to divalproex, the initial lamotrigine dosage should be reduced, and titrated more slowly than usual. When divalproex is added to lamotrigine, the lamotrigine dosage should be reduced by 50%. Conversely, the metabolism of divalproex can be increased by enzyme-inducing drugs such as carbamazepine and phenytoin, while divalproex may simultaneously slow metabolism of the other agents.[35]

Carbamazepine

Although long utilized as a mood-stabilizing drug, an extended-release formulation of carbamazepine has only recently received FDA approval for treatment of bipolar disorder. Like divalproex, it also has efficacy for mood stabilization, but is considered possibly less desirable as a first-line agent because of safety and drug interactions. It is sometimes reserved for patients who fail to respond to lithium or for patients with rapid cycling or mixed bipolar disorder. Carbamazepine can be used as monotherapy or in combination with lithium or an antipsychotic drug.[24,32]

Mechanism of Action The mechanism of action of carbamazepine is not well understood. It blocks ion channels and inhibits sustained repetitive neuronal excitation, but whether this explains its effect as a mood-stabilizing drug is not known.[32]

Dosing and Monitoring Carbamazepine is usually initiated at 400 to 600 mg/day. The sustained-release formulation can be given in two divided doses. In addition to a formulation that is completely sustained-release, an additional extended-release formulation contains a matrix of 25% immediate-release, 40% extended-release, and 35% enteric-release beads.[24] The suggested therapeutic serum concentration is 4 to 12 mcg/mL (17–51 μmol/L). As with divalproex, some patients require high-milligram dosages to achieve a desired serum concentration and therapeutic effect. The dosage can be increased by 200 to 400 mg per day as often as every 2 to 4 days to achieve the desired effect. Serum concentration monitoring is suggested at least every 2 weeks until stabilized, then less frequently.[32]

Adverse Effects The most common adverse effects are drowsiness, dizziness, ataxia, lethargy, and confusion. At mildly toxic serum concentrations, it also causes diplopia and dysarthria. These effects can be minimized through dosage adjustments, use of sustained-release formulations, and giving more of the drug late in the day. Gastrointestinal upset is also common. Carbamazepine has an antidiuretic effect similar to the syndrome of inappropriate antidiuretic hormone secretion and can cause hyponatremia. Mild elevations in liver enzymes can occur, but hepatitis is less common. Mild, dose-related leukopenia is not unusual and not usually an indication for stopping the drug. More serious blood count abnormalities such as aplastic anemia and agranulocytosis are rare, but life-threatening.[32] Suggested baseline and routine laboratory monitoring is reviewed in Table 36–6.

Drug Interactions Carbamazepine induces the hepatic metabolism of many drugs, including other antiepileptic drugs, antipsychotics, some antidepressants, oral contraceptives, and

antiretroviral agents. Carbamazepine is also an autoinducer (i.e., it induces its own metabolism). The dosage may require an increase after 1 month or so of therapy because of this effect. Conversely, the metabolism of carbamazepine can be slowed by enzyme-inhibiting drugs such as some antidepressants, macrolide antibiotics including erythromycin and clarithromycin, azole antifungal drugs including ketoconazole and itraconazole, and grapefruit juice. Carbamazepine should not be given concurrently with clozapine because of the added risk of agranulocytosis.[35]

Lamotrigine

Lamotrigine is effective for the maintenance treatment of bipolar disorder. It is more effective for depression relapse prevention than for mania relapse. Its primary limitation as an acute treatment is the time required for titration to an effective dosage. In addition to maintenance monotherapy, it is sometimes used in combination with lithium or divalproex, although combination with divalproex increases the risk of rash, and lamotrigine dosage adjustment is required.[37]

Mechanism of Action The mechanism of action of lamotrigine appears to involve blockage of ion channels and effects on glutamate transmission, although the precise mechanism in bipolar disorder is not clear.[33]

Dosing and Monitoring Lamotrigine is usually initiated at 25 mg daily for the first 1 to 2 weeks, then increasing in a dose-doubling fashion every 1 to 2 weeks to a target dosage of 200 to 400 mg per day. If lamotrigine is added to divalproex, the starting dosage is 25 mg every other day with a slower titration to reduce the risk of rash. If divalproex is added to lamotrigine, the lamotrigine dosage should be reduced by 50% for the same reason. If lamotrigine therapy is interrupted for more than a few days, it should be restarted at the initial dosage. Serum concentration monitoring is not routinely recommended for patients with bipolar disorder.[33]

Adverse Effects The lamotrigine adverse effect of greatest significance is a maculopapular rash, occurring in up to 10% of patients.[33] Although usually benign and temporary, some rashes can progress to life-threatening Stevens-Johnson syndrome. The risk of rash is greater with a rapid dosage titration and when given concurrently with divalproex. The risk is minimal when the dosage titration schedule is slow. Other side effects include dizziness, drowsiness, headache, blurred vision, and nausea. In contrast to other mood-stabilizing drugs such as lithium and divalproex, lamotrigine does not significantly influence body weight.

Drug Interactions Drug interactions involving lamotrigine are usually due to induction or inhibition of its metabolism by other drugs. It does not affect drug-metabolizing hepatic enzymes on its own, but other drugs that affect these pathways can have a significant effect on lamotrigine's clearance. In particular, divalproex slows the rate of elimination of lamotrigine by about half, necessitating dosage reduction. Conversely, carbamazepine increases the rate of lamotrigine metabolism. Upward adjustment in the lamotrigine dosage may be needed as a result.[35]

Oxcarbazepine

Oxcarbazepine is an analogue of carbamazepine, developed as an antiepileptic drug. An advantage over carbamazepine is that routine monitoring of hematology profiles and serum concentrations are not indicated, as the drug is less likely to cause hematologic abnormalities. Additionally, drug interactions are less significant, although it is at least a mild inducer of certain metabolic pathways, and vigilance for drug interactions is needed, especially with oral contraceptives. Oxcarbazepine appears in the most recent treatment algorithms for bipolar disorder,[17] but clinical trial data are limited and do not include randomized, prospective, controlled trials at the time of this writing. Data are limited to open-label and retrospective studies or add-on therapy with other mood-stabilizing agents.[38]

Adverse Effects Adverse effects due to oxcarbazepine include drowsiness, dizziness, gastrointestinal upset, and hyponatremia, the latter two of which may be more likely than with carbamazepine. It is less likely than carbamazepine to cause hematologic abnormalities.[34]

Others

High-potency benzodiazepine agents such as clonazepam have been used as adjunctive therapy, especially during acute mania episodes, to reduce anxiety and improve sleep.[39] Topiramate is commonly used for its putative mood-stabilizing effects, but unpublished, well-designed, randomized, controlled trials sponsored by the manufacturer showed no difference between topiramate and placebo for treatment of bipolar disorder. Uncontrolled, open-label data suggest possible use as an adjunctive agent.[38] Gabapentin has shown no efficacy over placebo and is not recommended for patients with bipolar disorder. Case reports or case series involving zonisamide, tiagabine, pregabalin, and levetiracetam have been published, but no controlled trials have been conducted to date.[38]

Antipsychotic Drugs

Conventional antipsychotic drugs such as chlorpromazine and haloperidol have long been used in the treatment of acute mania. More recently, atypical antipsychotic drugs including aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone have been approved for the treatment of bipolar mania or mixed mood episodes as monotherapy or in combination with mood-stabilizing drugs.[25] Aripiprazole and olanzapine are also approved for maintenance therapy. The combination of olanzapine and fluoxetine is approved for treatment of bipolar depression. Quetiapine is approved for treatment of

bipolar depression. Approval of antipsychotic drugs in bipolar disorder patients applies without regard to the presence of psychotic symptoms. In comparative studies, atypical antipsychotic drugs are equivalent in efficacy to lithium and divalproex for treatment of acute mania. Treatment guidelines include antipsychotic drugs as first-line therapy.[17] More limited studies in maintenance therapy indicate equivalent or possibly superior efficacy of atypical antipsychotic drugs compared to lithium, but these studies are sponsored and developed by manufacturers and have not been replicated widely.

The mechanisms of action, usual dosages, pharmacokinetics, adverse effects, and drug interactions involving antipsychotic drugs are discussed in detail in the chapter on schizophrenia. Dosages in bipolar disorder are similar to those used in schizophrenia. Higher dosages are often required to treat an acute episode than to prevent relapse. The recommended dosage of aripiprazole for bipolar disorder is 20 to 30 mg per day, somewhat higher than the average dosage used in schizophrenia.[40]

Atypical antipsychotic drugs are less likely than conventional agents to cause neurologic side effects, especially movement abnormalities. As a group, however, they are more likely to cause metabolic side effects such as weight gain, glucose dysregulation, and dyslipidemia.[36] Among the atypical antipsychotic drugs approved for treatment of bipolar disorder, olanzapine is more likely to cause metabolic side effects. Quetiapine and risperidone cause fewer metabolic effects than olanzapine. Aripiprazole and ziprasidone are neutral in effects on weight, glucose, and lipids. Adverse effects are discussed in detail in the chapter on schizophrenia.

Antidepressants

Treatment of depressive episodes in bipolar disorder patients presents a particular challenge because of the risk of a pharmacologic mood switch to mania, although there is not complete agreement about such risk. Treatment guidelines suggest lithium or lamotrigine as first-line therapy.[17,41] Olanzapine has also demonstrated efficacy in treatment of bipolar depression, and quetiapine is under review for approval of treatment of bipolar depression.[42] When these fail, efficacy data support use of antidepressants.

Guidelines agree that when antidepressants must be used, they should be combined with a mood-stabilizing drug to reduce the risk of mood switch to hypomania or mania.[17,41] The question of which antidepressant drugs are less likely to cause a mood switch is not resolved. Anecdotal reports suggested bupropion may be less likely to cause this effect, but systematic reviews have not supported this conclusion. Prevailing evidence recommends that tricyclic antidepressants be avoided.[41,43]

Duration of antidepressant therapy is also an unsettled question. It may be possible in some patients to prevent depressive relapse with a mood-stabilizing drug without maintenance antidepressant therapy following acute treatment with an antidepressant. If so, the risk of a mood switch with continued antidepressant therapy would be reduced.

Special Populations

Assessment and management by appropriate psychiatric specialists is important for special populations such as pediatrics, geriatrics, pregnancy, and others.

Pediatrics

Evidence regarding treatment of bipolar disorder in children and adolescents is more limited than in adults, reflecting the difficulty of conducting research in this population. Psychiatric comorbidity is common, which makes treatment and research more challenging. With these caveats, an increasing body of evidence supports the use of mood-stabilizing drugs and atypical antipsychotic drugs in children and adolescents with bipolar disorder.[44] The approach is similar to that used in adults, with monotherapy as first-line therapy, but only lithium is FDA-approved for children and adolescents as young as age 12. The guidelines additionally support divalproex, carbamazepine, olanzapine, quetiapine, and risperidone.[44] Aripiprazole and ziprasidone are not recommended at present because of a lack of published research, but evidence to support the other agents is mostly open-label trials or studies with small sample sizes. For patients with psychotic features, first-line therapy should include combined mood stabilizer and antipsychotic drugs. Patients who fail the initial choice of treatment can be switched to a different agent or augmented with the addition of a second agent.

Initial dosages of drug therapy in the pediatric population are lower than in adults. Metabolic elimination rates of many drugs are increased in children, however, so they may actually require higher dosages on a weight-adjusted basis. Dosages are titrated carefully according to response and tolerability. For lithium, divalproex, and carbamazepine, serum concentration monitoring is recommended as a guide to dosage adjustment and to minimize adverse effects.

Children and adolescent patients are often more sensitive to drug side effects than adults. In particular, they are more likely than adults to experience significant weight gain due to atypical antipsychotic drugs.[45] Cognitive toxicity, manifested as confusion, memory or concentration impairment, or impaired learning, is often difficult to detect and is a special consideration in the pediatric population so intellectual and educational development is not hindered by drug therapy.

Comorbid conditions must be addressed in order to maximize desired outcomes. For comorbid bipolar disorder and attention-deficit/hyperactivity disorder when stimulant therapy is indicated, treatment of mania is recommended before starting the stimulant in order to avoid exacerbation of mood symptoms by the stimulant.

Geriatrics

Treatment of elderly patients with bipolar disorder requires special care because of increased risks associated with concurrent non-psychiatric medical conditions and drug-drug interactions. General medical conditions including endocrine,

metabolic, or infectious diseases can mimic mood disorders. Patients should be evaluated for such medical illnesses that may cause or worsen mood symptoms. As physiologic systems change with aging, elimination of drugs is often slowed. Examples are slowed renal elimination of lithium and slowed hepatic metabolism of carbamazepine and valproic acid. As a result, dosages of drugs required for therapeutic effect are generally lower in geriatric patients. Also, changes in membrane permeability with aging increase risk of central nervous system side effects. Increased frequency of patient monitoring is often required, including serum drug concentration monitoring.

Vigilance for drug-drug interactions is required because of the greater number of medications prescribed to elderly patients and enhanced sensitivity to adverse effects. Pharmacokinetic interactions include metabolic enzyme induction or inhibition and protein binding displacement interactions (e.g., divalproex and warfarin). Pharmacodynamic interactions include additive sedation and cognitive toxicity, which increases risk of falls and other impairments.

Pregnancy

Treatment of bipolar disorder during pregnancy is fraught with controversy and conflicting recommendations. The key issue is the relative risk of teratogenicity with drug use during pregnancy versus risk of bipolar relapse without treatment with consequent potential harm to both the pregnant patient and the fetus. Judgment on an issue of such gravity depends on the history of the patient and whether the pregnancy is planned or unplanned. Treatment is best managed when the pregnancy is planned. Clinicians should discuss the issue with every patient with bipolar disorder who is of childbearing potential. A pregnancy test should be obtained prior to initiating drug therapy. For a patient with severe bipolar disorder, a history of multiple mood episodes, rapid cycling, or suicide attempt, discontinuing treatment, even for a planned pregnancy, is unwise. For a patient with a remote history of a single mood episode with subsequent long-term stability and who is contemplating pregnancy, the answer is less clear. Patients should be provided clear and reliable information about risks versus benefits of stopping or continuing therapy in order to make an informed decision. Patients who decide to discontinue drug therapy prior to pregnancy should taper medications slowly in order to reduce risk of relapse.[46]

Lithium is associated with Ebstein's anomaly, a downward displacement of the tricuspid valve into the right ventricle. Although more likely to occur in children of patients who took lithium during pregnancy, the absolute risk is considered small, around 0.1%. Pharmacokinetic handling of lithium changes as pregnancy progresses. Renal lithium clearance increases, which requires a dosage increase to maintain a therapeutic serum concentration. It may be advisable to decrease or discontinue lithium at term or the onset of labor to avoid toxicity postpartum when there is a large reduction in fluid volume.[46]

Lithium can cause hypotonicity and cyanosis in the neonate, usually termed the "floppy baby" syndrome. Most data indicate normal neurobehavioral development once these symptoms resolve. Lithium is readily transferred via breast milk. Breast-feeding is not advised for patients who are taking lithium.[30]

Valproic acid and carbamazepine are human teratogens. Neural tube defects such as spina bifida occur in up to 9% of infants exposed during the first trimester. The risk is related to exposure during the third and fourth weeks following conception. As such, women with unplanned pregnancies may not know they are pregnant until after the risk of exposure has occurred. Carbamazepine can cause fetal vitamin K deficiency. Vitamin K is important for facial growth and for clotting factors. Risk of facial abnormalities and neonatal bleeding is increased in infants of mothers who are treated with carbamazepine during pregnancy.[46]

Less data are available on other antiepileptic mood-stabilizing drugs. Birth defects in children of women who are prescribed lamotrigine during pregnancy appear to be no greater than in the general population, but based on an analysis of only several hundred cases.[47] The FDA has noted a possible, but inconclusive association between lamotrigine exposure during the first trimester and cleft lip and/or cleft palate.

Patient Encounter, Part 4: Outcome Evaluation

Following initial assessment, including evaluation of potential suicidality, support systems, and need for inpatient versus outpatient treatment, MW was hospitalized briefly, then followed in the community on medication along with psychotherapy. She has abstained from illicit substances and has returned to her job. She has responded well to treatment with sustained-release lithium carbonate 900 mg once daily at bedtime with a snack. Steady-state 12-hour serum lithium concentrations have stabilized at 0.9 mEq/L (0.9 mmol/L). She now returns to clinic for routine follow-up. She has tolerated the lithium except for a mild tremor and a gain of 7 pounds (3.2 kg). She is willing to accept these side effects for now, but asks about how long she must take medication since she is now feeling well.

- Assess therapeutic and adverse effects of treatment for this patient.
- Recommend strategies to maintain therapeutic efficacy while reducing or eliminating adverse effects.
- Educate the patient regarding need for continued maintenance treatment.

First-generation antipsychotic drugs have been available for many years, and more data are available on their use in pregnancy than for atypical antipsychotic drugs. Since experience with atypical antipsychotic drugs during pregnancy is limited, first-generation agents are often recommended for the treatment of acute mania during pregnancy.

Use of antidepressant drugs during pregnancy is discussed in the chapter on depression.

OUTCOME EVALUATION

Assessment of Therapeutic Effects

Effective interviewing skills and a therapeutic relationship with the patient are essential to assessing response to treatment. Understand the particular symptom profile and needs of individual patients. These become the primary therapeutic monitoring parameters. In addition to the clinical interview, some clinicians utilize symptom rating scales such as the Young Mania Rating Scale for mania and the Hamilton Depression Rating Scale (discussed in the chapter on depression). Check serum concentrations of mood-stabilizing drugs as a guide to dosage adjustment for optimal efficacy. The frequency of follow-up visits depends on response, tolerability, adherence, and other factors.

Adverse effects cause more non-adherence to prescribed therapy than any other factor. Monitor patients regularly for adverse effects and health status, especially since mood-stabilizing drugs and antipsychotic drugs commonly cause metabolic side effects such as weight gain. Repeat laboratory tests for renal and thyroid function for patients taking lithium, and hematology and liver function for patients taking carbamazepine or divalproex. Annual measurement of serum lipase may be advisable for patients taking divalproex. More specific discussion of metabolic side-effect monitoring of patients taking atypical antipsychotic drugs is discussed in the chapter on schizophrenia.

❽ *Patient education improves adherence to treatment, which reduces risk of relapse.* This is especially important since responsiveness to treatment declines as the number of mood episodes increases. Discuss the nature and chronic course of bipolar disorder and the risks of repeated relapses. Help patients understand that treatment of bipolar disorder is not a cure, but many patients can enjoy symptom-free or nearly symptom-free function. Make clear that long-term recovery is dependent on adherence to both pharmacologic and nonpharmacologic treatment. Explain the purpose of medication, common side effects to expect, and how to respond to them. Provide the patient and family with written information about medication indications, benefits, risks, and side effects. Discuss less frequent, but more dangerous side effects of drugs, and give written instructions on seeking medical attention immediately should they occur.

Patient Care and Monitoring

1. Assess the patient's symptoms and review the past history. Review the family history, including the history of response to treatment by family members.
2. Obtain an initial medical evaluation to rule out other causes of mood episodes.
3. Obtain a thorough medication use history, including present and past drugs; prescription and nonprescription drugs; the patient's self-assessment of response and side-effect problems; use of alcohol, tobacco, caffeine, and illicit substances; and use of herbal products and dietary supplements, as well as any allergies and adherence difficulties.
4. Assess potential drug-disease, drug-drug, and drug-food interactions.
5. Evaluate physiologic parameters that may influence pharmacokinetics.
6. Develop a plan for monitoring therapeutic outcomes, focusing on the individual symptom profile and level of function of each patient. Include a plan for dosage adjustments or alternate therapy if the patient fails to respond adequately. Include serum drug concentration monitoring as appropriate.
7. Develop a monitoring plan for drug side effects. Include measures to prevent side effects as well as management if they occur. Include appropriate laboratory measures.
8. Determine the role of nonpharmacologic therapy and how it is to be integrated with drug therapy.
9. Educate the patient on the nature of bipolar disorder and its treatment, what to expect with regard to response and side effects, and stress the need for adherence to treatment, even when feeling well.
10. Encourage a healthy lifestyle, including eliminating or stopping substance abuse and smoking, and encouraging proper nutrition and exercise.

37 Generalized Anxiety Disorder, Panic Disorder, and Social Anxiety Disorder

Sheila Botts, Tawny Bettinger, and Brian Greenlee

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Describe pathophysiologic findings in generalized anxiety, panic, and social anxiety disorder patients.
2. List common presenting symptoms of generalized anxiety, panic, and social anxiety disorders.
3. Identify the desired therapeutic outcomes for patients with generalized anxiety, panic, and social anxiety disorders.
4. Discuss appropriate lifestyle modifications and over-the-counter medication use.
5. Recommend psychotherapy and pharmacotherapy interventions for patients with generalized anxiety, panic, and social anxiety disorders.
6. Develop a monitoring plan for anxiety patients placed on specific medications.
7. Educate patients about their disease state and appropriate lifestyle modifications, as well as psychotherapy and pharmacotherapy for effective treatment.

Key Concepts

❶ The goals of therapy for generalized anxiety disorder are to acutely reduce the severity and duration of anxiety symptoms and restore overall functioning. The long-term goal in generalized anxiety disorder is to achieve and maintain remission.

❷ Antidepressants are considered first-line agents in the management of chronic generalized anxiety disorder.

❸ Benzodiazepines are recommended for acute treatment of generalized anxiety disorder when short-term relief is needed, as an adjunct during initiation of antidepressant therapy, or to improve sleep.

❹ The acute phase of panic disorder treatment lasts about 12 weeks and should result in marked reduction in panic attacks, ideally total elimination, and minimal anticipatory anxiety and social anxiety avoidance. Treatment should be continued to prevent relapse for an additional 12 to 18 months before attempting discontinuation.

❺ Panic disorder patients are more likely to experience stimulant-like side effects than patients with major depression and should be initiated on lower doses of antidepressant than those that are used for depression or other anxiety disorders.

❻ Antidepressants should be tapered when treatment is discontinued to avoid withdrawal symptoms, which include dysphoric mood, irritability, and agitation.

❼ The dose of benzodiazepine required for improvement in panic disorder generally is higher than that used in other anxiety disorders.

❽ Selective serotonin reuptake inhibitors (SSRIs) are considered the drugs of choice based on their tolerability and efficacy for social anxiety disorder as well as comorbid disorders.

❾ The onset of response to antidepressants in social anxiety disorder is delayed and may be as long as 8 to 12 weeks. Patients responding to medication should be continued on treatment for at least 1 year.

❿ Pharmacotherapy of social anxiety disorder should lead to improvement in physiologic symptoms of anxiety and fear, functionality, and overall well-being.

Anxiety is a normal response to stressful or fearful circumstances. Most people experience some degree of anxiety in reaction to stressful situations, such as final exams or giving a speech. This allows an individual to adapt to or manage the stressful/threatening situation. Anxiety symptoms generally

Patient Encounter 1, Part 1

AX, a 27-year-old African-American woman, presents to your clinic with gastrointestinal complaints (e.g., constipation, bloating, and cramping) and fatigue. She is a single mother of three (ages 2, 3, and 6 years) and is a full-time college student. She states that she worries about everything: her grades, finances, the 6-year-old riding the school bus, etc. She states that "even if it's not important, I still worry." She has difficulty sleeping and says that she often feels like she might jump out of her skin. On one occasion she felt like she might be having a "heart attack or something."

- What manifestations described above are suggestive of an anxiety disorder?
- What additional information do you need to establish a diagnosis and develop a treatment plan?

are short-lived and do not necessarily impair function. Anxiety that becomes excessive, causes irrational thinking or behavior, and impairs a person's functioning is considered an anxiety disorder.

Anxiety disorders are among the most frequent mental disorders encountered by clinicians. Anxiety disorders often are missed or attributed incorrectly to other medical illnesses, with most patients being treated inadequately. The burden of detection and diagnosis most often falls to primary-care clinicians, to whom most patients present in the context of other complaints. Untreated anxiety disorders may result in increased healthcare utilization, morbidity and mortality, and poorer quality of life.

EPIDEMIOLOGY AND ETIOLOGY

Epidemiology

Prevalence

With a lifetime prevalence of 28.8%, anxiety disorders collectively represent the most prevalent *Diagnostic and Statistical Manual of Mental Disorders,* 4th edition, Text Revision (DSM-IV-TR)[2] class of disorders, with specific phobia (12.5%) and social anxiety disorder (12.1%) being the most common.[3] Recent reports from the National Comorbidity Survey Revised (NCS-R) estimate the lifetime and 1-year prevalence of generalized anxiety disorder (GAD) for those 18 years of age and older to be 5.7% and 3.1%, respectively.[3,4] Rates for panic disorder (PD) are slightly lower, with an estimated 12-month prevalence of 2.7% and lifetime prevalence of 4.7%.

Most studies report higher rates of anxiety disorders among women (2:1 female:male) and older adults.[5] Data from the NCS-R show that while, in general, prevalence rates across the anxiety spectrum increase from the younger age group (18–29) to older age groups (30–44 and 45–59), rates are substantially lower for those older than age 59.[3]

Course of Illness

Anxiety disorders represent a diverse class of illnesses, with varied ages of onset. For example, according to the NCS-R epidemiologic study,[3] PD and GAD had a median age of onset of 24 and 31 years, respectively, whereas specific phobia and social anxiety disorder (SAD) tend to develop much earlier (median age of onset 7 and 13 years, respectively). Although GAD and PD may not manifest fully until adulthood, as many as half of adult anxiety patients report subthreshold symptoms during childhood.[6]

Anxiety disorders are characterized as chronic in nature with low rates of spontaneous symptom **remission** and high rates of relapse. Research illustrates that symptoms of anxiety disorders tend to wax and wane, with less than a third of patients remitting spontaneously.[7] In a 12-year follow-up study of anxiety disorder patients, recurrence rates were similar between PD with and without agoraphobia (56% and 58%, respectively) despite great differences seen in reported rates of remission (48% and 82% with treatment, respectively).[8] Fifty-eight percent of treated GAD patients experienced symptom remission, with 55% experiencing recurrence during the follow-up period. While individuals with SAD had the lowest remission rate with treatment (37%), those who did respond had the lowest rate of recurrence (39%) compared with patients with other anxiety disorders.

Remission, if achieved with treatment, is most likely to occur within the first 2 years of an index episode.[9] Similarly, the highest rates of relapse are seen within the first 2 years of the index episode. This suggests that many patients need ongoing maintenance treatment. Rates of remission do not appear to vary by sex.[9] Likewise, relapse rates do not appear to differ by sex for those who suffer from PD, GAD, or SAD. However, one study reported that women with PD without agoraphobia were three times more likely than men to experience a relapse of symptoms. Patients tend to spend a significant portion of time "being ill" during a particular episode. For example, in the 12-month follow-up study,[8] the average time spent "being ill" during an episode was 80% for SAD, 78% for PD, 74% for GAD, and 41% for PD without agoraphobia. With such a chronic course of illness and significant portion of time spent "being ill" during a particular episode, it is not surprising that patients afflicted with an anxiety disorder have been shown to display impaired psychosocial functioning and a compromised quality of life.[10,11] Appropriate treatment of an anxiety disorder has been shown to improve the patient's overall quality of life and psychosocial functioning.[11]

Comorbidity

Anxiety disorders rarely exist alone. More than 90% of individuals with an anxiety disorder have a lifetime history of one

or more other psychiatric disorders.[12] Depression is the most common lifetime comorbid illness, followed by alcohol- or substance-use disorders, as well as other co-occurring anxiety disorders, especially GAD and PD.[12] Generally speaking, the onset of SAD and GAD symptoms precedes major depressive disorder (MDD), whereas there is an equal chance of PD onset before, during, or after MDD. Regardless of when the comorbid psychiatric illness occurs, it can further complicate the anxiety picture and often is associated with even lower rates of remission and higher rates of relapse. It is essential that both disorders are addressed and treated appropriately.

Etiology

Both genetic and psychosocial factors appear to play a role in the initiation and expression of anxiety disorders.[13] Documentation of moderate genetic risk has been identified for all anxiety disorders, although some conflicting data do exist. Currently, no definitive gene or set of genes has been identified as being the causative factor for a specific anxiety disorder. Additionally, it is unclear if anxiety disorders share common genetic risk factors. Recent research suggests that genetic overlap may exist between GAD and PD and, to a lesser extent, SAD.[13]

It is possible that while genetics may create a vulnerable phenotype for an anxiety disorder, an individual's life stressors and means of coping with the stress also can play a significant role in precipitation and continued expression of the anxiety disorder.[14] In fact, some researchers believe that stressful life events may play a strong role in the onset of anxiety disorders, especially in GAD and PD.[13] It has been reported that those experiencing one or more negative life events have a three-fold increased chance of developing GAD.[5] Similar findings have been reported with PD.[14]

PATHOPHYSIOLOGY

The thalamus and amygdala are important in the generation of a normal fear response and play a central role in most anxiety disorders. They support the fundamental requirements of the nervous system's rapid detection and response system. Any such system requires a mechanism to detect a potential threat, evaluate the actual threat, and respond in a defensive or evasive manner. The thalamus plays a vital role in nearly every sensory modality, excluding olfaction and visceral sensation.[15] It provides the first real processing region to organize sensory data obtained from the environment. The thalamus passes information to higher cortical centers for finer processing and to the amygdala for rapid assessment of highly charged emotional information. The amygdala serves to provide emotional valence or the emotional importance of the information.[16] This helps the organism to act quickly on ambiguous but vital events. The cortex then performs a more detailed analysis, sending updates to the amygdala for comparison and any needed course corrections.[17] This finer evaluative process enables a decision on a course of action.

Anxiety becomes an anxiety disorder when activity of the fear-response network leads to maladaptive behavior or distress. Anxiety can become independent of stimuli as in PD, can be associated with benign stimuli as in phobias, or can continue beyond the necessary duration as in GAD. The precise mechanism by which these changes occur is unknown, but much has been discovered regarding how the amygdala effects changes throughout the brain and how this may be regulated by treatment[15] (Fig. 37–1).

Direct and indirect connections to the reticular activating system (RAS), a region spanning the medulla, pons, and midbrain, help to regulate arousal, vigilance, and fear. Modulation of these connections relies on the neurotransmitters serotonin

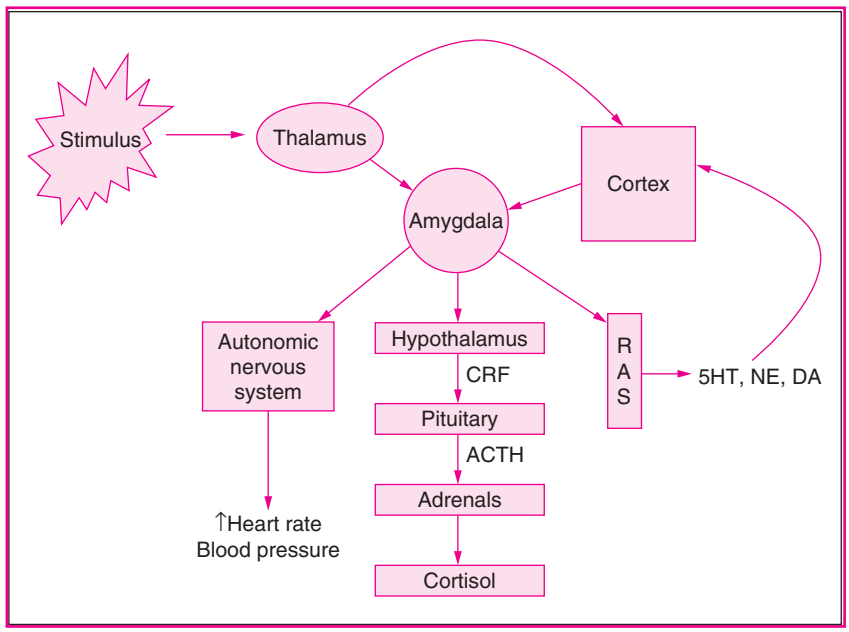

FIGURE 37–1. Neurocircuitry and key neurotransmitters involved in mediating anxiety disorders.

and norepinephrine, which have their primary origins in the RAS.[18] The amygdala sends projections to the hypothalamus influencing the autonomic nervous system to affect heart rate, blood pressure, and stress-associated changes. The amygdala also influences the **hypothalamic-pituitary-adrenal axis** (HPA axis), leading to a cascade of stress hormones.[19] One such hormone is cortisol, which, if elevated for prolonged periods, can have damaging effects on the brain and other organs. These are important targets in our understanding of how the amygdala regulates the fear response because they provide useful targets for current drug treatment and inform further research on anxiety disorders.

Noradrenergic System

Norepinephrine (NE)–producing cells reside primarily in a region of the brain called the **locus ceruleus (LC).** An increase in activity of cells in this region is associated with an increase in arousal, anxiety, and panic. Drugs such as yohimbine that increase activity of the LC can be anxiogenic, whereas drugs that decrease activity of the LC appear to improve anxiety symptoms. Furthermore, dysregulation of this region is implicated by elevated levels of NE or its metabolites in subjects with GAD, PD, and specific phobias.[19]

Serotonergic System

The **raphe nuclei** and the resident cell bodies of serotonin (5-HT)–producing neurons have an interesting yet complicated role in producing anxiety symptoms. One important role may be their ability to directly regulate the activity of cells in the LC. Activity of 5-HT cells in the raphe nuclei over time inhibits firing of noradrenergic cells in the LC. Other influences may be their ability to regulate cells in the prefrontal cortex and amygdala. Perhaps the strongest evidence for the involvement of the serotonergic system is the success of serotonin reuptake inhibitors in clinical treatment.[19]

GABA

Gamma-aminobutyric acid (GABA) plays an important role as an inhibitory neurotransmitter. The effects of GABA are nonspecific, and its role is complex. GABAergic drugs are used for acute anxiety reduction, but the lack of a specific target for their effect leads to multiple undesirable effects. Current research is focused on defining receptor subtypes that may allow for greater specificity in targeting anxiety symptoms.[20]

HPA Axis

The HPA axis provides a critical mechanism for regulation of the stress response and its effects on the brain and other organ systems. Several important hormones, including corticotropin-releasing hormone and cortisol, are involved in this pathway. These hormones regulate the effects of anxiety on the body and provide positive feedback to the brain.[19] A cycle of anxiety and sensitization by such feedback could, if unchecked, result in escalation of symptoms. Neuropeptides provide one mechanism to balance positive and negative feedback, helping to minimize such escalation.

Neuropeptides

Several neuropeptides are under current investigation for their role in anxiety disorders. Important neuropeptides include neuropeptide Y (NPY), substance P, and cholecystokinin. NPY appears to have a role in reducing the effect of stress hormones and inhibiting activity of the LC. Both mechanisms may contribute to the anxiolytic properties seen experimentally. Substance P may have anxiolytic and antidepressant properties. This may be due in part to its effects on corticotropin-releasing hormone.[21]

CLINICAL PRESENTATION AND DIAGNOSIS

Clinical Presentation and Diagnosis of GAD

General
Onset is typically in early adulthood. Anxiety emerges and dissipates more gradually than in PD. Laboratory evaluation usually is reserved for later onset, atypical presentation, or poor response to treatment.

Symptoms[2]
Excessive anxiety or worry involving multiple events or activities occurring more days than not for at least 6 months and associated with at least three of the following:

- Restlessness
- Easily fatigued
- Poor concentration
- Irritability
- Muscle tension
- Insomnia or unsatisfying sleep

Differential Diagnosis
Rule out underlying medical or psychiatric disorders and medications that may cause anxiety (Tables 37–1 and 37–2)

Laboratory Evaluation
- Basic metabolic panel
- Thyroid-stimulating hormone
- Polysomnogram

Clinical Presentation and Diagnosis of PD

General
Typically presents in late adolescence or early adulthood. Onset in older adults increases suspicion of relationship to medical disorders or substance use. Laboratory evaluation must be driven by history and physical examination.

Symptoms[2]
Recurrent, discrete episodes that typically develop rapidly and peak within 10 minutes involving at least four of the following symptoms:

- Palpitations or rapid heart rate
- Sweating
- Trembling or shaking
- Sensation of shortness of breath or smothering
- Feeling of choking
- Chest pain or discomfort
- Feeling dizzy or lightheaded
- Feeling of unreality or being detached from oneself
- Fear of dying
- Numbness or tingling sensation
- Chills or hot flushes

Differential Diagnosis
Rule out underlying medical or psychiatric disorders and medications that may cause anxiety (Tables 37–1 and 37–2).

Laboratory Evaluation
- Urine drug screen
- Basic metabolic panel
- Thyroid-stimulating hormone
- Electrocardiogram
- Holter monitor
- Electroencephalogram
- Urine vanillylmandelic acid (VMA)

TREATMENT: GENERALIZED ANXIETY DISORDER

Desired Outcomes

❶ *The goals of therapy for GAD are to acutely reduce the severity and duration of anxiety symptoms and restore overall functioning. The long-term goal in GAD is to achieve and maintain remission.* With a positive response to treatment, patients with GAD and comorbid depression should have minimal depressive symptoms.

General Approach to Treatment

Patients with GAD may be managed with psychotherapy, pharmacotherapy, or both. The treatment plan should be individualized based on the patient's symptom severity, comorbid illnesses, medical status, age, and preference. Patients with severe symptoms resulting in functional impairment should receive antianxiety medication.

Clinical Presentation and Diagnosis of SAD

General
Often occurs in context of other anxiety disorders. The feared social or performance situation can be limited to a specific social interaction (e.g., public speaking) or generalized to most any social interaction. Differs from specific phobia, in which the fear and anxiety are limited to a particular object or situation (e.g., insects, heights, public transportation).

Symptoms[2]
- Persistent fear of social interactions, during which time the individual is concerned about being embarrassed or being under scrutiny.
- Engaging in the feared activities can lead to extreme anxiety and panic.
- The fear leads to distress or avoidance of the situation sufficient enough to cause trouble in the patient's life.

Differential Diagnosis
Rule out underlying medical or psychiatric disorders and medications that may cause anxiety (Tables 37–1 and 37–2).

Laboratory Evaluation
Limited value. Laboratory investigation is of limited value and should be pursued only in context of other history or physical examination findings.

Patient Encounter 1, Part 2

AX returns to your clinic 4 months later stating that despite meeting with the school psychologist a few times, she continues to have problems. In addition to worrying and feeling nervous, she feels down a lot. "I don't have the energy to play with my children. I obsess over everything. My grades have really gone down hill. I cry a lot and feel hopeless."

PMH
Irritable bowel syndrome, GAD

FH
Mother treated for depression; father, ETOH dependence

SH
Drinks ETOH occasionally; cigarettes, 1 pack per day; lives independently with 3 children

Meds
Centrum multivitamin

- Given this information, what is your assessment of this patient?
- Develop a treatment plan, including nonpharmacologic and pharmacologic recommendations, duration of therapy, and monitoring plan.

TABLE 37–1. Medical Conditions That Can Cause Anxiety[2,22,23]

Psychiatric Disorders
Mood disorders, hypochondriasis, personality disorders, alcohol/substance abuse, alcohol/substance withdrawal, other anxiety disorders

Neurologic Disorders
CVA, seizure disorders, dementia, stroke, migraine, encephalitis, vestibular dysfunction

Cardiovascular Disorders
Angina, arrhythmias, congestive heart failure, mitral valve prolapse, myocardial infarction

Endocrine and Metabolic Disorders
Hypo/hyperthyroidism, hypoglycemia, Cushing's disease, Addison's disease, pheochromocytoma, hyperadrenocorticism, hyponatremia, hyperkalemia, vitamin B_{12} deficiency

Respiratory Disorders
Asthma, COPD, pulmonary embolism, pneumonia, hyperventilation

Other
Carcinoid syndrome, anemias, systemic lupus erythematosus

COPD, chronic obstructive pulmonary disease; CVA, cerebrovascular accident.

Nonpharmacologic Therapy

Nonpharmacologic therapy includes psychoeducation, exercise, stress management, and psychotherapy. Psychoeducation should address pertinent information on GAD and its management. Patients should be instructed to avoid stimulating agents such as caffeine, decongestants, diet pills, and excessive alcohol use. Regular exercise is also recommended. Cognitive-behavioral therapy (CBT) is the most effective psychological therapy for GAD patients. CBT helps patients to recognize and alter patterns of distorted thinking and dysfunctional behavior. Some trials suggest that treatment gains with CBT may be maintained for up to 1 year.[25] It is unclear if the combination of CBT and medication is more effective than either treatment alone.

TABLE 37–2. Medications Associated with Anxiety Symptoms[2,22–24]

Category	Examples
Anticonvulsants	Carbamazepine, ethosuximide
Antidepressants	Bupropion, SSRIs, TCAs
Antihypertensives	Felodipine
Antimicrobials	Cephalosporins, ofloxacin, isoniazid
Antiparkinson drugs	Levodopa
Bronchodilators	Albuterol, isoproterenol, theophylline
Corticosteroids	Prednisone, methylprednisolone
Decongestants	Pseudoephedrine, phenylephrine
Herbals	Ma huang, St. John's wort, ginseng, guarana, belladonna
NSAIDs	Ibuprofen, indomethacin
Stimulants	Amphetamines, caffeine, cocaine, methylphenidate
Thyroid hormones	Levothyroxine
Toxicity	Anticholinergics, antihistamines, digoxin
Withdrawal of CNS depressants (abrupt)	Alcohol, barbiturates, benzodiazepines

SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants; NSAIDs, non-steroidal anti-inflammatory drugs.

Pharmacologic Therapy

Antidepressants, benzodiazepines, buspirone, hydroxyzine, and pregabalin all have controlled clinical trial data supporting their use in GAD. Antidepressants have replaced benzodiazepines as the drugs of choice for chronic GAD owing to a tolerable side-effect profile, no risk for dependency, and efficacy in common comorbid conditions including depression, panic, obsessive-compulsive disorder (OCD), and SAD. Benzodiazepines remain the most effective and commonly used treatment for short-term management of anxiety where immediate relief of symptoms is desired. They are also recommended for intermittent or adjunctive use during GAD exacerbation or for sleep disturbance during the initiation of antidepressant treatment.[26] Buspirone and pregabalin are alternative agents for patients with GAD without depression. Hydroxyzine use is less desirable for long-term treatment owing to side effects.

Patients with GAD should be treated to remission of symptoms. While data are lacking on the optimal duration of pharmacotherapy, most guidelines recommend continuing treatment for an additional 3 to 10 months.[25–28] An algorithm for the pharmacologic management of GAD is shown in Fig. 37–2.

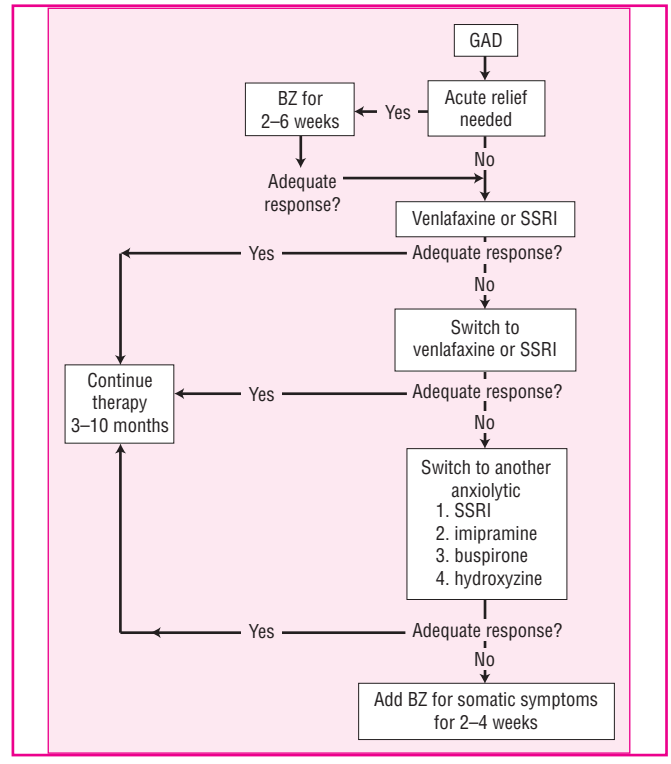

FIGURE 37–2. Treatment alogorithm for GAD. SSRI = selective serotonin reuptake inhibitor; BZ = benzodiazepine. (Reprinted, with permission, from reference 24.)

TABLE 37–3. Antidepressants Used in the Treatment of Generalized Anxiety Disorder[24,29,30]

Medication Class	Recommended Starting Dose (mg/day)	Usual Therapeutic Dosage Range (mg/day)
SSRIs		
Citalopram (Celexa)	20	20–50
Escitalopram[a] (Lexapro)	10	10–20
Fluoxetine (Prozac)	20	20–80
Fluvoxamine (Luvox)	50	100–300
Paroxetine	20	20–50
Paroxetine CR (Paxil, Paxil CR)	25	25–62.5
Sertraline (Zoloft)	50–100	50–200
SNRI		
Venlafaxine XR[a] (Effexor XR)	75	75–300
TCAs		
Imipramine (Tofranil)	50–75	75–200

[a]FDA approved for use in generalized anxiety disorder.
SSRIs, selective serotonin reuptake inhibitors; SNRIs, serotonin and norepinephrine reuptake inhibitors; TCAs, tricyclic antidepressant

Antidepressants

❷ *Antidepressants (Table 37–3) are considered first-line agents in the management of chronic GAD.* These agents reduce the psychic symptoms (e.g., worry and apprehension) of anxiety with a modest effect on autonomic or somatic symptoms (e.g., tremor, rapid heart rate, and/or sweating). All antidepressants evaluated have resulted in a similar degree of anxiety reduction. The onset of antianxiety effect is delayed 2 to 4 weeks. Venlafaxine and SSRIs usually are preferred over tricyclic antidepressants (TCAs) such as imipramine owing to improved safety and tolerability. Selection of a particular antidepressant agent generally is based on history of prior **response,** side-effect profile, drug-interaction profile (discussed Chap. 35), cost, or formulary availability.

Antidepressants modulate synaptic 5-HT, NE, and/or dopamine (DA) reuptake and receptor-activated neuronal signal transduction. These intracellular changes ultimately modify the expression of genes and proteins important in stress response (e.g., increase messenger RNA for glucocorticoid receptors and brain-derived neurotrophic factor and decrease mRNA expression for corticotropin-releasing factor).[31] Activation of these "stress adapting" pathways is thought to improve both somatic symptoms and psychic distress experienced in anxiety.[31]

SNRI (Venlafaxine)

Venlafaxine, a serotonin-norepinephrine reuptake inhibitor (SNRI), alleviates anxiety in GAD patients with and without depression. Venlafaxine was shown to reduce anxiety effectively at doses 75 to 225 mg/day in 8-week trials, and response was maintained over an additional 6 months of treatment.[32,33] Venlafaxine has more favorable safety and side-effect profiles than TCAs. The most common side effects reported with venlafaxine by GAD patients are nausea, somnolence, dry mouth, dizziness, sweating, constipation, and anorexia.[34]

SSRIs

The SSRIs paroxetine, escitalopram, and sertraline have been shown to be significantly more effective than placebo in reducing anxiety symptoms. Paroxetine at doses of 20 and 40 mg/day achieved response in 62% and 68% of patients, respectively, over 8 weeks of treatment.[35] Remission occurred in 30% and 36%, respectively. In a 24-week relapse-prevention study, paroxetine was more effective than placebo at maintaining response, and patients were more likely to achieve remission with continued treatment (42.5% at 8 weeks versus 73% at 24 weeks).[36] In GAD trials, paroxetine was associated with a high rate of somnolence, nausea, abnormal ejaculation, dry mouth, decreased libido, and asthenia compared with placebo.[35] Escitalopram, in a dose range of 10 to 20 mg/day, was more effective than placebo in patients with GAD without depression. Fifty-eight percent of patients on escitalopram achieved response versus 38% on placebo over the 8 weeks of treatment.[37] Escitalopram was associated with headache, nausea, somnolence, upper respiratory tract infection, decreased libido, ejaculation disorder, and anorgasmia.[37] Sertraline was more efficacious than placebo in patients with GAD being treated for 12 weeks. Sertraline treatment resulted in 56% of patients achieving response, whereas 31% achieved remission.[38] Sertraline was associated with increased rates of nausea, insomnia, sweating, decreased libido, diarrhea, fatigue, and ejaculation disorder.[38] Limited comparative trial data suggest comparable outcomes between these SSRIs.[39,40] SSRI therapy is better tolerated than TCAs, and tolerability is similar to that with venlafaxine.

TCAs

Imipramine treatment resulted in a higher rate of remission of anxiety symptoms than trazodone, diazepam, or placebo (e.g., 73% versus 69% versus 66% versus 47%) in an 8-week controlled trial of DSM-III–diagnosed GAD patients. Antidepressants were more effective than diazepam or placebo in reducing psychic symptoms of anxiety. The use of TCAs generally is limited by bothersome adverse effects (e.g., sedation, orthostatic hypotension, anticholinergic effects, and weight gain).

Benzodiazepines

❸ *Benzodiazepines are recommended for acute treatment of GAD when short-term relief is needed, as an adjunct during initiation of antidepressant therapy, or to improve sleep.*[25,26] Benzodiazepine treatment results in a significant improvement in 65% to 75% of GAD patients, with most of the

improvement occurring in the initial 2 weeks of therapy.[41] They are more effective in reducing somatic symptoms of anxiety than psychic symptoms. The major disadvantages of benzodiazepines are their lack of effectiveness in treating depression and the risk for dependency and abuse. Benzodiazepines should be avoided in patients with chemical dependency.

Benzodiazepines exert their effects by enhancing transmission of the inhibitory neurotransmitter GABA through interaction with the $GABA_A$-receptor complex.[25] Although all benzodiazepines possess anxiolytic properties, only 7 of the 13 currently marketed agents are approved by the Food and Drug Administration (FDA) for the treatment of anxiety disorders (Table 37–4). All benzodiazepines are expected to provide equivalent benefit when given in comparable doses. Benzodiazpines differ substantially in their pharmacokinetic properties and potency for the $GABA_A$-receptor site.

Benzodiazepines are metabolized by hepatic oxidation (cytochrome P-450 3A4) and glucuronide conjugation. Lorazepam and oxazepam bypass hepatic oxidation and are conjugated only. They are preferred agents for patients with reduced hepatic function secondary to aging or disease. Many benzodiazepines are metabolized to long-acting metabolites (Table 37–4) that provide long-lasting anxiety relief. Drugs that either inhibit or induce CYP450 isozymes or glucuronidation are the major source of drug interactions (Table 37–5).

The most common side effects associated with benzodiazepine therapy include central nervous system (CNS) depressive effects (e.g., drowsiness, sedation, psychomotor impairment, and ataxia) and cognitive effects (e.g., poor recall memory and **anterograde amnesia**). Anterograde amnesia is more likely to occur with high-potency benzodiazepines such as lorazepam or alprazolam.[42] Some patients also may be disinhibited with benzodiazepine treatment and experience confusion, irritability, aggression, and excitement.[42]

Discontinuation of benzodiazepines may be associated with withdrawal, rebound anxiety, and a high rate of relapse. Higher doses of benzodiazepines and longer duration of therapy increase the severity of withdrawal and risk of seizures after abrupt or rapid discontinuation. Patients should be tapered rather than discontinued abruptly from benzodiazepine therapy to avoid withdrawal symptoms. The duration of the taper should increase with extended duration of benzodiazepine therapy.[27] For example, patients on benzodiazepine therapy over 2 to 6 months should be tapered over 2 to 8 weeks, whereas patients receiving 12 months of treatment should be tapered over 2 to 4 months. A general approach to the taper is to reduce the dose by 25% every 5 to 7 days until reaching half the original dose and then decreasing by 10% to 12% per week until discontinued. Patients should expect minor withdrawal symptoms and discomfort even when tapering. Rebound symptoms (e.g., return of original symptoms at increased intensity) are transient. The patient should be counseled so that rebound anxiety is not interpreted as a relapse. Relapse or recurrence of anxiety may occur in as many as 50% of patients discontinuing benzodiazepine treatment.[41,43] It is unclear if this relapse rate represents an inferiority of benzodiazepines or supports the chronic nature of GAD.

TABLE 37–4. Benzodiazepine Comparison Chart[24,30]

Drug Name (Brand Name) *Active Metabolites*	Time to Peak Concentration (hour)	Half-Life Range (hour)	Approved Dosage Range (mg/day)	Dose Equivalent (mg)
Alprazolam[a,b] (Xanax)	1–2	12–15	1–4 (GAD) 1–10 (PD)	0.5
Chlordiazepoxide[a] (Librium)	1–4	5–30	25–100	10
Desmethylchlordiazepoxide		18		
Demoxepam		14–95		
Desmethyldiazepam		40–120		
Oxazepam		5–15		
Clonazepam[b] (Klonopin)	1–4	18–50	1–4	0.25
Clorazepate[a] (Tranzene)	1–2		7.5–60	7.5
Desmethyldiazepam		40–120		
Oxazepam		5–15		
Diazepam[a] (Valium)	0.5–2	20–80	2–40	5
Desmethyldiazepam		40–120		
Temazepam		8–15		
Oxazepam		5–15		
Lorazepam[a] (Ativan)	2–4	10–20	0.5–10	0.75–1
Oxazepam[a] (Serax)	2–4	5–15	30–120	15

[a]FDA approved for use in generalized anxiety disorder.
[b]FDA approved for use in panic disorder.
GAD, generalized anxiety disorder; PD, panic disorder.

TABLE 37–5. Pharmacokinetic Drug Interactions with Benzodiazepines[44]

Drug	Effect
Alcohol (chronic)	Increased Cl of BZs
Carbamazepine	Increased Cl of alprazolam
Cimetidine	Decreased Cl of alprazolam, diazepam, chlordiazepoxide, and clorazepate and increased $t_{1/2}$
Disulfiram	Decreased Cl of alprazolam and diazepam
Erythromycin	Decreased Cl of alprazolam
Fluoxetine	Decreased Cl of alprazolam and diazepam
Fluvoxamine	Decreased Cl of alprazolam and prolonged $t_{1/2}$
Itraconazole	Potentially decreased Cl of alprazolam and diazepam
Ketaconazole	Potentially decreased Cl of alprazolam
Nefazodone	Decreased Cl of alprazolam, AUC doubled, and $t_{1/2}$ prolonged
Omeprazole	Decreased Cl of diazepam
Oral contraceptives	Increased free concentration of chlordiazepoxide and slightly decreased Cl; decreased Cl and increased $t_{1/2}$ of diazepam and alprazolam
Paroxetine	Decreased Cl of alprazolam
Phenobarbital	Increased Cl of clonazepam and reduced $t_{1/2}$
Phenytoin	Increased Cl of clonazepam and reduced $t_{1/2}$
Probenecid	Decreased Cl of lorazepam and prolonged $t_{1/2}$
Propranolol	Decreased Cl of diazepam and prolonged $t_{1/2}$
Ranitidine	Decreased absorption of diazepam
Rifampin	Increased metabolism of diazepam
Theophylline	Decreased alprazolam concentrations
Valproate	Decreased Cl of lorazepam

AUC, area under the plasma concentration curve; BZ, benzodiazepine; Cl, clearance; $t_{1/2}$, elimination half-life.

Buspirone

Buspirone, a 5-HT_{1A} partial agonist, is thought to exert its anxiolytic effects by reducing presynaptic 5-HT firing.[44] Unlike benzodiazepines, it does not have abuse potential, cause withdrawal reactions, or potentiate alcohol and sedative-hypnotic effects. However, it has a gradual onset of action (i.e., 2 weeks) and does not provide immediate anxiety relief. Buspirone is considered a second-line agent for GAD owing to inconsistent data regarding its efficacy in chronic GAD or GAD with comorbid depression.[25,26] Some research suggests that buspirone is less effective in patients who have been treated previously (4 weeks to 5 years) with benzodiazepines.[45]

Buspirone should be initiated at a dose of 7.5 mg twice daily and titrated in 5 mg/day increments (every 2–3 days) to a usual target dose of 20 to 30 mg/day.[41] The maximum daily dose is considered to be 60 mg/day.

Buspirone generally is well tolerated and does not cause sedation. Most common side effects include dizziness, nausea, and headaches. Drugs that inhibit CYP3A4 (e.g., verapamil, diltiazem, itraconazole, fluvoxamine, nefazodone, and erythromycin) can increase buspirone levels. Likewise, enzyme inducers such as rifampin can reduce buspirone levels significantly. Bupirone may increase blood pressure when coadministered with an monoamine oxidase inhibitor (MAOI).

Alternative Agents

Hydroxyzine, kava kava, and pregabalin are alternative agents. Hydroxyzine may be effective for acute reduction of somatic symptoms of anxiety.[26] It does not improve psychic features of anxiety and does not treat depression or other common comorbid anxiety disorders. Kava kava, while potentially effective, is no longer recommended owing to reports of hepatotoxicity.[46] Pregabalin is mechanistically unique for an anxiolytic. It is a presynaptic modulator of excessive excitatory neurotransmitter release. It accomplishes this by selectively binding to the α_2-δ subunit of voltage-gated calcium channels. In a 4-week controlled trial versus alprazolam and placebo, pregabalin was effective for both somatic and psychic symptoms of anxiety with an onset of effect similar to alprazolam.[47] Pregabalin has an elimination half-life of approximately 6 hours and must be dosed two to three times daily. It is excreted renally and has a low risk of drug-drug interactions. Pregabalin is a schedule V controlled substance owing to a propensity to cause euphoria and risk of withdrawal symptoms when discontinued abruptly. Pregabalin should be used with caution in patients with a current or past history of substance abuse. Pregabalin is not beneficial for depression or other anxiety disorders, and long-term effectiveness in GAD is not yet established.

Outcome Evaluation

Assess patients for improvement of anxiety symptoms and for return to baseline occupational, social, and interpersonal functioning. With effective treatment, the patient should have no or minimal symptoms of anxiety or depression. While drug therapy is being initiated, evaluate patients more frequently to ensure tolerability and response. Increase the dose in patients exhibiting a partial response after 2 to 4 weeks on an antidepressant or 2 weeks on a benzodiazepine. Individualize the duration of treatment because some patients require up to one year of treatment.[27]

TREATMENT: PANIC DISORDER

Desired Outcomes

The main objectives of treatment are to reduce the severity and frequency of panic attacks, reduce anticipatory anxiety and agoraphobic behavior, and minimize symptoms of depression or other comorbid disorders.[48] The long-term goal is to achieve and sustain remission.

General Approach to Treatment

Treatment options include medication, psychotherapy (e.g., CBT preferred), or a combination of both. In some cases, pharmacotherapy will follow psychotherapy treatments when full response is not realized. Patients with panic symptoms without agoraphobia may respond to pharmacotherapy alone. Agoraphobic symptoms generally take longer to respond than panic symptoms. ❹ *The acute phase of PD treatment lasts about 12 weeks and should result in marked reduction in panic attacks, ideally total elimination, and minimal anticipatory anxiety and phobic avoidance. Treatment should be continued to prevent relapse for an additional 12 to 18 months before attempting discontinuation.*[48,49] Patients who relapse following discontinuation of medication should have therapy resumed.[49]

Nonpharmacologic Therapy

Patients with PD should be counseled to avoid stimulant agents (e.g., decongestants, diet pills, and caffeine) that may precipitate a panic attack. CBT consists of psychoeducation, continuous panic monitoring, breathing retraining, cognitive restructuring, and exposure to fear cues.[48] CBT is not a standardized treatment and may involve these features to varying degree. It is unclear if the individual components have differential benefits. Exposure therapy is useful for patients with phobic avoidance. CBT is considered a first-line treatment of PD, with efficacy similar to that of pharmacotherapy. In a large placebo-controlled trial comparing CBT with imipramine or combination (CBT + imipramine), CBT was as effective as the antidepressant after 12 weeks. Patients receiving CBT were less likely to relapse during the 6 months after treatment discontinuation.[50,51]

Pharmacologic Therapy

PD may be treated successfully with TCAs, SSRIs, SNRIs, or MAOIs, as well as benzodiazepines[51,52] (Table 37–6). While all these agents are similarly effective, SSRIs have become the treatment of choice in PD. Benzodiazepines often are used concomitantly with antidepressants, especially early in treatment,

TABLE 37–6. Antidepressants Used in the Treatment of Panic Disorder[24,30,51]

Medication Class	Recommended Starting Dose (mg/day)	Usual Therapeutic Dosage Range (mg/day)	Advantages	Disadvantages
SSRIs/SNRI			*SSRIs (in general)*	*SSRIs (in general)*
Citalopram	10	20–60	Antidepressant activity; antianxiety activity; single daily dosing (all but fluvoxamine); low toxicity; some available in generic	Activation; delayed onset of action; may precipitate mania; sexual side effects; GI side effects
Escitalopram	5–10	10–20		
Fluoxetine[a]	5–10	20–60		
Fluvoxamine	25	100–300		
Paroxetine[a]	10	20–60		
Sertraline[a]	25	50–200		
Venlafaxine XR[a]	37.5	75–225		
TCAs			*TCAs (in general)*	*TCAs (in general)*
Clomipramine	25 mg (twice a day)	75–250	Established efficacy; available in generic	Activation; sedation; anticholinergic effects; cardiovascular effects; delayed onset of action; may precipitate mania; sexual side effects; toxic in overdose; weight gain
Imipramine[a]	10–25	75–250		
MAOI				
Phenelzine	15	45–90	Antidepressant effects; available in generic	Dietary restrictions; drug interactions; weight gain; orthostasis; may precipitate mania

[a]FDA approved for use in panic disorder.
SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants; MAOI, monoamine oxidase inhibitor.

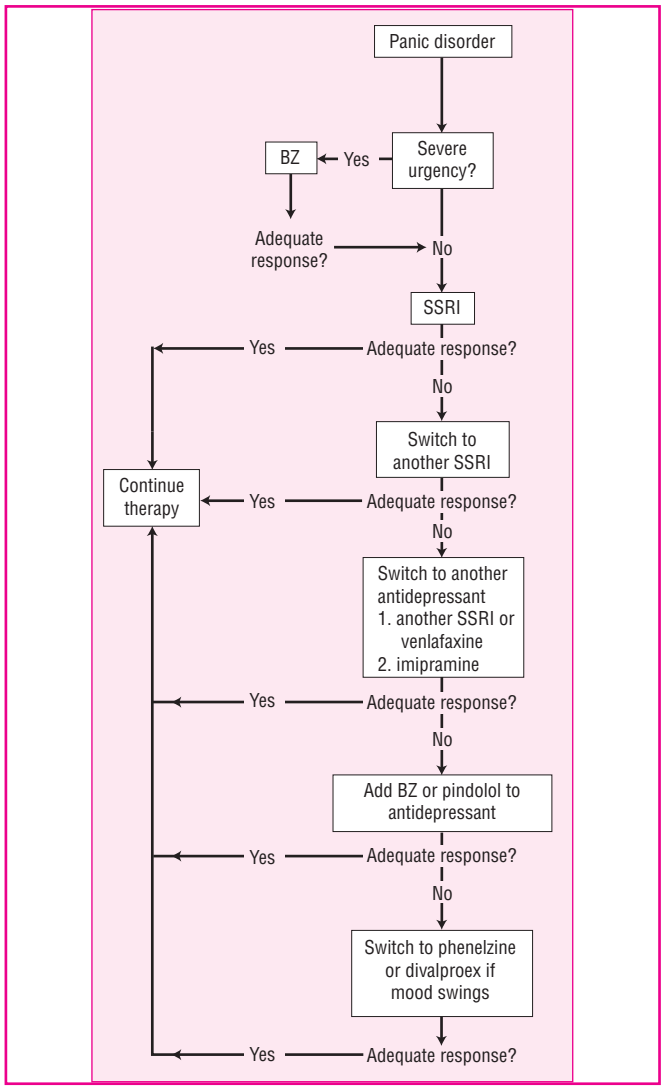

FIGURE 37–3. Algorithm for the pharmacotherapy of panic disorder. (Reprinted, with permission, from reference 24.)

or as monotherapy to acutely reduce panic symptoms. They are not preferred for long-term treatment but may be used when patients fail several antidepressant trials.[49] PD patients with comorbid depression should be treated with an antidepressant. An algorithm for pharmacologic management of PD appears in Fig. 37–3.

Antidepressants

Antidepressants have a delayed onset of antipanic effect, typically 4 weeks, with optimal response at 6 to 12 weeks. Reduction of anticipatory anxiety and phobic avoidance generally follows improvement in panic symptoms. ❺ *PD patients are more likely to experience stimulant-like side effects than patients with depression, and they should be initiated on lower doses (Table 37–6) of antidepressant than those that are used for depression or other anxiety disorders.* Target doses are similar to those used in depression. ❻ *Antidepressants should be tapered when treatment is discontinued to avoid withdrawal symptoms.*

TCAs

Treatment with imipramine, the most studied TCA, leaves 45% to 70% of patients panic free. Both desipramine and clomipramine have demonstrated effectiveness in PD as well. Despite their efficacy, TCAs are considered second- or third-line pharmacotherapy due to poorer tolerability and toxicity on overdose.[48,49] TCAs are associated with a greater rate of discontinuation from treatment than SSRIs.[53] PD patients taking TCAs may experience anticholinergic effects, orthostatic hypotension, sweating, sleep disturbances, dizziness, fatigue, sexual dysfunction, and weight gain. Stimulant-like side effects occur in up to 40% of patients.[49]

SSRIs

SSRIs are the drugs of choice for PD. All SSRIs have demonstrated effectiveness in controlled trials, with 60% to 80% of patients achieving a panic-free state.[28,48,49] With similar efficacy reported and no trials comparing SSRIs with other SSRIs, selection generally is based on pharmacokinetics, drug interactions, side effects, and cost differences (see Chap. 35 for more discussion). The most common side effects of SSRIs include headaches, irritability, nausea and other gastrointestinal complaints, insomnia, sexual dysfunction, increased anxiety, drowsiness, and tremor.[49] SSRIs should not be discontinued abruptly to avoid a withdrawal syndrome characterized by dysphoric mood, irritability, and agitation.

SNRIs

Venlafaxine was approved by the FDA recently for the treatment of PD. Venlafaxine in doses of 75 to 225 mg/day reduced panic and anticipatory anxiety in short-term controlled trials. The most common side effects include anorexia, dry mouth, constipation, somnolence, tremor, abnormal ejaculation, and sweating.[52]

MAOIs

MAOIs have not been evaluated systematically for treatment of PD under the current diagnostic classification and generally are reserved for patients who are refractory to other treatments.[48,49] MAOIs have significant side effects that limit adherence. Additionally, patients must adhere to dietary restriction of tyramine and avoid sympathomimetic drugs to avoid hypertensive crisis.

The reversible inhibitors of monoamine oxidase (RIMAs) brofaramine and meclobemide have been studied with mixed results.[48] Neither is approved for use in the United States, but they are available in Canada.

Others

Bupropion, trazodone, and nefazodone are not recommended for treatment of PD.

Benzodiazepines

Benzodiazpines are effective antipanic agents with significant effects on anticipatory anxiety and phobic behaviors. Alprazolam, the one studied most extensively, is associated with significant panic reduction after 1 week of therapy (e.g., 55%–75% panic free).[49] Benzodiazepines achieve similar outcomes to antidepressants over extended treatment, but benzodiazepine-treated patients are more likely to relapse when the drug is discontinued.[49] The risk for dependence and withdrawal and lack of efficacy for depression are significant concerns for long-term treatment of PD.[49] There is no evidence, however, that patients require dose escalation during extended treatment. This suggests that tolerance to therapeutic effect does not occur. Patients with PD do experience greater rebound anxiety and relapse when discontinuing benzodiazepines than do GAD patients. Tapering should be done at a slower rate and over a more extended period of time than with other anxiety disorders.[28,49]

❼ *The dose of benzodiazepine required for improvement generally is higher than that used in other anxiety disorders,* and this may explain why high-potency agents such as alprazolam and clonazepam generally are preferred. Lorazepam and diazepam, when given in equivalent doses, produce similar treatment benefits.[48,49] Doses should be titrated to response (Table 37–4). The use of extended-release alprazolam or clonazepam will minimize breakthrough panic symptoms that are sometimes observed with immediate-release alprazolam.[55]

Side effects associated with benzodiazepines in PD patients are similar to those observed in other disorders. Sedation, fatigue, and cognitive impairment are the most commonly reported side effects.[49] Benzodiazepines should be avoided in patients with current substance abuse, a history of such, dependence, or sleep apnea. Additionally, caution should be used in older adults because they have more pronounced psychomotor and cognitive effects.

Outcome Evaluation

Evaluate patients for symptom improvement frequently (e.g., weekly) during the first 4 weeks of therapy. The goal is to alleviate panic attacks and reduce anticipatory anxiety and phobic avoidance with resumption of normal activities. Alter the therapy of patients who do not achieve a significant reduction in panic symptoms after 6 to 8 weeks of an adequate dose of antidepressant or 3 weeks of a benzodiazepine. Regularly evaluate patients for adverse effects, and educate them about appropriate expectations of drug therapy.

Once the patient has achieved a significant response, continue therapy for at least 1 year. Evaluate for symptom relapse as well as adverse effects that may emerge with continued treatment (e.g., weight gain and sexual dysfunction). During drug discontinuation, monitor frequently for withdrawal, rebound anxiety, and relapse.

TREATMENT: SOCIAL ANXIETY DISORDER

Desired Outcomes

SAD is a chronic disorder that begins in adolescence and occurs with significant functional impairment and high rates of comorbidity. The goal of acute treatment is to reduce physiologic symptoms of anxiety, fear of social situations, and phobic behaviors. Patients with comordid depression should have a significant reduction in depressive symptoms. The long-term goal is to restore social functioning and improve the patient's quality of life.

General Approach to Treatment

Patients with SAD may be managed with pharmacotherapy or psychotherapy. There is insufficient evidence to recommend one treatment over the other, and data are lacking on the benefits of combining treatment modalities. Pharmacotherapy often is the first choice of treatment owing to relative greater access and reduced cost compared with psychotherapy.[56] Patients with SAD generally respond slowly to treatment, and many will not achieve a full response. Relapse is common when patients are discontinued after effective short-term treatment. Patients generally are continued on treatment for at least 1 year before attempting discontinuation.

Patient Encounter 2

BB, a 34-year-old white woman with generalized social anxiety disorder, is transferring her care to your clinic. She has been maintained on diazepam 10 mg twice daily for the past 4 years for her SAD. She states that her current therapy has her anxiety under control, and she is performing her duties as an office manager without problems. She has joined a gym recently and is attending a church social for single women once monthly. She has noticed she has difficulty thinking "sharply" and is more forgetful. She occasionally feels sad and becomes tearful but is usually able to "pick herself up." She is moderately overweight (BMI 29) with no other current medical problems. Denies ETOH or other substance use.

- Develop a treatment plan for this patient. Include (1) goals of therapy, (2) a detailed therapeutic plan, and (3) a monitoring plan for recommended therapy.

Nonpharmacologic Therapy

Patient education on disease course, treatment options, and expectations is essential given the chronic nature and functional impairment of SAD. Support groups may be beneficial for some patients. CBT targets avoidance-learning and negative-thinking patterns associated with social anxiety by exposing the patient to a feared situation. CBT is effective for reducing anxiety and phobic behaviors and leads to a greater likelihood of maintaining response after treatment discontinuation than does pharmacotherapy.[56]

Pharmacologic Therapy

Several pharmacologic agents have demonstrated effectiveness in SAD, including SSRIs, venlafaxine, phenelzine, RIMAs, benzodiazepines, gabapentin, and pregabalin. ❽ *SSRIs are considered the drugs of choice based on their tolerability and efficacy for SAD as well as comorbid disorders.* ❾ *The onset of response for antidepressants is delayed and may be as long as 8 to 12 weeks.*[28,57] *Patients responding to medication should be continued on treatment for at least 1 year.* Many will relapse on discontinuation, and there are no clear predictive factors of who will maintain response.[58] Some patients may elect more long-term treatment owing to fear of relapse. The clinician may use the suggested treatment algorithm (Fig. 37–4) to develop a treatment plan.

SSRIs and Venlafaxine

The efficacy of paroxetine, sertraline, and escitalopram was established in large controlled trials.[58–60] SSRIs improve social anxiety and phobic avoidance and reduce overall disability. Approximately 50% of patients achieve response during acute treatment. Limited data suggest that both fluvoxamine and citalopram are effective in SAD. Fluoxetine is not effective.[57,58]

The initial dose of SSRI is similar to that used in depression. Patients should be titrated as tolerated to response. Many patients will require maximum recommended daily doses. Patients with comorbid panic disorder should be started on lower doses (Table 37–4). When discontinuing SSRIs, the dose should be tapered slowly to avoid withdrawal symptoms, with the possible exception of fluoxetine. Relapse rates may be as high as 50%, and patients should be monitored closely for several weeks.[58] Side effects of SSRIs in SAD patients are similar to those seen in depression and most commonly include nausea, sexual dysfunction, somnolence, and sweating.

Venlafaxine extended release, in doses of 75 to 225 mg/day, improves social anxiety, performance, and avoidance behavior with a reduction in disability.[61] Treatment with venlafaxine results in response rates similar to those seen with paroxetine.[60] Venlafaxine may be effective in SSRI non-responders.[62] As with SSRIs, doses should be tapered slowly when discontinuing therapy. Tolerability is similar to that observed in depression trials with venlafaxine extended release. Common side effects are anorexia, dry mouth, nausea, insomnia, and sexual dysfunction.

MAOIs/RIMAs

The MAOI phenelzine and the RIMAs brofaramine and meclobemide are effective in SAD. Phenelzine is effective in 64% to 69% of SAD patients.[58] It is generally reserved for treatment-refractory patients owing to dietary restrictions,

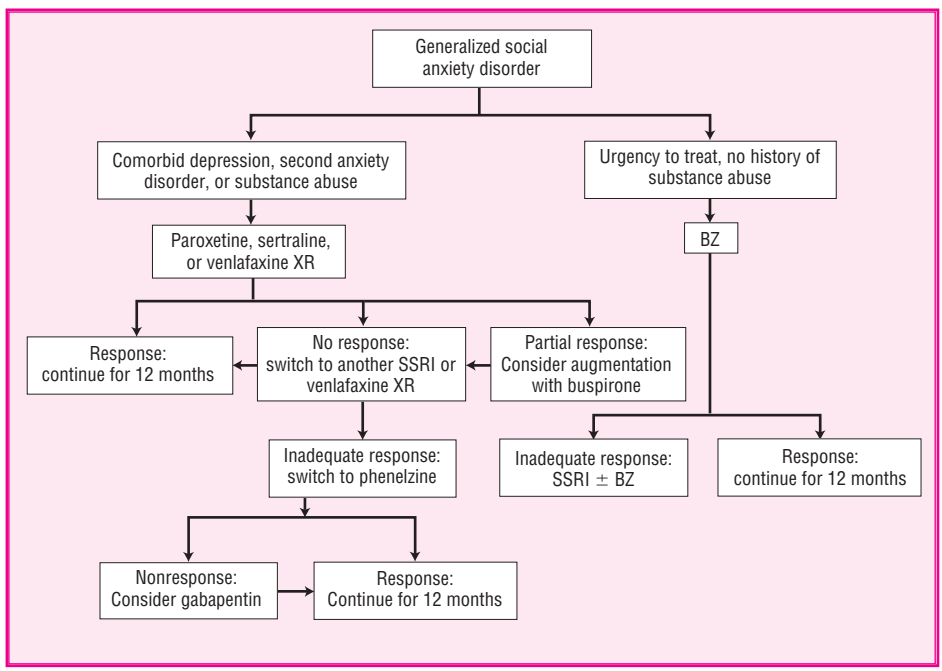

FIGURE 37–4. Algorithm for the pharmacotherapy of SAD. (Reprinted, with permission, from reference 24.)

drug interactions, and side effects. Neither brofaramine nor meclobemide is currently available in the United States, but they are available in Canada.

Alternative Agents

Benzodiazepines

Benzodiazepines are used commonly in SAD; however, there are limited data supporting their use. Clonazepam has been effective for social anxiety, fear, and phobic avoidance, and it reduced social and work disability during acute treatment.[58] Long-term treatment is not desirable for many SAD patients owing to the risk of withdrawal and difficulty with discontinuation, cognitive side effects, and lack of effect on depressive symptoms. Benzodiazepines may be useful for acute relief of physiologic symptoms of anxiety when used concomitantly with antidepressants or psychotherapy. Benzodiazepines are contraindicated in SAD patients with alcohol or substance abuse or history of such.

Anticonvulsants (Gabapentin, Pregabalin)

Gabapentin, a non-benzodiazapine GABA analog, was modestly effective in a 14-week controlled trial in SAD. Most patients were titrated to a maximal dose of 3600 mg/day.[58] Pregabalin 600 mg/day was effective for social anxiety, fear, and avoidance behavior in a 10-week controlled trial.[63] Pregabalin was well tolerated, and the most common side effects were somnolence and dizziness.

β-Blockers

β-Blockers decrease physiologic symptoms of anxiety and are useful for reducing performance anxiety. Propranolol or atenolol should be administered 1 hour before a performance situation. β-Blockers are not useful in generalized SAD.[58]

Outcome Evaluation

⑩ *Pharmacotherapy of SAD should lead to improvement in physiologic symptoms of anxiety and fear, functionality, and overall well-being.*[26] Many patients may not achieve full remission of symptoms but should have significant improvement. Monitor patients weekly during acute treatment (e.g., initiation and titration of pharmacotherapy). Once patients are stabilized, monitor monthly. Inquire about adverse effects and SAD symptoms at each visit. To aid in assessing improvement, ask patients to keep a diary to record fears, anxiety levels, and behaviors in social situations.[26] You may administer the Leibowitz Social Anxiety Scale (LSAS) to rate SAD severity and change, and the Social Phobia Inventory can be used as a "self-assessment" tool for SAD patients.

Counsel patients on appropriate expectations of pharmacotherapy in SAD, including the gradual onset of effect and the need for extended treatment of at least 1 year.

Patient Care and Monitoring

1. Review medical and laboratory data to rule out contributing causes of anxiety.
2. Assess the patient's symptoms and level of functional impairment to determine if pharmacotherapy is appropriate for the anxiety disorder.
3. Obtain a thorough history of prescription, non-prescription, and natural product use.
4. Determine what treatments have been tried or were useful in the past. Is the patient taking medication that may cause anxiety?
5. Educate the patient about lifestyle changes that will improve symptoms of anxiety. These include adequate sleep and exercise, stress management, meditation, and coping skills.
6. Inform patients of treatment options for anxiety disorders and the expected benefits of each (e.g., pharmacotherapy, psychotherapy, and combination treatment).
7. Develop a plan to assess the effectiveness of drug therapy during the first 12 weeks.
8. Determine an appropriate duration of treatment. Is long-term maintenance treatment needed?
9. Assess improvement in academic, social, interpersonal, and occupational functioning; quality of life; and well-being.
10. Evaluate the patient for the presence of adverse drug effects, drug-drug interactions, and drug allergies.
11. Stress the importance of adherence to medications to achieve and maintain response.
12. Provide patient education regarding disease state, lifestyle modifications, and pharmacotherapy.

- What differentiates anxiety from an anxiety disorder? How should it be treated?
- Potential complications of an untreated anxiety disorder.
- What potential adverse effects may occur? Is there a risk of dependence?
- Which drugs may interact with therapy?
- How to record symptoms (e.g., fears, panic attacks, avoidance behaviors) and report back to their clinician.

38 Sleep Disorders

John M. Dopp and Bradley G. Phillips

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Articulate the incidence and prevalence of sleep disorders, list the sequelae of undiagnosed or untreated sleep disorders, and appreciate the importance of successful treatment of sleep disorders.
2. Describe the mechanisms of the sleep disorders covered in this chapter, including insomnia, narcolepsy, restless-legs syndrome, obstructive sleep apnea, and parasomnias.
3. Assess patient sleep complaints, conduct sleep histories, and evaluate sleep studies to recognize day- and nighttime symptoms and characteristics of common sleep disorders.
4. Recommend and optimize appropriate sleep hygiene and nonpharmacologic therapies for the management and prevention of sleep disorders.
5. Recommend and optimize appropriate pharmacotherapy for sleep disorders.
6. Describe the components of a monitoring plan to assess safety and efficacy of pharmacotherapy for common sleep disorders.
7. Educate patients about preventive behavior, appropriate lifestyle modifications, and drug therapy required for effective treatment and control of sleep disorders.

Key Concepts

❶ Insomnia is most frequently a symptom or manifestation of an underlying disorder (secondary insomnia) but may occur in the absence of contributing factors (primary insomnia). Early treatment of insomnia may prevent the development of psychopathologic complications.

❷ Patients with sleep complaints should have a careful sleep history performed to assess for possible sleep disorders and to guide diagnostic and therapeutic decisions.

❸ Although clinical history guides diagnosis and therapy, only overnight polysomnography and multiple sleep latency tests (MSLTs) can definitively diagnose and/or guide therapy for obstructive sleep apnea, narcolepsy, and periodic limb movements of sleep.

❹ Treatment goals vary between different sleep disorders but generally include restoration of normal sleep patterns, elimination of daytime sequelae, improvement in quality of life, and prevention of complications and adverse effects from therapy.

❺ Benzodiazepine receptor agonists, including traditional benzodiazepines, zolpidem, zaleplon, and eszopiclone, are approved by the Food and Drug Administration (FDA) for the treatment of insomnia and are first-line therapies.

❻ Treatment of excessive daytime sleepiness in narcolepsy and other sleep disorders may require the use of sustained- and immediate-release stimulants to effectively promote wakefulness throughout the day and at key times that require alertness.

❼ Restless-legs syndrome treatment involves suppression of abnormal sensations and leg movements and consolidation of sleep. Dopaminergic and sedative-hypnotic medications are prescribed commonly.

❽ The main therapy for obstructive sleep apnea is nasal continuous positive airway pressure (CPAP) therapy because of its effectiveness.

❾ It is important to review patient medication profiles for drugs that may aggravate sleep disorders. Patients should be monitored for adverse drug reactions, potential drug-drug interactions, and adherence to their therapeutic regimens.

Normal humans sleep up to one-third of their lives and spend more time sleeping compared with any other single activity. Despite this, our understanding of the full purpose of sleep

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

and the mechanisms regulating sleep homeostasis remains incomplete. Sleep is necessary to maintain wakefulness, health, and welfare. Unfortunately, disruption of normal sleep is prevalent and represents a major cause of societal morbidity, lost productivity, and reduced quality of life.[1] The link between adequate sleep and optimal health is becoming increasingly apparent, and sleep disturbances may contribute to the development and progression of comorbid medical conditions.

Sleep is governed and paced by the suprachiasmic nucleus in the brain that regulates **circadian rhythm.** Environmental cues and amount of previous sleep also influence sleep on a daily basis. There are two main types of sleep: **rapid-eye-movement (REM) sleep,** where eye movements and dreaming occur but the body is mostly paralyzed, and **non-REM sleep,** which consists of four substages (stages 1 to 4). Stage 1 serves as a transition between wake and sleep. Most of the time asleep is spent in stage 2 non-REM sleep. Stage 3 and stage 4 sleep often are grouped together and referred to as *deep sleep,* or *delta sleep,* because prominent delta waves are seen on the electroencephalogram (EEG) during these sleep stages.

EPIDEMIOLOGY AND ETIOLOGY

Sleep disorders are common. Approximately 50% of adults will report a sleep complaint over the course of their lives.[2] In general, sleep disturbances increase with age, and each disorder may have gender differences. The full extent and impact of disordered sleep on our society are not known because many patients' sleep disorders remain undiagnosed. Normal sleep, by definition, is "a reversible behavioral state of perceptual disengagement from and unresponsiveness to the environment."[3] As a result, individuals with sleep disorders will exhibit or complain about consequent symptoms (e.g., daytime sleepiness), or a bed partner will observe hallmark characteristics of the sleep disorder. Insomnia, restless-legs syndrome (RLS), and sleep-related breathing disorders are the most common sleep disorders.

Patient Encounter, Part 1

CH, a 53-year-old man with a history of hypertension, comes to your clinic complaining of sleepiness in the daytime, "crawly legs" at bedtime, and frequent awakenings at night. After further questioning, he explains that for the last hour or so before bedtime he cannot keep his legs still. He reports that he falls asleep relatively easily during the day. The symptoms have been worsening gradually over the past year and occur nightly. His wife reports that he kicks his legs the first part of the night, snores, and occasionally gasps for air after a breathing pause. His body mass index (BMI) is 30 kg/m^2, and he has experienced recent weight gain and complains about morning headaches.

- What sleep disorders do his symptoms suggest?
- What sleep disorders could you diagnose subjectively? What is your initial recommendation?
- What additional information do you need to know before creating a treatment plan for this patient?

Insomnia

The prevalence of insomnia increases with age and is nearly 1.5 times greater in females than in males. Approximately one-third of patients older than age 65 have persistent insomnia.[4,5] In the adult population, about 10% will experience chronic insomnia and slightly more will experience short-term insomnia. ❶*Insomnia is most frequently a symptom or manifestation of an underlying disorder (secondary insomnia) but may occur in the absence of contributing factors (primary insomnia). Early treatment of insomnia may prevent the development of psychopathologic complications.* Forty percent of patients with psychiatric conditions will have accompanying insomnia.[6] Secondary insomnia is triggered by acute stress and disappears when the stress resolves. Numerous co-existing medical conditions, such as pain, thyroid abnormalities, asthma, reflux, and medications, including selective serotonin reuptake inhibitors (SSRIs), steroids, stimulants, and β-agonists, can interfere with sleep and cause secondary insomnia. In cases of secondary insomnia, the clinician should treat the underlying primary cause along with insomnia symptoms.

Narcolepsy

Although difficult to estimate, the prevalence of narcolepsy is between 0.03% and 0.06%.[7] Significant differences have been reported for various ethnic groups. Narcolepsy has a higher prevalence in the Japanese and a lower prevalence in the Israeli populations.[8,9] **Cataplexy** is not required for diagnosis; however, between 50% and 80% of patients with narcolepsy have accompanying cataplexy.[10]

Restless-Legs Syndrome

Restless-legs syndrome occurs in 5% to 15% of the population, making it a common sleep disorder.[11,12] The prevalence of RLS increases with age and in various medical conditions such as end-stage renal disease (ESRD), pregnancy, and iron deficiency.[13] RLS appears to be more common in women than in men and has a genetic link. The majority of RLS patients (63% to 92%) report a positive family history.[14]

Obstructive Sleep Apnea

Obstructive sleep apnea (OSA) is a common disorder that is often unrecognized, affecting 4% of middle-aged white men and 2% of middle-aged white women.[15] In women, the frequency of OSA increases after menopause. OSA is as common or more common in African Americans and less common in Asian

populations. The risk of OSA increases with age and obesity. Individuals with OSA experience repetitive upper airway collapse during sleep, which decreases or stops airflow, with subsequent arousal from sleep to resume breathing. The severity is determined by overnight **nocturnal polysomnography** and is graded by the number of episodes of apnea (total cessation of airflow) and hypopnea (partial airway closure with blood oxygen desaturation) experienced during sleep. The severity is expressed as the **respiratory disturbance index (RDI),** quantified in events per hour. Mild sleep apneics have an RDI of between 5 and 15 episodes per hour; moderate, 15 to 30; and individuals with severe OSA can exhibit more than 30 episodes per hour.

Parasomnias

Non-REM **parasomnias** have variable prevalence rates depending on patient age and different diagnoses. Sleep talking, bruxism, sleepwalking, sleep terrors, and enuresis occur more frequently in childhood than in adulthood. Nightmares appear to occur with similar frequency in adults and children. REM behavior disorder (RBD), an REM-sleep parasomnia, has a reported prevalence of 0.5% and frequently is associated with concomitant neurologic conditions.[16] Chronic RBD is more common in elderly men and may have a familial disposition.

PATHOPHYSIOLOGY

Complicated processes govern wakefulness, sleep, and the transitions leading to sleep initiation and maintenance. Although the neurophysiology of sleep is complex, certain neurotransmitters promote sleep and wakefulness in different areas of the central nervous system (CNS). Serotonin is thought to control non-REM sleep, whereas cholinergic and adrenergic transmitters mediate REM sleep. Dopamine, norepinephrine, **hypocretin,** substance P, and histamine all play a role in wakefulness. Perturbations of various neurotransmitters are responsible for some sleep disorders and explain why various treatment modalities are beneficial.

Insomnia

Since insomnia is a complex and multifaceted disorder, there is no single pathophysiologic explanation for its various manifestations. Current hypotheses focus on a combination of possible models that incorporate physiologic, cognitive, and cortical arousal. Most insomnia models focus on hyperarousal and its interference with the initiation or maintenance of sleep.

Narcolepsy

The onset of narcolepsy-cataplexy is typically in adolescence and not at birth, suggesting that the disease may require environmental influence to develop. Currently, it is believed that narcolepsy results from autoimmune insult to the CNS because it is associated with HLA (major histocompatibility complex) DQB1*0602 and DQ1A1*0102.[17,18] Concentrations of hypocretin (a wake-promoting neuropeptide) in the cerebrospinal fluid (CSF) of narcolepsy patients are reduced significantly, suggesting that the autoimmune attack is against hypocretin-producing cells in the hypothalamus.[19] Intact hypocretin neurons normally stimulate arousal and wake-promoting neurons to stimulate cortical activation and behavioral arousal.

Restless-Legs Syndrome and Periodic Limb Movements of Sleep (PLMS)

RLS is a neurologic medical condition characterized by an irresistible desire to move the limbs. It is thought that these abnormal sensations are a result of iron deficiency in the brain and iron-handling abnormalities in the CNS. Iron and H-ferritin concentrations, along with transferrin receptor and iron transporter numbers, are reduced in the substantia nigra of patients with RLS.[20] These iron abnormalities lead to dysfunction of dopaminergic transmission in the substantia nigra.

Obstructive Sleep Apnea

At least 20 muscles and soft-tissue structures control patency of the upper airway. Patients with OSA may have differences in upper airway muscle activity during sleep and may have smaller airways, predisposing them to upper airway collapse and consequent apneic episodes during sleep. The inability of the upper airway to contend with factors that promote collapse, including fat deposition in the neck, negative pressure in the airway during inspiration, and a smaller lower jawbone, also may play a role in the pathogenesis of OSA. Hallmarks of OSA include witnessed apneas, gasping, or both.

Poor sleep architecture and fragmented sleep secondary to OSA can cause excessive daytime sleepiness (EDS) and neurocognitive deficits. These sequelae can affect quality of life and work performance and may be linked to occupational and motor vehicle accidents. OSA is also associated with systemic disease such as hypertension, heart failure, and stroke.[21–23] OSA is likely an independent risk factor for the development of hypertension.[24] Further, when hypertension is present, it is often resistant to antihypertensive therapy. Fatal and non-fatal cardiovascular events are two- to threefold higher in male patients with severe OSA.[25] OSA is associated with or aggravates biomarkers for cardiovascular disease, including C-reactive protein and leptin.[26,27] Patients with sleep apnea often are obese and may be predisposed to weight gain. Hence, obesity may further contribute to cardiovascular disease in this patient population.

Several factors suggest an association between OSA and systemic disease. Breathing against a closed upper airway during

sleep causes intermittent and repetitive episodes of hypoxemia and hypercapnia, dramatic changes in intrathoracic pressure, and activation of the sympathetic nervous system. These responses can produce acute hemodynamic and humoral responses. Blood pressure can increase to 220/120 mm Hg with each apneic episode.[28] Concentrations of circulating vasoconstrictors, such as endothelin-1 and norepinephrine, are increased during OSA.[29] These acute responses to OSA may predispose to and enhance the progression of vascular disease in the longer term. This is supported by studies showing impaired endothelium-dependent vasodilation, an early marker for vascular disease, in patients with untreated moderate to severe OSA.[30]

Parasomnias

The pathogenesis of parasomnias (e.g., sleepwalking, enuresis, sleep talking) is variable and not well described and involves state dissociation, whereby two states of being overlap simultaneously. For example, abnormal activation of the central pattern generator of the spinal cord that produces motor movements is hypothesized to underlie sleepwalking behavior. In RBD, active inhibition of motor activity in the perilocus coeruleus region is lost, resulting in loss of paralysis and dream enactment.

Clinical Presentation

Patients with sleep disorders may complain about daytime symptoms. A bed partner may witness hallmark characteristics of the sleep disorder. ❷*Patients with sleep complaints should have a careful sleep history performed to assess their possible sleep disorder in order to guide diagnostic and therapeutic decisions.*

Daytime Symptoms and Associated Characteristics

EDS is the primary symptom described by patients with sleep disorders. It is usually described as not waking up refreshed in the morning or falling asleep or fighting the urge to sleep during the day despite a night of sleep. Other daytime characteristics of sleep disorders include:

- Irritability, fatigue, or depression
- Confusion or impaired performance at work or school
- Cataplexy
- Hypertension

Nighttime Sleep Complaints

Depending on the sleep disorder, patients may exhibit or experience various nocturnal complaints during sleep hours. Some of these complaints can be uncovered by clinical history alone (e.g., hallucinations, RLS, and snoring), whereas others can be diagnosed only during sleep studies (e.g., OSA, nighttime awakenings, somnambulism, PLMS, etc.). Frequent complaints include:

- Inability to fall asleep, nighttime awakenings
- Sleepwalking (somnambulism), sleep talking (somniloquy)
- Cessation of breathing (apnea), snoring
- Sleep paralysis and/or hallucinations when waking or falling asleep
- Restlessness (PLMS or RLS)

CLINICAL PRESENTATION AND DIAGNOSIS

❸*Although clinical history guides diagnosis and therapy, only overnight polysomnography and/or multiple sleep latency tests (MSLTs) can definitively diagnose and guide therapy for OSA, narcolepsy, and periodic limb movements of sleep.*

Insomnia (Difficulty Initiating or Maintaining Sleep)

Insomnia is often characterized by difficulty falling asleep, frequent nocturnal awakenings, and early-morning awakenings. Difficulty initiating or maintaining sleep may result in daytime impairments in concentration and school or work performance. In secondary insomnia, social factors (e.g., family difficulties, bereavement), medications, and co-existing medical conditions (e.g., depression, bipolar disorder) may help to explain difficulties in initiating and maintaining sleep. Insomnia may be described as transient (a few days), short term (less than 3 weeks), or chronic (greater than 1 month) in duration.

Narcolepsy

The hallmark of narcolepsy is EDS and the need for unwanted episodes of sleep during the day during favorable and unfavorable conditions. Patients with narcolepsy may experience repeated nighttime awakenings and terrifying dreams, along with difficulty falling asleep. Narcoleptics frequently experience abnormal manifestations of REM sleep, including hallucinations and sleep paralysis that occur on falling asleep and/or awakening. Cataplexy is a weakness or loss of skeletal muscle tone in the jaw, legs, or arms that is elicited by emotion (e.g., anger, surprise, laughter, or sadness).

Obstructive Sleep Apnea

Common characteristics of OSA include snoring, choking, gasping for air, nocturnal reflux symptoms, and morning headaches. A bed partner or roommate may observe these characteristics and witness episodes where the patient stops breathing during sleep. Obesity predisposes to and can worsen OSA. Patients with large neck sizes (greater than 45 cm or 17.7" neck circumference) and a BMI of 30 kg/m^2 or greater are at higher risk for OSA. Hypertension, depression, and hypothyroidism are found frequently in patients with OSA.

Periodic Limb Movements of Sleep or Restless-Legs Syndrome

Although RLS symptoms can vary, patients commonly report creepy-crawly, burning, tingling, or achy feelings in the legs or arms. These sensations create a desire to move the limbs and may produce motor restlessness. Symptoms are worse in the evening and are worse or exclusively present at rest, with temporary relief with movement. Symptoms also can occur during sleep and often lead to semirhythmic (periodic) limb movements during sleep (PLMS). PLMS are objective findings during overnight polysomnography recorded by leg electrodes. PLMS are present in most patients with RLS but can occur independently. PLMS frequently are described by a bed partner as restlessness or repeated kicking of legs or thrashing of arms during sleep.

Parasomnias

Parasomnias are characterized by undesirable physical or behavioral phenomena that occur during sleep [e.g., sleepwalking, sleep talking, bruxism (grinding of teeth), enuresis, night terrors, and RBD]. RBD patients act out their dreams during sleep, often in a violent manner.

Circadian Rhythm Disorders (CRDs)

The most common CRDs include jet lag, shift-work sleep disruption, delayed sleep-phase disorder, and advanced sleep-phase disorder. Jet lag occurs when a person travels across time zones, and the external environmental time is mismatched with the internal circadian clock. Delayed and advanced sleep-phase disorders occur when bed and wake times are delayed or advanced (by 3 or more hours) compared with socially prescribed bed and wake times.

Sleep Diagnostics

Complete overnight polysomnography is the "gold standard" for diagnosing and identifying sleep-disordered breathing, PLMS, parasomnias, and nocturnal sleep irregularities related to narcolepsy. Sleep is observed and monitored in a controlled setting using an EEG, electro-oculogram, electromyogram, electrocardiogram, air thermistors, abdominal and thoracic strain belts, and an oxygen saturation monitor. This setup assesses and records sleep onset, arousals, sleep stages, eye movements, leg and jaw movements, heart rhythm, arrhythmias, airflow during sleep, respiratory effort, and oxygen desaturations.

Evaluations of Daytime Sleepiness

The two most commonly performed objective evaluations to assess daytime sleepiness are the multiple sleep latency test (MSLT) and the maintenance of wakefulness test (MWT). The MSLT is a series of four to six 20-minute naps every 2 hours during the day beginning 2 hours after morning awakening (following a normal night's sleep) to evaluate physiologic sleepiness. The patient is instructed not to resist the urge to fall asleep. **Sleep latency** of less than 5 or 6 minutes is considered pathologically sleepy. The occurrence of an REM onset period during two naps is indicative of a diagnosis of narcolepsy. The MWT is performed to assess a patient's ability to avoid succumbing to sleepiness (manifest sleepiness). Similar nap opportunities are set up for the MWT, with the exception that the patient is instructed to lie down in bed and attempt to stay awake. A subjective assessment of sleepiness can be completed using the Epworth Sleepiness Scale (ESS). The ESS is a validated questionnaire that is easy to use and reliably predicts subjective sleepiness. The maximum score is 24, and any patient with a score greater than 10 is considered sleepy.

Patient Encounter, Part 2: The Medical History, Physical Examination, and Diagnostic Test

CH undergoes nocturnal polysomnography and returns to your clinic for follow-up.

PMH
Hypertension poorly controlled since 1999.

FH
Father died at age 70 from stroke. Mother is still alive with history of restless legs and hypothyroidism.

SH
Married, works as an accountant, never has smoked, 2 drinks per night on the weekends.

Meds
- Hydrochlorothiazide 25 mg PO once daily
- Amlodipine 10 mg PO once daily

ROS
(+) daytime sleepiness (ESS: 18/24).

PE
VS: BP 154/84, P 78, RR 16, T 37.0°C (98.6°F).
Mouth: Airway crowded, large tonsils and uvula.

Labs
Within normal limits.

Overnight polysomnogram: Frequent obstructive apneas, hypopneas, and leg movements.

- RDI: 12 events/hour
- 310 leg movements, mostly occurring in first half of the night
- Successful alleviation of apneas and hypopneas with nasal continuous positive airway pressure

- Given this additional information, summarize the patient's diagnosis.
- Identify your treatment goals and recommendations for the patient.
- What nonpharmacologic and pharmacologic alternatives are available for this patient if prescribed therapy is not successful or not tolerated?

TREATMENT

❹*Treatment goals vary between different sleep disorders but generally include restoration of normal sleep patterns, elimination of daytime sequelae, improved quality of life, and prevention of complications and adverse effects from therapy.* All patients presenting with sleep complaints should have a thorough inventory of their sleep habits and sleep hygiene investigated during the interview and history taking. Nonpharmacologic interventions for insomnia are outlined in Table 38–1. Sleep hygiene should be reinforced in all patients, and behavioral, cognitive, and stimulus-control interventions are used mainly for patients with insomnia-type complaints. Both pharmacologic and nonpharmacologic therapies are effective at improving sleep and reducing insomnia complaints. An algorithm for the initial assessment and first treatment step is provided in Fig. 38–1.

Insomnia

The ideal hypnotic drug would be effective at reducing sleep latency and increasing total sleep time and be free of unwanted side effects. ❺*Benzodiazepine receptor agonists, including traditional benzodiazepines, zolpidem, zaleplon, and eszopiclone, are approved by the Food and Drug Administration (FDA) for the treatment of insomnia and are first-line therapies.*[31,32] Not all products are available in all countries. Pharmacologic treatment of insomnia is recommended for transient and short-term insomnia. Long-term use of hypnotics is not contraindicated unless the patient has another contraindication to their use. Eszopiclone is approved by the FDA for chronic use up to 6 months.[33] Although not first line-agents for insomnia, sedating antihistamines are prescribed commonly, and the number of prescriptions has increased dramatically over the last 20 years.[34] These and other therapies, detailed below, are used to treat insomnia.

TABLE 38–1. Nonpharmacologic Therapies for Sleep

Sleep Hygiene
- Keep a regular sleep schedule.
- Exercise frequently but not immediately before bedtime.
- Avoid alcohol and stimulants (caffeine, nicotine) in the late afternoon and evening.
- Maintain a comfortable sleeping environment that is dark, quiet, and free of intrusions.
- Avoid consuming large quantities of food or liquids immediately before bedtime.

Stimulus Control
- Go to bed only when sleepy.
- Avoid daytime naps.
- If you cannot sleep, get out of bed and go to another room—only return to your bed when you feel the need to sleep.
- Bed is for sleep and intimacy only (no eating or watching TV in bed).
- Always wake up at the same time each day.

Relaxation Training
- Reduce somatic arousal (muscle relaxation).
- Reduce mental arousal (attention focusing procedures, imagery training, meditation, etc.).
- Biofeedback (use of visual or auditory feedback to reduce tension).

Cognitive Therapy
- Alter beliefs, attitudes, and expectations about sleep.

Benzodiazepine Receptor Agonists (BZDRAs)

There are currently eight BZDRAs approved for insomnia, and the pharmacokinetic differences between these agents help to guide selection depending on patient considerations and specific sleep complaints (Table 38–2). These agents occupy the benzodiazepine receptors on the gamma-aminobutyric acid (GABA) type A receptor complex, resulting in opening of chloride channels that facilitate GABA inhibition and promote sleepiness.[35] BZDRAs have become the first-line agents for treating insomnia and sleep-maintenance problems because they are all efficacious, have wide therapeutic indices, and in clinical use have a low incidence of abuse.[31,35]

Patients should be instructed to take BZDRAs at bedtime and to avoid engaging in activities requiring alertness after ingestion. The BZDRAs come closer to the "ideal hypnotic" compared with other agents because they reduce sleep latency and increase total sleep time (except for zaleplon) with fewer adverse effects. Although BZDRAs generally are well tolerated and have good safety profiles, mild to moderate side effects can occur, and precautions are warranted, especially in high-risk populations.

Precautions and Safety

The most common side effects associated with BZDRAs include residual sedation (a prolongation of the sedative effects into the waking hours after sleep), grogginess, and psychomotor impairment.[36] Careful selection of a hypnotic agent with a duration of action matching the patient's budgeted sleep time can help minimize the risk of residual sedation. BZDRAs should be initiated at low doses, and agents with active metabolites (Table 38–2) should be avoided in elderly patients. BZDRAs may cause anterograde amnesia, defined as memory loss of activities and interactions after ingestion of the drug. All hypnotics can cause anterograde amnesia, and higher doses increase the extent of amnesia.[37,38]

On discontinuation of hypnotic BZDRAs, patients can experience rebound effects, specifically rebound insomnia that may last for one to two nights. Rebound insomnia occurs more frequently after discontinuation of shorter-duration BZDRAs compared with long-duration BZDRAs. Intermittent hypnotic therapy with the lowest dose possible reduces the likelihood of tolerance, dependence, and withdrawal when therapy is stopped. Patients should be counseled that rebound insomnia is not necessarily a return of their original symptoms, and it may take a few nights for rebound symptoms to subside.

Sedating Antidepressants

The increasing popularity of sedating antidepressants for the treatment of insomnia resulted in trazodone being the most prescribed drug in 2002.[39] Other common antidepressants also

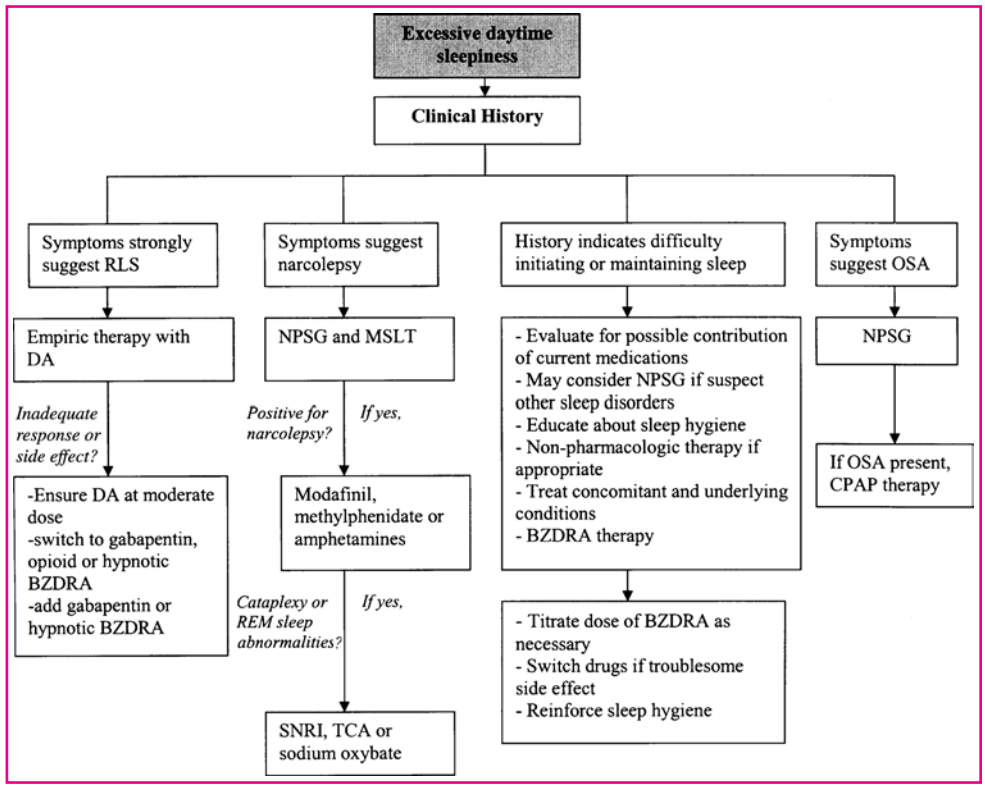

FIGURE 38–1. Primary assessment and initial treatment for complaint of excessive daytime sleepiness. RLS, restless-legs syndrome; NPSG, nocturnal polysomnography; OSA, obstructive sleep apnea; DA, dopamine agonist; MSLT, multiple sleep latency test; BZDRA, benzodiazepine receptor agonist; SNRI, serotonin and norepinephrine reuptake inhibitor; TCA, tricyclic antidepressant; CPAP, continuous positive airway pressure.

TABLE 38–2. Pharmacokinetics of Prescription Medications Used to Treat Insomnia

Generic Name	Parent $t_{1/2}$ (hour)	Duration of Action (hour)	Daily Dose Range (mg)	Metabolic Pathway	Clinically Significant Metabolites	Advantages and/or Disadvantages
Estazolam (Prosom®)	2	12–15	1–2	Oxidation	—	Moderate duration
Eszopiclone (Lunesta®)	6	8	2–3	Oxidation Demethylation	—	Can be used up to 6 months for chronic insomnia
Flurazepam (Dalmane®)	8	10–30	15–30	Oxidation N-dealkylation	Hydroxyethylflurazepam Flurazepam aldehyde N-DAF[b]	High risk of hangover and residual effects
Quazepam (Doral®)	2	25–41	7.5–15	Oxidation N-dealkylation	2-Oxo-quazepam N-DAF[a]	High risk of hangover and residual effects
Ramelteon (Rozerem®)	1–2.6	Unpublished[b]	8	Oxidation Glucuronidation	M-II[c]	Non-controlled substance, may be useful in patients with history of substance abuse
Temazepam (Restoril®)	10–15	7	7.5–30	Conjugation	—	Moderate duration, well-tolerated, inexpensive
Triazolam (Halcion®)	2	6–7	0.125–0.25	Oxidation	—	Short-acting, little residual hangover
Zaleplon (Sonata®)	1	6	5–10	Oxidation	—	Short-acting, only for difficulty falling asleep
Zolpidem (Ambien®)	2–2.6	6–8	5–10	Oxidation	—	Short–moderate duration, no effects on sleep architecture
Zolpidem CR (AmbienCR®)		Perhaps longer	6.25–12.5			

[a]N-desalkyl flurazepam.
[b]Data not available.
[c]M-II is the major active metabolite of ramelteon.

prescribed for insomnia include amitriptyline, mirtazapine, nefazadone, and doxepin. Antidepressants may be an appealing option for insomnia in patients with concomitant depression. However, at the doses frequently used for sleep, none of the agents exhibit significant antidepressant activity. Further, quality clinical studies demonstrating efficacy for treating insomnia are lacking. Side effects from antidepressants can be frequent and often are unpleasant, including carryover sedation, grogginess, anticholinergic effects, and weight gain. Tricyclic antidepressants (TCAs) should be used with caution in the elderly and patients with cardiovascular and hepatic impairment. Mirtazapine can cause daytime sedation, dizziness, and weight gain, a side effect that may worsen concomitant OSA.[40] Trazodone can cause hypotension and dizziness and should be used with caution in patients with heart disease or hypertension and those taking cardiovascular agents.[41,42]

Over-the-Counter and Miscellaneous Agents

Antihistamines such as diphenhydramine are known for their sedating properties and are frequently used over-the-counter medications (usual doses 25–50 mg) for difficulty sleeping. Diphenhydramine is approved by the FDA for the treatment of insomnia and can be effective at reducing sleep latency and increasing sleep time.[43] However, diphenhydramine produces undesirable anticholinergic effects and carryover sedation that limit its use. As with TCAs and BZDRAs, diphenhydramine should be used with caution in the elderly. Valerian root is an herbal sleep remedy that has inconsistent effects on sleep but may reduce sleep latency and efficiency at commonly used doses of 400 to 900 mg valerian extract. Ramelteon, a new melatonin receptor agonist, is indicated for insomnia characterized by difficulty with sleep onset. The recommended dose is 8 mg at bedtime. Ramelteon is not a controlled substance and thus may be a viable option for patients with a history of substance abuse.

Narcolepsy

Therapy for narcolepsy involves two key principles: (1) treatment of EDS with scheduled naps and CNS stimulants and (2) suppression of cataplexy and REM-sleep abnormalities with aminergic signaling drugs. Modafinil, methylphenidate, and amphetamines are effective FDA-approved drugs for the treatment of EDS with narcolepsy.[44] Modafinil is potentially advantageous in part because it is a schedule IV medication in contrast to CNS stimulants, which are schedule II. Modafinil is renewable for 6 months at a time and may have fewer peripheral and cardiovascular effects than traditional stimulants. Selegiline, a selective monoamine oxidase B enzyme inhibitor, is metabolized to amphetamines and can be successful at reducing daytime sleepiness. In an individual patient, one wake-promoting agent may work better than another, and if the first drug selected is not successful at adequate doses, a trial with another agent should be attempted. ❻ *Treatment of EDS in narcolepsy and other sleep disorders may require the use of sustained- and immediate-release stimulants to effectively promote wakefulness throughout the day and at key times that require alertness.* One potential treatment regimen includes a sustained-release preparation first thing in the morning and again at noon, followed by an immediate-release preparation as needed in the late afternoon or prior to driving to maintain wakefulness. One advantage of traditional CNS stimulants over modafinil is their ability to suppress REM sleep, which also may help to control cataplexy and REM-sleep abnormalities.

Traditional CNS stimulants have the potential to increase blood pressure and heart rate when used long term. In addition, excessive CNS stimulation can cause tremors and tics and can carry over into evening hours, where initiation of normal nighttime sleep can be disrupted. Caution should be used in patients with underlying cardiovascular or cerebrovascular disease and in patients with a history of seizures because stimulants may lower the seizure threshold.

Cataplexy

Traditionally, aminergic signaling antidepressants have been used effectively to control symptoms of cataplexy, sleep paralysis, and other REM-sleep manifestations of narcolepsy. These include TCAs and certain selective serotonin and serotonin/norepinephrine reuptake inhibitors (SSRIs and SNRIs). Clomipramine, protriptyline, imipramine, venlafaxine, and fluoxetine are the agents that have been used most frequently. In addition, low-dose selegiline also has been effective at reducing cataplexy. Although these drugs are not approved by the FDA for treatment of cataplexy, they effectively suppress REM sleep and have been the mainstay of anticataplectic therapy for years. Recently, sodium oxybate, a potent sedative with a very short duration of action, gained FDA approval for the treatment of narcolepsy with cataplexy. The mechanism whereby it reduces cataplexy is unknown. Two doses per night are taken, one at bedtime and one follow-up dose taken 2½ to 4 hours later. Patients frequently need to set an alarm to wake up to take their second dose. Sodium oxybate is tightly regulated and is only available from one central pharmacy owing to the high abuse potential of its active ingredient (gamma-hydroxybutyrate).

Restless-Legs Syndrome

❼ *RLS treatment involves suppression of abnormal sensations and leg movements and consolidation of sleep. Dopaminergic and sedative hypnotic medications are prescribed commonly.* In the last few years, dopamine agonists (DAs) have become the therapy of choice for the treatment of RLS, replacing levodopa/carbidopa as first-line agents. The DAs offer many advantages over levodopa/carbidopa, including longer half-lives to cover overnight symptoms, flexible dosing, and a reduced incidence of symptom augmentation. Up to 80% of patients who take levodopa/carbidopa eventually will experience symptom augmentation: RLS symptoms appear earlier in the day, previously unaffected body parts become involved, and higher doses of medication are required to control symptoms.[45] Ropinirole (Requip®) recently gained FDA approval for the treatment of RLS. Pramipexole and pergolide are also prescribed and have demonstrated efficacy in

clinical trials.[46,47] Gabapentin is an effective treatment for RLS, particularly in patients with painful symptoms.[48] BZDRAs such as temazepam, clonazepam, zolpidem, and zaleplon effectively reduce arousals associated with PLMS in patients with RLS.[49] Their main benefit is derived from improving sleep continuity in patients with RLS, particularly as adjunct treatment with other pharmacologic therapies. Opioids are effective for some patients' RLS symptoms, with oxycodone, propoxyphene, hydrocodone, and codeine being used most frequently. For both BZDRAs and opioids, caution should be used in the elderly, in patients who snore and are at risk for sleep apnea, and in patients with a history of substance abuse. Low iron levels frequently exacerbate RLS symptoms. Iron supplementation should be prescribed in patients who are iron-deficient. Iron supplementation in patients with serum ferritin concentrations of less than 50 mcg/L improves RLS symptoms. Medications frequently used for RLS are shown in Table 38–3.

Obstructive Sleep Apnea

❸ *The main therapy for OSA is nasal* ***continuous positive airway pressure (CPAP)*** *therapy because of its effectiveness.* CPAP alleviates sleep-disordered breathing by producing a positive pressure column in the upper airway using room air. The CPAP machine is small enough to be transportable and sits at the bedside. A flexible tube connects the CPAP machine to a mask that covers the nose. During overnight polysomnography, the pressure setting is increased until sleep-disordered breathing is eliminated. CPAP therapy has been shown to have a favorable impact on blood pressure and to attenuate some of the potential hemodynamic and neurohumoral responses that may link OSA to systemic disease.

Not all individuals tolerate CPAP therapy in part because it requires wearing a mask during sleep, and therapy can dry and irritate the upper airway. In some individuals, these barriers for adherence may be lessened or eliminated by properly fitting the mask, adding humidity or heat to therapy, or using bi-level positive airway pressure (BiPAP) therapy. BiPAP therapy applies a variable pressure into the airway during the inspiratory phase of respiration but, unlike CPAP, reduces the applied pressure during the expiratory phase of respiration.

There are other non-invasive therapies for OSA. Obesity can worsen sleep apnea, and weight management should be implemented for all overweight patients with OSA. In obese patients with mild OSA, weight loss alone can be effective, and studies have reported improvement in severity of OSA with gastric stapling. Oral appliances can be used to advance the lower jawbone and to keep the tongue forward to enlarge the upper airway. For individuals who suffer OSA only during certain positions (e.g., when on their back) during sleep, positional therapies may be effective. Surgical therapy (uvulopalatopharyngoplasty) opens the upper airway by removing the tonsils, trimming and reorienting the posterior and anterior tonsillar pillars, and removing the uvula and posterior portion of the palate. This is not a first-line option because it is invasive. In very severe cases, tracheostomy may be necessary. This procedure

TABLE 38–3. Frequently Used Medications for Restless-Legs Syndrome[49]

Medication	Half-Life (hour)	Dose Range (mg/day)[d]	Potential Side Effect or Disadvantage
Dopaminergic Agents[a]			
Levodopa/carbidopa (Sinemet®)	1.5–2	100–200 of levodopa	Nausea/vomiting, high incidence of symptom augmentation
Pramipexole (Mirapex®)	8–12[b]	0.125–1.5	Nausea/vomiting
Ropinirole (Requip®	6[c]	0.25–3	Nausea/vomiting
Pergolide (Permax®)	27	0.025–0.5	Nausea/vomiting, rare but serious heart valvulopathy and pleural fibrosis
Anticonvulsants			
Gabapentin (Neurontin®)	5–7[b]	300–3600	Dizziness, ataxia
Hypnotic Agents			
Clonazepam (Klonopin®)	30–40	0.5–2	Tolerance, carryover sedation
Temazepam (Restoril®)	10–15	7.5–30	Tolerance, sedation
Zolpidem (Ambien®)	2–2.6[c]	5–10	Tolerance, sedation
Zaleplon (Sonata®)	1[c]	5–10	Tolerance, sedation
Opioids			
Hydrocodone	3.8–4.5[c]	5–10	Constipation, nausea, sedation
Codeine	2.5–3.5[c]	30–60	Constipation, nausea, sedation
Propoxyphene	6–12[c]	100–600	Constipation, nausea, sedation
Oxycodone	3.2–12[b]	5–30	Constipation, nausea, sedation

[a]Dopaminergic agents are frequently given at bedtime or 2 hours prior to bedtime or the anticipated onset of RLS symptoms.
[b]May be longer in patients with renal dysfunction.
[c]May be longer in patients with hepatic dysfunction.
[d]Usual range, dosed at bedtime.

may be indicated in selected individuals who are morbidly obese, have severe facial skeletal deformity, experience severe drops in oxygen saturation (e.g., Sao_2 less than 70%), or have significant cardiac arrhythmias associated with their OSA.

There is no drug therapy for OSA. Drug therapy for symptoms of OSA may be considered in selected patients. For example, modafinil (Provigil®) is a wake-promoting medication that is approved by the FDA to improve wakefulness in patients who have residual daytime sleepiness while treated with CPAP. Initiation of wake-promoting medications should be attempted only after patients are using optimal CPAP therapy to alleviate sleep-disordered breathing. Other therapies (e.g., medroxyprogesterone) are not effective and may worsen OSA. Untreated or inadequately treated sleep apnea may hinder achieving blood pressure control in hypertensive patients. OSA should be considered and evaluated in hypertensive patients who are resistant to therapy or have signs and symptoms of OSA.

Parasomnias

Non-REM parasomnias usually do not require treatment. If needed, low-dose benzodiazepines such as clonazepam can be prescribed for bothersome episodes. Clonazepam reduces the amount of sleep time spent in stages 3 and 4 of non-REM sleep, where most non-REM parasomnias occur. For treating RBD, clonazepam 0.5 to 2 mg at bedtime is the drug of choice, although melatonin 3 to 12 mg at bedtime also may be effective. Patients with RBD also should have dangerous objects removed from the bedroom and cushions placed on the floor to reduce the chance of injury from breakthrough episodes.

Circadian Rhythm Disorders

Melatonin at doses of 0.5 to 5 mg taken at appropriate target bedtimes for east or west travel is becoming the drug of choice for jet lag. Melatonin significantly reduces jet lag and shortens sleep latency in travelers.[50] Hypnotic agents with relatively short durations of action (3 to 5 hours) also may be used to sustain sleep during the initial adaptation to the new time zone.

Drug-Disease and Drug-Drug Interactions

❾*It is important to review patient medication profiles for drugs that may aggravate sleep disorders. Patients should be monitored for adverse drug reactions and potential drug-drug interactions. They should be assessed for adherence to their therapeutic regimens.* Pharmacotherapy for sleep disorders should be individualized. Medications can be used commonly to treat several concomitant sleep disorders. Conversely, drug therapy may be effective for one sleep disorder and exacerbate another. For example, antidepressants may alleviate depressive symptoms but exacerbate symptoms of RLS. Medications that block dopaminergic transmission may worsen RLS symptoms. Smoking can worsen OSA, presumably by increasing upper airway edema. Alcohol and CNS depressants, including opiate analgesics, sedatives, and muscle relaxants, can worsen OSA, even in small doses, by reducing respiratory drive and relaxing the upper airway muscles responsible for maintaining patency. CNS depressants should be avoided, and if they are necessary, they should not be administered before sleep. Drug therapy for sleep disorders should be patient-specific, and careful consideration should be given to co-existing diseases, concomitant medications, and potential drug-drug and drug-disease interactions to optimize patient care and treatment.

Patient Encounter, Part 3: Modifying Treatment Plan

CH returns to the clinic 3 months later. The physician previously diagnosed him with obstructive sleep apnea and RLS. He received a prescription for CPAP, for OSA and ropinirole 0.5 mg at bedtime for RLS at his last visit. Via phone calls, his ropinirole dose has been increased to 3 mg at bedtime. He has received moderate relief of his RLS symptoms, but on occasion, he still awakens and cannot fall back asleep. His sleepiness and RLS symptoms are improved: ESS: 13/24.

- Based on the information presented, recommend additional therapy for the patient.
- What medications would you consider adding to reduce RLS symptoms and reduce awakenings?
- How would you assess the patient's CPAP therapy and adherence?
- What precautions would you want to counsel the patient on about his therapy?

OUTCOME EVALUATION

To determine the success of treatment, evaluate whether the treatment plan restored normal sleep patterns, reduced daytime sequelae, and improved quality of life without causing adverse effects. Schedule patients for follow-up within 3 weeks for insomnia and within 3 months for other sleep disorders. Perform a detailed clinical history to determine the patient's perception of treatment progress and symptoms along with medication effectiveness and side effects.

Instruct patients to keep sleep diaries of nightly sleep (number of hours, number of awakenings, and worsening or improved sleep) and daytime symptoms, along with documentation of episodes such as cataplexy or RBD. Increase medication to effective doses, and if necessary, start additional therapy to control symptoms. Patients with sleep disorders should experience relief of symptoms the first night of drug therapy but may not receive maximal benefit (effect on daytime symptoms) for a few weeks. Perform a detailed history of prescription, non-prescription, and non-traditional medications, and review the patient's sleep diary, daytime symptoms, and non-pharmacologic therapies on a regular basis.

Patient Care and Monitoring

Insomnia

1. Ideally limit hypnotic therapy to short-term use, and reevaluate after 2 to 3 weeks of therapy.
2. Evaluate improvement in the specific sleep complaint (e.g., how has therapy affected sleep latency?).
3. Inquire about carryover sedation and other side effects associated with the selected agent. Use a lower dose or select a drug with a shorter duration of action if the patient experiences carryover sedation.
4. Address other medical conditions that frequently coexist with insomnia and can worsen a patient's symptoms (e.g., psychiatric disorders, benign prostatic hypertrophy).

Narcolepsy

1. Administer the ESS at each visit to monitor progress with modafinil or stimulant therapy. Unfortunately, EDS in narcolepsy patients rarely is fully reversed.
2. Evaluate how sleepiness changes throughout the day to best determine how to use sustained- and immediate-release stimulants to maintain wakefulness. If the patient complains of sleep disruption from stimulant therapy, move the dosing time a few hours earlier until sleep disruption is avoided.
3. Review patients' sleep diaries to track the number of cataplexy, sleep paralysis, and hallucinatory events and when they occur.

RLS

1. Carefully assess both the patients' and bed partners' reports of the patients' nighttime limb movements.
2. Measurement of sleepiness (via ESS) and RLS symptoms should be completed at each visit to track progress with therapy.
3. Evaluate potential side effects of therapy, including nausea, drowsiness, sleep attacks, and headaches for the DA agents.
4. Review the sleep diaries and timing of RLS symptoms to watch for possible symptom augmentation.
5. If symptoms are not resolved, increase the dose of DA agent or add another agent such as gabapentin or a hypnotic benzodiazepine.

OSA

1. Evaluate CPAP therapy annually or at any time individuals experience symptoms (e.g., daytime sleepiness) despite CPAP therapy. For example, change in pressure settings to alleviate OSA may be needed if weight gain occurs.
2. Monitor compliance with CPAP therapy. CPAP machines have a built-in compliance meter to measure the hours used at effective pressure. Patients should use CPAP therapy for at least 5 hours each night. In addition to alleviating sleep-disordered breathing, CPAP therapy may improve cardiovascular outcomes.

Parasomnias

1. Ask patients and family members about any bothersome or dangerous sleepwalking episodes since the last visit and if therapy has reduced the frequency of these events.
2. For RBD, review the sleep diaries and interview bed partners to determine the number and nature of episodes.
3. Inquire about carryover sedation and anterograde amnesia from therapy.

ABBREVIATIONS

BiPAP:	bi-level positive airway pressure
BMI:	body mass index

39 Attention-Deficit Hyperactivity Disorder

Kevin W. Cleveland and John Erramouspe

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Explain the *Diagnostic and Statistical Manual of Mental Disorders,* 4th edition, Text Revision criteria necessary for the diagnosis of attention-deficit hyperactivity disorder.
2. Recommend a therapeutic plan, including initial doses, dosage forms, and monitoring parameters, for a patient with attention-deficit hyperactivity disorder.
3. Differentiate between the available pharmacotherapy used for attention-deficit hyperactivity disorder with respect to pharmacology and pharmaceutical formulation.
4. Recommend second-line and/or adjunctive agents that can be effective alternatives in the treatment of attention-deficit hyperactivity disorder when stimulant therapy is less than adequate.
5. Address potential cost-benefit issues associated with pharmacotherapy of attention-deficit hyperactivity disorder.
6. Recommend strategies for minimizing adverse effects of attention-deficit hyperactivity disorder medications.

Key Concepts

❶ To meet present attention-deficit hyperactivity disorder diagnostic criteria, patients need to display either hyperactivity, impulsivity, and/or inattentiveness before 7 years of age.

❷ The exact cause of attention-deficit hyperactivity disorder is unknown, but dysfunction in neurotransmitters norepinephrine and dopamine has been implicated as a key component.

❸ Attention-deficit hyperactivity disorder is rarely encountered without comorbid conditions.

❹ Treatment goals for attention-deficit hyperactivity disorder are to improve behavior, increase attention/response inhibition (ability to stay on task), and minimize side effects associated with pharmacotherapy.

❺ Pharmacotherapy is superior to behavioral therapy in the treatment of attention-deficit hyperactivity disorder. Behavior modification provided by parents and teachers in conjunction with pharmacotherapy improves treatment outcomes more than behavior therapy alone.

❻ Stimulants are first-line agents for the treatment of attention-deficit hyperactivity disorder. If the initial trial of a stimulant therapy fails, then a second trial of an alternative stimulant should be tried. On failure of a second trial of stimulant pharmacotherapy, it is rational to attempt a third trial with another stimulant formulation or select a non-stimulant agent such as bupropion, imipramine, or atomoxetine.

Attention-deficit hyperactivity disorder (ADHD) is the most common mental disorder that occurs in the pediatric population.[1–3] This disorder must begin in childhood before 7 years of age and can continue into adulthood. ADHD is characterized by a core group of symptoms: hyperactivity, impulsivity, and inattention. Further, ADHD can be classified into three basic forms: inattentive, hyperactive/impulsive, and combined. It can have a severe impact on a patient's ability to function in both academic and social environments, leading to a significant burden on family and school personnel. The exact cause of ADHD is unknown, but twin studies strongly suggest a genetic etiology.[3–5] Early diagnosis and appropriate treatment are essential to compensate for areas of deficit and to allow the patient to cope in both family and social environments.

Patient Encounter, Part 1

A single mother and her rambunctious 6-year-old boy, AD, come to your clinic. The mother is concerned because her neighbor, who watches AD after school for no charge, has complained about the problems he is causing among her own children (4½- and 6-year-old boys). AD refuses to wait for his own turn in games and frequently hits the younger boy. The neighbor has said that unless AD becomes more manageable, she will not watch him after school. This is very distressing to AD's mother, who barely provides for her son and herself by working at the local convenience store for minimum wage. She cannot afford a professional babysitter for AD. She does not qualify for medical assistance. Further, she explains that his performance at school is getting worse, and he is becoming unmanageable in the classroom.

- Which of the patient's symptoms are suggestive of ADHD?
- What other information do you need to assess for ADHD?
- What help/suggestions could you offer to AD's mother?

EPIDEMIOLOGY AND ETIOLOGY

❶*This disorder usually begins by 3 years of age but must occur prior to 7 years of age to meet diagnostic criteria.* In the United States, ADHD is the most common neurobehavioral disorder that affects children.[1–3,6] ADHD has been estimated to occur between 4.3% and 12% of school-aged children.[6,7] ADHD tends to occur at a greater incidence in males than in females by approximately 3:1 in school-aged children.[7] However, during adolescence, the incidence of ADHD is equal between males and females. As adults, females have a greater incidence of ADHD symptoms than males.

Although ADHD generally is considered a childhood disorder, symptoms can persist into adolescence and adulthood. The prevalence of adulthood ADHD is estimated to be 4%, with 60% of adults having manifested symptoms of ADHD from childhood.[8,9] Further, problems associated with ADHD (e.g., social, marital, academic, career, anxiety, depression, smoking, and substance-abuse problems) increase with the transition of patients into adulthood.

PATHOPHYSIOLOGY

❷*The exact pathologic cause of ADHD has not been identified.* ADHD is generally thought of as a disorder of self-regulation or response inhibition. Patients who meet the criteria for ADHD have difficulty maintaining self-control, resisting distractions, and concentrating on ideas.[4,6] Further, children with ADHD often alternate between inattentiveness to monotonous tasks and overexcitement. Multiple brain studies have failed to elucidate any pathophysiologic basis for ADHD, although they have associated ADHD with atypical brain development in early childhood. Cerebral volume, the prefrontal cortex, the basal ganglia, and the caudate tend to be significantly smaller in children with ADHD than in children without the disorder.[4]

❷*Dysfunction in the roles of the* ***neurotransmitters*** *dopamine and norepinephrine is thought to be key in the pathology of ADHD.* Norepinephrine is responsible for maintaining alertness and attention, whereas dopamine is responsible for regulating learning, motivation, goal setting, and memory. Both these neurotransmitters predominate in the frontal subcortical system, an area of the brain responsible for maintaining attention and memory. Also, the propensity for a genetic link with this disorder is high. There is a 50% chance that a child who has a parent with ADHD will develop ADHD. Further, studies of twins have demonstrated a concordance rate of 92% for ADHD. An association has been made between the development of ADHD and predisposing factors such as fetal alcohol syndrome, lead poisoning, maternal smoking, and hypoxia.[4]

CLINICAL PRESENTATION AND DIAGNOSIS

Clinical Presentation

General

Patients with ADHD can present with inattention and/or hyperactivity-impulsivity. ADHD is rarely encountered without comorbid conditions.

Symptoms

- *Inattention*—has difficulty paying attention to details in school, work, and social activities, difficulty completing tasks that require a lot of mental effort; is easily distracted, forgetful.
- *Hyperactivity/impulsivity*—has difficulty sitting still, fidgets, has trouble playing quietly and waiting turns, frequently interrupts.
- *Combined*—exhibit both inattention and hyperactivity/impulsivity.

Diagnostic Criteria

- Must exhibit symptoms before 7 years of age that persist for greater than 6 months.
- Symptoms must be present in two or more settings and adversely affect functioning in social situations, school, or work.
- Must meet the diagnostic criteria in DSM-IV-TR (Table 39–1).
- Symptoms cannot be better explained by another mental disorder (e.g., autism).

TABLE 39–1. DSM-IV Diagnostic Criteria for ADHD

I. Either A or B:
  A. ***Inattention***. Must have at least six or more of the following symptoms of inattention for at least 6 months:
    1. Does not pay close attention to details in schoolwork, work, or other activities.
    2. Has trouble maintaining attention to tasks or activities.
    3. Has trouble actively listening when directly spoken to.
    4. Has difficulty following instructions and fails to finish important daily tasks (i.e., homework, chores, responsibilities at work).
    5. Demonstrates difficulty in organizing tasks/activities.
    6. Tends to avoid or put off activities that require concentration.
    7. Tends to misplace items needed to complete tasks or activities.
    8. Is easily distracted from current tasks or activities.
    9. Forgetful.
  B. ***Hyperactivity/impulsivity.*** Must have at least six or more of the following symptoms of hyperactivity/impulsivity for at least 6 months:
    Hyperactivity
    1. Fidgets and is restless in a sitting position.
    2. Cannot sit still for extended periods.
    3. Runs around when it is not appropriate.
    4. Cannot play quietly.
    5. Often "on the move."
    6 Talks excessively.
    Impulsivity
    7. Answers questions prematurely.
    8. Difficulty waiting one's turn.
    9. Interruptive or intrudes on others.
II. Above symptoms were present before 7 years of age.
III. Above symptoms are present in two or more settings.
IV. Impairment is clearly evident in social, school, or work functioning.
V. Symptoms cannot be attributed to another mental disorder (e.g., anxiety, depression, autism, or a personality disorder).

Based on the above criteria, ADHD can be divided into three types:
1. ADHD combined type: Both 1A and 1B.
2. ADHD inattentive type: 1A criteria are met.
3. ADHD hyperactive-impulsive type: 1B criteria are met.

Reprinted, with permission, from the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, Text Revision, (Copyright 2000). American Psychiatric Association.[11]

❸ *ADHD is rarely encountered without comorbid conditions and often is underdiagnosed.* Between 40% and 75% of patients with ADHD will have one or more comorbidities (e.g., learning disabilities, oppositional defiant conduct, anxiety, or depressive disorders).[10] It is important to identify other coexisting conditions in patients with ADHD to assist in initial and ongoing selection of treatment.

When a patient presents with inattention, hyperactivity, academic underachievement, and/or behavior problems, he or she should be evaluated for ADHD. Initial evaluation of the patient primarily should be for the purpose of information gathering. Evidence of the patient's behavior should be obtained from various settings, including the family and school. Information is gathered from parent interviews, school reports, and an interview with and observation of the patient. This information should include the age of onset, frequency, severity, and duration of symptoms.[10]

The most useful diagnostic criteria for ADHD is the *Diagnostic and Statistical Manual of Mental Health Disorders,* 4th edition, Text Revision (DSM-IV-TR) (Table 39–1). The DSM-IV-TR defines three subtypes of ADHD: (1) predominately inattentive, (2) predominantly hyperactive/impulsive, and (3) combined, in which both inattentive and hyperactive symptoms are evident.[11]

Other diagnostic tests, such as brain imaging, electroencephalograms, and continuous performance examinations, should be regarded as investigational and not used clinically for diagnosis. While some brain studies have demonstrated differences in brain morphology between ADHD patients and control individuals, these differences are not diagnostic.[4]

Although ADHD is considered a childhood disorder, signs and symptoms persist into adolescence and adulthood in approximately 40% to 80% and 60% of cases, repectively.[1,9] Adult ADHD is difficult to assess, and diagnosis is always suspect in patients failing to display clear symptoms prior to 7 years of age.[4] Adults with ADHD have higher rates of psychopathology, substance abuse, social dysfunction, and occupational underachievement.

Patient Encounter, Part 2: Medical History, Physical Examination, and ADHD Evaluation

AD's baseline physical examination was unremarkable. Family history is positive for cardiovascular disease, and there is no documented history of ADHD in the family. Patient weight: 20 kg (44 lbs)

Allergies
None known

Patient height: 45 in (144 cm)
BP: 96/55 mm Hg
Pulse: 80 beats/minute
AD's mother does not qualify for medical assistance, and she can hardly afford the monthly expenses.

- What stimulant and/or non-stimulant regimen(s) is(are) available that might control AD's symptoms?
- Which medications will facilitate adherence, minimize potential side effects, and offer an acceptable cost for AD's mother?
- What other information do you need before starting certain pharmacotherapy options?
- What are important counseling points to discuss with AD's mother?

TREATMENT

Desired Outcomes

❹*The primary therapeutic objectives in ADHD are to improve behavior and increase attention; secondary goals of treatment are to*

- Improve relationships with family, teachers, and peers
- Decrease disruptive behavior in academic and social settings
- Improve academic performance
- Increase independence in activities
- Minimize undesirable adverse effects of therapy

Nonpharmacologic (Behavioral) Therapy

Behavioral therapy can be used to treat patients with ADHD; however, it is generally not recommended as first-line monotherapy.[8] ❺*Several studies have demonstrated that treatment with medication alone is superior to behavioral intervention alone in improving attention.*[12] *However, behavioral therapy in combination with stimulant therapy was better at improving oppositional and aggressive behaviors.*[12] Behavioral modification involves training parents, teachers, and caregivers to change the physical and social environment and establishment of a reward/consequence system.[13] Success of behavioral modifications depends on the cooperation and involvement of the patient's parents and teachers.

Pharmacologic Therapy

The proposed mechanism of ADHD pharmacotherapy is to modulate neurotransmitters in order to improve academic and social functioning. Pharmacologic therapy can be divided into two categories: stimulants and non-stimulants. Stimulant medications include methylphenidate, dexmethylphenidate, amphetamine salts, and dextroamphetamine, whereas non-stimulant medications include atomoxetine, tricyclic antidepressants (e.g., imipramine), clonidine, guanfacine, and bupropion.

Stimulants

❻*Psychostimulants (e.g., methylphenidate and dextroamphetamine with or without amphetamine) are the most effective agents in treating ADHD. Once the diagnosis of ADHD has been made, a stimulant medication should be used first line in treating ADHD* (Fig. 39–1). Stimulants are safe and effective, with a response rate of 70% to 90% in patients with ADHD.[3,13,14] Generally, a trial of at least 3 months on a stimulant is appropriate, and this includes dose titration to response

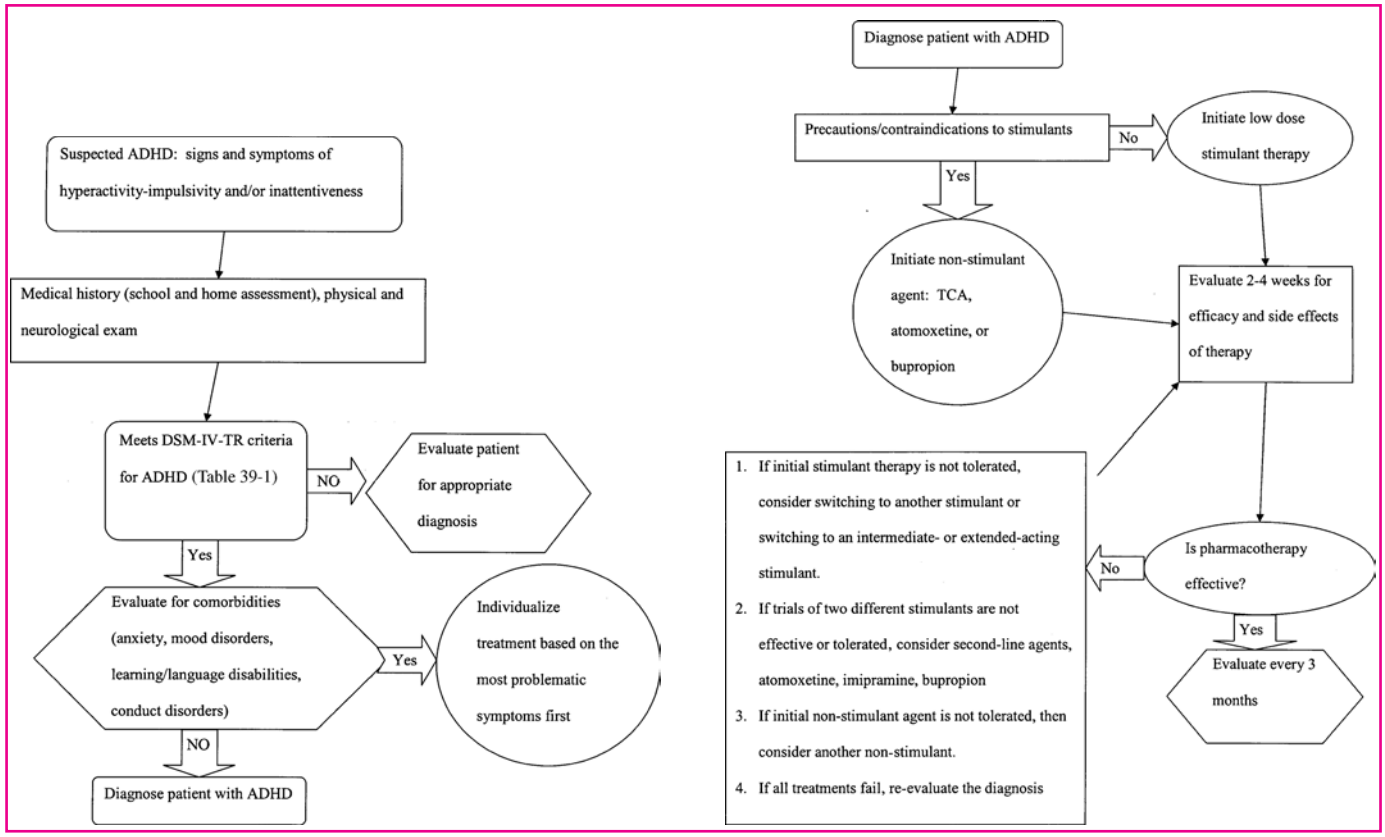

FIGURE 39–1. ADHD diagnosis and treatment algorithm.[8,13,16]

while balancing side effects.[8,13] ❻*If treatment with the first stimulant formulation fails, it is recommended to switch to a different stimulant formulation.*[13] For example, if the patient was started on methylphenidate but could not tolerate the side effects, switching to dextroamphetamine with or without amphetamine is rational. The majority of patients who fail one stimulant will respond to an alternative stimulant.[13] ❻ *If the patient fails two appropriate trials of different stimulant medications, a third stimulant formulation or second-line non-stimulant such as bupropion, imipramine, or atomoxetine can be considered.* The diagnosis of ADHD should be revalidated as well.

Stimulants theoretically exert their effect by blocking the reuptake of dopamine and norepinephrine, thus improving academic performance and decreasing motor activity in ADHD patients. Stimulants have been shown to decrease fidgeting and finger tapping, increase on-task classroom behavior and positive interactions at home and in social environments, and ameliorate conduct and anxiety disorders.[14]

Stimulants should be initiated at recommended starting doses and titrated up with a consistent dosing schedule to the appropriate response while minimizing side effects (Table 39–2). Generally, stimulants should not be used in patients who have glaucoma, severe hypertension or cardiovascular disease, hyperthyroidism, severe anxiety, or previous illicit or stimulant drug abuse. Further, stimulants can be used, albeit cautiously, in patients with seizure disorders, Tourette's syndrome, and **motor tics.**[14]

Initial response to short-acting stimulant formulations (e.g., methylphenidate and dextroamphetamine) is seen within 30 minutes and can last for 4 to 6 hours.[13,14] This short duration of effect frequently requires that short-acting stimulant formulations be dosed at least twice daily, thus increasing the chance of missed doses and non-compliance. Further, patients using any stimulant formulation but especially short-acting formulations can experience a **rebound effect** of ADHD symptoms as the stimulant wears off.[14]

To minimize rebound problems associated with short-acting formulations and still maintain early stimulant release, once-daily products (Adderall XR®, Concerta®, Metadate CD®, and Ritalin LA®) have been developed. Stimulant drug formulations can be divided into short-, intermediate-, and extended-acting preparations (Table 39–2). Most intermediate-acting agents release the medication in a slow, continuous fashion without any early release (except Dexedrine Spansules®). All extended-acting formulations have early release of medication and deliver a delayed release of stimulant in either a pulsed or continuous manner. Most of the extended-acting stimulants are capsules containing coated beads that can be opened and sprinkled on semisolid food. The exception, Concerta® tablets, uses an oral osmotic controlled-release delivery system (the empty tablet shell can be detected in the stool).

Adverse effects of stimulants can be generalized to the whole class (Table 39–3). Most of these side effects can be managed by changing dosing routine (i.e., giving with food, dividing daily dose, or giving the dose earlier in the day). Serious side effects such as hallucinations and abnormal movements require discontinuation of medication.[13,14]

Growth suppression or delay is a major concern for parents of children taking stimulants. However, the evidence of this side effect is not clear. At present, growth delay appears to be transient and to resolve by midadolescence, but more data are needed to firmly resolve this issue.[10] Another concern is the risk of substance abuse with stimulant use. A diagnosis of ADHD alone increases the risk of substance abuse in adolescents and adults. However, stimulant use has not been shown to further increase this risk but actually may decrease this risk, provided ADHD is treated adequately.[15]

The choice of ADHD medication should be made based on the patient's condition, the prescriber's familiarity with the medications, the ease of administration, and cost. Stimulants should be used first line in most ADHD patients, although there is no clear advantage of using one stimulant over another in managing symptoms of ADHD.[16]

Non-stimulants

Atomoxetine

Atomoxetine is the most recent addition to the ADHD armamentarium in both children and adults. In clinical studies, atomoxetine has demonstrated superior efficacy over placebo and equivalent efficacy when compared with a suboptimal immediate-release methylphenidate dose.[17–20] However, it is not clear whether atomoxetine is superior to typical methylphenidate doses or other stimulant formulations. ❻*Atomoxetine may be used as a second- or third-line medication for ADHD.*

Atomoxetine selectively inhibits the reuptake of adrenergic neurotransmitters, principally norepinepherine.[17–20] Atomoxetine is metabolized through the cytochrome P-450 CYP2D6 pathway. Approximately 5% to 10% of the population are CYP2D6 poor metabolizers, and atomoxetine's half-life is increased significantly in this population.[21] The recommended dosing for atomoxetine depends on the weight of the patient and is given daily in either a single or two divided doses[21] (Table 39–2). In poor metabolizers, atomoxetine should be dosed once daily at 25% to 50% of the dose typically used in normal metabolizers.[21] The maximum therapeutic effect of atomoxetine may take up to 4 weeks to be seen, which is significantly longer than what is required with stimulants. Common side effects of atomoxetine are similar to those of stimulants: dyspepsia, nausea, vomiting, somnolence, and decreased appetite. Some studies have reported an increase in blood pressure and heart rate.[18–20] There is evidence that atomoxetine can slow growth rate and cause weight loss; thus, height and weight should be monitored routinely in pediatric patients[18–20] (Table 39–3). Further, atomoxetine labeling includes strong warnings about severe hepatotoxicity and increased association with suicidal thinking.

TABLE 39–2. Selected Medications in Treating ADHD[a]

Drug, Generic (Brand)	Initial Dose	Titration Schedule	Typical Dosing Range (Maximum Dose)
Stimulants			
Short-acting			
Methylphenidate[b] (Methylin, Ritalin)	5 mg two times daily	↑ 5–10 mg/day in weekly intervals	5–20 mg two to three times daily (60 mg/day)
Dexmethylphenidate[b] (Focalin)	2.5 mg two times daily	↑ 2.5–5 mg/day in weekly intervals	5–10 mg twice daily (20 mg/day)
Dextroamphetamine[b] (Dexedrine)	2.5–5 mg every morning	↑ 2.5–5 mg/day in weekly intervals	5–20 mg twice daily (40 mg/day)
Intermediate-acting			
Methylphenidate[b] (Ritalin SR, Metadate ER, Methylin ER)	10 mg once daily	↑ 10 mg/day in weekly intervals	20–40 mg daily in the morning (60 mg/day)
Dextroamphetamine/ amphetamine[b] (Adderall)	2.5–5 mg once to twice daily	↑ 2.5–5 mg in weekly intervals	10–30 mg every morning or 5–20 mg twice daily (40 mg/day)
Dextroamphetamine[b] (Dexedrine Spansule)	5 mg every morning	↑ 5 mg/day in weekly intervals	5–30 mg daily or 5–15 mg twice daily (40 mg/day)
Extended-acting			
Methylphenidate[b] (Concerta)	18 mg every morning	↑ 9–18 mg/day in weekly intervals	18–54 mg every morning (54 mg/day)
(Metadate CD)	20 mg every morning	↑ 10–20 mg/day in weekly intervals	20–40 mg daily in the morning (60 mg/day)
(Ritalin LA)	20 mg every morning	↑ 10 mg/day in weekly intervals	20–40 mg daily in the morning (60 mg/day)
Dextroamphetamine/ amphetamine[b] (Adderall XR)	5–10 mg every morning (children) 20 mg once daily (adults)	↑ 5–10 mg/day in weekly intervals	10–30 mg every morning or 5–15 mg twice daily (30 mg/day, children) (60 mg/day, adult)
Dexmethylphenidate[b] (Focalin XR)	5 mg every morning (children) 10 mg every morning (adults)	↑ 5 mg/day in weekly intervals	10–20 mg daily in the morning (20 mg/day)
Non-stimulants			
Atomoxetine[b] (Strattera)	Less than or equal to 70 kg: 0.5 mg/kg per day divided once to twice daily	↑ to target dose of 1.2 mg/kg per day after 3 days	40–60 mg/day (1.4 mg/kg or 100 mg/day, whichever is less)
	Greater than 70 kg: 40 mg once daily	↑ 40 mg/day after 3 days (may ↑ to total of 100 mg/day after 2–3 weeks)	40–80 mg/day divided once to twice daily (100 mg/day)
Imipramine (Tofranil)	1.5 mg/kg per day in one or two divided doses	↑ 1 mg/kg per day every 3 to 4 days	1.5–3 mg/kg per day in one or two divided doses (5 mg/kg per day, child) 100–300 mg/day in one or two divided doses (300 mg/day, adult)
Clonidine (Catapres)	0.05 mg once daily	↑ 0.05 mg/day every 3 to 7 days	0.1 mg once to four times daily (0.4 mg/day)
Guanfacine (Tenex)	0.5 mg at bedtime	↑ 0.5 mg every 3 to 14 days	1.5–3 mg/day divided into two or three times daily (4 mg/day)
Bupropion (Wellbutrin, Wellbutrin SR, Wellbutrin XL)	3 mg/kg per day for 7 days (children); 150 mg once daily of SR or XL (adults)	↑ 3 mg/kg per day in weekly intervals (children); ↑ 150–300 mg/day in weekly intervals (adults)	6 mg/kg per day or 400 mg/day—whichever is smaller (children); 150–450 mg/day (400 mg/day SR; 450 mg/day XL - adults)

[a]Pediatric dosing except where adult dosing specified.
[b]FDA approved for treatment of ADHD.

Atomoxetine is similar to extended-acting stimulants in that it can be given once daily in many patients. Atomoxetine appears to lack any abuse potential and is not a controlled substance.[22] One big disadvantage of atomoxetine is cost compared with other ADHD medications (Table 39–4).

Due to the high cost and lack of long-term efficacy and comparison studies with stimulants, atomoxetine should be advocated only if the patient has failed or is intolerant to the standard stimulant therapy (Fig. 39–1).

Bupropion

Bupropion is a monocyclic antidepressant that inhibits the reuptake of norepinephrine and dopamine. Bupropion is effective for relieving symptoms of ADHD in children but is

TABLE 39–3. ADHD Medication Side-Effect Profiles, Management, and Monitoring

Drug	Side Effects	Management	Monitoring
Stimulants			
Methylphenidate, dextroamphetamine, mixed-salts amphetamine	GI upset, nausea, decreased appetite, potential growth delay	Administer after meals Encourage high-calorie meals Divide dose Give snacks in the evening Change to shorter-acting stimulant Use drug holiday or different medication if severe growth delay	Height, weight, blood pressure, pulse Eating and sleeping patterns Evaluate every 2 to 4 weeks until stable dose is achieved; then evaluate every 3 months
	Sleep disturbance	Give dose earlier in the day Give clonidine or guanfacine at bedtime Discontinue all doses given afternoon Change to a shorter-acting stimulant	
	Rebound symptoms	Change to longer-acting stimulant Overlap stimulant dosing	
	Moodiness	↓ Dose or change to longer-acting stimulant Verify diagnosis/comorbidity	
	Irritability	Evaluate time of occurrence Early onset: ↓ dose or change to longer-acting stimulant Late onset: Switch to longer-acting stimulant Evaluate for comorbidity	
	↑ Blood pressure and pulse	↓ Dose or change to longer-acting stimulant	
	Tics	Discountinue or change to a different stimulant Give clonidine or guanfacine	
Non-stimulants			
Atomoxetine	↑ Blood pressure and pulse, nausea, vomiting, fatigue, and insomnia	↓ Dose or change to another medication	Same as above but with baseline and routine liver function tests for hepatotoxicity
	Hepatotoxicity, suicidal thoughts	Discountinue or change to a another medication	
Tricyclic antidepressants (imipramine)	Sedation	Administer later in the day	Blood pressure, pulse, sleeping pattern
	Cardiac conduction delay, dizziness, ↑ pulse	↓ Dose or change medication	Evaluate every 3 days until stable dose is achieved; then evaluate every 3 months
	Anticholinergic effects (constipation, dry mouth, difficulty urinating, blurry vision)	↓ Dose or change medication	
Clonidine and guanfacine	Sedation, arrthymias, constipation, dizziness (↓ blood pressure)	Sedation: administer later in the day ↓ Dose or change medication	Same as above but with electrocardiogram (ECG)
Bupropion	GI upset, restlessness, sleep disturbances, rash, tics, risk of seizures	↓ Dose or change medication Tics, rash, and seizures: discontinue medication	Height, weight, blood pressure, pulse every month Eating and sleeping patterns

TABLE 39–4. 30-Day Cost[a] of Selected ADHD Medication Regimens

Generic	Regimen (Brand)	Cost[a]
Short-Acting Stimulants		
Methylphenidate		
Generic	5-, 10-, or 20-mg tab twice daily	$
Methylin®	5 mg/5 mL soln twice daily	$$
Dexmethylphenidate		
Focalin®	2.5-mg tab twice daily	$
	5- or 10-mg tab twice daily	$$
Dextroamphetamine		
Generic	5- or 10-mg tab twice daily	$
Intermediate-Acting Stimulants		
Methylphenidate		
Methylin ER®	10- or 20-mg ER tab daily	$
Dextroamphetamine[c]		
Dexedrine Spansule®	5-, 10-, or 15-mg cap daily	$$
Dextroamphetamine/amphetamine		
Generic	5-, 7.5-, 10-, 12.5-, 15-, 20-, or 30-mg tab daily	$
Extended-Acting Stimulants		
Methylphenidate		
Concerta®[c]	18-, 27-, 36-, or 54-mg tab daily	$$$
Metadate CD®[b]	10-, 20-, or 30-mg cap daily	$$$
Ritalin LA®[b]	10-, 20-, 30-, or 40-mg cap daily	$$$
Dextroamphetamine/amphetamine		
Adderall XR®[b]	5-, 10-, 15-, 20-, 25-, or 30-mg cap daily	$$$
Dexmethylphenidate		
Focalin XR®[b]	5-, 10-, or 20-mg cap daily	$$$
Non-stimulants		
Atomoxetine		
Strattera®	10-, 18-, 25-, 40-, 60-, 80-, or 100-mg cap daily	$$$$
Imipramine		
Generic	10-, 25-, or 50-mg tab twice daily	$
Clonidine		
Generic	0.1-, 0.2-, or 0.3-mg tab twice daily	$
Guanfacine		
Generic	1-mg tab twice daily	$
	2-mg tab twice daily	$$
Bupropion		
Generic	75- or 100-mg tab twice daily	$$
Wellbutrin SR®	100- or 150-mg SR tab twice daily	$$$
	200-mg SR tab twice daily	$$$$
Wellbutrin XL®	150- or 300-mg XL tab daily	$$$$

[a]Cost based on brand regimen specified without a dispensing fee or discount for a 1-month supply. Costs are current as of November 2006.
[b]Bimodal release (early then late; mimics twice daily dosing of shorter-acting stimulant counterpart).

not as effective as stimulants.[23,24] Similar results have been shown in adults.[23] Specific dosing recommendations are outlined in Table 39–2. Bupropion is well tolerated with minimal side effects (e.g., insomnia, headache, and nausea). Side effects typically disappear with continuation of therapy and are minimized with slow titration of dose. Bupropion can worsen tics and movement disorders. Bupropion is a rational choice in an ADHD patient with comorbid depression.[23] However, seizures have been associated with bupropion doses greater than 6 mg/kg per day.[25] Seizures related to high doses can be minimized by reducing the dose or switching to a longer-acting formulation. Owing to the propensity of seizures with bupropion, its use is contraindicated in patients with seizure and eating disorders.

Tricyclic Antidepressants

The tricyclic antidepressants (TCAs), such as imipramine, can alleviate symptoms of ADHD. Like bupropion, TCAs likely will improve symptoms associated with comorbid anxiety and depression. The mechanism of action of TCAs is in blocking norepinephrine transporters, thus increasing norepinephrine concentrations in the synapse; the increase in norepinephrine is believed to alleviate the symptoms of ADHD. TCAs have been demonstrated to be an effective non-stimulant option for ADHD but less effective than stimulants. However, their use in ADHD has declined owing to case reports of sudden death and anticholinergic side effects[6,13] (Table 39–3). Further, TCAs may lower seizure threshold and increase the risk of cardiotoxicity, (e.g., arrythmias). Patients starting on TCAs should have a baseline and routine electrocardiograms.

Clonidine and Guanfacine

Clonidine and guanfacine are central α_2-adrenergic agonists that inhibit the release of norepinephrine presynaptically. Both these agents are less effective than stimulants in treating symptoms of ADHD but typically are used as adjuncts to stimulants to control disruptive or aggressive behavior and alleviate insomnia.[26] Guanfacine will last 3 to 4 hours longer than clonidine and requires less frequent dosing. Common side effects with clonidine and guanfacine are low blood pressure and sedation. Sedation is transient and should subside after 2 to 3 weeks of therapy.[26] Rarely, severe side effects such as bradycardia, rebound hypertension, irregular heart beats, and sudden death have been reported.

Pharmacoeconomic and Treatment Adherence Considerations

Proper ADHD treatment is a substantial financial burden.[27,28] Annual health care costs of patients with ADHD are more than double those of patients without ADHD ($1343 versus $503, respectively).[27] Further, the total cost of ADHD in the United States in 2000 was $31.6 billion.[28] The financial burden of ADHD can be attributed to the direct cost of pharmacotherapy, office visits, diagnostic measurements, therapy monitoring, and indirect costs (e.g., lost work time and productivity). It is estimated that children with ADHD are up to nine times more likely than other children to have prescriptions filled and incur office visits.

When selecting a treatment for an ADHD patient, the cost burden to the patient's family should be considered. Immediate-release stimulants may be more cost-effective in many patients compared with longer-acting stimulant formulations (Table 39–4), but in certain circumstances, longer-acting stimulant formulations may provide a cost benefit owing to increased adherence to the medication and prolonged control of symptoms of ADHD. Some non-stimulant ADHD medications (e.g., TCAs, α_2-adrenergic agonists, and bupropion) appear to be less costly than many stimulant formulations; however, these agents have not been proven to have superior efficacy over stimulants in treating ADHD. Decisions on selection of specific ADHD medications should not be based solely on cost, but efficacy and safety, along with adherence to the prescribed regimen, should be considered foremost.

OUTCOME EVALUATION

It is important to carefully document core ADHD symptoms at baseline to provide a reference point from which to evaluate effectiveness of treatment. Improvement in individualized patient outcomes are desired, such as (1) family and social relationships, (2) disruptive behavior, (3) completing required tasks, (4) self-motivation, (5) appearance, and (6) self-esteem. It is very important to elicit evaluations of the patient's behavior from family, school, and social environments in order to assess the preceding. Using standardized rating scales (e.g., Conners Rating Scales–Revised, Brown Attention-Deficit Disorder Scale, and IOWA Conners Scale) in both children and adults with ADHD helps to minimize variability in evaluation.[29] After initiation of therapy, evaluations should be done every 2 to 4 weeks to determine efficacy of treatment, height, weight, pulse, and blood pressure. Physical examination or liver function tests may be used to monitor for adverse effects.

Typically, therapeutic benefits will be seen within days of initiating stimulants and within a month or two with atomoxetine and bupropion. Once a maintenance dosing has been achieved, schedule follow-up visits every 3 months. At these visits, assess height and weight, and screen for possible adverse drug effects. If a patient has failed to respond to multiple agents, re-evaluate for other possible causes of behavior dysfunction. Counsel patients and their families that treatment is generally long term. Typically, appropriately treated patients learn to better control their ADHD symptoms as adults.

Patient Care and Monitoring

1. Assess the patient's symptoms and parent/teacher evaluations to determine whether they meet the DSM-IV-TR diagnostic criteria for ADHD. Evaluate whether the symptoms can be explained by another disorder.
2. Interview the patient and/or caregivers to obtain a complete medical history, which should include family medical history, current and past prescription and non-prescription medications, and dietary intake. Determine whether the patient is taking medication/supplements that could interfere with the therapy.
3. Educate the patient's parents and/or caregivers that behavioral therapy is not as effective as stimulant therapy. Educate parents regarding the issues of growth delay and substance abuse risks with stimulants.
4. Perform a baseline physical examination before starting stimulant therapy. Include blood pressure, pulse, and height and weight measurements. In patients taking stimulants, perform a general physical examination yearly, and monitor blood pressure quarterly in adults.
5. Start patients on a low initial dose of a stimulant and titrate up to the desired response in order to minimize side effects and costs.
6. If the patient is not responding to therapy after an adequate trial, assess compliance with the prescribed regimen. If the patient is not compliant, counsel the patient and caregivers and explore reasons for non-compliance. In some cases, switching to another stimulant formulation may improve compliance.
7. Important counseling points to convey to the patient and/or caregiver:
   - What is ADHD?
   - What are the complications of untreated ADHD?
   - When to take medications and what to expect with therapy.
   - What side effects to expect and what to do if these occur.
   - Controversy over substance abuse and growth delay with stimulant therapy.
   - What medications, prescription and non-prescription, to avoid.

40 Diabetes Mellitus

Christopher L. Cook, John T. Johnson, and William E. Wade

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Discuss the incidence and economic impact of diabetes.
2. List screening and diagnostic criteria for diabetes.
3. Distinguish clinical differences in type 1, type 2, and gestational diabetes mellitus.
4. Discuss therapeutic goals for blood glucose, blood pressure, and lipids for a patient with diabetes.
5. Recommend nonpharmacologic therapies, including meal planning and physical activity, for patients with diabetes.
6. Compare oral agents used in treating diabetes by their mechanisms of action, time of action, side effects, contraindications, and effectiveness.
7. Select appropriate insulin therapy based on onset, peak, and duration of action.
8. Develop a comprehensive therapeutic patient monitoring plan for a patient with diabetes based on patient-specific factors.

Key Concepts

❶ Diabetes mellitus (DM) describes a group of chronic metabolic disorders that are characterized by hyperglycemia and are associated with long-term microvascular, macrovascular, and neuropathic complications.

❷ Glycemic control remains the primary objective in managing diabetes and its complications.

❸ Type 2 DM is the most prevalent form of diabetes and accounts for approximately 90% to 95% of all diagnosed cases. Type 2 DM is usually slow and progressive in its development and often is preceded by pre-diabetes. Rising blood glucose levels result from increasing insulin resistance and impaired insulin secretion leading to a situation of relative insulin deficiency.

❹ Although type 1 DM may appear at any age, it is encountered most commonly in individuals younger than 30 years of age. Type 1 DM is characterized by an absolute deficiency in insulin resulting from pancreatic β-cell destruction.

❺ Patients and clinicians can evaluate blood glucose control through a combination of self-monitoring of blood glucose data and hemoglobin HbA_{1c} testing.

❻ Several classes of oral agents are available to treat patients with type 2 DM who are unable to achieve glycemic control through diet and exercise.

❼ Insulin is the essential treatment for patients with type 1 DM and can overcome insulin resistance in patients with type 2 DM.

❶ ***Diabetes mellitus*** *(DM) describes a group of chronic metabolic disorders characterized by* ***hyperglycemia*** *that may result in long-term microvascular, macrovascular, and neuropathic complications.* These complications contribute to diabetes being the leading cause of (1) new cases of blindness among adults, (2) end-stage renal disease, and (3) non-traumatic lower limb amputations. In addition, the increased cardiovascular risk associated with DM contributes to it being the sixth leading cause of death in the United States. The financial impact of DM in 2002 was approximately $132 billion, or 1 of every 10 dollars spent on health care in the United States. This averages to an annual health care cost of $13,243 for patients with diabetes versus $2560 for those without diabetes.[1]

While prevention and treatment of DM remain a challenge, several landmark studies have shown that complications associated with DM can be delayed or prevented through proper

blood glucose management.[2,3] ❷ Thus, *glycemic control remains the primary objective in diabetes management.*

EPIDEMIOLOGY AND ETIOLOGY

DM is characterized by a complete lack of insulin, a relative lack of insulin, or insulin resistance. These defects result in an inability to properly use glucose for energy. DM affects an estimated 20.8 million persons in the United States, or 7% of the population. While an estimated 14.6 million persons have been diagnosed, another 6.2 million people who have DM are unaware they have the disease. Worldwide, the number of people with DM is expected to rise to 35% by the year 2025.[1]

The increasing prevalence of DM is due in part to three influences: lifestyle, ethnicity, and age. Sedentary lifestyle coupled with greater consumption of high-fat foods and larger portion sizes has resulted in increasing rates of persons being overweight or obese. Current estimates indicate that 65% of the United States population is overweight and 30% is obese. Overweight is defined as **body mass index** (BMI) of greater than 25 kg/m^2, whereas a BMI of greater than 30 kg/m^2 constitutes obesity. The Centers for Disease Control and Prevention (CDC) estimates that 25% to 33% of Americans do not engage in an adequate amount of daily activity.[4] Compounding this lifestyle trend, certain ethnic groups are at a disproportionately high risk of DM. Individuals of Native American and Alaskan native, African-American, and Hispanic/Latino-American descent have a 1.7 to 2.2 times greater risk of developing DM compared with non-Hispanic whites.[1] In addition, African-American and Hispanic/Latino-American populations are growing at a faster rate than the general United States population. The third contributing factor is increasing age. The prevalence of DM increases with age from approximately 2% of individuals 20 to 39 years of age to 20.9% of individuals older than 60 years of age.[1] As the population ages, the incidence of DM is expected to increase.

❸ *Type 2 DM, previously referred to as* adult-onset *or* non-insulin-dependent DM, *is the most prevalent form of the disease and accounts for approximately 90% to 95% of all diagnosed cases.*[1] Type 2 DM is characterized by a relative insulin deficiency and insulin resistance.

❸ *Type 2 DM is usually slow and progressive in its development and often is preceded by* ***pre-diabetes****.* The development of pre-diabetes places the individual at high risk of eventually developing diabetes. It is currently estimated that 41 million persons in the United States have pre-diabetes. Pre-diabetes is defined as having either a fasting and/or a postprandial blood glucose level higher than normal but not high enough to be classified as DM. Because progression from pre-diabetes to diabetes is not inevitable, interventions during pre-diabetes are gaining popularity.

Risk factors for type 2 diabetes include:

- First-degree family history of DM (i.e., parents or siblings)
- Overweight or obese
- Habitual physical inactivity
- Race or ethnicity (Native American, Latino/Hispanic-American, Asian-American, African-American, and Pacific Islanders)
- Pre-diabetes (i.e., previously identified with impaired glucose tolerance or impaired fasting glucose)
- Hypertension (Greater than or equal to 140/90 mm Hg)
- High-density lipoprotein (HDL) less than 35 mg/dL (0.91 mmol/L) and/or a triglyceride level greater than 250 mg/dL (2.83 mmol/L)
- History of gestational diabetes or delivery of a baby weighing greater than 9 pounds (4.09 kg)
- History of vascular disease
- History of polycystic ovary disease
- Other conditions associated with insulin resistance (e.g., **acanthosis nigricans**)[5]

Type 1 DM, previously referred to as *insulin-dependent* or *juvenile-onset DM,* constitutes 5% to 10% of all diagnosed cases of DM. ❹ *Type 1 DM usually is diagnosed in children and adults younger than 30 years of age, although the disease can present at any age. This form of the disease is characterized by an absolute deficiency in insulin resulting from pancreatic β-cell destruction.* Latent autoimmune diabetes in adults (LADA), slow-onset type 1 or type 1.5 DM, is a form of autoimmune type 1 diabetes that occurs in individuals older than the usual age of onset. Patients often are mistakenly thought to have type 2 diabetes because the person is older and may respond initially to treatment with oral hypoglycemic agents. However, these patients do not have insulin resistance, but antibodies are present in the blood that are known to destroy pancreatic β-cells.

It has been suggested that the easiest way to differentiate between type 1 and type 2 DM is by measuring C-peptide levels. Type 1 diabetics have C-peptide levels below 1 ng/mL (0.33 nmol/L), whereas those with type 2 disease will have values greater than 1 ng/mL (0.33 nmol/L).

Glucose intolerance diagnosed in women during pregnancy is called gestational diabetes mellitus (GDM) and occurs in approximately 7% of all pregnancies. Women who have GDM have a 20% to 50% chance of developing diabetes within 5 to 10 years. Risk factors for GDM include obesity, **glycosuria,** strong family history of DM, age greater than 35 years of age, pre-diabetes detected before pregnancy, previous delivery of babies with birth weights greater than 9 pounds (4.09 kg), and ethnicity (African-American, Hispanic/Latino-American, or Native American). Clinical detection of and therapy for GDM are important because blood sugar control produces significant reductions in perinatal morbidity and mortality.

Rare forms of DM have been reported and account for 1% to 5% of all diagnosed cases. Causes of these rare forms of DM include specific genetic conditions, surgery, drugs, malnutrition,

TABLE 40–1. Medications That May Affect Glycemic Control[a]

Drug	Effect on Glucose	Mechanism/Comment
Angiotensin-converting enzyme inhibitors	Slight reduction	Improves insulin sensitivity
Alcohol	Reduction	Reduces hepatic glucose production
α-Interferon	Increase	Unclear
Diazoxide	Increase	Decreases insulin secretion, decreases peripheral glucose use
Diuretics	Increase	May increase insulin resistance
Glucocorticoids	Increase	Impairs insulin action
Nicotinic acid	Increase	Impairs insulin action, increases insulin resistance
Oral contraceptives	Increase	Unclear
Pentamidine	Decrease, then increase	Toxic to β-cells; initial release of stored insulin, then depletion
Phenytoin	Increase	Decreases insulin secretion
β-Blockers	May increase	Decreases insulin secretion
Salicylates	Decrease	Inhibition of I-kappa-B kinase-beta (IKK-beta) (only high doses, e.g., 4–6 g/day)
Sympathomimetics	Slight increase	Increased glycogenolysis and gluconeogenesis
Clozapine and olanzapine	Increase	Unclear; weight gain

[a]This list is not inclusive of all medications reported to cause glucose changes.
Reproduced, with permission, from DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiological Approach*. 6th ed. New York: McGraw-Hill; 2005, Table 72–10, p. 1346.

infections, and other illnesses. Table 40-1 contains a list of medications that may affect glycemic control. While the use of these medications is not contraindicated in persons with DM, caution and awareness of the effects on blood glucose should be taken into account when managing patient care.

PATHOPHYSIOLOGY

Normal Carbohydrate Metabolism

The body's main energy source is the metabolism of glucose. Cells metabolize glucose completely through glycolysis and the Kreb cycle, producing water and carbon dioxide as waste products. Glucose not immediately needed for energy is stored in the liver and muscles as glycogen. Later, when energy is needed, **glycogenolysis** converts stored glycogen back to glucose. Excess glucose also can be converted to triglycerides and stored in fat cells. Triglycerides subsequently undergo lipolysis, yielding glycerol and free fatty acids. While usually reserved for other functions, proteins also can be converted to glucose through a process called **gluconeogenesis.** Normal homeostasis is achieved through a balance of the metabolism of glucose, free fatty acids, and amino acids to maintain a blood glucose level sufficient to provide an uninterrupted supply of glucose to the brain.[6]

Insulin and glucagon are produced in the pancreas by cells known as islets of Langerhans. β-Cells make up 70% to 90% of the islets and produce insulin, whereas β-cells produce glucagon. The main function of insulin is to decrease blood glucose levels, whereas glucagon, along with other counterregulatory hormones, such as growth factor, cortisol, and epinephrine, increase blood glucose levels. While blood glucose levels vary, the opposing actions of insulin and glucagon, along with the counterregulatory hormones, maintain these values between 70 and 120 mg/dL (3.89 and 6.66 mmol/L).

Type 1 Diabetes

❹ *The primary defect in type 1 DM is an absolute insulin deficiency resulting from pancreatic β-cell destruction.* β-Cell destruction is most commonly the result of an autoimmune process usually precipitated through genetic susceptibility and/or an environmental trigger. Certain genetic markers can be measured to determine if a person is at risk of diabetes. The presence of human leukocyte antigens (HLAs), especially HLA-DR, is strongly associated with the development of type 1 diabetes. Over 95% of people with type 1 DM have HLA-DR3 and HLA-DR4 present. In addition, persons with DM often develop islet-cell antibodies, insulin autoantibodies, or glutamic acid decarboxylase autoantibodies. More than 90% of persons with type 1 DM have at least one diabetes-related antibody present. As more β-cells are destroyed, glucose metabolism becomes compromised due to reduced insulin release following a glucose load. At the time of diagnosis, most patients have a 90% loss of β-cell function. The remaining 10% of β-cell function at diagnosis creates a "honeymoon period" during which blood glucose levels are easier to control and smaller amounts of insulin are required. Once this remaining β-cell function is lost, patients become completely insulin-deficient and require more exogenous insulin. Figure 40–1 describes the progression of type 1 DM.

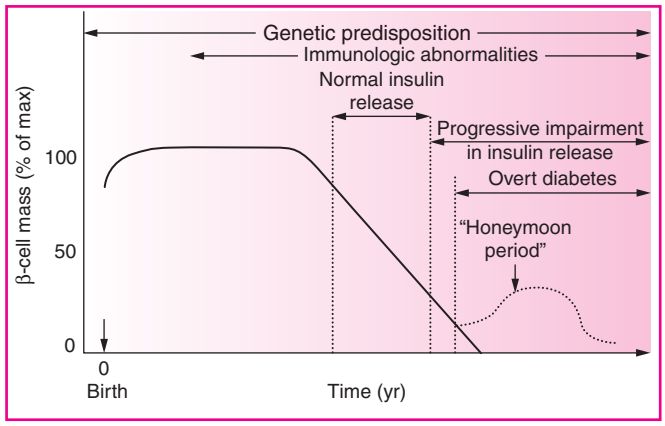

FIGURE 40–1 Scheme of the natural history of the β-cell defect in type 1 diabetes mellitus. (Used, with permission, from DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiological Approach*. 6th ed. New York: McGraw-Hill; 2005, Fig. 72–4, p. 1339.) yr, year.

Type 2 Diabetes

Type 2 DM is characterized by a slow, gradual onset of hyperglycemia that often is asymptomatic. The underlying metabolic dysfunction contributing to this disease is thought to be a combination of both genetic and environmental factors. ❸ *Rising blood glucose levels result from increasing insulin resistance and impaired insulin secretion leading to relative insulin deficiency.* Prior to describing these two insulin defects, it is necessary to understand normal insulin action and its role in glucose control.

Normal Insulin Action

During periods of fasting, most circulating glucose is produced in the liver by glycogenolysis. This **endogenous** production of glucose serves to ensure the brain a constant glucose supply. Insulin secretion during fasting periods is a low, steady basal rate of 0.5 to 1 units/hour.[6] On eating, blood glucose levels rise, and the insulin-secretion response occurs in two phases. An initial burst, known as *first phase insulin response,* lasts approximately 10 minutes and serves to suppress hepatic glucose production. This bolus of insulin minimizes hyperglycemia during meals and during the postprandial period. The loss of this first phase insulin response is an early event in the progression from glucose intolerance to DM. The *second phase of insulin response* is characterized by a gradual increase in insulin secretion, which stimulates glucose uptake by peripheral insulin-dependent tissues. Approximately 80% to 85% of glucose metabolism during this time occurs in muscle. The slower release of insulin allows the body to respond to the new glucose entering from digestion while maintaining blood glucose levels.

Impaired Insulin Secretion

A pancreas with normal β-cell function is able to adjust insulin production to maintain normal blood glucose levels. **Hyperinsulinemia,** or high blood levels of insulin, is an early finding in the development of type 2 DM. More insulin is secreted to maintain normal blood glucose levels until eventually the pancreas can no longer produce sufficient insulin. The resulting hyperglycemia is enhanced by extremely high insulin resistance, pancreatic burnout in which β-cells lose functional capacity, or both. Patients with type 2 DM typically have approximately 40% β-cell function at diagnosis. Decreasing β-cell function also results in a reduced ability to produce a first-phase insulin response sufficient to signal the liver to stop producing glucose during the fed state. As DM progresses, large numbers of patients with type 2 disease eventually lose all β-cell function and require **exogenous** insulin to maintain blood glucose control.

Insulin Resistance

Insulin resistance is the primary factor that differentiates type 2 DM from other forms of diabetes. Insulin resistance may be present up to 10 years prior to the diagnosis of DM and can continue to progress throughout the course of the disease. Resistance to insulin occurs most significantly in skeletal muscle and the liver. Insulin resistance in the liver poses a double threat because the liver becomes non-responsive to insulin for glucose uptake, and hepatic production of glucose during the fed state does not cease. Hyperglycemia results because ingested glucose and continued hepatic glucose production combine to raise blood glucose levels.

Metabolic Syndrome

Insulin resistance has been associated with a number of other cardiovascular risks, including abdominal obesity, hypertension, dyslipidemia, hypercoagulation, and hyperinsulinemia. The clustering of these risk factors has been termed metabolic syndrome. It is estimated that 50% of the United States population older than 60 years of age have metabolic syndrome. The most widely used criteria to define metabolic syndrome were established by the National Cholesterol Education Program Adult Treatment Panel III Guidelines (summarized in Table 40–2).

TABLE 40–2. Five Components of Metabolic Syndrome[20]

Risk Factor	Defining Level
1. Abdominal obesity	
• Men	Waist circumference greater than 102 centimeters (40 inches)
• Women	Waist circumference greater than 88 centimeters (35 inches)
2. Triglycerides	Greater than 150 mg/dL (1.70 mmol/L)
3. HDL cholesterol	
• Men	Less than 40 mg/dL (1.04 mmol/L)
• Women	Less than 50 mg/dL (1.3 mmol/L)
4. Blood pressure	Greater than or equal to 130/85 mm Hg
5. Fasting glucose	Greater than or equal to 100 mg/dL (5.55 mmol/L)

Note: Individuals having at least three of the five above meet the diagnostic criteria for metabolic syndrome.

Patients having this convergence of factors have been found to be at a much higher cardiovascular risk than would be expected from the individual components of the syndrome. Therefore, it is important to assume a more aggressive treatment plan for each of the individual abnormal components. Since pre-diabetes and DM are one of the component risk factors in the diagnostic criteria, a patient with pre-diabetes or DM having the convergence of factors may be treated more aggressively than a patient having pre-diabetes or DM alone.

CLINICAL PRESENTATION AND DIAGNOSIS

Screening

Currently, the American Diabetes Association (ADA) recommends routine screening for type 2 DM every 3 years in all adults starting at 45 years of age. Earlier and more frequent screening should be reserved for patients who are at higher risk. The ADA does not recommend screening for type 1 diabetes owing to the low incidence and acute presentation of symptoms.[7] See Table 40–3 for complete screening guidelines.

Gestational Diabetes

Risk assessment for GDM should be performed early in pregnancy with a random glucose test. If the normal diagnostic threshold for diabetes is exceeded during the first test and confirmed on a subsequent day, a diagnosis of GDM can be made. Otherwise, all women should be screened with an oral glucose tolerance test (OGTT) between weeks 24 and 28 of gestation unless they are in the low-risk category. The diagnostic

Patient Encounter, Part 1

MF is a large-framed 32-year-old Caucasian man who is 5 ft, 10 in (178 cm) tall and weighs 295 lb (134 kg). He has not been to the doctor in 5 years. He is diagnosed with irritable bowel syndrome today. He visits the local free clinic, and the following is discovered when labs and physical assessment are performed:

Fasting glucose: 189 mg/dL (10.49 mmol/L)
BUN: 13 mg/dL (4.64 mmol/L)
Creatinine: 1.2 mg/dL (106 µmol/L)
AST/SGOT: 26 IU/L (0.43 µKat/L)
ALT/SGPT: 26 IU/L (0.43 µKat/L)
TSH: 1.264 microunits/mL (1.26 mU/L)
Total cholesterol: 277 mg/dL (7.17 mmol/L)
LDL: 187 mg/dL (4.84 mmol/L)
HDL: 29 mg/dL (0.75 mmol/L)
Triglycerides: 305 mg/dL (3.45 mmol/L)
Hemoglobin A_{1c}: 11%
BP (blood pressure): 167/98 mm Hg

- What information is suggestive of diabetes?
- What criteria must be met before a diagnosis of diabetes can be made?
- What type of diabetes do you think MF has based on his clinical characteristics?
- What challenges can you identify for optimal clinical outcomes through the initial assessments for MF?
- What additional information do you need to know before creating a treatment plan for this patient?

Typical Clinical Presentation of Diabetes Mellitus

Characteristic	Type 1 DM	Type 2 DM
Age of onset	Childhood or adolescence	Greater than 40 years of age
Speed of onset	Abrupt	Gradual
Family history	Negative	Positive
Body type	Thin	Obese or history of obesity
Metabolic syndrome	No	Often
Autoantibodies	Present	Rare
Symptoms	**Polyuria**, **polydipsia**, **polyphagia**, rapid weight loss	Asymptomatic
Ketones at diagnosis	Present	Uncommon
Acute complications	**Diabetic ketoacidosis (DKA)**	Rare
Microvascular complications at diagnosis	Rare	Common
Macrovascular complications at or before diagnosis	Rare	Common

TABLE 40–3. American Diabetes Association Screening Recommendations for Diabetes Mellitus[5]

Asymptomatic Type 1

The American Diabetes Association does not recommend screening for type 1 diabetes due to the low incidence in the general population and to the acute presentation of symptoms.

Asymptomatic Type 2

1. The American Diabetes Association recommends screening for type 2 diabetes every 3 years in all adults beginning at 45 years of age, particularly in those with a body mass index greater than or equal to 25 kg/m^2.
2. Testing should be considered for persons younger than 45 years of age or more frequently in individuals who are overweight (body mass index greater than or equal to 25 kg/m^2) and have additional risk factors:

- Habitually inactive
- First-degree relative with diabetes
- Member of a high-risk ethnic population (e.g., African-American, Latino, Native American, Asian-American, Pacific Islander)
- Delivered a baby weighing greater than 9 lb (4.09 kg) or previous diagnosis of gestational diabetes mellitus
- Hypertensive (greater than or equal to 140/90 mm Hg)
- High density lipoprotein (HDL) cholesterol level less than 35 mg/dL (0.91 mmol/L) and/or a triglyceride level greater than 250 mg/dL (2.83 mmol/L)
- Polycystic ovary syndrome
- Previous impaired glucose tolerance or impaired fasting glucose
- Other clinical conditions associated with insulin resistance (e.g., acanthosis nigricans)
- History of vascular disease

Type 2 in Children and Adolescents

Criteria:

- Overweight (body mass index greater than 85th percentile for age and sex, weight for height greater than 85th percentile, or weight greater than 120% of ideal for height)

Plus any **two** of the following risk factors:

- Family history of type 2 diabetes in first- or second-degree relatives
- Race/ethnicity (Native American, African-American, Latino/Hispanic-American, Asian-American, Pacific Islander)
- Signs of insulin resistance or conditions associated with insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, or polycystic ovary disease)

Age of initiation: Age 10 or at onset of puberty, if puberty occurs at a younger age
Frequency of testing: Every 2 years
Test method: Fasting plasma glucose preferred
Clinical judgment should be used to test for diabetes in high-risk patients who do not meet these criteria.

Gestational Diabetes

1. Risk assessment performed at first prenatal visit with random glucose screen.
2. All women should be screened with an oral glucose tolerance test between weeks 24 and 28 of gestation unless they are in the low-risk category.

criteria for OGTT are listed in Table 40–4. Women considered low risk include those of normal weight before pregnancy; younger than 25 years of age; without first-degree relatives with diabetes; non-Hispanic, African-American, or Native American ethnicity; and no prior history of glucose intolerance or poor obstetric outcome.[5]

Any woman diagnosed with GDM should be retested at 6 weeks postpartum. If the fasting plasma glucose (FPG) level is normal, then reassessment for DM should occur every 3 years. Family planning for subsequent pregnancies should be discussed, and monitoring for the development of symptoms of DM should be undertaken.

TABLE 40–4. Diagnosis of Gestational Diabetes with a 100 or 75 g Glucose Load[8]

	Plasma Glucose	
Time	**mg/dL**	**mmol/L**
100 g Glucose Load		
Fasting	95	5.3
1 hour	180	10.0
2 hours	155	8.6
3 hours	140	7.8
75 g Glucose Load		
Fasting	95	5.3
1 hour	180	10.0
2 hours	155	8.6

Note: Two or more venous plasma concentrations must be met or exceeded for a positive diagnosis of diabetes to be made. The test should be done in the morning after an 8- to 14-hour fast and after at least 3 days of unrestricted diet and unlimited physical activity. The patient should remain seated and should not smoke during the test.

Diagnostic Criteria

Diagnosis of DM includes glycemic outcomes exceeding threshold values with one of three testing options (Table 40–5). Confirmation of abnormal values must be made on a subsequent

TABLE 40–5. Criteria for the Diagnosis of Diabetes Mellitus[5]

1. Symptoms of diabetes plus a casual plasma glucose concentration greater than or equal to 200 mg/dL (11.1 mmol/L). *Casual* is defined as any time of day without regard to time since last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.

or

2. Fasting plasma glucose greater than or equal to 126 mg/dL (7.0 mmol/L). *Fasting* is defined as no caloric intake for at least 8 hours.

or

3. Two-hour postload glucose greater than or equal to 200 mg/dL (11.1 mmol/L) during an oral glucose tolerance test. The test should be performed as described by the World Health Organization, using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.

Note: In the absence of unequivocal hyperglycemia, these criteria should be confirmed by repeat testing on a different day. The oral glucose tolerance test is not recommended for routine clinical use.

day for diagnosis unless unequivocal symptoms of hyperglycemia exist, such as polydipsia, polyuria, and polyphagia. The ADA recommends FPG determination as the principal tool for diagnosis of DM in non-pregnant adults owing to ease of use, acceptability to patients, and lower cost.[7] While the OGTT is more sensitive and modestly more specific than FPG determination, it is difficult to reproduce the results and is rarely performed in practice today.

The ADA categorizes patients demonstrating impaired fasting glucose (IFG) or impaired glucose tolerance (IGT) as having pre-diabetes.[8] The categorization thresholds of glucose status for FPG determination and the OGTT are listed in Table 40–6. These two conditions may co-exist or may be identified independently. FPG level represents hepatic glucose production during the fasting state, whereas postprandial glucose levels in the OGTT may reflect glucose uptake in peripheral tissues, insulin sensitivity, or a decreased first-phase insulin response.

TABLE 40–6. Categorization of Glucose Status[8]

	mg/dL	mmol/L
Fasting Plasma Glucose (FPG)		
• Normal	Less than 100	Less than 5.6
• Impaired fasting glucose (IFG)	100–125	5.6–6.9
• Diabetes mellitus[a]	Greater than or equal to 126	7.0
2-Hour Postload Plasma Glucose (Oral glucose tolerance test)		
• Normal	Less than 140	7.8
• Impaired glucose tolerance (IGT)	140–199	7.8–11.0
• Diabetes mellitus[a]	Greater than or equal to 200	11.1

[a]Provisional diagnosis of diabetes (diagnosis must be confirmed; see Table 40–5).

TREATMENT

Goals of Therapy

DM treatment goals include reducing long-term microvascular and macrovascular complications, preventing acute complications from high blood glucose levels, minimizing hypoglycemic episodes, and maintaining the patient's overall quality of life. To achieve these goals, near-normal blood glucose levels are fundamental. Two landmark trials, the Diabetes Control and Complications Trial[2] and the United Kingdom Prospective Diabetes Study,[3] showed that lowering blood glucose levels decreased the risk of developing chronic complications. A near-normal blood glucose level can be achieved with appropriate patient education. Proper care of DM requires goal setting and assessment for glycemic control, self-monitoring of blood glucose (SMBG) level, monitoring of blood pressure and lipid levels, regular monitoring for the development of complications, dietary and exercise lifestyle modification, and proper medication use. The complexity of proper DM self-care principles has a dramatic impact on a patient's lifestyle and requires a highly disciplined and dedicated person to maintain long-term control.

Setting and Assessing Glycemic Targets

❺ *Patients and clinicians can evaluate blood glucose control through the combination of the self-monitoring of blood glucose data and the hemoglobin A_{1c} (HbA_{1c}) test.* Self-monitoring of blood glucose enables patients to obtain their current blood glucose level at any time easily and relatively inexpensively. The HbA_{1c} test provides a weighted-mean blood glucose level from the previous 3 months.

Self-Monitoring of Blood Glucose

Self-monitoring of blood glucose is the standard method for routinely checking blood glucose levels. Each reading provides a point-in-time evaluation of glucose control that can vary widely depending on numerous factors, including food, exercise, stress, and time of day. By examining multiple individual points of data, patterns of control can be established. Therapy can be evaluated from these patterns, and adjustments can be made to improve overall blood glucose control. The ADA pre-meal plasma glucose goals are 90 to 130 mg/dL (5–7.22 mmol/L), and peak postprandial plasma glucose goals are less than 180 mg/dL (10 mmol/L).[5] The American Association of Clinical Endocrinologists (AACE) supports tighter SMBG controls, with pre-meal goals of less than 110 mg/dL (6.11 mmol/L) and peak

post-meal goals of less than 140 mg/dL (7.77 mmol/L).[9] For patients with type 1 DM, the ADA recommends that SMBG be performed at least three times daily. The frequency of testing in patients with type 2 DM is still controversial. The ADA recommends testing frequently enough to gain and maintain blood glucose control. While the majority of practitioners recommend SMBG to their patients with type 1 DM, the role of SMBG in improving glucose control in type 2 DM is unproven.[10]

Typically, in SMBG, a drop of blood is placed on a test strip that is then read by a glucometer. Recent technological advancements have decreased the blood sample size required to as small as 0.3 microliters, provided the capability of alternate site testing, and provided readings in as few as 5 seconds. Many SMBG devices can download or transfer information to a computer program that can summarize and produce graphs of the data. Identifying patterns in the patient's blood glucose data can aid practitioners in modifying treatment for better glucose control. Specific therapy adjustment can be made for patterns found at certain times of the day, on certain days, or with large day-to-day variances. While most testing occurs by lancing the fingertip to produce a blood droplet, alternate-site testing has been approved for testing the palm, arm, leg, and abdomen. Alternate-site testing was developed as a means to decrease the pain encountered with repeated fingersticks by using body locations that have a lower concentration of nerve endings.

In choosing a glucose meter for a patient, several additional factors may aid in the best selection for the patient. Larger display areas or units with audible instructions and results may be better suited for older individuals and those with visual impairment. Patients with arthritis or other conditions that decrease dexterity may prefer larger meters with little or no handling of glucose strips. Younger patients or busy professionals, on the other hand, may prefer the smaller meters with features such as faster results, larger memories, reminder alarms, and downloading capabilities that facilitate individuals checking their blood glucose levels.

Hemoglobin A_{1c}

Hemoglobin A_{1c} (HbA_{1c}) is the "gold standard" for evaluating long-term glycemic control.[11] Glucose interacts spontaneously with hemoglobin in red blood cells to form glycosylated derivatives. The most prevalent derivative is HbA_{1c}. Greater amounts of glycosylation occur when blood glucose levels increase. Because hemoglobin has a life span of approximately 120 days, levels of HbA_{1c} provide a marker reflecting the average glucose levels over this timeframe. The ADA goal for persons with DM is less than 7%, whereas the AACE supports a goal of less than 6.5%. Testing HbA_{1c} levels should occur at least twice a year for patients who are meeting treatment goals and four times per year for patients not meeting goals or those who have had recent changes in therapy.[5]

Blood Pressure, Lipids, and Monitoring for Complications

The ADA standards of medical care address many of the common comorbid conditions, as well as complications that result from the progression of DM. Table 40–7 presents goals for blood pressure measurements, lipids values, and monitoring parameters for complications associated with diabetes.

General Approach to Therapy

Type 1 DM

Treatment of type 1 DM requires providing exogenous insulin to replace the endogenous loss of insulin from the non-functional pancreas. Ideal insulin therapy mimics normal insulin physiology.

Patient Encounter, Part 2: The Follow-up Visit

MF comes back 1 week later for you to review the laboratory results with him and to determine if medications are necessary. When you check his FBG level today, the result is 210 mg/dL (11.7 mmol/L). A diagnosis of DM is made, but you have no other blood glucose records. The following information is gained from MF during the visit:

PMH
- Occasional sinus infections over the last several years
- Reports last eye examination about 6 years ago; believes he could use new glasses
- No other problems reported

FH
- Father: 64 years of age; history of alcohol abuse, hypertension, and myocardial infarction
- Mother: 62 years of age; history of type 2 DM, hypertension, and obesity
- Sister: 34 years of age; history of hypothyroid and obesity

SH
- Drinks 3 to 4 times per week and smokes cigarettes 1 to 2 packs per day for 20 years
- No steady employment

Meal history
Usually has a donut and large coffee in the mornings, fast-food "value meal" for lunch, and a diner meal for supper (meat and two vegetables)

Physical activity
No regular physical activity routine but does walk around about 30 minutes a day

- What are your treatment goals for MF regarding blood glucose, blood pressure, and lipids?
- What nonpharmacologic and pharmacologic approaches are available for MF?
- Are there any specialist care providers you would refer MF to?

TABLE 40–7. American Diabetes Association Recommended Goals of Therapy

Area	Goals
Glycemia	
HbA_{1c}	Less than 7% Every 3 months until in goal; then every 6 months
Preprandial plasma glucose	90–130 mg/dL (5.0–7.2 mmol/L)
Peak postprandial plasma glucose[a]	Less than 180 mg/dL (less than 10 mmol/L)
Blood Pressure	Less than 130/80 mm Hg Evaluate at every visit
Lipids	Evaluate at least yearly
Low-density lipoprotein (LDL)	Less than 100 mg/dL (2.59 mmol/L) or less than 70 mg/dL (1.81 mmol/L) if high risk
High-density lipoprotein (HDL)	Greater than 40 mg/dL (1.04 mmol/L) for males; greater than 50 mg/dL (1.3 mmol/L) for females
Triglycerides	Less than 150 mg/dL (1.70 mmol/L)
Monitoring for Complications	
Eyes	Dilated eye exam yearly
Feet	Feet should be examined at every visit
Urinary microalbumin	Yearly

[a]Peak postprandial glucose measurements should be made 1 to 2 hours after the beginning of the meal.

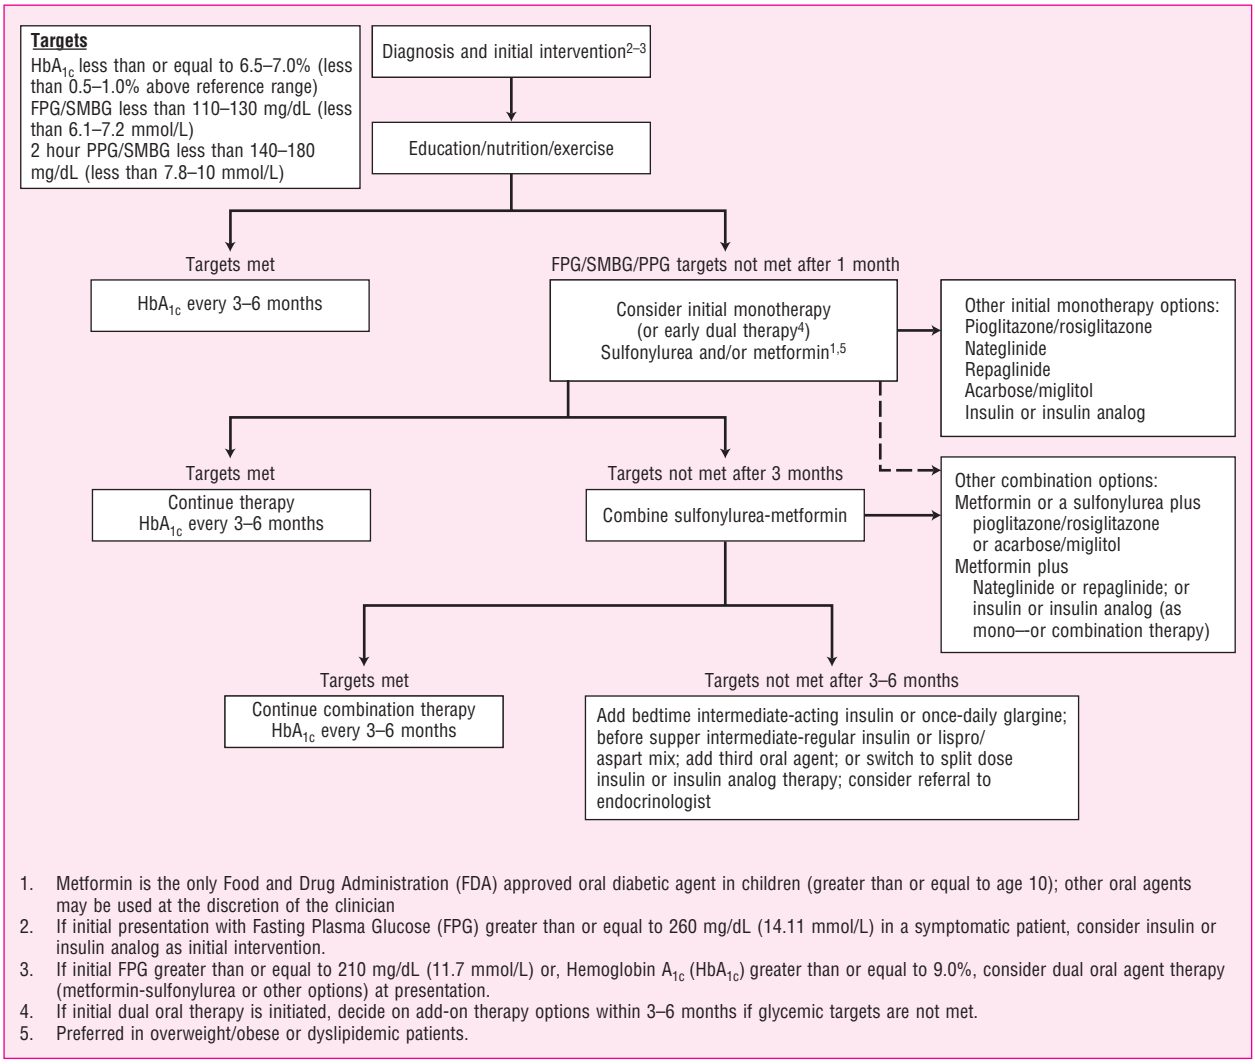
The basal-bolus approach attempts to reproduce basal insulin response through the use of intermediate- or long-acting insulin, whereas short- or rapid-acting insulin replicates bolus release of insulin physiologically seen around a meal in nondiabetics. A number of different regimens have been used through the years to more closely follow natural insulin patterns. As a general rule, basal insulin makes up approximately 50% of the total daily dose. The remaining half is provided with bolus doses around three daily meals. Exact doses are individualized to the patient and the amount of food consumed. Type 1 DM patients frequently are started on about 0.6 units/kg per day, and then doses are titrated until glycemic goals are reached. Most type 1 DM patients use between 0.6 and 1 unit/kg per day.

Currently, the most advanced form of insulin therapy is the insulin pump, also referred to as continuous subcutaneous insulin infusion (CSII). Using the short- or rapid-acting insulins only, these pumps are programmed to provide a slow release of small amounts of insulin as the basal portion of therapy, and then larger bolus doses are injected by the patient to account for the consumption of food.

Type 2 DM

Treatment of type 2 DM has changed dramatically over the past decade with the addition of a number of new drugs and the ADA recommendations to maintain tighter glycemic control. Figure 40–2 details an algorithm for type 2 diabetes. Lifestyle modifications, including education, nutrition, and exercise, are paramount to managing the disease successfully. Many patients assume that once pharmacologic therapy is initiated, lifestyle modifications are no longer necessary. Practitioners should educate patients regarding this misconception. Since type 2 diabetes is a progressive disease, blood glucose levels will eventually increase making insulin therapy and lifestyle modifications the eventual required therapy.

Gestational Diabetes



An individualized meal plan consisting of three meals and three snacks per day is recommended commonly in GDM. Preventing **ketosis,** promoting adequate growth of the fetus, maintaining satisfactory blood glucose levels, and preventing nausea and other undesired gastrointestinal side effects are desired goals in these patients. Controlling blood sugar levels is important to prevent harm to the baby. An abundance of glucose causes excessive insulin production by the fetus, which, if left uncontrolled, can lead to the development of an abnormally large fetus. Infant **hypoglycemia** at delivery, hyperbilirubinemia, and complications associated with delivery of a large baby also may occur when blood glucose levels are not controlled adequately.

Insulin should be used when blood glucose levels are not maintained adequately at target levels by diet and physical activity. Only human insulin should be used for treating GDM to prevent the transfer of anti-insulin antibodies. Oral glucose-lowering agents are not recommended during pregnancy. Additionally, women with pre-pregnancy hypertension and dyslipidemia should have their medications reevaluated at conception.

Nonpharmacologic Therapy

Diet

Despite the popular notion, there is not a "diabetic diet." The recommended diet for patients with diabetes is a meal plan low in fat, high in fiber, low to moderate in calories, and achieving a balance of the various components and nutrients needed.[12] Medical nutrition therapy (MNT) is considered an integral component of diabetes management and diabetes self-management education. People with DM should receive individualized MNT, preferably by a registered dietitian. As part of the diabetes management plan, MNT is not a single

1. Metformin is the only Food and Drug Administration (FDA) approved oral diabetic agent in children (greater than or equal to age 10); other oral agents may be used at the discretion of the clinician
2. If initial presentation with Fasting Plasma Glucose (FPG) greater than or equal to 260 mg/dL (14.11 mmol/L) in a symptomatic patient, consider insulin or insulin analog as initial intervention.
3. If initial FPG greater than or equal to 210 mg/dL (11.7 mmol/L) or, Hemoglobin A_{1c} (HbA_{1c}) greater than or equal to 9.0%, consider dual oral agent therapy (metformin-sulfonylurea or other options) at presentation.
4. If initial dual oral therapy is initiated, decide on add-on therapy options within 3–6 months if glycemic targets are not met.
5. Preferred in overweight/obese or dyslipidemic patients.

FIGURE 40–2 Glycemic control algorithm for type 2 DM in children and adults. (Adapted with permission, from DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiological Approach*. 6th ed. New York: McGraw-Hill; 2005, Fig. 72–8, p. 1356. Also refer to Nathan DM, Buse JB, Davidson MB, et al. Management of Hyperglycerin in type 2 diabetes: a consensus algorithm for the initiation and adjustment of therapy. Diabetes Care 2006; 29:1963–1972.) PPG, postprandial glucose; SMBG, self-monitoring of glucose.

visit to a dietitian but rather an ongoing continuing dialog to assist the patient to integrate healthier choices into his or her daily lifestyle decisions. As such, MNT should be customized to take into account cultural, lifestyle, and financial considerations. MNT plans should integrate a variety of foods that the patient enjoys and allow for flexibility to encourage patient empowerment and improve patient adherence.

During these MNT educational and planning sessions, patients receive instructions on appropriate food selection, preparation, and proper portion control. The primary focus of MNT for patients with type 1 DM is matching optimal insulin dosing to carbohydrate consumption. In type 2 DM, the primary focus is calorie reduction to achieve weight loss.

The ADA does not recommend low-carbohydrate diets in diabetes management. Although carbohydrates are a primary contributor to post-meal glucose levels, they are also an important source of energy, water-soluble vitamins, minerals, and fiber. Thus, the ADA recommends that carbohydrate intake consists of 45% to 65% of total calories.

Weight Management

Moderate weight loss has been shown to reduce cardiovascular risk, as well as delay or prevent the onset of DM in those with pre-diabetes. The recommended primary approach to weight loss is therapeutic lifestyle change (TLC), which integrates a 500 to 1000 kcal/day reduction in calorie intake and

an increase in physical activity.[12] A slow but progressive weight loss of 1 to 2 lb (0.45–0.91 kg) per week is preferred. While individual target caloric goals should be set, a general rule for weight-loss diets is that they should supply at least 1000 to 1200 kcal/day for women and 1200 to 1600 kcal/day for men. Since 80% of patients with type 2 diabetes are overweight, this strategy works best for these patients.

Physical Activity

Physical activity is also an important component of a comprehensive DM management program. Regular physical activity has been shown to improve blood glucose control and reduce cardiovascular risk factors, such as hypertension and elevated serum lipid levels. Physical activity is also a primary factor associated with long-term maintenance of weight loss and overall weight control. Regular physical activity also may prevent the onset of type 2 DM in high-risk persons.

Prior to initiating a physical activity program, several considerations should be made. Patients should undergo a detailed physical examination, including screening for microvascular or macrovascular complications that may be worsened by a particular activity. Initiation of physical activities in an individual with a history of a sedentary lifestyle should begin with a modest increase in activity. Walking, swimming, and cycling are examples of low-impact exercises that could be encouraged. At the same time, gardening and usual house-cleaning tasks are good exercises as well. Long-term goals are to perform at least 30 minutes of aerobic activity as many days a week as possible.[13]

Preventing Diabetes

The Diabetes Prevention Program was a 3-year study that showed that lifestyle modifications, including exercise (30 minutes/day, 5 days/week) and moderate (5%–10%) weight loss, reduce the probability of developing DM by 58% in patients with pre-diabetes. Results from this study suggest that diet, exercise, and behavior modification are effective in preventing type 2 DM in high-risk patients.[14]

Psychological Assessment and Care

Mental health and social state have been shown to have an impact on a patient's ability to carry out DM management care tasks. Approximately one in four patients with DM experience episodes of major depression. Therefore, clinicians should incorporate psychological assessment and treatment into routine care. The ADA guidelines recommend psychological screening, which includes determining the patient's attitudes regarding DM, expectations of medical management and outcomes, mood and affect, general and diabetes-related quality of life, and financial, social, and emotional resources. Patients demonstrating non-compliance, depression, an eating disorder, and/or cognitive functioning that impairs judgment should be referred to a mental health specialist familiar with DM.[5]

Patient Encounter, Part 3: Creating a Care Plan

Create a care plan for MF's DM, including:

- Statement of drug-related needs and/or problems
- Goals for therapy
- Detailed plan with nonpharmacologic and pharmacologic therapy
- Follow-up plan to evaluate whether MF's goals for therapy have been achieved and adverse effects avoided

Immunizations

Influenza and pneumonia are common preventable infectious diseases that increase mortality and morbidity in persons with chronic diseases including DM.[5] Yearly influenza vaccinations, commonly called flu shots, are recommended for patients with DM. Pneumococcal vaccination also is recommended for patients with DM as a one-time vaccination for most patients.

Pharmacologic Therapy

A number of therapeutic advancements and new options for managing patients with DM have become available over the past decade, including α-glucosidase inhibitors, biguanides, non-sulfonylurea secretagogues, and thiazolidinediones (TZD).[15] In addition, a number of new insulin formulations have been added to the armamentarium, including rapid-acting insulins, combination mixtures, and basal insulins.[16] Finally, a number of emerging therapies have been approved recently, including pramlintide, exanatide, inhaled insulin and the dipeptidyl peptidase-4 (DPP-IV) inhibitors. The following section describes the current oral agents available to treat type 2 DM. Later in this section, the insulins and other injectible medications for type 1 and type 2 DM will be addressed.[17, 18]

❻ *Oral agents currently available are indicated in patients with type 2 DM who are unable to achieve glycemic control through diet and exercise.* Oral agents commonly used in the management of type 2 DM typically are classified according to their mechanism of action. **Insulin secretagogues** include sulfonylureas and non-sulfonylurea secretagogues. These agents stimulate and enhance endogenous insulin release. **Insulin sensitizers** include the thiazolidinediones that decrease insulin resistance in the periphery. The biguanides decrease hepatic glucose output and the DPP-IV inhibitors enhance the incretin system. Each of these agents may be used as monotherapy (Table 40–8) or in combination with other medications for synergistic effects.

Sulfonylureas

Sulfonylureas represent the first class of oral antidiabetes agents approved for use in the United States. These drugs are classified as being either first- or second-generation agents. Both classes of sulfonylureas are equally effective when given at

TABLE 40–8. Oral Agents for the Treatment of Type 2 Diabetes Mellitus

Generic Name	Brand	Generic Available	Dosage Strengths (mg)	Starting Dosage (mg/day)	Doses/Day	Titration Intervals	Maximum Dose (mg)	Effect (hour)	Comments/Cautions
Sulfonylureas—First Generation									
Major adverse events: Hypoglycemia, weight gain									
Acetohexamide	Dymelor	Y	250, 500	250	1–2	5–7 days	1500	Up to 16	Metabolized in liver, excreted in kidneys
Chlorpropamide	Diabinese	Y	100, 250	250	1	3–5 days	500	Up to 72	Caution in elderly and kidney disease, disulfiram-like reaction with alcohol
Tolazamide	Tolinase	Y	100, 250, 500	100–250	1–2	Weekly	1000	Up to 24	Excreted via kidney, less side effects than tolbutamide
Tolbutamide	Orinase	Y	250, 500	1000–2000	2–3	3–5 days	3000	Up to 12	Excreted via kidney, but can be useful in kidney disease
Sulfonylureas—Second Generation									
Major adverse event: Hypopglycemia									
Glipizide	Glucotrol,	Y	5, 10	5	1–2	3–5 days	40	Up to 20	Take immediate release
Slow release	Glucotrol XL	N	2.5, 5, 10, 20	5	1	3–5 days	20	24	tablets on an empty stomach; caution in elderly
Glyburide	Diaβeta,	Y	1.25, 2.5, 5	5	1–2	Weekly	20	Up to 24	Metabolized in liver and excreted in kidneys and bile, caution in
	Micronase,	Y							
Micronized	Glynase	N	1.5, 3, 6	3	1–2	Weekly	12	Up to 24	elderly
Glimepiride	Amaryl	N	1, 2, 4	1–2	1	3–5 days	8	24	60% renal and 40% liver elimination, take with first main meal
Non-sulfonylurea Secretagogues									
Hypoglycemia and weight gain are at a reduced risk due to short duration of action									
Nateglinide	Starlix	N	60, 120	120	3 with meals	Not applicable	120 per meal	Up to 4	Frequency of dosing dependent on frequency of meals
Repaglinide	Prandin	N	0.5, 1, 2	0.5–1	3 with meals	Weekly	4 per meal; 16 daily	Up to 4	Frequency of dosing dependent on frequency of meals
Biguanides									
Major adverse events: GI symptoms, nausea, diarrhea, lactic acidosis									
Metformin	Glucophage	Y	500, 850, 1000	500	2	1–2 weeks	2550	Up to 24	Renally excreted unmetabolized
Extended release	Glucophage XR	N	500, 750	500–1000	1	Weekly	2000	Up to 24	Discontinue if serum creatinine greater than 1.4 mg/dL (females) or 1.5 mg/dL (males)

Thiazolidinediones									
Major adverse events: Edema, weight gain; discontinue use if alanine aminotranferase (ALT) greater than 3 times normal; monitor liver function tests at baseline and periodically thereafter									
Pioglitazone	Actos	N	15, 30, 45	15	1	8–12 weeks	45	24	Metabolism by cytochrome P-450 2C8 and 3A4 pathways, days for onset of action
Rosiglitazone	Avandia	N	2,4, 8	2–4	1–2	8–12 weeks	8 mg/day or 4 mg twice daily	Up to 24	Metabolism by cytochrome P-450 2C8 and 2C9 pathways, days for onset of action
α-Glucosidase Inhibitors									
Major adverse events: GI symptoms including flatulence, cramps, and abdominal distension									
Acarbose	Precose	N	25, 50, 100	25	1–3 with meals	4–8 weeks	100 mg 3 times daily	Up to 3	Eliminated in bile, take with first bite of meal, little absorption
Miglitol	Glyset	N	25, 50, 100	25	1–3 with meals	4–8 weeks	100 mg 3 times daily	Up to 3	Eliminated through kidney and feces, take with first bite of meal
Dipeptidyl peptidase-4 inhibitors									
Major adverse events: Nasopharyngitis, upper respiratory tract infection									
Sitegliptin	Januvia	N	25, 50, 100	100	1	Not applicable	100	24	Reduce dosage for renal insufficiency
Combination Products									
Glyburide/ Metformin	Glucovance	N	1.25/250 2.5/500 5/500	2.5–5/500	2 with meals	2 weeks	[a]	[a]	[a] [a]
Glipizide/ Metformin	Metaglip	N	2.5/250, 2.5/500, 5/500	2.5–5/500	2 with meals	2 weeks	[a]	[a]	
Rosiglitazone/ Metformin	Avandamet	N	1/500, 2/500, 4/500, 2/1000, 4/1000	1–2/500	2 with meals	[a]	[a]	[a]	[a]
Pioglitazone/ Metformin	Actosplus Met	N	15/500, 15/850	15/500 or 15/850	1–2	[a]	[a]	[a]	[a]

equipotent doses. Today, the vast majority of patients receiving a sulfonylurea are prescribed a second-generation agent.

Sulfonylureas enhance insulin secretion by blocking ATP-sensitive potassium channels in the cell membranes of pancreatic β-cells. This action results in membrane depolarization, allowing an influx of calcium to cause the translocation of secretory granules of insulin to the cell surface, and enhances insulin secretion. The extent of insulin secretion depends on the blood glucose level. More insulin is released in response to higher blood glucose levels, whereas the additional insulin secretion from sulfonylureas is less at near-normal glucose levels. Insulin is then transported through the portal vein to the liver, suppressing hepatic glucose production.[6]

All sulfonylureas undergo hepatic biotransformation, with most agents being metabolized by the cytochrome P-450 2C9 pathway. First-generation sulfonylureas are more likely to cause drug interactions than second-generation agents. All sulfonylureas except tolbutamide require a dosage adjustment or are not recommended in renal impairment. In elderly patients or those with compromised renal or hepatic function, lower starting dosages are necessary.

Monotherapy with sulfonylureas generally produce a 1.5% to 2% decline in HbA_{1c} concentrations and a 60 to 70 mg/dL (3.33–3.89 mmol/L) reduction in FBG levels. Secondary failure with these drugs occurs at a rate of 5% to 7% per year as a result of continued pancreatic β-cell destruction. One limitation of sulfonylurea therapy is the inability of these products to stimulate insulin release from β-cells at extremely high glucose levels, a phenomenon called glucose toxicity.

Non-sulfonylurea Secretagogues

While producing the same effect as sulfonylureas, non-sulfonylurea secretagogues, also referred to as meglitinides, have a much shorter onset and duration of action. Non-sulfonylurea secretagogues also produce a pharmacologic effect by interacting with ATP-sensitive potassium channels on the β-cells; however, this binding is to a receptor adjacent to those to which sulfonylureas bind.

The primary benefit of non-sulfonylurea secretagogues is in reducing post-meal glucose levels by about 40 mg/dL (2.22 mmol/L). These agents have demonstrated a reduction in HbA_{1c} levels between 0.6% and 1%. Owing to the rapid onset and short duration of action of these agents, non-sulfonylurea secretagogues are to be taken within 15 minutes of a meal. They also may be used in combination therapy with other drugs to achieve synergistic effects. Combining a non-sulfonylurea secretagogue with a sulfonylurea usually improves glucose control.

Biguanides

The only biguanide approved by the Food and Drug Administration (FDA) and currently available in the United States is metformin. Metformin was approved in the United States in 1995, although it has been used extensively in Canada and Europe since 1959. This agent is thought to lower blood glucose by increasing insulin sensitivity in both hepatic and peripheral muscle tissues; however, the exact mechanism of action remains unknown. Metformin has been shown to reduce HbA_{1c} levels by 1.5% to 2% and FPG levels by 60 to 80 mg/dL (3.33–4.44 mmol/L) when used as monotherapy. The response to metformin can vary according to the starting point of the patient. Larger effects can be seen in patients with a higher initial HbA_{1c} level (e.g., greater than 10%) than in patients beginning therapy with a relatively lower value (e.g., less than 8%). It is effective in reducing fasting as well as post-meal blood glucose levels. Metformin does not affect insulin release from β-cells of the pancreas, so hypoglycemia is not a common side effect. While the onset of action begins within days, the maximum therapeutic effect of this agent may not be observed until after 2 weeks of therapy.

Metformin also has been shown to produce beneficial effects on serum lipid levels and thus has become a first-line agent for type 2 DM patients with metabolic syndrome. Triglyceride and low-density lipoprotein (LDL) cholesterol levels often are reduced by 8% to 15%, whereas high-density lipoprotein (HDL) cholesterol improves by approximately 2%. A modest weight loss of 2 to 3 kg (4.4–6.6 lb) also has been reported with metformin therapy. Metformin often is used in combination with a sulfonylurea or a thiazolidinedione for synergistic effects.

Metformin does not undergo significant protein binding and is eliminated from the body unchanged in the urine. Elderly patients with a calculated creatinine clearance of less than 70 to 80 mL/minute should not receive this product. It is contraindicated in patients with a serum creatinine level greater than or equal to 1.4 mg/dL (124 μmol/L) in women and 1.5 mg/dL (133 μmol/L) in men. Additionally, therapy with metformin should be withheld in patients undergoing radiographic procedures in which a nephrotoxic dye is used. Therapy should be withheld the day of the procedure, as well as for the following 2 to 3 days.

Primary side effects associated with metformin therapy are gastrointestinal in nature, including decreased appetite, nausea, and diarrhea. These side effects can be minimized through slow titration of the dose and often subside within 2 weeks. Discontinuation because of side effects occurs in only 3% to 5% of patients.

Biguanides such as metformin are thought to inhibit mitochondrial oxidation of lactic acid, thereby increasing the chance of lactic acidosis occurring. Fortunately, the incidence of lactic acidosis in clinical practice is rare. Patients at greatest risk for developing lactic acidosis include those with liver disease or heavy alcohol use, severe infection, heart failure, and shock. Thus, it is common practice to evaluate liver function prior to initiation of metformin.

Thiazolidinediones

Commonly referred to as TZDs or glitazones, thiazolidinediones have established a significant role in type 2 DM therapy. As monotherapy, both rosiglitazone and pioglitazone reduce

FPG levels by 30 to 50 mg/dL (1.67–2.78 mmol/L), and the overall effect on HbA_{1c} is a 1% to 1.5% reduction. Onset of action for thiazolidinediones is delayed for several weeks and may require up to 12 weeks before maximum effects are observed. Combining a sulfonylurea, non-sulfonylurea secretagogue, metformin, or insulin with a thiazolidinedione can improve HbA_{1c} reductions to 2% to 2.5%.

Additional effects of thiazolidinediones are seen in the lipid profile. Both pioglitazone and rosiglitazone increase HDL cholesterol by 3 to 9 mg/dL (0.08–0.23 mmol/L). Pioglitazone has been shown to decrease serum triglycerides by 10% to 20%, whereas no substantial effect is observed with rosiglitazone. LDL cholesterol concentrations increase by 5% to 15% with rosiglitazone, whereas no significant increase has been reported for pioglitazone.

Thiazolidinediones are known to increase insulin sensitivity by stimulating peroxisome proliferator-activated receptor gamma (PPAR-γ). Stimulation of PPAR-γ results in a number of intracellular and extracellular changes, including an increased number of insulin receptors, increased insulin receptor sensitivity, decreased plasma fatty acid levels, and an increase in a host of intracellular signaling proteins that enhance glucose uptake.

Thiazolidinediones may produce fluid retention and edema; however, the mechanism by which this occurs is not completely understood. It is known that blood volume increases approximately 10% with these agents, resulting in approximately 6% of patients developing edema. Thus, these drugs are contraindicated in situations in which an increased fluid volume is detrimental, such as heart failure. Fluid retention appears to be dose-related and increases when combined with insulin therapy.

A few cases of hepatotoxicity have been reported with rosiglitazone and pioglitazone, but no serious complications have been reported, and symptoms typically reverse within several weeks of discontinuing therapy. Therefore, periodic liver function tests should be performed at baseline and during thiazolidinedione therapy. Patients with a baseline alanine aminotransferase (ALT) level greater than 2.5 times the upper limit of normal should not receive a TZD. If ALT levels rise to greater than 3 times the upper limit of normal in patients receiving a TZD, the medication should be discontinued.

α-Glucosidase Inhibitors

Acarbose and miglitol are α-glucosidase inhibitors currently approved in the United States. As monotherapy, α-glucosidase inhibitors reduce FPG concentrations by between 40 and 50 mg/dL (2.22–2.78 mmol/L); however, HbA_{1c} reductions range only from 0.3% to 1%. While these agents have been popular in Europe and other parts of the world, they have failed to gain widespread use in the United States. High incidences of gastrointestinal side effects, including flatulence (41.5%), abdominal discomfort (11.7%), and diarrhea (28.7%), have limited their use. Low initial doses followed by gradual titration may minimize gastrointestinal side effects.

Patient Encounter, Part 4: Oral to Insulin Therapy

Several years have passed since you have been following MF's therapy. His weight is down to 230 lb (104.6 kg), and he tries to maintain his diet and exercise. His recent HbA_{1c} levels have increased up to 8.4% from 7.2% despite combination therapy with sulfonylureas and metformin. The physician believes that it is time to start insulin therapy for MF and asks you to initiate therapy and follow his regimen.

- What insulin therapy would you choose for MF?
- How would you transition MF to insulin?

α-Glucosidase is an enzyme along the brush border of intestinal cells that breaks down complex carbohydrates into simple sugars, resulting in absorption. α-Glucosidase inhibitors work by delaying the absorption of carbohydrates from the intestinal tract, which reduces the rise in postprandial blood glucose concentrations. Gastrointestinal side effects occur as the result of intestinal bacteria in the distal gut metabolizing undigested carbohydrates and producing carbon dioxide and methane gas. α-Glucosidase inhibitors are contraindicated in patients with short-bowel syndrome or inflammatory bowel disease. In addition, neither drug in this class is recommended for patients with a creatinine clearance of less than 25 mL/minute.

Dipeptidyl peptidase-4 inhibitors

The newest therapeutic class of oral agents for DM is the dipeptidyl peptidase-4 (DPP-IV) inhibitors. Sitagliptin is the first and only agent in this class to be FDA approved, but vildagliptin and saxagliptin are currently in clinical trials and may soon join this class as therapeutic options. Sitagliptin is indicated for patients with type 2 DM as monotherapy or in combination therapy with metformin or a thiazolidinedione. The DPP-IV inhibitors slow the inactivation of incretin hormones within the gut. The incretin hormones are released throughout the day by the intestines and increased levels are produced in response to a meal. Normal or elevated incretin hormones, including glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP), increase insulin production and release by the pancreatic beta cells. In addition, GLP-1 has been shown to decrease glucagon secretion from the pancreatic alpha cells which leads to a decrease in hepatic glucose production. Since DPP-IV inhibitors increase and prolong only active incretin levels, the resulting increase in insulin release and glucagon reduction occur in a glucose dependent manner.

Reductions in HbA_{1c} of 0.7%–0.8% were found in clinical trials verses placebo in both monotherapy and combination therapy using the recommended dose of sitagliptin 100 mg daily taken with or without food. Dosage adjustments to 50 mg and 25 mg daily are recommended for patients with moderate

(CrCl greater than or equal to 30 to less than 50 mL/minute) and severe (CrCl less than 30 mL/minute) renal impairment respectively. Renal function monitoring is recommended prior to initiation and periodically thereafter. Adverse events in clinical trials included nasopharyngitis (5.2%), upper respiratory tract infection (6.3%), and headache (5.1%). Currently, no significant drug interactions are known.

Insulins

Insulin is the one agent that can be used in all forms of DM for blood sugar control. ❼ *Insulin is the essential treatment for patients with type 1 DM and can overcome insulin resistance in patients with type 2 DM.* Insulin is available commercially in various formulations that vary markedly in terms of onset and duration of action and the source from which a product is obtained. Insulins can be divided into four separate classes based on their length of action. Most formulations are available as U-100, indicating a concentration of 100 units/mL. Insulin is typically refrigerated, and most vials are good for 28 days at room temperature. Specific details of insulin products are listed in Table 40–9.

The most common route of administration for insulin is subcutaneous injection using a syringe or pen device. Insulin syringes are distinguished according to the syringe capacity, syringe markings, and needle gauge and length. The most common insulin syringe capacities are 30, 50, and 100 units. The 30- and 50-unit syringes are marked at 1-unit increments, whereas the 100-unit syringe is marked at 2-unit intervals. Syringe needles range from 28 to 31 gauge and $^{5}/_{16}$- to $^{1}/_{2}$-in length. The insulin pens are self-contained systems of insulin delivery. The primary advantage of the pen system is that the patient does not have to draw up the dose from the insulin vial.

Regular Insulin

Regular insulin is unmodified crystalline insulin commonly referred to as natural insulin. It is a clear solution that has a relatively rapid onset and short duration of action. On subcutaneous injection, regular insulin forms small aggregates called hexamers that undergo conversion to dimers followed by monomers before systemic absorption can occur. Therefore, patients should be counseled to inject regular insulin subcutaneously 30 minutes prior to consuming a meal. Regular insulin is the only insulin that can be administered intravenously.

Rapid-Acting Insulin

Three rapid-acting insulins have been approved in the United States: lispro, aspart, and glulisine. Substitution of one or two amino acids in regular insulin results in the unique pharmacokinetic properties characteristic of these agents. Onset of action of rapid-acting insulins varies from 15 to 30 minutes, with peak effects occurring 1 to 2 hours following administration.

Intermediate-Duration Insulin

Neutral Protamine Hagedorn, better known as NPH insulin, is prepared by a process in which protamine is conjugated with regular insulin, rendering a product with a delayed onset but extended duration of action. With the advent of the long-acting insulins, NPH insulin use has declined due to: (1) an inability to predict accurately when peak effects occur, and (2) a duration of action of less than 24 hours. Additionally, protamine is a foreign protein that may increase the possibility of an allergic reaction.

NPH insulin can be mixed with regular insulin and used immediately or stored for future use up to 1 month at room temperature or 3 months in refrigeration. NPH insulin can be mixed with either aspart or lispro insulins, but it must be injected immediately after mixing. Whenever mixing insulin products with NPH insulin, the shorter-acting insulin should be drawn into the syringe first.

Long-Duration Insulin

Two long-duration insulin preparations are approved for use in the United States. Glargine and detemir are designed as once-daily-dosing basal insulins. Insulin glargine differs from regular insulin by three amino acids, resulting in a low solubility at physiologic pH. The clear solution is supplied at a pH of 4, which precipitates on subcutaneous administration. Given this property, glargine cannot be administered intravenously or mixed with other insulin products. Both glargine and detemir do not produce peak serum concentrations and can be administered irrespective of meals or time of day.

Combination Insulin Products

A number of combination insulin products are available commercially. NPH is available in combinations of 70/30 and 50/50 with regular insulin. Two short-acting insulin analog mixtures are also available. Humalog Mix 75/25 contains 75% insulin lispro protamine suspension and 25% insulin lispro. Novolog Mix 70/30 contains 70% insulin aspart protamine suspension and 30% insulin aspart. The lispro and aspart insulin protamine suspensions were developed specifically for these mixture products and will not be commercially available separately.

Oral Inhalation Insulin

The first inhaled insulin product was approved in early 2006. Exubera, recombinant human insulin, is an alternative to mealtime injectible insulin available in the United States. It has an onset of action of between 10 to 20 minutes, which is similar to rapid-acting insulin, and a duration of action of around 6 hours, which is similar to regular insulin. Inhaled insulin will not totally replace injectible insulin because long-acting insulin injections are necessary for basal control. This product is available in 1 and 3 mg blister packs, which are equivalent to about 3 to 8 units of injectible insulin. Some patients may need multiple inhalations to attain their mealtime dose. Exubra is not recommended for patients with chronic lung disease such as asthma or chronic obstructive pulmonary disease, patients who smoke, or patients who have stopped smoking within the past 6 months. Monitoring of lung function should be performed at baseline and 6 months' post initiation of therapy.

TABLE 40–9. Insulin Agents for the Treatment of Type 1 and Type 2 Diabetes Mellitus

Generic Name (Insulin)	Brand	Manufacturer	Strength	Onset (minutes)	Peak (hours)	Duration (hours)	Administration Options
Rapid-Acting Insulin							
Lispro	Humalog	Eli Lilly	U-100	15–30	0.5–2.5	3–4	10 mL vial, 3 mL cartridge and disposable pen
Aspart	Novolog	Novo-Nordisk	U-100	15–30	1–3	3–5	10 mL vial, 3 mL cartridge and disposable pen
Glulisine	Apidra	Aventis	U-100	15–30	1–2	3–4	10 mL vial, 3 mL cartridge and disposable pen
Short-Acting Insulin							
Regular	Humulin R	Eli Lilly	U-100, U-500	30–60	2–3	3–6	U-100 10 mL vial; U-500 20 mL vial
	Novolin R	Novo-Nordisk	U-100				10 mL vial, 3 mL cartridge, 3 mL *Innolet*
Intermediate-Acting Insulin							
Neutral protamine Hagedorn	Humulin N	Eli Lilly	U-100	2–4 hours	4–6	8–12	10 mL vial, 3 mL cartridge
	Novolin N	Novo-Nordisk	U-100				10 mL vial, 3 mL cartridge, 3 mL *InnoLet*
Long-Acting Insulin							
Glargine	Lantus	Aventis	U-100	4–5 hours	Flat	22–24	10 mL vial, 3 mL cartridge for *Opticlik*
Detemir	Levmir	Novo-Nordisk	U-100	3–4 hours	Flat	Up to 24	10 mL vial, 3 mL cartridge, 3 mL *Innolet*, 3 mL disposable *FlexPen*
Combination Insulin Products							
Neutral protamine Hagedorn and regular	Humulin 70/30	Eli Lilly	U-100	30–60	1.5–16	10–16	10 mL vial, 3 mL disposable pen
	Novolin 70/30	Novo Nordisk	U-100	30–60	2–12	10–16	10 mL vial, 3 mL cartridge, 3 mL *Innolet*
	Humulin 50/50	Eli Lilly	U-100	30–60	2–5.5	10–16	10 mL vial
Neutral protamine lispro and lispro	Humalog Mix 75/25	Eli Lilly	U-100	15–30	1–6.5	15–18	10 mL vial, 3 mL disposable pen
Neutral protamine aspart and aspart	Novolog Mix 70/30	Novo Nordisk	U-100	15–30	1–4	Up to 24	10 mL vial, 3 mL cartridge, 3 mL disposable *FlexPen*
Oral Inhalation Insulin							
Recombinant human insulin	Exubera	Pfizer	1 mg = ~3 units injectible insulin	10–20	0.5–1.5	6	1 mg, 3 mg blister packs

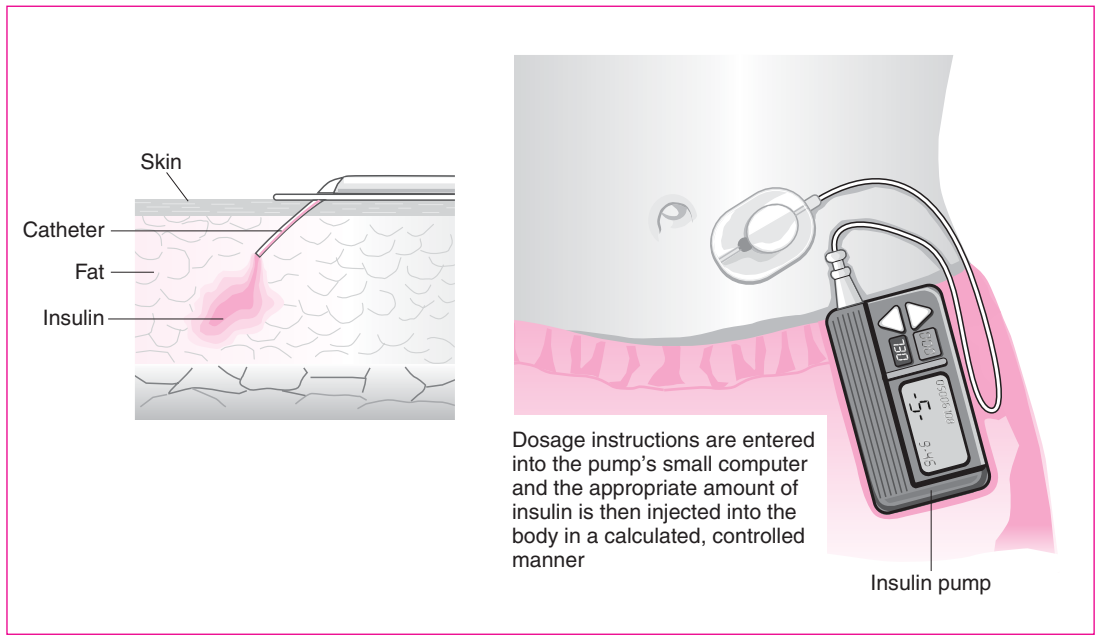

FIGURE 40–3 Insulin pump.

Insulin Pump Therapy

Insulin pump therapy consists of a programmable infusion device that allows for basal infusion of insulin 24 hours daily, as well as bolus administration following meals. As seen in Fig. 40–3, an insulin pump consists of a programmable infusion device with an insulin reservoir. This pump is attached to an infusion set with a small needle that is inserted in subcutaneous tissue in the patient's abdomen, thigh, or arm. Most patients prefer insertion in abdominal tissue because this site provides optimal insulin absorption. Patients should avoid insertion sites along belt lines or in other areas where clothing may cause undue irritation. Infusion sets should be changed every 2 to 3 days to reduce the possibility of infection.

Patients use a carbohydrate-to-insulin ratio to determine how many units of insulin are required. To determine an individual's ratio, the 450 rule is used for patients using regular insulin, whereas the 500 rule is used for lispro or aspart pump users. To calculate the ratio using the 500 rule, the patient would divide 500 by his or her total daily dose of insulin. For example, if a patient were using 25 units of insulin daily, his or her carbohydrate-to-insulin ratio would be 500:25, or 20:1. This ratio theoretically means that 1 unit of lispro or aspart insulin should cover 20 g of carbohydrate. If blood sugar levels are below or above the desired blood glucose target, the amount of insulin can be adjusted. Once this ratio is determined, patients can eat more or fewer carbohydrates at a given meal and adjust the bolus dose accordingly.

Insulin pump therapy may be used to lower blood glucose levels in any type of DM; however, patients with type 1 DM are the most likely candidates for this form of treatment. Use of an insulin pump may improve blood glucose control, reduce wide fluctuations in blood glucose levels, and allow individuals to have more flexibility in timing and content of meals and exercise schedules. Nonetheless, insulin pump therapy is not for everyone. The complexity associated with its use, cost, increased need for blood glucose monitoring, and psychological factors may prevent individuals from using this technology optimally.

Incretin Mimetics

Incretin mimetics are agents with biologic activities similar to incretin hormones but have longer durations of action. Incretin hormones are substances produced by the gastrointestinal tract in response to food that act to stimulate insulin secretion. Obese, insulin-resistant patients with type 2 diabetes have lower levels of incretin hormones. Exanatide is the first incretin mimetic approved by the FDA and is indicated as adjunct therapy in type 2 DM in which adequate blood glucose control has not been achieved with sulfonylureas, metformin, or both (Table 40–10). HbA_{1c} reductions ranging from 0.5% to 1% have been observed with this agent, whereas FPG concentrations decrease by 8 to 10 mg/dL (0.44–0.56 mmol/L). Postprandial glucose values decline by 60 to 70 mg/dL (3.33–3.89 mmol/L).

Exanatide lowers blood glucose levels by producing glucose-dependent insulin secretion; reducing post-meal glucagon secretion, which decreases post-meal glucose output; increasing satiety, which decreases food intake; and regulating gastric emptying, which allows nutrients to be absorbed into the circulation more smoothly. Serum levels peak approximately 2 hours after subcutaneous administration. Exanatide is eliminated renally and is not recommended in patients with a creatinine clearance of less than 30 mL/minute.

An increased risk of hypoglycemia occurs when exanatide is used in combination with a sulfonylurea; however, this is not encountered in exanatide monotherapy or in conjunction

with metformin and/or thiazolidinedione therapy. Side effects include nausea (44%), vomiting (13%), and diarrhea (13%). No major drug interactions have been found with exanatide. The extent and rate of absorption of orally administered drugs may be affected with concomitant use of exanatide; however, no clinical significance has been established to date.

Exanatide is available in 5 and 10 mcg injectible prefilled disposable pens. Initial therapy is 5 mcg twice daily, injected before the two largest meals of the day. Meals should be separated by at least 5 to 6 hours. Doses then are increased after a month to 10 mcg if the patient's blood glucose is improving and nausea is limited. Exanatide can be given up to 60 minutes before a meal, but practical use indicates that injection just before a meal may decrease nausea. An average weight loss of 3 to 5 pounds (1.36–2.27 kg) commonly occurs with the 5 mcg dose, whereas a weight loss of 5 to 10 pounds (2.27–4.55 kg) is observed with the 10 mcg dose.

Amylin

Pramlintide acetate was approved for use in the United States in March 2005 (Table 40-10). This agent is a synthetic analog of human amylin, which is a naturally occurring neuroendocrine peptide that is co-secreted by the β-cells of the pancreas in response to food. Amylin secretion is completely or relatively deficient in patients with diabetes. Pramlintide is given by subcutaneous injection before meals to lower postprandial blood glucose elevations. However, unlike insulin, it does not cause weight gain. Use of pramlintide actually results in an average weight loss of 2.2 to 4.4 lb (1–2 kg).

Pramlintide is indicated as combination therapy with insulin in patients with type 1 or 2 DM. It has been shown to decrease HbA_{1c} by an additional 0.4% to 0.5%. Pramlintide slows gastric emptying without altering absorption of nutrients, suppresses glucagon secretion, and leads to a reduction in food intake by increasing satiety. By slowing gastric emptying, the normal initial post-meal spike in blood glucose is reduced.

Hypoglycemia, nausea, and vomiting are the most common side effects encountered with pramlintide therapy, although pramlintide itself does not produce hypoglycemia. To decrease the risk of hypoglycemia, doses of short-acting, rapid-acting, or premixed insulins should be reduced by 50% before pramlintide is initiated. Pramlintide is metabolized primarily by the kidneys, but dosage adjustments in liver or kidney impairment are not required. Pramlintide has the potential to delay the absorption of orally administered medications. When rapid absorption is needed for efficacy of an agent, pramlintide should be administered 2 hours before or 1 hour after this drug. Pramlintide should not be used in patients receiving medications that alter gastrointestinal motility, such as anticholinergic agents, or drugs that slow the absorption of nutrients, such as α-glucosidase inhibitors.

Treatment of Concomitant Conditions

Coronary Heart Disease

Nearly two-thirds of patients with DM will die of coronary heart disease (CHD). Interventions targeting smoking cessation, glycemic control, blood pressure control, lipid management, antiplatelet therapy, and lifestyle changes, including diet and exercise, can reduce the risk of cardiovascular events. Patients with diabetes should receive at least an aspirin daily unless contraindicated. Refer to appropriate chapters in the text concerning CHD.

TABLE 40–10. Non-insulin Injectible Agents for the Treatment of Diabetes Mellitus

Generic Name (Brand)	Type of Diabetes Mellitus	Dosage Strengths (mcg)[b,c]	Starting Dosage	Doses/Day	Titration Interval	Maximum Dose (mcg)	Time to Effect (minute)	Comments/Cautions
Pramlintide[a] (Symlin)	1	15, 30, 45, 60	15	3	3–7 days	60	20	Take just before major meals; reduce insulin by 50% Maintenance dose 30–60 mcg
	2	60, 120	60	3	3–7 days	120	20	Side effects: Hypoglycemia, nausea, vomiting May delay oral drug absorption
Exanatide[a] (Byetta)	2	5, 10	5	2	1 month	10	15–30	Take just before morning and evening meal; prefilled disposable pen; may delay absorption of oral drugs; separate doses by 1 hour Side effects: Nausea, vomiting, diarrhea, increased hypoglycemia with sulfonylureas

[a]Generic not available in United States.
[b]Pramlintide supplied as 0.6 mg/mL in 5 mL vials.
[c]Exanatide supplied as 250 mcg/mL, 1.2 mL for the 5 mcg prefilled pen and 2.4 mL for the 10 mcg per dose prefilled pen.

Hyperlipidemia

The National Cholesterol Education Program Adult Treatment Panel III guidelines classify the presence of DM to be of the same risk equivalence as CHD. The primary target for lipid-lowering treatment of LDL cholesterol is less than 100 mg/dL (2.59 mmol/L). For patients at high cardiovascular risk, LDL target is 70 mg/dL (1.81 mmol/L). Treatment with an HMG-CoA reductase inhibitor, commonly called a *statin,* often is required to achieve these goals. After LDL cholesterol goals are reached, triglyceride and HDL goals also should be achieved. Treatments including niacin or fibrate therapy may be used to reach these secondary goals. However, caution should be used with statin-fibrate combination therapy because a higher risk of adverse events has been reported (see Chapter 9).

Hypertension

Uncontrolled blood pressure plays a major role in the development of macrovascular events and nephropathy in patients with DM. The ADA recommends that blood pressure goals for patients with DM be less than 130/80 mm Hg. In addition, there are several general principles regarding the treatment of hypertension in diabetes patients. Angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers, and calcium channel blockers are recommended as initial therapy because of their beneficial effects on renal function. Low-dose thiazide diuretics also can be used as either first- or second-line therapy. The most common use of thiazide diuretics for patients with DM is in synergistic combination with other agents. β-Blockers also can be used as either first- or second-line therapies. While β-blockers may mask the symptoms of hypoglycemia, it is generally believed that the benefit of β-blockers outweighs the low risk of hypoglycemia in the patient with type 2 DM. In order to achieve blood pressure goals, most patients require combination therapy with two or three antihypertensive agents (see Chapter 2).

Treatment of Acute Complications

Hypoglycemia

Hypoglycemia, or low blood sugar, can be defined clinically as a blood glucose level of less than 50 mg/dL (2.78 mmol/L). Individuals with DM can experience symptoms of hypoglycemia at varying blood glucose levels. Patients who have regular blood glucose levels as high as 300 to 400 mg/dL (16.65–22.2 mmol/L) may experience symptoms of hypoglycemia once blood glucose levels are lowered to the middle to upper 100 mg/dL (5.55 mmol/L) range. Most people whose blood glucose levels are controlled adequately may experience symptoms when levels fall below 70 mg/dL (3.89 mmol/L). Symptoms of hypoglycemia include shakiness, sweating, fatigue, hunger, headaches, and confusion. Common causes of hypoglycemia include delayed or inadequate amounts of food intake, especially carbohydrates, excessive doses of medications (e.g., sulfonylureas and insulin), exercising when insulin doses are reaching peak effect, or inadequately adjusted drug therapy in renally or hepatically impaired patients. Patients experiencing symptoms of hypoglycemia should check their blood glucose level, consume 15 g of carbohydrate, and wait 10 to 15 minutes for symptom resolution. Examples of acceptable treatments may include a small box of raisins, 4 oz (approximately 120 mL) of orange juice, 8 oz (approximately 240 mL) of skim milk, or three to six glucose tablets. In patients receiving an α-glucosidase inhibitor in combination with a sulfonylurea or insulin, hypoglycemia should be treated with glucose tablets or skim milk owing to the mechanism of action of the α-glucosidase inhibitors. If the blood glucose level has dropped below 50 mg/dL (2.78 mmol/L), as much as 30 g of carbohydrate may be necessary to raise blood glucose levels adequately. For patients with hypoglycemia experiencing a loss of consciousness, a glucagon emergency kit should be administered by intramuscular or subcutaneous route, and emergency medical personnel should be contacted. The patient should be rolled onto his or her side to prevent aspiration since many patients receiving the glucagon injection will vomit.

Diabetic Ketoacidosis

Diabetic ketoacidosis (DKA) is a reversible but potentially life-threatening medical emergency that results from a relative or absolute deficiency in insulin. Without insulin, the body cannot use glucose as an energy source and must obtain energy via **lipolysis**. This process produces ketones and leads to acidosis. While DKA occurs frequently in young patients with type 1 DM on initial presentation, it can occur in adults as well as with patients who have type 2 DM. Often precipitating factors such as infection or errors in administration of insulin or oral diabetes medications can cause DKA. Signs and symptoms develop rapidly over a few hours and commonly include fruity or acetone breath, nausea, vomiting, dehydration, polydipsia, polyuria, and deep, rapid breathing. Non-specific symptoms include lethargy, headache, and weakness. Hallmark diagnostic criteria for DKA include hyperglycemia (greater than 250 mg/dL, 13.9 mmol/L), ketosis (anion gap greater than 10), and acidosis (arterial pH less than or equal to 7.25). Typical fluid deficit is 6 L or more, with major deficits of serum sodium and potassium common. The severity of DKA depends on the magnitude of the decrease in arterial pH, serum bicarbonate levels, and the mental state rather than the magnitude of the hyperglycemia.

Treatment goals of DKA consist of reversing the underlying metabolic abnormalities, rehydrating the patient, and normalizing the serum glucose. Fluid replacement with normal saline at 1 L/hour is recommended to rehydrate the patient and to ensure that the kidneys are perfused. Potassium and other electrolytes are supplemented as indicated by laboratory assessment. The use of sodium bicarbonate in DKA is controversial and generally is not recommended when the pH is greater than or equal to 7.1. Regular insulin at 0.1 to 0.2 unit/kg per hour by continuous intravenous infusion is the preferred treatment in DKA to regain metabolic control rapidly. Once plasma glucose values

TABLE 40–11. Management of Diabetic Ketoacidosis

1. Confirm diagnosis (↑ plasma glucose, positive serum ketones, metabolic acidosis).
2. Admit to hospital; intensive-care setting may be necessary for frequent monitoring or if pH less than 7.0 or unconscious.
3. Assess: Serum electrolytes (K^+, Na^+, Mg^{2+}, Cl^-, bicarbonate, phosphate)
   Acid-base status—pH, HCO_3^-, P_{CO_2}, β-hydroxybutyrate
   Renal function (creatinine, urine output)
4. Replace fluids: 2–3 L of 0.9% saline over first 1–3 hours (5–10 mL/kg per hour); subsequently, 0.45% saline at 150–300 mL/hour; change to 5% glucose and 0.45% saline at 100–200 mL/hour when plasma glucose reaches 250 mg/dL (14 mmol/L).
5. Administer regular insulin: IV (0.1 units/kg) or IM (0.4 units/kg), then 0.1 units/kg per hour by continuous IV infusion; increase 2- to 10-fold if no response by 2–4 hours. If initial serum potassium is less than 3.3 mmol/L (3.3 mEq/L), do not administer insulin until the potassium is corrected to greater than 3.3 mmol/L (3.3 meq/L).
6. Assess patient: What precipitated the episode (non-compliance, infection, trauma, infarction, cocaine)? Initiate appropriate work-up for precipitating event (cultures, CXR, ECG).
7. Measure capillary glucose every 1–2 hours; measure electrolytes (especially K^+, bicarbonate, phosphate) and anion gap every 4 hours for first 24 hours.
8. Monitor blood pressure, pulse, respirations, mental status, and fluid intake and output every 1–4 hours.
9. Replace K^+: 10 mEq/hour when plasma K^+ less than 5.5 mEq/L, ECG normal, urine flow and normal creatinine documented; administer 40–80 mEq/hour when plasma K^+ less than 3.5 mEq/L or if bicarbonate is given.
10. Continue above until patient is stable, glucose goal is 150–250 mg/dL, and acidosis is resolved. Insulin infusion may be decreased to 0.05–0.1 units/kg per hour.
11. Administer intermediate or long-acting insulin as soon as patient is eating. Allow for overlap in insulin infusion and subcutaneous insulin injection.

CXR, chest x-ray; ECG, electrocardiogram; IM, intramuscularly; IV, intravenous.
Source: Adapted from M Sperling, in *Therapy for Diabetes Mellitus and Related Disorders*, American Diabetes Association, Alexandria, VA, 1998; and AE Kitabchi et al: Diabetes Care 24:131, 2001.

drop below 250 mg/dL (13.9 mmol/L), the insulin infusion may be decreased, and dextrose 5% to 10% can be added to the intravenous fluids. During the recovery period, it is recommended to continue administering insulin and to allow patients to eat as soon as possible. Dietary carbohydrates combined with insulin assist in the clearance of ketones. Resolution of DKA is indicated by a blood glucose level of less than 200 mg/dL (11.1 mmol/L), a bicarbonate level of greater than or equal to 10 mEq/L (10 mmol/L), and a venous pH of greater than 7.3. See Table 40–11 for the management of DKA.[19]

Hyperosmolar Hyperglycemic State

Hyperosmolar hyperglycemic state (HHS) is a life-threatening condition similar to DKA that also arises from inadequate insulin, but HHS occurs primarily in older patients with type 2 DM. DKA and HHS also differ in that HHS lacks the lipolysis, ketonemia, and acidosis associated with DKA. Patients with hyperglycemia and dehydration lasting several days to weeks are at the greatest risk of developing HHS. Illness and infection are common precipitating causes of HHS. Two main diagnostic criteria for HHS are a plasma glucose value of greater than 600 mg/dL (33.3 mmol/L) and a serum osmolality of greater than 320 mOsm/kg. The extreme hyperglycemia and large fluid deficits resulting from osmotic diuresis are major challenges to overcome with this condition. Similar to DKA, the treatment of HHS consists of aggressive rehydration, correction of electrolyte imbalances, and continuous insulin infusion to normalize serum glucose. However, in patients with HHS, blood glucose levels should be reduced gradually to minimize the risk of cerebral edema.

Treatment of Long-Term Complications

Retinopathy

Diabetic retinopathy occurs when the microvasculature that supplies blood to the retina becomes damaged. This damage permits leakage of blood components through the vessel walls. Diabetic retinopathy is the leading cause of blindness in adults 20 to 74 years of age in the United States. Retinopathy is staged as either non-proliferative or proliferative. Non-proliferative retinopathy often causes no visual disturbances and may remain asymptomatic for years. Proliferative retinopathy occurs when new retinal vessels form as a result of retinal ischemia in a process called **neovascularization.** Vision loss from proliferative retinopathy may range from mild blurring, to obstruction of vision, to complete blindness. Blurred vision is the presenting symptom for many patients who are diagnosed with diabetes. The ADA recommends that patients with DM receive a dilated eye examination annually by an ophthalmologist or optometrist. Glycemic control is the best prevention for slowing the progression of retinopathy. Early retinopathy may be reversed with improved glucose control.

Neuropathy

Peripheral neuropathy is the most common complication reported in type 2 DM. This complication generally presents as pain, tingling, or numbness in the extremities. The feet are affected more often than the hands and fingers. A number of treatment options have been tried with mixed success. Current options include pregabalin, gabapentin, low-dose tricyclic antidepressants, duloxetine, venlafaxine, topiramate, non-steroidal anti-inflammatory drugs, and topical capsaicin.

Autonomic neuropathy is also a common complication as DM progresses. Clinical presentation of autonomic neuropathy may include **gastroparesis,** resting tachycardia, orthostatic hypotension, impotence, constipation, and hypoglycemic autonomic failure. Therapy for each individual autonomic complication is addressed separately.

Microalbuminuria and Nephropathy

DM is the leading contributor to end-stage renal disease. Early evidence of nephropathy is the presence of albumin in the urine. Therefore, as the disease progresses, larger amounts of protein spill into the urine. The ADA recommends urine protein tests annually in type 2 DM patients. For children with type 1 DM, annual urine protein testing should begin with the onset of puberty or 5 years after the diagnosis of diabetes. The most common form of screening for protein in the urine is a random spot collection for measurement of the urine albumin/creatinine ratio. The desirable value is less than 30 mcg of albumin per milligram of creatinine. Microalbuminuria is defined as between 30 and 300 mcg of albumin per milligram of creatinine. The presence of microalbuminuria is a strong risk factor for future kidney disease in type 1 DM patients. In type 2 DM patients, microalbuminuria has been found to be a strong risk factor for macrovascular disease. Glycemic control and blood pressure control are primary measures for the prevention of progression of nephropathy. ACE inhibitors and angiotensin II receptor blockers prevent the progression of renal disease in type 2 DM patients. Treatment of advanced nephropathy includes dialysis and kidney transplantation.

Foot Ulcers

Lower extremity amputations are one of the most feared and disabling sequelae of long-term uncontrolled DM. A foot ulcer is an open sore that develops and penetrates to the subcutaneous tissues. Complications of the feet develop primarily as a result of peripheral vascular disease, neuropathies, and foot deformations. Peripheral vascular disease causes ischemia to the lower limbs. This decreased blood flow deprives the tissues of oxygen and nutrients and impairs the ability of the immune system to function adequately. Symptoms of peripheral vascular disease include intermittent claudication, cold feet, pain at rest, and loss of hair on the feet and toes. Smoking cessation is the single most important treatment for peripheral vascular disease. In addition, exercising by walking to the point of pain and then resting and resuming can be a vital therapy to maintain or improve the symptoms of peripheral vascular disease. Pharmacologic intervention with pentoxifylline or cilostazol also may be useful to improve blood flow and reduce the symptoms of peripheral vascular disease.

Neuropathies play a large part in the development of foot ulcers. Loss of sensation in the feet allows trauma to go unnoticed. Autonomic neuropathy can cause changes in the blood flow, perspiration, skin hydration, and possibly bone composition of the foot. Motor neuropathy can lead to muscle atrophy, resulting in weakness and changes in the shape of the foot. To prevent foot complications, the ADA recommends daily visual examination of the feet and a foot check performed at every physician visit. Sensory testing with a 10-gauge monofilament can detect areas of neuropathy. Treatment consists of glycemic control, preventing infection, debriding dead tissues, applying dressings, treating edema, and limiting ambulation. Untreated foot problems may develop gangrene, necessitating surgical intervention.

Special Situations

Hospitalized Care

Aggressive treatment of hyperglycemia in hospitalized patients can prevent unnecessary cost to patients and health care systems. When patients are either physically or emotionally stressed, counterregulatory hormones are released, increasing blood glucose levels. Insulin drip therapy for patients with blood glucose levels greater than 140 mg/dL (7.77 mmol/L) is considered superior to sliding-scale insulin. Sliding-scale insulin therapy typically lags the blood glucose level instead of proactively addressing the increased blood glucose levels. Blood glucose levels can be measured by several methods. Arterial samples are usually 5 mg/dL (0.28 mmol/L) higher than capillary values and 10 mg/dL (0.56 mmol/L) greater than venous values.

When preparing an insulin infusion for a patient, several factors must be considered. Insulin will absorb to glass and plastic, reducing the amount of insulin actually delivered by 20% to 30%. Priming the tubing will decrease variability of insulin infused. Therefore, when patients can be converted safely from infusion to needle and syringe therapy, the total daily dose should be reduced by 20% to 50% of the daily infusion amount.

Sick Days

Patients should monitor their blood glucose levels more closely during sick days because it is common for illness to increase values. Additional insulin coverage may be necessary to prevent DKA. Patients should monitor for the presence of urine ketones by a urine dipstick test that changes color in the presence of ketones. Sugar and electrolyte solutions such as sports drinks may be used by type 1 DM patients to prevent dehydration, electrolyte depletion, and hypoglycemia. However, patients with type 2 DM may require sugar-free products if blood glucose levels are elevated consistently. With proper management, patients can decrease their chance of illness-induced hospitalization.

Outcome Evaluation

- The success of therapy for DM is measured by the ability of the patient to manage his or her disease appropriately between health care provider visits.
- Appropriate therapy necessitates adequate patient education about the disease, development of a meal plan to which patients can comply, and integration of a regular exercise program.
- Patient care plans should include a number of daily evaluations to be performed by the patient, such as examination of the feet for any sores, cuts, or abrasions; checking the skin for dryness to prevent cracking and chafing; and monitoring blood glucose values as directed. Weekly appraisals of weight and blood pressure are also advised.

- Until HbA_{1c} levels are at goal, quarterly visits with the patient's primary health care provider are recommended. Table 40–7 summarizes the specific ADA goals for therapy. The practitioner should review SMBG data and a current HbA_{1c} level for progress and address any therapeutic or educational issues.
- At minimum, yearly laboratory evaluation of serum lipids, urinary microalbumin, and serum creatinine should be performed. If the patient is on a thiazolidinedione, liver function tests should be performed at least once a year.

Patient Care and Monitoring

1. Assess the patient for development or progression of DM and DM-related complications.
2. Evaluate SMBG for glycemic control, including FPG and postprandial levels.
   - Are the blood glucose values too high or low?
   - Are there specific times of day or specific days not in control?
   - Is hypoglycemia occurring?
3. Assess the patient for changes in quality-of-life measures, such as physical, psychological, and social functioning and well-being.
4. Perform a thorough medication history of prescription, over-the-counter, and herbal product use.
   - Are there any medication problems, including presence of adverse drug reactions, drug allergies, and drug interactions?
   - Is the patient taking any medications that may affect blood glucose control?
5. Review all available laboratory data (some settings may have only patient-reported values) for attainment of ADA goals (Table 40–7). What therapy goals are not being met, and what tests or referrals to other members of the health care team are needed?
6. Recommend appropriate therapy, and develop a plan to assess effectiveness.
7. Stress adherence to prescribed lifestyle and medication regimen.
8. Provide patient education on diabetes, lifestyle modifications, appropriate monitoring, and drug therapy:
   - Causes of DM complications and how to prevent them.
   - How lifestyle changes including diet and exercise can affect diabetes.
   - How to perform SMBG and what to do with the results.
   - When to take medications and what to expect.
   - What adverse effects may occur?
   - What warning sign(s) should be reported to the physician?

41 Thyroid Disorders

Michael D. Katz

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Explain the major components of the hypothalamic-pituitary-thyroid axis and the interaction among these components.
2. Discuss the prevalence of thyroid disorders, including subclinical (mild) and overt (typical signs and/or symptoms present) hypothyroidism and hyperthyroidism.
3. Discuss the relationship between serum thyroid-stimulating hormone (TSH) levels and primary thyroid disease and the advantages for the use of TSH levels over other tests such as serum T_4 (thyroxine) and T_3 (triiodothyroinine) levels.
4. Identify the typical signs and symptoms of hypothyroidism and the consequences of inadequate treatment.
5. Describe the clinical use of levothyroxine in the treatment of hypothyroidism, including initial dose and dose titration, and patient monitoring.
6. Discuss the issues regarding levothyroxine product bioequivalence and the advantages of maintaining patients on the same product.
7. Identify the typical signs and symptoms of Graves' disease and the consequences of inadequate treatment.
8. Describe the management of hypothyroidism and hyperthyroidism in pregnant women.
9. Discuss the pharmacotherapy of Graves' disease, including the advantages and disadvantages of antithyroid drugs versus radioactive iodine, adverse effects, and patient monitoring.
10. Describe the potential effects of amiodarone, lithium, and interferon-α on thyroid function.

Key Concepts

❶ In most patients with thyroid hormone disorders, the measurement of a serum thyroid-stimulating hormone (TSH) level is adequate for the diagnosis of hypothyroidism and hyperthyroidism. The target TSH for most patients being treated for thyroid disorders should be the mean normal value of 1.4 milliunits/L or 1.4 microunits/mL (target range 0.5–2.5 milliunits/L or 0.5–2.5 microunits/mL).

❷ Hypothyroidism can affect virtually any tissue or organ in the body. However, the most common symptoms, such as fatigue, lethargy, sleepiness, cold intolerance, and dry skin, are nonspecific and are seen with many other disorders. The classic overt signs, such as myxedema and delayed deep tendon reflexes, are seen uncommonly now because more patients are screened or seek earlier medical attention. Patients with mild hypothyroidism may have subtle symptoms that progress so slowly that they are not noticed easily by the patient or family. The lack of overt or specific signs and symptoms emphasizes the importance of using the serum TSH level to identify patients with hypothyroidism.

❸ There are three major goals in the treatment of hypothyroidism: replace the missing hormones, relieve symptoms, and achieve a stable biochemical euthyroid state.

❹ Despite the availability of a wide array of thyroid hormone products, it is clear that synthetic levothyroxine (LT_4) is the treatment of choice for almost all patients with hypothyroidism. LT_4 mimics the normal physiology of the thyroid gland, which secretes mostly T_4 as a prohormone. As needed, based on metabolic demands, peripheral tissues convert thyroxine (T_4)

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

to triiodothyronine (T_3). If T_3 is used to treat hypothyroidism, the peripheral tissues lose their ability to control local metabolic rates. LT_4 also has distinct pharmacokinetic advantages over T_3. With a 7-day half-life, LT_4 provides a very smooth dose-response curve with little peak and trough effect.

❺ There is no evidence that one LT_4 product is better than another. However, given the likelihood that these products do have different bioavailabilities, patients should be maintained on the same LT_4 product. Given the generic substitution regulations of most states, this is best accomplished by prescribing a brand-name product. The prescriber should not allow substitution in the way mandated by state regulations.

❻ The goals of treating hyperthyroidism are to relieve symptoms, to reduce thyroid hormone production to normal levels and achieve biochemical euthyroidism, and to prevent long-term adverse sequelae.

❼ Agranulocytosis is one of the most serious adverse effects of antithyroid drug therapy.

❽ The growth and spread of thyroid carcinoma are stimulated by TSH. An important component of thyroid carcinoma management is the use of LT_4 to suppress TSH secretion. Early in therapy, patients receive the lowest LT_4 dose sufficient to fully suppress TSH to undetectable levels. Controlled trials show that suppressive LT_4 therapy reduces tumor growth and improves survival.

❾ Patients receiving amiodarone must receive monitoring for thyroid abnormalities. Baseline measurements of serum TSH, FT_4, FT_3, antithyroid peroxidase antibody (anti-TPOAb) and TSH receptor-stimulating antibodies (TSHR-SAb) should be performed. TSH, FT_4, and FT_3 should be checked 3 months after initiation of amiodarone and then every 3 to 6 months.

Thyroid disorders are common. Over 2 billion people, or 38% of the world's population, have iodine deficiency, resulting in 74 million people with **goiters.** While iodine deficiency is not a significant problem in developed countries, a number of common thyroid problems exist. The most common problems related to thyroid function, **hypothyroidism** and **hyperthyroidism,** often require long-term pharmacotherapy. Undetected or improperly treated thyroid disease can result in long-term adverse sequelae, including increased mortality. It is important that clinicians are aware of the prevalence of thyroid disorders, methods of identifying thyroid disorders, and appropriate therapy. This chapter focuses on the most common pharmacologically treated thyroid disorders.

THYROID HORMONE PHYSIOLOGY AND BIOSYNTHESIS

The thyroid gland is the largest endocrine gland in the body, residing in the neck, anterior to the trachea, between the cricoid cartilage and the suprasternal notch. The thyroid gland produces two biologically active hormones, thyroxine (T_4) and triiodothyronine (T_3). Thyroid hormones are essential for proper fetal growth and development, particularly development of the central nervous system (CNS). After delivery, the primary role of thyroid hormone is in the regulation of energy metabolism. These hormones can affect the function of virtually every organ in the body. The parafollicular C cells of the thyroid gland produce calcitonin. The function of calcitonin and its therapeutic use are discussed in other chapters in this book.

T_4 and T_3 are produced by the organification (binding of iodine to tyrosine residues of thyroglobulin) of iodine in the thyroid gland. Iodine is actively transported into the thyroid follicular cells. This inorganic iodine is oxidized by **thyroid peroxidase** and covalently bound to tyrosine residues of **thyroglobulin**. The iodinated tyrosine residues monoiodotyrosine and diiodotyrosine couple to form T_4 and T_3. Eighty percent of thyroid hormone is synthesized as T_4 and is stored in the thyroid bound to thyroglobulin. Thyroid hormones are released from the gland when needed, primarily under the influence of thyroid-stimulating hormone (TSH) from the anterior pituitary. T_4 and T_3 are transported in the blood by three proteins, 70% to thyroid-binding globulin (TBG), 15% to transthyretin (thyroid-binding prealbumin), and 15% to albumin. T_4 is 99.97% protein-bound, and T_3 is 99.7% protein-bound, with only the unbound or free fractions physiologically active. The high degree of protein binding results in a long half-life of these hormones: approximately 7 days for T_4 and 24 hours for T_3.

Most of the physiologic activity of thyroid hormones is from the actions of T_3. T_4 can be thought of primarily as a prohormone. Eighty percent of needed T_3 is derived from the conversion of T_4 to T_3 in peripheral tissue under the influence of tissue deiodinases. These deiodinases allow end organs to produce the amount of T_3 needed to control local metabolic functions. These enzymes also catabolize T_3 and T_4 to biologically inactive metabolites. Thyroid hormones bind to intracellular receptors and regulate the transcription of various genes.

The production and release of thyroid hormones are regulated by the hypothalamic-pituitary-thyroid axis (Fig. 41–1). Hypothalamic thyrotropin-releasing hormone (TRH) stimulates the release of TSH (thyrotropin) when there are physiologically inadequate levels of thyroid hormones. TSH promotes the production and release of thyroid hormones from the gland. As circulating thyroid hormone levels rise to needed levels, negative feedback results in decreased release of TSH and TRH. The release of TRH is inhibited by somatostatin and its analogs, and the release of TSH can be inhibited by dopamine, dopamine agonists, and high levels of glucocorticoids.

SPECTRUM OF THYROID DISEASE

There are two general modes of presentation for thyroid disorders: changes in the size or shape of the gland and changes in secretion of hormone from the gland. In some cases, structural changes can result in changes in hormone secretion. Thyroid nodules and goiters in **euthyroid** patients

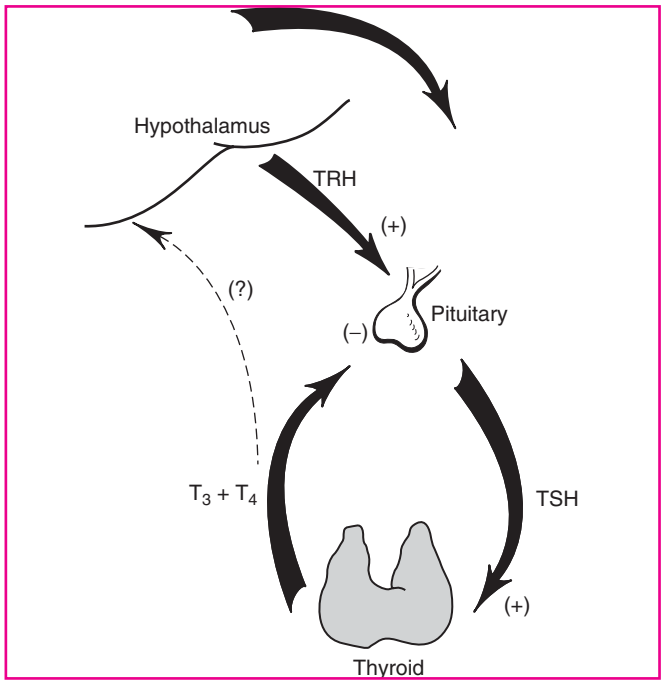

FIGURE 41–1. Hypothalamic-pituitary-thyroid axis. Thyrotropin-releasing hormone (TRH) is synthesized in the neurons within the paraventricular nucleus of the hypothalamus. TRH is released into the hypothalamic-pituitary portal circulation and carried to the pituitary, where it activates the pituitary to synthesize and release thyrotropin (TSH). TSH activates the thyroid to stimulate the synthesis and secretion of thyroxine (T_4) and triiodothyronine (T_3). T_4 and T_3 inhibit TRH and TSH secretion, closing the feedback loop.

are common problems. Patients with a goiter often require no specific pharmacotherapy, unless the goiter is due to iodine deficiency. In developing countries, iodized salt is the primary therapy in treating goiter. Thyroid nodules, seen in 4% to 7% of adults, may be malignant or autonomously secrete thyroid hormones. A discussion of thyroid nodules is beyond the scope of this chapter. However, thyroid cancer will be discussed briefly in the context of levothyroxine (LT_4) suppressive therapy. The reader is referred to other resources for a more extensive review of thyroid cancer management.

Changes in hormone secretion can result in hormone deficiency or excess. While patients with overt hypothyroidism and hyperthyroidism may have dramatic signs and symptoms, most patients have subtle signs and symptoms that progress slowly over time. The availability of sensitive and specific biochemical tests for the diagnosis of thyroid hormone disorders has facilitated screening and earlier diagnosis, including those with subclinical thyroid disorders. Screening of newborns for congenital hypothyroidism has reduced the incidence of mental retardation and **cretinism** dramatically in the United States. However, congenital hypothyroidism owing to iodine deficiency remains a significant worldwide public health problem.

Epidemiology of Thyroid Disease

A number of studies have assessed the epidemiology of thyroid hormone abnormalities. The Third National Health and Nutrition Examination Survey (NHANES III)[1] reported the prevalence of thyroid hormone disorders in 17,353 people 12 years and over in a sample representing the geographic and ethnic distribution of the United States population. Hypothyroidism was found in 4.6% (4.3% subclinical) and hyperthyroidism in 1.3% (0.7% subclinical) of the sample. Antithyroid peroxidase antibodies (anti-TPOAb) were found in 11.3% of this population. The prevalence of hypothyroidism was higher in older age groups and in whites and Hispanics, whereas blacks had a lower prevalence of antithyroid antibodies and hypothyroidism. The Colorado Thyroid Health Survey[2] assessed thyroid function in 25,862 subjects attending a health fair. The overall prevalence of an abnormal TSH level was 11.7% of the study population, with 9.4% hypothyroid (9% subclinical) and 2.2% hyperthyroid (2.1% subclinical). Of the 916 subjects taking thyroid medication, 60% were euthyroid, with an equal distribution between subclinical hypothyroidism and hyperthyroidism. These findings imply that many patients who are receiving thyroid medications are not being managed successfully.

PATIENT ASSESSMENT AND MONITORING

The assessment of patients for thyroid disorders entails a history and physical examination. In many patients with subclinical or mild thyroid disease, there may be an absence of specific signs and symptoms, and the physical examination may be normal. Various diagnostic tests can be used, including serum thyroid hormone(s), TSH, and thyroid antibody levels and imaging techniques to evaluate patients for thyroid disorders. Normal values for selected laboratory tests are given in Table 41–1.

TABLE 41–1. Selected Thyroid Tests for Adults

Test	Normal Range	Comments
TSH	0.5–2.5 milliunits/L (0.5–2.5 microunits/mL)[a]	Gold standard; may be lowered by dopamine, dopamine agonists, glucocorticoids, octreotide, recovery from severe nonthyroidal illness
Free T_4	0.7–1.9 ng/dL (9.0–24.5 pmol/L)	May be normal in mild thyroid disease
Anti-TPOAb	Less than 100 units/mL	Present in autoimmune hypothyroidism; predicts more rapid progression from subclinical to overt hypothyroidism
TSHR-SAb	Undetectable	Confirms Graves' disease

[a]milliunits/L = microunits/mL; clinical laboratories use either unit of measurement. Anti-TPOAb, antithyroid peroxidase antibody; T_4, thyroxine; TSH, thyroid-stimulating hormone; TSH-SAb, TSH receptor-stimulating antibodies.

TSH Levels

❶ *In most patients with thyroid hormone disorders, the measurement of a serum TSH level is adequate for the diagnosis of hypothyroidism and hyperthyroidism.* TSH is a highly sensitive bioassay of the thyroid axis. A two-fold change in serum free T_4 levels will result in a 100-fold change in TSH levels. This biologic magnification by TSH allows the TSH to be used in early diagnosis as well as in closely titrating therapy in hypothyroidism and hyperthyroidism.[3] In patients with hypothyroidism or hyperthyroidism resulting from gland dysfunction (primary thyroid disease), there is an inverse relationship between the TSH level and thyroid function. High TSH signifies hypothyroidism (or iatrogenic underreplacement), and low TSH signifies hyperthyroidism (or iatrogenic overreplacement). There is controversy regarding the normal or laboratory reference ranges for TSH. NHANES III[1] showed that the mean TSH level in a normal population was 1.4 milliunits/L (milliunits/L = microunits/mL; clinical laboratories use either unit of measurement), but the values were not normally distributed. While most laboratories quote the upper limit of normal for TSH as 4.5 milliunits/L based on the NHANES III data, 95% of subjects had a TSH level of between 0.5 and 2.5 milliunits/L. The population of subjects whose TSH level was 2.5 to 4.5 milliunits/L probably had mild hypothyroidism and should not have been included as part of the normal reference range for TSH. It has been proposed that the reference TSH range be redefined with an upper limit of normal of 2.5 or 3 milliunits/L.[4] ❶ *The target TSH for most patients being treated for thyroid disorders should be the mean normal value of 1.4 milliunits/L or 1.4 microunits/mL (target range 0.5–2.5 milliunits/L or 0.5–2.5 microunits/mL).*

Serum Hormone Levels

Serum T_4 and T_3 levels were used commonly to assess thyroid function. Screening thyroid function tests measure total serum T_4 or T_3 levels. Because of the high degree of protein binding of these hormones, the free fraction can be altered by changes in the levels of binding proteins or the degree of protein binding. Since a number of factors can alter protein binding, the older assays are very insensitive and should no longer be used, even with protein-binding adjustment factors such as the free thyroxine index. Free or unbound T_4 (FT_4) and T_3 (FT_3) assays are readily available and are more sensitive in identifying thyroid dysfunction than the older total assays.[5] However, patients with mild hypothyroidism or hyperthyroidism will have a normal FT_4 level despite an abnormal TSH level.

The laboratory assessment of patients with suspected thyroid disorders must be based on the continuum of disease from subclinical or mild to overt (Fig. 41–2).

Other Diagnostic Tests

Global tests of thyroid gland function can be performed to assess the rate of hormone synthesis. The radioactive iodine uptake (RAIU) will be elevated in hyperthyroidism and can aid in identifying **thyrotoxicosis** owing to non-thyroid gland sources. Radionuclide thyroid scans are used in the evaluation of thyroid nodules. Since many thyroid disorders are autoimmune, measurement of various serum antithyroid antibodies can be performed. Antithyroid peroxidase (anti-TPOAb) and antithyroglobulin antibodies (anti-TGAb) are present in many patients with hypothyroidism. Most patients with Graves' disease will have TSH stimulating receptor antibodies (TSHR-SAb) as well as elevated anti-TPOAb and antimicrosomal antibodies.

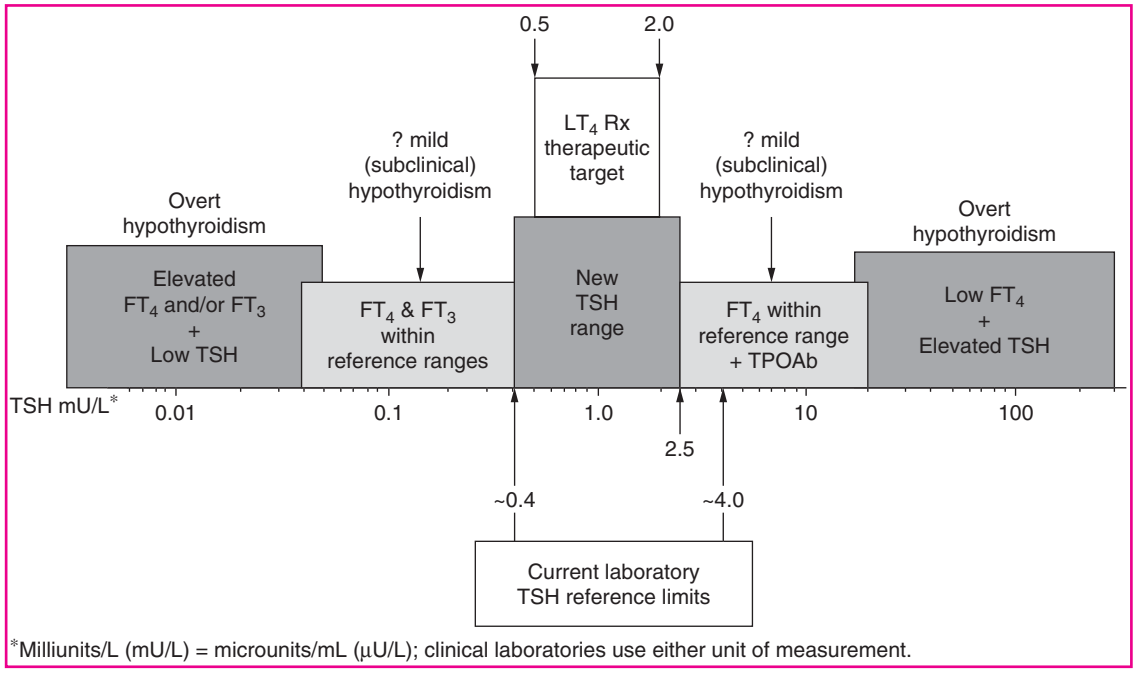

FIGURE 41–2. TSH and the continuum of thyroid disorders. FT_3, free T_3; FT_4, free T_4; LT_4, levothyroxine; TPOAb, thyroid peroxidase antibody; TSH, thyroid-stimulating hormone. (Reprinted, with permission, from reference 4.)

HYPOTHYROIDISM

Hypothyroidism is the most common clinical disorder of thyroid function. It is the clinical syndrome that results from inadequate secretion of thyroid hormones from the thyroid gland. The vast majority of hypothyroid patients have primary gland failure, whereas rare patients have pituitary or hypothalamic failure. Most studies define hypothyroidism based on a serum TSH level above the upper limit of the laboratory reference range. In adults, 1.4% of women and 0.1% of men are biochemically hypothyroid. However, the incidence is highly age-dependent. In the Colorado Thyroid Health study,[2] by age 64, 12% of women and 5% of men were hypothyroid, and in the over 74 years age group, the incidence in men approached that of women. Most epidemiologic studies of hypothyroidism in the elderly show a prevalence of 6% to 12%. There is a strong correlation between the presence of anti-TPOAb or anti-TGAb and the risk of developing hypothyroidism. In patients with subclinical hypothyroidism and positive anti-TPOAb, 5% per year will progress to overt hypothyroidism.[6] Other risk factors for the development of hypothyroidism include postpartum state, family history of autoimmune thyroid disorders, a previous history of head and neck or thyroid surgery, head and neck irradiation, other autoimmune endocrine disorders such as type 1 diabetes and Addison's disease, other non-endocrine autoimmune diseases such as celiac disease and pernicious anemia, prior history of treatment for thyrotoxicosis, and treatment with amiodarone or lithium.

Screening for Hypothyroidism

Because the prevalence of hypothyroidism is high in certain populations, screening may be useful. Screening for hypothyroidism in women over age 35 is as cost-effective as screening for breast cancer and hypertension,[7] although some organizations recommend screening of adults over the ages of 50 or 60. Others advocate a case-finding approach, i.e., to perform a TSH determination in patients based on risk factors or the presence of signs and symptoms.[8,9]

Causes of Hypothyroidism

The most common causes of hypothyroidism are listed in Table 41–2. Up to 90% of patients with autoimmune thyroiditis have circulating anti-TPOAbs. The autoimmune inflammatory response results in a lymphocytic infiltration of the thyroid gland and its eventual destruction.

Iatrogenic hypothyroidism can follow thyroid irradiation or surgery and excessive doses of antithyroid drugs. Several drugs can cause hypothyroidism, including iodine-containing drugs such as amiodarone and radiocontrast media, lithium, interferon-α, p-aminosalicylic acid, and aminoglutethimide.[5] Iodine deficiency is a common worldwide cause of hypothyroidism, including congenital hypothyroidism in newborns. Patients with hypothalamic or pituitary disease often have other signs of pituitary disease, such as hypogonadism, and the TSH level will be low.

TABLE 41–2. Common Causes of Hypothyroidism[10,12]

Primary Hypothyroidism
Autoimmune thyroiditis (Hashimoto's disease)
Iatrogenic (irradiation, surgery)
Drugs (amiodarone, radiocontrast media, lithium, α-interferon)
Silent thyroiditis (including postpartum)
Secondary Hypothyroidism
Pituitary disease
Hypothalamic disease

Signs and Symptoms of Hypothyroidism

❷ *Hypothyroidism can affect virtually any tissue or organ in the body. The most common symptoms, such as fatigue, lethargy, sleepiness, cold intolerance, and dry skin, are non-specific and can*

Clinical Presentation and Diagnosis of Hypothyroidism[10]

Symptoms
- Fatigue
- Lethargy
- Sleepiness
- Mental impairment
- Depression
- Cold intolerance
- Hoarseness
- Dry skin
- Decreased perspiration
- Weight gain
- Decreased appetite
- Constipation
- Menstrual disturbances
- Arthralgia
- Paresthesia

Signs
- Slow movements
- Slow speech
- Hoarseness
- Bradycardia
- Dry skin
- Non-pitting edema (myxedema)
- Hyporeflexia
- Delayed relaxation of reflexes

Screening/Diagnosis

A TSH level of 4.5 to 10 milliunits/L constitutes mild or subclinical hypothyroidism, and some patients with a TSH level of 2.5 to 4.5 milliunits/L also may be mildly hypothyroid. A TSH level greater than 10 milliunits/L signifies overt hypothyroidism.* The free T_4 level will be normal (0.7–1.9 ng/dL or 9.0–24.5 pmol/L) in mild or subclinical hypothyroidism and low (less than 0.7 ng/dL or 9.0 pmol/L) in patients with obvious signs and/or symptoms.

*Milliunits/L (mU/L) = microunits/mL (μU/L); clinical laboratories use either unit of measurement.

be seen with many other disorders. The classic overt signs, such as ***myxedema*** *and delayed deep tendon reflexes, are seen uncommonly now because more patients are screened or seek medical attention earlier. Patients with mild hypothyroidism may have subtle symptoms that progress so slowly that they are not noticed easily by the patient or family. The lack of overt or specific signs and symptoms emphasizes the importance of using the serum TSH level to identify patients with hypothyroidism.*

Sequelae of Hypothyroidism

Hypothyroidism is a chronic disease that may result in significant long-term sequelae. Hypercholesterolemia is associated with hypothyroidism, increasing the long-term risk of cardiovascular disease. Between 4% and 14% of patients with hypercholesterolemia are found to be hypothyroid. The Colorado Thyroid Health Study[2] showed a direct correlation between the degree of TSH elevation and the rise in serum cholesterol. Hypothyroidism also may result in increased systemic vascular resistance, decreased cardiac output, and increased diastolic blood pressure. Hypothyroidism can cause significant neuropsychiatric problems, including a dementia-like state in the elderly that is reversible with levothyroxine (LT_4) therapy. Maternal hypothyroidism can have dire consequences for the developing fetus. The fetus is almost completely dependent on maternal thyroid hormones during the first trimester, a time crucial for development of the CNS. Inadequately treated maternal hypothyroidism results in increased risk of miscarriage and developmental impairment in the child.[11]

Myxedema coma is seen in advanced hypothyroidism. These patients develop CNS depression, respiratory depression, cardiovascular instability, and fluid and electrolyte disturbances. Myxedema coma often is triggered by an underlying acute medical condition such as infection, stroke, trauma, or administration of CNS depressant drugs.

TREATMENT

Pharmacotherapy of Hypothyroidism

❸ *There are three major goals in the treatment of hypothyroidism: replace the missing hormones, relieve symptoms, and achieve a stable biochemical euthyroid state.* While these goals should not be difficult to achieve, 20% to 40% of treated patients are not receiving optimal pharmacotherapy.

Thyroid Hormone Products

A number of thyroid hormone products are marketed in the United States (Table 41–3). These products include synthetic LT_4 and T_3, combinations of synthetic LT_4 and T_3, and animal-derived products. ❹ *Despite the availability of a wide array of thyroid hormone products, it is clear that synthetic LT_4 is the treatment of choice for almost all patients with hypothyroidism.*[12] *Using LT_4 mimics the normal physiology of the thyroid gland, which secretes mostly T_4 as a prohormone. Peripheral tissues convert T_4 to T_3 as needed, based on metabolic demands. If T_3 is used to treat hypothyroidism, the peripheral tissues lose their ability to control local metabolic rates. LT_4 also has distinct pharmacokinetic advantages over T_3. With a 7-day half-life, LT_4 provides a very smooth dose-response curve with little peak and trough effect.* T_3, with a 24-hour half-life, provides a significant peak and trough effect, and many patients will have symptoms of thyrotoxicosis after each dose is administered. For patients who have difficulty adhering to a once-daily regimen, a once-weekly LT_4 regimen is safe and effective.

Animal-derived products such as desiccated thyroid and thyroglobulin are derived from cow and pig thyroid and have various degrees of purity. These products contain both LT_4 and T_3, but the amount of T_3 is much higher (T_4:T_3 = 4:1) than what would be found in the human thyroid gland (T_4:T_3 = 14:1). With the desiccated thyroid products, there are concerns about standardizing the amount of hormone and lot-to-lot variability. While some patients want to use these agents because they are "natural," they are not natural for humans. With the strong evidence supporting the safety and efficacy of LT_4 in the treatment of hypothyroidism, there is no rationale for the use of these animal-derived products. Patients who are being treated with these agents should be strongly encouraged to switch to synthetic LT_4. Also, patients should be encouraged not to purchase thyroid-containing products from health food stores or from questionable Internet sites.

Liotrix is a fixed-ratio LT_4/T_3 product, although the LT_4:T_3 ratio is not physiologic for humans. Several studies have been published that evaluate the use of LT_4 and T_3 combinations in ratios that mimic human physiology. While early studies with these combinations showed improved neuropsychiatric and quality-of-life outcomes compared with LT_4 monotherapy, subsequent randomized, controlled trials have shown no outcome benefit.[13] Except in rare circumstances (such as patients with impaired T_4-to-T_3 conversion), there is no rationale for using combinations of LT_4 and T_3 to treat hypothyroidism.

Bioequivalence and LT_4 Product Selection

LT_4 products have a long history of bioavailability problems.[14] Over the years, LT_4 bioavailability has increased, so maintenance doses today are significantly lower than those seen in the 1970s and early 1980s. Currently, the average bioavailability of LT_4 products is about 80%. Because of long-standing concerns about LT_4 bioequivalence, and because LT_4 products had never undergone formal approval by the Food and Drug Administration (FDA) under the 1938 Food, Drug, and Cosmetics Act, the FDA mandated that all manufacturers of LT_4 products submit an Abbreviated New Drug Application (ANDA) to keep their products on the United States market after 2001.[15] Products approved under this process would have to comply with FDA manufacturing and bioequivalence standards. This FDA action has resulted in many changes in the United States LT_4 market, as well as renewed interest in LT_4 bioequivalence. By 2006, several brand and generic products had been approved by the FDA. Some of the generic products carry AB ratings (bioequivalence) to certain brand products.[16]

TABLE 41–3. Thyroid Preparations

Drug/Dosage Form	Content	Relative Dose	Comments
Levothyroxine (Synthroid®, Levoxyl®, Unithroid®), other brands, and generics	Synthetic LT_4; 25, 50, 75, 88, 100, 112, 125, 137, 150, 175, 200, and 300 mcg tablets; 500 mcg vial for injection	60 mcg	Gold standard for treating hypothyroidism; products not therapeutically equivalent; full replacement dose 1–1.6 mcg/kg per day; when switching from animal product, lower calculated daily dose by 25–50 mcg; intravenous form rarely needed
Liothyronine (Cytomel®)	Synthetic T_3; 5, 25, and 50 mcg tablets	15 mcg	Rarely needed in treatment of hypothyroidism; rapid absorption and pharmacologic effect; increased toxicity versus LT_4; no outcome benefit to combining with LT_4
Thyroid (desiccated) USP (Armour®, others)	Desiccated pork or beef thyroid glands; contains T_3 and T_4; 0.25, 0.5, 1, 1.5, 2, 3, 4, and 5-grain tablets	1 grain (65 mg)	Non-physiologic for humans; unpredictable hormone content and stability; T_3 content may cause toxicity
Thyroglobulin (Proloid®)	Partially purified pork thyroglobulin; 32, 65, 100, 130, and 200 mg tablets	65 mg	Non-physiologic T_4: T_3 ratio; T_3 content may cause toxicity; removed from United States market
Liotrix (Thyrolar®)	Synthetic T_4, T_3 in fixed 4:1 ratio; $\frac{1}{4}$, $\frac{1}{2}$, 1, 2, 3 strength tablets	12.5/50 mcg T_3: T_4 (1 strength)	Non-physiologic T_4: T_3 ratio; T_3 content may cause toxicity

LT_4, levothyroxine; T_3, triiodothyronine; T_4, thyroxine.

For many years, there have been concerns regarding the FDA bioequivalence methodology for LT_4 products. FDA bioequivalence standards allow a –20% to +25% variance in pharmacokinetic parameters between the test and reference products. Many people feel that this degree of allowed variance is not appropriate for a narrow-therapeutic-index (NTI) drug such as LT_4.[17] Also, there are unique challenges to performing bioequivalence studies in an endogenous hormone such as LT_4. Since these single-dose pharmacokinetic studies are done in healthy volunteers, the pharmacokinetic data are a combination of endogenous and exogenous LT_4. Seventy percent of the area under the curve (AUC) in these studies consists of the subjects' endogenous T_4. Thus, it is doubtful that bioavailability differences among products could be detected. Blakesley and colleagues[18] showed that the standard FDA bioequivalence methodology would rate 600, 450, and 400 mcg LT_4 doses as bioequivalent. This study also showed that mathematically removing the subjects' endogenous T_4 level (baseline correction) improves the sensitivity of the analysis, allowing a distinction between 33% and 25% but not 12.5% dose differences. Based on these data, the FDA, since 2003, has required that LT_4 bioequivalence data undergo baseline correction. While this method has improved the ability to identify large differences in LT_4 bioequivalence, small but clinically significant differences will not be identified.

More important than bioequivalence is the therapeutic equivalence of LT_4 products. Will patients have the same outcomes if bioequivalent products are used? The study by Dong and colleagues[19] helps to answer this question. Twenty-two well-controlled hypothyroid women were randomly switched to the same dose of four different products every 6 weeks. Non-baseline corrected bioequivalence data showed these products to be bioequivalent. However, as each product switch occurred, more of the subjects had an abnormal TSH level.[20] By the end of the third product switch, 52% had an abnormal TSH level. This is strong evidence that LT_4 products are not therapeutically equivalent even if they are rated as bioequivalent by the FDA.

Evidence does exist that small differences in the LT_4 dose can result in large changes in TSH. The impact on TSH of small changes in LT_4 dose was assessed in 21 adult hypothyroid patients.[21] When the daily dose was reduced by 25 mcg, 78% had an elevated TSH level. When the daily dose was increased by 25 mcg, 55% had a low TSH level. Clearly, differences in the LT_4 dose or bioavailability within the FDA-allowed variance for bioequivalent products can cause significant changes in TSH.

❺ *There is no evidence that one LT_4 product is better than another. However, given the likelihood that these products do have different bioavailabilities, patients should be maintained on the same LT_4 product. Given the generic substitution regulations of most states, this is best accomplished by prescribing a brand-name product and not allowing substitution in the way mandated by state regulations.* While practitioners are pressured by managed-care organizations and employers to substitute LT_4 products as a cost-saving measure, such switching is not in the best interest of the patient and should not be allowed. If patients are

switched to a different product, a TSH determination should be done in 6 to 8 weeks to allow retitration. The economic impact of retitration must be considered when formularies are changed to reduce the drug acquisition cost.

Therapeutic Use of LT_4

LT_4 is indicated for patients with overt hypothyroidism.[22] However, the need for treatment is controversial in patients with mild or subclinical disease (TSH less than 10 milliunits/L). There are no large clinical trials that show an outcome benefit with treating these patients, and the therapeutic decision must be individualized.[1,23] Many patients with "subclinical" hypothyroidism do, in fact, have subtle symptoms that improve with LT_4 replacement. If the patient's serum cholesterol is elevated,[24] or if serum anti-TPOAbs are present, many clinicians recommend LT_4 therapy.

In patients younger than age 65 with overt hypothyroidism, the average LT_4 replacement dose is 1.6 mcg/kg per day (use ideal body weight in obese patients[25]). If there is no history of cardiac disease, these patients may be started on the full replacement dose. The full replacement dose in patients over age 75 is lower, about 1 mcg/kg per day.[26] In the elderly, the starting dose is 25 to 50 mcg/day, and the dose is titrated to the full replacement dose. In patients with ischemic heart disease, start with 12.5 to 25 mcg/day and slowly titrate to the full replacement dose. If the patient develops angina or other forms of myocardial ischemia, lower the dose and titrate more slowly. At the start of therapy and with each change in dose, recheck the TSH in 6- to 8-week intervals. If the TSH is not in the target range (0.5–2.5 milliunits/L), change the dose by 10% to 20% and then recheck the TSH 6 to 8 weeks later. As the dose is titrated, assess the patient's symptoms. Many patients will improve quickly, and many patients will feel the best if the TSH is titrated to low-normal to middle-normal levels (0.5–1.5 milliunits/L).

Patients with mild or subclinical hypothyroidism do not need to be started on the full replacement dose because they still have some endogenous hormone production. Start these patients on 25 to 50 mcg/day, and titrate every 6 to 8 weeks based on TSH levels. Over time, it is likely that the LT_4 dose will need to be increased slowly as the patient's thyroid gland loses residual function.

Patient Encounter 1, Part 1

HT, a 34-year-old woman, comes to the clinic complaining of fatigue, lethargy, and having a "fuzzy head" for the past 6 months. She thought it was because she was working too hard, but the symptoms have not improved despite a better work schedule. She has noticed a 5-lb (2.3-kg) weight gain, her menses have become heavier, she feels cold all the time, and her skin is drier. She takes no medications other than occasional acetaminophen for headache and milk of magnesia for constipation. Her vital signs and physical examination, including pelvic examination are normal.

Labs

Serum cholesterol: 220 mg/dL (5.7 mmol/L; normal less than 200 mg/dL, or 5.2 mmol/L)
TSH: 9.7 milliunits/L (normal 0.5–2.5 milliunits/L)*
Free T_4: 0.6 ng/dL (7.7 pmol/L; normal 0.7–1.9 ng/dL, or 9–24.5 pmol/L)
She weighs 66 kg (145 lb), and she is 5 ft, 7 in (170 cm) tall.

- Why should HT receive LT_4 therapy?
- What dose would you initiate?
- How would you monitor and titrate her therapy?
- What would you tell HT regarding the significance of her symptoms, elevated TSH level, and risk versus benefits of LT_4 therapy?

*Milliunits/L (mU/L) = microunits/mL (μU/L); clinical laboratories use either unit of measurement.

Risks of Over- and Undertreatment

Patients receiving LT_4 therapy who are not maintained in a euthyroid state are at risk for long-term adverse sequelae. In general, overtreatment and a suppressed TSH is more common than undertreatment[27] with an elevated TSH. Patients with long-term overtreatment may be at higher risk for atrial fibrillation and other cardiovascular morbidities, depression, and post-menopausal osteoporosis. Patients who are undertreated are at higher risk for hypercholesterolemia and other cardiovascular problems, depression, and obstetric complications.

Alterations in LT_4 Dose Requirements

A number of factors can alter LT_4 dose requirements (Table 41–4). The most common cause of increased dose requirement is the co-administration of LT_4 with calcium or iron supplements. Counsel patients that they should take the LT_4 dose at least 2 hours before or 6 hours after the calcium or iron dose.

Patient Monitoring

Patients on stable LT_4 therapy do not need frequent monitoring. In most patients, measuring a TSH every 6 to 12 months, along with an assessment of clinical status, is adequate (Table 41–5). If the patient's clinical status changes (e.g., pregnancy, etc.), more frequent monitoring may be necessary. LT_4 prescriptions should be written as microgram doses to avoid potential errors when written as milligram doses (e.g., 250 mcg dispensed when 0.025 mg is ordered).

Patient education is an important component of care. Educate patients about the benefits of proper therapy, the importance of adherence, and the importance of receiving a consistent LT_4 product. Some patients will take excessive amounts of LT_4 in an effort to "feel better" or as a weight-loss treatment. Explain to patients that excessive amounts of LT_4 will not improve symptoms more than therapeutic doses and that this drug is not an effective treatment for obesity.

TABLE 41–4. Factors That Alter LT_4 Dose Requirements

Increased Dose Requirement	Decreased Dose Requirement
Decreased LT_4 absorption	Aging
Malabsorption syndromes	Delivery of pregnancy
	Withdrawal of interacting substance

Special Populations and Conditions

Hypothyroidism and Pregnancy

Hypothyroidism during pregnancy has a variety of maternal and fetal adverse effects.[11] During pregnancy, β-human chorionic gonadotropin (β-hCG) acts as a TSH receptor agonist, increasing the amount of thyroid hormone available for fetal growth and development. Maternal hypothyroidism results in an increased rate of miscarriage and decreased intellectual capacity of the child. Endocrinologists recommend a TSH measurement as soon as the pregnancy is confirmed. Most hypothyroid women who become pregnant will quickly need an increased dose of LT_4, averaging 50% above the pre-pregnancy dose.[28] The increased dose should be maintained throughout the pregnancy, with monthly TSH monitoring to keep the TSH in the middle- to low-normal range. After delivery, the LT_4 dose can be reduced to pre-pregnancy levels. Since prenatal vitamins contain significant amounts of calcium and iron, remind these patients to take the LT_4 dose at least 2 hours before or 6 hours after the vitamin.

TABLE 41–5. Monitoring LT_4 Therapy

Serum TSH:
Every 6–12 months or if change in clinical status
6–8 weeks after any dose or product change
In first trimester pregnancy, then monthly
Same product prescribed/dispensed with every refill.
Watch for mg/mcg dosing errors.
Assess patient's understanding of disease, therapy, and need for adherence and tight control.
Assess for signs/symptoms of over- and undertreatment.
Identify potential interactions between LT_4 and foods and/or drugs.

LT_4, levothyroxine; TSH, thyroid-stimulating hormone.

Patient Encounter 1, Part 2

One year later, HT comes to you and excitedly states that she is pregnant. She just saw her obstetrician, who started her on a prenatal vitamin. She states that she has felt very well since her LT_4 was started and that she is amazed at how much better she feels ("I didn't know how bad I felt until I started the thyroid medicine"). The most recent TSH determination, obtained 6 months ago, was 1.5 milliunits/L (normal 0.5–2.5 milliunits/L).* Her current LT_4 dose is 88 mcg/day.

- How will pregnancy affect HT's LT_4 dose requirement?
- What would you recommend regarding her LT_4 dose and monitoring?
- What would you tell HT regarding the potential impact of her pregnancy on her LT_4 therapy and the potential risks to her baby if she is not given an adequate dose of LT_4 during her pregnancy?

*Milliunits/L (mU/L) = microunits/mL (μU/L); clinical laboratories use either unit of measurement.

Children

Congenital hypothyroidism is still seen in the United States, and all newborns in the United States undergo screening with a TSH level. As soon as the hypothyroid state is identified, the newborn should receive the full LT_4 replacement dose. The replacement dose of LT_4 in children is age-dependent. In newborns, the usual dose is 10 to 17 mcg/kg per day. LT_4 tablets may be crushed and mixed with breast milk or formula. Serum FT_4 levels (target 1.6–2.2 ng/dL or 20.59–28.31 pmol/L) are used for dose titration in infants because the TSH level may not respond to treatment as it does in older children and adults. By 6 months of age, the required dose is reduced to 5 to 7 mcg/kg per day, and from ages 1 to 10 years, the dose is 3 to 6 mcg/kg per day. After age 12, adult doses can be given.

Myxedema Coma

This is a life-threatening condition owing to severe, long-standing hypothyroidism and has a mortality rate of 60% to 70%. These patients are given 300 to 500 mcg intravenous LT_4 initially, using caution in patients with underlying cardiac disease. While administration of T_3 would provide a more

Hypothyroidism Patient Care and Monitoring

1. Use serum TSH to identify patients with hypothyroidism and to monitor LT_4 replacement therapy.
2. Use synthetic LT_4 as the treatment of choice for hypothyroidism.
3. Provide LT_4 replacement to patients with overt hypothyroidism.
4. Consider replacement therapy in patients with a TSH level of greater than 2.5 but less than 10 milliunits/L* who have subtle symptoms (e.g., mild fatigue, lethargy, etc.), elevated cholesterol, or positive anti-TPOAbs.
5. Provide the calculated full replacement LT_4 dose (1.6 mcg/kg per day based on ideal body weight if obese) to patients with overt hypothyroidism who are older than 12 and younger than 65 years of age and who do not have cardiac disease.
6. Patients with mild hypothyroidism may be started at 25 to 50 mcg/day of LT_4.
7. Elderly patients or those with cardiac disease should be started at a lower LT_4 dose (e.g., 12.5–25 mcg/day).
8. Measure serum TSH 6 to 8 weeks after starting or any dose change. If the TSH level is not in the target range, alter the dose by 10% to 20% increments.
9. The target TSH for patients on LT_4 replacement therapy for hypothyroidism is 0.5 to 2.5 milliunits/L. Most patients feel best at a TSH level in the low- to middle-normal range (i.e., 0.5–1.5 milliunits/L).*
10. Provide a brand-name LT_4 product, and do not allow the patient to be switched to different products. If the product is switched, check a TSH in 6 weeks and retitrate the dose.
11. Write LT_4 prescriptions as microgram not milligram doses to avoid errors.
12. Check a TSH every 6 to 12 months in stable patients receiving LT_4 replacement.
13. Make sure that patients understand the importance of adherence and the risks of over- and underuse of LT_4.
14. At each visit, assess the patient for signs and symptoms of over- and undertreatment.
15. Monitor for drug interactions, such as LT_4 absorption problems caused by calcium and iron.
16. Check a TSH in pregnant women as soon as the pregnancy is diagnosed. In hypothyroid pregnant women, check the TSH monthly, and expect to raise the LT_4 dose during the first trimester. Maintain the TSH in the low- to middle-normal range. After delivery, reduce the LT_4 dose to the pre-pregnancy dose.

*Milliunits/L (mU/L) = microunits/mL (μU/L); clinical laboratories use either unit of measurement.

rapid onset of action, there is no evidence that T_3 improves outcomes in myxedema coma. Historically, glucocorticoids, such as hydrocortisone 50 to 100 mg every 6 hours, are administered owing to concern about simultaneous adrenal insufficiency. While there is no strong evidence for an outcome benefit, the use of glucocorticoids is reasonable because such treatment may be lifesaving, and the risks of a short course of corticosteroids at this dose are low. As patients improve, the LT_4 dose can be given orally in a typical full replacement dose.

HYPERTHYROIDISM/THYROTOXICOSIS

Hyperthyroidism is much less common than hypothyroidism. In NHANES III,[1] 1.3% of the population was hyperthyroid (0.5% overt, 0.8% subclinical), with the highest incidences in women overall and in men and women in the 20 to 39 and over 80 years of age groups. The Colorado Thyroid Health Study[2] showed a hyperthyroid incidence of 2.2% (2.1% subclinical).

Causes of Thyrotoxicosis

The common causes of thyrotoxicosis are shown in Table 41–6.[29,30] Thyrotoxicosis can be related to the presence or absence of excess hormone production (hyperthyroidism). Graves' disease is the most common cause of hyperthyroidism. Thyrotoxicosis in the elderly is more likely due to toxic thyroid nodules or multinodular goiter than to Graves' disease. Excessive intake of thyroid hormone may be due to overtreatment with prescribed therapy. Surreptitious use of thyroid hormones also may occur, especially in health professionals or as a self-remedy for obesity. Thyroid hormones can be obtained easily without a prescription from health food stores or Internet sources.

Clinical Manifestations of Thyrotoxicosis

Many of the signs and symptoms seem to be related to autonomic hyperactivity. As with hypothyroidism, the clinical

TABLE 41–6. Causes of Thyrotoxicosis[29]

Primary hyperthyroidism
Graves' disease
Toxic multinodular goiter
Toxic adenoma
Thyroid cancer
Struma ovarii
Iodine excess (including radiocontrast, amiodarone)
Thyrotoxicosis without hyperthyroidism
Subacute thyroiditis
Silent (painless) thyroiditis
Excess thyroid hormone intake (thyrotoxicosis factitia)
Secondary hyperthyroidism
TSH-secreting pituitary tumors
Trophoblastic (hCG-secreting) tumors
Gestational thyrotoxicosis

Adapted, with permission. hCG, human chorionic gonadotropin; TSH, thyroid-stimulating hormone.

Clinical Presentation and Diagnosis of Hyperthyroidism[29,30]

Symptoms
- Nervousness
- Fatigue
- Weakness
- Increased perspiration
- Heat intolerance
- Tremor
- Hyperactivity, irritability
- Palpitations
- Appetite change (usually increased)
- Weight change (usually weight loss)
- Menstrual disturbances (often oligomenorrhea)
- Diarrhea

Signs
- Hyperactivity
- Tachycardia
- Atrial fibrillation (especially in elderly)
- Hyperreflexia
- Warm, moist skin
- Ophthalmopathy, dermopathy (Graves' disease)
- Goiter
- Muscle weakness

Screening/Diagnosis
- Low TSH level (less than 0.5 milliunit/L) will signify thyrotoxicosis.
- Free T_4 is elevated in overt hyperthyroidism.
- Increased radioiodine uptake in the thyroid indicates increased hormone production by the thyroid gland.
- Almost all patients with Graves' disease will have positive TSHR-SAbs and positive anti-TPOAbs.

manifestations may be subtle initially and slowly progressive. Screening of patients for thyroid disease may identify patients with subclinical or mild thyrotoxicosis. Patients may seek medical attention only after a long period of thyrotoxicosis or owing to an acute complication such as atrial fibrillation. The clinical manifestations of thyrotoxicosis in the elderly may be blunted or atypical. These patients may present only with atrial fibrillation or depression.

Subclinical Thyrotoxicosis

Subclinical or mild thyrotoxicosis is defined as a low TSH with a normal FT_4 level. While there may be few or no symptoms in these patients, there are several areas of concern.[31,32] Many patients will progress to overt thyrotoxicosis. Patients with subclinical hyperthyroidism have been shown to suffer long-term cardiovascular and bone sequelae. In a 10-year follow-up of 2007 patients over age 60,[33] patients with an undetectable TSH level had a 3.1-fold increased risk of atrial fibrillation versus those with a normal TSH. In a different 10-year follow-up study[34] of 1191 patients over age 60, patients with a suppressed TSH had a 2.1-fold increased risk of all-cause mortality and a 3.3-fold increased risk of cardiovascular mortality versus patients with a normal TSH. Recent studies have shown that prolonged subclinical thyrotoxicosis speeds the loss of bone mineral density and increases fracture rates in postmenopausal women.[35,36]

Graves' Disease

Graves' disease[30] is an autoimmune syndrome that includes hyperthyroidism, diffuse thyroid enlargement, **exophthalmos** and other eye findings, and skin findings. The prevalence of Graves' disease in the United States is approximately 0.4% in women and 0.1% in men. The peak age of incidence is 20 to 49 years, with a second peak after 80 years of age. Hyperthyroidism results from the production of TSHR-SAbs in at least 80% of patients. These antibodies have TSH agonist activity, thereby stimulating hormone synthesis and release. These antibodies cross-react with orbital and fibroblastic tissue, resulting in ophthalmopathy and dermopathy. While the underlying cause of Graves' disease is not known, heredity seems to play a role. Subclinical Graves' disease may become acutely overt in the presence of iodine excess, infection, stress, parturition, smoking, and lithium and cytokine therapy.

There are several features of Graves' disease that are distinct from other forms of thyrotoxicosis. Clinically apparent ophthalmopathic changes are seen in 20% to 40% of patients and include exophthalmos, **proptosis, chemosis, conjunctival injection,** and periorbital edema. Lid retraction causes a typical staring or startled appearance (Fig. 41–3). Patients may complain of vague eye discomfort and excess tearing. In severe cases, the eyelids are unable to close completely, resulting in corneal damage. In very severe cases, the optic nerve can be compressed, resulting in permanent vision loss. All patients with suspected or known Graves' disease must be evaluated and monitored by an ophthalmologist.

Dermopathy occurs in 5% to 10% of patients with Graves' disease and usually is associated with severe ophthalmopathy. Skin findings include hyperpigmented, non-pitting induration of the skin, typically over the pretibial area (pretibial myxedema), the dorsa of the feet, and shoulder areas. **Clubbing** of the digits (thyroid acropachy) is associated with long-standing thyrotoxicosis.

Treatment of Hyperthyroidism

Treatment of thyrotoxicosis due to hyperthyroidism is similar, regardless of the underlying cause. ❻ *The goals of treating hyperthyroidism are to relieve symptoms, to reduce thyroid hormone production to normal levels and achieve biochemical euthyroidism, and to prevent long-term adverse sequelae.*

β-Blockers

Because many of the manifestations of hyperthyroidism appear to be mediated by the β-adrenergic system, β-adrenergic

FIGURE 41–3. Features of Graves' disease. *A*. Facial appearance: exophthalmos, lid retraction, periorbital edema, and proptosis. *B*. Thyroid dermopathy over lateral aspects of shins. *C*. Thyroid clubbing (acropachy). (Reprinted, with permission, from Jameson JL, Weetman AP. Disorders of the thyroid gland. In: Kasper DL, Braunwald E, Fauci AS, et al, (eds.) *Harrison's Principles of Internal Medicine*. 16th edition. New York: McGraw-Hill; 2004: 2114.)

blockers are used to rapidly relieve palpitations, tremor, anxiety, and heat intolerance. Since β-blockers do not reduce the synthesis of thyroid hormones, they are used only until more specific antithyroid therapy is effective. Since non-selective agents can impair the conversion of T_4 to T_3, propranolol and nadolol are used. An initial propranolol dose of 20 to 40 mg four times daily should be titrated to relieve signs and symptoms. β-Blockers should not be used in patients with decompensated heart failure or asthma. When a contraindication to β-blockers exists, clonidine or diltiazem may be used.

Methods to Reduce Thyroid Hormone Synthesis

Excess production of thyroid hormone can be reduced in four ways: iodides, antithyroid drugs, radioactive iodine, and surgery.[30,37,38]

Iodide

Large doses of iodide inhibit the synthesis and release of thyroid hormones. Serum T_4 levels may be reduced within 24 hours, and the effects may last for 2 to 3 weeks. Iodides are used most commonly in Graves' disease patients prior to surgery and to quickly reduce hormone release in patients with thyroid storm. Potassium iodide is administered either as a saturated solution (SSKI) that contains 38 mg iodide per drop or as Lugol's solution, which contains 6.3 mg iodide per drop. The typical starting dose is 120 to 400 mg/day. Iodide therapy should start 7 to 14 days prior to surgery. Iodide should not be given prior to radioactive iodine treatment because the iodide will inhibit concentration of the radioactivity in the thyroid. Iodides also are used to protect the thyroid from radioactive iodine fallout after a nuclear accident or attack. Daily administration of 30 to 100 mg iodide will markedly reduce thyroid gland uptake of radioactive iodine. The most frequent toxic effects with iodide therapy are hypersensitivity reactions, "iodism" (characterized by palpitations, depression, weight loss, and pustular skin eruptions), and gynecomastia.

Antithyroid Drugs

The thionamide agents propylthiouracil and methimazole are used in the United States to treat hyperthyroidism.[39] Carbimazole, a methimazole analog, is available in Europe. These drugs inhibit thyroid hormone synthesis by interfering with thyroid peroxidase–mediated iodination of tyrosine residues in thyroglobulin. Propylthiouracil has the added effect of inhibiting the conversion of T_4 to T_3. The thionamides also have immunosuppressant effects. In patients with Graves' disease treated with thionamides, TSHR-SAb levels and other immune mediators decrease over time. Both drugs are well absorbed from the gastrointestinal tract. Propylthiouracil has a half-life of 1 to 2.5 hours, whereas the half-life of methimazole is 6 to 9 hours.

Antithyroid drugs are used as primary therapy for Graves' disease or as preparative therapy before surgery or radioactive iodine administration. The decision to use antithyroid drugs as

primary therapy must be weighed against the risks and benefits of radioiodine or surgery. Patient preference must be considered.

In most patients, there is no clear advantage of one thionamide over the other. While propylthiouracil has the advantage of inhibiting T_4- to T_3-conversion, methimazole can be given as a single daily dose. The usual starting dose of methimazole is 15 to 30 mg/day, and the usual starting dose of propylthiouracil is 100 mg three times daily. Thyroid hormone levels drop in 2 to 3 weeks, and after 6 weeks, 90% of patients with Graves' disease will be euthyroid. Thyroid function testing should be performed every 4 to 6 weeks until stable. After the patient becomes euthyroid, the antithyroid drug dose often can be decreased (5–10 mg/day methimazole, 100–200 mg/day propylthiouracil) to maintain the euthyroid state. Excessive doses of antithyroid drugs will result in hypothyroidism. Methimazole is preferred to normalize thyroid function prior to radioactive iodine therapy because propylthiouracil increases the failure rate of radioactive iodine therapy.

Remission of Graves' disease occurs in 40% to 60% of patients after 1 to 2 years of therapy. Levels of TSHR-SAb after a course of treatment may have predictive value in that antibody-positive patients almost always will relapse. However, antibody-negative patients also may relapse after therapy is stopped. Antithyroid therapy may be stopped or tapered after 12 to 24 months. Relapse usually occurs in the first 3 to 6 months after stopping antithyroid therapy. About 75% of women in remission who become pregnant will have a postpartum relapse. When therapy is discontinued, a therapeutic strategy should be in place in the event of relapse. Many patients will opt for radioactive iodine as a long-term solution.

Antithyroid drugs are associated with a low rate of adverse effects. Skin rash, arthralgias, and gastrointestinal upset are seen in 5% of patients. While the drug can be continued in the presence of a minor skin rash, the development of arthralgia warrants discontinuation. Hepatotoxicity is an uncommon but potentially serious adverse effect, occurring in 0.1% to 0.2% of patients. However, transient rises in aminotransferase enzyme levels are seen in up to 30% of patients treated with propylthiouracil. Severe hepatocellular damage can occur from propylthiouracil, whereas methimazole can cause cholestatic jaundice. Vasculitis is another potentially serious but uncommon reaction that is more common with propylthiouracil. Patients may develop a drug-induced lupus syndrome, and some, particularly Asians, can develop antineutrophil cytoplasmic antibody-positive vasculitis.

Agranulocytosis is the most feared side effect of antithyroid drug therapy. Agranulocytosis must be distinguished from a transient decrease in white blood cell count seen in up to 12% of adults and 25% of children with Graves' disease. Agranulocytosis occurs in 0.3% of patients, and the incidence is the same with propylthiouracil and methimazole. Agranulocytosis almost always occurs within the first 3 months of therapy, and it occurs suddenly and unpredictably. Patients will present with fever, malaise, and sore throat, and the absolute neutrophil count will be less than 1000/mm^3. Patients may develop sepsis and die rapidly. Agranulocytosis is thought to be autoimmune-mediated. If agranulocytosis occurs, discontinue the antithyroid drug immediately, administer broad-spectrum antibiotics if the patient is febrile, and consider the administration of granulocyte colony-stimulating factor. The white blood cell count should recover in a week or two. Patients who develop agranulocytosis should not be switched to another thionamide drug. Monitoring for agranulocytosis is controversial owing to its sudden and predictable nature. Most practitioners do not recommend routine monitoring of the complete blood count, although early detection could improve patient outcomes. Patients initiating thionamide therapy must be informed about the signs

Patient Encounter 2, Part 1

GD is a 24-year-old woman who comes to the clinic stating, "I'm so nervous and hungry, and I'm losing weight. What is wrong with me?" She first noticed these symptoms 2 months ago, and they have worsened steadily. She feels anxious for no reason and has trouble sleeping. She has noticed that her appetite has increased, although she has lost about 5 lb (2.3 kg). Sometimes she can feel her heart beating in her chest, but she denies chest pain or syncope. She also has noticed that she is always sweaty and that her menses have become very light. Her only medications are a hormonal oral contraceptive and occasional naproxen for dysmenorrhea. She thinks that her mother had some kind of thyroid problem when she was pregnant.

PE

VS: Pulse 112 beats per minute, blood pressure 108/72, RR 12, temperature 37.4°C (99.32°F)
HEENT: Diffusely enlarged thyroid; mild exophthalmos
CV: Tachycardic, RRR
Exts: Fine tremor
Skin: Warm and moist
ECG: Sinus tachycardia

Labs

Electrolytes, complete blood count normal. Urine hCG negative. TSH less than 0.5 milliunit/L (normal 0.5–2.5 milliunits/L);* FT_4 3.1 ng/dL (39.9 pmol/L; normal 0.7–1.9 ng/dL, or 9.0–24.5 pmol/L); +TSHR-SAbs

- What therapeutic options exist for GD's Graves' disease?
- What would you recommend?
- How would you initiate and titrate therapy?
- What would you tell GD regarding the cause of her signs and symptoms, significance of her abnormal thyroid function tests, and therapeutic options?

*Milliunits/L (mU/L) = microunits/mL (μU/L); clinical laboratories use either unit of measurement.

and symptoms of agranulocytosis and other serious side effects. Patients should be asked to report signs and symptoms suggestive of infection such as fever and sore throat lasting more than 2 or 3 days or any bruising.

Radioactive Iodine

Radioactive iodine, typically ^{131}I, produces thyroid **ablation** without surgery. ^{131}I is well absorbed after oral administration. The iodine is concentrated in the thyroid gland and has a half-life of 8 days. Over a period of weeks, thyroid cells that have taken up the ^{131}I begin to develop abnormalities and necrosis. Eventually, thyroid cells are destroyed, and hormone production is reduced. After a single dose, 40% to 70% of patients will be euthyroid in 6 to 8 weeks, and 80% will be cured. In most patients, hypothyroidism will develop, and long-term LT_4 replacement will be necessary. Because ^{131}I has a slow onset of action, most patients are treated initially with β-blockers and antithyroid drugs. Thionamide drugs must be withdrawn for at least 4 to 6 days prior to ^{131}I administration to allow adequate accumulation of the radioactive iodine in the gland. β-Blockers can be continued during ^{131}I therapy. The dose of ^{131}I is based on the estimated weight of the patient's thyroid gland. Radioactive iodine therapy is contraindicated during pregnancy and breastfeeding. Radioactive iodine therapy may acutely worsen Graves' ophthalmopathy. Patients with prominent eye disease may be started on prednisone 40 mg/day, with the dose tapered over 2 to 3 months. Radioactive iodine also may cause a painful thyroiditis, which may necessitate anti-inflammatory therapy. Any long-term carcinogenic effect of ^{131}I has not been demonstrated in long-term clinical trials.

Surgery

Subtotal thyroidectomy is indicated in patients with very large goiters and thyroid malignancies and those who do not respond or cannot tolerate other therapies. Patients must be euthyroid prior to surgery, and patients often are administered iodide preoperatively to reduce gland vascularity. The overall surgical complication rate is 2.7%. Postoperative hypothyroidism occurs in 10% of patients who undergo subtotal thyroidectomy.

Special Conditions and Populations

Graves' Disease and Pregnancy

Pregnancy may worsen or precipitate thyrotoxicosis in women with underlying Graves' disease owing to the TSH agonist effect of hCG. Untreated maternal thyrotoxicosis may result in increased rates of miscarriage, premature delivery, eclampsia, and low-birth-weight infants. Fetal and neonatal hyperthyroidism may occur as a result of transplacental passage of TSHR-SAbs. Because radioactive iodine is contraindicated and surgery is best avoided during pregnancy, most patients are treated with antithyroid drugs. Propylthiouracil is considered the treatment of choice, and the lowest possible dose to maintain maternal euthyroidism should be used. Antithyroid therapy in excessive doses may suppress fetal thyroid function.

Patient Encounter 2, Part 2

One month later, GD is back for a follow-up visit. She notes that her thyrotoxic symptoms are gone, and overall, she feels great. She is receiving propylthiouracil 100 mg three times daily. Her most recent TSH was 0.9 milliunit/L (normal 0.5–2.5 milliunits/L)*, and her free T_4 was 1.6 ng/dL (20.6 pmol/L; normal 0.7–1.9 ng/dL, or 9.0–24.5 pmol/L). However, over the past few days she has developed a sore throat and feels achy. She wonders if she has the flu. Her vital signs show a pulse of 92 beats/minute and a temperature of 38.3°C (101°F). A complete blood count reveals a total white blood cell count of 100/mm^3 or 0.1 × 10^9/L (normal 4000–10,000/mm^3 or 4–10 × 10^9/L) with 15 neutrophils (absolute neutrophil count 150).

- What has happened to GD?
- What are you concerned about?
- How will you manage this problem?
- What will you tell GD regarding the possible cause of her new symptoms, the significance of her low white blood cell count, and recommended actions?

*Milliunits/L (mU/L) = microunits/mL (μU/L); clinical laboratories use either unit of measurement.

Neonatal and Pediatric Hyperthyroidism

Some neonates born to mothers with Graves' disease will be hyperthyroid at delivery. Antithyroid drug therapy (propylthiouracil 5–10 mg/kg per day or methimazole 0.5–1 mg/kg per day) may be required for up to 12 weeks. One drop per day of SSKI may be used in the first few days to rapidly reduce thyroid hormone synthesis and release.

Thyroid Storm

Thyroid storm is a life-threatening condition caused by severe thyrotoxicosis. Signs and symptoms include high fever, tachycardia, tachypnea, dehydration, delirium, coma, and gastrointestinal disturbances. Thyroid storm is precipitated in a previously hyperthyroid patient by infection, trauma, surgery, radioactive iodine treatment, and sudden withdrawal from antithyroid drugs. Patients are treated with a short-acting β-blocker such as intravenous esmolol, intravenous or oral iodide, and large doses of propylthiouracil (900–1200 mg/day in three to four divided doses). Supportive care with acetaminophen to suppress fever, fluid and electrolyte management, and antiarrhythmic agents are important components of therapy. Intravenous hydrocortisone 100 mg every 8 hours is used often due to the potential presence of adrenal insufficiency.

Hyperthyroidism Patient Care and Monitoring

1. A low or undetectable TSH level identifies thyrotoxicosis.
2. Refer the patient for a diagnostic assessment to identify the underlying cause. Identify Graves' disease by the presence of eye and/or skin findings and the presence of TSHR-SAbs.
3. Refer patients with Graves' disease to an ophthalmologist for assessment and monitoring.
4. Treat severe or troublesome autonomic signs and symptoms with a non-selective β-blocker such as propranolol 20 to 40 mg four times daily. Titrate the β-blocker dose based on signs and symptoms.
5. In patients with excess thyroid hormone production, reduce hormone production with an antithyroid drug and/or radioactive iodine. Choose therapy based on patient-specific factors and preference.
6. Antithyroid drugs have a delayed effect. After 2 to 4 weeks of therapy, adjust the dose if the TSH is not in the target range (0.5–2.5 milliunits/L).* Once the patient is euthyroid, consider reducing the dose of antithyroid drug to avoid hypothyroidism.
7. Consider stopping antithyroid therapy in Graves' disease after 12 to 18 months to see if remission has occurred.
8. Monitor patients on antithyroid drugs for signs and symptoms of adverse effects.
9. Monitor for symptoms of neutropenia (e.g., fever or sore throat), and check white blood cell count if symptoms occur.
10. If radioactive iodine is given, make sure that antithyroid drugs are stopped 4 to 6 days prior to treatment.
11. Several months after radioactive iodine, expect that the patient will require permanent LT_4 replacement.
12. Treat pregnant hyperthyroid women with propylthiouracil.

*Milliunits/L (mU/L) = microunits/mL (μU/L); clinical laboratories use either unit of measurement.

NON-THYROIDAL ILLNESS (EUTHYROID SICK SYNDROME)

A number of changes in the hypothalamic-pituitary-thyroid axis occur during acute illness.[40] These changes are termed nonthyroidal illness or euthyroid sick syndrome. The type and degree of abnormalities depend on the severity of illness. Mild to moderate medical illness, surgery, or starvation causes a decrease in serum T_3 levels owing to decreased peripheral conversion of T_4 to T_3. The reduced T_3 levels do not correlate with ultimate mortality and are thought to be an adaptive response to stress. Patients with more severe illness, especially those in the intensive-care unit, frequently have reduced total T_4 levels, although FT_4 levels usually are normal. In the critically ill, there is a correlation between the degree of serum T_4 reduction and mortality. In most acutely ill patients who are euthyroid, the TSH level is normal. However, administration of dopamine, octreotide, or high doses of glucocorticoids can reduce TSH levels. During recovery from acute illness, the TSH level may become modestly elevated to renormalize serum T_4 levels. During this time, thyroid function tests may be misinterpreted to indicate hypothyroidism. Despite the sometimes very low T_4 levels, there is no evidence that LT_4 administration has any benefit. Patients with possible thyroid abnormalities during acute illness should be evaluated by an endocrinologist.

THYROID CANCER AND LT_4 SUPPRESSION

The growth and spread of thyroid carcinoma is stimulated by TSH. An important component of thyroid carcinoma management is the use of LT_4 to suppress TSH secretion. Early in therapy, patients receive the lowest LT_4 dose sufficient to fully suppress TSH to undetectable levels. Controlled trials show that suppressive LT_4 therapy reduces tumor growth and improves survival. These patients are purposefully "overtreated" with LT_4 and rendered subclinically hyperthyroid. Postmenopausal women should receive aggressive osteoporosis therapy to prevent LT_4-induced bone loss. Other thyrotoxic complications, such as atrial fibrillation, should be monitored and managed appropriately.

DRUG-INDUCED THYROID ABNORMALITIES

Drugs can affect thyroid function in a number of ways.[41] Effects of drugs on thyroid hormone protein binding, LT_4 absorption, and metabolism have been discussed previously. Several commonly used medications can alter thyroid hormone secretion.

Amiodarone

Amiodarone[42] is a commonly prescribed antiarrhythmic drug that contains two iodide atoms, constituting 38% of its mass. Each 200 mg dose of amiodarone provides 75 mg iodide. Amiodarone deiodination releases about 6 mg of free iodine daily, 20 to 40 times more than the average daily intake of iodine in the United States. Amiodarone blocks conversion of T_4 to T_3, inhibits entry of T_3 into cells, and decreases T_3 receptor binding. Amiodarone will cause thyroid abnormalities in 11% of previously euthyroid patients. Amiodarone causes rapid reduction in serum T_3 levels, increases free and total T_4 levels, and increases TSH level. After 3 months of therapy, TSH levels usually return to normal, although the serum T_3 and T_4 level changes may remain. Most of these patients are euthyroid because the free T_3 levels are in the low-normal range. Amiodarone-induced hypothyroidism is more common in iodine-sufficient areas of the world. Patients with

underlying autoimmune thyroiditis are much more likely to develop amiodarone-induced hypothyroidism. Amiodarone-induced hypothyroidism occurs most commonly within the first year of therapy. If amiodarone cannot be discontinued, LT_4 therapy will be effective in most patients. If amiodarone can be stopped, thyroid function will return to normal in 2 to 4 months.

Amiodarone is more likely to cause thyrotoxicosis in iodine-deficient areas. Type 1 amiodarone-induced thyrotoxicosis is caused by iodine excess and typically occurs in patients with preexisting multinodular goiter or subclinical Graves' disease. Type 2 amiodarone-induced thyrotoxicosis is a destructive thyroiditis that occurs in patients with no underlying thyroid disease. Amiodarone-induced thyrotoxicosis is more common in men. Because amiodarone has β-blocking activity, palpitations and tachycardia may be absent. In type 1 thyrotoxicosis, amiodarone should be discontinued. If amiodarone therapy cannot be stopped, larger doses of antithyroid drugs may be needed to control thyrotoxicosis. In type 2 thyroiditis, stopping amiodarone may not be necessary because spontaneous resolution may occur. Prednisone 40 to 60 mg/day will quickly improve thyrotoxic symptoms. Prednisone may be tapered after 1 to 2 months of therapy.

❾ *Patients receiving amiodarone must receive monitoring for thyroid abnormalities. Baseline measurements of serum TSH, FT_4, FT_3, anti-TPOAbs, and TSHR-SAbs should be performed. TSH, FT_4, and FT_3 should be checked 3 months after initiation of amiodarone and then every 3 to 6 months.*

Lithium

Lithium is associated with hypothyroidism in up to 34% of patients, and hypothyroidism may occur after years of therapy. Lithium appears to inhibit thyroid hormone synthesis and secretion. Patients with underlying autoimmune thyroiditis are more likely to develop lithium-induced hypothyroidism. Patients may require LT_4 replacement even if lithium is discontinued.

Interferon-α

Interferon-α causes hypothyroidism in up to 39% of patients being treated for hepatitis C infection. Patients may develop a transient thyroiditis with hyperthyroidism prior to becoming hypothyroid. The hypothyroidism may be transient as well. Asians and patients with preexisting anti-TPOAbs are more likely to develop interferon-induced hypothyroidism. The mechanism of interferon-induced hypothyroidism is not known. If LT_4 replacement is initiated, it should be stopped after 6 months to re-evaluate the need for replacement therapy.

Outcome Evaluation

- Desired outcomes include relieving signs and symptoms and achieving a euthyroid state.
- Success of therapy for thyroid disorders must be based not only on short-term improvement of the patient's clinical status and abnormal laboratory values but also on achievement of a long-term euthyroid state. Maintaining the TSH level in the normal range improves symptoms and reduces the risk of long-term complications.
- Because pharmacotherapy often is lifelong, especially in patients with hypothyroidism, patients must undergo periodic monitoring to avoid the long-term complications of hypothyroidism and hyperthyroidism. In the hypothyroid patient, such monitoring may involve simply asking the patient about signs and symptoms and a yearly measurement of the TSH level.
- Any change in the patient's clinical status, such as a new pregnancy or a major change in body weight, necessitates a reevaluation of therapy. Patients at high risk for complications, such as pregnant women, the elderly, and patients with underlying cardiac disease, must be monitored more closely.
- Patients should be educated and periodically reminded about the importance of adherence and long-term tight control, the need for periodic clinical and laboratory monitoring, and the importance of staying on one LT_4 product.
- In the hyperthyroid patient, relieving signs and symptoms and achieving a euthyroid state are the desired outcomes. The method of achieving these outcomes may change over time with the use of antithyroid drugs versus radioactive iodine.
- Patients with hyperthyroidism also must undergo periodic clinical and laboratory monitoring, with more frequent monitoring if there is a change in the patient's clinical status.
- Patients who receive antithyroid drugs must be monitored for adverse drug events such as agranulocytosis.
- Patients who receive radioactive iodine must be monitored for the development of hypothyroidism.
- In patients with thyroid cancer, the desired outcomes with LT_4 therapy often are different from those in the hypothyroid patient.
- LT_4 doses sufficient to suppress tumor growth may result in a suppressed TSH and mild hyperthyroidism. These patients must be monitored closely for complications of the mild hyperthyroid state, such as bone mineral loss and development of atrial fibrillation.

ABBREVIATIONS

ANDA:	Abbreviated New Drug Application
anti-TGAb:	antithyroglobulin antibody
anti-TPOAb:	antithyroid peroxidase antibody
AUC:	area under the (time-concentration) curve
β-hCG:	beta-human chorionic gonadotropin
CNS:	central nervous system
FDA:	Food and Drug Administration (United States)
FT_3:	free T_3
FT_4:	free T_4
hCG:	human chorionic gonadotropin
LT_4:	levothyroxine
NHANES:	National Health and Nutrition Examination Survey

NTI:	narrow therapeutic index
RAIU:	radioactive iodine uptake
SSKI:	saturated solution of potassium iodide
T_3:	triiodothyronine
T_4:	thyroxine

42 Adrenal Gland Disorders

Devra K. Dang, Judy T. Chen, Frank Pucino, Jr., and Karim Anton Calis

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Explain the regulation and physiologic roles of hormones produced by the adrenal glands.
2. Recognize the clinical presentation of patients with adrenal insufficiency.
3. Describe the pharmacologic management of patients with acute and chronic adrenal insufficiency.
4. Recommend therapy monitoring parameters for patients with adrenal insufficiency.
5. Recognize the clinical presentation of Cushing's syndrome and the physiologic consequences of cortisol excess.
6. Recommend strategies to prevent the development of Cushing's syndrome associated with exogenous glucocorticoid administration.
7. Describe the pharmacologic and nonpharmacologic management of patients with Cushing's syndrome.
8. Recommend therapy monitoring parameters for patients with Cushing's syndrome.

Key Concepts

❶ Signs and symptoms of adrenal insufficiency reflect the disturbance of normal physiologic carbohydrate, fat, and protein homeostasis caused by inadequate cortisol production and inadequate cortisol action.

❷ Lifelong glucocorticoid replacement therapy may be necessary for patients with adrenal insufficiency, and mineralocorticoid replacement therapy usually is required for those with Addison's disease.

❸ During an acute adrenal crisis, the immediate treatment goals are to correct volume depletion, manage hypoglycemia, and provide glucocorticoid replacement.

❹ Patients who experience excessive stress should be educated regarding the need for additional glucocorticoid replacement and prompt medical attention.

❺ Patients with Cushing's syndrome owing to endogenous or exogenous glucocorticoid excess typically present with similar clinical manifestations.

❻ Surgical resection is considered the treatment of choice for Cushing's syndrome from endogenous causes if the tumor can be localized and if there are no contraindications.

❼ Pharmacotherapy generally is reserved for patients: (1) in whom the ectopic adrenocorticotropic hormone–secreting tumor cannot be localized; (2) who are not surgical candidates; (3) who have failed surgery; (4) who have had a relapse after surgery; or (5) in whom adjunctive therapy is required to achieve complete remission.

❽ In drug-induced Cushing's syndrome, discontinuation of the offending agent is the best management option. However, abrupt withdrawal of the glucocorticoid can result in adrenal insufficiency or exacerbation of the underlying disease.

❾ Glucocorticoid doses of less than 7.5 mg/day of prednisone (or its equivalent) for fewer than 3 weeks generally would not be expected to lead to suppression of the hypothalamic-pituitary-adrenal axis.

The adrenal glands are important in the synthesis and regulation of key hormones. They play a crucial role in water and electrolyte homeostatsis, as well as regulation of blood pressure, carbohydrate and fat metabolism, physiologic response to stress, and sexual development and differentiation. This chapter focuses on pharmacologic and nonpharmacologic management of the two most common conditions associated

with adrenal gland dysfunction: glucocorticoid insufficiency (e.g., Addison's disease) and glucocorticoid excess (Cushing's syndrome). Other adrenal disorders such as **congenital adrenal hyperplasia, pheochromocytoma,** hypoaldosteronism, and hyperaldosteronism are beyond the scope of this chapter.

PHYSIOLOGY, ANATOMY, AND BIOCHEMISTRY OF THE ADRENAL GLAND

The adrenal gland is located on the upper segment of the kidney (Fig. 42–1). It consists of an outer cortex and an inner medulla. The adrenal medulla secretes the catecholamines epinephrine (also called adrenaline) and norepineprhine (also called noradrenaline), which are involved in regulation of the sympathetic nervous system. The adrenal cortex consists of three histologically distinct zones: zona glomerulosa, zona fasciculata, and an innermost layer called the zona reticularis. Each zone is responsible for production of different hormones (Fig. 42–2).

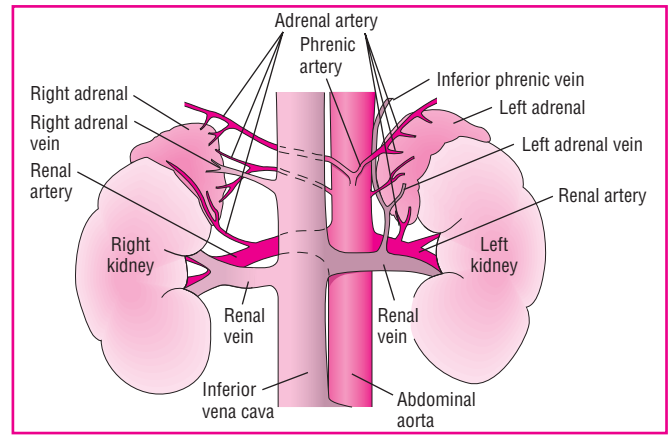

FIGURE 42–1. Anatomy of the adrenal gland. (Reprinted, with permission, from Gums JG, Tovar JM. Adrenal gland disorders. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. New York: McGraw-Hill; 2005: 1391–1406.)

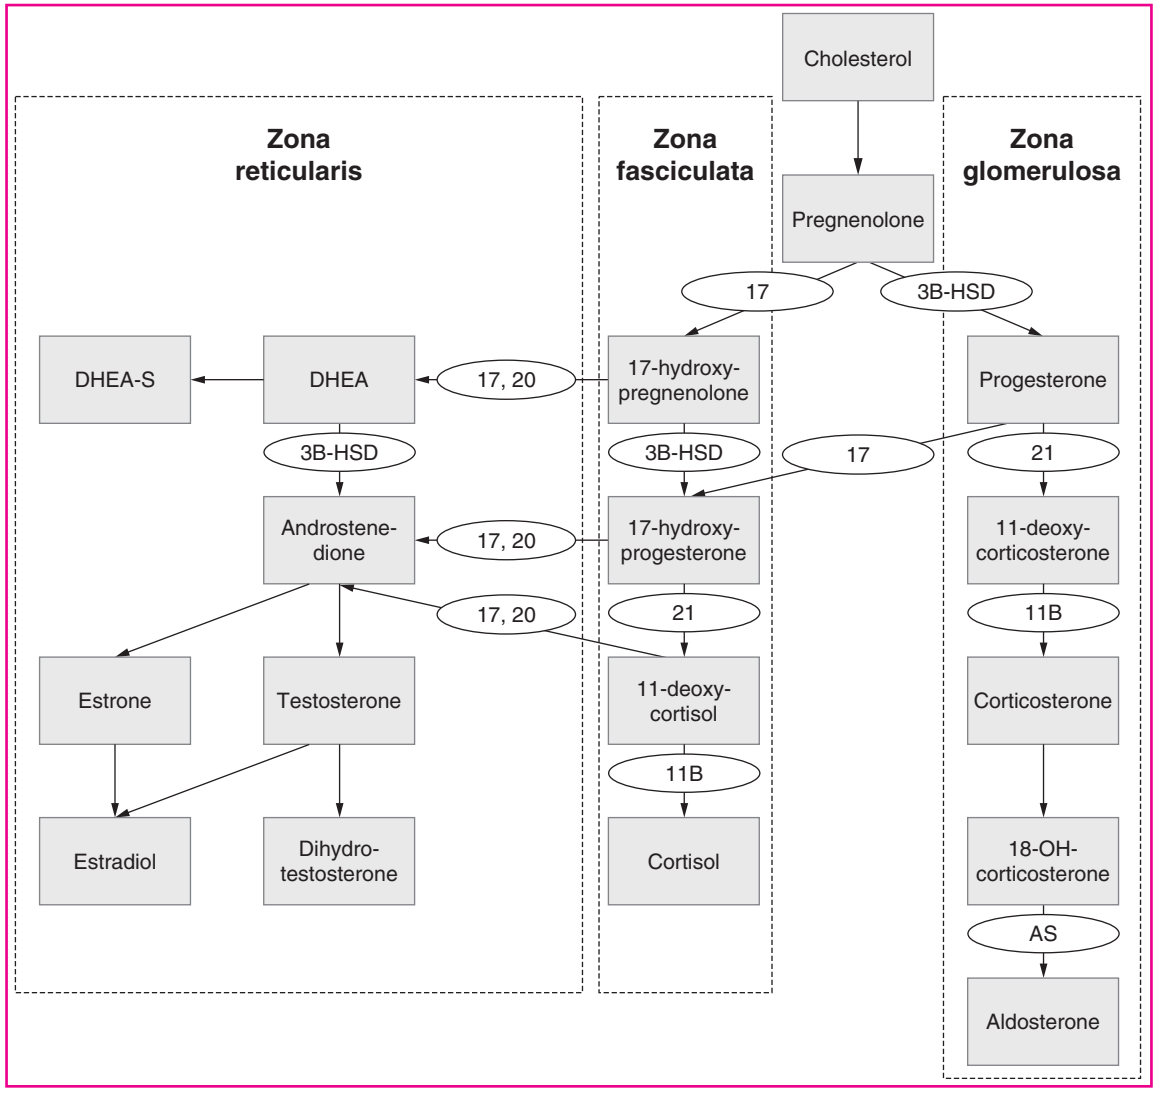

FIGURE 42–2. Adrenal steroid synthesis. The adrenal cortex consists of three histologically distinct zones: the zona glomerulosa, zona fasciculata, and an innermost layer called the zona reticularis. Each zone is responsible for production of different hormones. (17 = 17-hydroxylase; 3B-HSD = 3β-hydroxysteroid dehydrogenase; 21 = 21α-hydroxylase; 17,20 = 17,20-lyase; 11B = 11β-hydroxylase; AS = aldosterone synthase; DHEA = dehydroepiandrosterone; DHEA-S = sulfated form of dehydroepiandrosterone.)

The zona glomerulosa is responsible for the production of the mineralocorticoids **aldosterone,** deoxycorticosterone, and 18-hydroxy-deoxycorticosterone. Aldosterone promotes renal sodium retention and excretion of potassium. Its synthesis and release are regulated by renin in response to decreased vascular volume and renal perfusion. Adrenal aldosterone production is regulated by the **renin-angiotensin-aldosterone system.**

The zona fasciculata produces the glucocorticoid hormone **cortisol.** Cortisol is responsible for maintaining homeostasis of carbohydrate, protein, and fat metabolism. Its secretion follows a circadian rhythm, with the highest secretion occurring in the early-morning hours (peaking around 8 A.M.). Thereafter, cortisol levels decrease throughout the day, approach 50% of the peak value by 4 P.M., and reach their nadir around midnight.[1] The normal rate of cortisol production is approximately 8 to 15 mg/day.[2] Cortisol plays a key role in the body's response to stress. Its production increases markedly during physiologic stress, such as during acute illness, surgery, or trauma. In addition, certain conditions, such as alcoholism, depression, anxiety disorder, obsessive-compulsive disorder, poorly controlled diabetes, morbid obesity, starvation, anorexia nervosa, and chronic renal failure, are associated with increased cortisol levels. High total cortisol levels are also observed in the presence of increased cortisol-binding globulin (the carrier protein for 80% of circulating cortisol molecules), which is seen in pregnancy or other high-estrogen states (e.g., exogenous estrogen administration).[1] Cortisol is converted in the liver to an inactive metabolite known as cortisone.

The zona reticularis produces the androgens androstenedione, dehydroepiandrosterone (DHEA), and the sulfated form of dehydroepiandrosterone (DHEA-S). Only small amounts of testosterone and estrogen are produced in the adrenal glands. Androstenedione and DHEA are converted in the periphery, largely to testosterone and estrogen.

Adrenal hormone production is controlled by the hypothalamus and pituitary gland. **Corticotropin-releasing hormone** (CRH) is secreted by the hypothalamus and stimulates secretion of **adrenocorticotropic hormone** (ACTH), also known as *corticotropin* from the anterior pituitary. ACTH, in turn, stimulates the adrenal cortex to produce cortisol. When sufficient or excessive cortisol levels are reached, a negative feedback is exerted on the secretion of CRH and ACTH, thereby decreasing overall cortisol production. The control of adrenal androgen synthesis also follows a similar negative-feedback mechanism.

ADRENAL INSUFFICIENCY

Epidemiology and Etiology

Adrenal insufficiency generally refers to the inability of the adrenal glands to produce adequate amounts of cortisol for normal physiologic functioning or in times of stress. The condition is usually classified as primary, secondary, or tertiary depending on the etiology (Table 42–1). Chronic adrenal insufficiency is rare. The estimated prevalences of primary and secondary adrenal insufficiency are approximately 60 to 143 and 150 to 280 cases per 1 million persons, respectively. Primary adrenal insufficiency usually is diagnosed in the third to fifth decades of life, whereas secondary adrenal insufficiency is commonly detected during the sixth

TABLE 42–1. Etiologies of Adrenal Insufficiency[1,4–6,21,22]

Primary Adrenal Insufficiency (Addison's Disease)
- Autoimmune—accounts for 70%–90% of all cases of primary adrenal insufficiency
- Infectious or granulomatous diseases
  - Tuberculosis
  - Sarcoidosis
  - Cytomegalovirus
  - Fungal (histoplasmosis, coccidioidomycosis, cryptococcosis, *Blastomyces dermatitidis* infection)
  - Human immunodeficiency virus, AIDS
    - Mycobacterial, cytomegaloviral, and *Pneumocystis carinii* (*P. jiroveci*) infection
- Medications—inhibitors of steroidogenesis (aminoglutethimide, etomidate, ketoconazole, metyrapone, mitotane)
- Hemorrhagic
  Bilateral adrenal hemorrhage or infarction—usually due to anticoagulant therapy, coagulopathy, thromboembolic disease, or meningococcal infection. Causes acute adrenal insufficiency.
- Adrenalectomy
- Adrenoleukodystrophy (in males)
- Adrenomyeloneuropathy
- Infiltrative disorders—amyloidosis, hemochromatosis
- Genetic causes
  - Congenital adrenal hyperplasia
  - Familial glucocorticoid deficiency and hypoplasia
- Metastatic malignancy

Secondary Adrenal Insufficiency
- Drug-induced (most common cause of secondary adrenal insufficiency)
  - Chronic glucocorticoid administration at supraphysiologic doses
  - Megestrol acetate—has glucocorticoid-like activity
  - Mifepristone (RU 486)—antagonizes glucocorticoid receptors
- Post-cure of Cushing's syndrome

Panhypopituitarism
- Pituitary tumor
- Transsphenoidal pituitary microsurgery
- Pituitary irradiation
- Traumatic brain injury

Tertiary Adrenal Insufficiency
- Hypothalamic failure
- Drug-induced—chronic glucocorticoid administration at supraphysiologic doses

AIDS, acquired immunodeficiency syndrome
Partially adapted, with permission, from Aron DC, Findling JW, Tyrrell JB. Glucocorticoids and adrenal androgens. In: Greenspan FS, Gardner DG, (eds.) *Basic and Clinical Endocrinology*. New York: Lange Medical Books/McGraw-Hill; 2004: 362–413.

decade.[1,3] Adrenal insufficiency is more prevalent in women than in men with a ratio of 2.6:1.[1]

Pathophysiology

Primary adrenal insufficiency (also known as Addison's disease) occurs when the adrenal glands are unable to produce cortisol. It occurs from destruction of the adrenal cortex, usually from an autoimmune process. In general, the clinical manifestations are observed when destruction of the cortex exceeds 90%.[4] ❶ *Signs and symptoms of adrenal insufficiency reflect the disturbance of normal physiologic carbohydrate, fat, and protein homeostasis caused by inadequate cortisol production and inadequate cortisol action.* Primary adrenal insufficiency usually develops gradually. Patients may remain asymptomatic in the early stages, with signs and symptoms present only during times of physiologic stress. Persistent signs and symptoms of hypocortisolism typically occur with disease progression. Additionally, adrenal insufficiency may be accompanied by a reduction in aldosterone and androgen production.

Secondary adrenal insufficiency occurs as a result of a pituitary gland dysfunction whereby decreased production and secretion of ACTH leads to a decrease in cortisol synthesis. Tertiary adrenal insufficiency is a disorder of the hypothalamus that results in decreased production and release of CRH, which, in turn, decreases pituitary ACTH production and release. In contrast to Addison's disease (i.e., primary adrenal insufficiency), aldosterone production is unaffected in the secondary and tertiary forms of the disease. Chronic adrenal insufficiency often has a good prognosis if diagnosed early and treated appropriately.

Acute adrenal insufficiency (i.e., adrenal crisis) results from the body's inability to increase endogenous cortisol sufficiently during periods of excessive physiologic stress. Adrenal crisis can occur when patients with chronic adrenal insufficiency do not receive adequate glucocorticoid replacement during stressful conditions (such as those experienced during surgery, infection, acute illness, invasive medical procedures, or trauma). Acute adrenal insufficiency also can result from bilateral adrenal infarction owing to hemorrhage, embolus, sepsis, or adrenal vein thrombosis. Additionally, abrupt discontinuation or rapid tapering of glucocorticoids (given chronically in supraphysiologic doses) may lead to adrenal crisis. This condition results from prolonged suppression of the hypothalamic-pituitary-adrenal (HPA) axis and subsequent adrenal gland atrophy and hypocortisolemia. Other drugs associated with adrenal insufficiency include those that inhibit production (e.g., ketoconazole) or increase metabolism [e.g., the cytochrome P-450 subfamily IIIA polypeptide 4 (CYP450 3A4) inducer rifampin] of cortisol.[4] Regardless of etiology, patients experiencing an adrenal crisis require immediate glucocorticoid treatment because manifestations (such as circulatory collapse) can lead to life-threatening sequelae.

Clinical Presentation and Diagnosis of Chronic Adrenal Insufficiency[1,3,4,6]

General
- The symptoms, especially in the early stages, may be vague and mimic those of other medical conditions.
- The cardinal symptoms and signs are weakness and fatigue requiring rest periods, gastrointestinal symptoms, weight loss, and hypotension.
- Patients with autoimmune adrenal insufficiency may have other autoimmune disorders such as type 1 diabetes mellitus and autoimmune **thyroiditis.**

Symptoms
- Weakness and fatigue are the most common.
- Anorexia, nausea, and diarrhea (these may range from mild to severe with vomiting and abdominal pain).
- Hypoglycemia may occur in some patients.
- **Amenorrhea**
- Salt craving may occur in some patients with primary adrenal insufficiency.

Signs
- Weight loss
- Hypotension (less than 110/70 mm Hg) and **orthostasis**
- Dehydration, hypovolemia, and hyperkalemia (in primary adrenal insufficiency only)
- Decreased serum sodium and chloride levels
- Increased serum blood urea nitrogen (BUN) and creatinine owing to dehydration
- **Hyperpigmentation** of skin (usually around creases, pressure areas, areolas, genitalia, and new scars) and mucous membranes. Dark freckles and patches of vitiligo may be present. Hyperpigmentation, owing to increased ACTH levels, occurs in primary adrenal insufficiency.
- Personality changes (irritability and restlessness)
- Loss of axillary and pubic hair in women owing to decreased androgen production
- Blood count abnormalities (e.g., normocytic, normochromic anemia, relative lymphocytosis, neutrophilia, eosinophilia)

Laboratory Tests (Table 42–2)
- Decreased basal and stress-induced cortisol levels
- Decreased aldosterone level (in primary adrenal insufficiency only)
- Lack of increase in cortisol and aldosterone level after ACTH stimulation

Other Diagnostic Tests (Table 42–2)
- Computed tomography (CT) or magnetic resonance imaging (MRI) of the adrenal glands, pituitary, and/or hypothalamus can aid in determining the etiology.
- The presence of anti-adrenal antibodies is suggestive of an autoimmune etiology.

TABLE 42–2. Tests for Diagnosing Adrenal Insufficiency[4,6]

Test	Test Procedure and Measurement Rationale	Typical Finding in Adrenal Insufficiency	Comments
Screening Tests to Confirm Diagnosis of Adrenal Insufficiency			
Rapid ACTH stimulation test (also called **cosyntropin** stimulation test)	Measure serum cortisol 30–60 minutes after administering cosyntropin 1 mcg IV or 250 mcg IV[a] Increased cortisol secretion in normal individuals in response to ACTH stimulation but not in adrenal insufficiency	• Serum cortisol concentration less than 18 mcg/dL (497 nmol/L)	• False negative results occur if the ACTH deficiency is of recent onset. • To differentiate between primary and secondary or tertiary adrenal insufficiency, use same blood samples to measure plasma aldosterone level (see below).
Unstimulated serum cortisol measurement	Measure serum cortisol at 6–8 A.M. Serum cortisol level peaks in the early morning.	• Serum cortisol greater than 18 mcg/dL (497 nmol/L) is normal • Serum cortisol less than 3 mcg/dL (83 nmol/L) is indicative of adrenal insufficiency	
Insulin tolerance test (insulin-induced hypoglycemia test)	Administer insulin IV to induce hypoglycemia; then measure serum cortisol during symptomatic hypoglycemia [confirm that blood glucose is less than 40 mg/dL (2.22 mmol/L)]. Evaluates ability of entire HPA axis to respond to stress (hypoglycemia)	• Serum cortisol concentration less than 18 mcg/dL (497 nmol/L) is indicative of secondary adrenal insufficiency	• Distinguishes between normal individuals and patients with secondary adrenal insufficiency • Contraindicated in patients with a seizure history, older than 60 years, or with cardiovascular or cerebrovascular disease • Requires close medical supervision • Contraindicated in adrenal crisis
Overnight metyrapone test (rarely used)	Administer metyrapone at midnight then measure serum cortisol at 8 A.M. the next day. Metyrapone inhibits cortisol synthesis. Its administration leads to rise in levels of ACTH and the precursor of cortisol. Patients with adrenal insufficiency do not exhibit this.	• Normal response is a decrease in serum cortisol to less than 5 mcg/dL (138 nmol/L) and an increase in the cortisol precursor to more than 7 mcg/dL (193 nmol/L). Response not seen in secondary adrenal insufficiency.	• Distinguishes between normal individuals and patients with secondary adrenal insufficiency • Contraindicated in adrenal crisis

Tests to Determine Diagnosis of Primary, Secondary, and Tertiary Adrenal Insufficiency		
Test	**Test Procedure and Measurement**	**Rationale to Distinguish Between Etiologies**
Plasma aldosterone concentration	Measure plasma aldosterone from same blood samples as those used in ACTH stimulation test.	• Primary adrenal insufficiency: low plasma aldosterone level. • Secondary or tertiary adrenal insufficiency: aldosterone level is normal [greater than or equal to 5 ng/dL (139 pmol/L)]
Plasma ACTH concentration	Measure plasma ACTH	• Primary adrenal insufficiency: hypocortisolism leads to elevated plasma ACTH (via positive HPA axis feedback). • Secondary or tertiary adrenal insufficiency: plasma ACTH low or inappropriately normal.

ACTH, adrenocorticotropic hormone or corticotropin; FDA, Food and Drug Administration; HPA, hypothalamic-pituitary-adrenal; IV, intravenously.
[a]The 250 mcg dose has also been administered intramuscularly in an outpatient setting. The 1 mcg dose is not FDA-approved.

TABLE 42–3. Pharmacologic Characteristics of Commonly Used Glucocorticoids[4]

Glucocorticoid	Estimated Potency Relative to Hydrocortisone: Glucocorticoid (Anti-Inflammatory) Activity	Mineralocorticoid (Sodium-Retaining) Activity	Equivalent Dose Expressed in Milligrams
Short-Acting (Half-Life Less than 12 Hours)			
Hydrocortisone	1	1	20
Cortisone	0.8	0.8	25
Intermediate-Acting (Half-Life 12–36 Hours)			
Prednisone	4	0.25	5
Prednisolone	4	0.25	5
Methylprednisolone	5	Less than 0.01	4
Triamcinolone	5	Less than 0.01	4
Long-Acting (Half-Life Greater than 48 Hours)			
Betamethasone	25	Less than 0.01	0.6–0.75
Dexamethasone	30–40	Less than 0.01	0.75

Modified, with permission, from Williams GH, Dluhy RG. Disorders of the adrenal cortex. In: Kasper DL, Braunwald E, Fauci A, et al, (eds.) *Harrison's Principles of Internal Medicine*. New York: McGraw-Hill; 2005: 2127–2148.

Treatment and Outcome Evaluation

Chronic Adrenal Insufficiency

The general goals of treatment are to manage symptoms and prevent development of adrenal crisis. ❷*Lifelong glucocorticoid replacement therapy may be necessary for patients with adrenal insufficiency, and mineralocorticoid replacement therapy usually is required for those with Addison's disease.* Glucocorticoids with sufficient mineralocorticoid activity generally are required. However, the addition of a potent mineralocorticoid such as fludrocortisone (along with adequate salt intake) sometimes is needed to prevent sodium loss, hyperkalemia, and intravascular volume depletion. Mineralocorticoid supplementation typically is not indicated for the treatment of secondary or tertiary adrenal insufficiency because aldosterone production often is unaffected. Moreover, patients with secondary or tertiary adrenal insufficiency may require only replacement therapy until the HPA axis recovers. Hydrocortisone often is prescribed because it most closely resembles endogenous cortisol (with its relatively high mineralocorticoid activity and short half-life) and allows the design of regimens that simulate the normal circadian cycle.[6] Other glucocorticoids, however, can be used. The pharmacologic characteristics of commonly used glucocorticoids are presented in Table 42–3. Since patients with primary adrenal insufficiency can experience DHEA deficiency, DHEA replacement also has been tried. Several small clinical studies, consisting mostly of women, suggest that treatment with DHEA can improve mood and fatigue and provide a general sense of well-being.[7–9] Nonetheless, use of DHEA remains controversial and requires further study. Table 42–4 lists the treatment guidelines and monitoring parameters for chronic adrenal insufficiency.

Patient Encounter 1, Part 1: Presentation and Medical History

AB is a 60-year-old woman presenting to the clinic with a chief complaint of fatigue and weakness. She has noticed a gradual increase in symptoms over the past year but attributed this to "old age." Recently, she has required more frequent rest breaks than before. On further questioning, she complained of intermittent nausea leading to decreased appetite and a 10 lb (4.55 kg) weight loss over the past year. She also reported darkening of a recent scar.

PMH
- Type 1 diabetes mellitus since age 5, currently controlled
- Hypothyroidism, currently controlled
- Osteoarthritis (knees) for 5 years

FH
Unknown

SH
Retired secretary; denies smoking, alcohol use, or illicit drug use

Current meds
- Insulin glargine 30 units at bedtime
- Lispro insulin three times daily with meals—practices carbohydrate counting
- Levothyroxine 75 mcg once daily
- Acetaminophen 1000 mg every 8 hours as needed for joint pain
- Capsaicin 0.075% cream three times a day for joint pain

(*Continued*)

PE

VS: Sitting BP: 108/70 mm Hg; P: 74 beats/minute; standing BP: 96/68 mm Hg; P: 86; RR: 14 breaths/minute; weight: 150 lb (68.18 kg); height: 5 ft, 5 in (165.1 cm)
Skin: Hyperpigmentation on creases of palms and around nipples, darkening of scar on left leg
CV: RRR, normal S_1, S_2; no murmurs, rubs, or gallops

Labs

Serum electrolytes: sodium 132 mEq/L (132 mmol/L), potassium 5.2 mEq/L (5.2 mmol/L), chloride 98 mEq/L (98 mmol/L), bicarbonate 30 mEq/L (30 mmol/L), blood urea nitrogen (BUN) 25 mg/dL (8.9 mmol/L), creatinine 1.3 mg/dL (115 µmol/L), glucose 120 mg/dL (6.66 mmol/L)

- Which signs or symptoms of adrenal insufficiency does AB exhibit?
- Does AB's presentation offer any clues as to the etiology or classification of adrenal insufficiency?
- Which tests would be most useful for determining the etiology and confirming the diagnosis of adrenal insufficiency?

Clinical Presentation and Diagnosis of Acute Adrenal Insufficiency (Adrenal Crisis)[1,3,4]

General

Onset of symptoms is acute and precipitated by excessive physiologic stress.

Symptoms

- Severe weakness and fatigue
- Abdominal or flank pain

Signs

- Severe dehydration leading to hypotension and shock (circulatory collapse). Hypovolemia may not be responsive to intravenous hydration and may require the use of vasopressors.
- Tachycardia
- Nausea, vomiting
- Fever
- Confusion
- Hypoglycemia
- Laboratory abnormalities are similar to those observed in chronic adrenal insufficiency.

Laboratory Tests

The unstimulated serum cortisol and rapid ACTH stimulation tests are useful in the diagnosis of adrenal crisis (Table 42–2). The insulin tolerance test is contraindicated owing to preexisting hypoglycemia. The metyrapone test is also contraindicated because metyrapone inhibits cortisol production.
Note: Given the life-threatening nature of this condition, empirical treatment should be started before laboratory confirmation in patients who present with the clinical picture of an acute adrenal crisis.

TABLE 42–4. Management Strategies for Chronic Adrenal Insufficiency[1,3,6]

Primary Adrenal Insufficiency (Addison's Disease)

- Give oral hydrocortisone 12–15 mg/m^2 divided into two doses, with two-thirds of the dose given in the morning upon awakening (to mimic the early-morning rise in endogenous cortisol) and the remaining one-third of the dose given in the late afternoon (to avoid insomnia).
  - Monitor weight, blood pressure, and serum electrolytes and assess resolution of clinical features and patient's feeling of general well-being. Adjust dosages accordingly.
  - Monitor for adverse reactions from hydrocortisone administration. Glucocorticoid therapy at physiologic replacement doses should not lead to the development of Cushing's syndrome. However, careful monitoring should still be performed. Use the smallest effective dose.
  - Doses of hydrocortisone may need to be increased or decreased in patients taking CYP450 3A4 inducers (e.g., phenytoin, rifampin, barbiturates) or inhibitors (e.g., protease inhibitors), respectively.
  - Educate patients regarding need for increased hydrocortisone dosage during excessive physiologic stress.
- Give oral fludrocortisone at a daily dose of approximately 0.05–0.2 mg in the morning.
  - Monitor for resolution of hypotension, dizziness, dehydration, hyponatremia, and hyperkalemia. Increase the dose as clinically necessary.
  - Monitor for adverse reactions from mineralocorticoid administration (e.g., hypertension, hypokalemia, fluid retention) and decrease the dose if these occur. Remember that hydrocortisone also possesses mineralocorticoid activity.
  - Maintain an adequate sodium intake (about 3–4 g/day).
- Although controversial, consider giving DHEA 50 mg/day (in the morning) to female patients who do not experience an improvement in mood and well-being even with adequate glucocorticoid and mineralocorticoid replacement.
  - Monitor serum DHEA-S (aim for the middle range of normal levels in healthy young people) and free testosterone level.

Secondary and Tertiary Adrenal Insufficiency

- Give 2–15 mg/m^2 of oral hydrocortisone as described above. Patients may require a lower dose of glucocorticoid than those with primary adrenal insufficiency. Some patients will only require glucocorticoid replacement temporarily, which can be discontinued after recovery of the HPA axis (e.g., drug-induced adrenal insufficiency, adrenal insufficiency following treatment for Cushing's syndrome).
- Fludrocortisone therapy is generally not needed.
- Monitor for progression of the underlying etiology.

CYP450 3A4, cytochrome P-450 subfamily IIIA polypeptide 4; DHEA, dehydroepiandrosterone; DHEA-S, the sulfated form of dehydroepiandrosterone; HPA, hypothalamic-pituitary-adrenal.

Patient Encounter 1, Part 2: Treatment

After appropriate laboratory and diagnostic tests are performed, AB is diagnosed with Addison's disease.

- How should her chronic adrenal insufficiency be treated?
- What monitoring parameters (therapeutic and toxic) should be implemented?

Adrenal Insufficiency: Patient Care and Monitoring

1. Evaluate patients presenting with the typical clinical manifestations for chronic or acute adrenal insufficiency.
2. Perform initial screening tests to confirm the presence of adrenal insufficiency.
3. Once diagnosis is confirmed, perform further testing to differentiate between primary, secondary, and tertiary adrenal insufficiency.
4. In patients presenting with acute adrenal crisis who have not been diagnosed previously with adrenal insufficiency, immediate treatment with injectable hydrocortisone and intravenous saline and dextrose solutions should be initiated prior to confirmation of the diagnosis because of the life-threatening nature of this condition. Determine and correct the underlying cause of the acute adrenal crisis (e.g., infection).
5. Glucocorticoid replacement therapy is necessary for patients with adrenal insufficiency, and mineralocorticoid replacement therapy is required for those with Addison's disease.
6. In patients with chronic adrenal insufficiency, when excessive physiologic stress is anticipated (e.g., pending surgery), devise a strategy to give supplemental doses of glucocorticoid during this period. Monitor the patient for signs of an acute adrenal crisis, and develop a plan to treat this emergency condition.
7. Monitor the patient for adequacy of treatment, as well as adverse reactions from glucocorticoid and/or mineralocorticoid therapy.
8. Determine the duration of treatment for patients with secondary and tertiary adrenal insufficiency.
9. Provide patient education regarding disease state and treatment:
   - Causes of adrenal insufficiency, including drug-induced etiologies.
   - How to recognize the clinical manifestations.
   - How to prevent an acute adrenal crisis (adhere to therapy, and do not stop glucocorticoid treatment abruptly). There may be a need to increase the dose of glucocorticoid during excessive physiologic stress.
   - Administration of parenteral glucocorticoid during an acute adrenal crisis.
   - Need to notify all health care providers of the condition.
   - Encourage wearing or carrying medical alert identification (e.g., bracelet or card).
   - Counsel on dietary and pharmacologic therapy, including duration of treatment and potential adverse consequences of glucocorticoid and mineralocorticoid replacement.

Acute Adrenal Insufficiency

❸*During an acute adrenal crisis, the immediate treatment goals are to correct volume depletion, manage hypoglycemia, and provide glucocorticoid replacement* (Table 42–5). In patients with known adrenal insufficiency, additional glucocorticoid replacement (higher dose and parenteral route) must be given prior to major surgery to prevent adrenal crisis (Table 42–6 lists a sample protocol). ❹*Patients who experience excessive stress should be educated regarding the need for additional glucocorticoid replacement and prompt medical attention*. Although the dosage of glucocorticoid generally is individualized, a common recommendation is to double the maintenance dose of hydrocortisone if the patient experiences fever or undergoes invasive dental or diagnostic procedures.[6] Patients who experience vomiting or diarrhea may not absorb oral glucocorticoids adequately and may benefit from parenteral therapy until symptoms resolve.

TABLE 42–5. Treatment of Acute Adrenal Crisis

General and Supportive Measures
1. Promptly correct volume depletion, dehydration, and hypoglycemia with large volumes of intravenous normal saline and 5% dextrose (about 2–3 L).
2. Evaluate and correct infection or other precipitating factors.

Glucocorticoid Replacement
1. Administer hydrocortisone sodium phosphate or hydrocortisone sodium succinate, 100 mg intravenously every 6 to 8 hours for 24 hours.
2. If the patient is hemodynamically stable, reduce the dosage to 50 mg every 6 to 8 hours.
3. Increase the dose of hydrocortisone to 200–400 mg/day if complications occur or persist.
4. Taper hydrocortisone to maintenance therapy by day 4 or 5 and add fludrocortisone as needed.

Adapted, with permission, from Aron DC, Findling JW, Tyrrell JB. Glucocorticoids and adrenal androgens. In: Greenspan FS, Gardner DG, (eds.) *Basic and Clinical Endocrinology*. New York: Lange Medical Books/McGraw-Hill; 2004: 362–413.

TABLE 42–6. Glucocorticoid Treatment of Adrenal Insufficiency in Patients Undergoing Surgery

1. Correct electrolytes, blood pressure, and fluid status as necessary.
2. Give 100 mg of hydrocortisone sodium phosphate or hydrocortisone sodium succinate intramuscularly (provide "on call" to the operating room).
3. Give 50 mg of hydrocortisone intramuscularly or intravenously in the recovery room and then every 6 hours for the first 24 hours.
4. If patient is hemodynamically stable, reduce dosage to 25 mg every 6 hours for 24 hours and then taper to maintenance dosage over 3–5 days.
5. Resume previous fludrocortisone dose when the patient is taking oral medications.
6. Maintain or increase hydrocortisone dosage to 200–400 mg/day if fever, hypotension, or other complications occur.

Adapted, with permission, from Aron DC, Findling JW, Tyrrell JB. Glucocorticoids and adrenal androgens. In: Greenspan FS, Gardner DG, (eds.) *Basic and Clinical Endocrinology*. New York: Lange Medical Books/McGraw-Hill, 2004:362–413. Originally from Miller WL, Tyrrell JB, in: *Endocrinology and Metabolism*. Felig P, Baxter JD, Frohman LA, (eds.) New York: McGraw-Hill, 1995:555–711.

HYPERCORTISOLISM (CUSHING'S SYNDROME)

Epidemiology and Etiology

Cushing's syndrome refers to the pathophysiologic changes associated with exposure to supraphysiologic cortisol concentrations (endogenous hypercortisolism) or pharmacologic doses of glucocorticoids (exogenous hypercortisolism). Cushing's syndrome from endogenous causes is a rare condition, with an estimated incidence of 2 to 5 cases per 1 million persons per year.[10] Patients receiving chronic supraphysiologic doses of glucocorticoids, such as those with rheumatologic disorders, are at high risk of developing Cushing's syndrome.

Pathophysiology

Cushing's syndrome can be classified as ACTH-dependent or ACTH-independent (Table 42–7). ACTH-dependent Cushing's syndrome results from ACTH-secreting (or rarely, CRH-secreting) **adenomas.** ACTH-independent Cushing's syndrome is due either to excessive cortisol secretion by the adrenal glands (independent of ACTH stimulation) or to exogenous glucocorticoid administration. ❺*Patients with Cushing's syndrome owing to endogenous or exogenous glucocorticoid excess typically present with similar clinical manifestations.* The term *Cushing's disease* refers specifically to Cushing's syndrome from an ACTH-secreting pituitary adenoma. The plasma ACTH concentration is elevated in ACTH-dependent conditions but not in ACTH-independent cases because elevated cortisol concentrations suppress pituitary ACTH secretion via negative feedback. Adrenocorticotropic hormone and cortisol concentrations are elevated episodically in ACTH-dependent disease due to random hypersecretion of ACTH.[4] Other major differences among the vast etiologies of Cushing's syndrome are shown in Table 42–8.

Physiologic cortisol secretion follows a circadian pattern, with cortisol levels rising in the early morning, peaking at approximately 8 A.M., and then declining steadily throughout the remainder of the day until they reach a nadir at midnight. This circadian rhythm is lost in most patients with Cushing's syndrome. As such, detection of elevated midnight cortisol concentrations can be useful in the diagnosis of Cushing's syndrome.

Cushing's disease and adrenal **carcinomas** cause adrenal androgen hypersecretion in high enough concentrations to result in signs of androgen excess (such as acne, menstrual irregularities, and **hirsutism**) and cause **virilization** in women.[4]

Drug-induced Cushing's syndrome from glucocorticoid administration occurs most commonly in patients receiving oral therapy, but other routes (e.g., inhalation, dermal, nasal, and intra-articular) also have been implicated.[11] Over-the-counter products, including non-prescription medications and herbal products, also should be evaluated because they may contain corticosteroids or agents that possess glucocorticoid-like activity. The risk of glucocorticoid-induced Cushing's syndrome appears to increase with higher doses and/or longer treatment durations.[11]

Left untreated, patients with Cushing's syndrome may experience severe complications of hypercortisolism, resulting in up to a nearly four-fold increase in mortality.[14] Mortality in patients with Cushing's syndrome is mostly attributed to cardiovascular disease. Hypertension, hyperglycemia, and hyperlipidemia are common findings and can be associated with cardiac hypertrophy, atherosclerosis, and hypercoagulability. Osteopenia, osteoporosis, and increased fractures also have been reported.[14] Children may experience linear growth retardation from reduced growth hormone secretion and inhibition of epiphyseal cartilage development in long bones.[10,14]

TABLE 42–7. Etiologies of Cushing's Syndrome[1,11–13]

ACTH-Dependent
- ACTH-secreting pituitary tumor (Cushing's *disease*)—70% of cases of endogenous Cushing's syndrome
- ACTH-secreting non-pituitary tumors (ectopic ACTH syndrome)—15% of cases of endogenous Cushing's syndrome; usually from small cell lung carcinoma, bronchial carcinoids, pheochromocytoma, or thymus, pancreatic, ovarian, or thyroid tumor. The tumor is usually disseminated (difficult to localize).
- CRH-secreting non-pituitary tumors (ectopic CRH syndrome)—rare

ACTH-Independent—15% of cases of endogenous Cushing's syndrome
- Unilateral adrenal adenoma
- Adrenal carcinoma
- Bilateral nodular adrenal hyperplasia—rare (less than 1%)

Drug-Induced Cushing's Syndrome (ACTH-independent)—most common cause of Cushing's syndrome
- Prescription glucocorticoid preparations (most routes of administration)
- Non-prescription and herbal products with glucocorticoid activity (e.g., non-prescription anti-itch products with hydrocortisone, herbal products with magnolia bark or those claiming to contain adrenal cortex extracts or other by-products)
- Other drugs with glucocorticoid activity (e.g., megestrol acetate, medroxyprogesterone)

ACTH, adrenocorticotropic hormone or corticotropin; CRH, corticotropin-releasing hormone.

Treatment

The goal of treatment in patients with Cushing's syndrome is reversal of hypercortisolism and management of the associated comorbidities, including the potential for long-term sequelae such as cardiac hypertrophy. ❻*Surgical resection is considered the treatment of choice for Cushing's syndrome from endogenous causes if the tumor can be localized and if there are no contraindications.* The treatment of choice for Cushing's syndrome from exogenous causes is gradual discontinuation of the offending agent.

Clinical Presentation and Diagnosis of Cushing's Syndrome[1,10,11]

General

- Patients with Cushing's syndrome due to either endogenous or exogenous glucocorticoid excess typically present with similar clinical manifestations.
- Differential diagnoses include diabetes mellitus and metabolic syndrome because patients with these conditions share several similar characteristics with Cushing's syndrome patients (e.g., obesity, hypertension, hyperlipidemia, hyperglycemia, and insulin resistance). In women, the presentations of hirsutism, menstrual abnormalities, and insulin resistance are similar to those of polycystic ovary syndrome. Cushing's syndrome can be differentiated from these conditions by identifying the classic signs and symptoms of truncal obesity, "moon faces" with facial plethora, a "buffalo hump" and supraclavicular fat pads, red-purple skin striae, and proximal muscle weakness.
- True Cushing's syndrome also must be distinguished from other conditions that share some clinical presentations (as well as elevated plasma cortisol concentrations), such as depression, alcoholism, obesity, and chronic illness—the so-called pseudo-Cushing's states.

Signs and Symptoms (Percent Prevalence)

General appearance

- Weight gain and obesity, manifesting as truncal obesity (90%)
- A rounded and puffy face ("moon face") (75%)
- Dorsocervical ("buffalo hump") and supraclavicular fat accumulation
- Hirsutism (excessive hair growth) (75%)

Skin changes (from atrophy of dermis and connective tissue)

- Thin skin
- Facial plethora (70%)
- Skin striae ("stretch marks" that are usually red or purple in appearance and greater than 1 cm) (50%)
- Acne (35%)
- Easy bruising (40%)
- Hyperpigmentation

Metabolic

- Hyperglycemia that can range from impaired glucose tolerance (75%) to diabetes mellitus (20% to 50%)
- Hyperlipidemia (70%)
- Polyuria (30%)
- Kidney stones (15% to 50%)
- Hypokalemic alkalosis (from mineralocorticoid effect of cortisol)

Cardiovascular

- Hypertension (from mineralocorticoid effect of cortisol) (85%)
- Patients are at risk for the cardiovascular complications of hypertension, hyperlipidemia, and hyperglycemia.
- Peripheral edema

Genitourinary

- Menstrual irregularities (the most typical presentation is amenorrhea) (70%)
- Erectile dysfunction (85%)

Other

- Psychiatric changes such as depression, emotional lability, psychosis, euphoria, anxiety, and decreased cognition (85%)
- Sleep disturbances
- Osteopenia (80%) and osteoporosis, usually affecting trabecular bone
- Linear growth impairment in children
- Proximal muscle weakness (65%)
- Avascular necrosis (more common in iatrogenic cases)
- Glaucoma and cataracts
- Impaired wound healing and susceptibility to opportunistic infections
- Hypothyroidism

Laboratory Tests

- The diagnosis of Cushing's syndrome and its etiology often are complex and generally require the involvement of endocrinologists and specialized testing centers.
- Initial screening tests to confirm the presence of hypercortisolism and differentiate Cushing's syndrome from conditions with similar presentations include 24-hour urinary free cortisol determination and overnight low-dose dexamethasone suppression test (DST) (Table 42–9).
- The midnight plasma cortisol determination and combined dexamethasone suppression plus CRH test are used less commonly.
- Typically, a combination of at least two screening tests is used to establish the preliminary diagnosis.
- Once the diagnosis is confirmed, additional tests can be performed to determine the etiology.

Other Diagnostic Tests

Imaging studies may be used to distinguish between pituitary, ectopic, and adrenal tumors (Table 42–8).

Nonpharmacologic Therapy

Transsphenoidal pituitary microsurgery is the treatment of choice for Cushing's disease. Removal of the pituitary tumor can bring about complete remission (cure) in 78% to 97% of cases. HPA axis suppression associated with chronic hypercortisolism can result in prolonged adrenal insufficiency lasting for months after surgery and requiring exogenous glucocorticoid administration. Pituitary irradiation or bilateral **adrenalectomy** usually is reserved for patients who are not surgical candidates or for those who relapse or do not achieve complete remission following pituitary surgery. Because the response to pituitary irradiation can be delayed (several months to years), concomitant treatment with cortisol-lowering medication may be necessary. Bilateral adrenalectomy is also used for the management of adrenal carcinoma and in patients with poorly controlled ectopic Cushing's in whom the ACTH-producing lesion cannot

TABLE 42–8. Differences among the Major Etiologies of Cushing's Syndrome[4,9,14,23]

	ACTH-Dependent		ACTH-Independent		
	Pituitary Dependent (Cushing's Disease)	Ectopic ACTH Syndrome	Exogenous Glucocorticoid Administration	Adrenal Adenoma	Adrenal Carcinoma
Onset of signs and symptoms	Gradual	Rapid	Gradual to rapid	Gradual	Rapid
Symptoms severity	Mild to moderate	Atypical	Mild to severe	Mild to moderate	Severe
Dominant sex/age	Female; 20–40 years (range: childhood to 70 years)	Male; adults	Female and male; all ages	Female	Female; children
Virilization	+	+	+	+	+++
Abdominal mass	0	0	0	0	++
Plasma ACTH concentration	Slightly elevated	Elevated	Low	Low	Low
CRH stimulation test	Response	Rare response	Decreased or no response	No response	No response
High-dose dexamethasone suppression test	Between 50% and 80% cortisol suppression	Less cortisol suppression	No cortisol suppression	No cortisol suppression	No cortisol suppression
Pituitary MRI	Tumor	Normal	Normal	Normal	Normal
Adrenal gland CT or MRI	Normal or bilateral hyperplasia	Normal or bilateral hyperplasia	No change	Mass(es)	Mass(es)

ACTH, adrenocorticotropic hormone or corticotropin; CRH, corticotropin-releasing hormone; CT, computed tomography; MRI, magnetic resonance imaging; 0, none; +, mild; ++, moderate; +++, pronounced.

be localized. Bilateral laparoscopic adrenalectomy achieves an immediate and total remission (nearly 100% cure rate), but these patients will require lifelong glucocorticoid and mineralocorticoid supplementation.[15,16] **Nelson's syndrome** may develop in nearly 20% to 50% of patients who undergo bilateral adrenalectomy without pituitary irradiation. This condition presumably results from persistent hypersecretion of ACTH by the intact pituitary adenoma, which continues to grow because of the loss of feedback inhibition by cortisol. Treatment of Nelson's syndrome may involve pituitary irradiation or surgery.[4]

The treatment of choice in patients with adrenal adenomas is unilateral laparoscopic adrenalectomy. These patients require glucocorticoid supplementation during and after surgery owing to atrophy of the contralateral adrenal gland and suppression of the HPA axis. Glucocorticoid therapy is continued until recovery of the remaining adrenal gland is achieved. Patients with adrenal carcinomas have a poor prognosis (5-year survival of 20% to 58%) due to the advanced nature of the condition (metastatic disease). Surgical resection to reduce tumor burden and size, pharmacologic therapy, and bilateral laparoscopic adrenalectomy are the treatment options used commonly to manage this condition.[1,16]

Pharmacologic Therapy

❼ *Pharmacotherapy generally is reserved for patients: (1) in whom the ectopic ACTH-secreting tumor cannot be localized; (2) who are not surgical candidates; (3) who have failed surgery; (4) who have had a relapse after surgery; or (5) in whom adjunctive therapy is required to achieve complete remission.*[17] The drugs used are classified according to their mechanism and site of action (Table 42–10). The most widely used therapeutic class is the adrenal steroidogenesis inhibitors.[17] Agents in this class include ketoconazole, mitotane, metyrapone, and aminoglutethimide. Steroidogenesis inhibitors can improve hypercortisolism by inhibiting enzymes involved in the biosynthesis of cortisol. Because of their potential to cause adrenal suppression, temporary glucocorticoid replacement (and, in some cases, mineralocorticoid supplementation) may be needed during and after treatment.

❽ *In drug-induced Cushing's syndrome, discontinuation of the offending agent is the best management option. However, abrupt withdrawal of the glucocorticoid can result in adrenal insufficiency or exacerbation of the underlying disease.*[11]

❾ *Glucocorticoid doses less than 7.5 mg/day of prednisone (or its equivalent) for fewer than 3 weeks generally would not be expected to lead to suppression of the HPA axis.*[2,5] However, in patients receiving pharmacologic doses of glucocorticoids for prolonged periods, gradual tapering to near-physiologic levels (5–7.5 mg/day of prednisone or its equivalent) should precede drug discontinuation. Administration of a short-acting glucocorticoid in the morning and use of alternate-day dosing may reduce the risk of

TABLE 42–9. First-Line Screening Tests in Patients with Characteristics of Cushing's Syndrome[1,10,14]

Test	Test Procedure and Measurement Rationale	Typical Finding in Cushing's Syndrome	Comments
24-Hour urinary free cortisol	Collect urine over 24 hours and measure unbound cortisol that is excreted by kidneys Urinary cortisol is elevated in hypercortisolic states	Urinary free cortisol greater than 4 times the upper reference limit is indicative of Cushing's syndrome. Values between 1 and 4 times the upper reference limit suggest either Cushing's syndrome or pseudo-Cushing's syndrome	• Easy to perform but should not be used alone because sensitivity and specificity depend on the assay used. • To exclude periodic hypercortisolism, three or more samples should be obtained (with urinary creatinine measurement to assess completeness of the collection). • Distinguishes Cushing's syndrome from obesity (no elevation). However, false-positive if other pseudo-Cushing's states, physiologic stress, or pregnancy. • False-negative if decreased renal function or subclinical hypercortisolism.
Overnight low-dose dexamethasone suppression test (DST)	Give 1 mg oral dexamethasone at 11 P.M., then measure plasma cortisol at 8–9 A.M. the next morning Dexamethasone administration suppresses morning plasma cortisol in normal individuals	Plasma cortisol greater than 14.3 mcg/dL (395 nmol/L) is diagnostic for Cushing's syndrome. Plasma cortisol less than 1.2 mcg/dL (33 nmol/L) is not suggestive of Cushing's syndrome	• Simple to perform and inexpensive. • Can be used in conjunction with or instead of the urinary free cortisol test. • Can also use the two-day 2 mg DST. • False-positive if pseudo-Cushing's states, physiologic stress, pregnancy, estrogen treatment, uremia, taking inducers of dexamethasone metabolism (phenytoin, etc.), or decreased dexamethasone absorption. • False-negative if subclinical hypercortisolism or slow metabolism of dexamethasone.
Late-night salivary cortisol	Collect salivary cortisol concentration at 11 P.M. Loss of circadian rhythm of cortisol secretion (no nadir at night) in Cushing's syndrome but not in pseudo-Cushing's states	Elevated late-night salivary cortisol	• Diagnostic criteria need further validation. • Easiest screening test to perform (sample can be collected at home by patient). • Can be used in conjunction with, or instead of, the urinary free cortisol test.

DST, dexamethasone suppression test.

Patient Encounter 2

EF is a 45-year-old woman who presents to the dermatologist for evaluation of facial acne. She has a history of a 25 lb (11.36 kg) weight gain, irregular menses, and frequent vaginal yeast infections over the past 2 years. She complains of increased facial hair growth and lower extremity muscle weakness. Physical examination reveals facial acne, facial hirsutism, truncal obesity, thin skin, and purple abdominal striae. Her past medical history is significant for hypertension, type 2 diabetes mellitus, hyperlipidemia, and rheumatoid arthritis.

- Which findings are suggestive of Cushing's syndrome?
- Is there anything in EF's history that would suggest an exogenous cause of her presumed Cushing's syndrome?

adrenal suppression. Testing of the HPA axis may be useful in assessing adrenal reserve. In some cases, supplemental glucocorticoid administration during excessive physiologic stress may be needed for up to 1 year after glucocorticoid discontinuation.[11] Table 42–11 lists strategies to prevent the development of hypercortisolism and hypocortisolism.

Outcome Evaluation

- Monitor patients receiving surgical, medical, or radiation therapy for resolution of the clinical manifestations of hypercortisolism. Symptoms often improve immediately after surgery and soon after initiation of drug therapy. However, it may take months for symptoms to resolve following radiation therapy.
- Monitor for normalization of serum cortisol concentrations.
- The Patient Care and Monitoring text box (page 699) discusses additional evaluation strategies.

TABLE 42–10. Pharmacologic Treatments for Cushing's Syndrome[17–20]

Drug	Mechanism of Action	Dosage: Initial, Usual, Maximum	Common and/or Major Adverse Reactions	Comment
Inhibitors of Adrenal Steroidogenesis				
Aminoglutethimide (oral administration)	Inhibits conversion of cholesterol to pregnenolone, 11β-hydroxylase, 18-hydroxylase, and conversion of androstenedione to estrone.	250 mg every 6 hours Increase by 250 mg per day every 1–2 weeks 2 g/day	High incidence of adverse reactions: lethargy, somnolence, dizziness, ataxia, rash, nausea, headache. Tolerance to adverse reactions develops with continued use. Hematologic disturbances and hypothyroidism also seen.	• Used in ACTH-independent cases and ectopic ACTH syndrome. • Less effective as monotherapy due to reflex rise in ACTH but can be combined with metyrapone or with pituitary radiation. • Glucocorticoid and mineralocorticoid replacements needed. • High potential for drug interactions due to potent induction of hepatic enzymes.
Ketoconazole (oral administration)	Inhibits several cytochrome P-450 enzymes, including 17,20-lyase, 17-hydroxylase, and 11β-hydroxylase. Also inhibits cholesterol synthesis.	200 mg twice daily 600–800 mg/day in two divided doses 1200 mg/day in two divided doses	Generally well tolerated. Transaminase elevations, GI intolerance, and rash. Gynecomastia, testicular function impairment, and adrenal insufficiency at high doses (more than 600 mg/day).	• Effective in a majority of causes; rapid clinical improvement seen. • May be used with aminoglutethimide if inadequate efficacy as monotherapy. • Monitor efficacy with urinary cortisol. • Monitor liver transaminases for hepatotoxicity. • Useful in women with hirsutism and patients with hyperlipidemia.
Metyrapone (oral administration)	Inhibits 11-hydroxylase. Also suppresses aldosterone synthesis.	750 mg/day 500–4000 mg/day in four divided doses 6 g/day	Generally well tolerated. Hirsutism, acne, adrenal insufficiency, GI intolerance, rash, hypokalemia, edema, hypertension.	• Used in Cushing's disease, ectopic ACTH syndrome, and adrenal carcinoma. • Allows lower doses of aminoglutethimide if used in combination.
Etomidate (intravenous administration)	Inhibits 17, 20-lyase, 17-hydroxylase, and 11β-hydroxylase.	Limited clinical experience, 1.6–4.2 mg/hour intermittently	Injection-site pain, nausea, vomiting, myoclonus.	• Intravenous route of administration limits use.
Adrenolytic Agent				
Mitotane (oral administration)	Inhibits steroidogenesis at lower doses and is adrenolytic at higher doses. Inhibits 11β-hydroxylase and cholesterol side-chain cleavage. Reduces aldosterone synthesis.	2–6 g/day in 3–4 divided doses 9–10 g/day in 3–4 divided doses 16 g/day in 3–4 divided doses	GI intolerance (high incidence), fatigue, dizziness, somnolence, gynecomastia. Hyperlipidemia requiring lipid-lowering treatment. Adrenal insufficiency requiring glucocorticoid replacement therapy.	• Used primarily for adrenal carcinoma but can be used in other types of Cushing's syndrome. • Efficacy takes several weeks. • Lower rate of relapse when used with pituitary radiation. Also enables lower doses and therefore lower rate of adverse reactions.

(*Continued*)

TABLE 42–10. Pharmacologic Treatments for Cushing's Syndrome[17–20] (*Continued*)

Drug	Mechanism of Action	Dosage: Initial, Usual, Maximum	Common and/or Major Adverse Reactions	Comment
Central Neuromodulators of ACTH Release				
Bromocriptine (oral administration)	Dopamine agonist	3.75–30 mg/day, also reported up to 40 mg/day	Postural hypotension, dizziness, nausea, nasal congestion.	• Low rate of efficacy in Cushing's disease and Nelson's syndrome.
Cyproheptadine (oral administration)	Antagonizes serotonin receptors. May also inhibit histamine receptors. May have direct inhibitory effect on hypothalamus or pituitary.	20–32 mg/day	Sedation, increased appetite, GI intolerance.	• Efficacy variable. • Slow onset of clinical improvement (2–3 months). • Has been used in pregnant Cushing's disease patients.
Octreotide (subcutaneous or intravenous administration)	Long-acting somatostatin analog	300–1200 mcg/day reported	Injection site pain, nausea, diarrhea, hypoglycemia or hyperglycemia, hypothyroidism, dizziness, biliary disease.	• Most useful in Nelson's syndrome and ectopic ACTH syndrome. • Not effective as monotherapy in Cushing's disease but may be effective when used with ketoconazole. • Not effective in adrenal tumors.
Ritanserin (oral administration)	Selectively antagonizes central serotonin-2 receptors.	10–15 mg/day	Low incidence of central nervous system reactions.	• Few clinical experiences. • Published reports of efficacy in some cases of Cushing's disease.
Sodium valproate (oral administration)	Inhibits GABA aminotransferase. May decrease CRH secretion.	600–1200 mg/day	Neurologic disturbances, GI intolerance, weight gain.	• Variable efficacy seen in Cushing's disease and Nelson's syndrome.
Peripheral Glucocorticoid Antagonist				
Mifepristone (RU 486) (oral administration)	Antagonizes glucocorticoid receptors.	Up to 20 mg/kg per day	GI intolerance, rash, drowsiness, gynecomastia, hypoadrenalism. Has abortifacient and embryotoxic properties.	• Requires cautious use since few clinical experiences and no biochemical markers available to monitor efficacy of treatment. • Increases cortisol level via antagonism of negative feedback of ACTH secretion.

ACTH, adrenocorticotropic hormone or corticotropin; CRH, corticotropin-releasing hormone; GABA, γ-aminobutyric acid; GI, gastrointestinal.

TABLE 42–11. Principles of Glucocorticoid Administration to Avoid Hypercortisolism or Hypocortisolism

To Prevent Hypercortisolism and Development of Cushing's Syndrome

- Give the lowest glucocorticoid dose that will manage the disease being treated and for the shortest possible duration.
- If possible, give glucocorticoid via administration routes that minimize systemic absorption (such as inhalation or dermal).
- Administer glucocorticoid treatment every other day (calculate the total 48-hour dose and give as a single dose of intermediate-acting glucocorticoid in the morning).[4]
- Avoid concurrent administration of drugs that can inhibit glucocorticoid metabolism.

To Prevent Hypocortisolism and Development of Adrenal Insufficiency or Adrenal Crisis

- Assess patients at risk for adrenal insufficiency with screening tests (serum cortisol, plasma ACTH stimulation, etc.)
- If the patient requires discontinuation from chronic treatment with supraphysiologic doses of glucocorticoid, the following discontinuation protocol can be used:[4]
  - Gradually taper the dose to approximately 20 mg of prednisone or equivalent per day, given in the morning, then
  - Change glucocorticoid to every other day administration, in the morning.
  - Stop the glucocorticoid when the equivalent physiologic dose is reached (20 mg/day of hydrocortisone or 5–7.5 mg/day of prednisone or equivalent).
  - Understand that recovery of the HPA axis may take up to a year after glucocorticoid discontinuation during which the patient may require supplementation therapy during periods of physiologic stress.
- Evaluate patients at risk for adrenal insufficiency as a result of treatment(s) of Cushing's syndrome and initiate glucocorticoid and mineralocorticoid replacement therapy as appropriate.
- Avoid concurrent administration of drugs that can induce glucocorticoid metabolism.
- Educate patients about:
  - The need for replacement or supplemental glucocorticoid and mineralocorticoid therapy
  - How to administer parenteral glucocorticoid if unable to immediately access medical care during an emergency
  - Need to wear or carry medical identification regarding their condition (e.g., card, bracelet)

ACTH, adrenocorticotropic hormone or corticotropin; HPA, hypothalamic-pituitary-adrenal.

Cushing's Syndrome: Patient Care and Monitoring

1. Patient evaluation should include a thorough history of all medications and herbal or dietary supplements.
2. Perform initial screening tests to confirm Cushing's syndrome and rule out those with pseudo-Cushing's conditions (in other words, until it is determined that it is not a pseudo-Cushing's syndrome).
3. Once diagnosis is confirmed, perform further testing to determine the etiology of Cushing's syndrome.
4. Attempt to taper glucocorticoid if Cushing's syndrome is from exogenous administration.
5. If endogenous Cushing's syndrome, determine if patient is an appropriate candidate for surgical resection of the tumor. Does the patient have any conditions that contraindicate surgical resection, such as advanced disease (metastatic adrenal carcinoma)?
6. Develop a formal plan to assess the response and complications associated with surgery:[15]
   - Measure plasma cortisol after surgery to determine if the patient displays persistent hypercortisolism (surgical treatment failure) or hypocortisolism (adrenal insufficiency requiring steroid replacement therapy).
   - In patients demonstrating hypocortisolism:
     - Monitor for signs and symptoms of glucocorticoid withdrawal (e.g., headache, fatigue, malaise, and myalgia).
     - Monitor for signs and symptoms of adrenal insufficiency.
     - Monitor morning cortisol or response to ACTH stimulation every 3 to 6 months to assess for HPA axis recovery. Discontinue glucocorticoid replacement therapy when cortisol concentrations are greater than 19 mcg/dL (524 nmol/L) on either test.
     - Monitor cortisol, ACTH, low-dose dexamethasone suppression, or other tests to assess for risk of relapse of hypercortisolism.
   - Monitor for development of pituitary hormone deficiency.
7. If surgical resection does not achieve satisfactory disease control or is not indicated, evaluate the patient for pituitary radiation or bilateral adrenalectomy with concomitant pituitary radiation.
   - Monitor patients treated with pituitary radiation for development of pituitary hormone deficiency.
8. Evaluate patients with adrenal adenomas for unilateral adrenalectomy.
9. Give glucocorticoid and mineralocorticoid replacement to patients who undergo adrenalectomy (permanently in the case of bilateral adrenalectomy).
10. Evaluate the patient for appropriateness of pharmacologic therapy depending on etiology of Cushing's syndrome.
11. Monitor patient for response to therapy, need for dose adjustments, and presence of adverse drug reactions.
12. Once disease control is achieved, continue to monitor biochemical markers and patient for development of complications of Cushing's syndrome because relapse may occur.
13. Provide patient education regarding disease state and treatment:
    - Causes of Cushing's syndrome, including drug-induced etiologies.
    - How to recognize the clinical manifestations of Cushing's syndrome.
    - Possible sequelae of Cushing's syndrome.
    - How to reduce the modifiable cardiovascular and metabolic complications.
    - Advantages and disadvantages of potential treatment options.
    - Possible adverse consequences of treatment.
    - Need for glucocorticoid and mineralocorticoid replacement after treatment, if appropriate.
    - Importance of adherence to therapy.

43 Pituitary Gland Disorders

Judy T. Chen, Devra K. Dang, Frank Pucino, Jr., and Karim Anton Calis

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. List the mediators and primary effects of the pituitary hormones.
2. Identify the clinical features of patients with acromegaly.
3. Discuss the role of surgery and radiation therapy for patients with acromegaly.
4. Select appropriate pharmacotherapy for patients with acromegaly based on patient-specific factors.
5. Identify the clinical features of children and adults with growth hormone deficiency and select appropriate pharmacotherapy for these patients.
6. List the monitoring parameters necessary to assess therapeutic outcomes and adverse effects in patients receiving growth hormone therapy.
7. List the common etiologies of hyperprolactinemia.
8. Identify the clinical features of patients with hyperprolactinemia.
9. Select appropriate pharmacologic and nonpharmacologic treatments for patients with hyperprolactinemia based on patient-specific factors.

Key Concepts

❶ Surgical resection of the pituitary tumor through transsphenoidal pituitary microsurgery is the treatment of choice for most patients with growth hormone–producing pituitary adenomas.

❷ Somatostatin analogs are the mainstay of pharmacotherapy for the treatment of acromegaly when surgery and radiation are contraindicated or have failed.

❸ Pegvisomant is indicated for patients who do not tolerate or fail other treatments or for those with extremely elevated insulin-like growth factor I levels.

❹ Dopamine agonists may be appropriate for patients with mildly elevated insulin-like growth factor I levels who have growth hormone and prolactin co-secreting tumors.

❺ Prolonged exposure to elevated growth hormone and insulin-like growth factor I levels can lead to serious complications in patients with acromegaly. Aggressively manage comorbid conditions such as hypertension, diabetes, arrhythmias, coronary artery disease, and heart failure to prevent vascular and neuropathic complications.

❻ Recombinant growth hormone therapy is the main pharmacologic treatment for growth hormone deficiency in both children and adults.

❼ Although comparative trials have not been conducted, recombinant growth hormone products appear to have similar efficacy for treating growth hormone deficiency.

❽ Dopamine agonists are the first-line treatment of choice for all patients with hyperprolactinemia; transsphenoidal surgery and radiation therapy are reserved for patients who are resistant to or severely intolerant of pharmacologic therapy.

❾ Women who become pregnant while on a dopamine agonist should discontinue treatment immediately to minimize fetal exposure. Because cabergoline has a long half-life, women who plan to become pregnant should discontinue the drug at least 1 month before planned conception.

PHYSIOLOGY OF THE PITUITARY GLAND

The pituitary gland, located at the base of the brain, is a small endocrine gland about the size of a pea weighing approximately 600 mg. The pituitary gland is referred to as the "master gland" because it is responsible for the regulation of other endocrine glands and body systems. Growth, development, metabolism, reproduction, and stress homeostasis are among the functions influenced by the pituitary. Functionally, the gland consists of two distinct sections: the anterior pituitary lobe (adenohypophysis) and the posterior pituitary lobe (neurohypophysis). The human intermediate pituitary lobe has minimal structure and function. The pituitary receives neural and hormonal input from the inferior hypothalamus via blood vessels and neurons contained in the pituitary stalk.

The posterior pituitary is innervated by direct nervous stimulation from the hypothalamus, resulting in the release of specific hormones. The hypothalamus synthesizes two hormones, oxytocin and vasopressin. These hormones are stored in and released from the posterior pituitary lobe. Oxytocin exerts two actions: (1) it promotes uterine contractions during labor, and (2) it contracts the smooth muscles in the breast to stimulate the release of milk from the mammary gland during lactation. Vasopressin is an antidiuretic hormone (ADH) essential for proper fluid and electrolyte balance in the body. Specifically, vasopressin increases the permeability of the distal convoluted tubules and collecting ducts of the nephrons to water. This causes the kidney to excrete less water in the urine. Consequently, the urine becomes more concentrated as water is conserved.

In contrast to the posterior pituitary lobe, the anterior pituitary lobe is under the control of several releasing and inhibiting hormones secreted from the hypothalamus via a portal vein system. The anterior pituitary lobe, in turn, synthesizes and secretes six major hormones. Figure 43–1 summarizes the physiologic mediators and effects of each of these hormones.

HORMONAL FEEDBACK REGULATORY SYSTEMS

The hypothalamus is responsible for the synthesis and release of hormones that regulate the pituitary gland. Stimulation or inhibition of the pituitary hormones elicits a specific cascade of responses in peripheral target glands. In response, these glands secrete hormones that exert a negative feedback on other hormones in the hypothalamic-pituitary axis (Fig. 43–1). This negative feedback serves to maintain body system homeostasis. High circulating hormone levels inhibit the release of hypothalamic and anterior pituitary hormones.

Damage and destruction of the pituitary gland may result in secondary hypothyroidism, **hypogonadism,** adrenal insufficiency, growth hormone deficiency, hypoprolactinemia, or insufficiency or absence of all anterior pituitary hormones (i.e., **panhypopituitarism**). A tumor located in the pituitary gland may result in excess secretion of a hormone or may physically compress the gland and suppress adequate hormone release. The type, location, and size of a pituitary tumor often determine a patient's clinical presentation. This chapter discusses the pathophysiology and role of pharmacotherapy in the treatment of acromegaly, growth hormone deficiency, and **hyperprolactinemia**. The following hormones are discussed elsewhere in this book: adrenocorticotropic hormone (ACTH or corticotropin), thyroid-stimulating hormone (TSH or thyrotropin), luteinizing hormone (LH), follicle-stimulating hormone (FSH), vasopressin (antidiuretic hormone or ADH), and oxytocin.

GROWTH HORMONE (SOMATOTROPIN)

Somatotropin or growth hormone (GH) is the most abundant hormone produced by the anterior pituitary lobe. The GH-secreting **somatotropes** account for 50% of hormone-secreting cells in the anterior pituitary. GH is regulated primarily by the hypothalamic-pituitary axis. The hypothalamus releases growth hormone–releasing hormone (GHRH) to stimulate GH synthesis and secretion, whereas **somatostatin** inhibits it.[1] On stimulation by GHRH, somatotropes release GH into the circulation, thereby stimulating the liver and other peripheral target tissues to produce insulin-like growth factors (IGFs). These IGFs, also known as somatomedins, are the peripheral GH targets. There are two types of IGFs: IGF-I and IGF-II. IGF-II is responsible primarily for regulating fetal growth, whereas IGF-I is the hormone responsible for growth of bone and other tissues. High levels of IGF-I inhibit GH secretion through negative feedback, thereby inhibiting GHRH secretion.[1] The hypothalamus also may stimulate the release of somatostatin to inhibit GH secretion. Effects of IGF-I in peripheral tissues are both GH-dependent and GH-independent.[2] GH is an anabolic hormone with direct "anti-insulin" metabolic effects. By stimulating protein synthesis and shifting the body's energy source from carbohydrates to fats, GH promotes a diabetic state[2] (Table 43–1). GH controls somatic growth and has a critical role in the development of normal skeletal muscle, myocardial muscle, and bone.

In healthy individuals, GH is secreted in a pulsatile pattern throughout a 24-hour period, with several short bursts occurring mostly during the night. The most intense period of GH secretion occurs within the first 1 to 2 hours of slow-wave sleep (stage 3 or 4 deep sleep).[1] In between these bursts, basal concentration of GH falls to very low or undetectable levels because of its short half-life in the blood (19 minutes). The amount of GH secretion fluctuates throughout a person's lifetime. Secretion of GH is lowest during infancy, increases during childhood, peaks during adolescence, and then declines gradually during the middle years.[1] These changes are parallel

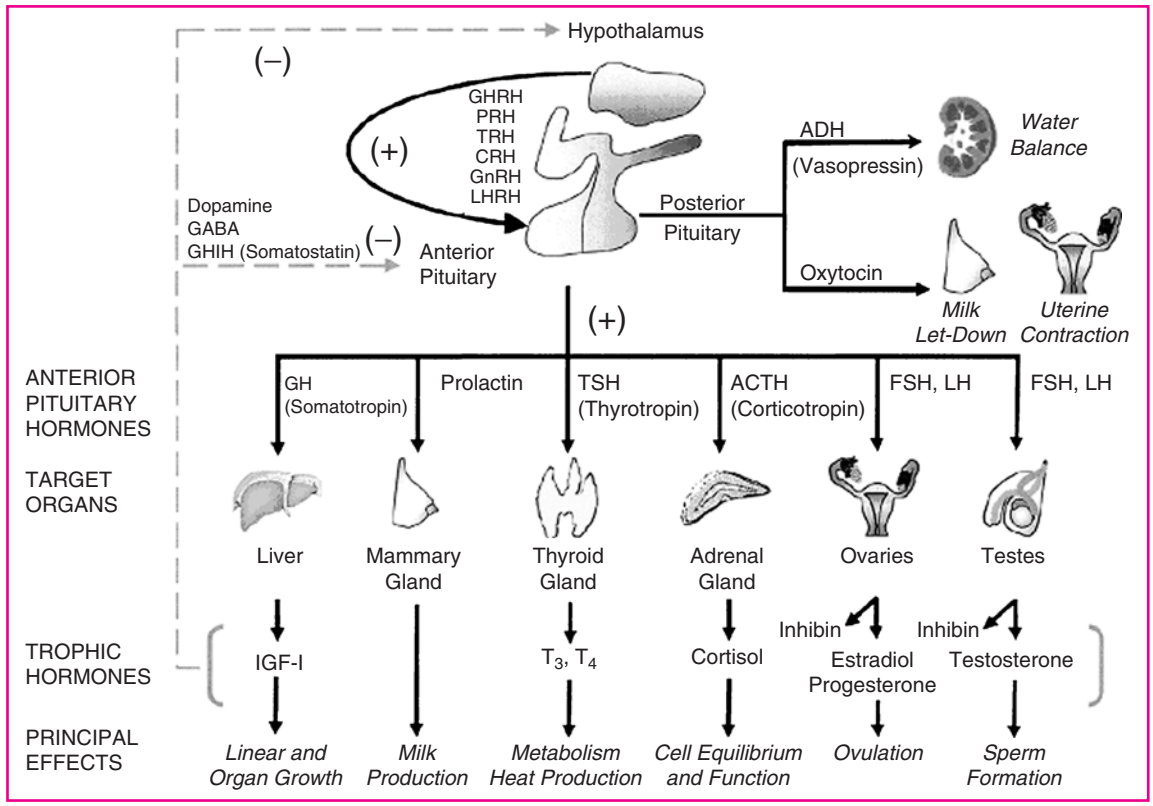

FIGURE 43–1. Hypothalamic-pituitary-target-organ axis. Trophic hormones are hormones that regulate the activity of endocrine glands. The hypothalamic hormones regulate the biosynthesis and release of eight pituitary hormones. Stimulation of each of these pituitary hormones produces and releases trophic hormones from their associated target organs to exert their principal effects. Subsequently, increased serum concentration of the trophic hormones released from the target organs can inhibit both the hypothalamus and the anterior pituitary gland to maintain homeostasis (negative feedback). Inhibin is produced by the testes in the male and ovaries in the female during pregnancy. Inhibin acts in direct negative feedback on pituitary production of follicle-stimulating hormone (FSH). Melanocyte-stimulating hormone (MSH) produced by the anterior pituitary is not illustrated in the figure.
(–) = inhibit; (+) = stimulate; ACTH = adrenocorticotropic hormone (corticotropin); ADH = antidiuretic hormone (vasopressin); CRH = corticotropin-releasing hormone; FSH = follicle-stimulating hormone; GABA = γ-aminobutyric acid; GH = growth hormone (somatotropin); GHIH = growth hormone–inhibiting hormone (somatostatin); GHRH = growth hormone–releasing hormone; GnRH = gonadotropin-releasing hormone; IGF-I = insulin-like growth factor I; LH = luteinizing hormone; LHRH = luteinizing hormone–releasing hormone; PRH = prolactin-releasing hormone; T_3 = triiodothyronine; T_4 = thyroxine; TRH = thyrotropin-releasing hormone; TSH = thyroid-stimulating hormone (thyrotropin).

to an age-related decline in lean muscle mass. In addition to GH itself, several internal and external factors also modulate GH synthesis (e.g., serotonin, dopamine, and γ-adrenergic agonists), including low plasma glucose, exercise, stress, trauma, emotional excitement, and ingestion of protein-rich meals.[1]

Growth Hormone Excess

Epidemiology and Etiology

Acromegaly affects both genders equally; the average age of presentation is 44 years. Approximately 50 to 70 people per 1 million population are affected, with an estimated annual incidence of 3 to 4 cases per 1 million people.[3,4] In more than 95% of the cases, overproduction of GH is due to a benign pituitary tumor (adenoma), whereas malignant tumors occur in less than 1%.[4] Most pituitary adenomas occur spontaneously as a result of a genetic mutation acquired during life. Depending on the size of the tumor, pituitary adenomas are classified as: (1) microadenomas if they are 10 mm or less in diameter or (2) macroadenomas if they are greater than 10 mm. Rarely, non-pituitary tumors may cause acromegaly. These tumors can produce GH, but more commonly they secrete GHRH and result in excessive GH and IGF-I production.

TABLE 43–1. Effects of Growth Hormone[2]

	Action(s)	Effect(s)
Lipid metabolism	Increases the use of fat by stimulating triglyceride breakdown and oxidation of adipocytes.	Increases breakdown of fat (lipolysis) Increases circulating fatty acid levels Increases lean body mass
Protein metabolism	Stimulates protein anabolism by increasing amino acid uptake and protein synthesis and decreasing oxidation of proteins.	Increases muscle mass
Carbohydrate metabolism	Suppresses the ability of insulin to stimulate uptake of glucose in peripheral tissues.	Decreases glucose utilization
	Decreases insulin receptor sensitivity.	Insulin resistance
	Impairs post–receptor insulin action.	Hyperglycemia
	Stimulates glucose synthesis in the liver (gluconeogenesis)	Increases hepatic glucose output

Pathophysiology

Acromegaly is a rare, insidious disorder that manifests gradually over time. It is caused by an adenoma of the pituitary that overproduces GH and stimulates excessive production of IGF-I during adulthood. This typically occurs after fusion of the epiphyses (growth plates) of the long bones.[4] The facial features of an acromegalic patient are depicted in Fig. 43–2. **Gigantism** refers to GH excess that occurs during childhood before epiphyseal closure and results in excessive linear growth.

Diagnosis of acromegaly is based on both clinical and biochemical findings. Because secretion of GH fluctuates throughout the day, a single random measurement is never reliable for diagnosing GH excess. However, GH-mediated IGF-I production results in relatively stable serum IGF-I concentrations during the day, which correlate positively with 24-hour mean GH levels.[1] This makes elevated IGF-I levels an ideal screening test for acromegaly and a reliable monitoring biochemical marker to assess disease activity and response to therapy.[5,6] Because IGF-I levels may fluctuate with age and gender, it is important to compare IGF-I levels with age- and sex-matched population values.[5,6] Other conditions such as nutritional status, liver dysfunction, insulin levels, and illness also can affect IGF-I levels. Almost all IGF-I in the circulation is bound to IGF-binding proteins (IGFBPs), which also regulate IGF bioactivity. The major carrier protein for circulating IGF-I is the GH-dependent protein IGFBP-3, which also can be used to assess therapeutic response.[2] Low IGFBP-3 levels are associated with GH deficiency, GH insensitivity, and malnutrition. The measurement of serum GH secreted by the pituitary in response to an oral glucose tolerance test (OGTT) is considered the primary biochemical test for diagnosing acromegaly. GH is suppressed after administration of a 75 g oral glucose challenge because postprandial hyperglycemia inhibits secretion of GH for at least 1 hour. If the GH level does not decline to less than 1 ng/mL (1 mcg/L) during the test, the patient is diagnosed with acromegaly.[4] Elevation of IGF-I serum concentrations and the clinical presentation help to confirm the diagnosis.

Acromegaly Treatment Goals

Patients with acromegaly experience a two- to three-fold increase in mortality rate.[8] Normalization of GH and IGF-I levels reverses the mortality risk and alleviates significant comorbid complications, especially cardiovascular, pulmonary, and metabolic abnormalities. Reduction of IGF-I levels alone does

FIGURE 43–2. Before and after photographs of an acromegalic patient. Compare the photographs of an acromegalic woman (*A*) before the onset of acromegaly and (*B*) after approximately 20 years, when the diagnosis was well established. Notice the coarsening of facial features, with enlarged nose, lips, and forehead.

Clinical Presentation and Diagnosis of Acromegaly[3,7–9]

General

The patient will experience slow development of soft-tissue overgrowth affecting many body systems. Signs and symptoms may progress gradually over 10 to 15 years.

Symptoms

- Headache and compromised visual function (loss of peripheral vision and blurred vision) caused by the actual tumor mass and its close proximity to the optic structures.
- Loss of other hormonal functions (i.e., LH, FSH, TSH, and ACTH) caused by massive tumor size compressing the anterior pituitary lobe.
- Absence of regular menstrual periods (**amenorrhea**), impotence, and decreased libido caused by disruption of the gonadotropin secretion.
- Excessive sweating, joint pain, nerve pain, and abnormal neurologic sensations (paresthesias) related to elevated GH and IGF-I levels.

Signs

- Coarsening of facial features
- Increased hand volume
- Increased ring and shoe size
- Increased spacing between teeth
- Increased acne/oily skin
- Enlarged tongue
- Deepening of voice
- Thick, irregular, patchy skin discoloration
- Enlarged nose, lips, and forehead (frontal bossing)
- Abnormal protrusion of the mandible (prognathia)
- Inappropriate secretion of breast milk (**galactorrhea**)
- Abnormal enlargement of interior organs (organomegaly)
- Carpal tunnel syndrome caused by nerve compression from the swollen tissue

Laboratory Tests

- GH level greater than 1 ng/mL (1 mcg/L) following an oral glucose tolerance test (OGTT) and elevated IGF-I level compared with age- and sex-matched control values.
- Glucose intolerance may be present in up to 50% of patients.

Additional Clinical Sequelae

- Cardiovascular diseases: hypertension, coronary heart disease, cardiomyopathy, left ventricular hypertrophy, and arrhythmia.
- Osteoarthritis and joint damage develop in up to 90% of patients.
- Respiratory disorders and **sleep apnea** occur in up to 60% of patients.
- Type 2 diabetes mellitus develops in up to 40% of patients.
- Increase risk for the development of esophageal, colon, and stomach cancer.

Other Diagnostic Tests

- Perform magnetic resonance imaging (MRI) examination and computed tomography (CT) of the pituitary to locate the tumor and validate the diagnosis.
- Without obvious pituitary tumor but proven acromegaly, measurement of GHRH may be helpful to detect ectopic tumors.

Patient Encounter 1: The Medical History, Physical Examination, and Diagnostic Tests

EB, a 48-year-old woman, presents to a new primary care clinic. EB's chief complaints are chronic pain of the knee and "pins and needles" and "numbness" in both hands. Over the past few years, she feels that her body has been changing. EB reports increased urinary frequency, excessive sweating, worsening headaches, an increase of two shoe sizes, and facial hair that she shaves once a week. She says that her hands have enlarged to the point that "my wedding band won't fit anymore."

PMH
Hypertension for 12 years, currently controlled
Hyperlipidemia for 10 years, currently controlled
Osteoarthritis for 5 years

FH
Mother died of colon cancer at age of 58 years. Father died of myocardial infarction at an unknown age.

SH
Married, a nurse practitioner, highly educated, and physically active (bikes four times per week)

Meds
Lisinopril/hydrochlorothiazide 20/12.5 mg once daily
Atorvastatin 10 mg once daily
Acetaminophen 500 mg every 8 hours as needed for joint pain

ROS
(+) coarse facial hair. Deepening of voice. Ophthalmic examination reveals normal visual acuity and fields.

PE
VS: 118/76 mm Hg, P 78 beats per minute, RR 18 breaths/minute, T 37.5°C (99.5°F)
ENT: (+) protruding jaw and large fleshy nose
CV: RRR, normal S_1, S_2; no murmurs, rubs, gallops
Abd: Soft, non-tender, non-distended; (+) bowel sounds, no hepatosplenomegaly, heme (–) stool

Labs
Electrolytes and renal function are within normal limits. Fasting blood glucose level is 206 mg/dL (11.43 mmol/L), HbA_{1c} is 8.5%, and (–) microalbumin. GH level following an oral glucose tolerance test is 8 ng/mL (8 mcg/L). Elevated IGF-I at 790 ng/mL (790 mcg/L)
MRI and CT scan: Both reveal a pituitary tumor approximately 5 mm in diameter.

- Given this information, what signs and symptoms does EB have for acromegaly?
- Identify your treatment goals for EB.
- What nonpharmacologic and pharmacologic treatment options are available for EB?

TABLE 43–2. Goals for Management of Acromegaly[4,8,11–13]

1. Normalize biochemical disease markers
   a. Reduce GH to less than 1 ng/mL (1 mcg/L) after oral glucose tolerance test (OGTT)[a]
   b. Normalize IGF-I levels to age- and sex-matched control values
2. Ablate or reduce tumor size to relieve tumor mass effect
3. Prevent tumor recurrence and control tumor size
4. Preserve normal pituitary function
5. Improve clinical signs and symptoms
6. Alleviate significant morbidities
7. Reduce mortality rates to that of the general population

[a]When using the older GH assay, suppression of GH levels to less than 1 ng/mL (1 mcg/L) after OGTT is the biochemical target. When using new, highly specific and sensitive assays, GH levels less than or equal to 0.4 ng/mL (0.4 mcg/L) are the biochemical target.[11–13]
GH, growth hormone; IGF-I, insulin-like growth factor I.

not appear to be a reliable predictor of long-term outcome.[6,10] The goals of therapy are presented in Table 43–2.[4,8,11–13]

General Approaches to Treatment

The American Association of Clinical Endocrinologists (AACE) published medical guidelines for the diagnosis and treatment of acromegaly (Fig. 43–3). According to these guidelines, ❶ *surgical resection of the pituitary tumor through* ***transsphenoidal pituitary microsurgery*** *is the treatment of choice for most patients with GH-producing pituitary adenomas.*[4] Most microadenomas can be resected successfully, resulting in prompt normalization of GH levels. Complete resection of a macroadenoma may be difficult if the tumor has already invaded the surrounding nerves and tissues. In such cases, debulking of the tumor, along with adjunctive radiation and/or pharmacotherapy, may improve treatment outcome. The success rate for normalization of GH levels is approximately 90% in patients with well-defined microadenomas and 46% to 48% in patients with macroadenomas.[14,15] Normalization of GH resulted in a 10-year survival rate of 88%, which is similar to that of the general population.[14] Major but infrequent surgical complications include meningitis, serious visual impairment, cerebrospinal fluid leakage requiring surgical repair, permanent **hypopituitarism,** and death. Minor complications include diabetes insipidus, local nasal complications, transient hyponatremia, and cerebrospinal fluid leakage not requiring surgical repair.[14] Repeat surgery is rarely an option because of the high risk of serious complications. The relative contraindications to surgery include patient frailty, acromegaly-associated comorbidities, and medically unstable conditions such as airway difficulties, severe hypertension, or uncontrolled diabetes.[4]

Pharmacologic Therapy

Pharmacologic therapy is often necessary for patients in whom surgery is not an option.[4] Somatostatin analogs, GH receptor antagonists, and dopamine agonists are the primary pharmacologic therapies used for the management of acromegaly (Table 43–3). Pharmacologic therapy avoids hypopituitarism and other surgical risks.

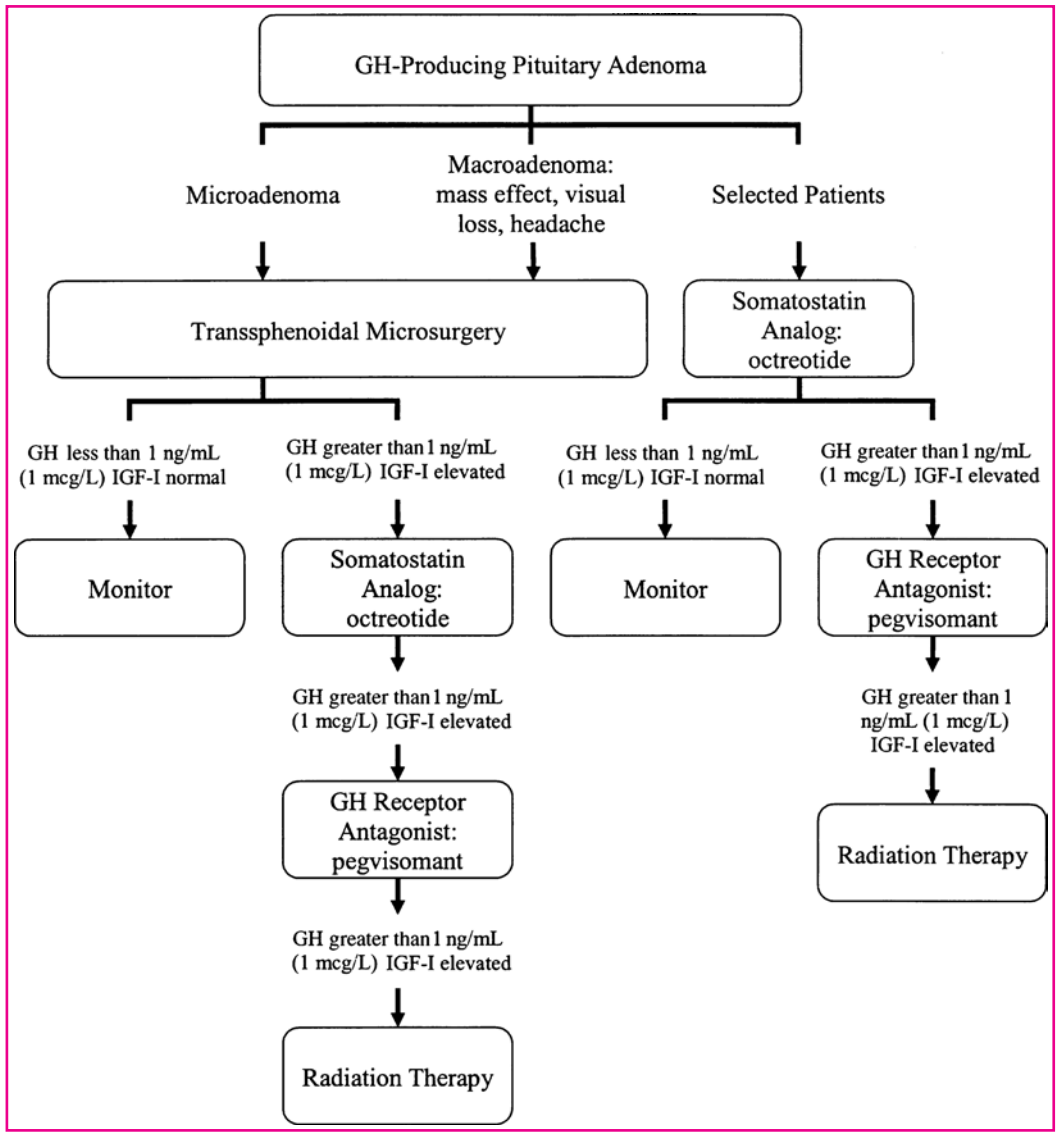

FIGURE 43–3.
Recommended schema for management of growth hormone–producing adenomas.[4] GH = growth hormone; IGF-I = insulin-like growth factor I. (Adapted, with permission, from AACE Medical Guidelines for Clinical Practice for the diagnosis and treatment of acromegaly. Endocr Pract 2004; 10(3):213–225.)

Somatostatin Analog (Growth Hormone–Inhibiting Hormone)

❷ *Somatostatin analogs are the mainstay of pharmacotherapy for the treatment of acromegaly when surgery and radiation are contraindicated or have failed.* These agents mimic endogenous somatostatins and bind to the somatostatin receptors in the pituitary to cause potent inhibition of GH, insulin, and glucagon secretion. Somatostatin analogs effectively control GH and IGF-I levels in 50% to 70% of patients, with 41% to 67% achieving normal IGF-I levels.[16,17] Previous epidemiologic studies reported that a reduction of GH levels of between 2 and 5 ng/mL (2 and 5 mcg/L) resulted in a mortality rate similar to that of the general population.[4,6] Long-term treatment can sustain hormone suppression and alleviate soft-tissue manifestations. Although somatostatin analogs can achieve substantial relief of clinical symptoms, they produce modest tumor size reduction in less than 50% of patients.[18] If treatment is discontinued, monitor patients for tumor recurrence.

Use of the first-generation somatostatin analog octreotide is limited by its extremely short duration of action and requirement for subcutaneous administration at least three times a day. If a patient's GH level returns to baseline before the end of an 8-hour dosing interval, the frequency of octreotide administration can be increased to every 4 to 6 hours. Most patients require octreotide in doses of 100 to 200 mcg three times daily.[19,20] To improve patient tolerance to gastrointestinal (GI) adverse effects, start octreotide at 50 mcg every 8 hours.[20] Assess IGF-I serum concentrations every 2 weeks after initiating therapy to further titrate dose in increments of 50 mcg per dose.

Transient GI disturbances such as diarrhea, abdominal pain, flatulence, constipation, and nausea are commonly associated with somatostatin analogs.[19,20] These adverse GI effects usually

TABLE 43–3. Comparison of Various Drugs for Treatment of Acromegaly[4]

Drug Type and Agent	Starting Dose	Maximal Dose	Side Effects	Monitoring Suggestions	Preferred Indication
Dopamine Agonist					
Cabergoline (Dostinex®)	1 mg/week orally	4 mg/week orally	Nausea, GI cramps, headache	GH, IGF-I	GH and prolactin co-secreting tumors
Somatostatin analog					
Octreotide (Sandostatin®)	50 mcg SQ three times daily	200 mcg SQ three times daily	Nausea, GI cramps, gallstones	GH, IGF-I, ultrasonography of gallbladder (if symptoms)	Somatostatin analog–responsive tumor
Octreotide LAR (Sandostatin LAR®)	10 mg IM every 4 weeks	30 mg IM every 4 weeks	Nausea, GI cramps, gallstones	GH, IGF-I, ultrasonography of gallbladder (if symptoms)	Somatostatin analog–responsive tumor
Lanreotide[a]	60 mg IM every 2 weeks	120 mg IM every 7 days	Nausea, GI cramps, gallstones	GH, IGF-I, ultrasonography of gallbladder (if symptoms)	Somatostatin analog–responsive tumor
Lanreotide Autogel[a]	60 mg deep SQ every 28 days	120 mg deep SQ every 28 days	Nausea, GI cramps, gallstones	GH, IGF-I, ultrasonography of gallbladder (if symptoms)	Somatostatin analog–responsive tumor
GH Receptor Antagonist					
Pegvisomant (Somavert®)	10 mg SQ daily	40 mg SQ daily	Headache, fatigue, abnormal liver enzymes	Liver function tests monthly for 6 months, then every 6 months; MRI every 6 months. IGF-I (not GH) after first year, then yearly.	High IGF-I levels not responsive to somatostatin analog–therapy

[a]Lanreotide is currently not available in the United States.
GH, growth hormone; GI, gastrointestinal; IGF-I, insulin-like growth factor I; IM, intramuscularly; LAR, long-acting release; MRI, magnetic resonance imaging; SQ, subcutaneously.

subside within the first 3 months of therapy. Octreotide inhibits gallbladder contractility and decreases bile secretion. The major adverse effect of octreotide is development of **biliary sludge** and asymptomatic **gallstones (cholelithiasis).** Biliary sludge occurs in 20% of patients and is felt to be a predisposing factor for the high incidence of cholelithiasis observed in 10% to 20% of patients treated with octreotide.[19] Development of gallstones typically occurs in patients treated for 12 months or longer and is unrelated to age, gender, or dose. Octreotide may suppress pituitary release of TSH, leading to decreased thyroid hormone secretion and subsequent hypothyroidism in 12% of treated patients. Additionally, octreotide can alter the balance of the counterregulatory hormones (i.e., glucagon, insulin, and GH), resulting in either hypoglycemia or hyperglycemia. Sinus bradycardia, conduction abnormalities, and arrhythmias have been reported with octreotide therapy. Thus, patients taking insulin, oral hypoglycemic agents, β-blockers, or calcium channel blockers may require dose adjustment when these agents are used concurrently with octreotide.

To increase patient compliance, the long-acting formulation of octreotide acetate (Sandostatin LAR®) is preferred in the majority of cases. Sandostatin LAR® is administered as a deep intramuscular injection in doses of 10 to 30 mg every 4 weeks and is as effective as short-acting octreotide.[17,21,22] Typically, at least a 2-week trial of short-acting octreotide is recommended to determine efficacy and tolerance before switching to the long-acting preparation. Counsel patients to perform alternate injections in the gluteal region and to avoid injections in the deltoid region because of significant injection-site discomfort. Although antibody formation to octreotide occurs in up to 25% of patients, development of these antibodies does not cause serious adverse effects or compromise treatment efficacy.[23]

Growth Hormone Receptor Antagonist

Growth hormone receptor antagonist represents a novel approach to the treatment of acromegaly. Pegvisomant is the only genetically engineered GH-receptor antagonist that blocks the action of GH. The effects of pegvisomant work independently of

tumor characteristics, somatostatin, and dopamine receptors.[24] Up to 97% of acromegalic patients treated with pegvisomant (10–20 mg/day) achieved normal age-related IGF-I levels and experienced significant improvement in clinical symptoms of GH excess by 1 year of therapy.[25,26] Pegvisomant therapy is not associated with deterioration in glucose tolerance (body's ability to metabolize glucose) or insulin sensitivity (capacity of cells to respond to insulin). A preliminary study in seven acromegalic patients suggested that insulin sensitivity and glucose tolerance improved in patients converted from octreotide to pegvisomant.[27] However, use of pegvisomant is associated with statistically significant dose-dependent increases in GH despite the declining IGF-I levels.[25,26] The dose-dependent increase in GH is troubling because it has been suggested that persistent elevation of GH levels may be indicative of tumor growth. Although patients did not experience a significant change in tumor volume during studies, theoretical concerns remain because pituitary tumors are slow growing. Thus, practitioners should use caution when administering pegvisomant to patients with large tumors extended toward the optic chiasm to prevent visual damage caused by possible tumor growth. ❸ *Pegvisomant is indicated for patients who do not tolerate or fail other treatment options or for those with extremely elevated IGF-I levels (greater than 900 ng/mL or 900 mcg/L).*[4] Long-term efficacy and safety profiles of pegvisomant in acromegaly remain to be established. Available data to date suggest that pegvisomant appears well tolerated with minimal adverse effects such as self-limiting injection-site reactions, nausea, diarrhea, and flu-like symptoms. Safety concerns about antibody development with pegvisomant do not reduce the efficacy of therapy. Rare cases of hepatotoxicity have been reported in clinical trials;[25,26] therefore, use caution when administering pegvisomant to patients with elevated baseline liver function tests. Start subcutaneous pegvisomant at 10 mg/day, and increase at 3-month intervals until IGF-I levels are normalized. In a recent study, combination of pegvisomant once weekly and long-acting somatostatin analogs once monthly was as effective as daily pegvisomant monotherapy. This combination has the potential to improve patient adherence and cost-effectiveness of therapy.[28]

Dopamine Agonists

Dopamine is one of the neurotransmitters that can increase GH secretion in healthy adults. However, dopamine agonists administered to patients with acromegaly exert the opposite effect and suppress GH release from the tumor. The first dopamine agonist for acromegaly, bromocriptine, achieved normal IGF-I levels in fewer than 10% of patients and was associated with significant adverse effects, including nausea, dizziness, and headaches.[29] The large doses of bromocriptine required to achieve the desired response often are associated with dose-limiting toxicity, such as GI discomfort and orthostatic hypotension. Cabergoline, the newer, selective long-acting agonist with improved tolerability, effectively can normalize IGF-I levels in 35% of patients and reduce GH levels to less than 2 ng/mL (2 mcg/L) in 44% of treated patients.[30] Acromegalic patients with co-existing hyperprolactinemia also had a more favorable response to cabergoline, with 50% of patients achieving normal IGF-I levels, 56% GH suppression, and 65% tumor shrinkage.[30] Although orally administered dopamine agonists are the least expensive medical therapy for managing acromegaly, the major disadvantage is their relative lack of efficacy compared with existing therapeutic options. ❹ *Dopamine agonists may be appropriate for patients with mildly elevated IGF-I levels who have GH and prolactin (PRL) co-secreting tumors.*[4]

Radiation Therapy

Radiation therapy involves the use of radiation to kill rapidly growing tumor cells and often results in a reduction in tumor size. Radiation therapy is extremely effective but may take 10 to 20 years before the full effects become evident. A major complication resulting from radiation therapy is hypopituitarism, requiring lifelong hormone replacement.[4] There is also the potential for optic nerve damage if the pituitary tumor is near the optic tracts. Radiation therapy is an important adjunctive therapy in patients with residual GH excess after surgery or pharmacologic therapies. Owing to delay in onset of radiation effectiveness, pharmacologic therapies often are indicated as bridge therapy.[4,19,20] Men and women who desire to have children should be warned that radiation therapy may impair the function of the ovaries and testes.[4]

Outcome Evaluation

- Following a baseline evaluation, monitor patients regularly for symptom relief.
- Lifelong biochemical assessment is critical for determining therapeutic outcomes. Although some patients may experience a rapid decline in GH levels following transsphenoidal microsurgery, stabilization of IGF-I levels usually occurs 3 months following surgery but rarely may be delayed for up to 12 months. Measure GH and IGF-I levels 3 months postoperatively to assess treatment response.[6]
- Since up to 10% of pituitary tumors may recur within 15 years following surgery,[6,14] continual postoperative monitoring is recommended.
- For patients treated with somatostatin analogs, assess baseline fasting blood glucose, thyroid function tests, and heart rate. Thereafter, periodically monitor patients for adverse reactions such as GI disturbances, glucose intolerance, signs and symptoms of thyroid abnormalities, bradycardia, and arrhythmias in patients receiving long-term octreotide therapy. Reevaluate IGF-I and GH levels at 3-month intervals to determine therapeutic response. Since the frequency of symptomatic gallstones associated with octreotide varies among studies, the need for routine ultrasound evaluation remains controversial. However, ultrasonography of the gallbladder would be indicated if the patient develops symptoms of biliary abnormalities.
- For patients treated with a GH receptor antagonist, GH levels are not measured because pegvisomant is a modified GH molecule that is detected in commercial GH assays, resulting in falsely

elevated GH levels.[31] Therefore, IGF-I level is the principal biochemical marker used to assess response to pegvisomant therapy. After appropriate dose titration, monitor IGF-I levels every 6 months.[6] Concern for tumor growth requires careful monitoring of tumor size; therefore, performing magnetic resonance imaging (MRI) every 6 months during the first year of therapy and annually thereafter is recommended.[6] Because of abnormal liver function associated with pegvisomant therapy, it is mandatory to monitor all patients' liver function tests monthly during the first 6 months and every 6 months thereafter.[6]

- For patients receiving dopamine agonists, the maximal suppression of GH and IGF-I levels may take up to 3 months to achieve. Once stable control of biochemical markers is achieved with dopamine agonists or somatostatin analogs, monitor GH and IGF-I levels annually.[6]
- With conventional multidose radiation therapy, the most rapid decline in GH serum levels occurs within the first 2 years; monitor GH levels at the second year and annually thereafter.[6] Patients who receive single-dose radiation therapy should be evaluated at 6-month intervals because response is observed earlier.
- For patients receiving concurrent pharmacologic therapy with radiation therapy, withdraw therapies every 6 to 12 months to evaluate endogenous GH secretion and assess the development of hypopituitarism.[6]

❺ *Prolonged exposure to elevated GH and IGF-Is can lead to serious complications in patients with acromegaly. Aggressively manage comorbid conditions such as hypertension, diabetes, arrhythmias, coronary artery disease and heart failure to prevent vascular and neuropathic complications.* It is critical to monitor patients indefinitely for management of the comorbidities associated with acromegaly[8] (Table 43–4).

TABLE 43–4. Assessment of Acromegaly Complications at Diagnosis and Follow-Up[8]

At Diagnosis	During Long-Term Follow-Up
Glucose tolerance testing (samples for blood glucose and GH only)	Fasting blood glucose, HbA_{1c} if diabetes present (as appropriate)
Serum cholesterol and lipid profile	Annually
Echocardiography	Annually
Electrocardiogram (ECG)	Annually
Exercise ECG	If angina present
Colonoscopy	Every 2–3 years
DEXA (hypogonadal only)	Every 2–3 years
Sleep assessment	Annually (if altered at diagnosis)
Blood pressure monitoring	Annually or change of treatment (if hypertensive)
Echo-Doppler of carotid artery	As indicated by clinical features

DEXA, dual-energy x-ray absorptiometry; ECG, electrocardiogram; GH, growth hormone; HbA_{1c}, glycosylated hemoglobin A_{1c}.

Acromegaly: Patient Care and Monitoring

1. Assess patient's clinical signs and symptoms to determine severity of acromegaly.
2. Review the biochemical disease markers to assess severity of acromegaly.
3. Review the available diagnostic data to determine pituitary tumor size and location. Determine if the patient has a coexisting prolactin-secreting tumor. Determine if the tumor extends toward the optic chiasm or if it is continuous on the optic tracts.
4. Assess presence of acromegaly complications. Identify any significant comorbidities associated with acromegaly that require immediate treatment or early diagnosis.
5. Determine what treatment options the patient has tried in the past.
6. Evaluate the patient for the presence of surgical contraindications to transsphenoidal microsurgery. Determine if the patient is able or willing to undergo surgical intervention.
7. Develop a formal plan to assess patient's response to and complications of surgical intervention. Measure both GH and IGF-I levels.
8. If surgical intervention does not achieve satisfactory disease control, select subsequent appropriate pharmacologic therapy based on patient-specific factors. In selecting therapy, be sure to consider if the patient has any contraindications or allergies to therapies.
9. Evaluate patient for presence of adverse drug reactions, drug allergies, and drug interactions.
10. Develop a plan to assess efficacy of pharmacologic therapy. Also consider if the patient's therapy requires any dose adjustments.
11. Assess biochemical markers annually once disease control is achieved.
12. Routinely assess acromegaly complications, including blood pressure, glucose tolerance, fasting lipid profile, cardiac evaluations (if clinically indicated), colonoscopy, dual-energy x-ray absorptiometry (DEXA) scan (hypogonadal only), evaluation of residual pituitary function, and evaluation of sleep apnea.
13. Provide patient education with regard to disease state and non-drug and drug therapy. Discuss with the patient:
    - Possible complications of acromegaly
    - How to reduce the modifiable cardiovascular and metabolic risk factors
    - Potential disadvantages and effectiveness of existing treatment options
    - Importance of adherence to therapy
    - The potential for adverse effects to occur

Growth Hormone Deficiency

Epidemiology and Etiology

In the United States, GH deficiency affects 50,000 adults, with 6,000 new cases diagnosed annually.[34] Approximately 10,000 to 15,000 children have growth failure owing to GH deficiency. Children may present with GH deficiency at any time during their developmental stages. The evaluation for GH deficiency in a short child should be deferred until appropriate exclusion of other identifiable causes of growth failure, such as hypothyroidism, chronic illness, malnutrition, genetic syndromes, and skeletal disorders.[39] Several medications, such as methoxamine, isoproterenol, glucocorticoids, cimetidine, methylphenidate, and amphetamines, also may induce GH insufficiency.[32]

Pathophysiology

GH deficiency exists when GH is absent or produced in inadequate amounts. GH deficiency may be congenital, acquired, or result from disruption of the hypothalamus-pituitary axis. The diagnosis of GH deficiency remains a clinical challenge because no "gold standard" currently exists. Because GH is frequently undetectable with random sampling, a stimulation or provocative test usually is performed to confirm the diagnosis in both adults and children in whom GH deficiency is suspected. Numerous pharmacologic agents such as insulin-induced hypoglycemia, levodopa, arginine, arginine plus levodopa, arginine plus GHRH, clonidine, and glucagon have been used to stimulate the pituitary to produce GH. However, no single test perfectly predicts GH deficiency or displays 100% sensitivity and specificity.[33] Additionally, administration of each of these tests is associated with adverse effects requiring close medical supervision. Further, current abnormal cutoffs to determine diagnosis are arbitrarily defined and lack universal consensus.[33] With further studies, these diagnostic criteria are likely to evolve and become more accurate.[34]

In children, the diagnosis of GH deficiency is further supported if height is more than two standard deviations (SD) below the population mean (age- and sex-matched).[35] Failure of linear growth is an almost universal presenting feature of childhood GH deficiency.

Childhood GH deficiency may or may not continue into adulthood. Most adults with GH deficiency have overt pituitary disease and present with nonspecific clinical disorders distinct from pediatric GH deficiency, thereby making diagnosis of GH deficiency in adults more difficult than in children. Additionally, adult GH deficiency presumably is associated with increased risk of death from cardiovascular diseases.[34]

Treatment Goals for GH Deficiency

The goal of treatment for GH deficiency is to correct associated clinical symptoms.[34,35] In children, prompt diagnosis and early initiation of treatment are important to maximize final adult height. In adults, efforts should be made to achieve normal physiologic GH levels in an attempt to reverse the metabolic abnormalities associated with increased cardiovascular risks and decreased quality of life.

Clinical Presentation and Diagnosis of GH Deficiency in Children[7,34,35]

General

The patient will have a physical height that is greater than two standard deviations below the population mean for a given age and gender.

Signs

- The patient will present with reduced growth velocity and delayed skeletal maturation.
- Children with GH-deficient or GH-insufficient short stature also may present with abdominal obesity, prominence of the forehead, and immaturity of the face.

Laboratory Tests

- The patient will exhibit a peak GH level of less than 10 ng/mL (10 mcg/L) following a GH stimulation test.
- Reduced IGF-I and IGFBP-3 concentrations also may be present.
- Because GH deficiency may be accompanied by the loss of other pituitary hormones, hypoglycemia and hypothyroidism also may be noted.

Other Diagnostic Tests

- Perform MRI or CT of the hypothalamic-pituitary region to detect structural or developmental anomaly.
- Perform x-ray of left wrist and hand for children over 1 year of age to estimate bone age (knee and ankle for children younger than 1 year of age).

Source: Adapted, with permission, from Heck AM, Yanovski JA, Calis KA. Pituitary Gland Disorders. In: DiPiro JT, Talbert RL, Yee GC, et al. (eds.) *Pharmacotherapy. A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill, 2005: 1407–1423.

Pharmacologic Therapy

Growth Hormone Therapy

❻ *Recombinant GH therapy is the main pharmacologic treatment for GH deficiency in both children and adults.* It promotes skeletal, visceral, and general body growth; stimulates protein anabolism; and affects bone, fat, and mineral metabolism[2] (Table 43–1). GH therapy requires daily subcutaneous or intramuscular administrations. Since two-thirds of GH secretion normally occurs during sleep, it is recommended to administer subcutaneous injections in the evening.[37] Many preparations of synthetic GH are available with a variety of injection devices to make administration more appealing and easier. Protropin® (somatrem) and Tev-Tropin™ (somatropin) are approved by the Food and Drug Administration (FDA) for use in children, whereas other somatropin products such as Nutropin®, Nutropin AQ®, Humatrope®, Norditropin®, Genotropin®, and Saizen® are FDA approved in both children and adults.

Clinical Presentation and Diagnosis of GH Deficiency in Adults[34,36,37]

General

The patient likely will have a history of childhood-onset GH deficiency, hypothalamic or pituitary disorder, or the presence of three or four other pituitary hormone deficiencies caused by head trauma, tumor, infiltrative diseases, surgery, or radiation therapy.

Symptoms

- Reduced strength and exercise capacity
- Defective sweating
- Psychological problems
  - Low self-esteem
  - Depression
  - Fatigue/listlessness
  - Sleep disturbance
  - Anxiety
  - Social isolation
  - Emotional lability and impaired self-control
  - Poor marital and socioeconomic performance

Signs

- Increased fat mass (especially abdominal obesity)
- Reduced lean body mass
- Reduced muscle strength
- Reduced exercise performance
- Thin, dry skin; cool peripheries; poor venous access
- Depressed affect, labile emotions
- Impaired cardiac function

Laboratory Tests

- The patient will exhibit a peak GH level of less than 5 ng/mL (5 mcg/L) following a GH stimulation test.
- Low or low-normal IGF-I level also may be present.
- Increased low-density lipoprotein cholesterol, total cholesterol, triglycerides; decreased high-density lipoprotein cholesterol.
- Reduced bone mineral density associated with an increased risk of fracture.
- Increased insulin resistance and increased prevalence of impaired glucose tolerance.
- GH deficiency may be accompanied by the loss of other pituitary hormones.

❼ *Although comparative trials have not been conducted to date, recombinant GH products appear to have similar efficacy for treating GH deficiency as long as the regimen follows currently approved guidelines.* Adults with GH deficiency often require substantially lower replacement doses (6–25 mcg/kg per day) than prepubertal children (25–50 mcg/kg per day).[38] The conversion of international units (IU or mU) to milligrams is a 3:1 ratio.[34] Selection of an injection device depends on patient preference because there is currently no difference in clinical outcomes among the various injection systems.[38]

Over the last four decades, evidence has suggested that GH treatment in GH-deficient children can increase short-term growth and improve final adult height.[39] Beneficial effects of GH therapy in adults with GH deficiency have been demonstrated in subsequent studies to normalize body composition and metabolic process; improve cardiac risk profile, bone mineral density, quality of life and psychological well-being; and increase muscle strength and exercise capacity.[40,41] Nonetheless, long-term efficacy in improving cardiovascular risks and reducing mortality in adults treated with GH therapy remains to be established.

Begin GH therapy as soon as possible to optimize long-term growth, especially for young children in whom GH deficiency is complicated by fasting hypoglycemia.[35] Selection of the optimal GH replacement dose will need to be individualized depending on response, financial resources, and product availability. Although the appropriate time to discontinue therapy remains controversial in childhood GH deficiency, it is reasonable to continue GH replacement until either the child has reached satisfactory adult height, achieved documented epiphyseal closure, or failed to respond to therapy.[34] Management of the transition between pediatric and adult GH replacement remains a challenge because there are no current data to indicate the correct approach. Starting GH therapy at a low dose and gradually titrating upward may decrease the potential for adverse effects. The need for GH replacement therapy may be lifelong.

Children treated with GH replacement therapy rarely experience significant adverse effects, whereas adults are more susceptible to dose-related adverse effects. Treatment with GH may mask underlying hypothyroidism. GH-induced symptoms, such as edema, arthralgia, myalgia, and carpal tunnel syndrome, are common and necessitate dose reductions in up to 40% of adults. Benign increases in intracranial pressure may occur with GH therapy and generally are reversible with discontinuation of treatment. Often, GH therapy can be restarted with smaller doses without symptom recurrence.

In rapidly growing children, a slipped capital femoral epiphysis may occur when the head of the femur shifts in a backward direction.[38] There is no evidence that this problem is caused by GH therapy, but any child who experiences a change in gait during treatment should be evaluated by an orthopedic surgeon.[38] Treatment with GH may induce insulin resistance and lead to the development of glucose intolerance in patients with preexisting risk factors. Presently, there is no compelling evidence that GH replacement therapy is associated with an increased risk of leukemia, solid tumor, or tumor recurrence.[34,35,37] However, in children with a history of malignancies, it would be prudent to wait for a 1-year tumor-free period (5 years for adults) before initiating GH therapy.[34] Any patients treated for a prior malignancy may be at risk for a second malignancy and should be monitored carefully for tumor recurrence.[34] Other rare findings associated with GH replacement therapy include breast development, pancreatitis, juvenile osteochondritis (inflammation of a bone and its cartilage), worsening of **scoliosis,** and increased pigmentation.[38]

Growth Hormone Deficiency in Children: Patient Care and Monitoring

1. Assess the child's growth characteristics, and compare physical height with a population standard.
2. Obtain a thorough history and physical examination that may indicate the possible presence of GH deficiency. Exclude other identifiable causes of growth failure, such as hypothyroidism, chronic illness, malnutrition, genetic syndromes, and skeletal disorders.
3. Perform imaging tests of the hypothalamic-pituitary region to detect structural or developmental anomalies. Perform x-ray to estimate bone age.
4. Perform a provocative test to measure GH, IGF-I, and/or IGFBP-3 levels.
5. Initiate GH replacement therapy based on patient preference. Make sure that the child does not have any contraindications to GH therapy.
6. Develop a formal plan to assess response (increase in height and change in height velocity) and adverse effects of GH replacement therapy. Make dosage adjustments when appropriate.
7. May continue GH replacement therapy until a child reaches satisfactory adult height, achieves documented epiphyseal closure, or fails to respond to treatment.
8. Review and retest the child using adult GH deficiency diagnostic criteria once the child reaches final adult height.
9. Provide patient education in regard to disease state and drug therapy. Discuss with the child and parents:
   - GH deficiency
   - Potential disadvantages and effectiveness of existing GH replacement therapy
   - Importance of adherence to therapy
   - Potential for adverse effects or need for lifelong replacement

Insulin-Like Growth Factor I Therapy

Mecasermin rinfibate (Iplex™ and Increlex™) is the only recombinant once-daily IGF-I replacement therapy for the treatment of growth failure in children with severe primary IGF-I deficiency or with GH gene deletions who have developed neutralizing antibodies to GH. This product has not been evaluated in patients with GH deficiency aside from the genetic abnormalities.

Outcome Evaluation

- Children with GH deficiency should be evaluated by a pediatric endocrinologist every 3 to 6 months. Monitor for an increase in height and change in height velocity to assess response to GH therapy.[35] Every effort should be made to maximize height before the onset of puberty. Once final adult height is reached and GH is discontinued for at least 1 month, retest and reevaluate the patient using the adult GH-deficiency diagnostic criteria.[35]
- Assess patients with scoliosis for further curvature of the spine.
- Although GH and IGF-I levels do not always correlate with growth response, measure IGF-I levels yearly to assess adherence to therapy and patient response. If the IGF-I levels are substantially above the normal range 2 years after GH replacement therapy, the dose should be reduced.[38] IGF-I level may be used as a guide to gradually reduce replacement dose after epiphyseal closure.
- Routine monitoring of fasting lipid profile, bone mineral density, and body composition in children is not typically required during GH replacement but should be done before and after discontinuation of therapy.[35]
- In adults, measurement of serum IGF-I, along with careful clinical evaluation, appears to be the most reliable way to assess the appropriateness of the GH dose.
- Continuously monitor for dose-related adverse effects such as edema, arthralgia, myalgia, and carpal tunnel syndrome.
- Assess patient's body composition, psychological well-being, fasting lipid profile, bone mineral density, and metabolic status.
- Patients with a history of cancer or those at risk for malignancy should be monitored closely.
- Measure a free thyroxine serum concentration at baseline and at 6- to 12-month intervals thereafter.[34]
- Measure blood glucose levels at baseline and every 3 months to assess for glucose intolerance and insulin resistance. Periodic measurement of glycosylated hemoglobin (HbA_{1c}) also may be useful.[34]

Growth Hormone Deficiency in Adults: Patient Care and Monitoring

1. Assess patient's clinical signs and symptoms to determine severity of GH deficiency.
2. Perform a provocative test to measure GH and IGF-I levels.
3. Evaluate the patient for the presence of metabolic abnormalities and cardiovascular and fracture risks.
4. Initiate GH replacement therapy based on patient preference. Make sure that the patient does not have any contraindications to GH therapy.
5. Develop a plan to assess the efficacy and adverse effects of GH therapy, and consider if the patient's therapy requires any dose adjustments based on IGF-I level, patient response, and adverse effects.
6. Provide patient education in regard to disease state and drug therapy. Discuss with the patient:
   - Possible complications of GH deficiency
   - How to reduce the modifiable cardiovascular and metabolic risk factors
   - Potential disadvantages and effectiveness of existing GH replacement therapy
   - Importance of adherence to therapy
   - Potential for adverse effects or need for lifelong replacement

PROLACTIN

Prolactin is an essential hormone for normal production of breast milk following childbirth. It also plays a pivotal role in a variety of reproductive functions. Prolactin is regulated primarily by the hypothalamus-pituitary axis and secreted solely by the lactotroph cells of the anterior pituitary gland. Under normal conditions, secretion of prolactin is predominantly under inhibitory control by dopamine and acts on the D_2 receptors located on the lactotroph cells. Increase of hypothalamic thyrotropin-releasing hormone (TRH) in primary hypothyroidism can stimulate the release of prolactin.

Hyperprolactinemia

Epidemiology and Etiology

Hyperprolactinemia commonly affects women of reproductive age more than men. Although this disorder occurs in less than 1% of the general population, the estimated prevalence in women with reproductive disorders (e.g., amenorrhea) is as high as 9% to 17%.[43] Numerous etiologies of hyperprolactinemia are presented in Table 43–5.[43,44] Any medications that block dopamine or increase the release of dopamine can induce hyperprolactinemia[7,32,43,45] (Table 43–6). Therefore, it is important to exclude medication-induced hyperprolactinemia from other common causes such as pregnancy, primary hypothyroidism, benign prolactin-secreting pituitary adenoma (prolactinoma), and renal insufficiency. Prolactinomas are the most common pituitary tumors. They are classified as microprolactinomas if they are less than 10 mm in diameter and as macroprolactinomas if they are 10 mm or greater in diameter.[46] In general, microprolactinomas rarely increase in size, whereas macroprolactinomas have the potential to enlarge and invade the surrounding tissues.[46]

TABLE 43–5. Causes of Hyperprolactinemia[43,44]

Physiologic Causes
Pregnancy
Stress (including exercise and hypoglycemia)
Orgasm
Sleep
Meal
Increased Prolactin Production
Ovarian: polycystic ovarian syndrome
Pituitary tumors:
Adenomas
Microprolactinoma (less than 10 mm diameter)
Macroprolactinoma (greater than or equal to 10 mm diameter)
Hypothalamic stalk interruption (prevent dopamine from reaching the pituitary)
Hypophysitis (inflammation)
Ectopic tumors
Hypothalamic Prolactin Stimulation
Primary hypothyroidism
Adrenal insufficiency
Reduced Prolactin Elimination
Chronic renal failure
Hepatic cirrhosis
Neurogenic Causes
Breast stimulation
Breast-feeding
Chest-wall injury (e.g., surgery, herpes zoster)
Abnormal Molecules
Macroprolactinemia

Pathophysiology

Hyperprolactinemia is a condition of elevated serum prolactin.[43] It is the most common endocrine disorder of the hypothalamic-pituitary axis. High prolactin levels inhibit the release of gonadotropin-releasing hormone (GnRH) by the hypothalamus and subsequently suppress secretion of LH and FSH from the anterior pituitary. High prolactin levels result in reduced gonadal hormone levels, often leading to reproductive dysfunction and **galactorrhea** (inappropriate breast milk production).

In combination with clinical symptoms, at least three repeated measures of serum prolactin levels greater than 20 ng/mL (20 mcg/L) are needed to confirm the diagnosis because prolactin,

Clinical Presentation and Diagnosis of Hyperprolactinemia[7,43,44]

General

Hyperprolactinemia most commonly affects women of reproductive age and is very rare in men.

Signs and Symptoms

Pre-menopausal women

- Headache and compromised or loss of vision caused by the prolactin-secreting tumor and its close proximity to the optic structures.
- Clinical presentation is associated with the degree of prolactin elevation:
  - Prolactin greater than 100 ng/mL (100 mcg/L): hypogonadism, galactorrhea, and amenorrhea
  - Prolactin 51 to 75 ng/mL (51–75 mcg/L): **oligomenorrhea** (infrequent menstruation).
  - Prolactin 31 to 50 ng/mL (31–50 mcg/L): decreased libido and infertility.
  - Increased body weight may be associated with prolactin-secreting pituitary tumor.
  - The degree of hypogonadism generally is proportionate to the degree of prolactin elevation.
  - Excessive hair growth (**hirsutism**) and acne also may be present owing to relative androgen excess compared with low estrogen levels.

Men

- Decreased libido, decreased energy, erectile dysfunction, impotence, decreased sperm production, infertility, gynecomastia, and rarely, galactorrhea.
- Impotence is unresponsive to treatment and is associated with reduced muscle mass, loss of pubic hair, and osteoporosis.

Laboratory Tests

- Prolactin serum concentrations at rest will be greater than 20 ng/mL (20 mcg/L) in men or 25 ng/mL (25 mcg/L) in women with at least three measurements.
- Obtain β-human chorionic gonadotropin (β-hCG) level to exclude pregnancy.
- Obtain TSH level to exclude primary hypothyroidism.
- Obtain blood urea nitrogen and serum creatinine tests to exclude renal failure.

Other Diagnostic Tests

- Perform MRI to locate the tumor, exclude a pseudoprolactinoma, and validate the diagnosis.
- Consider a bone mineral density test in patients with long-term hypogonadism.

Additional Clinical Sequelae

- The prolonged suppression of estrogen in pre-menopausal women with hyperprolactinemia leads to decreases in bone mineral density and significant risk for the development of osteoporosis.
- Risk for ischemic heart disease may be increased with untreated hyperprolactinemia.

Source: Adapted, with permission, from Heck AM, Yanovski JA, Calis KA. Pituitary Gland Disorders. In: Dipiro JT, Talbert RL, Yee GC, et al (eds.) *Pharmacotherapy. A Pathophysiologic Approach.* 6th ed. New York: McGraw Hill; 2005: 1407–1423.

similar to GH, is released in a pulsatile manner. To make an accurate diagnosis, obtain the prolactin measurements in a fasting state, before breast stimulation, and at rest. If an intravenous line is present or planned, it is prudent to wait at least 2 hours after line insertion before measuring serum prolactin to decrease detecting transient physiologic increases in prolactin level[43,44] (Table 43–5). Medication-induced hyperprolactinemia typically is associated with prolactin levels of less than 150 ng/mL (150 mcg/L), whereas prolactin levels greater than 250 ng/mL (250 mcg/L) are almost always associated with macroprolactinoma.[46]

Treatment Goals for Hyperprolactinemia

Because hyperprolactinemia is often associated with hypogonadism, the goals for management of hyperprolactinemia are to restore the clinical consequences of hypogonadism and reduce its associated risk for osteoporosis[44] (Table 43–7).

TABLE 43–7. Goals for Management of Hyperprolactinemia[44]

1. Normalize prolactin level
2. Improve clinical symptoms
3. Restore normal fertility
4. Restore and maintain normal gonadal function
5. Protect against development of osteoporosis
6. Prevent disease recurrence

If a pituitary tumor is present:

- Ablate or reduce tumor size to relieve tumor mass effect.
- Preserve normal pituitary function.
- Prevent progression of pituitary tumor or hypothalamic disease.

General Approaches to Treatment

Management of drug-induced hyperprolactinemia is to discontinue the offending agent, if possible, and start an appropriate therapeutic alternative. In situations where the offending agent cannot be discontinued, cautious use of hormone replacement, biphosphonate therapy, and/or dopamine agonists may be considered depending on the patient's clinical circumstances.[45] Treatment options for the management of hyperprolactinemia include (1) clinical observation, (2) pharmacologic therapy with dopamine agonists, (3) transsphenoidal pituitary adenomectomy, and (4) radiation therapy. Figure 43–4 demonstrates the approach to management of hyperprolactinemia.[44] Clinical observation and close monitoring are justifiable in patients with asymptomatic elevation of prolactin.[43] ❽ *Dopamine agonists are the first-line treatment of choice for all patients with hyperprolactinemia; transsphenoidal surgery and radiation therapy are reserved for patients who are resistant to or severely intolerant of pharmacologic therapy.*[43,47,48]

Pharmacologic Therapy

Dopamine is the principal neurotransmitter responsible for the inhibition of prolactin secretion from the anterior pituitary. Thus, dopamine agonists are the main pharmacologic therapy used for management of hyperprolactinemia.[47] Treatment with dopamine agonists has proven to be extremely effective in normalizing serum prolactin level, restoring gonadal function, decreasing tumor size, and improving visual fields.[47] Patients with macroprolactinomas generally require a higher dose to normalize prolactin levels compared with patients with microprolactinomas.[46]

Three dopamine agonists are used for the management of hyperprolactinemia, bromocriptine, cabergoline, and pergolide[47] (Table 43–8). Because these three dopamine agonists are ergot derivatives, they are contraindicated in combination with potent cytochrome P-450 subfamily IIIA polypeptide 4 (CYP3A4) inhibitors, including protease inhibitors (e.g., ritonavir and indinavir), azole antifungals (e.g., ketoconazole and itraconazole), and some macrolide antibiotics (e.g., erythromycin and clarithromycin). Furthermore, ergot derivatives can cause constriction of peripheral and cranial blood vessels. These medications are also contraindicated in patients with uncontrolled hypertension, severe ischemic heart disease, or peripheral vascular disorders. Caution should be exercised with concomitant use of other ergot derivates and in patients with impaired renal or hepatic function, dementia, concurrent antihypertensive therapy, or a history of psychosis, peptic ulcer disease, or cardiovascular disease.

Patient Encounter 2: The Medical History, Physical Examination, and Diagnostic Tests

WB, a 27-year-old woman, presents to the Women's Health Clinic. Her chief complaint is milky fluid discharge from both breasts. WB also mentions that her menstrual periods have stopped since she stopped taking her oral contraceptive 8 months ago with the hope of conceiving. Her menstrual cycle was regular before starting the oral contraceptive. WB has no recent weight change, excessive hair growth, or acne. She does not exercise excessively and is otherwise healthy.

PMH
None

FM
Both parents are still alive and healthy.

SH
Married, a high school teacher, and physically active (walks 3 miles twice a week)

Meds
NuvaRing® use as directed (discontinued 8 months ago)
Acetaminophen 325 mg 2 tablets every 4 to 6 hours as needed for mild headaches

ROS
Ophthalmic examination reveals normal visual acuity and fields.

PE
HEENT: (–) goiter
VS: 100/62 mm Hg, P 82 beats per minute, RR 18 breaths/minute, T 37.1°C (98.8°F)
CV: RRR, normal S_1, S_2; no murmurs, rubs, or gallops
Breasts: (+) bilateral expressible galactorrhea with no other abnormality
Abd: Soft, non-tender, non-distended; (+) bowel sounds; no hepatosplenomegaly; heme (–) stool

Labs
Electrolytes, renal and thyroid function, FSH, LH, and testosterone are within normal limits. Elevated prolactin at 115 ng/mL (115 mcg/L). Pregnancy test is negative.

MRI
Reveals a pituitary tumor approximately 9 mm in diameter.

- Given this information, what signs and symptoms does WB have for hyperprolactinemia?
- Identify your treatment goals for WB.
- What nonpharmacologic and pharmacologic treatment options are available for WB?

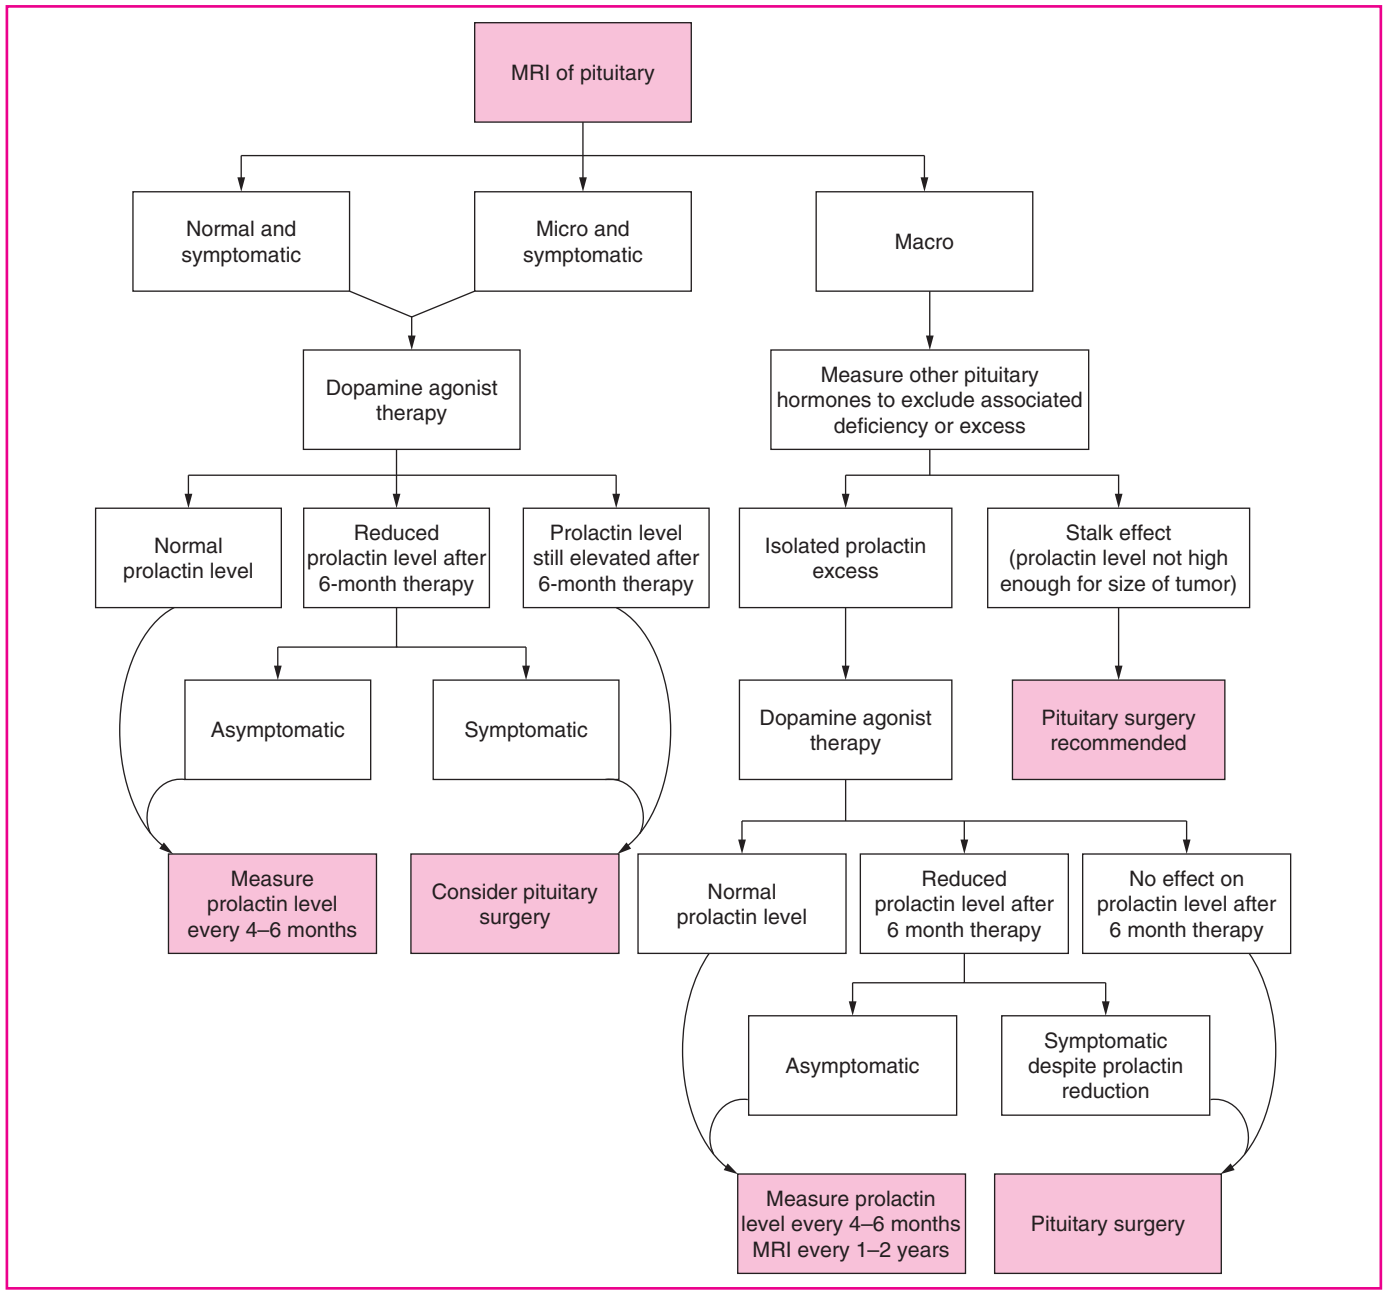

FIGURE 43–4. Approach to management of hyperprolactinemia.[44] MRI = magnetic resonance imaging. (Reprinted, with permission, from Serri O, Chik CL, Ezzat S. Diagnosis and management of hyperprolactinemia. Can Med Assoc J 2003; 169(9): 575–581. © 2003 by CMA Media, Inc.)

Bromocriptine

Bromocriptine directly binds to the D_2 receptors on the lactotroph cells to exert its effect. Bromocriptine normalizes prolactin level, restores menstrual cycles, and reduces tumor size in approximately 90% of patients.[49] Adverse effects such as nausea, dizziness, and orthostatic hypotension often limit 5% to 10% of patients from continuing treatment. Thus, start bromocriptine at a low dose (e.g., 0.625–1.25 mg) at bedtime (taken with a snack) to decrease adverse effects. Slowly titrate up to the optimal therapeutic dose (2.5–15 mg/day) because most adverse effects subside with continual treatment.[46] If the adverse GI effects are not tolerable, bromocriptine can be administered vaginally at a reduced dose (2.5 mg/day).[47] Owing to its short half-life of only 6 hours, bromocriptine must be administered in divided doses, which may compromise patient adherence.

TABLE 43–8. Comparison of Dopamine Agonists for Treatment of Hyperprolactemia[47]

Generic Name (Brand)	Starting Dose	Titrating Dose	Usually Effective Dose	Maximal Dose	Dosing Frequency	Adverse Effects	Cost
Bromocriptine (Parlodel®)	0.625–1.25 mg/day at bedtime	1.25 mg increments at 1-week interval	2.5–15 mg/day	40 mg/day	2 to 3 divided doses per day	Dizziness, headache, syncope, nausea, vomiting, GI cramps, orthostatic hypotension	$$
Cabergoline (Dostinex®)	0.5 mg/week or 0.25 mg twice/week	0.5 mg increment at 4-week intervals	1–2 mg/week	4.5 mg/week	Once or twice weekly	Similar but orthostatic hypotension less common	$$$
Pergolide[a] (Permax®)	25 mcg/day at bedtime	25 mcg increment at 1-week interval	50 mcg/day at bedtime	100 mcg/day	Once daily	Similar but somnolence and hypotension more common	$

[a]Withdrawn from United States market in 2007.
GI, gastrointestinal; $, relatively inexpensive; $$, moderately expensive; $$$, more expensive.

Cabergoline

Cabergoline was developed with a higher affinity for dopamine D_2 receptors than bromocriptine. It is a long-acting dopamine agonist capable of inhibiting pituitary prolactin secretion for at least 7 days after a single oral dose.[47] The prolonged duration of action allows for once- or twice-weekly administration. Adverse effects of cabergoline appear to be significantly better tolerated than those of bromocriptine.[47] However, transient elevations of serum alkaline phosphatase, bilirubin, and aminotransferases have been reported in a few patients treated with cabergoline. Cabergoline is also more effective in normalizing prolactin levels and restoring menses than bromocriptine.[47] It also may be effective in treating hyperprolactinemia in patients who are resistant or intolerant to bromocriptine and in men and women with micro- and macroprolactinomas.[47,50] Given the favorable safety, efficacy, and administration profile of cabergoline, it has replaced bromocriptine as first-line treatment for the management of hyperprolactinemia.

Pergolide

Pergolide is a dopamine agonist with affinity for D_1 and D_2 receptors. It is 10 to 1000 times more potent than bromocriptine on a milligram-per-milligram basis. This agent has a duration of action longer than 24 hours and offers the advantage of once-daily administration. Trials outside the United States have demonstrated pergolide to be as safe and effective as bromocriptine for lowering prolactin level and reducing tumor size.[47] Because pergolide has been associated with daytime sedation, carefully advise patients to use caution in performing activities that require alertness. Monitor and report daytime sedation or any episodes of falling asleep while engaged in the activities of daily living. In 2007, pergolide was withdrawn from the United States market due to reports of serious heart valve damage in patients receiving the drug for Parkinson's disease.

Nonpharmacologic Therapy

In a small number of patients who have failed or are intolerant of dopamine agonists, transsphenoidal adenomectomy may be necessary. Surgical treatment is also considered in patients with non-prolactin-secreting tumors or macroprolactinomas that jeopardize the optic chiasm.[43] Nonetheless, surgical intervention does not reliably lead to long-term cure and may cause permanent complications.[44] Radiation therapy is reserved for failures of both pharmacologic therapy and surgery.[48] However, normalization of prolactin levels with radiation therapy may take 10 years to show full benefit, and radiation-induced hypopituitarism may require lifelong hormone replacement.

Management of Hyperprolactinemia in Pregnancy

Most women with hyperprolactinemia require dopamine agonist therapy to achieve regular ovulatory cycles and pregnancy. Since restoration of the ovulatory cycle may occur within 1 week of initiating therapy, caution patients regarding their potential to become pregnant.[51]

Overall, there is reassuring worldwide experience that bromocriptine use during pregnancy does not increase fetal malformations, spontaneous miscarriage, ectopic pregnancy, or multiple births.[47,48] Furthermore, no teratogenic effects have been reported in women who received cabergoline during the

first and second trimesters of pregnancy.[47] Despite these data, ❾ *women who become pregnant while on a dopamine agonist should discontinue treatment immediately to minimize fetal exposure. Because cabergoline has a prolonged half-life, women who plan to become pregnant should discontinue the drug at least 1 month before planned conception.*[47,48]

Microadenomas rarely cause complications during pregnancy. However, untreated macroprolactinomas carry about 15% to 35% risk of tumor enlargement and potentially can jeopardize vision.[46] Therefore, monitor women with macroprolactinomas closely for the development of headache and visual impairments. Baseline and routine visual field examinations are essential. Evidence of abnormal visual fields may indicate tumor growth and should be followed by an MRI. Should tumors enlarge, bromocriptine is the preferred choice over cabergoline because of greater experience with this drug during pregnancy.[51]

Outcome Evaluation

- Assess patients for tolerability to dopamine agonists.
- Monitor clinical symptoms associated with hyperprolactinemia every month for the first 3 months to assess therapeutic efficacy and assist with dose titration.
- Evaluate the patient for symptoms, such as headache, visual disturbances, menstrual cycles in women, and sexual function in men, to assess clinical response to therapy.
- Once the prolactin level is normalized and clinical symptoms of hyperprolactinemia have resolved, monitor prolactin level every 6 to 12 months.[43,44,46]
- Evaluate pregnant patients every 2 months.[44]
- If the prolactin level is well controlled with dopamine agonist therapy for 2 to 3 years, gradually taper therapy to the lowest effective dose. Check prolactin levels after each dose reduction.[46]
- If the prolactin levels remain unchanged for 1 year at the reduced dose, dopamine agonist therapy may be discontinued.
- It is essential to monitor prolactin levels every 6 months or annually to detect the possibility of permanent remission of pituitary disease.[43,44]
- The need to continue dopamine agonists in postmenopausal women must be reassessed because these patients have a higher probability of maintaining normal prolactin levels after treatment is discontinued.[52]
- In patients with macroprolactinomas, monitor visual field at baseline and repeat the test 1 month after initiation of a dopamine agonist.
- Repeat the MRI 6 months after initiating therapy or if an increase in symptoms or rise in prolactin levels suggests the presence of tumor growth.[43,46]
- Discontinuation of therapy in patients with macroprolactinomas usually leads to tumor regrowth and recurrence of hyperprolactinemia. This decision warrants careful consideration.

Hyperprolactinemia: Patient Care and Monitoring

1. Assess patient's clinical signs and symptoms of hyperprolactinemia.
2. Review the available diagnostic data to determine severity and exclude other common causes of hyperprolactinemia.
3. Obtain a thorough medication history to exclude medication-induced hyperprolactinemia.
4. Determine patient's plan regarding pregnancy because this influences treatment.
5. Educate patient about safety and efficacy of dopamine agonists. Make sure that the patient does not have any contraindications or allergies to drug therapies.
6. Develop a formal plan to assess response and adverse effects of dopamine agonists. When appropriate, be sure to make dose adjustments.
7. If the prolactin level remains normal for 2 years, reassess the need to continue treatment. Make sure that the patient is taking the lowest effective dose for management of hyperprolactinemia.
8. Provide patient education in regard to disease state and non-drug and drug therapy. Discuss with the patient:
   - Risk factors associated with hyperprolactinemia
   - Potential disadvantages and effectiveness of existing dopamine agonist therapy
   - Potential disadvantages and effectiveness of surgery and radiation treatment
   - Importance of adherence to therapy
   - Potential for adverse effects or long-term complications

LHRH: luteinizing hormone–releasing hormone
MAOI: monoamine oxidase inhibitor
MRI: magnetic resonance imaging
MSH: melanocyte-stimulating hormone
OGTT: oral glucose tolerance test
PIH: prolactin-inhibiting hormone
PRH: prolactin-releasing hormone
PRL: prolactin
SD: standard deviation
SQ: subcutaneously
SSRI: selective serotonin reuptake inhibitor
T_3: triiodothyronine
T_4: thyroxine
TCA: tricyclic antidepressant
TRH: thyrotropin-releasing hormone
TSH: thyroid-stimulating hormone or thyrotropin

44 Pregnancy and Lactation: Therapeutic Considerations

Deborah Sturpe and Kari Alperovitz-Bichell

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Identify the stages of fetal development when birth defects are most likely to occur.
2. Describe hormonal regulation of lactation.
3. Determine trimesters and a due date for a pregnancy based on the last menstrual period.
4. List routine pregnancy care and screenings that should be provided for women with uncomplicated pregnancies.
5. Discuss characteristics that affect drug transfer across the placental barrier and into breast milk.
6. Discuss general methods by which teratogenic risk and drug exposure during pregnancy and lactation can be minimized.
7. Identify drugs whose use should be strictly avoided in pregnancy or lactation.
8. Recommend nonpharmacologic therapy for the following disorders when they occur during pregnancy or lactation: nausea and vomiting, constipation, heartburn, pain, and cough and cold.
9. Recommend an appropriate dose and formulation of folic acid to a woman desiring to become pregnant.
10. Recommend a pharmacotherapy regimen that is likely to minimize risk to the fetus or baby for the following disorders that are commonly experienced during pregnancy: nausea and vomiting, constipation, hemorrhoids, heartburn, pain, and upper respiratory symptoms.
11. Recommend a pharmacotherapy regimen for asymptomatic bacteriuria in a pregnant female that is likely to be safe and effective.
12. Recommend treatment (including drug selection, dosing, monitoring, and alternative treatments) for bacterial vaginosis, vulvovaginal candidiasis, and sexually transmitted diseases in a pregnant female based on guidelines from the Centers for Disease Control and Prevention.
13. Recommend a pharmacotherapy regimen for preterm labor that will prolong time to delivery and enhance fetal lung development while minimizing maternal side effects.
14. Recommend treatment (including drug selection, dosing, monitoring, and alternative treatments) for group B *Streptococcus* based on guidelines of the Centers for Disease Control and Prevention.
15. Recommend treatment (including drug selection, dosing, monitoring, and alternative treatments) for induction of labor.
16. Recommend a pharmacotherapy regimen that is likely to minimize risk to the infant for the following disorders experienced during lactation: acute mastitis, nipple candidiasis, and insufficient milk production.

Key Concepts

❶ Although the risk of drug-induced teratogenicity is of concern, actual risk of birth defects from most drug exposures is small. Choose agents with the longest safety record in pregnancy or lactation first.
❷ The critical time for organogenesis is during the first eight weeks of pregnancy; thus, the risk for birth defects is highest during the first trimester.
❸ While unnecessary medication clearly should be avoided during pregnancy or lactation, clinicians also should avoid undertreating conditions that can lead to adverse maternal, fetal, or neonatal outcomes.
❹ Treat most benign pregnancy conditions with nonpharmacologic therapy prior to using drug therapy.
❺ Advise most women of childbearing potential to take a multivitamin containing 400 mcg folic acid.

Clinicians often must weigh the risks and benefits of drug therapy during pregnancy or lactation. Owing to fear of adverse effects on the developing fetus or newborn infant, a common solution is avoidance of therapy. However, many chronic medical conditions, acute medical conditions, and pregnancy- and lactation-related disorders necessitate therapy to preserve the health of the mother or the baby. Since few prospective clinical trials enroll pregnant or lactating women, clinicians must make decisions based largely on case reports and surveillance data. This chapter discusses available resources that help to guide therapy choices, general strategies that reduce risks of drug use in this population, and specific treatment recommendations for some conditions commonly experienced during pregnancy and lactation.

EPIDEMIOLOGY AND ETIOLOGY

Medication use in pregnancy is a common phenomenon. In North America, up to 50% of pregnancies are unplanned,[1] and up to 82% of women of childbearing age use a medication on a routine basis.[2] Consequently, many women unknowingly expose the fetus to a medication before discovering the pregnancy. Some pregnant women may be unaware of their condition and will continue use of medications for acute and chronic conditions. Overall, up to 86% of women are reported to use some type of prescription medication during pregnancy at an average of 2.9 medications per patient.[3]

Based on these usage patterns, it may be inevitable that some drugs will act as **teratogens**. ❶ *But actual risk of birth defects from most drug exposures is small. Congenital defects are found in approximately 5% of all live births, but only 10% of these events are due to external factors (e.g., chemical, physical, or biologic).*[4] *Of this 10%, only 1% is estimated to be due to medication use.*[4] Despite this low risk, many women unnecessarily terminate pregnancies due to fear of drug-induced malformations.[1]

There are fewer data on the frequency of medication use during lactation. Use does appear to be common. A recent Dutch study reported that 53% of all breast-feeding mothers had taken a medication, herb, or supplement (exclusive of iron, vitamins, and homeopathic remedies).[5] Furthermore, more women in the United States are now abiding by the recommendation to breast-feed. It is now estimated that up to 50% of United States women breast-feed for at least a short time.[6]

PATHOPHYSIOLOGY

Teratogenic risk is determined largely by timing of drug exposure. Establishment of full implantation of the fertilized egg takes 1 to 2 weeks. Thus, negative effects of drug exposure during this time typically result in spontaneous abortion.[3,7] ❷ *The critical time for organogenesis is during the first 8 weeks of pregnancy; thus, the risk for birth defects is highest during the first trimester*[3,7] (Fig. 44–1). After 8 weeks, most teratogenic effects are related to **fetal growth restriction** or functional deficits such as mental retardation.[3]

Multiple physical and hormonal changes take place during pregnancy that may cause related problems. Anemia is common due to a 30% to 50% increase in plasma volume with a disproportionate increase in red blood cell mass.[3] Increased levels of progesterone slow gastrointestinal motility, relax esophageal sphincter pressure, and increase mucosal edema.[8] This leads to constipation, heartburn, and rhinitis. Increased venous pressure and constipation often result in hemorrhoids.[9] ***Human chorionic gonadotropin*** produced by the placenta is thought to induce nausea and vomiting of pregnancy (commonly termed *morning sickness*).[10] Increasing abdominal girth and posture changes commonly cause back pain.[11] ❸ *Finally, preterm labor and fetal growth restriction often are caused by infection during pregnancy (e.g., chlamydia, bacterial vaginosis, and bacteriuria) or untreated maternal chronic disease (e.g., diabetes mellitus).*

After birth, a rapid drop in progesterone level initially triggers lactation through reversal of inhibitory effects on prolactin (Fig. 44–2). Nipple stimulation then enables lactation to continue once established. During lactation, ineffective removal of milk from the breast, trauma, and skin breaks may lead to problems such as milk stasis, nipple pain, and mastitis.[12] Additionally, some women have difficultly initiating lactation due to improper technique and/or activity of inhibitors such as dopamine (Fig. 44–2).

TREATMENT

Desired Outcomes

The primary goal for drug use during pregnancy and lactation is to treat maternal or fetal conditions as necessary while minimizing risk to the developing fetus or neonate. Numerous situations may necessitate drug therapy, including maternal

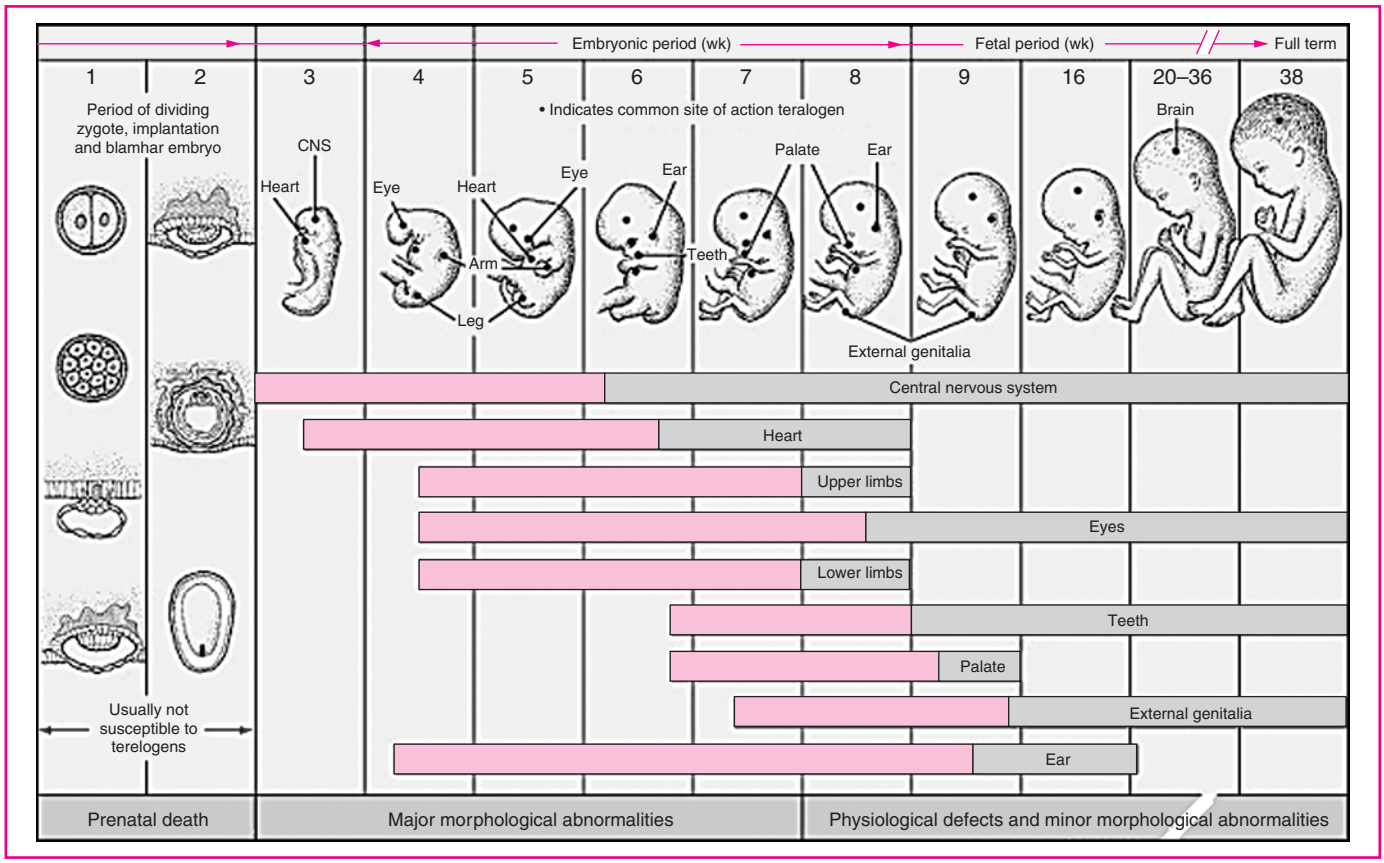

FIGURE 44–1. Embryonic development. (Reprinted, with permission, from Moore KL, *The Developing Human*. New York: Elsevier, 1874; p 96; copyright 1974.) The horizontal bars represent potential sensitivity to teratogens. The pink areas represent the more critical times.

chronic disease, symptomatic conditions associated with pregnancy or lactation, and conditions associated with adverse fetal or neonatal outcomes.

General Approach to Treatment

Sources of Information for Drug Use during Pregnancy or Lactation

The Food and Drug Administration (FDA) pregnancy labeling system is the most commonly used source for information regarding safety of drug use during pregnancy (Table 44–1). This system has several faults that include lack of data regarding drug use in lactation, reliance on animal studies for categorization, and lack of consideration for altered maternal pharmacokinetics and timing of exposure.[13] Furthermore, many older drugs have no FDA pregnancy category, and categorization may not be updated when new data prove that a medication is safer than originally believed. Consequently, the FDA pregnancy labeling system is currently under review.

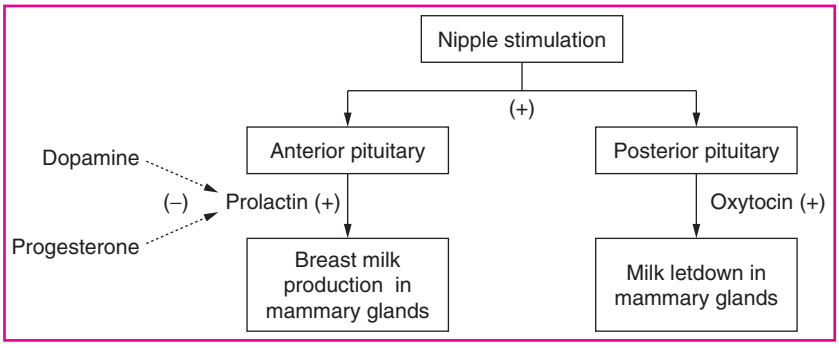

FIGURE 44–2. A simplistic schematic of the hormonal control of lactation. During pregnancy, high levels of progesterone block the effect of prolactin. After delivery, nipple stimulation enhances prolactin and oxytocin release from the pituitary gland, allowing for milk production and letdown in the mammary glands. Data from references 48 and 50.

Clinical Presentation and Diagnosis

Confirmation of Pregnancy

Positive urine human chorionic gonadotropin followed by positive ultrasound, fetal heart sounds, and/or fetal movement.

Pregnancy Dating and Gestational Age

Calculated from the first day of the last menstrual period. Due dates typically are estimated at 40 weeks' gestation; however, infants delivered at between 38 and 42 weeks are considered full term.

Pregnancy Symptoms

First trimester: Menstrual spotting, missed menses, fatigue, breast tenderness, increased urination, mood swings, nausea/vomiting, headache, heartburn, constipation
Second trimester: Frequent urination, heartburn, constipation, dry skin, edema, **linea nigra, melasma**
Third trimester: Backache, edema, shortness of breath

Routine Pregnancy Visits

In a normal, uncomplicated pregnancy, visits should occur monthly until 28 weeks' gestation, every 2 to 3 weeks from 28 to 36 weeks' gestation, and then weekly until birth. Examination for each of the following is performed at each visit:

- Blood pressure
- Weight
- Urine for protein and glucose
- Uterine size
- Fetal heart rate
- Fetal movement

Routine Lab Testing for Normal Pregnancies (First Trimester Unless Otherwise Indicated)

- Human immunodeficiency virus
- Purified protein derivative (PPD) test for tuberculosis
- Venereal Disease Research Laboratory slide test (VDRL) for syphilis
- Rubella immunity
- Cervical cytology
- Blood and Rh type
- Hepatitis B surface antigen
- Hepatitis C antibodies (if high risk)
- Bacterial vaginosis testing if symptomatic or at high risk (previous preterm labor)
- Antibody screen for Rh antibodies
- Hemoglobin and hematocrit for anemia (repeated at 26–32 weeks)
- Urinalysis with culture for asymptomatic bacteriuria
- Gonorrhea and chlamydia
- Screens for Down's syndrome and neural tube defects (at 15–20 weeks)
- Gestational diabetes screening (at 24–28 weeks)
- Group B *Streptococcus* screening (at 35–37 weeks)

Assessing Suitability of the Cervix for Labor Induction

Suitability is based on cervical dilation, length, consistency, and position. These findings are translated to a numerical rating called the *Bishop score*. A Bishop score of less than 6 indicates that pharmacologic therapy is needed to ripen the cervix prior to delivery.

Select Problems Experienced During Pregnancy or Lactation

Hyperemesis gravidarum. Severe, persistent nausea and vomiting during pregnancy accompanied by dehydration, electrolyte disturbance, ketonuria, and/or weight loss.
Bacteriuria. Often asymptomatic in pregnancy. Diagnosed by positive urine culture.
Bacterial vaginosis. Clinically diagnosed by presence of three of the following:

- White, non-inflammatory discharge
- **Clue cells** on microscopic examination
- Vaginal pH greater than 4.5
- A fishy odor before or after addition of 10% potassium hydroxide (i.e., "whiff" test)

Vulvovaginal candidiasis. Typical symptoms include vaginal itching and discharge. Clinical characteristics include:

- Vaginal pH less than 4.5
- Observation of yeast on Gram stain or wet preparation
- Thick, white, "cottage cheese–like" discharge

Chlamydia and gonorrhea. Typically asymptomatic. Diagnosed by positive culture.
Genital herpes simplex virus. Characterized by vesicular or ulcerative lesions. Diagnosis confirmed by virologic or serologic testing. Prodrome manifests as pain, burning, or itching at the site where lesions will develop.
Pelvic inflammatory disease. Difficult to diagnose in pregnancy. Symptoms may include:

- Uterine/ovarian tenderness
- Cervical motion tenderness
- Fever
- Abnormal cervical or vaginal discharge
- Presence of white blood cells in vaginal secretions
- Elevated erythrocyte sedimentation rate
- Elevated C-reactive protein

Syphilis. Early disease may be characterized by a single genital lesion. Diagnosed by positive serologic testing [e.g., VDRL or rapid plasma reagin (RPR) test].
Trichomoniasis. Symptoms may include vulvar irritation and yellow-green discharge. Diagnosed after microscopic visualization of the organism.
Preterm labor. Onset of labor prior to 37 weeks' gestation.
Group B Streptococcus. Diagnosed by positive culture on vaginal or rectal swab.
Mastitis. Characterized by localized redness, tenderness, and warmth on one breast accompanied by fever and flulike symptoms. Although uncommon, symptoms also may be bilateral.
Nipple candidiasis. Typical symptoms include nipple pain, itching, burning, and/or breast pain that persist after feeding.
Gestational diabetes. See Chapter 40.
Hypertension in pregnancy. Categorized as one of the following:

- Chronic hypertension (blood pressure greater than or equal to 140/90 mm Hg prior to pregnancy or prior to 20 weeks' gestation that lasts more than 12 weeks postpartum)
- Preeclampsia (blood pressure greater than or equal to 140/90 mm Hg after 20 weeks' gestation accompanied by proteinuria)
- Chronic hypertension with superimposed preeclampsia (onset of proteinuria after 20 weeks' gestation in a woman with chronic hypertension)
- Gestational hypertension (hypertension without proteinuria after 20 weeks' gestation)
- Transient hypertension (diagnosis made retrospectively when blood pressure returns to normal before 12 weeks postpartum)

Patient Encounter, Part 1

LC is a 28-year-old woman who comes to your practice because she thinks that she is pregnant. She reports that she has not had a period in 9 weeks. When she first missed her period just over 1 month ago, she was not concerned because her cycle had become very light. However, when she missed her cycle again, she took a home pregnancy test. That test was positive. In your practice, a repeat urine pregnancy test confirms that the patient is pregnant.

- What additional medical history do you need to gather from this patient?
- What is the estimated gestational age of the fetus?
- What physical examination, laboratory testing, or other testing would you perform at this time?

Data regarding safety of drug use during lactation are also lacking. Most resources list only milk to plasma ratios for drugs secreted into breast milk. Unfortunately, this ratio gives no information regarding the amount of drug ingested by an infant or the effects of that drug on the infant.

Sources of information other than FDA pregnancy labeling exist that may provide more useful information to the clinician (Table 44–2). It still should be noted that these resources share the limitation of deriving recommendations largely from data from case reports and surveillance data. Consequently, clinicians often are forced to advise patients based on limited evidence.

TABLE 44–1. FDA Pregnancy Categories

Category A: Adequate, well-controlled studies in pregnant women have not shown an increased risk of fetal abnormalities.

Category B: Animal studies have revealed no evidence of harm to the fetus, however, there are no adequate and well-controlled studies in pregnant women, *or* animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus.

Category C: Animal studies have shown an adverse effect and there are no adequate and well-controlled studies in pregnant women, *or* no animal studies have been conducted and there are no adequate and well-controlled studies in pregnant women.

Category D: Studies, adequate well-controlled or observational, in pregnant women have demonstrated a risk to the fetus. However, the benefits of therapy may outweigh the potential risk.

Category X: Studies, adequate well-controlled or observational, in animals or pregnant women have demonstrated positive evidence of fetal abnormalities. The use of the product is contraindicated in women who are or may become pregnant.

TABLE 44–2. Sources of Information for Drug Use in Pregnancy and Lactation

- Hale TW. *Medications and Mother's Milk*. 11th ed. Amarillo, TX: Pharmacoft, 2004. (*Provides alphabetical list of drugs with references; calculates theoretical infant dose received after maternal use.*)
- American Academy of Pediatrics Committee on Drugs. The transfer of drugs and other chemicals into breast milk. *Pediatrics*. 2001; 108(3):776–789. (*Lists drugs that are considered "compatible with breast-feeding"; list is periodically updated.*)
- Motherisk (www.motherisk.org) (*Includes online information, fact-sheets, and has a "warm-line" phone number for advice for patients and clinicians during normal business hours.*)
- Organization of Teratology Information Services (www.otispregnancy.org) (*Lists and links to teratology information services by locale; many have telephone "warm-lines."*)

General Principles of Drug Use in Pregnancy and Lactation

❸ *While unnecessary medications clearly should be avoided during pregnancy or lactation, clinicians also should avoid undertreating conditions that can lead to adverse maternal, fetal, or infant outcomes. Additionally, clinicians should avoid unnecessarily discouraging breast-feeding because breast milk provides nutritional and immunologic benefit to the infant.*

Several general strategies may be employed to minimize drug exposure to the fetus or neonate. First, avoid drugs with known teratogenic effects and infant complications (Tables 44–3 and 44–4). Second, choose single-drug, short-acting therapy with agents having the longest safety record in pregnancy or lactation. Third, choose drugs with characteristics such as high molecular weights, strong ionization, high protein binding, and high water solubility to limit entry into the placental circulation or breast milk through passive diffusion.[3] Finally, counsel women to take agents immediately after breast-feeding to allow milk concentrations to fall prior to the next feeding.[14]

Preconception Planning

Planning prior to pregnancy is an important strategy for reducing the risks of birth defects and fetal or neonatal complications. Clinicians should consider childbearing potential when selecting therapy for chronic medical conditions and follow the same general principles of drug selection described earlier. This is especially important for the treatment of conditions such as hypertension or epilepsy because many medications used for these conditions are known teratogens. Engage women in discussions regarding the potential risks to an exposed fetus prior to starting therapy.[1] Further information regarding treatment of chronic medical conditions such as hypertension, human immunodeficiency virus, epilepsy and diabetes may be found in Chapters 2, 84, 27, and 40.

TABLE 44–3. Drugs with Known Teratogenic Effects[1,3,4]

Drug or Class	Teratogenic Effect
Angiotensin-converting enzyme inhibitors	Renal damage, growth restriction
Barbiturates	Neonatal withdrawal syndrome
Benzodiazepines	Neonatal withdrawal syndrome
Carbamazepine	Neural tube defects
Chemotherapeutic agents	Multiple malformations (including central nervous system, facial, and limb)
Isotretinoin	Central nervous system, ear, and heart malformations
Lithium	Cardiovascular malformations
Misoprostol	Limb and central nervous system malformations
Non-steroidal anti-inflammatory agents	Premature closing of the patent ductus arteriosus (late second and third trimesters), hemorrhage, necrotizing enterocolitis
Opioids	Neonatal withdrawal syndrome
Phenytoin	Central nervous system malformations, fetal growth restriction
Tetracyclines	Tooth and bone malformations
Thalidomide	Limb and internal organ malformations
Valproic acid	Neural tube defects
Warfarin	Growth restriction, fetal hemorrhage, skeletal and central nervous system malformations

TABLE 44–4. Contraindicated Drugs and Drugs of Concern During Lactation[3,14,25]

Drug or Class	Effect
Contraindicated Drugs and Drug Classes	
Amiodarone	Neonatal hypothyroidism and pulmonary toxicity
Bromocriptine	Lactation suppression
Chemotherapeutics	Neonatal immune suppression and neutropenia
Ergotamine	Neonatal diarrhea, vomiting, convulsions; lactation suppression
Isotretinoin	Possible neonatal tumors
Lithium	Neonatal central nervous system and cardiovascular disturbances
Drugs and Drug Classes of Concern	
Acebutolol	Neonatal hypotension, bradycardia, tachypnea
Aluminum-containing antacids	Developmental retardation
Antidepressants	Unknown, but possibly of concern
Antipsychotics	Unknown, but possibly of concern
Atenolol	Neonatal bradycardia, cyanosis
Benzodiazepines	Unknown, but possibly of concern
Clemastine	Neonatal drowsiness, irritability
Metronidazole	In vitro mutagen
Phenobarbital	Infantile spasms, neonatal sedation
Primodone	Neonatal sedation
Radioactive drugs	Transfer of radioactivity

Counsel all women of childbearing potential regarding lifestyle modifications that may improve pregnancy outcome. These include healthy eating habits, multivitamin use, cessation of tobacco use, cessation of illicit substance use, and moderation of alcohol intake.[15]

Nonpharmacologic Therapy

❹ *Treat most benign pregnancy conditions with nonpharmacologic therapy prior to using drug therapy.* These conditions include nausea and vomiting of pregnancy, constipation, hemorrhoids, heartburn, pain, and upper respiratory symptoms.

Nausea and Vomiting

Nonpharmacologic measures recommended for nausea and vomiting of pregnancy (e.g., morning sickness) include lifestyle and dietary changes, acupuncture, and acupressure. Counsel women to avoid or minimize nausea triggers such as objectionable odors and food textures, rapid positional changes, and car rides.[10] Advise administration of the prenatal vitamin at bedtime because the iron content often triggers nausea. Counsel women to eat small, frequent meals that are bland, high in carbohydrates, and low in fat.[10] Clinicians also may advise women to keep saltine crackers, water, or ginger ale (small sips only) at the bedside so that they can ingest a small snack immediately before getting out of bed. If nausea occurs, advise the patient to lie down because this strategy has been shown to relieve symptoms.[10]

Effectiveness of acupuncture and acupressure for nausea and vomiting of pregnancy has not been clearly proven in clinical studies, but both methods are safe to recommend.[10,16] Benefits may include a reduction in nausea and dry heaving but not in vomiting.[10]

Constipation and Hemorrhoids

Nonpharmacologic treatment is the mainstay of treatment for constipation and hemorrhoids in pregnant patients.[9,17] Advise women to eat a high-fiber diet, drink plenty of fluids, and avoid foods such as white rice and cheese that often exacerbate constipation. Patients should avoid prolonged time on the toilet, which increases pressure within hemorrhoids. Soaking in warm sitz baths also may help hemorrhoids by relaxing the anal sphincter. Icing the area may decrease pain and inflammation. If hemorrhoids are severe, surgical resection or banding can be performed. However, it is generally preferable to delay even minor surgery until after delivery.

Heartburn

Nonpharmacologic recommendations for the treatment of heartburn in a pregnant patient do not differ from those given

to non-pregnant patients. Primary recommendations include eating small, frequent meals, remaining upright after eating, elevating the head of the bed, and avoiding foods known to decrease lower esophageal sphincter tone (such as chocolate, coffee, fatty foods, and peppermint).

Pain

Women often experience pelvic and back pain during pregnancy. Systematic review suggests that water aerobics, pillows that support the abdomen, physiotherapy, and acupuncture offer back-pain relief.[18]

Common Cold

Rest, fluids, humidified air, and nasal saline are the mainstays of nonpharmacologic therapy for the common cold. Pregnant women experiencing cold symptoms should be advised of these strategies and reminded that cold symptoms typically last only 7 to 10 days.

Pharmacologic Therapy

Preconception Care

❺ *Advise most women of childbearing potential to take a multivitamin containing 400 mcg folic acid.* Folic acid deficiency is a major cause of **neural tube defects** because dietary intake alone is seldom sufficient to prevent the occurrence.[19] Neural tube defects are the second most common major congenital defect and occur in approximately 1.4 to 2 per 1000 pregnancies.[19] Defects usually develop during the first 2 weeks of pregnancy, prior to the woman knowing she has conceived; thus, preconception counseling regarding folic acid intake is especially important. For most women, over-the-counter multivitamins provide an adequate amount of supplementation (Table 44–5). Women at increased risk of delivering a child with neural tube defects, e.g., those with a personal or family history of neural tube defects and/or women taking medications known to cause neural tube defects, require higher doses (Table 44–5). In such instances, clinicians should recommend specific folic acid supplementation rather than extra doses of multivitamins because increasing the number of multivitamins may cause vitamin A toxicity.[19] Additional benefits of multivitamin intake include the calcium and iron components (Table 44–5).

Gastrointestinal Disturbances

Nausea and Vomiting

The combination of pyridoxine (vitamin B_6) and doxylamine appears to offer the most favorable benefit-to-risk ratio for the treatment of nausea and vomiting in pregnancy[10,16] (Table 44–5). Long-term usage data show no fetal risk with the regimen.[10] The combination was once marketed in the United States under the brand name Bendectin®, but the drug was withdrawn from the United States market in 1984. Women can approximate the dosage by taking each component separately.

Data also support that ginger is safe and effective when used as an antinausea agent in pregnancy[16] (Table 44–5). However, it may be difficult for most women to reproduce the type and dose of ginger used in clinical trials.

Second-line agents for nausea and vomiting include first-generation antihistamines such as diphenhydramine, dopamine agonists such as metoclopramide, and the serotonin agent ondansetron[10] (Table 44–5). Limited data address their safety, and maternal side effects may be experienced more commonly with these drugs than with first-line agents. Antihistamine use often is associated with drowsiness, and metoclopramide may cause **extrapyramidal symptoms.** Hyperemesis gravidarum often requires hospitalization and administration of intravenous therapy with 5-hydroxytryptamine type 3 receptor antagonists such as ondansetron.

Constipation

Bulk-forming laxatives such as psyllium and calcium polycarbophil are safe for use in pregnancy and lactation[17] (Table 44–5). If these methods fail, then stimulant laxatives such as bisacodyl and senna are acceptable second-line agents for short-term or intermittent use, but side effects of diarrhea and abdominal pain may limit use[17] (Table 44–5). Stool softeners such as docusate are recommended commonly but have shown little efficacy for the treatment of chronic constipation.[9] Avoid magnesium-containing laxatives or phosphosoda owing to the potential for electrolyte disturbances and fluid retention. During lactation, bulk-forming laxatives and the stimulant laxative senna are likely safe for use.[14]

Hemorrhoids

Studies are lacking regarding the safety and efficacy of hemorrhoid treatment during pregnancy.[20] At this time, recommend only topical anti-inflammatory agents such as witch hazel (Tucks® pads). Although prospective studies in pregnancy are lacking, witch hazel is used commonly during pregnancy and lactation without adverse incidence.

Heartburn

A recent consensus panel recommends calcium- or magnesium-containing antacids as first-line therapies for heartburn in pregnancy.[21] This recommendation was based on the added benefit of calcium and magnesium supplementation. Avoid antacids containing aluminum hydroxide owing to associations with fetal neurotoxicity.[22]

If antacids fail to improve symptoms, recommend ranitidine (Table 44–5). Although most H_2 blockers are thought to be safe in pregnancy, ranitidine is the only agent with double-blind, randomized trials evaluating its use in this population.[23]

Other agents that appear to be safe for use in pregnancy include the proton pump inhibitors, sucralfate, and metoclopromide (Table 44–5). The proton pump inhibitor with the largest body of human safety data during pregnancy is omeprazole.[24]

TABLE 44–5. Summary of Medication Dosing Recommendations[9,10,12,14,23,27,38,41,43,44, 48]

Drug	Dose	Comments
Preconception and Routine Pregnancy Care		
Calcium (Tums, Os-cal, Maalox, Citracal)	1300 mg orally per day (age 14–18) 1000 mg orally per day (age 19–50)	
Folic acid	400 mcg orally daily 4 mg orally daily if high risk	High risk = personal or family history of neural tube defects or on medication known to cause neural tube defects
Iron (Feosol, FeroSul)	27 mg elemental iron daily	Increase to 60–120 mg daily if iron-deficiency anemia present
Nausea and Vomiting of Pregnancy		
Diphenhydramine (Benadryl, Genahist)	12.5–25 mg orally four times daily	Second-line agent
Ginger	250 mg orally four times daily	First-line agent
Metoclopramide (Reglan)	5–10 mg orally three to four times daily	Second-line agent
Ondansetron (Zofran)	20 mg intravenously every 8 hours	Second-line agent, may be preferred for hyperemesis
Pyridoxine/doxylamine (Vitamin B_6/Unisom)	25 mg/12.5 mg orally three times daily	First-line agent
Constipation		
Bisacodyl (Dulcolax, Correctol)	5–10 mg orally (tabs) or rectally (suppositories) as needed	Second-line agent after bulk laxatives
Polycarbophil (Fiberlax, Fibercon)	2 tabs one to four times daily	First-line agent
Psyllium (Metamucil, Genfiber)	Product specific dosing, usually 1 packet/scoopful in water up to three times daily	First-line agent
Senna (ExLax, Senokot)	17.2 mg orally as needed	Second-line agent after bulk laxatives
Heartburn		
Antacids (various) (Tums, Maalox, Rolaids, GasEx)	15–30 mL or 250 mg–1.5 g up to four times daily	First-line agent (avoid aluminum-containing preparations)
Metoclopramide (Reglan)	5–10 mg orally three to four times daily	Third-line agent
Omeprazole (Prilosex)	20 mg orally daily	Third-line agent
Ranitidine (Zantac)	150 mg orally twice daily	Second-line agent after antacids
Sucralfate (Carafate)	1 g orally four times daily	Third-line agent (pregnancy); first-line agent (lactation)
Pain		
Acetaminophen (Tylenol)	500–650 mg orally four times daily	First-line agent
Codeine	15 mg every 4 to 6 hours	Third-line agent
Ibuprofen (Advil, Motrin)	200–400 mg orally four times daily	Second-line agent in first trimester only. Do not use in second or third trimester.
Naproxen (Aleve)	200–400 mg orally twice daily	Second-line agent in first trimester only. Do not use in second or third trimester.
Upper Respiratory Symptoms		
Budesonide (Rhinocort)	32 mcg spray, 1–4 sprays in each nostril daily	Preferred corticosteroid for allergic rhinitis.
Cetirizine (Zyrtec)	10 mg orally daily	Second-line agent for allergic rhinitis during second and third trimesters only.
Chlorpheniramine (Chlortrimeton)	4 mg every 4–6 hours	Preferred agent if first-generation antihistamines are to be used for allergic rhinitis.
Dextromethorphan (Robitussin Cough Gels, Vicks 44, Simply Cough, Delsym)	30 mg orally every 6–8 hours	First-line agent for cough/cold.
Guaifenesin (Hytuss, Mucinex, Robitussin)	200–400 mg orally every 4 hours	First-line agent for cough/cold.
Loratadine (Claritin, Alavert)	10 mg orally daily	Second-line agent for allergic rhinitis during second and third trimesters only.
Oxymetazoline (Afrin, Neo-Synephrine 12-hour)	0.05% spray, 2–3 sprays in each nostril twice daily for 3 to 5 days	First-line agent for cough/cold. Limit use to 3 to 5 days to avoid rebound congestion.
Pseudoephedrine (Sudafed)	60 mg every 4–6 hours	Second and third trimesters only.

TABLE 44–5. Summary of Medication Dosing Recommendations[9,10,12,14,23,27,38,41,43,44, 48] (*Continued*)

Drug	Dose	Comments
Bacteriuria		
Amoxicillin (Trimox, Amoxil)	500 mg three times daily for 3 days	
Cephalexin (Keflex)	250–500 mg four times daily for 3 days	
Nitrofurantoin macrocrystals (Macrobid)	100 mg twice daily for 3 days	
Bacterial Vaginosis		
Clindamycin (Cleocin)	300 mg orally twice daily for 7 days 100 mg cream or suppository intravaginally at bedtime for 3 days	Oral administration is second-line agent in pregnancy; vaginal administration is first-line agent in lactation, but contraindicated in pregnancy
Metronidazole (Flagyl)	250 mg three times daily for 7 days	First-line agent in pregnancy; avoid during lactation
Vulvovaginal Candidiasis		
Clotrimazole (Mycelex, Gyne-Lotrimin)	1% cream, 5 g intravaginally for 7 days 100-mg vaginal tablet daily for 7 days	
Miconazole (Monistat)	2% cream, 5 g intravaginally for 7 days 100-mg vaginal suppository daily for 7 days	
Terconazole (Terazol)	0.4% cream, 5 g intravaginally for 7 days	
Chlamydia		
Amoxicillin (Trimox, Amoxil)	500 mg orally three times daily for 7 days	First-line agent in pregnancy; third-line agent in lactation
Azithromycin (Zithromax)	1 g orally once	Third-line agent in pregnancy; first-line agent in lactation
Doxycycline (Vibramycin)	100 mg orally twice daily for 7 days	Avoid during pregnancy; first-line agent in lactation
Erythromycin base (Ery-tab)	500 mg orally four times daily for 7 days	Second-line agent in pregnancy
Gonorrhea		
Cefixime (Suprax)	400 mg orally once	First-line agent in pregnancy or lactation
Ceftriaxone (Rocephin)	125 mg intramuscularly once	First-line agent in pregnancy or lactation
Ciprofloxacin (Cipro)	500 mg orally once	Contraindicated in pregnancy; first-line agent in lactation, except for residents of California or Hawaii.
Ofloxacin (Floxin)	400 mg orally once	Both ofloxacin: levofloxacin should have description given for cipro.
Levofloxacin (Levaquin)	250 mg orally once	
Spectinomycin (Trobicin)	2 g intramuscularly once	Second-line agent in pregnancy for cephalosporin-allergic patients
Herpes Simplex Virus		
Acyclovir (Zovirax)	400 mg orally three times daily for 7–10 days, or 800 mg orally twice daily for 5 days	7–10-day therapy for initial episode; 5-day therapy for recurrent episodes
Pelvic Inflammatory Disease		
Clindamycin *plus* gentamicin (Cleocin/Garamycin)	Clindamycin 900 mg intravenously every 8 hours; gentamicin dosed based on pharmacokinetics × 14 days	
Syphilis		
Benzathine penicillin G (Bicillin)	2.4 million units intramuscularly once	Desensitize penicillin-allergic patients during pregnancy; also first-line agent during lactation.
Doxycycline (Vibramycin)	100 mg twice daily for 14 days	Alternative during lactation (but not pregnancy) for penicillin-allergic patients
Tetracycline (Sumycin)	500 mg four times daily for 14 days	Alternative during lactation (but not pregnancy) for penicillin-allergic patients
Trichomoniasis		
Metronidazole (Flagyl)	2 g orally once	Safe during pregnancy. During lactation, temporarily stop breast-feeding for 12–24 hours.
Antenatal Steroids		
Betamethasone (Celestone)	12 mg intramuscularly every 24 hours for two doses	
Dexamethasone (Decadron, Dexasone, Cortastat)	6 mg intramuscularly every 12 hours for two doses	
Tocolytics		
Indomethacin (Indocin)	50–100 mg oral load, then 25–50 mg orally every 6 hours × 48 hours	
Magnesium sulfate	4–6 mg intravenous bolus over 20 minutes, then 2–3 g per hour intravenous drip	Generally not favored

(Continued)

TABLE 44–5. Summary of Medication Dosing Recommendations[9,10,12,14,23,27,38,41,43,44,48] (*Continued*)

Drug	Dose	Comments
Nifedipine (immediate release) (Procardia)	30 mg oral load, then 10–20 mg every 4–6 hours	First-line agent
Terbutaline (Brethine)	0.25 mg subcutaneously every 20 minutes to 3 hours	
Group B *Streptococcus*		
Ampicillin (Principen)	2 g intravenously initially, then 1 g intravenously every 4 hours until delivery	See Fig. 44–3
Cefazolin (Ancef)	2 g intravenously initially, then 1 g intravenously every 8 hours until delivery	
Clindamycin (Cleocin)	900 mg intravenously every 8 hours until delivery	
Erythromycin (Erythocin)	500 mg intravenously every 6 hours until delivery	
Penicillin G (Pfizerpen)	5 million units intravenously initially, then 2.5 million units intravenously every 4 hours until delivery	
Vancomycin (Vancocin, Vancoled)	1 g intravenously every 12 hours until delivery	
Labor Induction		
Oxytocin	2–6 milliunits per minute intravenous infusion (high dose) 1–2 milliunits per minute intravenous infusion (low dose)	
Cervical Ripening		
Dinoprostone gel (Prepidil)	1 application (0.5 mg) every 6 hours to maximum of 3 doses in 24 hours	Store in refrigerator and bring to room temperature before use
Dinoprostone vaginal insert (Cervidil)	Insert once (releases 0.3 mg per hour) for up to 12 hours	
Misoprostol (Cytotec)	25 mcg intravaginally every 3–6 hours	Contraindicated if previous cesarean section
Mastitis		
Cephalexin (Keflex)	250 mg orally four times daily × 10–14 days	First-line agent
Dicloxacillin	125 mg orally four times daily × 10–14 days	First-line agent
Erythromycin (Ery-tab)	333 mg orally three times daily × 10–14 days	Second-line agent in penicillin-allergic patients
Nipple Candidiasis		
Fluconazole (Diflucan)	100 mg orally daily	Second-line agent when topical azoles fail
Ketoconazole (Nizoral)	2% cream—apply to affected areas after each feeding	First-line agent
Miconazole (Micatin, Monistat-Derm)	2% cream—apply to affected areas after each feeding	First-line agent
Nystatin drops (Mycostatin)	200,000 units (2 mL) orally four times daily	For concurrent treatment of the neonate/infant regardless of maternal drug choice
Nystatin topical (Mycostatin)	100,000 units/g—apply to affected areas after each feeding	
Enhancement of Lactation		
Metoclopramide	10 mg orally three times daily for 7–10 days	

During lactation, sucralfate may be the best choice for treatment of heartburn because it is not absorbed systemically.[25] If symptoms are not controlled, the H_2 blockers are acceptable alternatives.[14,25] Avoid aluminum-containing antacids during lactation owing to reports of aluminum toxicity in otherwise healthy infants.[22]

Pain

Acetaminophen generally is considered the drug of choice for the treatment of pain during pregnancy (Table 44–5). If acetaminophen does not relieve pain, non-steroidal anti-inflammatory drugs (NSAIDs) may be used cautiously during the first trimester only in women who do not have a history of gastrointestinal bleed, peptic ulcer, or aspirin allergy (Table 44–5). Also avoid NSAID use in women who have had difficulty conceiving or have experienced miscarriage.[26] Use of NSAIDs in the late second or third trimester has been associated with multiple fetal and neonatal complications (Table 44–3).

Avoid opioid use during pregnancy owing to reports of fetal growth restriction, neonatal dependence, and neonatal

Patient Encounter, Part 2

During your first encounter with LC, you collect the following data:

PMH
Seasonal allergic rhinitis

FH
Mother delivered two preterm infants.

SH
Works as a librarian. Denies use of alcohol, tobacco, or illicit substances.

Meds
- Loratadine 10 mg daily
- Ibuprofen 400 mg prn headache (uses approximately once weekly)
- Ortho-Tri-Cyclen Lo® daily
- Multivitamin (generic for Centrum®) daily

ROS
(+) Nausea with occasional vomiting on awakening each morning × 2 weeks. Lasts for 1 to 2 hours. Has missed 3 days of work owing to symptoms. Remainder of ROS within normal limits.

VS: Blood pressure 118/62, pulse 72 beats per minute, respiratory rate 12, temperature 37°C (98.6°F)
The patient states that she wants to have this baby but expresses concern over the medications she has been using over the last 9 weeks. She states that neither she nor her husband could handle having a "deformed" baby, and she asks you if she should consider terminating the pregnancy.

- What resources can you use to help determine the risk of her drug exposures?
- Based on that information, what advice would you give her regarding the risk to her baby?
- What do you recommended for her morning sickness?

respiratory depression. However, brief treatment with small doses of codeine is acceptable for severe pain unresponsive to acetaminophen or NSAIDs.[1] For lactating women, acetaminophen, NSAIDs, and most opioids are considered compatible with breast-feeding by the American Academy of Pediatrics.[14]

Upper Respiratory Symptoms

For common cold symptoms such as congestion and cough, recommend nasal oxymetazoline, oral guaifenesin, and dextromethorphan according to joint guidelines from the American College of Obstetricians and Gynecologists and the American College of Allergy, Asthma, and Immunology[27] (Table 44–5). Counsel patients using oxymetazoline to limit use to 3 to 5 days in order to minimize the incidence of rebound congestion. Oral pseudoephedrine is also acceptable for treatment of congestion during the second and third trimesters, but avoid use in the first trimester owing to the risk of fetal gastroschisis (incidence 20 per 10,000 treated women).[28] Codeine is not a preferred therapy for cough in this population.[27]

Treat allergy symptoms with nasal corticosteroids during pregnancy.[28] Budesonide has extensive safety data in pregnant women and may be the drug of choice in the treatment of naive patients. If antihistamines are indicated, chlorpheniramine is preferred owing to its record of safe use during pregnancy. Fewer data are available regarding the safety of second-generation antihistamines during pregnancy. Animal and human studies seem to suggest overall safety for cetirizine and loratadine.[28–30] However, guidelines recommend their use only in women on topical corticosteroid therapy who are unable to tolerate chlorpheniramine.[28] Avoid fexofenadine owing to reports of teratogenic effects in animals.[28]

During lactation, oral or nasal decongestants, nasal steroids, and loratadine are acceptable for treatment of upper respiratory symptoms.[14] However, one case of adverse neonatal outcome has been reported with the first-generation antihistamine clemastine.[14] Few data are available regarding the safety of other first-generation antihistamines during lactation. Therefore, avoid use of this drug class during lactation.

Bacteriuria

❸ *Bacteriuria during pregnancy, including asymptomatic disease, is associated with pyelonephritis, low birth weight, and preterm delivery. Treatment improves these risks; thus, treat all women testing positive for bacteriuria empirically with antimicrobial therapy targeted at* Escherichia coli *infection.*[31] Safe agents for empirical therapy include amoxicillin, cephalexin, and nitrofurantoin[32,33] (Table 44–5). Sulfonamides and ampicillin also have been used, but increasing bacterial resistance to these agents renders them second-line choices.[32] Avoid quinolones owing to the possible risk of bone and cartilage malformations. Once culture and sensitivity results are available, change the antimicrobial regimen if necessary. Recommend standard 3-day antimicrobial therapy because there is insufficient evidence among pregnant women to support 1-day regimens.[32,34]

Bacterial Vaginosis

Bacterial vaginosis is associated with preterm delivery, but treating asymptomatic disease does not appear to decrease this risk.[35–37] Consequently, treat only symptomatic disease (Table 44–5).

The Centers for Disease Control and Prevention (CDC) recommend oral metronidazole for the treatment of bacterial vaginosis in pregnant women.[38] Metronidazole is deemed safe for use by the CDC during all stages of pregnancy despite package labeling listing a contraindication in the first trimester.[38] Oral clindamycin is an option for women not tolerating metronidazole.[38]

It is not a first-line agent owing to lower efficacy compared with oral metronidazole in non-pregnant populations.[38] Avoid clindamycin vaginal cream due to associations with premature labor and neonatal infection.[38]

Counsel women taking metronidazole regarding potential for nausea, vomiting, and abdominal pain. Counsel patients to avoid alcohol or alcohol-containing substances during therapy with metronidazole owing to the risk of **disulfuram-like reactions**.

Clindamycin vaginal cream is the preferred therapy for bacterial vaginosis during lactation because metronidazole is listed as a drug of concern by the American Academy of Pediatrics (AAP)[14] (Tables 44–4 and 44–5). Counsel patients that clindamycin cream weakens latex condoms and diaphragms, potentially rendering them ineffective.

Vulvovaginal Candidiasis

Treat symptomatic vulvovaginal candidiasis in pregnant women with topical azole therapy according to CDC guidelines.[38] Oral fluconazole is not recommended. Asymptomatic disease does not require treatment. Vulvovaginal candidiasis during pregnancy is considered a "complicated" case; thus, 7-day therapy (instead of 1- to 3-day therapy) is recommended[38] (Table 44–5).

During lactation, topical azoles remain the drug of choice for vulvovaginal candidiasis.[38] Oral fluconazole is not recommended in order to minimize the development of fluconazole-resistant *Candida* species in the general population. Counsel women using topical azoles that the medication weakens latex condoms and diaphragms, potentially rendering them ineffective for preventing pregnancy and transmission of sexually transmitted infections.

Sexually Transmitted Infections

Chlamydia

❸ *Treat chlamydia infections during pregnancy, including those that are asymptomatic, with erythromycin or amoxicillin in order to reduce risk of preterm labor*[38] (Table 44–5). Systematic review suggests that amoxicillin is better tolerated than erythromycin and has fewer discontinuations owing to adverse drug reactions than erythromycin.[39] Azithromycin may be a safe alternative in women unable to take, tolerate, or adhere to these first-line recommendations.[38] However, azithromycin is a third-line therapy because there are longer safety records for erythromycin and amoxicillin in pregnancy. Avoid doxycycline in pregnant women owing to known teratogenic effects (Table 44–3).

During lactation, azithromycin and doxycycline are first-line choices for chlamydia[38] (Table 44–5). Both are deemed compatible with breast-feeding by the AAP and generally are more effective and better tolerated than erythromycin or amoxicillin.[14,38]

Gonorrhea

❸ *Treat gonorrheal infections during pregnancy, including those that are asymptomatic, with cefixime or ceftriaxone in order to reduce the risk of preterm labor*[38] (Table 44–5). Spectinomycin is an alternative choice for penicillin- or cephalosporin-allergic women.[38] Avoid tetracyclines during pregnancy owing to known teratogenic effects (Table 44–3). Also avoid quinolones owing to the possible risk of bone or cartilage malformations.

During lactation, all CDC first-line recommended therapies for gonorrhea (Table 44–5) are deemed compatible with breast-feeding by the AAP.[14] Quinolone therapy is not recommended for women residing in California or Hawaii due to the increasing numbers of quinolone-resistant species.[38]

Herpes Simplex

Herpes simplex virus may be transmitted to the neonate if active vaginal lesions or the prodrome is present at the time of birth. Consequently, cesarean section often is recommended for these women. Vaginal delivery is indicated if vaginal lesions or the prodrome are not present.

Recommend oral acyclovir for treatment of genital herpes simplex episodes during pregnancy in order to help reduce the need for cesarean section[38] (Table 44–5). Intravenous therapy may be indicated for very severe episodes. Safety of acyclovir has not been firmly established, but surveillance data do not suggest an increased risk of teratogenic effects. Acyclovir is preferred over valacyclovir or famcyclovir because experience with the latter agents in pregnancy is limited.

During lactation, acyclovir is deemed compatible with breast-feeding by the AAP even though the drug does concentrate in milk.[14] No recommendation has been made regarding the safety of valacyclovir or famcyclovir during lactation.

Pelvic Inflammatory Disease

❸ *Treat pelvic inflammatory disease during pregnancy with intravenous clindamycin plus gentamicin in order to reduce maternal morbidity, preterm delivery, and fetal death*[38] (Table 44–5). Avoid regimens using doxycycline owing to known teratogenic effects (Table 44–3), and avoid quinolones owing to the possible risk of bone and cartilage malformations.

Syphilis

❸ *Treat syphilis during pregnancy with benzathine penicillin G in order to prevent transmission of syphilis to the fetus and to cure the disease in the fetus*[38] (Table 44–5). Penicillin-allergic women must undergo desensitization to the drug.[38] Alternative therapies used in non-pregnant patients are either teratogenic (e.g., tetracycline and doxycycline) or will not cure disease in the fetus (e.g., erythromycin).[38]

Treat syphilis during lactation with benzathine penicillin G or any of the CDC-recommended alternatives for penicillin-allergic patients (Table 44–5). All choices are deemed compatible with breast-feeding by the AAP.[14]

Trichomoniasis

Treat symptomatic trichomoniasis with oral metronidazole in order to alleviate maternal symptoms (Table 44–5). Do not treat asymptomatic disease. There is no evidence suggesting that treatment of asymptomatic disease will reduce the incidence of preterm labor or low birth weight, and systematic review suggests that this practice may even increase the incidence of preterm birth.[40]

Advise women requiring treatment for trichomoniasis during lactation to discontinue breast-feeding for 12 to 24 hours after receiving single-dose metronidazole therapy in order to minimize risk to the infant.[14] During this time, advise women to pump and discard breast milk in order to avoid engorgement.

Counsel women taking metronidazole to avoid drinking alcohol or using alcohol-containing substances during therapy.

Preterm Labor

❸ *Administration of **antenatal** corticosteroids during preterm labor having an onset prior to 34 weeks' gestation has been proven to decrease the risk of neonatal respiratory distress, intraventricular hemorrhage, necrotizing enterocolitis, and death*[15,41] (Table 44–5). No benefit from antenatal corticosteroids is gained if labor starts after 34 weeks' gestation. In order to allow for administration of antenatal steroids, **tocolytic** therapy often is used to prolong time to delivery by 2 to 7 days.[36] Agents commonly used as tocolytics in the United States include magnesium sulfate, terbutaline, indomethacin, and nifidepine (Table 44–5).

Systemic review concludes that tocolytic therapy with the calcium channel blockers offers the best benefit-to-risk ratio.[42] However, few head-to-head comparisons have been made between agents. Guidelines from the American College of Obstetricians and Gynecologists (ACOG) therefore recommend selecting an agent based on maternal status and potential adverse drug reactions.[41] Do not recommend combination tocolytic therapy, maintenance tocolytic therapy, or repeated courses of acute tocolytic therapy owing to increased fetal risk and lack of efficacy.[41]

Data proving that magnesium sulfate prolongs pregnancy is lacking.[36] It is contraindicated for use in women with myasthenia gravis, and serious complications such as maternal pulmonary edema and cardiac arrest have been reported.[41] More benign side effects such as flushing, headache, and nausea often cause discontinuation of therapy.[36]

Terbutaline has been shown to prolong pregnancy but has not been associated with decreased neonatal morbidity.[36] It is contraindicated for use in women with preexisting cardiac arrhythmia. Potentially serious adverse effects include pulmonary edema, cardiac arrhythmia, or myocardial ischemia in the mother. Reported fetal and neonatal adverse effects include tachycardia, hyperglycemia, and hyperinsulinemia.[41]

Indomethacin prolongs pregnancy but has not been independently associated with decreased neonatal morbidity.[36] It may be of particular benefit in women with **hydramnios.**[36] Avoid use in women with a history of severe renal or hepatic impairment, aspirin allergy, or a history of peptic ulcer disease or other bleeding disorders. Although typically well tolerated by the mother, reports of increased risk of postpartum hemorrhage and **patent ductus arteriosus** is worrisome.[36]

The calcium channel blockers have been associated with both prolonged pregnancy and decreased neonatal morbidity.[36,42] When compared with β-mimetics (e.g., terbutaline) and magnesium, they show better neonatal outcome and a lower incidence of serious maternal side effects.[42] Potential minor maternal adverse effects include headache, flushing, dizziness, and transient hypotension.[41]

Group B *Streptococcus*

❸ *Maternal transmission of group B* Streptococcus *during the **intrapartum** period is a cause of neonatal sepsis and death. All pregnant women should be screened for group B* Streptococcus *disease using vaginal and rectal swabs between 35 and 37 weeks' gestation. Antibiotic therapy has been proven to reduce the incidence of early-onset neonatal disease in high-risk groups of women*[43] (Table 44–6). Start treatment at the time of membrane rupture and continue until delivery. If women receive therapy owing to unknown group B *Streptococcus* status and no growth is seen 48 hours after culture, discontinue therapy. Therapy is not required in women undergoing planned cesarean section who have not experienced membrane rupture.

The antibiotic of choice for group B streptococcal disease is penicillin G, although ampicillin is an alternative.[43] No resistance to either agent has been reported, and their narrow spectrum of activity makes them ideal choices.[43] Resistance has developed with the use of alternative choices for penicillin-allergic patients. A treatment algorithm for group B *Streptococcus* is shown in Fig. 44–3, and dosing recommendations are shown in Table 44–5.

Labor Induction

Up to 33.7% of pregnancies are delivered through labor induction.[44] Prior to pharmacologically inducing contractions, the cervix must be favorable for labor. Two drugs have proven efficacy for cervical ripening: the prostaglandin E analog dinoprostone (available as a gel or a vaginal insert) and misoprostol (Table 44–5). Guidelines from the ACOG recommend using either drug and give no clear guidance on choosing one over the other.[45]

TABLE 44–6. Characteristics of Women Who Should Receive Intrapartum Treatment for Group B *Streptococcus* per CDC Guidelines[43]

- Previous delivery of a group B *Streptococcus*–positive infant
- Positive group B *Streptococcus* screen
- Group B *Streptococcus* bacteriuria
- Unknown group B *Streptococcus* status plus one or more of the following:
  - Less than 37 weeks' gestation
  - Membrane rupture of greater than 18 hours
  - Intrapartum body temperature greater than or equal to 38°C (100.4°F)

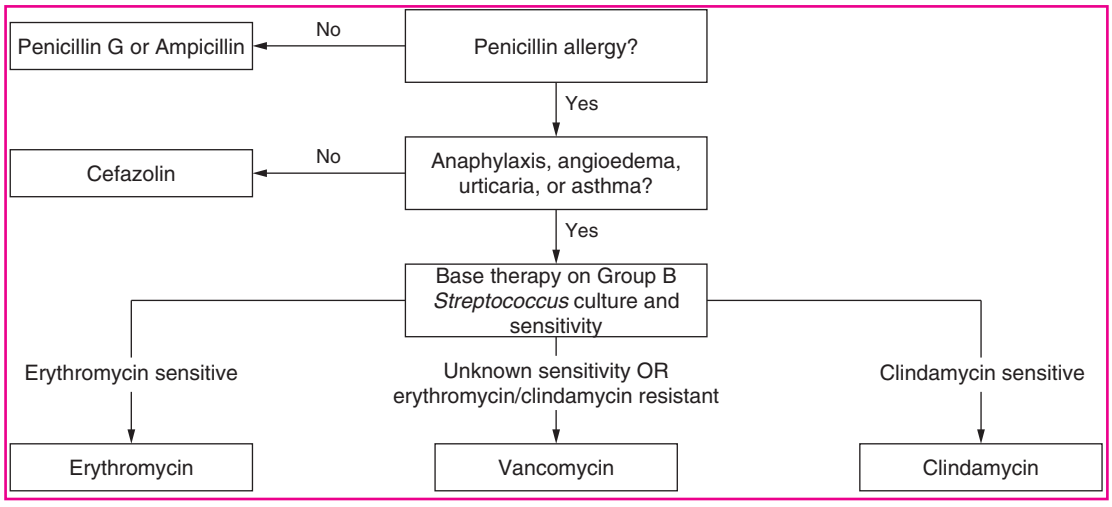

FIGURE 44–3. Algorithm for intrapartum antibiotic therapy against group B *Streptococcus*.[43]

Systematic review concludes that misoprostol shows greater efficacy versus dinoprostone, but this benefit is offset by a greater incidence of side effects.[46] Compared with dinoprostone, misoprostol is associated with a higher incidence of uterine hyperstimulation, alterations in fetal heart rate, and fetal distress.[46] Misoprostol also has been associated with uterine rupture in patients with previous delivery by cesarean section and should be avoided in this population.[44]

Despite these limitations to misoprostol's use, it is much cheaper than the dinoprostone products. The average cost of misoprostol is less than $1 per dose versus a cost of $65 to $75 for dinoprostone gel.[45] At $165, the dinoprostone insert is more expensive than the dinoprostone gel but offers the advantage of quick removal should adverse events occur.[45]

Pharmacologic agents used for cervical ripening often induce contractions. However, if contractions do not begin within 6 to 12 hours of dinoprostone use or within 3 hours of misoprostol use, oxytocin may be administered.[44] Both high- and low-dose oxytocin regimens have been studied (Table 44–5). Both regimens appear to have equal efficacy and are recommended by the ACOG.[44,45] High-dose oxytocin may shorten the time to delivery, but this advantage is offset by a higher incidence of uterine hyperstimulation and fetal heart rate changes.[47]

Breast Infections

Acute Mastitis

Treat acute mastitis with antistaphylococcal antibiotics such as dicloxacillin or cephalexin for 10 to 14 days in order to prevent recurrent disease and breast abscess[12] (Table 44–5). Penicillin-allergic women alternatively may be treated with erythromycin.[12] Occasionally, intravenous antibiotics are needed for resistant, recurrent, or chronic cases. Encourage women to continue breast-feeding through acute mastitis and to empty all leftover milk from the affected breast.[12]

Nipple Candidiasis

Treat nipple candidiasis by applying topical ketoconazole, nystatin, or miconazole to the nipples after each feeding and by administering oral nystatin drops to the breast-feeding infant[12] (Table 44–5). In severe or recurrent cases, the mother may be treated with oral fluconazole.[12,14] Although messy, gentian violet applied topically to both the nipples and the infant's mouth is also effective for resistant cases.[12]

Enhancement of Lactation

Metoclopramide is the drug of choice for enhancement of lactation when improved feeding technique fails to increase milk flow[48] (Table 44–5). Metoclopramide exerts its effect through dopamine antagonism. Increases in milk production should be noted within 2 to 5 days of metoclopramide initiation. Monitor patients for extrapyrimidal symptoms.

Other agents used for lactation enhancement include domperidone and fenugreek. Like metoclopramide, domperidone is a dopamine antagonist. Risk of extrapyramidal effects is lower with domperidone because it does not cross the blood-brain barrier. However, the FDA issued a warning against domperidone use owing to reports of cardiac arrhythmia, myocardial infarction, and sudden death associated with the intravenous formulation.[49] Data regarding fenugreek's efficacy are anecdotal, and the herb should not be recommended unless other efforts fail.[48]

Patient Encounter, Part 3

LC had an uneventful pregnancy before arriving at the hospital in labor at 31 weeks' gestation.

- What do you recommend at this time?

OUTCOME EVALUATION

Report birth defects that are believed to be teratogenic effects. At a minimum, complete an FDA Medwatch Form (available at www.fda.gov/medwatch). Additionally, clinicians may report events to local teratology information services (links available at www.otispregnancy.org). Some pharmaceutical companies have developed pregnancy registries for their drugs. In such instances, report both positive and negative outcomes of drug exposure during pregnancy to those companies.

Monitor the mother for efficacy and adverse effects of drug therapy used during pregnancy or lactation. Monitor all parameters that would be followed in a non-pregnant or lactating population. At times, additional monitoring is required owing to pregnancy, and these exceptions are discussed below. Some conditions also require monitoring of the fetus or neonate.

Conditions Requiring Only Monitoring for Symptomatic Improvement

Little special monitoring is required for the treatment of gastrointestinal disturbances, upper respiratory symptoms, and pain experienced during pregnancy or lactation. Response to therapy is judged by maternal symptomatic relief. Change therapy if no relief is obtained within 1 to 2 weeks after initiating therapy. In the case of severe, persistent nausea and vomiting, monitor maternal weight, orthostatic blood pressure, and electrolytes to diagnose possible hyperemesis gravidarum.

Infections during Pregnancy

Owing to the risk of preterm labor that is associated with gynecologic infections during pregnancy, pregnant women require follow-up objective testing for most of these infections. This includes:[38]

- Repeat urine culture 10 days after completion of therapy for bacteriuria
- Repeat culture for bacterial vaginosis 1 month after completion of therapy
- Repeat culture for gonorrhea or chlamydia 3 weeks after completion of therapy

Some pregnancy infections can be passed to the neonate. In such instances, monitor the baby for signs and symptoms of disease. This includes the following:

- Group B *Streptococcus*. Observe the neonate for signs and symptoms of sepsis until 48 hours after birth. If present, start a full diagnostic work-up (including complete blood cell count and blood culture) and empirical antibiotic therapy.[43]
- Genital herpes simplex virus. Infants born to mothers with active disease at birth should be monitored for signs and symptoms of disease. Surveillance culture of mucosal surfaces is optional.[38]

Monitor mothers suffering from breast infections during lactation for clinical improvement as judged by physical examination and pain relief. Improvement should be noted within 1 week of initiating therapy.

Preterm Labor

Many tocolytic drugs require special monitoring of both mother and fetus. Monitor cardiac status by electrocardiogram and pulmonary status by physical examination in mothers receiving terbutaline or magnesium sulfate owing to the risk of cardiac arrhythmia, cardiac ischemia, and pulmonary edema. Monitor blood pressure and heart rate in mothers receiving terbutaline, magnesium sulfate, or nifedipine owing to the risk of hypotension. Check fetal heart rate during therapy and neonatal heart rate, respiratory rate, and oxygen saturations after delivery.

Labor Induction

Continuously monitor uterine activity and fetal heart rate when giving drug therapy for cervical ripening or oxytocin. Total duration of monitoring depends on the agent used, and current guidelines recommend the following[44,45]:

- Dinoprostone gel. Start monitoring 15 minutes prior to gel insertion and continue for 30 to 120 minutes after administration.
- Dinoprostone insert. Start monitoring 15 minutes prior to insertion and continue for 15 minutes after removal.
- Misoprostol. Start monitoring 15 minutes prior to insertion and continue for 3 hours after administration.
- Oxytocin. Monitor until delivery.

Patient Care and Monitoring

1. Provide prenatal counseling regarding appropriate medication use during pregnancy. If possible, alter the drug regimen for chronic medical conditions to one that is least likely to cause fetal harm. Obtain good control of maternal conditions prior to conception.
2. Recommend appropriate folic acid, calcium, and iron intake prior to conception.
3. After pregnancy is achieved, encourage routine pregnancy monitoring and care.
4. Treat conditions during pregnancy that pose a risk to the fetus or neonate. Choose therapy as recommended by guidelines or those with the longest history of safe use in pregnancy.
5. Treat conditions that cause bothersome maternal symptoms during pregnancy with drug therapy only after nonpharmacologic methods fail. Choose therapy with the longest history of safe use in pregnancy.
6. Encourage breast-feeding. If drug therapy is required during breast-feeding, try to choose short-acting agents with the longest history of safe use in lactation and administer immediately after feedings.
7. Monitor infants for birth defects and/or unusual reactions that may be due to maternal drug use. Report suspected drug-related reactions to the FDA and other appropriate registries.

45 Contraception

Julie M. Koehler and Kathleen B. Haynes

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Discuss the physiology of the normal female reproductive system.
2. Compare the efficacy of oral contraceptives with that of other methods of contraception.
3. State the mechanism of action of hormonal contraceptives.
4. Discuss the risks associated with the use of contraceptives, and state absolute and relative contraindications to their use.
5. List side effects associated with the use of various contraceptives, and recommend strategies for minimizing or eliminating such side effects.
6. Describe advantages and disadvantages of various contraceptives, including both oral and non-oral formulations.
7. Cite important drug interactions with oral contraceptives.
8. Provide appropriate patient education regarding the important differences between various barrier contraceptives.
9. Discuss how emergency contraception may be employed to prevent accidental pregnancy.
10. Provide appropriate patient education regarding the use of oral contraceptives, and recommend and discuss the use of non-oral contraceptives when appropriate.

Key Concepts

❶ Heavy smokers (greater than or equal to 15 cigarettes per day) over the age of 35, as well as patients with a history of thromboembolic disease, stroke, coronary artery disease, any estrogen-dependent neoplasm, or undiagnosed abnormal uterine bleeding, should not take estrogen-containing contraceptives.

❷ Side effects associated with the use of combined oral contraceptives may be minimized by appropriately adjusting either the total estrogen or progestin content.

❸ Antibiotic administration during contraceptive use may decrease the efficacy of many combined contraceptives.

❹ Non-oral forms of contraceptives, such as the transdermal patch and the transvaginal ring, avoid the need for daily administration and, as such, may enhance convenience of use for the patient.

❺ Oral, transdermal, and transvaginal contraceptives, as well as intrauterine devices and most barrier contraceptives, do not protect against sexually transmitted diseases.

❻ When a contraceptive dose is missed, the risk of accidental pregnancy may be increased. Depending on how many doses were missed, the contraceptive formulation being used, and the phase of the cycle during which doses were missed, counseling regarding the use of additional methods of contraception may be warranted.

Historically, the 1950s represented an important time in the control of human fertility. It was during that decade that the first combined oral contraceptives were developed. Shortly after the discovery that the exogenous administration of hormones such as progesterone successfully blocked ovulation, the use of hormonal steroids quickly became the most popular method of contraception worldwide. Specifically, combined oral contraceptives represent the most commonly used reversible form of contraception today, and it is estimated that nearly 100 million women worldwide take oral contraceptives.[1] Further, in the United States, it is estimated that at some time during their lives, more than 80% of women born since 1945 have used oral

contraceptives.[1,2] Since the introduction of oral contraceptives, many newer forms of contraceptives have been developed and are available for use in the United States. New hormone delivery systems, such as transdermal systems, transvaginal systems, and intrauterine devices (IUDs), offer women effective and more convenient alternatives to oral contraceptives.

EPIDEMIOLOGY

According to the National Survey of Family Growth, approximately 6.3 million pregnancies occur annually in the United States.[3] Of these pregnancies, it is estimated that nearly 3.15 million are unintended.[3,4] Contributing to the risk of unintended pregnancy is the fact that approximately 7.5% of all women who are at risk of becoming pregnant do not use any form of contraception.[3,4] In addition, many women who do use contraceptives use their chosen method of contraception imperfectly, and this also increases the risk of undesired pregnancy. Given these statistics, the provision of appropriate and adequate instruction to patients regarding how to use contraceptive methods effectively is essential in order to reduce the risk of unwanted pregnancy.

Exposure to sexually transmitted diseases (STDs) is also a concern for women who are sexually active. It is estimated that 15 million people in the United States become newly infected annually with an STD.[5] Given that not all methods of contraception protect the user adequately against STDs, the provision of proper patient education by health care professionals regarding this risk is absolutely essential.

PHYSIOLOGY

The female menstrual cycle is divided into four functional phases: follicular, ovulatory, luteal, and menstrual.[6] The follicular phase starts the cycle, and ovulation generally occurs on day 14. The luteal phase then begins and continues until menstruation occurs.[6] The menstrual cycle is regulated by a negative-feedback hormone loop between the hypothalamus, anterior pituitary gland, and ovaries[6] (Fig. 45–1).

Initially, the hypothalamus releases gonadotropin-releasing hormone (GnRH), which stimulates the anterior pituitary to produce follicle-stimulating hormone (FSH) and luteinizing hormone (LH). The levels of FSH and LH released vary depending on the phase of the menstrual cycle. Just prior to ovulation, FSH and LH both are at their peak levels. The FSH helps to promote growth of the follicle in preparation for ovulation by causing granulose cells lining the follicle to grow and produce estrogen. The LH promotes androgen production by theca cells in the follicle, promotes ovulation and oocyte maturation, and converts granulose cells to cells that secrete progesterone after ovulation.

Conception is most likely to occur when viable sperm are present in the upper region of the reproductive tract at the time of ovulation. Fertilization occurs when a spermatozoan penetrates an ovum. Approximately 6 to 8 days after ovulation, attachment of the early embryo to the lining of the uterine cavity, or implantation, occurs.

PREVENTION OF PREGNANCY: CONTRACEPTIVES AND DEVICES

Goals of Contraception/Desired Outcome

As to be expected, the most common goal of contraception is the prevention of pregnancy. However, some patients may use contraceptive methods for other benefits, such as menstrual cycle regulation, reduction of premenstrual symptoms, or treatment of acne.

Choice of Contraceptives: Important Considerations

When helping a patient decide on a contraceptive, the most important goal is to find an option that the patient is comfortable with and that the clinician feels will be beneficial for the patient. It is imperative to explain the side effects, safety concerns, and non-contraceptive benefits of each alternative to the patient so that she may make an informed decision. Fertility goals can be different for each patient. It must be determined if the goal is to postpone contraception, space out the next pregnancy, or avoid further pregnancy altogether. Also, a clinician must understand the patient's desire to have or not have a regular bleeding pattern because many contraceptives will affect menses.

As discussed later in this chapter, contraindications exist for various forms of contraception. Patients must be evaluated completely by a health care professional to rule out any medical contraindications to certain contraceptives. The physical examination also will allow health care professionals to determine if there are other medical concerns, such as hypertension, diabetes, or liver disease, that need to be considered when determining the appropriate contraceptive agent. Clinicians also should review family history for potential risks with certain forms of birth control.

Sexual behavior of the female must be determined to understand the risk for STDs. Women who are not in a monogamous relationship must consider their risk of STDs as a factor in their contraceptive decision. Some barrier methods protect against STDs, but agents such as hormonal contraceptives are not capable of preventing STDs if used alone.

Personal preference plays a large role when determining the best contraceptive option. For instance, if a woman is not interested in using a method that will interrupt sexual activity, then a diaphragm would not be appropriate. Preference of the sexual partner may be important as well. Certain agents such as male condoms require the male partner to play an active role in contraception.

Cost is also another related issue for patients. Insurance may not cover all forms of contraception, and patients may have to bear the entire cost for certain options.

Efficacy of Contraceptives

The accidental pregnancy rate for women who do not use any form of contraception is unknown. Therefore, it is difficult to determine the true efficacy of contraceptives in preventing unwanted pregnancy. Table 45–1 shows the percentage of women who experience unintended pregnancy within 1 year of use of a contraceptive.[7]

Oral Contraceptives (Combined)

Combined oral contraceptives contain a combination of a synthetic estrogen and one of several steroids with progestational activity. Most oral contraceptives contain one of two types of estrogen: ethinyl estradiol, which is pharmacologically active, or mestranol, which must be converted by the liver to ethinyl estradiol. Many different progestins are found in the various oral contraceptives. These include norethindrone, norethindrone acetate, ethynodiol diacetate, norgestrel, levonorgestrel, desogestrel, norgestimate, and drospirenone.

The primary mechanism by which combined oral contraceptives prevent pregnancy is through inhibition of ovulation. FSH and LH regulate the production of estrogen and progesterone by the ovaries. Secretion of estrogen and progesterone by the ovaries occurs in a cyclic manner, which, in turn, determines the regular hormonal changes that occur in the uterus, vagina, and cervix associated with the menstrual cycle. Cyclic changes in the levels of estrogen and progesterone in the

TABLE 45–1. Unintended Pregnancy Rates[7]

blood, together with FSH and LH, modulate the development of ova and the occurrence of ovulation. The estrogen component of combined oral contraceptives is most active in inhibiting FSH release.[1] However, at high enough doses, estrogens also may cause inhibition of LH release. In low-dose combination oral contraceptives, the progestin component causes suppression of LH.[1] Ovulation is prevented by suppression of the mid-cycle surge of both FSH and LH,[1] and this suppression, which is induced by combined oral contraceptives, mimics the physiologic changes that occur during pregnancy.

Although suppression of FSH and LH is the primary mechanism by which combined oral contraceptives prevent ovulation, there are other mechanisms by which these hormones work to prevent pregnancy. Other mechanisms include reduced penetration of the egg by sperm, reduced implantation of fertilized eggs, thickening of cervical mucus to prevent sperm penetration into the upper genital tract, and slowed tubal motility, which may delay transport of sperm.[1] Thus, in addition to inhibition of ovulation, combined oral contraceptives induce changes in the cervical mucus and endometrium that make sperm transport and implantation of the embryo unlikely.[1]

Table 45–2 contains a partial listing of the many oral contraceptives available today.[8] Although the efficacy of combined oral contraceptives was quickly demonstrated following their introduction into the market, it took longer to determine their safety and acceptability for patients. Since the mid-1960s, ethinyl estradiol has been the primary estrogen used in most combined oral contraceptives. However, the amount of ethinyl estradiol used in combined oral contraceptives has decreased progressively since that time, and most pills now contain 35 mcg of ethinyl estradiol or less. In addition, to reduce side effects and improve tolerability associated with oral contraceptive use, new progestins and different routes of administration have been explored. In an attempt to minimize the undesirable androgenic side effects associated with

the progestins of combined oral contraceptives, the type of synthetic progestin was modified to create "third generation" progestins (e.g., desogestrel and norgestimate). These synthetic progestins are extremely potent in their ability to inhibit ovulation and prevent pregnancy.

Combined oral contraceptives are available in monophasic, biphasic, and triphasic preparations. Monophasic preparations contain fixed doses of estrogen and progestin in each active pill. Although all three preparations contain both estrogens and progestins, biphasic and triphasic preparations differ from monophasic preparations in that they contain varying proportions of one or both hormones during the pill cycle. These preparations were introduced to reduce the amount and total monthly dose of progestins, as well as to mimic more closely the hormonal changes of the menstrual cycle. However, there is no evidence to suggest that the biphasic and triphasic preparations offer any clinical advantage over the monophasic pills.[8]

Non-contraceptive Benefits of Combined Oral Contraceptives

In addition to preventing pregnancy, there are several non-contraceptive benefits associated with the use of combined oral contraceptive pills. Many of the potential non-contraceptive benefits are highlighted below.

Reduction in the Risk of Endometrial Cancer

The risk of endometrial cancer among women who have used oral contraceptives for at least 1 year is approximately 40% less than the risk in women who have never used oral contraceptives.[9] There is additional evidence to suggest that the benefit of reduced risk for endometrial cancer is detectable within 1 year of use[10–12] and that the benefit may persist for years following discontinuation of oral contraceptives.[9]

Reduction in the Risk of Ovarian Cancer

When compared with women who have never used oral contraceptives, women who have used oral contraceptives for 4 years or less are 30% less likely to develop ovarian cancer. There is also additional evidence to suggest that the longer the duration of oral contraceptive use, the greater the reduction in the risk of ovarian cancer. Women who have taken oral contraceptives for 5 to 11 years are 60% less likely to develop ovarian cancer, and women who have taken oral contraceptives for more than 12 years are 80% less likely to develop ovarian cancer. As with the reduced risk of endometrial cancer, there is evidence to suggest that the benefit of the reduced risk of ovarian cancer may persist for years following discontinuation of oral contraceptives.[10–12]

Improved Regulation of Menstruation

Women who take oral contraceptives typically experience more regular menstrual cycles. In general, oral contraceptive use is associated with less cramping and **dysmenorrhea.**[1,8] Also, women who take oral contraceptives experience fewer days of menstruation each month and as a result experience less blood loss with each menstrual period.[1,13] Some studies suggest that oral contraceptive use decreases overall monthly menstrual flow by 60% or more, which may be particularly beneficial in women who are anemic.[1]

Relief of Benign Breast Disease

Women who use oral contraceptives are less likely to develop benign breast cysts or **fibroadenomas.**[1,8]

Prevention of Ovarian Cysts

Because oral contraceptives suppress ovarian stimulation, women who take them are less likely to develop ovarian cysts.[8]

Reduction in the Risk of Symptomatic Pelvic Inflammatory Disease

The risk of hospitalization owing to symptomatic pelvic inflammatory disease caused by gonorrheal infection is reduced in oral contraceptive users.[14] While the exact protective mechanism is unknown, it is believed that thickening of the cervical mucus and/or reduction in the ability of pathogens to enter the fallopian tubes may contribute.[1]

Improvement in Acne Control

All combination oral contraceptives can improve acne by increasing sex hormone–binding globulin and decreasing free testosterone concentrations.[8] The newer progestins, such as desogestrel and norgestimate, are believed to have less androgenic activity.[8] However, it is not clear that combined oral contraceptives containing these progestins confer any advantage over other combined oral contraceptives with respect to their ability to improve acne control. Only Ortho Tri-Cyclen® (ethinyl estradiol and norgestimate) and Estrostep Fe® (ethinyl estradiol and norethindrone acetate) are approved by the Food and Drug Administration (FDA) for the treatment of acne.[1,8]

Potential Risks of Combined Oral Contraceptives

While there are many non-contraceptive benefits associated with the use of combined oral contraceptives, their use is not without risk or potential for adverse effects.

Sexually Transmitted Diseases

Since the use of combined oral contraceptives may decrease the use of selected barrier contraceptive methods that do protect against STDs (e.g., latex condoms), one of the most common risks associated with the use of oral contraceptives is the risk of acquiring an STD.[8]

Cardiovascular Events and Hypertension

A World Health Organization (WHO) collaborative study found that high-dose (50 mcg or more of ethinyl estradiol) oral contraceptive users with uncontrolled hypertension have an increased risk of experiencing a myocardial infarction or stroke.[8,15] In this study, women who had the lowest risk for experiencing a myocardial infarction or stroke were those who did not smoke, took low-dose oral contraceptives, and had their blood pressure checked prior to beginning oral contraceptives.[16–18] Hypertension secondary to oral contraceptive use is thought to occur in up to 1% to 3% of women, and this is believed to be attributed to the effect that estrogens and progestins can have on aldosterone activity.[1] Given this and the risk for cardiovascular events, women should have their blood pressure checked prior to initiating oral contraceptives, as well as periodically throughout oral contraceptive use. If significant elevations in blood pressure are noted, oral contraceptives should be discontinued. Estrogen-containing contraceptives are not recommended for smokers who are older than 35 years of age, for women with hypertension, or for women who experience migraine headaches (especially those with focal neurologic symptoms).[8,19]

Venous Thromboembolism

It is believed that the estrogen component of combined oral contraceptives stimulates the liver to produce higher levels of clotting factors. Lower-dose estrogen pills have been associated with a three- to four-fold increase in the risk of venous thromboembolism compared with women who do not use oral contraceptives.[8] Contraceptive users at greatest risk for the development of venous thromboembolism include those who are obese, those who smoke, those who have hypertension, and those with diabetes complicated by end-organ damage. It is important to note, however, that the increase in risk of venous thromboembolism in oral contraceptive users is lower than that of pregnant women.[8] Newer progestins, such as desogestrel, were reported initially to be associated with a higher risk of venous thromboembolism.[20,21] However, prospective studies validating this risk are lacking. In general, progestin-only contraceptives are preferred for women who are at increased risk of cardiovascular or thromboembolic complications, including women with a prior history of thromboembolic disease.[8]

Glucose Intolerance

Older oral contraceptive formulations containing higher doses of hormones were shown in some cases to induce hyperglycemia.[1] Because estrogens may inhibit the release of insulin from islet cells of the pancreas, low-dose estrogen formulations may be preferred in patients with diabetes. Progesterone competes with insulin for binding to its receptor. Although it is thought that progestins may increase insulin resistance, the newer progestins are thought to be less androgenic and have little effect on carbohydrate and lipid metabolism. In general, the use of combined oral contraceptives is relatively contraindicated in patients with diabetes.

Gallbladder Disease

In women with preexisting gallstones, low-dose estrogen-containing oral contraceptives may enhance the potential for the development of symptomatic gallbladder disease.[1] Although this risk has not been demonstrated with the use of higher-dose oral contraceptives, combined oral contraceptives containing estrogen should be used with caution in patients with a history of gallbladder disease.

Hepatic Tumors

Although the use of oral contraceptives is not associated with an increased risk for the development of hepatocellular

carcinoma, long-term use of high-dose oral contraceptives has been associated with the development of benign liver tumors.[1] Because even benign liver tumors may pose significant risk to the patient, oral contraceptives should be discontinued if liver enlargement is noted on physical examination.

Cervical Cancer

There appears to be an increased risk for the development of cervical cancer among long-term users of oral contraceptives.[1] Whether or not this increase in risk can be attributed directly to the use of oral contraceptives is uncertain, however. Data suggest that oral contraceptive users, on average, tend to have more sexual partners and use condoms less frequently, and as a result, this may increase their susceptibility to becoming infected with human papilloma virus (HPV), a known risk factor for cervical cancer.

Breast Cancer

While a history of breast cancer traditionally has been considered an absolute contraindication to the use of oral contraceptives, most recent studies evaluating the relationship between oral contraceptive use and the risk for breast cancer suggest little, if any, association between the two. A recent study illustrated that current or past use of oral contraceptives among women between the ages of 35 and 64 was not associated with an increased risk for the development of breast cancer.[22] In older studies that have suggested a link between oral contraceptive use and the diagnosis of breast cancer, the cancers diagnosed in those studies were found to be more localized.[23] Although the relationship between oral contraceptive use and the potential for breast cancer in older patients is becoming better understood, still the question of risk for breast cancer diagnosis in oral contraceptive users under age 35 is less clear.[1]

Patient Encounter, Part 1

RC, a 22-year-old woman, presents to your clinic requesting information on contraception. You begin to take a history and determine that the patient is currently sexually active and is not using any method of birth control. Her past medical history is significant only for acne, and she takes no medications except occasional ibuprofen for menstrual cramps. On further questioning, you discover that she has a positive family history for hypertension and coronary artery disease. As you begin to discuss various contraceptive options with the patient, it is clear that she has a preference for an oral contraceptive agent.

- What additional information do you need to know before recommending a contraceptive for this patient?
- Based on the information provided by the patient, what oral contraceptive agent would you recommend for the patient and why?
- What education would you provide to this patient regarding the risks associated with oral contraceptive use?

TABLE 45–3. ❶ Contraindications to the use of Combined Oral Contraceptives[1]

Absolute Contraindications
History of thromboembolic disease
History of stroke (or current cerebrovascular disease)
History of (or current) coronary artery disease
History of carcinoma of the breast (known or suspected)
History of any estrogen-dependent neoplasm
Undiagnosed abnormal uterine bleeding
Pregnancy (known or suspected)
Heavy smokers (greater than or equal to 15 cigarettes per day) who are greater than 35 years of age
History of hepatic tumors (benign or malignant)
Active liver disease
Relative Contraindications
Smoking (less than or equal to 15 cigarettes per day) at any age
History of migraine headache disorder
Hypertension
Fibroid tumors of the uterus
Breast-feeding
Diabetes

❶ Absolute and relative contraindications to the use of oral contraceptives are listed in Table 45–3.[1]

Adverse Effects of Oral Contraceptives and Their Management

As with all medications, there are potential adverse effects with combined oral contraceptives (COCs). ❷*Many side effects can be minimized or avoided by adjusting the estrogen and/or progestin content of the oral contraceptive.* It is also important to have proper patient selection for oral contraceptives because some women are at increased risk for potentially serious side effects.

Many women stop their oral contraceptives owing to side effects such as headaches, nausea, vomiting, or weight gain that occur during oral contraceptive use. Package labeling reports a higher incidence of these side effects, although it cannot be determined if they occurred because of the pill or just happened when the women were on the pill.[1] One double-blind trial compared women taking oral contraceptives with women taking placebo for 6 months. A similar percentage of patients in each group experienced headaches, nausea, vomiting, **mastalgia,** and weight gain, and there were no significant differences in the traditional "hormone-related" side effects.[24] Given that oral contraceptives often are discontinued owing to side effects, proper counseling before initiation of COCs is necessary.

Between 30% and 50% of women complain of breakthrough bleeding or spotting when initiated on oral contraceptives. These side effects tend to resolve by the third or fourth cycle.[1] Before changing formulations, other more serious causes of bleeding or spotting, such as pregnancy, infection, poor absorption of the oral contraceptive owing to drug interaction, or gastrointestinal problems should be ruled out. Once these causes

have been ruled out, the timing of the spotting must be determined in order to adjust the formulation appropriately.

Women who have spotting or bleeding before they finish their active pills need a higher progestin content to increase endometrial support. Either a monophasic formulation with a higher progestin or a triphasic formulation with an increasing dose of progestin would be appropriate. Women with continued bleeding after menses need more estrogen support. Either increasing the estrogen component or having a lower early progestin component (in triphasic pills) should be sufficient. If mid-cycle bleeding occurs, it is more difficult to ascertain the reasoning. It may be best to increase both the estrogen and progestin component for these women.[1]

Hormonal methods of contraception usually will decrease the amount of withdrawal bleeding quite significantly, and patients need to be made aware of this. Lower-dose estrogen formulations may increase the risk of breakthrough bleeding. Switching to a higher estrogen formulation or to a triphasic formulation will help to minimize breakthrough bleeding and will increase the amount of withdrawal bleeding if desired by the patient.

Acne, oily skin, and **hirsutism** are all side effects from progestins with increased androgenicity. Older progestins such as norgestrel and levonorgestrel have more androgenic effects, whereas agents containing norgestimate or desogestrel are less likely to have such side effects. If patients are complaining of such side effects, switching to a product with a lower risk of androgenic effects is appropriate.

Gastrointestinal complaints are seen often with oral contraceptives. Estrogen can induce nausea and vomiting via the central nervous system, whereas progesterone slows peristalsis, causing constipation and feelings of bloating and distention.[1] Most women will adjust to the symptoms, and the symptoms often will resolve within 1 to 3 months. If women are unable to tolerate the gastrointestinal side effects, then either a decrease in ethinyl estradiol to a low-dose 20 mcg formulation may minimize nausea or a decrease in progestin may minimize bloating and constipation. Progestin-only products may be considered if even low-dose ethinyl estradiol causes nausea. It also can be suggested to take the medication with food or at night to minimize gastrointestinal side effects.

Headaches are a common occurrence for women but must be evaluated because they are a major warning sign for stroke. If headaches begin or become worse after initiation of COCs, all differential diagnoses must be considered. A patient's blood pressure should be evaluated to rule out hypertension. If any neurologic symptoms or blurred vision occur with the headache, the oral contraceptive should be stopped immediately. Migraine headaches with aura showed a significant increase in the risk for ischemic stroke in one WHO study.[17] If the headaches are not serious but still are troublesome to the patient, the following changes are suggested: (1) discontinue the oral contraceptive, (2) lower the dose of estrogen, (3) lower the dose of progestin, and (4) eliminate the pill-free interval for two to three consecutive cycles (for women with headaches during the pill-free interval only).[1]

Although rare, some women may complain of a decrease in libido. This often is found to coincide with feelings of depression. Alterations to vaginal lubrication and free testosterone levels may occur with some COCs, and both can relate to decreased libido.[25] Low levels of estrogen can decrease vaginal lubrication as well and make intercourse painful. Use of the vaginal hormonal ring (NuvaRing®) may help with lubrication problems.[1]

Dyslipidemias can occur from hormone therapy. Estrogen is known to cause an increase in high-density lipoprotein cholesterol (HDL-C), triglycerides, and total cholesterol levels and to decrease low-density lipoprotein cholesterol (LDL-C). Androgenic progestins are more likely to decrease HDL-C and triglycerides and increase LDL-C. Depending on the ratio of estrogen to progestin content, the HDL-C, LDL-C, and triglyceride levels may fluctuate up or down. In women with no risk factors for dyslipidemias, it is not necessary to obtain a baseline lipid panel. However, if the lipid panel is monitored, and if dyslipidemia occurs, then it is recommended to go with a more estrogenic and less androgenic formulation. In women with a triglyceride level greater than 350 mg/dL (3.96 mmol/L) at baseline, estrogen-containing formulations should be used only with caution, and low doses of 20 to 25 mcg ethinyl estradiol or a progestin-only formulation might be preferred.[1]

Mastalgia can occur in up to 30% of women taking oral contraceptives and is most likely due to the estrogen component. The average woman has a 20% increase in breast volume in the luteal phase owing to venous and lymphatic engorgement. Estrogen also causes adipose cell hypertrophy in the breast.[1] Lower-dose pills (20 mcg) produce less mastalgia than those with 35 mcg of ethinyl estradiol.[26] If tenderness occurs prior to menses, switching to a contraceptive that offers extended cycle length (see "Unique Oral Contraceptives" below) can minimize problems as well.

Women often are concerned about using oral contraceptives for fear of gaining weight. It has been proven that low-dose oral contraceptives (less than or equal to 50 mcg ethinyl estradiol) do not increase the risk of weight gain in women compared with placebo.[24] Estrogen can cause hypertrophy of adipose cells, and therefore, women see an increase in measurement of their breasts, hips, and thighs.[1] Decreasing the estrogen content of the COCs will minimize this effect. Weight gain associated with premenstrual fluid retention may occur with the combination of estrogen and a higher androgenic progestin. Switching to a lower-dose estrogen and a progestin with less androgenic activity may be beneficial in this situation.[1]

Additional side effects have been noted in some women. Women with contact lenses may have visual changes and more disturbances with lenses. If normal saline eye drops do not help, referral to an ophthalmologist is recommended. **Melasma** and **chloasma** can occur secondary to estrogen stimulation of melanocyte production. Women with darker pigmentation are more susceptible. The melasma may not be

completely reversible on discontinuation. Progestin-only products may be preferable, and sunscreen use is highly recommended.[1]

As described earlier, many of the side effects of COCs may be minimized by adjusting the amount of hormones within the pill. However, while low- and ultra-low-dose COCs may cause fewer side effects, it is important to note that in the event that doses are missed, such COCs may be more likely to result in contraceptive failure.

Progestin-Only Pills

For women unable to take estrogen-containing oral contraceptives, there is an alternative—oral contraceptives containing only progestin. There are two active ingredients used in this form of contraception, norethindrone and norgestrel. These agents are slightly less effective than COCs but have other advantages over COCs. Progestin-only products have not shown the risk of thromboembolic events as products containing estrogen have. Therefore, women at increased risk for or with a history of thromboembolism may be good candidates for progestin-only oral contraceptives. Also, these products can minimize menses, and some women have **amenorrhea.** These products should be taken at the same time every day, and there is no pill-free or hormone-free period.

Unique Oral Contraceptives

Along with varying doses of ethinyl estradiol and different progestins, there are also formulation modifications that may benefit various patient situations. These formulations include products such as Seasonale®, Ortho Tri-Cyclen®, Estrostep Fe®, Yasmin®, Mircette®, and Ovcon 35®. Each of these products may show benefit in certain women owing to their unique characteristics.

Seasonale® (levonorgestrel/ethinyl estradiol) is a monophasic combination that has been marketed previously. This product is packaged as a 91-day treatment with 84 active tablets that are taken consecutively and then 7 placebo tablets. The extended cycle length of this product allows for one menstrual cycle per "season," or four per year. This formulation may be appealing to women with perimenstrual side effects or those at higher risk for anemia with menstrual bleeding. Seasonale® may improve anxiety, headache, fluid retention, dysmenorrhea, breast tenderness, bloating, and menstrual migraines. Although, in the SEA 301 clinical trial comparing the efficacy of Seasonale® with that of an equivalent-dosage 28-day cycle regimen, 7.7% versus 1.8% of women discontinued prematurely for unacceptable bleeding.[27] The risk of intermenstrual bleeding and/or spotting is higher for patients taking Seasonale® than for patients taking 28-day-regimen COCs.[27]

Ortho Tri-Cyclen® (norgestimate/ethinyl estradiol) and Estrostep Fe® (norethindrone acetate/ethinyl estradiol) both have an approved indication for treatment of moderate acne vulgaris in females 15 years of age or older desiring contraception who have failed topical antiacne medication. This can help clinicians to streamline medications by serving dual purposes.

Yasmin® (drospirenone/ethinyl estradiol) is the only oral contraceptive that uses the progestin drospirenone. This hormone not only has antiandrogenic properties but also showed antimineralcorticoid activity in preclinical trials. It has a unique application in young women who experience problems associated with producing too much androgen. Drospirenone is a spironolactone analog, and the 3 mg dose available in Yasmin® has antimineralcorticoid activity equal to 25 mg spironolactone. It can affect the sodium and water balance in the body, although it has not shown superior efficacy for side effects such as bloating compared with other oral contraceptives. Caution should be used in women with chronic conditions or other medications that may affect serum potassium.[28] It is advised to check a baseline potassium level in patients at risk for hyperkalemia, such as those taking angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers.

Mircette® (desogestrel/ethinyl estradiol) has a unique dosing schedule. After the usual 21 active tablets, there are only 2 tablets with inert ingredients. The last 5 tablets in the package have 10 mcg of ethinyl estradiol. In theory, this may minimize bleeding during the menstrual cycle, although the clinical significance of this dosing schedule has not been established.[29] It is important to counsel patients to complete the entire pack and not to discard the last 7 days of medication.

Finally, another unique formulation is a chewable tablet available to women who have difficulty swallowing medications. Ovcon® 35 (norethindrone/ethinyl estradiol) has all 28 tablets in chewable form and has added spearmint flavoring.[30] Along with each of these unique oral contraceptives, there are preparations currently being studied that contain 24 active pills and 4 placebo pills per pack, shortening the hormone-free period.[1]

Patient Encounter, Part 2: Adverse Effects

After 10 weeks of taking Desogen, RC returns to your clinic complaining of breakthrough bleeding during her third week of active pills. The patient also reports a 3-lb weight gain since starting Desogen, and because she has heard that birth control pills cause weight gain, she expresses concern and wants to discuss other birth control options.

- What are some potential causes of the breakthrough bleeding that the patient has been experiencing?
- What information can you provide to the patient regarding the potential association between weight gain and oral contraceptive use?
- What strategy would you recommend to eliminate or minimize the potential adverse effects experienced by the patient?

Drug Interactions with Oral Contraceptives

Ethinyl estradiol is metabolized in the liver via the cytochrome P-450 system. It is metabolized primarily via CYP450 3A4. When reviewing drug interactions of oral contraceptives, ❸ *it is important to keep in mind that antibiotic administration during contraceptive use may decrease the efficacy of many combined contraceptives.* Refer to Table 45–4 for a list of common drug interactions seen with oral contraceptives.[1, 31]

Non-oral Hormonal Contraceptives

❹ *As an alternative to oral contraceptive pills, which must be taken daily in order to reliably prevent pregnancy, non-oral contraceptives in the form of transdermal, transvaginal, and injectable preparations are available and offer patients safe and effective alternatives to the pills for prevention of pregnancy. These formulations also do not require daily administration, making them more convenient than the pill formulations.*

Ortho-Evra® is a transdermal patch that contains both an estrogen (20 mcg of ethinyl estradiol) and a progestin (150 mcg of norelgestromin). A new patch is applied to the abdomen, buttocks, upper torso, or upper (outer) arm once weekly for 3 weeks, followed by 7 patch-free days.[8] Although some women have noted irregular bleeding more commonly during the first two cycles of patch use, the patch has been demonstrated to provide similar menstrual cycle control and contraceptive efficacy to that of combined oral contraceptives.[32] It is important to note, however, that higher contraceptive failure rates are seen when the patch is used in women weighing more than 90 kg.[8,32] Further, Ortho McNeil (the manufacturer of Ortho-Evra®) recently updated the prescriber information for the product to indicate that women who take Ortho-Evra® are exposed to approximately 60% more estrogen than women who take COCs with 35 mcg estrogen.[33] The clinical significance of this is unknown. With the exception of a slightly higher reported incidence of breast discomfort and local skin irritation, the side effects seen with the patch are very similar to those observed with COCs.[8,34]

The NuvaRing® is a unique transvaginal delivery system that provides 15 mcg ethinyl estradiol and 120 mcg etonogestrel for the prevention of ovulation. The NuvaRing® is inserted into the vagina on or before day 5 of the menstrual cycle and is removed

TABLE 45–4. Commonly Seen Drug Interactions with COCs[1,31]

Medication	Mechanism	Clinical Effect
Anticonvulsants (carbamazepine, oxcarbazepine, phenytoin, phenobarbital, primidone, topiramate, and felbamate)	Increase metabolism of COCs via induction of various cytochrome P-450 enzymes	Decrease efficacy of OCs (EE doses less than 35 mcg are not recommended in women on these medications)
Benzodiazepines (alprazolam)	COCs may inhibit oxidative metabolism	Increase side effects of benzodiazepines
Corticosteroids (hydrocortisone, methylprednisolone, prednisone)	COCs may inhibit metabolism of corticosteroids	Increase side effects of corticosteroids
Griseofulvin	Increase metabolism of COCs	Decrease efficacy of COCs; backup method of contraception is recommended
Modafinil	Increase metabolism of COCs	Decrease efficacy of COCs; alternative method of contraception is recommended
Penicillins (amoxicillin, ampicillin); tetracyclines (doxycycline, minocycline, tetracycline)	Broad-spectrum antibiotics may alter intestinal flora, reducing enterohepatic circulation of estrogen metabolites; although the drop in estrogen levels has been shown to be only statistically significant, rather than clinically significant	Decrease efficacy of COCs, although the recommendation of a backup method of contraception is controversial
Protease inhibitors (amprenavir, nelfinavir, lopinavir, saquinavir, ritonavir)	Increase or decrease serum levels of estrogen and progestins	Decrease efficacy of COCs or increase side effects of COCs
Rifampin, rifabutin	Increase metabolism of COCs	Decrease efficacy of COCs; backup method of contraception is recommended
Selegiline	COCs decrease metabolism of selegiline	Increase side effects of selegiline; may adjust dose of selegiline if needed
St. John's wort	Increase metabolism of COCs via induction of various cytochrome P-450 enzymes	Decrease efficacy of COCs; avoid use with COCs
Theophylline	COCs decrease theophylline clearance by 34% and increase the $t_{1/2}$ by 33%	Increase side effects of theophylline

from the vagina after 3 weeks.[8] Seven days after the ring is removed, a new ring is inserted. In clinical trials, the NuvaRing® demonstrated comparable efficacy and cycle control with that of COCs.[8] Side effects seen with NuvaRing® are also similar to those observed in women taking COCs.[8,35] NuvaRing® should not be removed during intercourse. If the ring falls out or is removed for more than 3 hours, efficacy could be compromised, and a backup method of contraception is recommended until a new ring has been in place for 7 days.

Depo-Provera® is a progestin-only injectable contraceptive that contains depot medroxyprogesterone acetate. Depo-Provera® is administered intramuscularly as a 150-mg injection once every 3 months. An advantage of Depo-Provera® is that it provides an estrogen-free method of contraception either for women in whom estrogens are contraindicated or for women who cannot tolerate estrogen-containing preparations. Depo-Provera® is extremely effective in preventing pregnancy. However, the incidence of menstrual irregularities (including amenorrhea) and weight gain appears to be much greater than that seen with COCs. The use of Depo-Provera® also has been demonstrated to result in significant loss of bone mineral density (BMD).[36] Although it is not known whether the use of Depo-Provera® will increase the risk for osteoporotic fracture, a black-box warning within the product labeling cautions against the risk of potentially irreversible BMD loss associated with long-term use (e.g., greater than 2 years) of the injectable product. While the extended duration of activity of this product may offer women the advantage of less frequent administration, it is important to note that on discontinuation of Depo-Provera®, the return of fertility can be delayed by approximately 10 to 12 months (range 4–31 months).[8]

Depo-SubQ Provera 104® is also an injectable contraceptive product that contains only a progestin (depot medroxyprogesterone acetate). This product, which was approved by the FDA in 2005, is different from Depo-Provera® in that it is given subcutaneously rather than intramuscularly, and it provides only 104 mg medroxyprogesterone acetate (approximately 30% less hormone) every 3 months for the prevention of pregnancy.[37] Clinical trials have demonstrated that the subcutaneous formulation of depot medroxyprogesterone acetate is as effective as the intramuscular formulation in the prevention of pregnancy.[38] Although this product carries the same warning in its package labeling regarding possible effects on BMD as Depo-Provera®,[37] it is not yet known if the lower progestin dose will lessen the potential for long-term side effects.

Implantable Devices

Although IUDs are the most common form of reversible contraception in the world, only 1% of women in the United States use IUDs.[39] There are currently two IUD products available, one containing a progestin and one non-hormonal device. Mirena® is a levonorgestrel-releasing intrauterine system, and Paragard® T 380A is a copper intrauterine device. Mirena® is inserted for up to 5 years, and Paragard® T 380A is inserted for up to 10 years. Surveys have shown that IUDs have the highest satisfaction rate among patients using reversible contraceptives.

Although the mechanism of action for IUDs is not completely understood, various theories have been considered. The original theory is that the presence of a foreign body in the uterus causes an inflammatory response that interferes with implantation. It is believed that copper-containing IUDs may have a direct toxic effect on spermatozoa. Progestin-containing IUDs can have direct effects on the uterus, such as thickening of cervical mucus and alterations to the endometrial lining. Mirena® can inhibit ovulation because it contains levonorgestrel, but Paragard® T 380A does not prevent ovulation.

It is important to evaluate a patient to determine if she is an appropriate candidate for an IUD. IUDs are recommended for women with at least one child, in a monogamous relationship, who have no history of pelvic inflammatory disease (PID) and no history or risk of **ectopic pregnancy.** There are also multiple contraindications to IUD use. Evaluation of the patient is essential because IUDs cannot be used in the following situations: (1) pregnancy or suspected pregnancy, (2) anatomically abnormal or distorted uterine cavity, (3) acute PID or history of PID, unless there has been a subsequent intrauterine pregnancy, (4) postpartum **endometritis** or infected abortion in the past 3 months, (5) known or suspected uterine or cervical neoplasia or unresolved abnormal Pap smear, (6) genital bleeding of unknown etiology, (7) untreated acute **cervicitis** or vaginitis, (8) acute liver disease or liver tumor, (9) woman or her partner has multiple sexual partners, (10) previously inserted IUD still in place, (11) conditions associated with increased susceptibility to infections (e.g., leukemia or acquired immune deficiency syndrome), (12) genital actinomycosis, (13) hypersensitivity to any component of the IUD, (14) known or suspected carcinoma of the breast, (15) history of ectopic pregnancy or a condition that would predispose to ectopic pregnancy, and (16) **Wilson's disease.**[40,41]

There are potential side effects of IUD use. The most common adverse effects are cramping, abnormal uterine bleeding, and expulsion of the device. Other side effects seen are ectopic pregnancy, sepsis, PID, embedment of the device, uterine or cervical perforation, and ovarian cysts.[40,41]

Nonpharmacologic Contraceptive Methods

Barrier Contraceptives

As an alternative to hormonal contraceptives, several barrier contraceptive options are available for the prevention of pregnancy. While barrier contraceptives are associated with far fewer adverse effects compared with hormonal contraceptives, their efficacy is highly user-dependent. Overall, compared with both hormonal contraceptives and IUDs, barrier contraceptives are

associated with much higher accidental pregnancy rates [8] (Table 45–1).

Diaphragms and Cervical Caps

Diaphragms and cervical caps are dome-shaped rubber caps that are placed over the cervix to provide barrier protection during intercourse. Both diaphragms and cervical caps require fitting by a health care professional, and they must be refitted for the patient in the event of weight gain or weight loss. Diaphragms or cervical caps typically can be placed over the cervix as much as 6 hours prior to intercourse. They must be left in place for at least 6 hours after intercourse before they can be removed. Diaphragms should not be left in place longer than 24 hours, and smaller cervical caps should not be left in place longer than 48 hours owing to the risk of toxic shock syndrome (TSS). Diaphragms and cervical caps are used along with spermicides to prevent pregnancy. When sexual intercourse is repeated with the diaphragm, reapplication of the spermicide is necessary. However, when sexual intercourse is repeated with a cervical cap, reapplication of the spermicide typically is not necessary.[8] Whether or not diaphragms or cervical caps provide adequate protection against STDs without concurrent use of a spermicide remains unclear.[42]

Spermicides

Nonoxynol-9, a surfactant that destroys the cell membranes of sperm, is the most commonly used spermicide in the United States.[8,43] Nonoxynol-9 is available in a variety of forms, including a cream, foam, film, gel, suppository, and tablet. Spermicides may be used alone, with a barrier method, or adjunctively with other forms of contraceptives to provide additional protection against unwanted pregnancy.[43] To be used most effectively, spermicides must be placed in the vagina not more than 1 hour prior to sexual intercourse, and they must come in contact with the cervix.[8] While the efficacy of spermicides depends largely on how consistently and correctly they are used, their efficacy is enhanced when they are used in combination with a barrier contraceptive device.[43] Clinical trials assessing the ability of spermicides to protect against STDs have failed to produce positive results.[43] Further, there exists some evidence to suggest that frequent use of spermicides actually may increase risk for transmission of human immunodeficiency virus (HIV) secondary to vaginal mucosal tissue breakdown, which may allow a portal of entry for the virus.[8]

Condoms

Condoms, which are available for both male and female use, act as physical barriers to prevent pregnancy.[44] Condoms are easy to use, available without a prescription, and inexpensive. Most condoms are made of latex. When used correctly, condoms can be very effective in prevention of unwanted pregnancy. Condoms should be stored in a cool, dry place, away from exposure to direct sunlight. When stored improperly or when used with oil-based lubricants, however, latex condoms can break during intercourse, increasing the risk of pregnancy.[8] For latex-sensitive individuals, condoms made from lamb intestine ("natural membrane" condoms) and synthetic polyurethane condoms are available. Unlike latex condoms, condoms made from lamb intestine contain small pores that may permit the passage of viruses and therefore do not provide adequate protection against STDs.[44] ❺ *Both latex and synthetic condoms do provide protection against many STDs. Data from one meta-analysis suggested that HIV transmission can be reduced by as much as 90% when condoms are consistently used.*[45] *This is in contrast to hormonal contraceptives (oral, transdermal, or vaginal), IUDs, and most other barrier contraceptives, which do not protect against STDs.* Relative to male condoms, female condoms may offer even better protection against STDs because they provide more extensive barrier coverage of external genitalia, including the labia and the base of the penis.[46] It is important to note that the male and female condoms are not recommended to be used together because they may adhere to one another, causing displacement of one or both condoms.[46]

Sponge

The Today® sponge is a small, pillow-shaped polyurethane sponge containing nonoxynol-9.[46] It is an over-the-counter barrier contraceptive that has been shown to be generally less effective at preventing pregnancy than diaphragms.[47] The sponge is moistened with water and then is inserted and placed over the cervix for up to 6 hours prior to sexual intercourse. The sponge then is left in place for at least 6 hours following intercourse.[46] Although the sponge maintains efficacy for 24 hours (even if intercourse is repeated), as with diaphragms, the sponge should be removed after 24 hours owing to the risk of TSS.[8]

Fertility Awareness and Periodic Abstinence

Periodic abstinence and fertility awareness–based methods represent another nonpharmacologic means of pregnancy prevention. Although failure rates of such methods can be high, some couples still prefer these types of approaches. Fertility awareness–based methods depend on the ability of the couple to identify the woman's "fertile window," or the period of time in which pregnancy is most likely to occur as a result of sexual intercourse.[48] During the fertile window, the couple practices abstinence, or avoidance of intercourse, in order to prevent pregnancy. In some cases, rather than practicing abstinence during the fertile period, some couples may prefer to employ barrier methods or spermicides as a means of preventing pregnancy rather than to avoid intercourse altogether.[8] In order to identify the fertile window, a number of different fertility awareness–based methods may be tried. The calendar (rhythm) method involves counting the days in the menstrual cycle and then using a mathematical

equation to determine the fertile window.[48] The temperature method involves monitoring changes in the woman's basal body temperature.[48] The cervical mucus (or ovulation) method involves observing changes in the characteristics of cervical secretions throughout the cycle.[48] The symptothermal method, which is considered to be the most difficult to learn but potentially the most effective, is a combination of both the temperature method and the cervical mucus method.[8] In general, fertility awareness–based methods are not recommended for women who have irregular menstrual cycles or who have difficulty interpreting their fertility signs correctly.[48]

Emergency Contraception

Emergency contraception (EC) is used to prevent pregnancy after known or suspected unprotected sexual intercourse. There are two hormonal forms of FDA-approved emergency contraception: combination products containing an estrogen and a progestin and a progestin-only formulation[49] (Table 45–5). PREVEN® is a combination of ethinyl estradiol 0.05 mg and levonorgestrel 0.25 mg, and patients should take two tablets within 72 hours of intercourse and then two tablets 12 hours later. This method of using two hormones is also known as the *Yuzpe regimen*, after Alfred Yuzpe, who discovered it in 1974. Other marketed products containing ethinyl estradiol and levonorgestrel or norgestrel can be used with the same efficacy. The second and more preferred regimen uses only levonorgestrel and is marketed as Plan B®. With this formulation, patients take one 0.75-mg tablet within 72 hours of intercourse and then a second dose 12 hours later. In August of 2006, the FDA approved Plan B® for non-prescription sale to patients 18 years of age and older. It is important to note that EC is more effective the earlier it is used after unprotected intercourse. This progestin-only formulation has shown decreased risk of side effects such as nausea and vomiting, which decreases the risk of emergency contraception failure. The only other approved form of emergency contraception is the placement of a copper IUD within 5 days of intercourse, although this is most commonly used in women who are appropriate candidates for long-term use of such a device.

TABLE 45–5. Emergency Contraception Methods Available in the United States[49]

Levonorgestrel Only	Dose × 2 (12 Hours Apart)	Color
Plan B®[a]	1 + 1 pill	White pills
Ovrette®	20 + 20 pills	Yellow pills
EE + Levonorgestrel or Norgestrel	**Dose × 2 (12 Hours Apart)**	**Color**
PREVEN®[a]	2 + 2 pills	Blue pills
Ogestrel®[a]		White pills
Ovral®[a]		White pills
Alesse®	5 + 5 pills	Pink pills
Levlite™		Pink pills
Aviane™		Orange pills
Lessina™		Pink pills
Cryselle™[a]	4 + 4 pills	White pills
Low-Ogestrel®[a]		White pills
Lo/Ovral®[a]		White pills
Levora®		White pills
Levlen®		Light orange pills
Nordette®		Light orange pills
Triphasil®		Yellow pills
Tri-Levlen®		Yellow pills
Trivora®		Pink pills

[a]FDA approved agent for EC.

Patient Encounter, Part 3: Missed Doses

RC calls your clinic in a panic today because she forgot to start a new package of oral contraceptives. Three days have elapsed since she took her last placebo pill, and she reports having had unprotected sexual intercourse last night. The patient is very concerned about her risk of pregnancy, and she would like to discuss her options for prevention of pregnancy. ❻ *When a contraceptive dose is missed, the risk of accidental pregnancy may be increased. Depending on how many doses were missed, the contraceptive formulation being used, and the phase of the cycle during which doses were missed, counseling regarding the use of additional methods of contraception may be warranted.*

- Given this patient's reported imperfect use of her oral contraceptive, what information can you provide to the patient regarding her risk of pregnancy?
- Compare and contrast the available emergency contraceptive (EC) options for this patient, and provide a recommendation for this patient.
- Provide appropriate patient education regarding the adverse effects associated with the option you have recommended.

OUTCOME EVALUATION/MONITORING

Side effects of contraceptives tend to occur in the first few months of therapy. Thus, schedule a follow-up visit 3 to 6 months after initiating a new contraceptive. Yearly checkups usually are sufficient for patients who are doing well on a particular product.[1] At each follow-up visit, assess blood pressure, headache frequency, and menstrual bleeding patterns, as well as compliance with the prescribed regimen.

Patient Care and Monitoring

1. Obtain a thorough medical and family history and carefully evaluate each patient's risk factors prior to prescribing contraceptives.
2. Educate all women taking hormonal contraceptives to prevent pregnancy regarding self-monitoring for early warning signs that may precede adverse events. Health care professionals can easily recall the major warning signs by using the two simple pneumonics highlighted below:
   ACHES—for women taking hormonal contraceptives
   A = Abdominal pain. This may be an early warning sign of the presence of an abdominal thromboembolism, liver adenoma, or gallbladder disease.
   C = Chest pain. The presence of chest pain may indicate pulmonary embolism, angina, or myocardial infarction.
   H = Headaches. Headaches (particularly those associated with focal neurologic symptoms, such as blurred vision, speech impairment, and/or weakness) may represent strokelike symptoms. Headaches also may indicate poorly controlled blood pressure.
   E = Eye problems. Blurred vision and/or ocular pain may be early warning signs for stroke and/or blood clots. In addition, visual changes may occur in patients wearing contact lenses (secondary to changes in corneal shape).
   S = Severe leg pain. Patients taking hormonal contraceptives who complain of severe leg pain should be evaluated for the presence of venous thromboembolism.
   PAINS—for women with an IUD
   P = Period late
   A = Abdominal pain, pain with intercourse
   I = Infection, abnormal or odorous vaginal discharge
   N = Not feeling well, fever, chills
   S = String (missing, shorter, longer)
3. In addition to the preceding, monitor patients taking hormonal contraceptives for missed periods, signs of pregnancy, appearance of jaundice, and/or severe mood changes. Instruct patients to consult a health care professional on noticing or experiencing any of these warning signs.[1]
4. Stress the importance of adherence to the patient's chosen method of contraception in order to reliably prevent pregnancy. Educate the patient on what to do in the event of missed doses with hormonal contraception.

ABBREVIATIONS

BMD:	bone mineral density
COC:	combined oral contraceptive
EC:	emergency contraception
EE:	ethinyl estradiol
FDA:	Food and Drug Administration
FSH:	follicle-stimulating hormone
GnRH:	gonadotropin-releasing hormone
HDL:	high-density lipoprotein
HIV:	human immunodeficiency virus
HPV:	human papilloma virus
IUD:	intrauterine device
LDL:	low-density lipoprotein
LH:	luteinizing hormone

46 Menstruation-related Disorders

Elena M. Umland, Lara C. Weinstein, and Abby Morris

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Describe the underlying etiology and pathophysiology of amenorrhea, menorrhagia, anovulatory bleeding, and dysmenorrhea and how they relate to selection of effective treatment modalities.
2. Differentiate between premenstrual syndrome and premenstrual dysphoric disorder with respect to pathophysiology, clinical presentation, and treatment.
3. Describe the clinical presentation of amenorrhea, menorrhagia, anovulatory bleeding, dysmenorrhea, and premenstrual dysphoric disorder.
4. Recommend appropriate lifestyle and dietary modifications and pharmacotherapeutic interventions for patients with amenorrhea, menorrhagia, anovulatory bleeding, dysmenorrhea, premenstrual symptoms, and premenstrual dysphoric disorder.
5. Identify the desired therapeutic outcomes for patients with amenorrhea, menorrhagia, anovulatory bleeding, dysmenorrhea, premenstrual symptoms, and premenstrual dysphoric disorder.
6. Design a monitoring plan to assess the effectiveness and adverse effects of pharmacotherapy for amenorrhea, menorrhagia, anovulatory bleeding, premenstrual symptoms, and premenstrual dysphoric disorder.

Key Concepts

❶ Unrecognized pregnancy remains the most common cause of amenorrhea, and a urine pregnancy test should be one of the first steps in the evaluation of this disorder.

❷ Causes of menorrhagia can be divided into systemic disorders and specific uterine abnormalities.

❸ Intrauterine pregnancy, ectopic pregnancy, and miscarriage must be at the top of the differential diagnosis list for any woman presenting with heavy menses.

❹ Anovulatory bleeding, also referred to as dysfunctional uterine bleeding, is secondary to the effects of unopposed estrogen and does not include bleeding owing to an anatomic lesion of the uterus.

❺ For most conditions associated with primary and secondary amenorrhea, estrogen (along with a progestin to minimize the risk of endometrial hyperplasia) is provided.

❻ The reduction in menorrhagia-related blood loss with the use of non-steroidal anti-inflammatory drugs and oral contraceptives is directly proportional to the amount of pretreatment blood loss.

❼ The use of metformin and thiazolidinediones for anovulatory bleeding associated with polycystic ovary syndrome is beneficial for anovulatory bleeding and fertility and also improves glucose tolerance and decreases overall cardiovascular risk.

❽ Intrauterine devices (IUDs) are considered therapeutic options in a variety of menstrual-related disorders. Recent guidelines from the American College of Obstetricians and Gynecologists indicate that nulliparous and multiparous women at low risk of sexually transmitted diseases are good candidates for IUD use.

❾ First-line pharmacologic treatment options for premenstrual dysphoric disorder include the selective serotonin reuptake inhibitors (SSRIs).

Problems related to the menstrual cycle are exceedingly common in women of reproductive age. The issues considered in this chapter are the most frequently encountered menstrual-related difficulties and include amenorrhea, menorrhagia,

dysfunctional uterine bleeding, dysmenorrhea, and premenstrual syndrome/premenstrual dysphoric disorder. The need for effective treatments for these disorders stems from their impact on any or all of the following: a reduced quality of life, negative effects on reproductive health, and the potential for long-term detrimental health effects, such as osteoporosis in the case of amenorrhea and cardiovascular disease in the case of polycystic ovary disease.

AMENORRHEA

Amenorrhea traditionally is described as either primary or secondary in nature. **Primary amenorrhea** is the absence of menses by age 16 in the presence of normal secondary sexual development or the absence of menses by age 14 in the absence of normal secondary sexual development. **Secondary amenorrhea** is the absence of menses for three cycles or 6 months in a previously menstruating woman. However, in clinical practice, there is a significant amount of overlap. The initial evaluation of amenorrhea is often the same regardless of age of onset, except in unusual clinical situations.[1]

Epidemiology and Etiology

❶ *Unrecognized pregnancy remains the most common cause of amenorrhea, and a urine pregnancy test should be one of the first steps in the evaluation of this disorder.* To help organize an approach to diagnosis and treatment, it is helpful to consider the organs involved in the menstrual cycle, which include the uterus, ovaries, anterior pituitary, and hypothalamus.

After pregnancy, the five most common causes of secondary amenorrhea, in descending order of prevalence, include:[2]

- Hypothalamic suppression (33%)
- Chronic anovulation (28%)
- Hyperprolactinemia (14%)
- Ovarian failure (12%)
- Uterine disorders (7%)

Pathophysiology

The physiology of the normal menstrual cycle depends on a coordinated system of hormonal interactions involving the hypothalamus, anterior pituitary gland, ovary, and endometrium. Figures 46–1 and 46–2 summarize these points. Pulsatile gonadotropin-releasing hormone (GnRH) secretion from the hypothalamus stimulates the anterior pituitary to secrete follicle-stimulating hormone (FSH) and luteinizing hormone (LH). In the specialized cells of the ovarian follicle, FSH and LH stimulate the release of estradiol. Estradiol stimulates endometrial growth during the follicular phase of the cycle. Following the LH surge and ovulation, the follicle is transformed into the corpus luteum. Progesterone

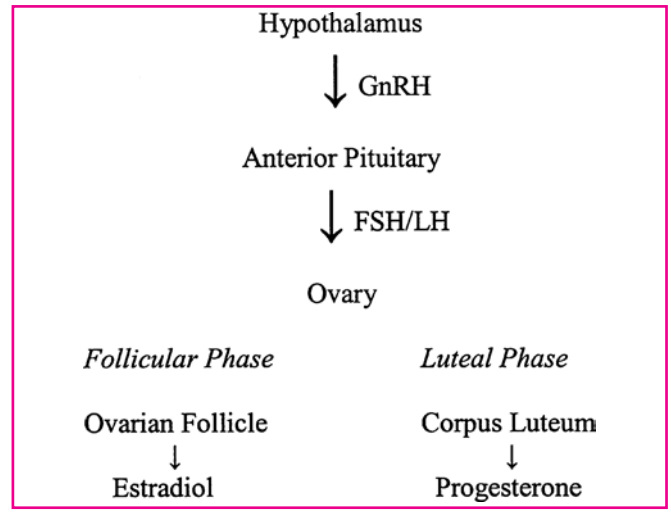

FIGURE 46–1. Summary of the normal menstrual cycle.

that is secreted by the corpus luteum during the luteal phase of the cycle causes endometrial "organization." If conception does not occur, the drop in estrogen and progesterone stimulates the shedding of the endometrium.[4]

Table 46–1 illustrates the pathophysiology of amenorrhea relative to the organ system(s) involved, as well as the specific condition that results in amenorrhea. Amenorrhea is also a normal side effect that may result from the use of low-dose oral contraceptives (OCs), extended-cycle OC pill use, or depot medroxyprogesterone acetate use.[5] Many women may experience delayed return of menses after discontinuation of OCs. Postpill amenorrhea usually is a self-limited condition. Further evaluation for other unrecognized conditions, such as polycystic ovary syndrome (PCOS), should be considered if spontaneous resolution of the amenorrhea does not occur within 3 to 6 months following discontinuation of the OCs.[6,7]

MENORRHAGIA

The traditional definition of **menorrhagia** is a menstrual blood loss of greater than 80 mL per cycle. This definition has been questioned for several reasons, including difficulty with quantifying menstrual blood loss in clinical practice. Many women with "heavy menses" but blood loss of less than 80 mL will merit consideration for treatment because of problems with containment of flow, unpredictable heavy flow days, and other associated symptoms.[8,9]

Epidemiology and Etiology

Rates of menorrhagia in healthy women range from 9% to 14%.[10] ❷ *Causes of menorrhagia can be divided into systemic*

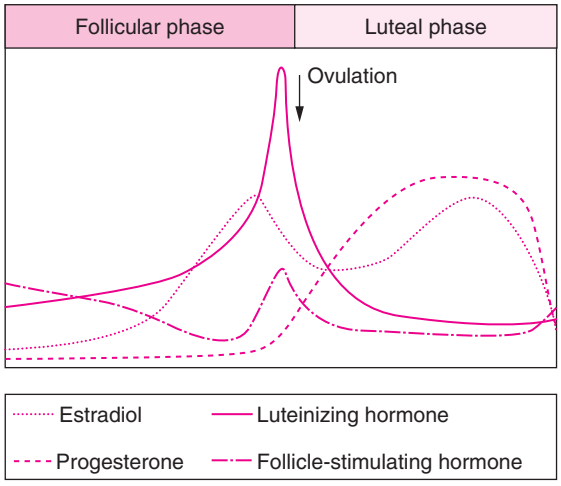

FIGURE 46–2. Hormonal fluctuations with the normal menstrual cycle. (Reprinted, with permission, from ref. 3.)

Clinical Presentation and Diagnosis of Amenorrhea

General
Patients may be concerned about cessation of menses and fertility implications but generally are not in acute distress.

Symptoms
- Cessation of menses
- Possible complaints of infertility, vaginal dryness, decreased libido

Signs
- Cessation of menses for longer than 6 months in women with established menstruation, or absence of menses by age 16 in the presence of normal secondary sexual development, or absence of menses by age 14 in the absence of normal secondary sexual development
- Recent significant weight loss or weight gain
- Presence of acne, hirsutism, hair loss, or **acanthosis nigricans** may suggest androgen excess.

Laboratory Tests
- Pregnancy test
- TSH
- Prolactin
- If suspect PCOS, consider free or total testosterone, 17-hydroxyprogesterone, fasting glucose, and fasting lipid panel.
- If suspect premature ovarian failure, consider FSH and LH.

Other Diagnostic Tests
- Progesterone challenge
- Pelvic ultrasound to evaluate for polycystic ovaries

Clinical Presentation and Diagnosis of Menorrhagia

General
Patient may or may not be in acute distress.

Symptoms
Complaints of heavy/prolonged menstrual flow and fatigue and light-headedness in the case of severe blood loss. These symptoms may or may not occur with dysmenorrhea.

Signs
Orthostasis, tachycardia, and pallor may be noted, especially in cases of significant acute blood loss.

Laboratory Tests
Complete blood count (CBC) and ferritin levels; hemoglobin and hematocrit results may be low.
If the history dictates, testing may be done to identify coagulation disorder(s) as a cause.

Other Diagnostic Tests
- Pelvic ultrasound
- Pelvic magnetic resonance imaging (MRI)
- Pap smear
- Endometrial biopsy
- Hysteroscopy
- Sonohysterogram

disorders and specific uterine abnormalities. ❸ *Pregnancy, including intrauterine pregnancy, ectopic pregnancy, and miscarriage, must be at the top of the differential diagnosis list for any woman presenting with heavy menses.* In several studies of adolescents with acute menorrhagia, underlying bleeding disorders accounted for 3% to 13% of emergency room visits. von Willebrand's disease has an incidence of 1% in the general population and may present initially as heavy menses in an adolescent.[5] Hypothyroidism also may be associated with heavy menses. Specific uterine causes of menorrhagia are more common in older childbearing women, and they include fibroids, adenomyosis, endometrial polyps, and gynecologic malignancies.

Pathophysiology

Table 46–1 illustrates the pathophysiology of menorrhagia relative to the organ system(s) involved, as well as the specific conditions that result in menorrhagia.

TABLE 46–1. Pathophysiology of Selected Menstrual Bleeding Disorders[1,10,11,13,15]

Organ System	Condition	Pathophysiology/Laboratory Findings
AMENORRHEA[1]		
Uterus	Asherman's syndrome	Postcurettage/postsurgical uterine adhesions
	Congenital uterine abnormalities	Abnormal uterine development
Ovaries	Turner's syndrome	Lack of ovarian follicles
	Gonadal dysgenesis	Other genetic anomalies
	Premature ovarian failure	Early loss of follicles
	Chemotherapy/radiation	Gonadal toxins
Anterior pituitary	Pituitary prolactin-secreting adenoma	↑ Prolactin suppresses HPO axis
	Hypothyroidism	TRH causing ↑ prolactin, other abnormalities
	Medications—antipsychotics, verapamil	↑ Prolactin suppresses HPO axis
Hypothalamus	"Functional" hypothalamic amenorrhea	↓ Pulsatile GnRH secretion in the absence of other abnormalities
	Disordered eating	↓ Pulsatile GnRH secretion, ↓ FSH and LH secondary to weight loss
	Exercise	↓ Pulsatile GnRH secretion, ↓ FSH and LH secondary to low body fat
	Anovulation/PCOS	Asynchronous gonadotropin and estrogen production, abnormal endometrial growth
ANOVULATORY BLEEDING		
Physiologic causes	Adolescence	Immaturity of the hypothalamic-pituitary-ovarian axis: no LH surge
	Perimenopause	Declining ovarian function
Pathologic causes	Hyperandrogenic anovulation—PCOS	Hyperandrogenism: high testosterone, high LH, hyperinsulinemia, and insulin resistance
	Hypothalamic dysfunction (physical or emotional stress, exercise, weight loss)	Suppression of pulsatile GnRH secretion and estrogen deficiency: low LH, low FSH
	Hyperprolactinemia (pituitary gland tumor, psychiatric medications)	High prolactin
	Hypothyroidism	High TSH
	Premature ovarian failure	High FSH
MENORRHAGIA		
Hematologic	von Willebrand disease	Factor VII defect causing impaired platelet adhesion and increased bleeding time
	Idiopathic thrombocytopenic purpura	Decrease in circulating platelets—can be acute or chronic
Hepatic	Cirrhosis	Decreased estrogen metabolism, underlying coagulopathy
Endocrine	Hypothyroidism	Alterations in HPO axis
Uterine	Fibroids	Alteration of endometrium, changes in uterine contractility
	Adenomyosis	Alteration of endometrium, changes in uterine contractility
	Endometrial polyps	Alteration of endometrium
	Gynecologic cancers	Various dysplastic alterations of endometrium, uterus, cervix

↑, high; ↓, low; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; HPO, hypothalamic-pituitary-ovarian axis; LH, luteinizing hormone; PCOS, polycystic ovary disease; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

ANOVULATORY BLEEDING

Anovulatory bleeding is irregular menstrual blood flow from the uterine endometrium that ranges from light spotting to heavy blood flow.[11] ❹ *Anovulatory bleeding, also referred to as dysfunctional uterine bleeding, is secondary to the effects of unopposed estrogen and does not include bleeding owing to an anatomic lesion of the uterus.* Anovulatory bleeding includes polycystic ovary syndrome (PCOS), which typically presents with irregular menstrual bleeding, **hirsutism,** obesity, or infertility.

Epidemiology

Anovulatory bleeding is the most common form of non-cyclic uterine bleeding.[11] Patients often seek medical care to regulate their menstrual cycle or improve fertility. All women of reproductive age should have a pregnancy test when presenting with irregular menstrual bleeding. Anovulation may be secondary to physiologic or pathologic causes. It is common at menarche and in the perimenopausal period. During adolescence, ovulatory menstrual cycles may not be regular for a year or more after menarche.[11] In the year following menarche, there may be an immature feedback mechanism in the hypothalamic-pituitary-ovarian (HPO) axis whereby the LH surge needed for ovulation does not occur. During perimenopause, anovulatory cycles may occur owing to a declining quality and quantity of ovarian follicles. As ovarian function declines, estrogen secretion continues, and progesterone secretion decreases. Chronic anovulatory cycles and unopposed estrogen secretion lead to endometrial proliferation and increased risk of polyps, endometrial hyperplasia, and carcinoma.

Patient Encounter, Part 1

TP, a 22 year-old woman, presents to your office for a routine gynecologic examination. She entered menarche at the age of 12. Her last menstrual period was 3 months ago. Her periods are often irregular and occur about every 2 to 3 months. She has had all normal Pap smears in the past and no history of sexually transmitted infections. She is currently in a monogamous relationship with a male partner. She has had a total of four sexual partners. She is not taking oral contraceptives and does not routinely use condoms. She has never been pregnant in the past, but she plans on starting a family in the near future. As you examine the patient, you note facial and chest acne, increased facial and abdominal hair, and obesity.

- What anovulatory disorder is most likely present, and what signs/symptoms support this conclusion?
- What diagnostic test should be done first in the office?

Anovulation also may occur at any time during the reproductive years due to a pathologic cause. The most common causes of non-physiologic ovulatory dysfunction and their prevalence rates[11] are:

- PCOS (70%)
- Hypothalamic amenorrhea (10%)
- Hyperprolactinemia (10%)
- Premature ovarian failure (10%)

PCOS, while responsible for 70% of the cases of ovulatory dysfunction, occurs in approximately 4% of women.[12]

Etiology

Anovulation may result from a problem at any level of the HPO axis. In addition to various physiologic life stages such as adolescence, perimenopause, pregnancy, and lactation, other causes of anovulation include:[11]

- Hyperandrogenic anovulation (PCOS, congenital adrenal hyperplasia, androgen-producing tumors)
- Hypothalamic dysfunction (anorexia nervosa, physical or emotional stress)
- Hyperprolactinemia
- Hypothyroidism
- Primary pituitary disease
- Premature ovarian failure

Pathophysiology

A normal ovulatory cycle consists of follicular development, ovulation, **corpus luteum** development, and **luteolysis.** During the cycle, the endometrium undergoes proliferation, secretory change, and desquamation. This cycle is influenced first by the effects of estrogen alone, then by estrogen and progesterone, and culminates with estrogen and progesterone withdrawal. Progesterone stops the growth of the endometrium and stimulates its differentiation. In patients with anovulation, a corpus luteum is not formed, and the ovary does not secrete progesterone. Without progesterone, there is no desquamation or differentiation of the endometrium. Chronic unopposed estrogen causes continuous endometrial proliferation, and the endometrium becomes vascular and fragile, resulting in non-cyclic menstrual bleeding. In addition, the endometrium may become hyperplastic and progress to a precancerous state, placing the patient at increased risk of endometrial cancer.[13] See Table 46–1 for the pathophysiology of anovulatory bleeding relative to the specific conditions that contribute to it.

The most common pathologic cause of anovulation is PCOS. It is a syndrome of ovarian dysfunction diagnosed by the presence of two of the following three characteristics: **oligoanovulation** or anovulation, clinical or laboratory evidence of hyperandrogenism, and polycystic ovary morphology on ultrasound.[14] No gene or environmental substance has been found to cause PCOS.[15] However, the observance of familial clustering of cases suggests that genetics plays a role.[16] It is thought that insulin resistance, hyperandrogenism, and changes in gonadotropins also influence the development of PCOS.[12] The underlying cause for increased androgens is unknown.[16]

PCOS is associated with a three to seven times increased risk of developing type 2 diabetes.[14] Patients diagnosed with PCOS should be screened for impaired glucose tolerance, diabetes, hypertension, and dyslipidemia.[12] If any of these conditions are present, there is an increased risk of cardiovascular events.

Clinical Presentation and Diagnosis of Anovulatory Bleeding

General
May or may not be in acute distress

Symptoms
Irregular, heavy, or prolonged vaginal bleeding, perimenopausal symptoms (hot flashes, etc.)

Signs
Acne, hirsutism, obesity

Laboratory Tests
- If suspect PCOS, consider free or total testosterone, fasting glucose, fasting lipid panel.
- If suspect perimenopause, FSH.

Other Diagnostic Tests
Pelvic ultrasound to evaluate for polycystic ovaries

Patient Encounter, Part 2: The Medical History, Physical Examination, and Diagnostic Tests

PMH
- Obesity
- Acne

FH
Father is living and has hypertension. Mother is living and has diabetes mellitus and hypercholesterolemia. Both parents are obese.

SH
The patient works as a secretary. She lives with her fiancée. She denies any tobacco or recreational drug use. She drinks about five alcoholic beverages per week. She is sedentary.

Meds
None

ROS
(+) acne, (+) hirsutism, (–) dysmenorrhea, (–) breast tenderness, (–) vaginal discharge

PE
- **VS:** blood pressure 128/82, pulse 80 beats per minute, respiratory rate 18, weight 270 lb (123 kg), height 5 ft, 3 in (160 cm), BMI 47.9 kg/m^2
- **Abd:** Obese, soft, non-tender, non-distended, (+) bowel sounds, no hepatosplenomegaly
- **Gyn:** Normal external appearance of labia minora and majora, vaginal walls within normal limits, cervix well visualized and without lesions, midposition uterus, no cervical motion tenderness, no adnexal masses palpated

Labs
Urine HCG negative, free testosterone 100 ng/dL (3.47 nmol/L) (elevated), TSH 2.1 mIU/L (2.1 mU/L) (within normal limits), prolactin 9 ng/mL (9 ug/L) (mcg/L) (within normal limits), fasting glucose 120 mg/dL (6.66 mmol/L). Fasting lipid panel: total cholesterol 181 mg/dL (4.69 mmol/L), HDL cholesterol 58 mg/dL (1.50 mmol/L), triglycerides 65 mg/dL (0.73 mmol/L), LDL cholesterol 110 mg/dL (2.85 mmol/L).

Pelvic ultrasound
15 follicles in right ovary, 14 follicles in left ovary, increased ovarian volume of 12 mL

- What treatment options are available for this patient?
- Will this patient have fertility problems in the future?
- Given this patient's fasting glucose results, what medication would you recommend?

DYSMENORRHEA

Dysmenorrhea is commonly defined as crampy pelvic pain occurring with or just prior to menses. Primary dysmenorrhea implies pain in the setting of normal pelvic anatomy and physiology, whereas secondary dysmenorrhea is associated with underlying pelvic pathology.[17]

Clinical Presentation and Diagnosis of Dysmenorrhea

General
Patient may or may not be in acute distress depending on the level of menstrual pain experienced.

Symptoms
Complaints of crampy pelvic pain beginning shortly before or at the onset of menses. Symptoms typically last from 1 to 3 days.

Laboratory Tests
- Sexually active females should have a pelvic examination to screen for sexually transmitted diseases.
- Gonorrhea, chlamydia cultures or PCR, wet mount.

Other Diagnostic Tests
Pelvic ultrasound may be used to identify anatomic abnormalities such as masses/lesions or to detect ovarian cysts and endometriomas.

Etiology and Epidemiology

Rates of dysmenorrhea range from 20% to 90%.[17–19] Dysmenorrhea can be associated with significant interference in attendance at work and school. Risk factors for dysmenorrhea include young age, heavy menses, and **nulliparity.**[17]

Pathophysiology

The most significant mechanism for primary dysmenorrhea is the release of prostaglandins in the menstrual fluid and possibly vasopressin-mediated vasoconstriction.[5,17] Causes of secondary dysmenorrhea may include cervical stenosis, endometriosis, pelvic infections, pelvic congestion syndrome, uterine or cervical polyps, and uterine fibroids.[20]

PREMENSTRUAL SYNDROME AND PREMENSTRUAL DYSPHORIC DISORDER

Epidemiology

Premenstrual syndrome (PMS) is a constellation of symptoms including mild mood disturbance and physical symptoms that occur prior to menses and resolve with initiation of menses. It is estimated that up to 70% of menstruating women experience symptoms of PMS. However, a spectrum of premenstrual mood disturbances exists and the most severe is **premenstrual dysphoric disorder (PMDD).** Approximately 4% to 7% of women have PMDD. A summary of the American Psychiatric Association's criteria for PMDD is as follows[1,21]:

- Symptoms are temporally associated with the last week of the luteal phase and remit with onset of menses.
- At least five of the following symptoms are present: markedly depressed mood, marked anxiety, marked affective lability,

marked anger or irritability, decreased interest in activities, fatigue, difficulty concentrating, changes in appetite, sleep disturbance, feeling overwhelmed, and physical symptoms such as breast tenderness or bloating.
- One of the symptoms must be marked depressed mood, anxiety, irritability, or affective lability.
- Symptoms interfere significantly with work or social relationships.
- Symptoms are not an exacerbation of another underlying psychiatric disorder.
- The criteria are confirmed prospectively by daily ratings over two menstrual cycles.

Etiology and Pathophysiology

PMDD is a complex psychiatric disorder with multiple biologic, psychological, and sociocultural determinants.[21] While cyclic hormonal changes are in some way related to PMS and PMDD, the association is neither linear nor simple. However, when ovulation is suppressed medically or surgically, symptoms do improve. There is some evidence to suggest that PMS and PMDD symptoms are related to low levels of the centrally active progesterone metabolite allopregnanolone in the luteal phase and/or lower cortical γ-aminobutyric acid (GABA) levels in the follicular phase.[21] Women with PMS and PMDD may have enhanced sensitivity to progesterone.[22] Studies of the relationship of PMS and PMDD to testosterone levels are conflicting.[21] A number of studies suggest a link between PMS and PMDD and low levels of serotonin.[21,22] A recent study suggests that despite similar affective symptoms, the function of the hypothalamic-pituitary-adrenal (HPA) axis in PMS and PMDD is distinct from that seen in major depressive disorder (MDD). Specifically, women with PMS show a decrease in stimulated HPA axis response, whereas this response is increased in MDD.[23]

Several cross-cultural studies suggest that while the physical symptoms of PMS are consistent across cultures, the negative affective symptoms are part of the negative "menstrual socialization" in Western culture.[1,21]

TREATMENT: AMENORRHEA

Desired Outcomes

Therapeutic modalities for amenorrhea are targeted at restoring the normal menstrual cycle. The goals of treatment are to preserve bone density, prevent bone loss, and restore ovulation, thus improving fertility as desired. Amenorrhea resulting from conditions contributing to hypoestrogenism also may affect quality of life via the induction of hot flashes (premature ovarian failure), dyspareunia, and in prepubertal females, lack of secondary sexual characteristics and absence of menarche.

Nonpharmacologic Therapy

Nonpharmacologic therapy for amenorrhea varies depending on its underlying cause. Amenorrhea secondary to anorexia may respond to weight gain. Such patients also would benefit from psychotherapy. In young women for whom excessive exercise is an underlying cause, a reduction in exercise is recommended.

Pharmacologic Therapy

Estrogen/Progestin Replacement Therapy

❺ *For most conditions associated with primary or secondary amenorrhea, a goal of therapy is to replace estrogen (along with a progestin to minimize the risk of endometrial hyperplasia) via an OC, conjugated equine estrogen (CEE), or an estradiol patch.* The purpose of estrogen therapy in this patient population is two-fold: to reduce the risk of osteoporosis and to improve quality of life.[24,25] Table 46–2 identifies a variety of therapeutic options for amenorrhea, including recommended doses. Figure 46–3 illustrates a treatment algorithm for the management of amenorrhea.

If hyperprolactinemia is identified as the cause of amenorrhea, the use of bromocriptine, a dopamine agonist, results in a reduction in prolactin concentrations and the resumption of menses.

Amenorrhea related to anovulation resulting from PCOS may respond to the use of agents that reduce insulin resistance. The use of metformin for this purpose will be discussed in the anovulatory bleeding section that follows.

Progestins have long been used to induce withdrawal bleeding in women with secondary amenorrhea. Several factors predict the efficacy of progesterone for this purpose.[27] These factors include estrogen concentrations greater than or equal to 35 pg/mL (128 pmol/L) and endometrial thickness (the greater it is, the greater is the amount of withdrawal bleeding).

The efficacy of progestins for secondary amenorrhea also varies depending on the formulation used. For example, progesterone in oil administered intramuscularly results in withdrawal bleeding in 70% of treated patients, whereas oral medroxyprogesterone acetate induces withdrawal bleeding in 95% of treated patients.[27] Table 46–2 identifies the types and doses of progesterones used for inducing withdrawal bleeding in women with secondary amenorrhea. Figure 46–3 illustrates when to consider the use of progesterone for the treatment of amenorrhea.

For all patients experiencing amenorrhea, owing to the negative impact this has on bone health, it is essential that a diet rich in calcium and vitamin D be followed.

Amenorrhea in Adolescents

Amenorrhea in the adolescent population is of great importance because this is the time in the female life cycle when peak bone mass is achieved. The cause of amenorrhea and appropriate treatment must be identified promptly in this population because hypoestrogenism contributes negatively to bone development. Estrogen replacement, typically via an OC, is important. In addition, ensuring that the patient is receiving adequate amounts of calcium and vitamin D is imperative.

TABLE 46–2. Therapeutic Agents for Select Menstrual Disorders[15,17,24–26,28,29]

Specific Menstrual Disorders(s)	Agent(s)	Dose Recommended	Common Adverse Effects
Amenorrhea (primary or secondary)	Conjugated equine estrogen (CEE)	0.625–1.25 mg by mouth daily on days 1–25 of the cycle[25]	Thromboembolism, breast enlargement, breast tenderness, bloating, nausea, gastrointestinal (GI) upset, headache, peripheral edema
	Ethinyl estradiol patch	50 mcg/24 hours[27]	
	Combination OC	30–40 mcg formulations[24]	
Amenorrhea (secondary)	Oral medroxyprogesterone acetate	5–10 mg by mouth on days 14–25 of the cycle[25]	Edema, anorexia, depression, insomnia, weight gain or loss, increase in serum total and LDL cholesterol, may reduce HDL cholesterol
Amenorrhea related to hyperprolactinemia	Bromocriptine	2.5 mg by mouth 2–3 times daily	Hypotension, nausea, constipation, anorexia, Raynaud's phenomenom
Anovulatory bleeding	Combination OC	Optimal dose unknown[15]	As noted above for CEE, ethinyl estradiol, and combination OC (progesterone side effects with the OC depend on agent chosen)
Dysmenorrhea	Combination OC	Less than 35 mcg formulations + norgestrel or levonorgestrel[28]; use of extended-cycle formulations are beneficial for this indication	As noted above for CEE, ethinyl estradiol, and combination OC (progesterone side effects with the OC depend on agent chosen)
	Depo-medroxyprogesterone acetate	150 mg intramuscularly every 12 weeks	Irregular menses, amenorrhea
	Levonorgestrel IUD[29]	20 mcg released daily	Irregular menses, amenorrhea
	NSAIDs—any are acceptable; the most commonly studied/cited are included in this table	Diclofenac 50 mg by mouth 3 times daily	GI upset, stomach ulcer, nausea, vomiting, heartburn, indigestion, rash, dizziness
		Ibuprofen 800 mg by mouth 3 times daily	
		Mefenamic acid 500 mg by mouth as a loading dose, then 250 mg by mouth up to 4 times daily as needed[17]	
		Naproxen 550-mg loading dose by mouth started 1–2 days prior to menses, followed by 275 mg by mouth every 6–12 hours as needed[28]	
		Treatment should begin 1–2 days prior to the suspected onset of menses[17]	
Menorrhagia	Combination OC	Optimal dose unknown	As noted above
	Levonorgestrel IUD	20 mcg released daily	As noted above
	Medroxyprogesterone acetate (oral)	5–10 mg by mouth on days 5–26 of the cycle ***or*** during the luteal phase[29]	As noted above
	NSAIDs	Doses as recommended for above; therapy should be initiated with the onset of menses[29]	As noted above
PCOS-related amenorrhea and/or anovulatory bleeding	Clomiphene[15]	50 mg by mouth daily × 5 days starting 3–5 days after the start of menses	Hot flashes, ovarian enlargement, thromboembolism, blurred vision, breast discomfort
	Depo-medroxyprogesterone acetate	150 mg intramuscularly every 12 weeks	As noted above
	Medroxyprogesterone acetate (oral)	10 mg by mouth × 10 days[15]	As noted above
	Metformin	1500–2000 mg by mouth daily in 2–3 divided doses[15]	Anorexia, nausea, vomiting, diarrhea, flatulence, lactic acidosis

TABLE 46–2. Therapeutic Agents for Select Menstrual Disorders[15,17,24–26,28,29] (*Continued*)

Specific Menstrual Disorders(s)	Agent(s)	Dose Recommended	Common Adverse Effects
	Thiazolidinediones[15]	Pioglitazone 15–45 mg by mouth daily; rosiglitazone 4–8 mg by mouth daily	Weight gain; increase in total, LDL, and HDL cholesterol; edema; headache; fatigue; hepatic injury (rare)
PMDD	Clomipramine[26]	25–75 mg by mouth daily taken continuously or only during the luteal phase	Dry mouth, fatigue, vertigo, sweating
	Drospirenone	3 mg (+30 mcg ethinyl estradiol) by mouth on days 1–21 of the menstrual cycle[31]	As noted with other OCs above; drospirenone may contribute to hyperkalemia in patients with reduced renal function
	Leuprolide	3.75 mg intramuscularly[26]	Hot flashes, night sweats, headache, nausea
	SSRIs	Citalopram 10–30 mg; fluoxetine 10–20 mg; fluvoxamine 50 mg; paroxetine 10–30; sertraline 25–150 mg; all agents are given by mouth daily and can be dosed continuously or during the luteal phase only[26]	Sexual dysfunction (reduced libido, anorgasmia), insomnia sedation, hypersomnia, nausea, diarrhea

TREATMENT: MENORRHAGIA

Desired Outcomes

Menorrhagia therapy should focus on reducing menstrual blood flow, improving the patient's quality of life, and deferring the need for surgical intervention. Table 46–2 identifies the various agents used in the management of menorrhagia. It also includes their dosing and common side effects. Figure 46–4 illustrates how to decide which treatment(s) to use and when.

Nonpharmacologic Therapy

Nonpharmacologic interventions for menorrhagia include surgical interventions that are reserved for patients not responding

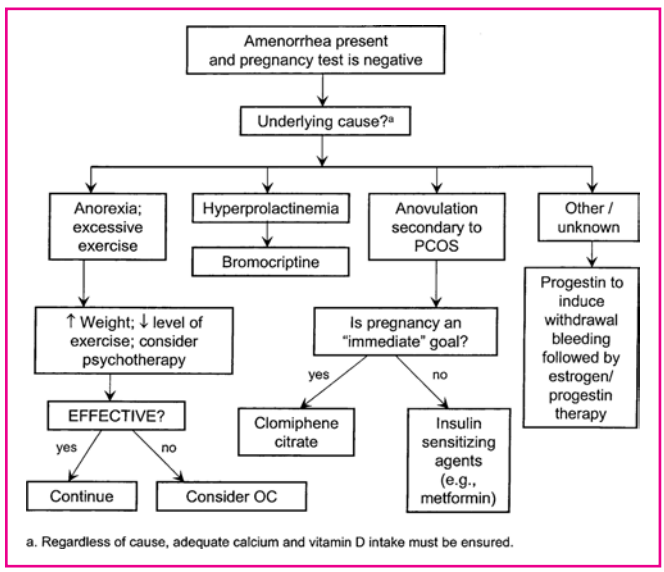

FIGURE 46–3. Treatment algorithm for amenorrhea.

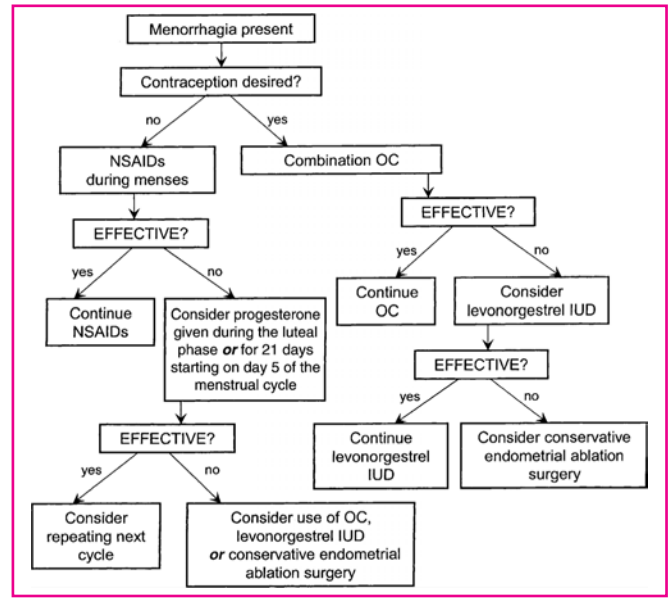

FIGURE 46–4. Treatment algorithm for menorrhagia.

to pharmacologic treatment. These interventions may vary from conservative endometrial ablation to hysterectomy.[32]

Pharmacologic Therapy

Non-steroidal anti-inflammatory drugs (NSAIDs) are first-line treatments for menorrhagia associated with ovulatory cycles.[33] They have the advantage of being taken only during menses, and their use is associated with a significant reduction in menstrual blood loss. A 20% to 50% reduction in blood loss has been observed in 75% of treated women.[29] In some patients, as much as an 80% reduction has been observed. ❻ *This reduction is directly proportional to the amount of pretreatment blood loss.*[29]

The use of OCs is beneficial in women with menorrhagia who do not desire pregnancy. A 43% to 53% reduction in menstrual blood loss has been observed in 68% of patients treated with OCs containing greater than or equal to 35 mcg estradiol for the treatment of menorrhagia.[29] As with the use of NSAIDs, ❻ *the reduction in blood loss is proportional to pretreatment blood loss.*

Menorrhagia also may be treated with the levonorgestrel-releasing intrauterine device (IUD). This is a very effective treatment that consistently reduces menstrual flow by 90% or greater.[29,30] Its use has resulted in the postponement or cancellation of scheduled endometrial resection surgery or hysterectomy. Specifically, 60% of treated patients have been able to avoid hysterectomy.[30,34,35]

Progesterone therapy either during the luteal phase of the menstrual cycle or for 21 days starting on day 5 after the onset of menses results in a 32% to 50% reduction in menstrual blood loss.[29] Its use has not been shown to be superior to other medical treatments, including NSAIDs.[29] In addition, it is not associated with any contraceptive benefit.[33]

TREATMENT: ANOVULATORY BLEEDING

Desired Outcomes

In the short term, the desired outcome is to stop acute bleeding. The long-term goals of therapy include preventing future episodes of non-cyclic bleeding, decreasing the long-term complications of anovulation (e.g., osteopenia and infertility), and improving overall quality of life.[11] Table 46–2 identifies the agents used in the management of anovulatory bleeding, their doses, and common side effects.

Nonpharmacologic Therapy

Nonpharmacologic treatment options for anovulatory bleeding depend on the underlying cause. In a woman of reproductive age with PCOS, weight loss may be beneficial. In women who have completed childbearing or who have failed medical management, endometrial ablation or resection and hysterectomy are surgical options. It is unclear as to which procedure is preferred. Short term, it appears that ablation or resection results in less morbidity and shorter recovery periods. However, a significant number of these women eventually undergo hysterectomy in the 5 years that follow.[11]

Pharmacologic Therapy

Estrogen is the recommended treatment for managing acute bleeding episodes because it promotes endometrial growth and stabilization.[11] Following its initial use for controlling acute bleeding episodes, it is necessary to continue therapy to prevent future occurrences. The use of OCs fulfills this role.

The role of OCs is to prevent recurrent anovulatory bleeding. They suppress ovarian hormones and adrenal androgen production. They also, indirectly, increase sex hormone–binding globulin (SHBG). This, in turn, binds and reduces circulating androgen. For women with high androgen levels and related signs (e.g., hirsutism), low-dose OCs (less than or equal to 35 mcg ethinyl estradiol) are the treatment of choice.[11] In theory, one may consider the use of an OC with a progesterone that has a larger impact on increasing SHBG. To date, there is no best OC choice for these women (e.g., those with PCOS).[15]

Specifically, for women with PCOS, the use of depot and intermittent oral medroxyprogesterone acetate suppresses pituitary gonadotropins and circulating androgens.[15] Further, the use of cyclic progesterone may benefit women over age 40 and in whom anovulatory bleeding occurs.[11]

The use of metformin and the thiazolidinediones pioglitazone and rosiglitazone results in improved insulin sensitivity. In patients with PCOS, this is associated with reducing circulating androgen concentrations, increasing ovulation rates, and improving glucose tolerance.[15] These improvements can be attributed to the increase in SHBG that occurs via increased insulin sensitivity. ❼ *These agents are of benefit not only for anovulatory bleeding and fertility but also because they improve glucose tolerance and decrease overall cardiovascular risk.*[15] If pregnancy is a desired outcome, it is important to note that metformin is a pregnancy category B agent, whereas pioglitazone and rosiglitazone are category C.

Although the use of insulin-sensitizing agents may improve fertility, if the goal of treatment is to improve fertility via inducing ovulation, then the treatment of choice is clomiphene citrate. Treatment with 50 mg/day for 5 days can be initiated between days 3 and 5 of the menstrual cycle. This often may occur following the induction of withdrawal bleeding with a progesterone such as medroxyprogesterone acetate at 10 mg/day by mouth for 10 days.

Anovulatory Bleeding in Adolescents

Anovulatory cycles are not unusual in the perimenarchal reproductive years. Ovulation typically is established a year or

more following menarche. When anovulatory bleeding occurs in this population, it may be excessive. If the bleeding is excessive, the patient should be evaluated for blood dyscrasias. The prevalence of blood dyscrasias, including von Willebrand's disease and prothrombin deficiency, and the prevalence of idiopathic thrombocytopenia purpura in this population ranges from 5% to 20%.[11]

In the adolescent population, specific blood dyscrasias should be treated. In addition, acute, severe bleeding may be managed with high-dose estrogen. Low-dose OCs (less than or equal to 35 mcg ethinyl estradiol) are the treatment of choice in adolescents with chronic anovulation.[11]

TREATMENT: DYSMENORRHEA

Desired Outcomes

The medical management of dysmenorrhea should relieve the related pelvic pain. Effective management of dysmenorrhea also results in a reduction in lost school and work days. Table 46–2 identifies the agents used in the management of dysmenorrhea, their recommended doses, and their common side effects. Figure 46–5 is a treatment algorithm for the management of dysmenorrhea.

Nonpharmacologic Therapy

Several nonpharmacologic interventions exist for the management of dysmenorrhea. Among these, topical heat therapy, exercise, and following a low-fat vegetarian diet all have been shown to reduce the intensity of the dysmenorrhea.[17,28] Dietary changes also may shorten the duration of dysmenorrhea. These interventions require little time and minimal cost and are associated with little risk. Other nonpharmacologic options that may be considered before or, in most cases, after a trial of pharmacologic interventions include the use of transcutaneous electric nerve stimulation (TENS), acupressure, and acupuncture.[17]

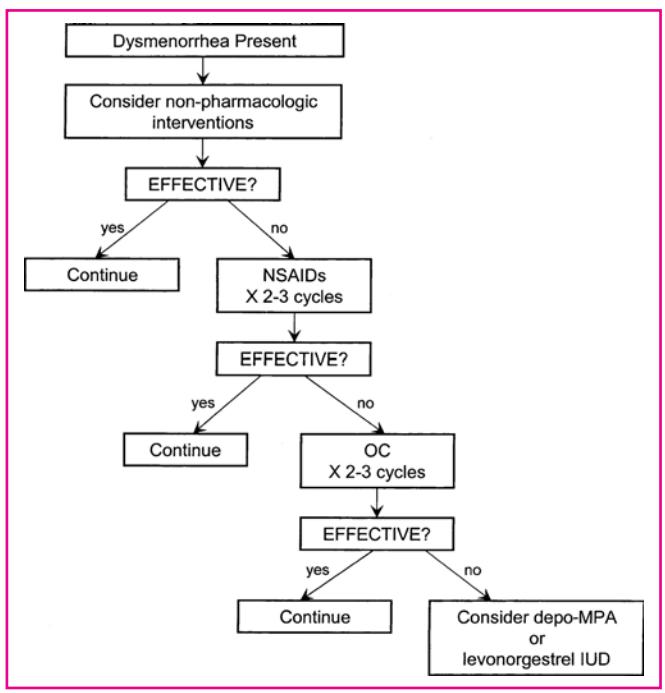

FIGURE 46–5. Treatment algorithm for dysmenorrhea.

Pharmacologic Therapy

Given the role of prostaglandins in the pathophysiology of dysmenorrhea, NSAIDs are the treatment of choice. There does not appear to be a difference between agents in efficacy. Choice of one agent over another may be based on cost, convenience, and patient preference.[17] The most commonly used agents are naproxen and ibuprofen.

It has been suggested that a loading dose (twice the usual single dose) of the NSAID be taken, followed by the usually recommended dose until symptoms resolve.[28] An alternate recommendation is to begin the NSAID at the onset of menses or perhaps even the day prior and to continue treatment around the clock instead of waiting until the onset of symptoms. For patients in whom NSAID use is contraindicated, the agents discussed below should be considered. The use of acetaminophen has been proven inferior to the use of NSAIDs for the treatment of this disorder.[17]

OCs help to improve dysmenorrhea by inhibiting the proliferation of endometrial tissue. This reduction in tissue translates into a reduction in endometrial-derived prostaglandins that are thought to contribute to the pelvic pain experienced.[28] A trial of 2 to 3 months of OC dosing is required to establish whether the patient is a responder or a non-responder.[36] Significant improvements in mild, moderate, and severe dysmenorrhea have been noted with the use of OCs. These agents have other benefits, such as the prevention of pregnancy, improving acne, and reducing ovarian cancer risk. While monophasic formulations may be more efficacious for this indication, the supporting evidence for this is limited.[17]

The benefit of depo-medroxyprogesterone acetate in dysmenorrhea is related to its ability to render most patients amenorrheic within 1 year of use.[17] This is an expected side effect. Since the pelvic pain of dysmenorrhea is related to the prostaglandins released during menses, in the setting of amenorrhea, the underlying cause of dysmenorrhea is removed.

Observational data illustrate a reduction in dysmenorrhea from 60% to 29% with the levonorgestrel-releasing IUD after 3 years.[17] As observed with depo-medroxyprogesterone acetate, this reduction is likely secondary to the increasing incidence of amenorrhea in users of this contraceptive device.

Dysmenorrhea in Adolescents

Dysmenorrhea is very common in adolescent females. Any of the treatment measures discussed earlier for other patients

would be appropriate in the adolescent population. While NSAIDs and OCs are among the top choices, use of the levonorgestrel IUD is also an option.[30] It had been thought previously that nulliparous females should avoid the use of IUDs secondary to an increased risk of pelvic inflammatory disease (PID) and a subsequent increased risk of infertility. ❽ *Recent guidelines from the American College of Obstetricians and Gynecologists (ACOG) state that any woman (regardless of parity) at low risk of sexually transmitted diseases and thus pelvic inflammatory disease is a good candidate for IUD use.*[30]

TREATMENT: PREMENSTRUAL SYNDROME AND PREMENSTRUAL DYSPHORIC DISORDER

Desired Outcomes

Interventions for managing PMS and PMDD focus on alleviation of the presenting symptoms and subsequent improvement in quality of life. See Table 46–2 for a listing of the various agents used in the management of this disorder, their recommended dosing, and common side effects.

Nonpharmacologic Therapy

It is recommended that lifestyle interventions be started and followed for 2 months while the patient charts her symptoms. While these interventions lack significant supporting clinical trial data, anecdotal reports do exist. Some lifestyle changes for women suffering from mild to moderate premenstrual symptoms include minimizing caffeine, refined sugar, and sodium intake and increasing exercise.[26] Vitamin and mineral supplements such as vitamin B_6 (50–100 mg/day) and calcium carbonate (1200 mg/day) have been observed anecdotally to help reduce the physical symptoms associated with PMS.[26] A review of clinical trials, however, supports that none of the following options should be recommended because of a lack of evidence for safety and efficacy: herbal medicines, homeopathic remedies, dietary supplements, relaxation, massage therapy, reflexology, chiropractic treatments, and biofeedback.[37]

Pharmacologic Therapy

If symptoms continue after 2 months of symptom charting and attempting lifestyle modifications, pharmacologic therapy may be considered for the management of diagnosed PMDD.

❾ *The first-line therapeutic options for PMDD include the selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine, fluvoxamine, sertraline, paroxetine, and citalopram.* These agents can be given either continuously or only during the luteal phase of the menstrual cycle, i.e., initiated at the time of ovulation and discontinued on the first day of menses.

SSRIs are efficacious in more than half of treated patients compared with only 20% of patients receiving placebo.[26] This improvement was noted to be a 50% or greater reduction in symptoms compared with baseline. Further, the improvement was noted to occur during the first cycle of use.[26]

The tricyclic antidepressant clomipramine also has been studied for PMDD. In placebo-controlled trials, both continuous daily dosing and luteal phase administration proved effective.[17] Compared with the SSRIs, however, clomipramine has a less desirable side-effect profile with low tolerability.

If treatment with an SSRI or another antidepressant such as clomipramine is not successful, hormonal treatment with a GnRH agonist, such as leuprolide, may be considered. The use of leuprolide improves premenstrual emotional symptoms as well as some physical symptoms such as bloating and breast tenderness. Cost, the need for intramuscular administration, and the side effects of hypoestrogenism (e.g., vaginal dryness and hot flashes) limit its use.

A randomized, double-blind, placebo-controlled trial evaluating the use of a monophasic OC containing 30 mcg ethinyl estradiol and 3 mg drospirenone, a progesterone with antiandrogenic effects, showed improvement in the treatment arm compared with placebo.[31] In particular, appetite, food cravings, and acne improved. However, active treatment was not associated with a statistically significant improvement in the overall outcome measure, the Calendar of Premenstrual Experiences (COPE) scale, perhaps because of the small sample size ($n = 82$).

OUTCOME EVALUATION

Measure the treatment success for the various menstruation-related disorders by the degree to which the care plan (1) relieves or reverses symptoms of the disorder, (2) prevents or reverses the complications of the disorder (e.g., osteoporosis, anemia, and infertility), and (3) minimizes side effects. The return of a regular menstrual cycle with minimal premenstrual symptoms or symptoms of dysmenorrhea should occur. Depending on the desire for conception and subsequent therapy, this cycle may be ovulatory or anovulatory.

Assess the effectiveness of therapy in resuming normal menstrual cycles with minimal related pain after an appropriate treatment interval (1–2 months). Assess improvement in quality-of-life measures such as physical, psychological, and social functioning and well-being. Evaluate the patient for adverse drug reactions, drug allergies, and drug interactions. Table 46–2 illustrates the common side effects that may occur for which monitoring is required. Table 46–3 illustrates the specific expected outcome measures for each of the menstruation-related disorders discussed in this chapter.

TABLE 46–3. Expected Outcome Measures for Select Menstrual Bleeding Disorders[8,10,11,15,18,20,22,33,36]

Menstrual Disorder	Expected Outcome Measures
Amenorrhea	***Efficacy:*** Normal breast development (especially primary amenorrhea in adolescents) preservation/improvement of BMD; return of menses. ***Time to relief/effect:*** Menses should occur within 1–2 months of therapy.
Menorrhagia	***Efficacy:*** Decline in the amount of blood lost with menses (monitor a decline in the number of times feminine hygiene products such as pads and tampons require changing during menses); monitor for an increase in hemoglobin/hematocrit if anemia was present as a result of menorrhagia. ***Time to relief/effect:*** A decline in menstrual blood loss should be realized within 1–2 cycles of therapy being initiated.
Anovulatory bleeding	***Efficacy:*** Alleviation of acute bleeding when present; ovulation and subsequent pregnancy in women desiring this; reduced risk of developing the long-term complications of, for example, PCOS (e.g., diabetes and cardiovascular disease); improved quality of life. ***Time to relief/effect:*** The acute treatment of heavy bleeding should result in a decline in bleeding within 10 days of therapy onset; the return of ovulation may require several months of therapy; when OCs are used, control of abnormal bleeding can be expected within 1–2 cycles of therapy.
Dysmenorrhea	***Efficacy:*** Reduction in/absence of pelvic pain related to menses; reduction in time lost from work/school; improved quality of life. ***Time to relief/effect:*** Improvement in pain may be observed within hours of NSAID therapy; improvement with other options such as OCs may be observed after a full 1–3 cycles of their use.
PMDD	***Efficacy:*** Reduction in/absence of initial symptoms; improved quality of life. ***Time to relief/effect:*** Improvements may be observed within 1–3 cycles of therapy.

BMD, bone mineral density; NSAID, non-steroidal anti-inflammatory drug; OCs, oral contraceptives; PCOS, polycystic ovary syndrome; PMDD, premenstrual dysphoric disorder.

Patient Care and Monitoring

1. Assess symptoms to determine if patient-directed therapy is appropriate (e.g., NSAIDs for dysmenorrhea) or whether the patient should be evaluated by a physician (e.g., amenorrhea, menorrhagia, anovulatory bleeding, or PMDD). Does the patient have any related complications, such as symptoms of anemia in patients presenting with menorrhagia or complaints of difficulty conceiving in women with amenorrhea or anovulatory bleeding.
2. Review any available diagnostic data, as appropriate, to determine hormonal, reproductive, and pregnancy status.
3. Obtain a thorough history of prescription, nonprescription, and natural drug product use. Determine which treatments have been helpful to the patient in the past.
4. Educate the patient on lifestyle modifications that will improve symptoms and prevent complications.
5. Is the patient taking the appropriate dose of the prescribed medication? If not, why not?
6. Develop a plan to assess effectiveness of the prescribed medication after 1 to 2 months of therapy.
7. Determine if long-term maintenance treatment is necessary.
8. Assess improvement in quality-of-life measures such as physical, psychological, social functioning and well-being.
9. Evaluate for adverse drug reactions, drug allergies, and drug interactions.
10. Stress the importance of adherence with the therapeutic regimen, including lifestyle modifications. Recommend a therapeutic regimen that is easy for the patient to adhere to.
11. Provide patient education regarding disease state, lifestyle modifications, and drug therapy by noting the following:
    - What causes the menstruation-related disorder?
    - What are the possible complications of the menstruation-related disorder?
    - What lifestyle modifications may help to reduce the risk associated with these complications?
    - When and how should patients take their medications?
    - What potential adverse effects may occur?
    - Which drugs may interact with their therapy?

ABBREVIATIONS

CBC:	complete blood count
CEE:	Conjugated equine estrogen
CNS:	central nervous system
COPE:	calendar of premenstrual experiences
FSH:	follicle-stimulating hormone
GABA:	γ-aminobutyric acid
GnRH:	gonadotropin-releasing hormone
HCG:	human chorionic gonadotropin
HPA:	hypothalamic-pituitary-adrenal
HPO:	hypothalamic-pituitary-ovarian
IUD:	intrauterine device
LH:	luteinizing hormone
MDD:	major depressive disorder
MPA:	medroxyprogesterone acetate
NSAID:	non-steroidal anti-inflammatory drug
OC:	oral contraceptive
PCOS:	polycystic ovarian syndrome
PID:	pelvic inflammatory disease
PMDD:	premenstrual dysphoric disorder
PMS:	premenstrual syndrome
SHBG:	sex hormone–binding globulin
SSRI:	selective serotonin reuptake inhibitor
TENS:	transcutaneous electrical nerve stimulation

47 Hormone-Replacement Therapy in Menopause

Nicole S. Culhane and Melissa A. Somma

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiologic changes associated with menopause.
2. Identify the signs and symptoms associated with menopause.
3. Determine the desired therapeutic outcomes for a patient taking hormone-replacement therapy.
4. Explain how to evaluate a patient for the appropriate use of hormone-replacement therapy.
5. Recommend nonpharmacologic therapy for menopausal symptoms.
6. List the adverse effects of and contraindications to hormone-replacement therapy.
7. Differentiate between topical and systemic forms of hormone-replacement therapy.
8. Explain the risks and benefits associated with hormone-replacement therapy.
9. Educate a patient regarding the proper use and potential adverse effects of hormone-replacement therapy.
10. Monitor a patient taking hormone-replacement therapy for efficacy and toxicity.
11. Recognize that alternative, non-hormonal therapies for menopausal symptoms exist and should be considered in some circumstances for women unable to take hormone-replacement therapy.

Key Concepts

❶ Common symptoms of menopause include hot flashes, night sweats, vulvovaginal atrophy, and vaginal dryness. Women less commonly may experience mood swings, depression, insomnia, arthralgia, myalgia, and urinary frequency.

❷ Hormone-replacement therapy remains the most effective treatment for vasomotor symptoms and vulvovaginal atrophy and should be considered for women experiencing these symptoms.

❸ Women should receive a thorough history and physical examination, including assessing coronary heart disease (CHD) and breast cancer risk factors, before hormone-replacement therapy is considered. Patients should be informed of the risks and the benefits of hormone-replacement therapy and should be encouraged to be involved in the decision-making process. If a woman does not have any contraindications to hormone-replacement therapy, including CHD or significant CHD risk factors, and also does not have a personal history of breast cancer, hormone-replacement therapy would be an appropriate therapy option.

❹ Oral or transdermal estrogen products should be prescribed at the lowest effective dose for the relief of vasomotor symptoms. Topical products in the form of creams, tablets, or rings should be prescribed for women exclusively experiencing vulvovaginal atrophy.

❺ Women who have an intact uterus should be prescribed a progestin in addition to estrogen in order to decrease the risk of endometrial hyperplasia and endometrial cancer.

❻ Hormone-replacement therapy is also indicated for the prevention of osteoporosis but is not recommended for long-term use. Alternatives such as bisphosphonates or raloxifene should be considered as first-line therapy for the prevention of osteoporosis, in addition to appropriate doses of calcium and vitamin D.

❼ Combined estrogen plus progestin should not be used in the prevention of chronic diseases because it increases the risk of CHD, stroke, breast cancer, and venous thromboembolism.

However, colorectal cancer and rates of fracture were reduced with combined hormonal treatment.

8. Hormone-replacement therapy improves overall well-being and mood in women with vasomotor symptoms but has not demonstrated an improvement in quality of life in women without vasomotor symptoms.
9. In appropriate women, hormone-replacement therapy should be recommended at the lowest dose for the shortest duration and should be tapered before discontinuation in order to prevent the recurrence of hot flashes.
10. Since the publication of the Women's Health Initiative study, there has been an increase in the use of non-hormonal therapies for the management of menopausal symptoms. Particularly for women with CHD and breast cancer risk factors, non-hormonal therapies may offer an alternative to assist with symptom management. A wide range of therapies, both prescription and herbal, have been studied with varying degrees of success. In choosing a particular therapy, it is important to match patient symptoms with a therapy that is not only effective but also safe.

Patient Encounter, Part 1

BW, a 50-year-old woman with a history of osteoarthritis and hypothyroidism, presents to the clinic complaining of hot flashes, vaginal dryness, and insomnia. She states that she experiences approximately two hot flashes per day and is awakened from sleep at least three to four times a week in a "pool of sweat" requiring her to change her clothes and bed linens. Her symptoms began about 3 months ago, and over that time, they have worsened to the point where they have become very bothersome. On questioning, she states her last menstrual period was 1 year ago.

- Which of the patient's symptoms and past medical history are consistent with menopause?
- What laboratory value(s) will help to confirm the diagnosis of menopause?
- What additional information do you need to know in order to make an appropriate therapeutic plan for this patient?

Menopause is the permanent cessation of menses owing to a loss of ovarian follicular function. The diagnosis of menopause is primarily a clinical one and is made after a women experiences amenorrhea for 12 consecutive months. The loss of ovarian follicular activity leads to an increase in follicle-stimulating hormone (FSH), which, on laboratory examination, may help to confirm the diagnosis.

Many women seek medical treatment for the relief of menopausal symptoms, primarily hot flashes; however, the role of hormone-replacement therapy (HRT) has changed dramatically over the years. HRT has long been prescribed for relief of menopausal symptoms and, until recent years, has been purported to protect women from CHD. The original reason behind recommending HRT in postmenopausal women revolved around a simple theory: If the hormones lost during menopause were replaced through drug therapy, women would be protected from both menopausal symptoms and chronic diseases that often follow after a woman experiences menopause. Recent studies have disproved this theory.

As of 1995, almost 38% of all women 50 to 75 years of age were using HRT.[1] It was in 1996 that the United States Preventive Services Task Force (USPSTF) first published its recommendations that not all postmenopausal women should be prescribed HRT, but rather, therapy should be individualized based on risk factors. This recommendation was further supported with publication of the Heart and Estrogen/Progestin Replacement Study (HERS) in 1998, which demonstrated that women who had established CHD were at an increased risk of experiencing a myocardial infarction within the first year of HRT use compared with a similar group of women without CHD risk factors. As a result, the authors concluded that HRT is not recommended for the secondary prevention of CHD.[2] Then, in 2002, the Women's Health Initiative (WHI) report was published. This trial demonstrated that HRT was not protective against CHD but rather could increase the risk in women with underlying CHD risk factors. The risk of breast cancer also was increased after a woman was on therapy for approximately 3 years. As a result of this study, the Food and Drug Administration (FDA) issued a statement that combined HRT should not be initiated or continued for the primary prevention of CHD.[3]

This series of trials, and many more, has led to the dramatic change in how HRT is currently prescribed and greater understanding of the associated risks. HRT, once thought of as a cure-all for menopausal symptoms, is now a therapy that should be used only to reduce the frequency and severity of **vasomotor symptoms** associated with menopause in women without risk factors for CHD or breast cancer. The changes that have occurred over the years in the use of HRT further support the importance of evidence-based practice and judicious medication use.

EPIDEMIOLOGY AND ETIOLOGY

Menopause is a period of time in a woman's life marked by the cessation of menses. It occurs in all women either naturally or surgically and usually occurs between the ages of 40 and 58 years. The median age for a woman to experience menopause is 52 years. However, women who have undergone a total abdominal hysterectomy (surgical menopause) generally experience menopause earlier compared with women who experience natural menopause. Some other factors that may be associated with early menopause include low body weight, increased menstrual cycle length, **nulliparity,** and smoking. Smokers generally experience menopause approximately 2 years earlier than non-smokers.[4]

The usual transitional period prior to menopause, known as **perimenopause** or the *climacteric,* is a period

when hormonal and biologic changes begin to occur. These changes may begin 2 to 8 years prior to menopause and eventually lead to irregular menstrual cycles, an increase in cycle interval, and a decrease in cycle length. During this time, women also may experience physical symptoms similar to menopausal symptoms, primarily vasomotor symptoms, and they may require treatment depending on symptom severity.[4,5]

Because the perimenopausal and postmenopausal periods are marked by many biologic and endocrinologic changes, women should inform their health care provider when they experience any signs and symptoms in order to discuss the most appropriate therapeutic approach.

PATHOPHYSIOLOGY

Reproductive physiology is regulated primarily by the hypothalamic-pituitary-ovarian axis. The hypothalamus secretes gonadotropin-releasing hormone (GnRH), which stimulates the anterior pituitary to secrete follicle-stimulating hormone (FSH) and luteinizing hormone (LH). FSH and LH regulate ovarian function and stimulate the ovary to produce sex steroids. These hormones are influenced by a negative-feedback system and will increase or decrease based on the levels of estradiol and progesterone.

The pathophysiologic changes that occur during the perimenopausal and menopausal periods are caused by the decrease and eventual loss of ovarian follicular activity. As women age, the number of ovarian follicles decreases, and the remaining follicles require higher levels of FSH for maturation and ovulation. During perimenopause, FSH concentrations

Clinical Presentation and Diagnosis

❶ Menopausal Symptoms
- Vasomotor symptoms (**hot flashes**, night sweats)
- Irregular menses
- Episodic amenorrhea
- Sleep disturbances
- Mood swings
- Vaginal dryness
- Depression

Less Common Symptoms
- Fatigue
- Irritability
- Migraine
- Arthralgia
- Myalgia

Diagnosis
- Amenorrhea for 1 year
- FSH greater than 40 mIU/mL
- Five-fold increase in LH

Patient Encounter, Part 2: Medical History, Physical Examination, and Diagnostic Tests

BW's work-up reveals the following additional information:

PMH
- Osteoarthritis of the lower back for 5 years controlled on acetaminophen 500 mg two tablets PO 3 to 4 times daily
- Hypothyroidism since age 25, currently controlled

FH
- Father: Alive with HTN and CHD (MI at age 60)
- Mother: Alive with hypothyroidism and GERD
- Siblings: Two sisters alive and well

SH
- Occupation: nurse
- Non-smoker
- Drinks one to two glasses of red wine with dinner on the weekends
- Denies illicit drug use

Meds
- Acetaminophen 500 mg two tablets PO 3 to 4 times daily
- Synthroid 0.075 mg PO once daily
- Multivitamin PO once daily

ROS
(+) hot flashes, night sweats, vaginal dryness and itching; (–) insomnia, myalgias, bowel changes, weight gain, constipation

PE
- **VS:** BP 128/82, P 78, RR 16, T 37.0°C (98.6°F), weight 164 lb (74.5 kg)
- **HEENT:** WNL
- **Neck:** Supple; no bruits, no adenopathy, no thyromegaly
- **Breasts:** Supple; no masses
- **CV:** RRR, normal S_1 and S_2; no murmurs, rubs, or gallops
- **Abd:** Soft, non-tender, non-distended; (+) BS, no masses
- **Genitourinary:** Pelvic examination normal except (+) mucosal atrophy

Labs
- FSH 76 mIU/mL
- TSH 2.5 mIU/L
- Chem-7: Na 135 mEq/L (135 mmol/L), K 4.5 mEq/L (4.5 mmol/L), Cl 109 mEq/L (109 mmol/L), CO_2 25 mEq/L (25 mmol/L), BUN 9 mg/dL (3.21 mmol/L), SCr 0.9 mg/dL (80 mmol/μmol per liter), Glucose 98 mg/dL (5.44 mmol/L)
- CBC: Hgb 13 g/dL (130 g/L or 8.06 mmol/L), Hct 39% (0.39 volume fraction), WBC $5.5 \times 10^3/mm^3$ ($5.5 \times 10^3/\mu L$ or $5.5 \times 10^9/L$), platelets $234 \times 10^3/mm^3$ ($234 \times 10^3/\mu L$ or $234 \times 10^9/L$)
- Fasting lipid levels: TC 232 mg/dL (6 mmol/L), LDL 145 mg/dL (3.76 mmol/L), HDL 45 mg/dL (1.17 mmol/L), TG 200 mg/dL (2.26 mmol/L)

- Assess the patient's condition based on this additional information.
- What are the goals of treatment for this patient?
- Assess the patient's risk factors for heart disease and breast cancer.
- Recommend nonpharmacologic and pharmacologic treatment for this patient. Justify your recommendations.

rise during some menstrual cycles but can fall again during subsequent menstrual cycles, leading to irregular and unpredictable menses. During menopause, FSH concentrations increase 10- to 15-fold, LH concentrations increase 5-fold, and levels of circulating estradiol decrease by over 90%.[6]

Vasomotor symptoms, as well as other menopausal symptoms, occur in over 50% of perimenopausal women and over 80% of menopausal women.[5] Menopausal symptoms tend to be more severe in women who undergo surgical menopause compared with natural menopause because of the more rapid decline in estrogen concentrations. Women who seek medical treatment should undergo laboratory evaluation to rule out other conditions that may present with similar symptoms, such as abnormal thyroid function or pituitary adenoma. Once other conditions have been excluded, HRT should be considered.

TREATMENT

Desired Outcomes

❷ *Hormone-replacement therapy remains the most effective treatment for vasomotor symptoms and vulvovaginal atrophy and should be considered for women experiencing these symptoms.* The goals of treatment are to alleviate or reduce menopausal symptoms and to improve the patient's quality of life while minimizing adverse effects of therapy. The appropriate route of administration should be chosen based on individual patient symptoms and should be continued at the lowest dose for the shortest duration consistent with treatment goals for each patient.

General Approach to Treatment

Women suffering from vasomotor symptoms should attempt lifestyle or behavioral modifications before seeking medical treatment. Women who seek medical treatment usually suffer from symptoms that start to disrupt their quality of life, such as multiple hot flashes per day or week, sleep disturbances, vaginal dryness, or mood swings. HRT should be considered for these women but is not the most appropriate choice for all women. ❸ *Women should receive a thorough history and physical examination, including assessing CHD and breast cancer risk factors, before HRT is considered. Patients should be informed of the risks and the benefits of HRT and encouraged to be involved in the decision-making process. If a woman does not have any contraindications to HRT, including CHD or significant CHD risk factors, and also does not have a personal history of breast cancer, HRT would be an appropriate therapy option.* Women who have undergone a hysterectomy need only be prescribed estrogen. A progestin should be prescribed only for women with an intact uterus. Alternative, non-hormonal treatment options are available for women who are not candidates for HRT, but they are less efficacious than hormonal therapies. Alternative treatments should be chosen based on the efficacy and safety profile of the treatment and the patient's past medical history and current medications.

Nonpharmacologic Therapy

Nonpharmacologic therapies for menopause-related symptoms have not been studied in large randomized trials, and evidence of benefit is not well documented. Owing to minimal adverse effects with these types of interventions, it may be prudent for patients to try lifestyle or behavioral modifications before and in addition to pharmacologic therapy. The most common nonpharmacologic interventions for vasomotor symptoms include[4,7,8]

- Smoking cessation
- Limit alcohol and caffeine
- Limit hot beverages (e.g., coffee/tea, soups)
- Limit spicy foods
- Keep cool, and dress in layers
- Stress reduction (e.g., meditation, relaxation exercises)
- Increase exercise
- Paced respiration

Exercise demonstrated an improvement in quality of life but did not improve vasomotor symptoms. Paced respiration, a form of deep, slow breathing, improved vasomotor symptoms in a small group of patients.

Dyspareunia may result from vaginal dryness. Water-based lubricants may provide relief for several hours after application. Moisturizers may provide relief for a longer period of time and potentially can prevent infections by maintaining the acidic environment in the vagina. Both these treatments require frequent application.

A decline in estrogen concentrations also may be associated with urinary stress incontinence. **Kegel exercises** are recommended as a first-line intervention, although pharmacologic therapy also may be necessary. Kegel exercises strengthen the pelvic floor muscles and help to keep the urethra from opening at inappropriate times, such as when lifting heavy objects, coughing, or sneezing. These exercises have no adverse effects, take little time, may be done inconspicuously, and when done correctly, may help to restore normal urine flow.

Pharmacologic Therapy

Estrogens

Estrogen currently is indicated for the treatment of moderate to severe vasomotor symptoms and vulvovaginal atrophy associated with menopause. In addition, it is indicated for the prevention of postmenopausal osteoporosis in women with significant risk; however, it is recommended that non-estrogen medications receive consideration for long-term use. ❹ *Oral or transdermal estrogen products should be prescribed at the lowest*

effective dose for the relief of vasomotor symptoms. Topical products in the form of creams, tablets, or rings should be prescribed for women exclusively experiencing vulvovaginal atrophy.

Many systemically administered estrogen products are available in the United States, but conjugated equine estrogens (CEEs), prepared from the urine of pregnant mares, is the most widely prescribed. Transdermal estrogen preparations are also available and usually are prescribed for patients who experience adverse effects, elevated triglycerides, or liver function abnormalities while taking an oral product. Transdermal preparations also have a lower incidence of venous thromboembolism than oral preparations.[9]

Progestins

❺ *Women who have an intact uterus should be prescribed a progestin in addition to estrogen in order to decrease the risk of endometrial hyperplasia and endometrial cancer.*[10] Progestins should be prescribed for at least 12 to 14 days of the month and often are prescribed continuously in order to completely prevent endometrial complications. Low doses of estrogen therapy, as well as some forms of vaginal preparations, require daily or intermittent administration of a progestin in order to provide endometrial protection. Table 47–1 lists estrogen and progestin preparations and dosages.

Adverse Effects

Therapy with estrogen with or without a progestin should be initiated at the lowest dose in order to minimize adverse effects. Because the adverse effects of these preparations can be similar, it may be difficult to assess whether the estrogen or the progestin is the cause. Changing preparations, particularly with the progestin, or changing the method of administration may help to alleviate adverse effects. Table 47–2 lists the adverse effects that may be associated with estrogen and progestin preparations.

Contraindications

HRT should not be prescribed to women with a history of or active thromboembolic disease, breast cancer or estrogen-dependent neoplasm, pregnancy, liver disease, or undiagnosed vaginal bleeding. It also should not be used for the prevention or treatment of cardiovascular disease, cerebrovascular disease, or dementia.[11]

Methods of Administration

Cyclic Estrogen and Progestin

Estrogen is administered daily, and progestin is administered for 12 to 14 days of the month. The disadvantage of this method of administration is the return of monthly menses in approximately 90% of women 1 to 2 days following the last progestin dose. However, the withdrawal bleeding does not last as long or is not as heavy as a typical menstrual period. Women also may view this disadvantage as an advantage

TABLE 47–1. Estrogen and Progestin Formulations and Dosages[11,41–44]

Product	Common Dosages
Oral Estrogens	
Conjugated equine estrogens (CEE) (Premarin®)	0.3–0.625 mg/day
Synthetic conjugated estrogens (Cenestin®)	0.3–0.625 mg/day
Esterified estrogens (Estratab®)	0.3–0.625 mg/day
Estradiol (Estrace®)	0.5–1 mg/day
Estropipate (Ogen®, Ortho-Est®)	0.625 mg/day
Transdermal Estrogens	
Estradiol patch (Alora®, Climara®, Esclim®, Estraderm®, FemPatch®, Vivelle®)	0.025–0.05 mg, changed weekly (Climara®) or changed twice weekly
Menostar®[a]	0.014 once weekly
Estradiol gel (Estragel 0.06%®)	1.25g/day
Topical Estrogens	
Vaginal creams	
Conjugated equine estrogens (Premarin®)	0.5–2g/day
Estradiol (Estrace®)	1 g 1–3 times/week
Estropipate (Ortho-Est®)	2–4 g/day
Vaginal rings	
Estradiol (Estring®, Femring®)	1 ring every 3 months
Vaginal tablet	
Estradiol (Vagifem®)	1 tablet 2 times/week
Emulsions	
Estradiol (Estrasorb®)	Apply daily
Oral Progestins[b,c]	
Medroxyprogesterone acetate (Provera®)	2.5–10 mg
Micronized progesterone	100–200 mg
Transdermal Progestins[b,c]	
Levonorgestrel	0.015 mg
Norethindrone acetate	0.25–1 mg
Norgestimate	0.09 mg
Combination Products	
Oral	
CEE + MPA (Prempro®, Premphase®)	0.3–0.625/2.5–5 mg/day
Estradiol + norethindrone (Activella®)	1/0.5 mg/day
Ethynyl estradiol + norethindrone (FemHRT®)	5 mcg/1 mg/day
Estradiol + norgestimate (Ortho-Prefest®)	1/0.09 mg/day
Transdermal	
Estradiol + norethindrone (Combipatch®)	0.05/0.14 or 0.05/0.25 mg twice weekly
Estradiol + levonorgestrel (Climara Pro®)	0.45/0.015 mg once weekly

[a]Indicated for the prevention of postmenopausal osteoporosis only.
[b]May be administered cyclically or continuously.
[c]Dose varies based on daily or weekly administration.
MPA, medroxyprogesterone acetate.

TABLE 47–2. Adverse Effects of Estrogens and Progestins[11,41,44,45]

Estrogens
Common adverse effects
Nausea
Headache
Bloating
Breast tenderness
Bleeding
Serious adverse effects
Coronary heart disease
Stroke
Venous thromboembolism
Breast cancer
Gallbladder disease
Progestins
Common adverse effects
Nausea
Headache
Weight gain
Bleeding
Irritability
Depression
Serious adverse effects
Venous thromboembolism
Decreased bone mineral density

because the bleeding is scheduled and can be anticipated, thus limiting spotting or soiling of undergarments.

Continuous Combined Estrogen and Progestin

Estrogen and progestin are administered daily and result in endometrial atrophy. Therefore, women do not experience a withdrawal bleed but may experience unanticipated breakthrough bleeding or spotting during the month. Although this may sound more appealing than a withdrawal bleed, women may view the unpredictable bleeding or spotting as a disadvantage to this type of administration. Patients should be educated that the bleeding or spotting usually resolves within 6 to 12 months. If bleeding persists beyond this time period, patients should seek medical attention to rule out more serious conditions such as endometrial hypertrophy or carcinoma.

Low-Dose Hormone Therapy

Lower doses of HRT, primarily CEE, have become more popular following publication of the WHI study results. There is an increasing body of evidence proving the effectiveness of these regimens in the management of menopausal symptoms. The Women's Health, Osteoporosis, Progestin/Estrogen (HOPE) trial demonstrated that lower doses of CEE ± medroxyprogesterone acetate (MPA) (CEE 0.45 mg or 0.3 mg ± MPA 2.5 or 1.5 mg) decreased hot flashes comparable with standard hormone therapy, improved vulvovaginal atrophy, increased bone mineral density (BMD) at the spine and hip, and provided sufficient endometrial protection.[12–15] Currently, no data are available on the effects of lower-dose HRT on the incidence of venous thromboembolism, breast cancer, or CHD. Lower-dose HRT provides women with an alternative to standard-dose HRT for menopausal symptoms but also should be recommended only for a short duration. Although many women have switched to lower-dose HRT, only time will tell if lower doses translate into lower risks.

Benefits of Hormone-Replacement Therapy

Vasomotor Symptoms

HRT is indicated primarily for the relief of moderate to severe vasomotor symptoms. It remains the most effective treatment for vasomotor symptoms and should be considered only in women experiencing those symptoms. Women with mild vasomotor symptoms may benefit from nonpharmacologic therapy alone; however, many women will seek medical treatment for these symptoms. The benefits of HRT outweigh the risks in women who do not have CHD or CHD and breast cancer risk factors; however, careful consideration should be given to alternative therapies for the relief of menopausal symptoms in women with these risks. Women should be involved in the decision and may choose to use HRT despite having some risk factors owing to the severity of their symptoms. Regardless of the situation, HRT should be prescribed at the lowest dose that relieves or reduces menopausal symptoms and should be recommended only for short-term use. Women should be reassessed every 6 to 12 months, and discontinuation of therapy should be considered.

Vulvovaginal Atrophy

HRT is indicated for the treatment of vulvovaginal atrophy. Approximately 50% of postmenopausal women experience vulvovaginal atrophy and seek medication attention for relief. Vulvovaginal atrophy is associated with vaginal dryness and dyspareunia and also may be associated with recurrent urinary tract infections, urethritis, and urinary urgency and frequency. Topical preparations generally should be prescribed as first-line therapy unless the patient is also experiencing vasomotor symptoms. Topical estrogen has demonstrated increased efficacy over systemic estrogen and does not require supplementation with a progestin in women with an intact uterus using low doses of micronized 17β-estradiol. Women using regular or high doses of other topical estrogen products do require intermittent treatment with a progestin. Although few data are available on the appropriate progestin dose, some data indicate that 10 days every 12 weeks may be sufficient to prevent endometrial hyperplasia.[16] Estradiol in the form of a tablet or a ring is not absorbed systemically and may be used safely in a woman with contraindications to estrogen therapy and symptoms of vulvovaginal atrophy.[17,18]

Osteoporosis Prevention

Postmenopausal osteoporosis is a condition that affects millions of women and is characterized by low bone mass with microarchitectural deterioration of bone tissue that can

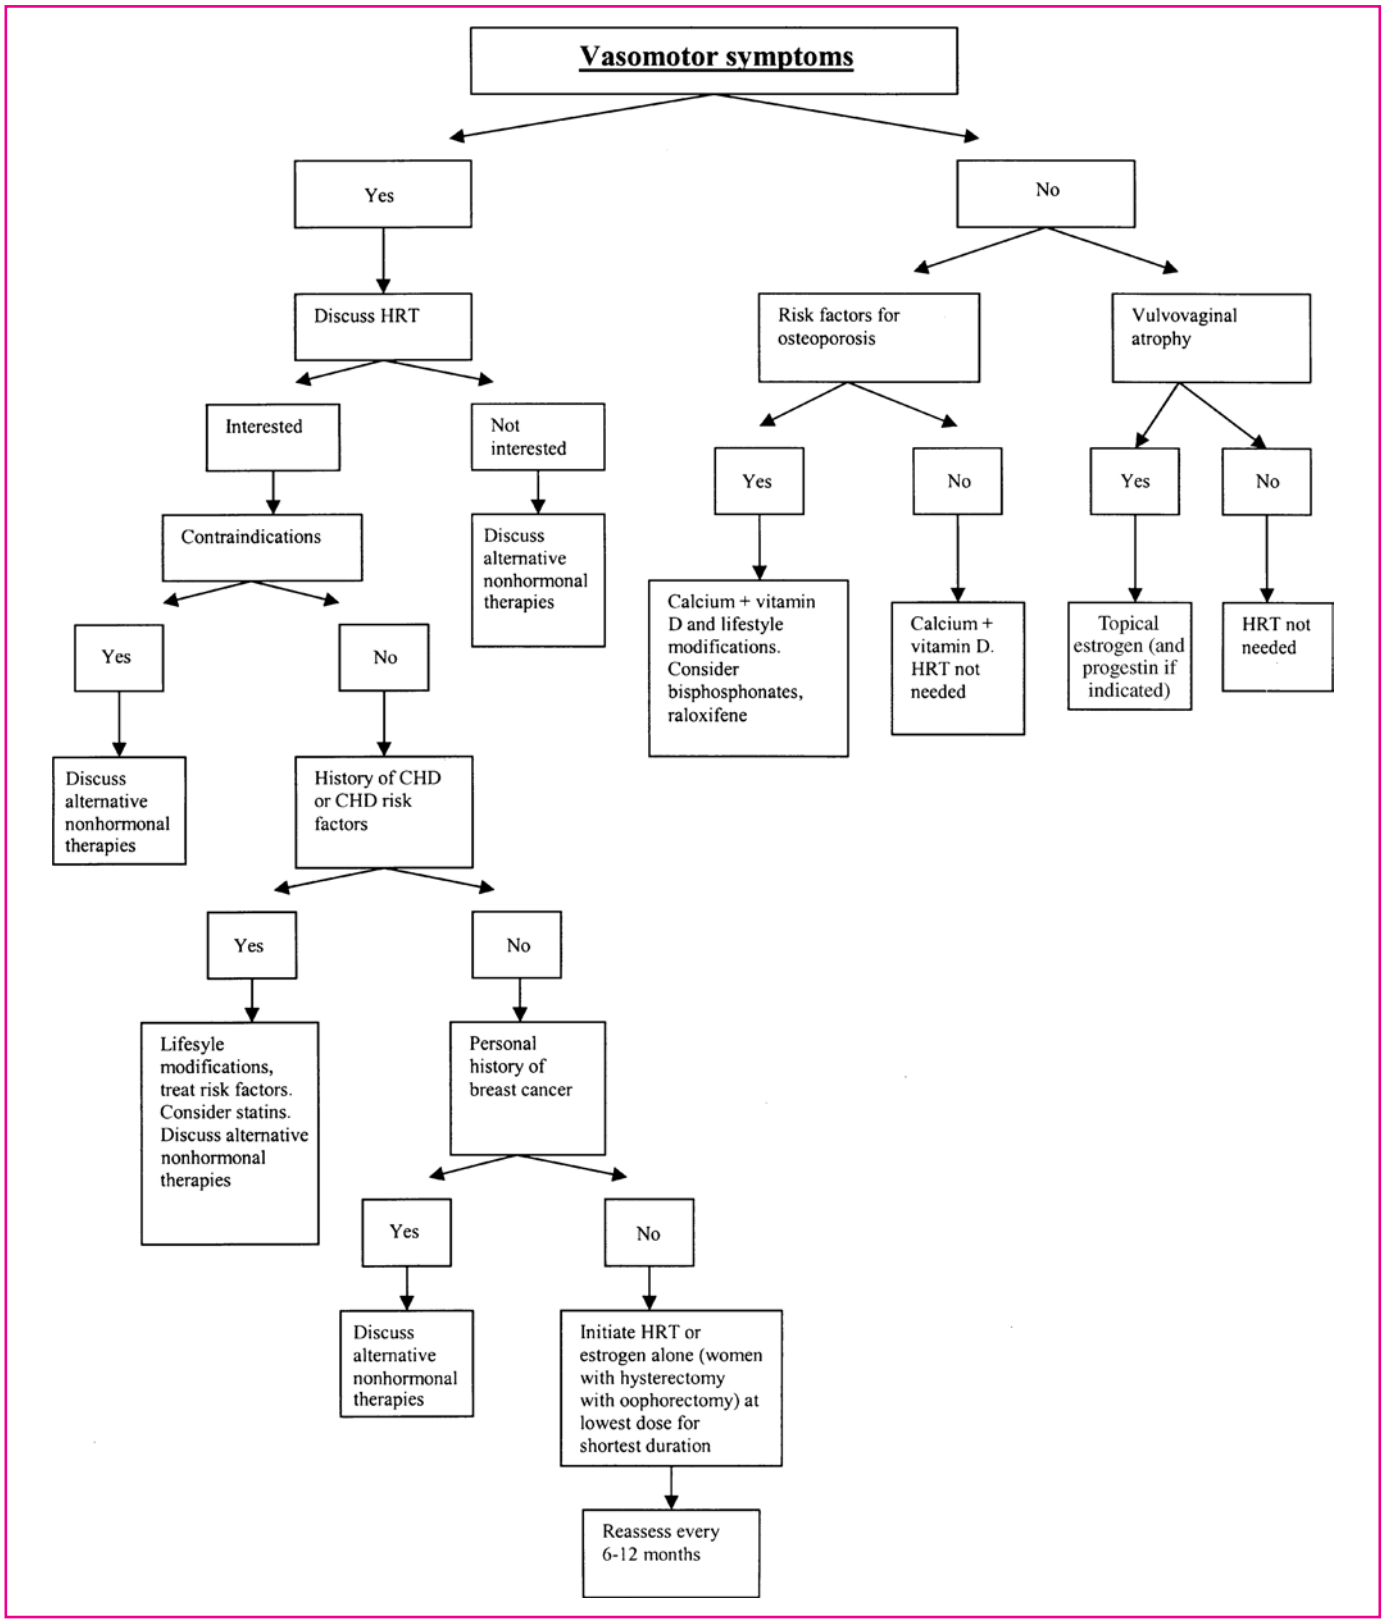

FIGURE 47–1. Treatment algorithm for postmenopausal women.[3,41,50]

lead to fractures.[19] Fractures, particularly hip fractures, are associated with a high incidence of morbidity and mortality and a decrease in quality of life (QOL). Before the WHI study, only observational data were available regarding the association of HRT and the reduction of fractures. The WHI was the first randomized controlled trial (RCT) that demonstrated a reduction in total fractures, including the hip, spine, and wrist. There were 138 fewer total fractures in women taking HRT (1.47%) compared with placebo (1.91%) [Hazard ratio (HR) 0.76, 95% confidence interval (CI) 0.69–0.85]. This translates into a number needed to treat (NNT) of 227 and 44 fewer overall fractures per year for every 10,000 women treated with HRT.[3,20] Similar benefit was found in the estrogen-alone arm.[21]

BMD will increase and the risk of fractures will decrease in women taking HRT. However, when therapy is discontinued, a decline in BMD will resume at the same rate as in women not on HRT. Therefore, therapy for osteoporosis prevention should be considered long term. ❻ *Since HRT should be maintained only for the short term, alternative therapies such as bisphosphonates or raloxifene should be considered as first-line therapy for the prevention of postmenopausal osteoporosis, in addition to appropriate doses of calcium and vitamin D.* Because of the risks associated with HRT, it should not be prescribed solely for the prevention of osteoporosis.

Colon Cancer

Retrospective observational studies suggested that HRT was associated with lower rates of colorectal cancer. The WHI was the first and largest RCT to confirm that HRT decreases the risk of colorectal cancer. In the WHI, there were 22 fewer cases of colorectal cancer in women taking HRT (0.1%) compared with placebo (0.16%) (HR 0.63, 95% CI 0.43–0.92). This translates into an NNT of 1666 and 6 fewer colorectal cancers per year for every 10,000 women treated with HRT.[3] In the WHI estrogen-alone arm, the cases of colorectal cancer were not lower in the estrogen group compared with the placebo group.[21] Unfortunately, these data are inconsistent and are not compelling enough to justify long-term use of estrogen-replacement therapy (ERT) or HRT.

Risks of Hormone-Replacement Therapy

Cardiovascular Disease

CHD is the leading cause of death among women in the United States. Retrospective data indicated that HRT was associated with a decrease in risk of CHD by 30% to 50%.[21] However, the results of recent RCTs demonstrate that HRT does not prevent or treat CHD in women and that it actually may cause an increase in CHD events. The HERS, published in 1998, was the first RCT conducted in women with established CHD. This trial demonstrated an increased incidence of CHD events within the first year of treatment with HRT and an increased risk of venous thromboembolism (VTE) and gallbladder disease. There was a trend of decreasing incidence of CHD death in years 3 to 5 that prompted a continuation of the study.[2] The HERS II was an open-label continuation of the HERS for an additional 2.7 years. No difference was found in CHD events between the HRT and placebo groups; however, there was an increased risk of VTE and biliary tract surgery in the HRT group.[22]

The WHI was the first RCT conducted in women without established CHD. Women aged 50 to 79 years with an intact uterus were assigned to receive HRT (CEE 0.625 mg + MPA 2.5 mg) daily for 8.5 years. The trial was stopped after only 5.2 years owing to an increased incidence of breast cancer in women taking HRT compared with placebo. The WHI demonstrated an increased risk of CHD within the first year of treatment of 0.37% in the HRT group compared with 0.3% in the placebo group (HR 1.29, 95% CI 1.02–1.63). This translates into a number needed to treat to harm (NNTH) of 1428. There also was an increased risk of stroke in the HRT group (0.29%) compared with placebo (0.21) (HR 1.41, 95% CI 1.07–1.85), with an NNTH of 1250. Therefore, for every 10,000 women treated per year with HRT, there would be 7 more CHD deaths and 8 more strokes.[3]

The estrogen-alone arm of the WHI, which included women aged 50 to 79 years with a history of hysterectomy, continued for another 1.6 years (average follow-up 6.8 years). This arm of the study did not demonstrate an increased risk of CHD in the ERT group compared with placebo. However, there was an increased risk of stroke in the ERT group (0.44%) compared with placebo (0.32%) (HR 1.39, 95% CI 1.10–1.77). This translates into an NNTH of 833 and 12 more strokes for every 10,000 women treated per year with ERT.[21]

The results of these trials demonstrate that ERT or HRT should not be prescribed for the prevention of CHD or in patients with preexisting CHD. For women suffering from vasomotor symptoms with a history of CHD, including CHD risk factors, alternative therapies should be considered. Additionally, lifestyle modifications should be implemented, and therapies to treat risk factors such as hypertension and hyperlipidemia should be prescribed. It is important to note that the average age of women included in the HERS and the WHI trials was 67 and 63 years, respectively. Therefore, these trials were unable to assess the true risk in younger, potentially healthier women with fewer cardiovascular risk factors.

Breast Cancer

Breast cancer is the most common cancer in women in the United States. Observational data indicated an association between HRT and breast cancer risk. The WHI was the first RCT to demonstrate an increased risk of invasive breast cancer among women taking HRT. In fact, the trial was stopped early owing to an increased incidence of breast cancer in women taking HRT (0.38%) compared with placebo (0.3%) (HR 1.26, 95% CI 1–1.59). This translates into an NNTH of 1250 and 8 more cases of invasive breast cancer for every 10,000 women treated per year with HRT. The risk of breast

cancer was evident after only 3 years of treatment and continued throughout the study duration. In this arm of the study, breast cancer was diagnosed at a more advanced stage in the HRT group compared with placebo. In addition, the percentage of women with abnormal mammograms after 1 year was significantly higher in women taking HRT than in those taking a placebo.[3,23]

Breast cancer was not increased in the ERT arm of the WHI, and in fact, the risk was non-significantly lower in the ERT group than in the placebo group.[21] These conflicting data point to a possible link of progestin with breast cancer risk; however, this theory needs to be studied further.

Because the WHI is the best evidence to date linking HRT with breast cancer, women with a personal history of breast cancer and possibly even a strong family history of breast cancer should avoid the use of HRT and consider non-hormonal alternatives for the treatment of vasomotor symptoms.

Venous Thromboembolism

The WHI demonstrated an increased risk in venous thromboembolic disease in the HRT group (0.34%) compared with placebo (0.16%) (HR 2.11, 95% CI 1.58–2.82). This translates into an NNTH of approximately 555 and 18 more cases of venous thromboembolic events for every 10,000 women treated per year with HRT.[3] The risk for deep vein thrombosis also was increased in the ERT arm of the WHI, but pulmonary embolism was not increased significantly.[21]

Observational and prospective data have consistently demonstrated an increased risk in thromboembolic events with the use of HRT.[2,3,19,20] Women taking HRT have approximately doubled the risk of those not taking HRT. Therefore, these risks need to be weighed carefully when considering the use of HRT for the treatment of vasomotor symptoms.

❼ *In summary, combined estrogen plus progestin should not be used for the prevention of chronic diseases because it increases the risk of CHD, stroke, breast cancer, and venous thromboembolism. However, colorectal cancer and rates of fracture were reduced with combined hormonal treatment.*

Other Effects of Hormone-Replacement Therapy

Quality of Life and Cognition

Although women generally consider QOL measures when deciding whether to use HRT, the effects of HRT on overall QOL have been inconsistent. HRT or ERT did not demonstrate a clinically meaningful effect on QOL; however, women taking HRT did have a small improvement in sleep disturbances, physical functioning, and bodily pain after 1 year of therapy.[24] Results from the HERS demonstrated that HRT did improve emotional measures such as depressive symptoms, but only if women suffered from flushing at trial entry. QOL scores declined significantly in women without flushing symptoms.[25] Although mood and well-being may be improved in women with vasomotor symptoms, HRT should not be prescribed for the sole purpose of improving QOL measures.

The prevalence of age-associated memory impairment is approximately 17% to 34% in the general population.[26] Observational studies have suggested a potential benefit of HRT on cognitive functioning and dementia. However, the WHI Memory Study (WHIMS), conducted in postmenopausal women aged 65 years or older, failed to demonstrate an improvement in cognitive function and demonstrated a dementia rate, including Alzheimer's disease, two times greater than with placebo (HR 2.05, 95% CI 1.21–3.48). In addition, women receiving HRT experienced a small decline in cognitive function compared with placebo.[26,27] The estrogen-alone arm of the WHIMS also demonstrated similar results.[28,29]

❽ *In summary, HRT improves overall well-being and mood in women with vasomotor symptoms, but it has not demonstrated an improvement in QOL in women without vasomotor symptoms, does not improve cognitive function, and has little effect, if any, on QOL measures.*

Discontinuation of HRT

❾ *In appropriate women, HRT should be recommended at the lowest dose for the shortest duration and should be tapered before discontinuation in order to prevent the recurrence of hot flashes.* It is not entirely clear what time interval is considered safe for HRT because some of the risks associated with HRT were found within the first year of treatment. It is also not clear how long vasomotor symptoms will last in each woman. Although vasomotor symptoms in most women will subside within 4 years, approximately 10% of women continue to experience symptoms that interfere with their QOL. Therefore, it is important to continually reassess a woman's vasomotor symptoms while taking HRT and to try to taper the therapy after 1 year. If symptoms return following a slow taper of HRT, it may be reinitiated and tried again at a later date. However, the literature suggests that one of every four women need to be reinitiated on HRT owing to persistent and bothersome symptoms.[30–32]

Discontinuing HRT can be complicated. Little evidence is available to guide health care providers regarding the most effective, safe, and least disruptive way to taper HRT. Slowly discontinuing HRT over time may be associated with less risk of symptom return. This rationale makes sense when you compare vasomotor symptoms in women who undergo surgical menopause with those in women undergoing natural menopause. It is generally thought that the rapid decline in estrogen concentrations leads to more severe vasomotor symptoms. However, the time frame for tapering HRT is unknown but can take up to 3 to 6 months or longer in some cases. Tapering HRT may be done in one of two ways: dose taper or day taper. The dose taper involves decreasing the dose of estrogen over several weeks to months and monitoring closely for a return of symptoms. If symptoms recur, the next reduction in dose should not occur until symptoms resolve or at least

stabilize on the current dose. The day taper involves decreasing the number of days of the week that a woman takes the HRT dose, e.g., decreasing a daily dose of 0.3 mg estrogen to 0.3 mg estrogen 5 days a week. Again, if symptoms recur, continue on the current dose until symptoms resolve or stabilize before trying a subsequent decrease. It is important to note that these tapering regimens have not been studied in clinical trials and may not prove to be beneficial in individual women.[32]

For women who cannot tolerate even a very slow taper, the benefits must be weighed against the risks of HRT, and often women choose to continue HRT. Alternative, non-hormonal therapies are available and may be beneficial in some women; however, the literature suggests that these therapies are less effective than HRT.

Non-hormonal Treatments

⓾ *Since publication of the WHI study, there has been an increase in the use of non-hormonal therapies for the management of menopausal symptoms. Particularly for women with CHD and breast cancer risk factors, non-hormonal therapies may offer an alterative to assist with symptom management. A wide range of therapies, both prescription and herbal, have been studied with varying degrees of success. In choosing a particular therapy, it is important to match patient symptoms with a therapy that is not only effective but also safe.*

A number of non-hormonal therapies have been studied for symptomatic management of vasomotor symptoms, including antidepressants [e.g., selective serotonin reuptake inhibitors (SSRIs) and venlafaxine], herbal products (e.g., soy, black cohosh, and dong quai), and a group of miscellaneous agents (e.g., gabapentin, clonidine, and megestrol). The choice of therapy depends on the patient's concomitant disease states, such as depression and hypertension, and the risk for potential adverse effects.

SSRIs are theorized to reduce the frequency of hot flashes by increasing serotonin in the central nervous system and by decreasing LH. Of the SSRIs, citalopram, paroxetine, and sertraline all have been studied and have demonstrated a reduction in hot flashes while treating other symptomatic complaints such as depression and anxiety.[33] Venlafaxine, which blocks the reuptake of serotonin and norepinephrine, has demonstrated a reduction in hot flashes primarily in the oncology population.[34] Overall, these antidepressant medications offer a reasonable option for women who are unwilling or cannot take hormonal therapies, particularly those who suffer from depression or anxiety. These agents should be prescribed at the lowest effective dose to treat symptoms and may be titrated based on individual response.

Herbal products used for the relief of menopausal symptoms are purported to act by a number of different mechanisms. Phytoestrogens are plant sterols that are structurally similar to human and animal estrogen. Soy protein is a common source of phytoestrogens and can be found in products such as tofu, soy milk, soy flour, and tempeh. Various studies have demonstrated conflicting results as to the efficacy of phytoestrogens in treating hot flashes.[33,35] It is also unknown as to whether phytoestrogens contribute to or protect from breast cancer. Therefore, careful consideration should be given before widely recommending soy protein to patients.

Black cohosh has been one of the most studied herbal remedies for vasomotor symptoms, and it has not demonstrated a substantial benefit over placebo. The mechanism of action, safety profile, drug-drug interactions, and adverse effects of black cohosh remain unknown. In non-placebo-controlled trials conducted for 6 months or less, black cohosh demonstrated a small reduction in vasomotor symptoms. It has not been shown to be effective for vasomotor symptoms in women with breast cancer.[33] There have been case reports of hepatotoxicity with the use of black cohosh.[36] Caution should be exercised when considering the use of this product, especially in patients with liver dysfunction.

Dong quai and several other herbal products, including evening primrose oil, passion flowers, sage, valerian root, flaxseed, and wild yam, have not demonstrated efficacy with regard to the relief of vasomotor symptoms, and the safety of these products is also questionable.[4,33,35] Therefore, these products should not be recommended for the relief of vasomotor symptoms in postmenopausal women.

There are a number of other prescription products that have been studied for the management of menopausal symptoms. Gabapentin is thought to exert its effect by affecting the thermoregulatory process of the pituitary-hypothalamic region through modulation of calcium currents that, in turn, affect adrenergic and serotonergic pathways. In an RCT, gabapentin was titrated to 300 mg three times daily for 12 weeks and demonstrated a 66% reduction in the frequency of hot flashes. Further symptom reduction was noted when the gabapentin dose was increased to 2700 mg daily and was safe for short-term therapy.[37] Clonidine is thought to work by reducing small-vessel response, both centrally and peripherally, to various stimuli. It has been studied in several small RCTs and demonstrated statistically significant reductions in hot flashes.[38,39] This agent may be considered in women with a history of hypertension, but the adverse effects of this medication may outweigh the benefits. Since the early 1970s, a combination of belladonna and phenobarbital (Bellergal S®) has been used to treat hot flashes. Bellergal S® is no longer available in the United States, but a similar product, Bellamine® and Bellamine S® [belladonna alkaloids (0.2 mg), ergotamine tartrate (0.6 mg), and phenobarbital (40 mg)] are available in the United States. Although early studies have demonstrated a reduction in hot flashes compared with placebo, the adverse events associated with these products have resulted in a greater than 30% withdrawal rate. Therefore, these products should not be recommended for hot flashes owing to the adverse-effect profile.[39] Lastly, megestrol has been used to manage hot flashes in patients with breast cancer and has demonstrated efficacy in this population. Long-term serious adverse effects limit its use, and it should not be prescribed routinely as an alternative to HRT for the relief of vasomotor symptoms.[40]

TABLE 47–3. Non-hormonal Therapies for Menopause[4,33,34,37–40,46–49]

Agent	Demonstrated Efficacy	Dosing	Adverse Effects/Precautions
Citalopram	Non-randomized trial demonstrated efficacy in hot flash reduction	20–60 mg daily	Nausea, dizziness, somnolence
Fluoxetine	RCT in breast cancer patients demonstrating 50% decrease in hot flash score	20 mg daily	Nausea, insomnia, nervousness, fatigue
Paroxetine	RCT demonstrating 37.8–62.2% reduction in hot flashes	10–20 mg daily	Headache, nausea, insomnia
Sertraline	Case series demonstrating efficacy in hot flash reduction	25–50 mg daily	Nausea, dizziness, somnolence
Venlafaxine	RCT in breast cancer patients demonstrating 55% reduction in hot flashes	12.5 mg twice daily	Nausea, dry mouth
Soy protein	Conflicting evidence; short-term (less than 6 weeks) symptomatic relief demonstrated; benefit questionable	50–80 mg isoflavones daily	GI upset; other adverse effects unknown
Black cohosh	Short-term (less than 6 months) symptomatic relief demonstrated	Varied dosing based on herbal product combination; most studied: *Reminfemin*® 20–80 mg twice daily	GI upset (take with food); potential hepatoxicity
Gabapentin	RCT demonstrating 45% reduction in hot flash frequency	300–1600 mg daily	Dizziness and somnolence
Clonidine	Demonstrated efficacy in hot flash reduction in most trials	Variety of dose regimens; most common 0.1–0.4 mg daily	Dry mouth, blood pressure lowering; monitor blood pressure
Bellamine S®	Decreased hot flashes versus placebo; withdrawal rate greater than 30% owing to adverse effects	2 tablets daily	Dry mouth, skin rash, dizziness, sleepiness
Megestrol	RCT in breast cancer patients demonstrating up to 80% reduction in hot flashes	20–40 mg daily	Vaginal bleeding, headache, weight gain, thromboembolism, edema
Dong quai	No demonstrated efficacy	Not recommended	Structurally similar to coumarins—avoid with warfarin because INR can increase
Evening primrose oil, passion flowers, sage, valerian root, and wild yam	No demonstrated efficacy	Not recommended	Caution with all plant products in women with hay fever and plant allergies

Overall, non-hormonal therapies are less effective in treating vasomotor symptoms than HRT but do offer an important option for women experiencing menopausal symptoms who cannot or are unwilling to take HRT. The antidepressants gabapentin and clonidine have the best evidence for efficacy of all the non-hormonal options and should be considered first as an alternative to HRT. The most important considerations in choosing an alternative therapy are the patient's comorbidities and the efficacy and safety of the medication.

OUTCOME EVALUATION

Evaluating the outcomes of any hormonal or non-hormonal therapy for menopausal symptoms focuses primarily on the patient's report of symptom resolution. Ask patients to report the resolution or reduction of hot flashes, night sweats, and vaginal dryness and any improvement or change in sleep patterns. Also ask women taking hormonal therapies to report any breakthrough bleeding or spotting. If abnormal or heavy bleeding occurs, refer the patient to her primary care provider. Monitor subjective parameters such as adverse effects and adherence to the therapy regimen, as well as monthly breast self-examinations. In addition, monitor objective parameters, including blood pressure, at every outpatient visit; encourage yearly clinical breast examinations, mammograms, and TSH determination, particularly for women with hypothyroidism on thyroid therapy, and conduct a BMD test every 5 years. Also perform endometrial studies, as necessary, in women with undiagnosed vaginal bleeding. Lastly, evaluate the patient's overall QOL. Because the management of menopause is largely symptomatic, it is important to document symptoms at the beginning of therapy and monitor symptom improvement and potential adverse effects at each visit. Frequent follow-up, proper monitoring, and education will help to ensure that the patient achieves optimal results from any hormonal or non-hormonal therapy chosen to treat menopausal symptoms.

Patient Encounter, Part 3: Creating a Care Plan

Based on the information presented, create a care plan for BW's hot flashes and vaginal dryness. The plan should include: (1) a statement identifying the patient problem and its severity, (2) goals of therapy, (3) a therapeutic plan based on individual patient-specific factors, (4) subjective and objective monitoring parameters, and (5) a follow-up evaluation to assess for adverse effects and adherence and to determine if the goals of therapy have been achieved.

Patient Care and Monitoring

1. Assess the patient for use of HRT by evaluating for the presence of vasomotor symptoms. If the patient is experiencing bothersome vasomotor symptoms, consider the use of HRT only after assessing for risk factors for heart disease and breast cancer. If vasomotor symptoms are tolerable and/or the patient has risk factors for heart disease and/or breast cancer, consider alternative, non-hormonal treatments for vasomotor symptoms.
2. Obtain a thorough medication history, including the use of over-the-counter and herbal products.
3. Educate the patient on lifestyle or behavioral interventions that may help to alleviate vasomotor symptoms.
4. Discuss methods of HRT administration, and have the patient decide in conjunction with the health care provider which one she feels will work best for her.
5. Recommend the appropriate dose of HRT, and use the lowest effective dose for the shortest duration possible.
6. Educate the patient regarding the proper administration, potential adverse effects, and expectations of HRT.
7. Monitor the patient for a reduction in vasomotor symptoms, vaginal dryness, and improvement in sleep. Also monitor for breakthrough bleeding and spotting, adverse effects of HRT, and improvement in QOL.
8. Monitor the following objective parameters:
   - Blood pressure at every outpatient visit
   - Yearly lipoprotein panels
   - Yearly fasting plasma glucose determinations
   - Yearly breast examinations and mammograms
   - Yearly TSH determinations, particularly for women with hypothyroidism on thyroid therapy
   - Endometrial studies in women with undiagnosed vaginal bleeding
9. Educate the patient regarding the importance of adhering to the medication regimen.
10. Educate the patient regarding the importance of obtaining a yearly mammogram and Papanicolaou (Pap) smear (if applicable), as well as performing a monthly breast self-examination.
11. Assess patient symptoms every 6 to 12 months, and consider tapering the HRT dose and discontinuing treatment after 1 year. If vasomotor symptoms return, determine if a longer tapering schedule is warranted or if long-term treatment is necessary.

48 Erectile Dysfunction

Cara Liday and Catherine Heyneman

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Identify the structures of the male reproductive system and describe the physiology of a penile erection.
2. Differentiate between organic and psychogenic erectile dysfunction (ED) and describe the etiology and pathophysiology of each.
3. Identify the drug classes most likely to contribute to erectile dysfunction.
4. Define the essential components of history, physical examination, and laboratory data needed to evaluate the patient presenting with ED.
5. Describe current nonpharmacologic and pharmacologic options for treating ED and determine an appropriate first-line therapy for a specific patient.
6. Compare and contrast the benefits and risks for the current phosphodiesterase inhibitors.
7. Identify patients with significant cardiovascular risk and recommend an appropriate treatment approach for their ED.

Key Concepts

❶ ED can be classified as organic, psychogenic, or mixed. Many patients may initially have organic dysfunction, but develop a psychogenic component as they cope with their inability to achieve an erection.

❷ The introduction of oral medications and direct-to-consumer advertising has made patients feel more comfortable approaching practitioners for treatment advice.

❸ A thorough medical history with emphasis on cardiac disease must be taken before starting any treatment for ED to assess for ability to safely perform sexual activity and to assess for possible drug interactions.

❹ A wide range of treatment options are now available for men with ED. These include medical devices, pharmacologic treatments, lifestyle modifications, surgery, and psychotherapy.

❺ When determining the best treatment for an individual, the role of the clinician is to inform the patient and his partner of all available options while understanding his medical history, desires, and goals. The choice of treatment is primarily left up to the couple, but most often treatment is initiated with the least invasive option and then progresses to more invasive options if needed.

❻ Vacuum erection devices and intracavernosal injections are highly effective for many patients, but side effects, lack of spontaneity, and fear of needles limit their widespread use as first-line therapy.

❼ Effectiveness of the three available phosphodiesterase inhibitors is essentially comparable, but differences exist in duration of action, and to a small degree, incidence of side effects and drug interactions.

❽ Androgens are important for general sexual function and libido, but testosterone supplementation is only effective in patients with documented low serum testosterone levels.

Erectile dysfunction (ED) is defined as the inability to achieve or maintain an erection sufficient for sexual intercourse. The definition is very subjective due to differences in desired or needed rigidity in patients of different ages and in different types of relationships. Patients may refer to their dysfunction as impotence, but the National Institutes of Health Consensus Development Conference recommends that the term "erectile dysfunction" replace the term impotence due to confusion with other forms of sexual dysfunction and the negative connotation associated with the term impotence.[1] Patients may also develop **libido** or ejaculatory disorders, but these are not considered erectile dysfunction.

Patient Encounter, Part 1

A 52-year-old man with type 2 diabetes, hypertension, and dyslipidemia returns to your clinic for follow-up on his chronic disease states. When reviewing his history, he describes problems achieving a firm erection. After further questioning, you determine that his dysfunction has progressively gotten worse over the last year. He is quite emotional and states that the problem is distressing and has caused significant marital discord. He wonders about "those ads on television" suggesting a pill.

- What other information do you need to assess for ED?
- Does he have risk factors for ED?
- Would his ED most likely be organic or psychogenic?

EPIDEMIOLOGY AND ETIOLOGY

ED becomes increasingly frequent as men age. According to data from the Massachusetts Male Aging Study the prevalence of ED of any degree is 40% among 40-year-old men and 70% among 70-year-old men.[2] The increase in incidence could be due to physiologic changes that occur with aging, the onset of chronic disease states associated with ED, increased medication use, lifestyle factors, or a combination of the above.

PATHOPHYSIOLOGY

The penis consists of three components, two dorsolateral corpora cavernosa and a ventral corpus spongiosum that surrounds the penile urethra and distally forms the glans penis. The corpora cavernosa consist of blood-filled sinusoidal or lacunar spaces, which are lined with endothelial cells, supported by trabecular smooth muscle, and surrounded by a thick fibrous sheath called the tunica albuginea. The cavernosal arteries, which are branches of the penile artery, penetrate the tunica albuginea and supply blood flow to the penis.

Sympathetic and parasympathetic nerves innervate the penis. In the flaccid state, α_2-adrenergic receptors mediate tonic contraction of the arterial and corporal smooth muscles. This maintains high penile arterial resistance and a balance exists between blood flow into and out of the corpora. With sexual stimulation, nerve impulses from the brain travel down the spinal cord to the thoracolumbar ganglia.[3] A decrease in sympathetic tone and an increase in parasympathetic activity then occurs, causing a net increase in blood flow into the erectile tissue. Erections may also occur as a result of a sacral nerve reflex arc while patients are sleeping (nocturnal erections).

Acetylcholine-mediated parasympathetic activity leads to production of the non-adrenergic–non-cholinergic transmitter nitric oxide. By enhancing the activity of guanylate cyclase, nitric oxide increases the production of cyclic guanosine monophosphate (cGMP). Vasoactive peptide and prostaglandins E_1 and E_2 stimulate increased production of cAMP. Both cyclic adenosine monophosphate (cAMP) and cGMP ultimately lead to a decrease in calcium concentration within smooth muscle cells of the penile arteries and the sinusoidal spaces, leading to smooth muscle relaxation and increased blood flow. As the sinusoidal spaces become engorged, intracavernosal pressure increases, subtunical venules are compressed, and the penis becomes rigid and elongated (Fig. 48–1).

Detumescence occurs with sympathetic discharge after ejaculation. Sympathetic activity induces smooth muscle contraction of arterioles and vascular spaces leading to a reduction in blood inflow, decompression of the sinusoidal spaces, and enhanced outflow.

Testosterone also plays a significant albeit complex role in erectile function. Testosterone is responsible for much of a man's libido. With low serum concentrations, libido declines. Additionally, testosterone helps with stabilization of intracavernosal levels of nitric oxide synthase, the enzyme responsible for triggering the nitric oxide cascade. Interestingly, some patients with low or borderline low serum concentrations of testosterone will have normal erectile function, while some with normal levels will have dysfunction.

Normal penile erections are complex events that require the full function of the vascular, neurologic, and hormonal systems. Anything that affects the function of these systems may lead to ED. ❶ *ED can be classified as organic, psychogenic, or a mixture of these.* Organic dysfunction includes abnormalities in the three systems responsible for a normal erection or may be medication-induced (Tables 48–1 and 48–2). Note that many of the risk factors for ED are the same as risk factors for cardiovascular disease. In many patients, ED is the first indication of the endothelial dysfunction associated with cardiovascular disease.[4] The presence of ED risk factors leads to the assumption that the patient has organic dysfunction. Most commonly, medical conditions that impair arterial flow into or out of the erectile tissue or affect the innervation will be strongly associated with ED. Patients with diabetes mellitus have exceptionally high rates of ED as a result of vascular disease and neuropathy.

Psychogenic dysfunction occurs if a patient does not respond to psychic arousal. It occurs in up to 30% of all cases of ED. Common causes include performance anxiety, strained relationships, lack of sexual arousability, and overt psychiatric disorders such as depression and schizophrenia.[5] It is postulated that the anxious or nervous man will have excessive stimulation of the sympathetic system, leading to smooth muscle contraction of arterioles and vascular spaces within erectile tissue.[6] ❶ *Many patients may initially have organic dysfunction, but develop a psychogenic component as they try to cope with their inability to achieve an erection.* It has been estimated that up to 80% of ED cases have an organic cause, with many having a psychogenic component as well.[1]

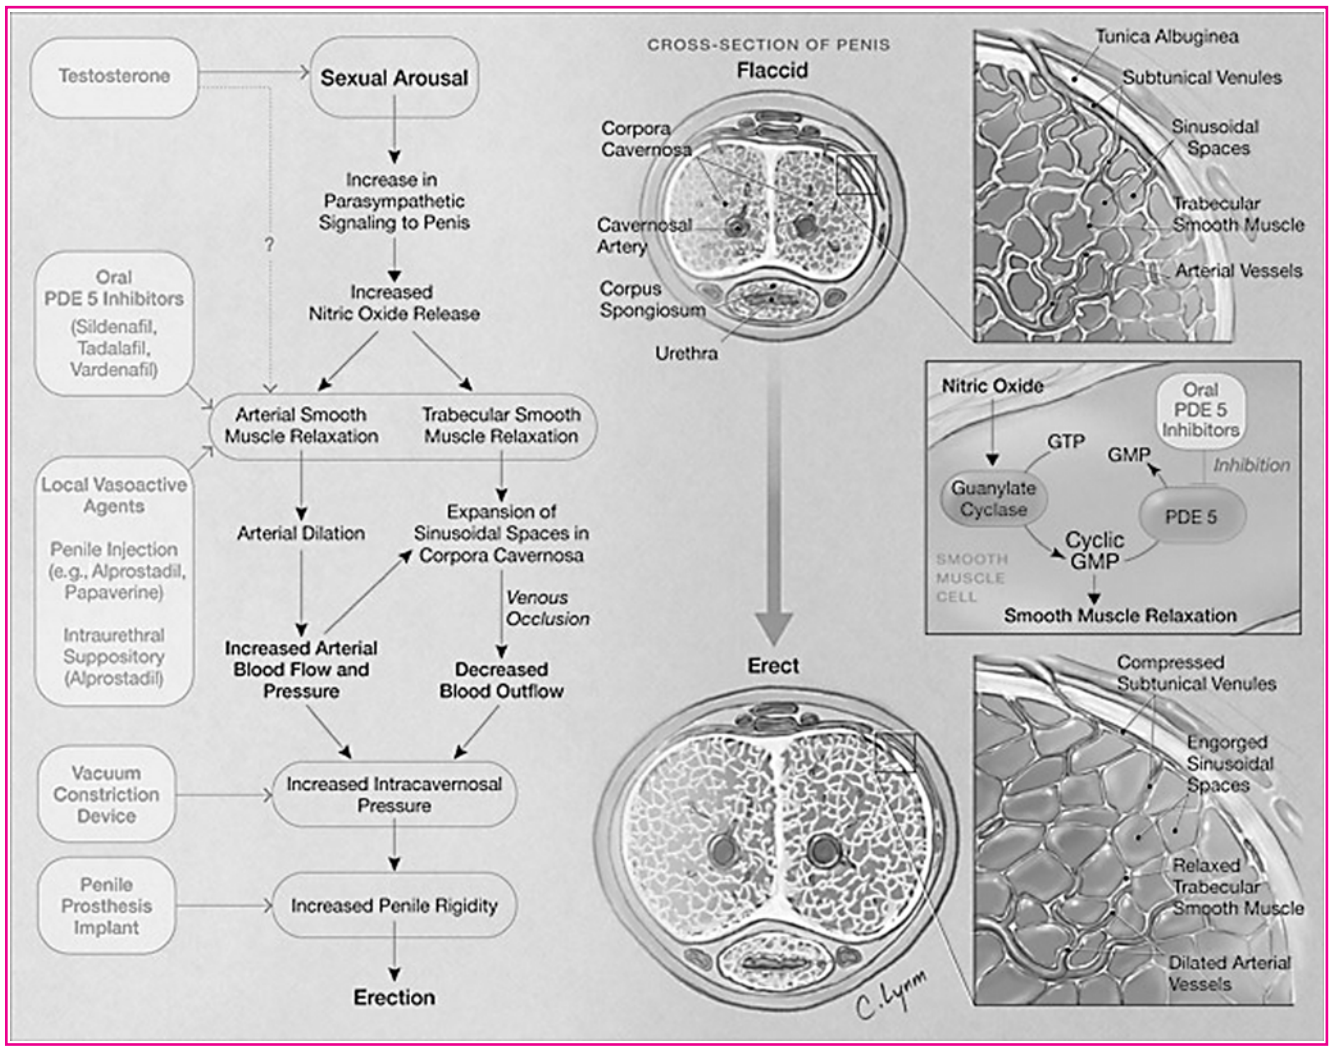

FIGURE 48–1. Mechanism of erection and sites of action of various treatment modalities for erectile dysfunction. Penile erection is achieved through relaxation of smooth muscle cells lining arterial vessels and sinusoidal spaces in the corpora cavernosa, which leads to increased arterial inflow and pressure, decreased venous outflow, and increased intracavernosal pressure. Smooth muscle relaxation is mediated by intracellular generation of cyclic guanosine monophosphate (cyclic GMP) from guanosine triphosphate (GTP) via activation of guanylate cyclase by nitric oxide. Treatment modalities for erectile dysfunction (shown in blue) include oral phosphodiesterase type 5 (PDE 5) inhibitors, which inhibit the breakdown of cyclic GMP, and local vasoactive agents. A link between testosterone and nitric oxide synthase has been demonstrated experimentally, but the significance of this observation in humans has not been established (indicated by the dashed line and question mark). Psychotherapy (not shown) may also be effective in selected individuals with erectile dysfunction. (From Morgentaler A. A 66-year-old man with sexual dysfunction. JAMA 2004;291:2996, with permission.)

CLINICAL PRESENTATION AND DIAGNOSIS

❸ *The evaluation of a patient presenting with ED should consist of a thorough medical history including sexual and psychosocial issues to determine if the dysfunction is psychogenic.* In addition, a directed physical exam and laboratory tests should be performed such as total and free serum testosterone, serum glucose, a fasting lipid panel, and a thyroid panel.[9] Identification of concomitant disease states is important for determining first line therapy. Some medical conditions and their associated medications contraindicate the use of some ED therapies or may lead to drug interactions. It is also necessary to assess the patient's ability to safely perform intercourse and to review lifestyle factors such as smoking, alcohol consumption, and regular exercise.

The International Index of Erectile Dysfunction (IIED) is the most widely used questionnaire to assess the severity of ED.[10] It consists of 15 questions with 5 domains: erectile function, libido, orgasmic function, sexual satisfaction, and overall satisfaction. The erectile function domain has a maximum score of 30 with a score of less than 26 indicating some degree of ED.

TABLE 48–1. Factors Associated with Erectile Dysfunction

Chronic Medical Conditions
Hypertension
Diabetes mellitus
Inflammatory conditions of the prostate
Coronary and peripheral vascular disease
Neurologic disorders (e.g., Parkinson's disease and multiple sclerosis)
Endocrine disorders (hypogonadism and pituitary, adrenal, and thyroid disorders)
Psychiatric disorders (depression, anxiety, and schizophrenia)
Hyperlipidemia
Renal failure
Liver disease
Penile disease (Peyronie's disease or anatomic abnormalities)
Surgical Procedures
Perineal surgery
Radical prostatectomy
Vascular surgery
Lifestyle
Age
Smoking
Excessive alcohol consumption
Obesity
Poor overall health and reduced physical activity
Trauma
Pelvic fractures
Spinal cord injuries

TABLE 48–2. Medication Classes Associated with Erectile Dysfunction[3,24,25]

Antihypertensives
β-Blockers (particularly non-selective)
Thiazide diuretics
Centrally acting agents (clonidine, methyldopa, and reserpine)
Spironolactone
α-Blockers
Lipid medications
Gemfibrozil
Antidepressants
Tricyclic antidepressants
Monoamine oxidase inhibitors
Selective serotonin reuptake inhibitors
Antipsychotics
Phenothiazines
Risperidone
Lithium
Anticonvulsants
Carbamazepine
Phenytoin
Histamine antagonists
Cimetidine
Anti-androgens and hormones
5α-Reductase inhibitors
Progesterone and estrogen
Recreational drugs
Ethanol
Cocaine
Marijuana

Clinical Presentation of ED[7,8]

❷ *The introduction of oral medications and direct-to-consumer advertising has made patients feel more comfortable approaching practitioners for treatment advice*. Despite this, some patients may only discuss their dysfunction when questioned directly by their provider or if their partner initiates the interaction. Patients may still feel that a loss in erectile function translates into a loss of masculinity.

Patients presenting with ED may show some of the following signs and symptoms:

- Embarrassment
- Anxiousness
- Anger
- Marital problems
- Low self-confidence or morale
- Full inability to achieve erections
- Ability to achieve partial erections, but not suitable for intercourse
- Erections sufficient for intercourse, but early detumescence
- The problem may have a slow or acute onset, or may wax and wane

ED may be the presenting symptom of other chronic disease states.

TREATMENT

Desired Outcomes

ED is not a life-threatening condition, but left untreated it can be associated with depression, loss of self-esteem, poor self-image, and marital discord.[11] The primary goal of therapy is achievement of erections suitable for intercourse and improvement in patient quality of life. Additionally, the ideal therapy should have minimal side effects, be convenient to administer, have a quick onset of action, and have few or no drug interactions.[7]

General Approach to Treatment

After determining if the ED is organic or psychogenic, the initial step in management is to identify associated disease states and lifestyle activities that adversely affect erectile function and treat them optimally. Medications suspected to cause or worsen ED should also be discontinued if possible.

❹ *A wide range of treatment options are now available for men with ED. These include medical devices, pharmacologic treatments, lifestyle modifications, surgery, and psychotherapy.*

❺ *When determining the best treatment for an individual, the role of the clinician is to inform the patient and his partner of all available options while understanding his medical history, desires, and goals. Most often treatment is initiated with the least invasive option and then treatment progresses to more*

Patient Encounter, Part 2: Medical History, Physical Exam, and Diagnostic Tests

PMH
Type 2 diabetes for 15 years; not controlled due to his stressful profession; he often works late, eats on the run, and has no time for exercise
Hypertension for 8 years, currently uncontrolled
Dyslipidemia for 8 years, currently controlled

FH
Father had type 2 diabetes and died of myocardial infarction at the age of 50 years; mother is alive at 75 with no major illnesses

SH
Works long hours as a business executive; drinks alcohol only occasionally, but smokes $^1/_2$ pack per day; has a 20 pack per year history

Meds
Metformin 1000 mg PO twice daily
Metoprolol XL 50 mg PO once daily
Zocor 20 mg PO once daily

ROS
(–) Morning, nocturnal, or spontaneous erections suitable for intercourse; (–) nocturia, urgency, symptoms of prostatitis; (+) significant life stressors; (+) mild pain in feet

PE
VS: Blood pressure 148/90 mm Hg, pulse 85 beats per minute, respiratory rate 18/minute, temperature 37.0°C (98.6°F)
CV: Normal exam
Genit/Rect: Normal scrotum and testicles w/o masses; penis without discharge or curvature

Labs
Complete metabolic panel, complete blood cell count, and thyroid panel within normal limits
Lipid panel: total cholesterol , low-density lipoproteins, high-density lipoproteins, triglycerides within normal limits
Hemoglobin A1c: 8.0% (0.08), testosterone: 700 ng/dL (24 nmol/L)

- Given this additional information, what is your assessment of the patient's condition? What is/are the most likely causes of his ED?
- Identify treatment goals for this patient.
- What pharmacologic and nonpharmacologic alternatives are available for this patient?
- Which of the above will be your treatments of choice based on degree of invasiveness, side effects, ease of use, and side-effect profile?
- What other information do you need before starting certain pharmacotherapeutic options?

invasive options if needed. Ultimately, the choice of therapy should be individualized, taking into account patient and partner preferences, concomitant disease states, response, administration, cost, tolerability, and safety. Common drug treatment regimens for ED are listed in Table 48–3.

Nonpharmacologic Therapy

Lifestyle Modifications

Lifestyle modifications should always be addressed in the management of ED. A healthy diet, increase in regular physical activity, and weight loss are associated with higher IIED scores and an improvement in erectile function.[12] The clinician should recommend smoking cessation, reduction in excessive alcohol intake, and discontinuation of the use of illicit drugs.

Psychotherapy

Psychotherapy is an appropriate treatment approach for patients with psychogenic or mixed dysfunction. It should address immediate causes of dysfunction, and if possible the partner should attend sessions as well. Effectiveness is not well documented for organic dysfunction unless combined with other therapies. Advantages include non-invasiveness and partner participation, while disadvantages include increased cost and time commitment.

Vacuum Erection Devices

Vacuum erection devices (VEDs) induce erections by creating a vacuum around the penis; the negative pressure draws blood into the penis by passively dilating arteries and engorging the corpora cavernosa. The erection is maintained with a constriction band placed at the base of the penis to reduce venous outflow (Fig. 48–2). They may be used as often as desired, but it is recommended that the constriction band not be in place longer than 30 minutes at a time.

❻ *VEDs are one of the most effective treatment modalities for ED. They have a success rate of greater than 90% in obtaining an erection sufficient for* ***coitus*** *and are considered a first-line non-invasive therapy.*[13] Rigidity may be improved by using a double pump technique in which the vacuum is applied for a couple of minutes, removed, then reapplied for another few minutes. Higher efficacy rates can also be achieved by combining VEDs with other therapies.

Onset of action is slow at around 30 minutes, which limits spontaneity. In addition, patients and partners may complain of a cold, lifeless, discolored penis that has a hinge-like feel. Painful ejaculation or inability to ejaculate are additional adverse effects. VEDs are contraindicated in persons with sickle cell disease and should be used with caution in patients on oral anticoagulants or who have bleeding disorders due to the increased possibility of **priapism**.

Prostheses

Penile prostheses are semi-rigid malleable or inflatable rods, which are inserted surgically into the corpus cavernosa to allow erections (Fig. 48–2). The malleable rods are rigid at all times, but may be bent into position by the patient when desired. The inflatable prostheses remain flaccid until the pump within the scrotum moves fluid from a reservoir to the cylinders within the penis. Detumescence is achieved when the fluid is then transferred back to the reservoir by activating a release button.

TABLE 48–3. Common Drug Treatment Regimens for Erectile Dysfunction

Route of Administration	Generic Name	Brand Name	Typical Dosing Range[a]	Maximum Dosing Frequency
Oral	Sildenafil	Viagra	25–100 mg 1 hour prior to intercourse	Once daily
	Tadalafil	Cialis	5–20 mg prior to intercourse	Once daily
	Vardenafil	Levitra	5–20 mg 1 hour prior to intercourse	Once daily
	Yohimbine[b]	Aphrodyne, Yocon	5.4 mg three times daily	N/A
Intracavernosal	Alprostadil	Caverject, Caverject Impulse, Edex	1.25–60 mcg 5–20 minutes prior to intercourse[c]	Three times weekly, 24 hours between injections
	Papaverine	N/A	Usually used in combination at variable doses	Three times weekly, 24 hours between injections
	Phentolamine	N/A	Usually used in combination at variable doses	Three times weekly, 24 hours between injections
Intraurethral	Alprostadil	MUSE	125–1000 mcg 5–10 minutes prior to intercourse[c]	Two times daily
Intramuscular	Testosterone cypionate	Depo-Testosterone	50–400 mg every 2–4 weeks	Once weekly
	Testosterone enanthate	Delatestryl	50–400 mg every 2–4 weeks	Once weekly
Topical	Testosterone patches	Testoderm	4–6 mg/day applied to scrotum	Once daily
		Testoderm TTS	4–6 mg/day applied to arm, back, or upper buttocks	Once daily
		Androderm	2.5–5 mg/day applied to back, abdomen, upper arms, or thighs	Once daily
	Testosterone gel	AndroGel 1%, Testim	5–10 g daily to shoulders, upper arms, or abdomen (AndroGel only)	Once daily
Buccal	Testosterone	Striant	30 mg every 12 hours to gum region above incisor; rotate to alternate sides with each dose	Twice daily

[a]Use the lowest effective dose to limit adverse effects.
[b]Not FDA approved for this indication.
[c]Initial dose must be titrated in physician's office.
MUSE, medicated urethral system for erection.

Because prostheses are the most invasive treatment available, they are only considered in patients who do not respond to medications or external devices, or those who have significant adverse effects from other therapies. Patient satisfaction rates can be as high as 80% to 90% with partner satisfaction rates just slightly lower.[9] The primary risks of insertion of prostheses are infection and device failure, although these only happen in 2% to 3% and 2% to 14% of patients, respectively. Higher infection rates have been reported in uncontrolled diabetic patients, paraplegics, and patients undergoing reimplantation or penile reconstruction.[14,15] Most prostheses can be expected to last from 7 to 10 years.[16]

Pharmacologic Therapy

Phosphodiesterase Type 5 Inhibitors

Sildenafil (Viagra®), tadalafil (Cialis®), and vardenafil (Levitra®) act by selectively inhibiting phosphodiesterase (PDE) type 5, an enzyme that breaks down cGMP. By inhibiting the breakdown of cGMP, smooth muscle relaxation is induced, leading to an erection (Fig. 48–1). However, the PDE inhibitors are only effective in the presence of sexual stimulation to drive the nitric oxide/cGMP system, making them facilitators of an erection, not initiators. Patients must be informed of the need for sexual stimulation to induce an erection, as it will not occur spontaneously.

❼ *Effectiveness of the three available phosphodiesterase inhibitors is essentially comparable, but differences exist in duration of action, and to a small degree, incidence of side effects and drug interactions* (Table 48–4). Studies directly comparing the side effects and efficacy of the drugs in this class have not been published. In addition, trials for vardenafil and tadalafil excluded subjects who did not respond to sildenafil. Review of available data for each individual agent shows a 50% to 80% response rate depending on the dose of agent used and the etiology of dysfunction. Patients with radical prostatectomy tend to have lower response rates.[6] Response rates are also lower in patients with diabetes, severe nerve damage, or severe vascular disease.[17] The PDE inhibitors are considered first-line therapies due to high efficacy rates, convenience of dosing, and minimal severe adverse effects.

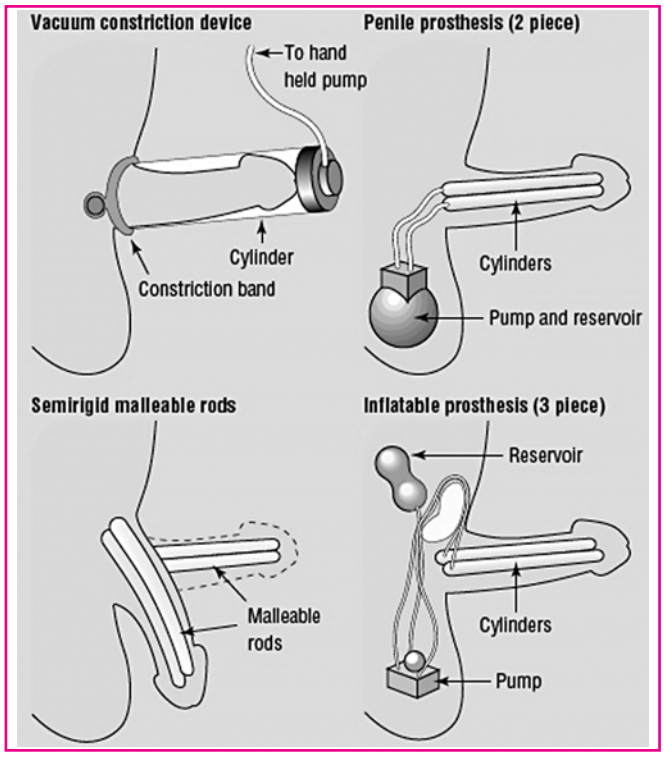

FIGURE 48–2. Available devices and prostheses used to treat erectile dysfunction. (From Wagner G, Saenz de Tejada I. Update on male erectile dysfunction. BMJ 1998;316:681, with permission.)

The most dramatic difference between the three agents is tadalafil's extended duration of action, earning it the nickname "the weekender drug." While sildenafil and vardenafil have average half-lives of 3 to 4 hours, tadalafil's half life is approximately 18 hours.[18] The extended half-life allows for more spontaneous sexual activity over a couple of days, but may increase the duration of adverse effects and liklihood of drug interactions or sildenafil.

The most common side effects experienced with PDE inhibitors include headache, facial flushing, nasal congestion, dyspepsia, and rarely priapism. Vardenafil and sildenafil may also cause difficulty in discriminating blue from green, bluish tones in vision, or difficulty seeing in dim light due to cross-reactivity with PDE 6 in the retina. There has also been a recent change in the labeling for all PDE inhibitors warning about non-arteritic ischemic optic neuropathy (NAION) in a small number of patients. This is a condition in which blood flow is blocked to the optic nerve. If patients experience sudden or decreased vision loss they should call a health care provider immediately.

Concern exists about the safety of using PDE inhibitors in patients with cardiovascular disease. Because of the numerous adverse cardiovascular events reported after the release of sildenafil, a management approach was developed to give recommendations for the use of PDE inhibitors in patients with cardiovascular disease[19] (Table 48–5). In addition to the inherent risk of renewing sexual activity, PDE inhibitors can lead to significant hypotension. Patients taking organic nitrates are

TABLE 48–4. Comparison of Phosphodiesterase Inhibitors

	Sildenafil (Viagra®)	Tadalafil (Cialis®)	Vardenafil (Levitra®)
Available strengths	25-, 50-, 100-mg tabs	5-, 10-, 20-mg tabs	2.5-, 5-, 10-, 20-mg tabs
Initial dosage in healthy adults (dosing range in mg)	50 mg every day taken 1 hour prior to sexual activity	10 mg every day taken 1 hour prior to sexual activity	10 mg every day taken 1 hour prior to sexual activity
Dosing range for healthy adults (mg)	25–100	5–20	5–20
Dosage in the elderly	25 mg every day	10 mg every day	5 mg every day
Dosage in renal impairment	50 mg every day (moderate[a]) 25 mg every day (severe[b])	5 mg every day (moderate[a] and severe[b])	5–20 mg every day
Dosage in hepatic impairment	25 mg every day	10 mg[c]	5–10 mg[d]
Time to onset	30 minutes	15 minutes	Less than 1 hour
Onset delayed by high-fat meal?	Yes	No	Yes
Duration of effect	Up to 4 hours	Up to 36 hours	Up to 4 hours
Half-life	3–4 hours	18 hours	3–4 hours
Metabolism	CYP3A4 (major) CYP2C9 (minor)	CYP3A4	CYP3A4 (major) CYP3A5 (minor) CYP2C (minor)
Drug present in semen?	18%	Less than 0.0005%	0.00018%
Clinically relevant drug interactions	Nitrates, protease inhibitors, azole antifungals	Nitrates, α_1-blockers[e], azole antifungals	Nitrates, anti-arrhythmic agents,[f] α_1-blockers

[a]Moderate renal impairment = creatinine clearance (CrCl) 31–50 mL/minute.
[b]Severe renal impairment = CrCl less than 30 mL/minute.
[c]Mild to moderate only—contraindicated in severe liver disease.
[d]Mild to moderate only—not yet evaluated in severe liver disease.
[e]Selective α_{1a}-blockers (such as 0.4 mg tamsulosin every day) are appropriate in combination with tadalafil.
[f]Vardenafil can cause QT-interval prolongation; this effect in combination with certain anti-arrhythmic agents can lead to life-threatening arrhythmias.
CYP, cytochrome P-450 isoenzyme.

TABLE 48–5. Cardiovascular Risk Assessment for Phosphodiesterase Inhibitors

Risk Category	Description of Patients' Conditions	Management Approach
Low risk	Has asymptomatic cardiovascular disease Has well-controlled hypertension Has mild, stable angina Has mild congestive heart failure (NYHA Class 1)	Patient can be started on phosphodiesterase inhibitor
Moderate risk	Has three or more risk factors for coronary artery disease Has moderate, stable angina Had a recent myocardial infarction or stroke within the past 6 weeks Has moderate congestive heart failure (NYHA Class 2)	Patient should undergo a complete cardiovascular work-up and treadmill stress testing to determine tolerance to increased myocardial energy consumption associated with increased sexual activity
High risk	Has unstable or symptomatic angina, despite treatment Has poorly controlled hypertension Has severe congestive heart failure (NYHA Class III or IV) Had a recent myocardial infarction or stroke within the past 2 weeks Has moderate or severe valvular heart disease	Phosphodiesterase inhibitor is contraindicated

From Lee M. Erectile dysfunction. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 1524, with permission.

the most at risk, as they potentiate the drop in blood pressure. All three PDE inhibitors are absolutely contraindicated in patients taking any form of nitrate, whether scheduled or sublingual for acute situations. Caution should be used when using a PDE inhibitor in patients taking α-blockers due to an increased risk of hypotension. In addition, the labeling for vardenafil contains a precautionary statement about the possibility of QT prolongation with the use of the drug. Other drug interactions and cautions vary slightly between agents and are described in Table 48–4.

The introduction of the oral PDE inhibitors has dramatically changed the treatment of ED. Direct-to-consumer advertising has informed patients of the availability of oral drugs for treatment. However, patients must be fully informed of side effects, drug interactions, mechanism of action, and dosing before being prescribed the medication. In addition, they need to understand the need for sexual stimulation to achieve the desired result and that a single trial is not adequate. It is estimated that six to eight attempts with a medication and specific dose may be needed before successful intercourse results.[20]

Alprostadil

Alprostadil is a prostaglandin E_1 analog that induces an erection by stimulating adenyl cyclase, which leads to an increase in smooth muscle relaxation, rapid arterial inflow, and increased penile rigidity. Alprostadil is available as an intracavernosal injection (Caverject® or Edex®) or a transurethral suppository (MUSE®, medicated urethral system for erection), but the injectable form is more effective (Fig. 48–3). Both forms of alprostadil are considered more invasive than oral medications or VEDs, and are therefore second-line therapies.[8]

MUSE consists of a urethral pellet of alprostadil with an applicator. Onset of action is within 5 to 10 minutes and it is effective for 30 to 60 minutes. Initial dose titration should occur in a physician's office to ensure correct dose and prevent adverse events. Although effectiveness rates in clinical trials have been as high as 65%,[21] its success in practice has been lower. Aching in the penis, testicles, legs, and perineum, warmth or burning sensation in the urethra, minor urethral bleeding or spotting, priapism, and lightheadedness are all possible adverse effects. In addition, partners may experience vaginal burning or itching. Disadvantages include lower effectiveness, high cost, adverse effects, complicated insertion technique, and a contraindication against use with a pregnant partner unless using a condom.

Alprostadil injected into the corpus cavernosum is the more effective form and is the only Food and Drug Administration (FDA)-approved agent for injection. The onset of action is

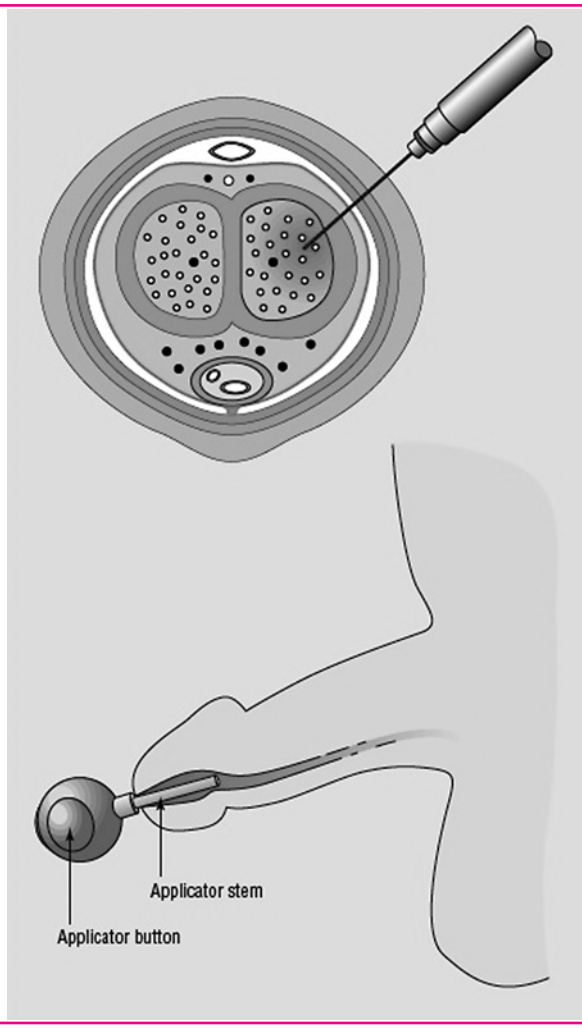

FIGURE 48–3. Intraurethral and intracavernosal administration of alprostadil. (From Wagner G, Saenz de Tejada I. Update on male erectile dysfunction. BMJ 1998;316:680, with permission.)

similar to transurethral alprostadil, but duration varies with dose and must be titrated in a physician's office to achieve an erection lasting no more than 1 hour. Injections should be done into one side of the penis directly into the corpus cavernosum, and then the penis should be massaged to distribute the drug. Because of cross-circulation, both corpora will become erect when massaging. Education is extremely important with intracavernosal injections. Patients must be adequately informed of technique, expectations, side effects, and when to seek help. ❻ *Intracavernosal injections are effective in up to 90% of patients, but side effects, lack of spontaneity, and fear of needles limit their widespread use as first-line therapy*, and therefore this therapy is most appropriate for patients in long-term stable relationships. Adverse effects include pain with injection, bleeding or bruising at the injection site, fibrosis, or priapism. Use with caution in patients with sickle cell disease, those on anticoagulants, or those who have bleeding disorders, due to an increased risk of priapism and bleeding.

Papaverine and Phentolamine

Papaverine and phentolamine are non–FDA-approved agents used for intracavernosal injection. Papaverine is a non-selective PDE inhibitor that induces an erection by relaxing smooth muscle and increasing blood flow. Phentolamine is a competitive α-adrenergic receptor antagonist that increases arterial inflow by opposing arterial constriction. Both drugs are rarely used alone, and are most often mixed in various concentrations with alprostadil for increased effectiveness and in an effort to reduce adverse effects with smaller doses of each medication. Patients typically must see a specialist for use of these medications in mixtures, as they are the most likely to compound them and adjust dosages.

Yohimbine

Yohimbine is an indole alkaloid produced in the bark of yohimbe trees. It selectively inhibits α_2-adrenergic receptors in the brain that are associated with libido and penile erection. Since there is only limited data supporting its efficacy, yohimbine is not a recommended treatment for any form of ED.[22] Adverse effects of the drug include nausea, irritability, headaches, anxiety, tachycardia, and hypertension.

Testosterone Supplementation

❽ *Androgens are important for general sexual function and libido, but testosterone supplementation is only effective in patients with documented low serum testosterone levels.* In patients with **hypogonadism**, testosterone replacement is the initial treatment of choice, as it corrects decreased libido, fatigue, muscle loss, sleep disturbances, and depressed mood. Improvements in ED may occur, but they should not be expected to occur in all patients.[23] The initial trial should be for 3 months. At that time, re-evaluation and the addition of another ED therapy is warranted. Routes of administration include oral, intramuscular, topical patches or gel, and a buccal tablet.

Injectable esters of testosterone offer the most inexpensive and effective replacement option. Testosterone cypionate and enanthate have the longest duration of action and are therefore the preferred agents. There are several drawbacks associated with parenteral testosterone including the need to administer deep intramuscular injections every 2 to 4 weeks. In addition, levels of hormone are well above physiologic values within the first few days. Concentrations then decline and eventually dip below physiologic levels just before the next dose. These extreme changes in concentration lead to mood swings and a reduced sense of well-being.[23]

Treatment with topical products is attractive to patients due to convenience, but they tend to be more expensive than

the injections. Testosterone patches and gels are administered daily and result in serum levels within the physiological range during the 24-hour dosing period.[23] Most patients prefer the non-scrotal patch or the gel since the scrotal patch requires shaving of the area, and the patch has a tendency to fall off. Care must be taken with the use of the gel to wash hands thoroughly after use and avoid baths or showers within 5 to 6 hours of application. The most common side effects of topical testosterone are dermatologic reactions caused by the absorption enhancers.

Oral testosterone products are also available for supplementation. Unfortunately, testosterone has poor oral bioavailability and undergoes extensive first-pass metabolism. Alkylated derivatives such as methyltestosterone and fluoxymesterone have been formulated to compensate for these problems, but this modification makes them considerably more hepatotoxic. This adverse effect makes oral replacement undesirable and this route of administration should not be used.

An alternative to the oral route is the buccal mucoadhesive system. The Striant® buccal system adheres to the inside of the mouth and the testosterone is absorbed through the oral mucosa and delivered to the systemic circulation. There is no first-pass effect, as the liver is bypassed by this route of administration. Patients apply a 30-mg tablet to the upper gum twice daily. The cost is similar to that of the patch or gel. Side effects unique to this dosage form include oral irritation, bitter taste, and gum edema.

General side effects of testosterone include gynecomastia, dyslipidemia, polycythemia, and acne. Weight gain, hypertension, edema, and exacerbations of congestive heart failure also occur due to sodium retention. Before initiating testosterone, the patient should undergo evaluation for benign prostatic hypertrophy and prostate cancer. Routine follow-up includes yearly prostate-specific antigen, digital rectal exam, hemoglobin, and liver function in addition to assessment of response.

OUTCOME EVALUATION

Successful therapy for ED results in an increase in erections suitable for intercourse, and most importantly in an improvement in the patient's quality of life. Ideally, the therapy chosen is free of significant adverse effects, discomfort, and inconvenience. Laboratory evaluation and a physical exam are not necessary for evaluation of effectiveness, but may be necessary to determine if adverse events are occurring.

Satisfaction and effectiveness are evaluated after a 4-week trial unless the patient initiates follow-up sooner. Some therapies such as intracavernosal injections will require multiple visits over the long term to detect adverse effects. If the initial therapy is not effective, the patient must be further evaluated to determine if the initial assessment of comorbid disease states, type of dysfunction, and patient goals were correct. After ensuring that patient goals are realistic and providing further counseling, providers will then increase the dose of drug if not at maximum, switch to another therapy, or add a therapy if indicated.

Patient Care and Monitoring

1. Assess the patient's specific symptoms to determine the type of dysfunction. Does the patient have ED or an ejaculatory or libido disorder?
2. If problems are with erectile ability, ask specific questions related to onset, frequency, and sexual relationships. Does the patient history imply psychogenic, organic, or mixed dysfunction?
3. A thorough medical history and physical exam should be performed to diagnose ED and to determine potential causes that may be treatable.
4. Perform a thorough history of prescription and non-prescription medications. Are any of the patient's medications associated with ED or are they contraindicated with possible ED therapies?
5. Generally treatment is started with the least invasive option and then progresses to more invasive options, but ultimately patient preference determines the initial therapy.
6. Discontinue medications that may cause ED if possible and optimally treat associated disease states.
7. If the patient is not satisfied, provide further counseling to ensure that they are using the therapy appropriately and that they have realistic goals.
8. Provide patient education with regard to disease state, lifestyle modifications, drug therapy, and device technique:
   - The causes of ED
   - The fact that therapy will not cure ED, but may be helpful in improving erections; it is important to have realistic expectations
   - The appropriate use of medications and devices
   - Typical adverse effects
   - Drug interactions
   - Warning signs and their management (e.g., vision changes, fibrosis, pain, priapism, or hypotension)
   - The importance of frequent follow-up with the provider

49 Benign Prostatic Hyperplasia

Mary Lee and Roohollah Sharifi

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiologic mechanisms underlying the symptoms and signs of benign prostatic hyperplasia.
2. Recognize the symptoms and signs of benign prostatic hyperplasia in individual patients.
3. List the desired treatment outcomes for a patient with benign prostatic hyperplasia.
4. Identify factors that guide selection of a particular α-adrenergic antagonist for an individual patient.
5. Compare and contrast α-adrenergic antagonists versus 5α-reductase inhibitors in terms of mechanism of action, treatment outcomes, adverse effects, and interactions when used for management of benign prostatic hyperplasia.
6. Describe the indications for combination drug treatment of benign prostatic hyperplasia.
7. Describe the indications for surgical intervention of benign prostatic hyperplasia.
8. Formulate a monitoring plan for a patient on a given drug treatment regimen based on patient-specific information.
9. Formulate appropriate counseling information for patients receiving drug treatment for benign prostatic hyperplasia.

Key Concepts

❶ The **lower urinary tract symptoms** and signs of benign prostatic hyperplasia are due to static, dynamic, or detrusor factors. The static factor refers to anatomic obstruction of the bladder neck caused by an enlarged **prostate** gland. The dynamic factor refers to excessive stimulation of α-adrenergic receptors in the smooth muscle of the prostate, urethra, and bladder neck. The detrusor factor refers to irritability of hypertrophied detrusor muscle as a result of long-standing bladder outlet obstruction.

❷ Drug treatment goals for benign prostatic hyperplasia include relieving obstructive and irritative voiding symptoms, preventing complications of disease, and reducing the need for surgical intervention.

❸ Single-drug treatment with an α-adrenergic antagonist is preferred for patients with moderate symptoms of benign prostatic hyperplasia. Single-drug treatment with a 5α-reductase inhibitor should be reserved for patients with significantly enlarged prostates of at least 40 g (1.4 oz).

❹ Surgical intervention should be reserved for patients with severe lower urinary tract symptoms of benign prostatic hyperplasia or those with complications of disease (such as recurrent urinary tract infections, renal failure, and bladder calculi).

❺ α-Adrenergic antagonists reduce the dynamic factor. They competitively antagonize α-adrenergic receptors, thereby causing relaxation of the bladder neck, prostatic urethra, and prostate smooth muscle. They do not shrink an enlarged prostate. The onset of action is days to weeks, depending on the need for up-titration of the daily dose to achieve a therapeutic response. Dose limiting adverse effects include hypotension and syncope. In addition, delayed or retrograde ejaculation has been reported. Combined use with antihypertensives, diuretics, or phosphodiesterase inhibitors can increase the risk of hypotensive episodes.

❻ Among the α-adrenergic antagonists, alfuzosin is considered functionally uroselective because in usual therapeutic doses, it produces relaxation of the bladder neck and prostatic smooth

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

muscle with minimal peripheral vascular relaxation. Although alfuzosin appears to produce less hypotension than terazosin and doxazosin, it is not clear if it has the same cardiovascular profile as tamsulosin. Tamsulosin is unique in that it is pharmacologically uroselective and exerts greater antagonism of α_{1A}- and α_{1D}-receptors, which predominate in prostatic and bladder detrusor muscle, respectively. Tamsulosin exerts comparatively low antagonism of vascular α_{1B}-receptors. Therefore, tamsulosin can be started with a therapeutic dose, which achieves peak effects sooner than with immediate-release formulations of terazosin and doxazosin, which must be up-titrated. Tamsulosin appears to have the lowest potential to cause hypotension. In various clinical trials, tamsulosin is well tolerated in the elderly, and in patients taking diuretics and antihypertensives. It is also commercially available in a controlled-release dosage formulation. Therefore, with chronic use, tamsulosin can be taken once daily at the patient's convenience.

❼ 5α-Reductase inhibitors shrink enlarged prostates, reducing symptoms caused by the static factor. They do so by inhibiting 5α-reductase which is responsible for intraprostatic conversion of testosterone to dihydrotestosterone, the active androgen which stimulates prostate tissue growth. The onset of action is slow with peak shrinkage of the prostate taking up to 6 months. Unlike treatment with α-adrenergic antagonists, 5α-reductase inhibitors have been shown to reduce the incidence of acute urinary retention and need for prostate surgery in patients with significantly enlarged prostate glands (more than 40 g), and those with elevated serum levels of **prostate-specific antigen.** Because 5α-reductase inhibitors do not produce cardiovascular adverse effects, they are preferred for treatment of moderate to severe symptoms of benign prostatic hyperplasia when the patient is at risk of hypotension, but wants to be treated medically. Adverse effects include gynecomastia, decreased libido, erectile dysfunction, and ejaculation disorders. Drug interactions are uncommon.

❽ When monitoring efficacy of drug treatment for benign prostatic hyperplasia, subjective endpoints include relief of obstructive and irritative voiding symptoms. Objective endpoints include improvements of urinary flow rates, decreased post-void residual urinary volume, and decreased complications of disease.

The prostate is a heart-shaped, chestnut-sized organ that encircles the portion of the proximal urethra that is located at the base of the urinary bladder. The prostate produces secretions which are part of the ejaculate.

Benign prostatic hyperplasia (BPH) is the most common benign neoplasm in males who are at least 40 years of age. BPH can produce lower urinary tract voiding symptoms that are consistent with impaired bladder emptying and bladder storage. A common mode of treatment to reduce symptoms and/or delay complications of the disease is drugs. For this reason, clinicians should be knowledgeable of the medical management of this disease.

EPIDEMIOLOGY AND ETIOLOGY

BPH is present as microscopic disease in many elderly males.[1] The prevalence increases with advancing patient age. However, only about 50% and 25% of patients with microscopic BPH disease develop an enlarged prostate on palpation and clinical voiding symptoms, respectively.[2] It is estimated that 25% of males 40 years of age or more have voiding symptoms consistent with BPH,[3] and 20% to 30% of all male patients who live to the age of 80 years will require a **prostatectomy** for severe voiding symptoms of BPH.

Two etiologic factors for BPH include advanced patient age and the stimulatory effect of androgens.

- Prior to 40 years of age, the prostate in the adult male stays the same size, approximately 15 to 20 g. However, in males who have reached 40 years of age, the prostate undergoes a growth spurt, which continues as the male advances in age. Enlargement of the prostate can result in BPH.
- The testes and adrenal glands produce 90% and 10%, respectively, of circulating testosterone. Testosterone enters prostate cells, where predominantly type II 5α-reductase activates testosterone to dihydrotestosterone, which combines with a cytoplasmic receptor. The complex enters the nucleus and induces changes in protein synthesis which promote glandular tissue growth of the prostate. Thus, 5α-reductase inhibitors (e.g., finasteride and dutasteride) directly interfere with one of the major etiologic factors of BPH.
- The prostate is composed of two types of tissue: (1) glandular or epithelial tissue, which produces prostatic secretions, and (2) muscle or stromal tissue, which can contract around the urethra when stimulated. Whereas androgens stimulate glandular tissue growth, androgens have no direct effect on stromal tissue growth. It has been postulated that stromal tissue growth may be stimulated by estrogen. Since testosterone is converted to estrogen in peripheral tissues in males, testosterone may be associated indirectly with stromal hyperplasia. Stromal tissue is innervated by α_{1A}-receptors. When stimulated, prostatic stroma contracts around the urethra, narrowing the urethra and causing obstructive voiding symptoms.

PATHOPHYSIOLOGY

❶ *The symptoms and signs of benign prostatic hyperplasia are due to static, dynamic, and/or detrusor factors. The static factor refers to anatomic obstruction of the bladder neck caused by an enlarged prostate gland. As the gland grows around the urethra, the prostate occludes the urethral lumen. The dynamic factor refers to excessive stimulation of α_{1A}-adrenergic receptors in the smooth muscle of the prostate and urethra, which results in smooth muscle contraction. This reduces the caliber of the urethral lumen. The detrusor factor refers to bladder detrusor muscle*

instability, in which bladder muscle fibers have decompensated as a result of excessive, prolonged hypertrophy in response to prolonged bladder outlet obstruction. Patients with detrusor muscle instability will develop irritative voiding symptoms such as urinary urgency and frequency.[3,4] Detrusor muscle fibers are embedded with α_{1D}-receptors. Therefore, it has been proposed that some α-adrenergic$_{1D}$ antagonists may be particularly useful for controlling these symptoms.[3]

In an enlarged gland, the epithelial/stromal tissue ratio is 1:5.[3] Androgens stimulate epithelial, but not stromal tissue hyperplasia. Hence, androgen antagonism does not induce a complete reduction in prostate size to normal. This explains one of the limitations of the clinical effect of 5α-reductase inhibitors.

Stromal tissue is the primary locus of α_1-adrenergic receptors in the prostate. It is estimated that 98% of the α-adrenergic receptors in the prostate are found in prostatic stromal tissue. Of the α_1-receptors found in the prostate, 70% of them are of the α_{1A}-sub-type.[5] This explains why α-adrenergic antagonists are effective for managing symptoms of BPH.[6]

Symptoms of BPH are classified as obstructive or irritative. Obstructive symptoms result from failure of the urinary bladder to empty urine when the bladder is full. The patient will complain of a reduced force of the urinary stream, urinary hesitation, dribbling, and straining to empty the bladder. Irritative symptoms result from the failure of the urinary bladder to store urine until the bladder is full. With long-standing bladder outlet obstruction, detrusor muscle fibers undergo hypertrophy so that the bladder can generate higher pressure to overcome the bladder outlet obstruction and empty urine from the bladder. Once maximal bladder muscle hypertrophy occurs, the muscle decompensates. The detrusor becomes irritable, contracting abnormally in response to small amounts of urine in the bladder. As a result, the patient complains of urinary frequency and urgency.

The natural history of untreated BPH is unclear in patients with mild symptoms. It is estimated that up to 38% of untreated men with mild symptoms will have symptom improvement over a 2.5- to 5.0-year period.[7] It may be that such patients attribute their symptoms to aging, grow tolerant of their symptoms, or adopt behavioral changes in their lifestyle that minimize their voiding symptoms. On the other hand, a significant portion of patients with mild symptoms will likely experience disease progression. In one Veterans Affairs study, approximately one-third of men with mild BPH symptoms, who were initially randomized to watchful waiting, developed progressive symptoms and required surgical intervention within 5 years of initial diagnosis.[8] In patients with moderate to severe symptoms, the likelihood of developing complications of BPH is higher.[9] Complications of BPH include acute refractory urinary retention, renal failure, urinary tract infection, urinary incontinence, bladder stones, large bladder diverticuli, and recurrent gross hematuria. Predictors of disease progression include an enlarged prostate of at least 40 g (1.4 oz) and a prostate-specific antigen (PSA) level of at least 4 ng/mL (4 mcg/L).[10]

CLINICAL PRESENTATION AND DIAGNOSIS[11]

Clinical Presentation of BPH

General

Patients may or may not be in acute distress. In early stages of disease, the patient may complain of obstructive voiding symptoms. If untreated, in late stages of disease the patient may complain of irritative voiding symptoms, or acute urinary retention, which is painful due to maximal distention of the urinary bladder. Also, the patient may be symptomatic of disease complications, including urosepsis, pyelonephritis, cystitis, or overflow urinary incontinence.

Symptoms

Patients may complain of obstructive voiding symptoms (e.g., urinary hesitancy, decreased force of urinary stream, straining to void, incomplete bladder emptying, dribbling, and intermittency) and/or irritative voiding symptoms (e.g., urinary frequency, nocturia, dysuria, urgency, and urinary incontinence). Severity of symptoms should be assessed by the patient using a standardized instrument [e.g., the American Urological Association (AUA) Symptom Scoring Index; Table 49–1]. However, it is important to recognize that a patient's perception of the bothersomeness of their voiding symptoms may not match with the AUA Symptom Score. In this case, after thorough evaluation of the signs and complications of BPH disease, if present, the physician and patient should discuss the bothersomeness of the patient's symptoms and decide together on the most appropriate course of treatment for the patient.[9] **Lower urinary tract symptoms** (LUTS) is a term that refers to the collection of obstructive and irritative voiding symptoms characteristic of, but not specific for, BPH. That is, other urologic diseases (e.g., urinary tract infection, prostate cancer, prostatitis, or neurogenic bladder) can also cause LUTS.

Signs

- Enlarged prostate on **digital rectal exam**; check for prostate nodules or induration, which would suggest prostate cancer instead of benign prostatic hyperplasia as the cause of the patient's voiding symptoms
- Distended urinary bladder
- Rule out meatal stenosis or urethral masses which could cause voiding symptoms similar to LUTS
- Check anal sphincter tone as an indirect assessment of peripheral innervation to the **detrusor** muscle of the bladder.

Complications of Untreated BPH

Upper and lower urinary tract infection, urosepsis, urinary incontinence refractory urinary retentions chronic, renal failure, bladder diverticuli, bladder stones, or recurrent gross hematuria.

Medical History

- Check the patient's general health including previous surgery, presence of diabetes mellitus, or medications that may cause or worsen voiding symptoms.
- Have the patient provide a diary of his voiding pattern for the past week: date and time of each voiding, volume voided, and whether or not the patient had urinary leakage during the day.

(*Continued*)

Clinical Presentation of BPH (*Continued*)

Laboratory Tests

- Serum prostate specific antigen (PSA) will be increased.
- Urinalysis to rule out infection as a cause of the patient's voiding symptoms; also check urinalysis for microscopic hematuria, which typically accompanies benign prostatic hyperplasia.
- Plasma blood urea nitrogen (BUN) and serum creatinine may be increased as a result of long-standing bladder outlet obstruction.
- Urinalysis to rule out urinary tract infection as the cause of irritative voiding symptoms.

Other Diagnostic Tests (Table 49–2)

- Decreased peak and mean urinary flow rate (less than 10 to 15 mL/s) on uroflowmetry; decreased urinary flow rate is not specific for BPH; it can also be due to other urological disorders (e.g., urethral stricture, meatal stenosis, or bladder hypotonicity)
- Increased **post-void residual urine volume** (more than 50 mL)
- Digital rectal exam to check for an enlarged prostate (more than 15 to 20 g)
- Transurethral cytoscopy reveals an enlarged prostate, which decreases urethral lumen caliber; information from this procedure helps the surgeon decide on the best surgical approach
- Transrectal ultrasound of the prostate; a transrectal probe is inserted to evaluate prostate size and best surgical approach
- Transrectal prostate needle biopsy to be done if the patient has areas of nodularity or induration on digital rectal examination; tissue biopsy can document the presence of prostate cancer, which can also cause enlargement of the prostate
- **Intravenous pyelogram** (IVP) will show retention of radiocontrast in the bladder if the patient has bladder outlet obstruction due to an enlarged prostate; only indicated in patients with recurrent hematuria, recurrent urinary tract infection, renal insufficiency, and urolithiasis
- Filling cystometry provides information on bladder capacity, detrusor contractility, and the presence of uninhibited bladder contractions, which could also cause LUTS

TABLE 49–1. Questions to Determine the American Urological Association Symptom Score[5]

Directions for the patient: The patient should be asked to respond to each question based on the absence or presence of symptoms over the past month. For each question, the patient can respond using a 1 to 5 scale, where 0 = not at all or none, 1 = less than 1 time in 5, 2 = less than half of the time, 3 = about half of the time, 4 = more than half of the time, and 5 = almost always.

Directions for the clinician: After the patient completes the questionnaire, the scores for individual items should be tallied for a final score. Scores of 0–7 = mild symptoms; scores of 8–19 = moderate symptoms; scores more than 20 = severe symptoms.

Questions to Assess Obstructive Voiding Symptoms

1. How often have you had a sensation of not emptying your bladder completely after you finished urinating?
2. How often have you found you stopped and started again several times when you urinated?
3. How often have you had a weak urinary stream?
4. How often have you had to push or strain to begin urinating?

Questions to Assess Irritative Voiding Symptoms

5. How often have you found it difficult to postpone urination?
6. How often had you had to urinate again less than 2 hours after you finished urinating?
7. How many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?

TREATMENT

Desired Outcomes

- ❷[11] *Reducing or eliminating obstructive and irritative voiding symptoms. An improvement in the AUA Symptom Score should be observed. Drug treatment with an α-adrenergic antagonist or 5a-reductase inhibitor is expected to reduce the AUA Symptom Score by 30% to 50%, improve peak and mean urinary flow rate by 1 to 3 mL/second, and decrease post-void residual urine volume to normal (less than 50 mL total) when compared to pretreatment baselines. The AUA Symptom Score may not correlate with response to therapy.*
- Slowing disease progression. When compared to baseline, serum BUN and creatinine should stabilize or decrease to the normal range with treatment.
- Preventing disease complications and reducing the need for surgical intervention.
- Avoiding or minimizing adverse treatment effects.
- Providing economical therapy.
- Maintaining or improving quality of life.

General Approach to Treatment

Until recently, the principal approach to treatment focused on reducing BPH symptoms.

For patients with mild symptoms, which the patient does not consider to be bothersome, watchful waiting is a reasonable approach to treatment (Fig. 49–1). The patient is instructed to schedule return visits to the physician every 3 to 6 months. At each visit, the patient's symptoms are reassessed using the AUA Symptom Scoring Index and results are compared to baseline (Table 49–3). In addition, the patient is educated about avoiding factors that worsen obstructive and irritative voiding symptoms. The digital rectal exam is repeated annually. If the patient's symptoms are unchanged, then watchful waiting is continued. If the patient's symptoms worsen, then specific treatment is initiated.[11]

For patients with moderate to severe symptoms, the patient is usually offered drug treatment first. ❸ *α-Adrenergic antagonists are preferred over 5α-reductase inhibitors because the former have a faster onset of action (days to a few weeks) and improve symptoms independent of prostate size. 5α-reductase inhibitors have a delayed onset of action (i.e., peak effect may*

TABLE 49–2. Objective Tests Used to Assess the Size of the Prostate and Complications of Benign Prostatic Hyperplasia (BPH)

Test	How the Test Is Performed	Normal Test Result	Test Result in Patients with BPH
Digital rectal exam of the prostate (DRE)	Prostate is palpated through the rectal mucosa; the physician inserts an index finger into the patient's rectum	Prostate is soft, symmetric, mobile; size is 15–20 g	Prostate is enlarged, greater than 20 g; no areas of induration or nodularity
Peak and mean urinary flow rate	Patient drinks water until bladder is full; patient empties bladder; volume of urine output and time to empty the bladder are measured; the flow rate (mL/second) is calculated	Peak and mean urinary flow rate are at least 10 mL/second	Peak and mean urinary flow rates are less than 10 mL/second
Post-void residual urine volume (PVR)	Measurement of urine left in the bladder after the patient has tried to empty out his bladder; assessed by urethral catheterization or ultrasonography	Post-void residual urine volume should be 0 mL	Post-void residual urine volume greater than 50 mL is a significant amount of retained urine; this is associated with recurrent urinary tract infection
Urinalysis	Midstream urine is analyzed microscopically for white blood cells and bacteria	Urine should have no white cells or bacteria in it	Urine with white cells and bacteria is suggestive of inflammation and infection; if positive, urine is sent for bacteriologic culture
Prostate needle biopsy	Transrectally, a biopsy needle is inserted into the prostate. Tissue core is sent to a pathologist for analysis	A normal prostate should have no evidence of BPH or prostate cancer	The biopsy is consistent with BPH
Prostate-specific antigen (PSA)	Blood test for this chemical secreted by the prostate	Less than 4 ng/mL (4 mcg/L)	Greater than or equal to 4 ng/mL (4 mcg/L)

be delayed for up to 6 months), and are seldom effective in patients with 2 smaller size gland (less than 40 g or 1.4 oz). Any drug treatment must be continued as long as the patient responds (Table 49–4).[11]

❹ *For patients with complications of BPH disease (e.g., recurrent urinary tract infection, urosepsis, urinary incontinence, refractory urinary retention, chronic renal failure, large bladder diverticuli, recurrent gross hematuria, or bladder calculi secondary to prolonged urinary retention), surgery is indicated.* Although it is potentially curative, surgery can result in significant morbidity, including erectile dysfunction, retrograde ejaculation, urinary incontinence, bleeding, or urinary tract infection. The gold standard is a prostatectomy, which can be performed transurethrally or as an open surgical procedure. To avoid complications of prostatectomy, minimally invasive surgical procedures, such as transurethral incision of the prostate and laser prostatectomy are becoming popular options. Drug treatment is used in patients with severe disease when the patient refuses surgery or when the patient is not a surgical candidate because of concomitant diseases.[11]

In the Multiple Treatment of Prostate Symptoms Study, it was found that selected patients with moderate to severe symptoms will benefit from a combination of α-adrenergic antagonist plus 5α-reductase inhibitor drug therapy.[12] Specifically, the use of doxazosin plus finasteride is more effective than doxazosin alone or finasteride alone in relieving symptoms, reducing the need for prostatectomy, and decreasing the incidence of BPH complications in patients at highest risk of developing disease complications [i.e., those with prostate size of at least 40 g (1.4 oz) and a PSA of at least 4 ng/mL (4 mcg/L)]. Combination therapy is more expensive than monotherapy and also produces more adverse effects. Therefore, the clinician should discuss the advantages and disadvantages of combination therapy with a patient before deciding on a final treatment regimen.

Patient Encounter 1, Part 1

AA is a 65-year-old male patient with an AUA symptom score of 19, urinary hesitancy, a slow urinary stream, urinary frequency, and nocturia. He wakes up three times every night to void. A digital rectal exam reveals an enlarged prostate of approximately 40 g (1.4 oz). His PSA is 4 ng/mL (4 mcg/L).

- What stage of BPH does this patient have?

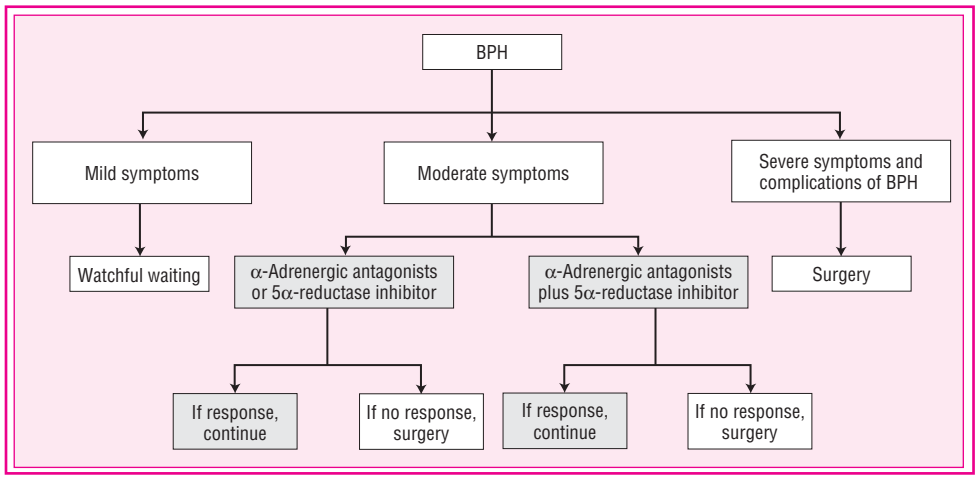

FIGURE 49–1. Algorithm for selection of treatment of BPH based on symptom severity. (From Lee M. Benign prostatic hyperplasia. In: DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005: 1539, with permission.)

Nonpharmacologic Therapy

To reduce nocturia, patients should be instructed to stop drinking fluids several hours before going to bed, and then voiding before going to sleep. During the day, patients should avoid excessive caffeine intake, as this may cause urinary frequency. In addition, toilet mapping (knowing the location of toilets on the way to and from various destinations) may help reassure the patient that he can still continue with many of his routine daily activities.

Below is a list of several items clinicians should tell patients to do to minimize obstructive and irritative voiding symptoms:

1. Discontinue or minimize oral fluid intake after 6 P.M.
2. Void before going to bed
3. If taking a diuretic, take the diuretic in the morning, not the evening
4. Avoid taking over-the-counter medications that can worsen obstructive voiding symptoms (e.g., antihistamines or decongestants) (Table 49–5)

TABLE 49–3. Staging the Severity of BPH Based on AUA Symptom Score and Example Signs of Disease

	AUA Symptom Score	Signs of Disease
Mild	Less than or equal to 7	Enlarged prostate on DRE, peak urinary flow rate less than or equal to 10 mL/second
Moderate	8–19	All of the above, PVR greater than 50 mL, irritative symptoms
Severe	Greater than 20	All of the above plus one or more complications of BPH

Note: The AUA Symptom Score focuses on seven items (incomplete emptying, frequency, intermittency, urgency, weak stream, straining, and nocturia) and asks that the patient quantify the severity of his complaints on a scale of 0 to 5. Thus, the score can range from 0 to 35.
AUA, American Urological Association; BPH, benign prostatic hyperplasia; DRE, digital rectal exam; PVR, post-void residual urine volume.

Pharmacologic Therapy

Alpha-Adrenergic Antagonist Monotherapy[12]

❺ *α-Adrenergic antagonists reduce the dynamic factor causing BPH symptoms. These drugs competitively antagonize α-adrenergic receptors, thereby causing relaxation of the bladder neck, prostatic urethra, and prostate smooth muscle.* A secondary mechanism of action may be that α-adrenergic antagonists induce prostatic apoptosis,[14] which suggests that these agents may cause some shrinkage of an enlarged prostate. However, the clinical importance of this remains to be elucidated.[3]

All α-adrenergic antagonists are considered equally effective in relieving symptoms.[11] In various clinical trials, 30% to 80% of patients experience improvement in AUA Symptom Score by 30% to 45% and 20% to 40% of patients experience urinary flow rate increases of 2 to 3 mL/second.[15] The onset of action is days to weeks, depending on the need for uptitration of the dose from a subtherapeutic starting dose to a therapeutic dose. An adequate clinical trial is considered to be at least 1 to 2 weeks of continuous treatment at a full maintenance dose with any of these agents.[11] Durable responses have been demonstrated for up to 5 years of continuous use of terazosin,[16] 10 years with doxazosin,[17] and 6 years with tamsulosin.[18] However, some patients will develop disease progression despite treatment.[19] α-Adrenergic antagonists are hepatically catabolized. Therefore, in patients with significant hepatic dysfunction, these drugs should be used in the lowest possible dose. None of these drugs require dosage modification in patients with renal dysfunction. These agents can be differentiated by their adverse effect profile. Dose limiting adverse effects include hypotension and syncope, which are more common with immediate-release terazosin and doxazosin,

TABLE 49–4. Comparison of α-Adrenergic Antagonists and 5α-Reductase Inhibitors for Treatment of Benign Prostatic Hyperplasia[47]

Characteristic	α-Adrenergic Antagonists	5α-Reductase Inhibitors
Relaxes prostatic smooth muscle	Yes	No
Reduces size of enlarged prostate	No	Yes
Useful in only enlarged prostates of at least 40 g	No (works independent of the size of the prostate)	Yes
Efficacy in relieving voiding symptoms and improving flow rate	++	+±
Frequency of daily dosing	Once or twice daily, depending on the agent	Once daily
Requirement for up-titration of dose	Yes (for terazosin and doxazosin immediate-release); no (for alfuzosin; possibly for doxazosin extended-release and tamsulosin)	No
Peak onset of action	Days to 6 weeks, depending on need for dose titration	6 months
Decreases PSA	No	Yes
Cardiovascular adverse effects	Yes	No
Drug-induced sexual dysfunction	Ejaculation disorders	Decreased libido, erectile dysfunction, ejaculation disorders

PSA, prostate-specific antigen.

less frequent with extended-release doxazosin and alfuzosin, and least frequent with tamsulosin.[20–22] Delayed or retrograde ejaculation has been reported most often with tamsulosin 0.8 mg orally once a day. Combined use with antihypertensives, diuretics, or phosphodiesterase inhibitors can lead to additive blood pressure–lowering effects; however, this appears to be less of a problem with tamsulosin.[20–22]

α-Adrenergic antagonists are recommended as first-line treatment for moderate to severe BPH. The agents in this pharmacologic class can be classified by several characteristics (Table 49–6):

TABLE 49–5. Drugs That Can Cause Irritative or Obstructive Voiding Symptoms

Pharmacologic Class	Example Drugs	Mechanism of Effect
Androgens	Testosterone	Stimulate prostate enlargement
α-Adrenergic agonists	Phenylephrine, pseudoephedrine	Stimulate contraction of prostatic smooth muscle
Anticholinergic agents	Antihistamines, phenothiazines, tricyclic antidepressants, antiparkinsonian agents	Block bladder detrusor muscle contraction, thereby impairing bladder emptying
Diuretics	Thiazides diuretics, loop diuretics	Produce polyuria

- Generation of α-adrenergic antagonist. First-generation agents (e.g., phenoxybenzamine) block presynaptic and postsynaptic α-adrenergic receptors. Whereas blockade of postsynaptic α-adrenergic receptors is desirable for BPH management, blockade of presynaptic α-adrenergic receptors is undesirable, as it results in release of catecholamines and tachycardia. Thus, first-generation α-adrenergic antagonists are not used for treatment of BPH.[3] Second-generation α-adrenergic antagonists selectively block post-synaptic α-adrenergic receptors. Examples include terazosin, doxazosin, and alfuzosin. Third-generation α-adrenergic antagonists (e.g., tamsulosin) selectively block postsynaptic α_{1A}-receptors.
- Uroselectivity. Pharmacologic uroselectivity refers to preferential inhibition of α_{1A}- and α_{1D}-receptors, which predominate in the prostatic stroma and bladder detrusor muscle, respectively. Pharmacologically uroselective α_{1A}-adrenergic antagonists have the potential to produce less hypotension, as they have a lower propensity to antagonize α-adrenergic$_{1B}$ receptors in the peripheral vasculature. Tamsulosin is the only commercially available α-adrenergic antagonist with pharmacologic uroselectivity. Despite the potential of inhibiting α-adrenergic receptors in both the prostate and peripheral vasculature, functionally uroselective α-adrenergic antagonists in usually-prescribed doses, produce effective relaxation of prostatic smooth muscle with minimal vascular vasodilation. Thus, blood pressure–lowering effects are mild or absent. The only functionally uroselective α-adrenergic antagonist is alfuzosin extended-release tablets. The mechanism of functional uroselectivity is unclear. It may be related to a drug formulation which produces a higher concentration

TABLE 49–6. Comparison of Pharmacologic Properties of α-Adrenergic Antagonists

	Terazosin	Doxazosin	Alfuzosin	Tamsulosin
Brand Name	Hytrin	Cardura	Uroxatral	Flomax
Generation	Second	Second	Second	Third
Uroselective	No	No	Functionally and clinically uroselective	Pharmacologically and clinically uroselective
Need for uptitration	Yes	Yes (with immediate-release); no (with extended-release)	No	No
Daily oral dose (mg)	5–20	2–8, immediate-release; 4–8, extended-release	10	0.4–0.8; 0.8-mg/day dose has not consistently produced clinical improvement over 0.4 mg/day[20]
Best time to take doses	At bedtime	Immediate-release: anytime during the day; however, it is typically given at bedtime Extended-release: anytime during the day	After meals for best oral absorption	On an empty stomach for best oral absorption; if taken 30 minutes after a meal, as recommended by the manufacturer, peak absorption time is delayed, thereby further reducing the potential for hypotensive adverse effects[20,24]
Half-life (hours)	12	22	5	10
Formulation	Immediate-release	Immediate-release and extended-release	Extended-release	Modified-release
Cardiovascular adverse effects	++	++	+	0 to +
Ejaculation disorders	+	+	+	++
Rhinitis	+	+	+	+
Malaise	+	+	+	+

in target tissues than in non-target tissues.[23,24] Both pharmacologic and functional uroselective agents appear to be clinically uroselective, in that they improve BPH symptoms without causing cardiovascular adverse effects in humans.[13]

Pharmacologic and functional uroselectivity are dose-related phenomena. Large daily doses of tamsulosin or alfuzosin may cause loss of uroselectivity with resultant hypotension and dizziness in some patients.

- Need for up-titration of daily dose. Up-titration is required for terazosin and immediate-release doxazosin. It is minimally required for extended-release doxazosin and tamsulosin. It is not required for extended-release alfuzosin.
- Plasma half-life. α-Adrenergic receptors with short plasma half-lives (e.g., prazosin) require multiple doses during the day. This is challenging for most patients, and, thus, prazosin is not recommended for BPH.[11]
- Dosage formulation. Immediate-release formulations of terazosin and doxazosin are quickly absorbed and produce high peak plasma levels. Modified- or extended-release formulations of doxazosin, alfuzosin, and tamsulosin produce lower peak levels, but more sustained therapeutic plasma levels, than immediate-release formulations and have less potential for producing hypotensive episodes, thereby allowing initiation of treatment with a therapeutic dose and once daily dosing.[25–27]
- Adverse effects. Hypotensive adverse effects of α-adrenergic antagonists can range from asymptomatic blood pressure reductions to dizziness and syncope. This adverse effect is most commonly associated with immediate-release terazosin and doxazosin, and is less commonly associated with extended-release alfuzosin, and least commonly associated with tamsulosin.[20–22] To minimize first-dose syncope from terazosin and doxazosin immediate-release, a slow up-titration from a subtherapeutic dose of 1 mg/day to a therapeutic dose is essential. The first dose should be given at bedtime so that the patient can sleep through the peak serum concentration of the drug when the adverse effect is most likely to occur. A 3- to 7-day interval between each dosage increase should be allowed and the patient should be maintained on the lowest effective dose of α-adrenergic antagonist. If the patient is non-compliant with his regimen of terazosin or doxazosin, and he skips or interrupts treatment, the α-adrenergic antagonist should be restarted using the usual starting dose and then retitrated up.[3] He should not be instructed to simply double up on missed doses or resume treatment with his currently prescribed daily dose, as this can lead to significant hypotension.

Ejaculation disorders, including delayed and retrograde ejaculation, occur with all adrenergic antagonists and are an

extension of the pharmacologic blockade of α-adrenergic receptors at the bladder neck (i.e., the bladder neck is unable to close during ejaculation in the presence of α-adrenergic blockade). However, the incidence appears to be dose-related and highest with tamsulosin 0.8 mg daily, occurring in up to 26% of treated patients.[28] Ejaculation disorders generally do not necessitate discontinuation of treatment. Although they may decrease the patient's satisfaction with the quality of sexual intercourse, ejaculation disorders are not harmful to the patient.

Rhinitis and malaise occur with α-adrenergic antagonists and are an extension of the pharmacologic blockade of α-adrenergic receptors in the vasculature of the nasal mucosa and in the central nervous system, respectively. Tolerance often develops to these adverse effects and they rarely require discontinuation of treatment. Avoid use of topical or oral decongestants, as these may exacerbate obstructive voiding symptoms. Cautious use of antihistamines with anticholinergic adverse effects is also recommended in patients with BPH, as these drugs may cause acute urinary retention in patients with an obstructed bladder neck.

Alfuzosin has been linked to two cases of hepatitis.[29,30] The cause-effect relationship remains to be elucidated.

- Potential for drug interactions. Hypotensive adverse effects of terazosin and doxazosin can be additive with those of diuretics, antihypertensives, and phosphodiesterase inhibitors (e.g., sildenafil). In patients at greatest risk for hypotension, or in those patients who tolerate hypotension poorly, including those with poorly controlled coronary artery disease or severe orthostatic hypotension, tamsulosin appears to be the safest choice.[22,31,32] In patients who cannot tolerate tamsulosin, a 5α-reductase inhibitor or prostatectomy should be considered. When using α-adrenergic antagonists in patients taking sildenafil, tadalafil, or vardenafil, patients should be instructed to allow a 4-hour interval between each drug to minimize the likelihood of hypotensive effects.

❻ *Among the α-adrenergic antagonists, tamsulosin is unique in that it is the only commercially available third-generation α-adrenergic antagonist. It is pharmacologically uroselective and exerts greater antagonism of α_{1A}- and α_{1D}-receptors, which predominate in prostatic and bladder detrusor muscle. Tamsulosin exerts comparatively low antagonism of vascular α_{1B}-receptors. Therefore tamsulosin can be started with a therapeutic dose, which achieves peak effects sooner than with terazosin and doxazosin immediate-release, which must be up-titrated. Tamsulosin appears to have the lowest potential to cause hypotension.[20–22] In various clinical trials, tamsulosin has minimal hypotensive adverse effects and is well tolerated in the elderly, as well as in patients taking diuretics, antihypertensives, or phosphodiesterase inhibitors. It is also commercially available in a modified-release dosage formulation, which is dosed at 0.4 mg orally once a day. With chronic use, tamsulosin can be taken at any time of the day and at the patient's convenience. Although the package insert states that the dose can be increased to 0.8 mg daily, no consistent improvement in clinical efficacy has been observed in patients taking the higher dose.[21,33]*

Patient Encounter 2

BB has moderate BPH symptoms and is started on tamsulosin 0.4 mg orally once a day. After 2 to 3 weeks, BB states that his symptoms have not improved. He is not experiencing any drug-related adverse effects.

- What should be the next step in management of this patient?

In patients with BPH and hypertension, it is not recommended to use an α-adrenergic antagonist alone to treat both disorders. In the ALLHAT study, where doxazosin was compared to other agents for treatment of essential hypertension, doxazosin was associated with a higher incidence of congestive heart failure. Therefore, in patients with hypertension and BPH, it is recommended that an appropriate antihypertensive be added to an α-adrenergic antagonist.[11]

5-Alpha-Reductase Inhibitor Monotherapy

❼ *5α-Reductase inhibitors reduce the static factor, which results in shrinkage of an enlarged prostate. They do so by inhibiting 5a-reductase which is responsible for intraprostatic conversion of testosterone to dihydrotestosterone, the active androgen which stimulates prostate tissue growth.* In the prostate, there are two subtypes of 5α-reductase; the majority is the type II isoenzyme type and the minority is the type I isoenzyme type. In addition, 5α-reductase inhibitors induce apoptosis of prostatic epithelial cells.[34] The onset of action is slow with peak shrinkage of the prostate taking up to 6 months.[11] Unlike treatment with α-adrenergic antagonists, 5α-reductase inhibitors have been shown to reduce the incidence of acute urinary retention and need for prostate surgery in patients with significantly enlarged prostate glands [greater than 40 g (1.4 oz)],[11] and those with serum levels of prostate-specific antigen of at least 4 ng/mL (4 mcg/L).[10] Because 5α-reductase inhibitors do not produce cardiovascular adverse effects, they are preferred for treatment of moderate to severe BPH when the patient has an enlarged prostate of at least 40 g (1.4 oz), is at risk of hypotension, and wants to be treated medically. When compared to α-adrenergic antagonists, 5α-reductase inhibitors relieve BPH symptoms in 30% to 70% of patients and increase urinary flow rate by 1 to 2 mL/second, which is less improvement than that seen with α-adrenergic antagonists.[11] A minimum of 6 months is required to evaluate the effectiveness of treatment. This is a disadvantage in patients with moderate to severe symptoms, as it will take that long to determine if the

drug is or is not effective. Durable responses have been demonstrated in responding patients treated up to 6 years with finasteride and 4 years with dutasteride.[35–38] These agents are hepatically metabolized. No specific recommendations for dosage modification are currently available in patients with significant hepatic dysfunction; however, due to drug specificity for its enzyme target, it is unlikely that any dosage adjustment will be required. No dosage adjustment is needed in patients with renal impairment. Adverse effects include decreased libido, erectile dysfunction, and ejaculation disorders, which generally decrease in frequency with continued use, and gynecomastia and breast tenderness.[34] Serum testosterone levels increase by 10% to 20% in treated patients; however, the clinical significance of this is not clear at this time.[11] Drug interactions are uncommon. These drugs do produce a mean 50% decrease in serum levels of PSA. Therefore, to preserve the usefulness of this laboratory test as a diagnostic and monitoring tool, it is recommended that prescribers obtain a baseline PSA prior to the start of treatment and repeat it at least annually during treatment. A significantly elevated PSA in treated patients is an indicator for further diagnostic work-up.[36] Exposure to 5α-reductase inhibitors is contraindicated in pregnant females, as the drugs may cause feminization of a male fetus. Pregnant females should not handle these drugs unless they are wearing gloves.

5α-Reductase inhibitors include finasteride and dutasteride. Finasteride is a selective type II 5α-reductase inhibitor, whereas dutasteride is a non-selective type I and II 5α-reductase inhibitor. When compared to finasteride, dutasteride produces a faster and more complete inhibition of 5α-reductase in prostate cells. However, no difference in clinical efficacy or adverse effects has been demonstrated between these two agents. Thus, finasteride and dutasteride are considered therapeutically interchangeable (Table 49–7).[39]

By reducing serum levels of dihydrotestosterone, which is linked to the development of prostate cancer, it has been hypothesized that 5α-reductase inhibitors may prevent the development of prostate cancer. The Predict Trial reported that finasteride reduced the detection of prostate cancer with prostatic needle biopsy by 25%; however, higher-grade tumors were more common in treated patients.[40] The ongoing Reduce Trial, which will follow dutasteride-treated patients for 4 years, may provide more clarification on this issue.[41]

TABLE 49–7. Comparison of Pharmacologic Properties of 5α-Reductase Inhibitors[36,48]

	Finasteride	Dutasteride
Brand name	Proscar	Avodart
Sub-type inhibition of the 5α-reductase enzyme	Type II	Types I and II
Percent of inhibition of serum dihydrotestosterone level	70–76	90–95
Percent of patients with reduction in serum dihyrotestosterone	49	Greater than 85
Time to peak onset of reduction in serum dihydrotestosterone level	6 months	1 month
Percent inhibition of intraprostatic dihydrotestosterone	85–90	Greater than 95
Half-life	6.2 hours	3–5 hours
Daily dosage (mg)	5	0.5

Patient Encounter 1, Part 2

AA is started on finasteride 5 mg orally once a day. Four weeks later the patient returns for a follow-up visit and complains that he is not experiencing any symptom improvement.

- What should be the next step in management of this patient?

Combination Therapy

A combination of an α-adrenergic antagonist and 5α-reductase inhibitor may be considered in patients at high risk of BPH complications, which are defined as those with an enlarged prostate of at least 40 g (1.4 oz) and a PSA of at least 4 ng/mL (4 mcg/L). In such patients, combination therapy may relieve voiding symptoms, and also reduce the risk of developing BPH-related complications and reduce the need for prostatectomy by 67%.[12] Since combination therapy is more expensive and associated with the array of adverse effects associated with each drug in the combination, clinicians should discuss the advantages and disadvantages of each treatment regimen with the patient before a final decision is made.[11]

To streamline and reduce the cost of treatment regimens, it has been suggested that the α-adrenergic antagonist may be discontinued after the first 6 to 12 months of combination therapy. However, long-term treatment is required to determine if such a regimen is as effective as continuous combination therapy.[42,43]

Another enhancement to BPH symptom management is the addition of an anticholinergic agent to an α-adrenergic antagonist. The rationale for the anticholinergic agent is that irritative symptoms are thought to be due to hyper-reactive bladder detrusor muscle contraction, which can be ameliorated by blockade of acetylcholine receptors.[4] A recent study documenting the addition of tolterodine to tamsulosin showed significant irritative symptom improvement, more than what was observed with tamsulosin alone. No cases of urinary retention were reported.[45] In another study, the addition of tolterodine to doxazosin improved overactive bladder symptoms in patients with BPH; however, acute urinary retention developed in 3.3% of patients treated with the combination. This adverse effect responded to discontinuation of tolterodine and insertion of an indwelling urethral catheter.[46]

OUTCOME EVALUATION

❽ *Once the peak effects of drug treatment are expected to occur, monitor the drug for effectiveness. Assess symptom improvement using the AUA Symptom Scoring Index. A reduction in symptom score is anticipated with symptom improvement. However, it should be noted that the AUA Symptom Score may not match the patient's perception of the bothersomeness of his voiding symptoms. If the patient perceives his symptoms as bothersome, independent of the AUA Symptom Score, consideration should be given to modifying the patient's treatment regimen. Similarly, a patient may regard his symptoms as not bothersome even though the AUA symptom score is high. In this case, the physician should objectively assess symptoms at baseline and during treatment by performing a repeat uroflowmetry, which can detect an improvement in peak and mean urinary flow rate. If the patient shows a response to treatment, instruct the patient to continue the drug regimen and have the patient return at 6-month intervals for monitoring. If the patient shows an inadequate response to treatment, the dose of α-adrenergic antagonist can be increased (except for extended-release alfuzosin) until the patient's symptoms improve or until the patient experiences adverse drug effects.*

For the α-adrenergic antagonists, the severity of hypotensive-related adverse effects, which may manifest as dizziness or syncope, may require a dosage reduction or a slower up-titration of immediate-release terazosin or doxazosin, or halting the up-titration of extended-release doxazosin or tamsulosin. Extended-release alfuzosin is only available as a single 10 mg tablet. If the patient develops adverse effects at this dose, the drug should be discontinued. Other adverse effects of α-adrenergic antagonists are nasal congestion, malaise, headache, and ejaculation disorders. None of these generally require discontinuation of treatment and these often improve as treatment continues. For the 5α-reductase inhibitors, the most bothersome adverse effects are decreased libido, erectile dysfunction, and ejaculation disorders. In sexually active males, erectile dysfunction may be improved with erectogenic drugs; however, this adverse effect may necessitate discontinuation of treatment.

During continuing treatment of BPH, the patient should undergo an annual repeat PSA and DRE. A rising PSA level suggests that the patient has worsening BPH, new-onset prostate cancer, or that the patient is non-compliant with his regimen of 5α-reductase inhibitor. An abnormal DRE suggestive of prostate cancer would reveal a nodule or area of induration on the prostate, or a gland which is fixed in place. In such a case, a prostate biopsy is required to rule out prostate cancer.

Drug treatment failures may result from a variety of factors. Initial failure to respond to α-adrenergic antagonists occurs in 20% to 70% of treated patients. It is likely in these patients that the static factor may predominate as the cause of symptoms in these patients. Initial failure to respond to 5α-reductase inhibitors occurs in 30% to 70% of treated patients. It is likely that the dynamic factor may predominate as the cause of symptoms in these patients. In contrast, drug treatment failures after an initial good response to drug therapy will likely be an indication of progressive BPH disease. In such patients, surgical intervention may be indicated.

Table 49–8 summarizes the adverse effects of the agents used to treat BPH and has management suggestions for these situations.

TABLE 49–8. Summary of Adverse Effects of α-Adrenergic Antagonists and 5α-Reductase Inhibitors and Management Suggestions

Drug Class	Adverse Reaction	Management Suggestion
α-Adrenergic antagonist	Hypotension	Start with lowest effective dose, give doses at bedtime, and slowly up-titrate at 0.5- to 1-week intervals to a full therapeutic dose, if using terazosin or doxazosin immediate-release Use tamsulosin, extended-release doxazosin, or alfuzosin, as alternatives to immediate-release products, particularly in patients taking other antihypertensives
	Malaise	Educate the patient that this is a common adverse effect; tolerance may develop to malaise; usually it is not so severe that it requires discontinuation of treatment
	Rhinitis	Educate the patent that this is a common adverse effect; tolerance may develop to rhinitis; usually it is not so severe that it requires discontinuation of treatment
	Retrograde ejaculation	Educate the patient that this is a common adverse effect and it is not harmful
5α-Reductase inhibitor	Gynecomastia	Educate the patient that this may be bothersome, but not harmful
	Decreased libido	If the patient is sexually active, sexual counseling may be helpful
	Erectile dysfunction	The addition of sildenafil or an other erectogenic drug may be helpful
	Ejaculation disorders	Educate the patient that this may occur but it is not harmful

Patient Care and Monitoring

- Monitor the patient for the drug's effectiveness in relieving symptoms by using the AUA Symptom Scoring Index. Monitor ensure that the score improves and that the patient subjectively feels that symptoms have improved. If the patient has no improvement after several weeks of a therapeutic dose of α-adrenergic antagonist or after 6 months of a 5α-reductase inhibitor, consider surgical intervention.
- If the patient is started on an α-adrenergic antagonist, monitor the patient for hypotension, dizziness, or syncope. If present, assess the severity of each symptom. Reduce the drug dose or discontinue the drug, as necessary. If the patient has malaise or rhinitis, reassure the patient that these are usual, but bothersome, adverse effect, that often improve with continued therapy.
- If the patient is started on a 5α-reductase inhibitor, monitor the patient for drug-induced decreased libido, erectile dysfunction, or ejaculation disorders. If severe, discontinue the drug.

50 Urinary Incontinence and Pediatric Enuresis

David R.P. Guay

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiology of the major types of urinary incontinence (urge, stress, overflow, and functional) and pediatric enuresis.
2. Recognize the signs and symptoms of the major types of urinary incontinence and pediatric enuresis in individual patients.
3. List the treatment goals for a patient with urinary incontinence or pediatric enuresis.
4. Compare and contrast anticholinergics/antispasmodics, α-adrenoceptor agonists, dual serotonin-norepinephrine reuptake inhibitors, vaginal estrogens, cholinomimetics, tricyclic antidepressants, and vasopressin analogues in terms of mechanism of action, treatment outcomes, adverse effects, and drug-drug interaction potential when used to manage urinary incontinence or pediatric enuresis.
5. Identify factors that guide drug selection for an individual patient.
6. Formulate a monitoring plan for a patient on a given treatment regimen based on patient-specific information.
7. Describe indicators for combination drug therapy of urinary incontinence or pediatric enuresis.
8. Describe nonpharmacologic treatment approaches (including surgery) for urinary incontinence or pediatric enuresis.
9. Formulate appropriate patient counseling information for patients undergoing drug therapy for urinary incontinence or pediatric enuresis.

Key Concepts

❶ Accurate diagnosis and classification of urinary incontinence type is critical to the selection of appropriate drug therapy.

❷ Patient-specific treatment goals should be identified. This frequently requires reaching a compromise between efficacy and tolerability of drug therapy. These goals are not static and may change with time.

❸ Patient characteristics (e.g., age, comorbidities, concurrent drug therapies, and ability to adhere to the prescribed regimen) can also influence drug therapy selection.

❹ Careful dose titration is necessary to maximize efficacy and tolerability.

❺ If therapeutic goals are not achieved, a switch to an alternative agent should be made.

❻ Many medications can influence the lower urinary tract, including those not used for managing genitourinary disorders, and can precipitate new onset or aggravate existing voiding dysfunction and urinary incontinence.

❼ Nonpharmacologic treatment can allow the use of lower drug doses. The combination of both therapies may have at least an additive effect on urinary incontinence signs and symptoms.

❽ The anticholinergic/antispasmodic drugs are the pharmacologic first-line treatments for urge urinary incontinence. They are the most effective agents in suppressing premature detrusor contractions, enhancing bladder storage, and relieving symptoms.

❾ Vaginally-administered estrogen plays only a modest role in managing stress urinary incontinence (urethral underactivity), unless it is accompanied by local signs of estrogen deficiency (e.g., atrophic urethritis or vaginitis).

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

⑩ The major impediment to using the α-adrenoceptor agonist class is the extensive list of contraindications.

⑪ The use of duloxetine in stress urinary incontinence is complicated by (1) the potential for multiple clinically relevant drug-drug interactions with cytochrome P-450 2D6 and 1A2 inhibitors, (2) withdrawal reactions if abruptly discontinued, (3) high rates of nausea and other side effects, (4) the hepatotoxicity that contraindicates its use in patients with any degree of hepatic impairment, and (5) its mild hypertensive effect.

⑫ In overflow urinary incontinence due to atonic bladder, a trial of bethanecol may be reasonable if contraindications do not exist.

⑬ In overflow urinary incontinence due to obstruction, the goal of treatment is to relieve the obstruction.

⑭ Considering that pharmacotherapy is inferior to select nonpharmacologic treatment modalities in pediatric enuresis, pharmacotherapy will be most valuable in patients who are not candidates for nonpharmacologic therapy due to nonadherence or who do not achieve the desired outcomes on nonpharmacologic therapy alone.

⑮ Desmopressin is the first-line drug choice in pediatric enuresis.

URINARY INCONTINENCE

Urinary incontinence (UI) is defined as the complaint of involuntary leakage of urine.[1] It is often associated with other bothersome lower urinary tract symptoms such as **urgency**, increased daytime **frequency**, and **nocturia**. Despite its prevalence across the lifespan and in both sexes, it remains an underdetected and underreported health problem that can have significant negative consequences for the individual's quality of life. Patients with UI may be depressed due to a perceived loss of self-control, loss of independence, and lack of self-esteem, and often curtail or substantially modify their activities for fear of an "accident." Serious medical and economic consequences may also occur in untreated or undertreated patients, including perineal dermatitis and infections, worsening or lack of healing of pressure ulcers, urinary tract infections (UTIs), falls, and the need for long-term institutionalization in extended care facilities [including skilled nursing facilities (SNFs), or nursing homes].

Patient Encounter, Part 1

A 50-year old woman with hypertension and diabetes comes into your clinic seeking advice about which incontinence pads work best. After questioning her, you determine that she has multiple issues of low volume urine loss daily, which is a significant change (increase) from 1 year ago. All episodes occur at times of physical activity. She's a single mother of three grown children, all delivered vaginally. Her last menstrual period was 11 months ago.

- What information suggests that she has UI?
- Does she have risk factors for UI?
- What additional information do you need to know before creating a treatment plan for this patient?

EPIDEMIOLOGY AND ETIOLOGY

The true prevalence of UI has been difficult to determine because of methodologic issues such as varying definitions of UI and reporting bias.[2] Although the condition occurs across the lifespan, the peak prevalence, at least in women, is around the age of menopause (~50 years) which is followed by a slight decrease in the 55- to 60-year-old age group, and then a steadily increasing prevalence after age 65. In general, the median prevalences of UI are as follows[3]:

- 20% to 30% in young females
- 30% to 40% in middle-aged females
- 30% to 50% in elderly females (50% to 75% in female SNF residents)
- 10% in adult males (in excess of 50% in elderly male SNF residents)

Urinary incontinence can result from abnormalities within (intrinsic to) and outside of (extrinsic to) the urinary tract. Within the urinary tract, abnormalities may occur in the urethra (including the bladder outlet and urinary sphincters), the bladder, or a combination of both structures. Focusing on abnormalities in these two structures, a simple classification scheme emerges for all but the rarest intrinsic causes of UI. ❶ *Accurate diagnosis and classification of UI type is critical to the selection of appropriate drug therapy.*

Stress Urinary Incontinence (SUI) (Urethral Underactivity)[4]

In SUI, the urethra and/or urethral sphincters cannot generate enough resistance to impede urine flow from the bladder when intra-abdominal pressures (that are transmitted to the bladder, which is an intra-abdominal organ) are elevated. Intra-abdominal pressures are elevated by exertional activities like exercise, running, lifting, coughing, and sneezing. The amount of urine lost is generally small with each episode. Nocturia and **enuresis** are rarely seen. The factors responsible for urethral underactivity are incompletely understood, although the loss of the **trophic** effects of estrogen on the uroepithelium at menopause is thought to be important. The peak of SUI prevalence in the perimenopausal years supports

this hypothesis. Clearly established risk factors for SUI include[5]:

- Pregnancy
- Childbirth (vaginal delivery)
- Menopause
- Cognitive impairment
- Obesity
- Increasing age

Unless the sphincter mechanism is compromised by surgery or trauma, SUI is exceedingly rare in males. The most common surgeries predisposing to SUI in males are radical prostatectomy for prostate cancer and transurethral resection of the prostate for benign prostatic hyperplasia.

Urge Urinary Incontinence (UUI) (Bladder Overactivity)[4]

In UUI, the detrusor (bladder) muscle is overactive and contracts inappropriately during the filling phase. The amount of urine lost per episode can be as large as the entire contents of the bladder may empty. Sleep may be disrupted by nocturia and enuresis.

In most patients, the cause of bladder overactivity is unknown (idiopathic). Clearly-established risk factors for UUI include:

- Increasing age
- Neurologic disorders (e.g., stroke, Parkinson's disease, multiple sclerosis, and spinal cord injury)
- Bladder outlet obstruction (e.g., benign or malignant prostatic enlargement or hyperplasia)

Overactivity may be myogenic or neurogenic in origin or a combination of both. These etiologies appear to be interconnected and complementary.

Overflow Urinary Incontinence (OUI) (Urethral Overactivity and/or Bladder Underactivity)[4]

In OUI, an important but uncommon form of UI in both sexes, the bladder is filled to capacity at all times but cannot empty, causing urine to leak out episodically. If caused by bladder underactivity, the detrusor muscle has weakened, in some cases enough to lose the ability to voluntarily contract. In this case, the bladder cannot be emptied completely and large volumes of residual urine remain after **micturition**. Clinically, this is most commonly seen in the setting of long-term chronic bladder outlet obstruction due to benign or malignant prostatic enlargement. However, this may also be a manifestation of neurogenic bladder, frequently a consequence of neuropathy in patients with diabetes. If due to urethral overactivity, the resistance of the urethra and/or sphincters cannot be overcome by detrusor contractility. This functional or anatomic obstruction results in incomplete bladder emptying. Clinically, in males this most frequently occurs in the context of long-term chronic bladder outlet obstruction as outlined previously. In females, urethral overactivity is rare but may result from **cystocele** formation or surgical overcorrection during anti-SUI surgery. In both sexes, systemic neurologic diseases such as multiple sclerosis or spinal cord injury may be the etiology.

Functional Urinary Incontinence[4]

Functional urinary incontinence is not generally caused by intrinsic urinary tract pathology. It is usually caused by factors extrinsic to the urinary tract. Examples of factors predisposing to functional incontinence include:

- Immobility (due to pain, traction, or use of non-portable medical devices)
- Lack of or slowed access to toileting facilities
- Cognitive impairment (difficulty with recognition of the urinary urge and proper response to it)
- UTIs
- Postmenopausal atrophic urethritis and/or vaginitis
- Diabetes mellitus (glucosuria leading to polyuria)
- Diabetes insipidus (polyuria due to decreased antidiuretic hormone)
- Pelvic malignancy (extrinsic pressure on urinary tract structures causing obstruction)
- Constipation or fecal impaction (see section on pelvic malignancy)
- Congenital malformations
- Central nervous system disorder resulting in a decreased level of consciousness (see section on cognitive impairment)
- Depression (apathy leading to recognition and response difficulties)

Mixed and Drug-Induced Urinary Incontinence[4]

Frequently, two or more types of UI may co-exist in a given patient, combinations termed mixed UI. This can lead to diagnostic and therapeutic difficulties due to the confusing array of presenting symptoms and the opposing effects that a given treatment can have in different types of UI (i.e., a given drug may reduce symptoms of one type of UI but worsen those of other types). Another interesting type of mixed UI is co-existing bladder overactivity (UUI) and impaired bladder contractility (OUI). Most common in the elderly, this combination is called *detrusor hyperactivity with impaired contractility* (DHIC).

❻ *Many medications can influence the lower urinary tract, including those not used for managing genitourinary disorders, and can precipitate new onset or aggravate existing voiding dysfunction and UI (Table 50–1).*

CLINICAL PRESENTATION AND DIAGNOSIS

Clinical Presentation of Urinary Incontinence Related to Urethral Underactivity[4]

General
The patient usually notes UI during activities like exercise, running, lifting, coughing, or sneezing. This type of UI is much more common in females (seen only in males with lower urinary tract surgery or injury compromising the sphincter).

Symptoms
Urine leakage with physical activity (volume is proportional to activity level). No UI with physical inactivity, especially when supine (no nocturia). May develop urgency and frequency as a compensatory mechanism (or as a separate component of bladder overactivity).

Diagnostic Tests
Observation of urethral meatus (opening) while patient coughs or strains.

Clinical Presentation of Urinary Incontinence Related to Bladder Overactivity[4]

General
Can have bladder overactivity and UI without urgency, if sensory input from the lower urinary tract is absent.

Symptoms
Urinary frequency (greater than 8 micturitions/day), urgency with or without urge incontinence; nocturia (greater than or equal to 2 micturitions/night) and enuresis may be present as well.

Diagnostic Tests
Urodynamic studies are the gold standard for diagnosis. Also urinalysis and urine culture should be negative (rule out urinary tract infection as cause of frequency).

Clinical Presentation of Urinary Incontinence Related to Urethral Overactivity and/or Bladder Underactivity[4]

General
Important but rare type of UI in both sexes. Urethral overactivity usually due to prostatic enlargement (males) or cystocele formation or surgical overcorrection following antiurethral underactivity (SUI) surgery (females).

Symptoms
Lower abdominal fullness, hesitancy, straining to void, decreased force of stream, interrupted stream, sense of incomplete bladder emptying. May have urinary frequency and urgency, too. Abdominal pain if acute urinary retention is also present.

Signs
Increased postvoid residual urine volume.

TABLE 50–1. Medications Influencing Lower Urinary Tract Function

Medication	Effect
Diuretics	Polyuria, frequency, urgency
α-Adrenoceptor antagonists	Urethral relaxation; may relieve obstruction in males, induces/worsens SUI in females
α-Adrenoceptor agonists	Urethral constriction; aggravates obstruction in males (may cause urinary retention), potential SUI treatment in females
Calcium channel blockers (dihydropyridines)	Urethral constriction (may cause urinary retention), especially in males
Opioid analgesics	Impaired bladder contractility (may cause urinary retention)
Sedative-hypnotics	Functional UI due to immobility, delirium, sedation
Psychotherapeutics with anticholinergic properties Anticholinergics	Urinary retention due to impaired bladder contractility or potential UUI treatment
TCAs	Combination of anticholinergic and α-adrenoceptor blocking activities can lead to unpredictable effects on UI
Ethanol	Polyuria and frequency (via effects on ADH), functional UI (delirium, sedation), urgency
ACEIs	Cough leading to SUI (ARBs do not induce cough)
Cyclophosphamide	Hemorrhagic cystitis due to acrolein metabolite (prevent with MESNA)

ACE-I, angiotensin-converting enzyme inhibitor; ADH, antidiuretic hormone (or vasopressin); ARB, angiotensin II receptor blocker, MESNA, sodium 2-mercaptoethanesulfonate; TCA, tricyclic antidepressant; UI, urinary incontinence; SUI, stress urinary incontinence; UUI, urge urinary incontinence.

The clinical presentation of UI depends on the underlying pathophysiology. The literature evaluating the prevalences of different UI types by age and sex has produced widely varying results due to a number of factors. The clinician should thus consider a given patient as having virtually any type of UI until ruled out during diagnostic evaluation.

A complete medical history and targeted physical examination are essential to correctly classify the type(s) of UI present. It is important to assess the degree of annoyance due to symptoms of the patient during the assessment. The degree of annoyance to the patient may not correlate well with the results of quantitative tests such as symptom frequency/severity, use of

absorbent products, frequency/severity of neurologic signs, and postvoid residual urine volume. This is especially the case in "hypersensitive" and "stoic" individuals. Items to address during the evaluation are illustrated in Table 50–2. Components of the physical examination include[4]:

- Abdominal examination (look for distended bladder)
- Neurologic evaluation of perineum and lower extremities (includes digital rectal exam to check rectal tone, reflexes, ability to perform a voluntary pelvic muscle contraction in females and size and surface quality of prostate in males)
- Pelvic exam (females) (look for evidence of **prolapse** of bladder, small bowel, rectum, or uterus, or estrogen deficiency)
- Genital/prostate exam (men)
- Direct observation of urethral meatus (opening) when patient coughs/strains (urine spurt consistent with SUI)
- Perineum exam (looking for skin maceration, redness, breakdown, ulceration and evidence of fungal skin infection)

TABLE 50–2. Items Which Should Be Addressed During Diagnostic Evaluation of Urinary Incontinence (UI)

Item	Comments
Urine leakage	
Use of absorbent products	Yes/no, type(s), quantity, times of day worn Quantity may relate more to personal preference and hygiene than to UI type and severity (e.g., use of large number of pads by a fastidiously hygienic patient with low volume loss)
Quantity lost per episode	Dribbling versus small volumes intermittently versus large volumes Consistent or varied quantities
Precipitants	Yes/no, physical activity, excessive fluid intake, drug(s)
Times of day	Daytime/nighttime/both
Symptoms	
Urgency	Yes/no, how often, how severe, duration from urge onset to micturition
Frequency	Yes/no, daytime/nighttime/both, how often
Nocturia	Yes/no, how often, proportion with UI
Obstructive symptoms	Yes/no, type(s) (**hesitancy**, strain to void, decreased force of stream, start and stop stream, sense of incomplete emptying), severity
Lower abdominal fullness	Yes/no, how often, how severe
Comorbidities	
Current medication use	See Table 50–1 Remember **CAMs**, OTCs
Evidence of preexisting or new-onset	
Diabetes mellitus	
Metastatic or genitourinary malignancy	
Multiple sclerosis or other neurologic disease	
CNS disease above the pons	Usually UUI
Spinal cord injury	UUI or OUI, depending on level and degree of completeness of injury
Recent non-genitourinary surgery	Functional UI
Previous local surgery/radiation	Prostate surgery, lower abdominal cavity surgery (direct injury vs. **denervation**), radiation (direct injury)
Gynecologic history	Childbirth (vaginal vs. cesarean section), prior gynecologic surgery, hormonal status (pre- vs. postmenopausal)
Pelvic floor disease	Constipation, diarrhea, fecal incontinence, **dyspareunia**, sexual dysfunction, pelvic pain
UTI	**Dysuria**, CVA tenderness, frequency
Gross hematuria	Possible bladder or other genitourinary cancer

CAM, complementary and alternative medications; CNS, central nervous system; CVA, costovertebral angle; OTC, over-the-counter; OUI, overflow urinary incontinence; SUI, stress urinary incontinence; UTI, urinary tract infection; UUI, urge urinary incontinence.

Patient Encounter, Part 2: The Medical History, Physical Examination, and Diagnostic Tests

PMH
Insulin-dependent diabetes mellitus since age 7; it is "reasonably well-controlled" per patient
Hypertension for 2 years, currently "controlled" per patient

FH
Mother had diabetes and died of a myocardial infarction at 62 years of age; father smoked 1 to 3 packs of cigarettes per day and developed fatal lung cancer at age 57

SH
Works two jobs as a waitress; denies alcohol use or smoking

Meds
NPH insulin 20 units before breakfast and 5 units before supper
Enalapril 10 mg twice daily
Aspirin 325 mg once daily

ROS
(+) Recurrent coughing, urinary incontinence, dyspareunia, vaginal itching, multiple UTIs; (–) nocturia, enuresis, urgency, dysuria, frequency, lower abdominal fullness, decreased force of stream

PE
VS: Blood pressure 124/70 mm Hg, pulse 80 beats per minute, respiratory rate 16/minute, temperature 37.0°C (98.6°F)
CV: RRR; normal S_1, S_2; no murmurs, rubs, gallops
Abd: Soft, non-tender, non-distended; (+) bowel sounds; bladder not palpable
Neuro: Within normal limits (gross sensory, motor, reflexes)
GU: Valsalva caused urine spurt; friable, bleeding vaginal lining on pelvic exam

Labs
Hemoglobin A1c 8.2% (0.082); rest within normal limits

- Given this additional information, what is your assessment of the patient's condition?
- Identify your treatment goals for the patient.
- What nonpharmacologic and pharmacologic alternatives are available to the patient?

TREATMENT

❷ *Patient-specific treatment goals should be identified. This frequently requires reaching a compromise between efficacy and tolerability of drug therapy. These goals are not static and may change with time.*

Desired Outcomes

- Restoration of continence
- Reduction of the number of UI episodes (daytime and nighttime) and frequency of nocturia
- Prevention of disease complications (e.g., dermatologic infections and skin breakdown, delay institutionalization)
- Avoidance or minimization of adverse consequences of treatment
- Minimization of treatment costs
- Improvement in patient's quality of life

Nonpharmacologic Treatment

At the primary care level, nonpharmacologic treatment of UI constitutes the chief approach to UI management. In patients in whom pharmacologic or surgical management is inappropriate or undesirable or refused, non-surgical nonpharmacologic treatment is the only option. Examples of patients fitting this scenario include:

- Those not medically fit for surgery
- Those who plan future pregnancies (as pregnancy/childbirth can compromise the long-term results of certain types of continence surgery)
- Those with OUI whose condition is not amenable to surgical or drug treatment
- Those with comorbidities which place them at high risk for significant side effects to drug therapy
- Those who wish to delay or avoid surgery
- Those with mild to moderate symptoms who do not wish to undergo surgery or take medication

Nonpharmacologic approaches include lifestyle modifications, scheduled voiding regimens, pelvic floor muscle rehabilitation, anti-incontinence devices, and supportive interventions.[4,6] Many of these are best utilized through attendance at multidisciplinary UI clinics staffed by specialist nurses and/or physical therapists in addition to physicians. Behavioral interventions are among the first-line treatment approaches for SUI, UUI, and mixed UI. However, these lifestyle modifications, scheduling regimens, and pelvic floor muscle rehabilitation methods require a motivated patient and/or caregiver who can play an active role in developing the treatment plan. Anything that interferes with active participation (including cognitive dysfunction) will render these approaches suboptimal. Patients/caregivers also must attend regular follow-up visits to monitor outcomes. Even if the results of nonpharmacologic treatment have not fully achieved the desired outcomes, if it has provided at least some improvement in UI signs and symptoms, it should be continued during pharmacologic treatment. ❼ *Nonpharmacologic treatment can allow the use of lower drug doses. The combination of both therapies may have at least an additive effect on UI signs and symptoms.*

Surgery is rarely a first-line treatment for UI. Surgery is generally considered only when the degree of bother or lifestyle compromise is sufficient and other non-operative therapies are either undesired or have been ineffective. Surgery can be used to manage urethral overactivity due to benign prostatic enlargement and

bladder outlet obstruction (via endoscopic incision using a cystoscope). Bladder underactivity cannot be managed surgically and rarely is surgery considered for UUI. Surgery is most effective in the management of SUI. Surgery for SUI is directed toward stabilizing the urethra and bladder neck and/or augmenting urethral resistance using periurethral collagen and other injectables. In males, SUI is best treated by implanting an artificial urinary sphincter.[4]

Pharmacologic Treatment

❽ *The anticholinergic/antispasmodic drugs are the first-line pharmacologic treatment for urge urinary incontinence. They are the most effective agents in suppressing premature detrusor contractions, enhancing bladder storage, and relieving symptoms.* It must be emphasized that the improvements in clinical and urodynamic parameters are modest at best, although still considered by experts in the field to be positive.[13] In a recent systematic review/meta-analysis of 56 clinical trials in UUI, only four statistically-significant differences in efficacy between drugs were found. Solifenacin produced greater reductions in the frequency of urgency episodes and frequency of micturition than did tolterodine immediate-release (IR). Oxybutynin extended-release (ER) produced a greater reduction in the frequency of incontinence episodes and a greater proportion of patients returned to continence compared to tolterodine long-acting (LA).[13]

The major problem with existing agents is their lack of selectivity to bladder muscarinic receptors, thus leading to dose-limiting side effects outside of the urinary tract. These include dry mouth, constipation, blurred vision, confusion, cognitive dysfunction, and tachycardia. With oxybutynin, orthostasis due to α-receptor blockade and sedation and weight gain due to histamine-receptor blockade may also occur. Dry mouth is the most problematic of the anticholinergic side effects and is frequently dose-limiting. In the systematic review and meta-analysis cited previously, there were multiple significant differences between agents. From the perspective of all-cause premature discontinuation from therapy, tolterodine LA followed by darifenacin and solifenacin were the best tolerated, while oxybutynin IR was the least tolerated. From the perspective of adverse-event profiles, oxybutynin IR 5 to 7.5 mg/day and tolterodine (IR and LA) were the best tolerated, while darifenacin, oxybutynin IR at greater than 7.5 mg/day, oxybutynin transdermal (TD), solifenacin (5 and 10 mg/day), and trospium chloride (40 mg/day) were the least tolerated. Oxybutynin IR at greater than 7.5 mg/day was the least tolerated compared to all other anticholinergics in 13/20 (65%) rate comparisons, and was the only drug to be significantly associated with urinary retention.[13]

Details regarding the pharmacokinetics, contraindications/precautions, and dosing of the five recommended agents (oxybutynin, tolterodine, trospium chloride, solifenacin, and darifenacin) are illustrated in Table 50–3.[7–12,14–16] A current clinical controversy is which of these agents should be considered first-line in UUI, and in the case of oxybutynin and tolterodine, which formulations should be recommended. There are few head-to-head clinical trials to assist in decision making and those few that exist have demonstrated either broad equivalence or clinically-unimportant differences in efficacy. ❸ *Patient characteristics (e.g., age, comorbidities, concurrent drug therapies, and ability to adhere to the prescribed regimen) can also influence drug therapy selection.* Drug selection frequently will be based on differences in tolerability (wherein the extended-release oral or transdermal formulations are better tolerated than the immediate-release formulations) and cost. ❹ *Careful dose titration is necessary to maximize efficacy and tolerability.* The selected agent should be titrated to the maximum tolerated dose and maintained there for at least 4 weeks in order to assure an adequate therapeutic trial. ❺ *If therapeutic goals are not achieved, a switch to an alternative agent should be made.* There is no rationale for use of two or more anticholinergics concurrently at low doses.

Other drugs, such as propantheline, flavoxate, tricyclic antidepressants (especially imipramine), dicyclomine, and scopolamine, are less effective, no safer, and/or have not been adequately studied; therefore, their use is not recommended.[6]

Women with mixed UI (UUI plus SUI) or UUI plus atrophic vaginitis and/or urethritis may also benefit from the addition of a locally-administered (per vagina) estrogen to anticholinergic therapy.

Stress Urinary Incontinence

The goal of pharmacologic therapy of urethral underactivity is to improve the urethral closure mechanism by one or more of the following:

- Stimulating α adrenoceptors in the smooth muscle of the proximal urethra and bladder neck
- Enhancing the supportive structures underlying the urethral mucosa
- Enhancing the positive effects of serotonin and norepinephrine in the afferent and efferent pathways of the micturition reflex

There is no role for pharmacologic therapy in SUI in males resulting from surgery or trauma.[17] It should be kept in mind that SUI (in contrast to UUI) is frequently curable by surgery, thus obviating years of drug therapy that may be incompletely effective in symptom relief.

Estrogens[4]

❾ *Vaginally-administered estrogen plays only a modest role in managing stress urinary incontinence (urethral underactivity), unless it is accompanied by local signs of estrogen deficiency (e.g., atrophic urethritis or vaginitis).*

Although not supported by rigorous clinical trial evidence, local (per vagina) and systemic estrogens have been considered mainstays of pharmacologic management since the 1940s. They are believed to work by a trophic effect on uroepithelial cells and underlying collagenous subcutaneous tissue,

TABLE 50–3. Anticholinergic/Antispasmodic Drugs Recommended For Urge Urinary Incontinence

Parameter	Oxybutynin	Tolterodine	Trospium chloride	Solifenacin	Darifenacin
Dosage forms	IR tablets, solution SR-XL tablets, SR-TD patch	IR tablets SR-LA capsules	IR tablets	IR tablets	ER tablets
Dosing	IR: 2.5–5 mg two to four times daily SR (oral): 5–30 mg once daily SR (TD): 3.9 mg/day patch applied twice weekly	IR: 1 or 2 mg twice daily SR: 2 or 4 mg once daily	20 mg twice daily	5–10 mg once daily	7.5–15 mg once daily
Kinetics	Active metabolite (N-desethyl) Not altered in renal or hepatic disease or advanced age	Active metabolite (5-hydroxymethyl) **Polymorphic** metabolism (CYP4502D6) Not altered in advanced age. Sign. altered in hepatic disease (decreased CL in cirrhosis) and renal disease (decreased CL)	Food decreased BA 70–80% Sign. altered in renal disease (decreased CL) but not hepatic disease or advanced age	Metabolized via CYP4503A4 but only one active metabolite (4-hydroxy) Sign. altered in severe renal impairment, moderate hepatic impairment (Child-Pugh B), and advanced age (decreased CL in all)	Complex metabolism (polymorphic CYP4502D6, CYP4503A4) Not altered in advanced age, renal impairment, mild hepatic impairment (Child Pugh A) Sign. altered in moderate hepatic impairment (Child-Pugh B) (decreased CL)
Contraindications and precautions	Use caution if CYP4503A4 inhibitors are also being taken (decreased oxybutynin CL)	Reduce dose 50% in those taking CYP4503A4 inhibitor(s) or with hepatic cirrhosis or with CrCl less than 30 mL/minute Antacid-SR (oral) prep. interaction (dose-dumping) (not seen with PPI)	Give on empty stomach Decrease dose 50% when CrCl less than 30 mL/minute	Do not exceed 5 mg/day if CrCl less than 30 mL/minute, patient has moderate hepatic impairment, or patient is taking CYP4503A4 inhibitor(s) If severe hepatic impairment, do not use	Do not exceed 7.5 mg/day if patient is taking potent CYP4503A4 inhibitor(s) Use caution if patient is taking moderate CYP4503A4 inhibitor(s) or CYP4503A4 or 2D6 substrate(s) Do not chew, divide, or crush the extended-release tablets

BA, bioavailability; CL, total body clearance; CrCl, creatinine clearance; CYP450, cytochrome P-450; ER, extended-release; IR, immediate-release; LA, long-acting; PPI, proton pump inhibitor; Sign., significantly; SR, sustained-release; TD, transdermal.

enhancement of local microcirculation, and enhancement of the number and/or sensitivity of α adrenoceptors. Open trials have supported the use of estrogens administered by the parenteral, oral, transdermal, and local routes of administration. However, randomized controlled trials have found no significant clinical or urodynamic effects of oral estrogen compared to placebo in SUI. Systemic estrogen therapy also carries numerous short- and long-term side effect risks (mastodynia, uterine bleeding, nausea, thromboembolism, cardiac and cerebrovascular ischemic events, and enhanced breast and endometrial cancer risks). If estrogens are to be used in SUI management, only locally-administered products should be used (Table 50–4).

TABLE 50–4. Drugs Used for Stress Urinary Incontinence

Parameter	Estrogens	Pseudoephedrine	Duloxetine
Dosage forms	Avoid systemic (parenteral, oral, TD); vaginal: tablet, cream, intravaginal ring	Tablets, solution	DR capsules
Dosing	Estradiol 25 mcg vaginal tablets (insert one PV daily × 14 days, then one PV twice weekly) CEE vaginal cream (1/2–2 g daily PV; consider 3 weeks on, 1week off; may be able to decrease frequency of use over time) Estradiol 2 mg vaginal ring (1 ring PV every 3 months)	15–60 mg three times daily	40–80 mg/day (1 or 2 doses)
Kinetics	Use local route to minimize systemic BA and side effects	Less than 1% of dose is metabolized (inactive metabolite) Primarily renal elimination of unchanged drug Would not expect hepatic impairment to have an effect (no data) Expect sign. effect of renal impairment and no effect of advanced age (beyond decreased CrCl with age) (no data)	Extensive metabolism via CYP4502D6 and 1A2 (inactive metabolites) Not altered in advanced age, mild to moderate renal impairment, mild hepatic impairment (Child-Pugh A). Sign. altered in severe renal disease and moderate hepatic impairment (Child-Pugh B) Systemic exposure to duloxetine decreased by 1/3 in smokers (dose change not recommended)
Contraindications/ Precautions	Contraindications include known or suspected breast or endometrial cancer Abnormal genitourinary bleeding of unknown etiology Active thromboembolism (or history of TE assoc. with previous estrogen use)	Contraindications include hypertension, tachyarrhythmias, coronary artery disease, MI, cor pulmonale, hyperthyroidism, renal failure, narrow-angle glaucoma	Multiple drug-drug interactions possible with CYP4502D6 and 1A2 substrates/ inhibitors Avoid if CrCl less than 30 mL/minute and in all patients with hepatic disease Can raise BP Do not discontinue abruptly (withdrawal syndrome) Suicide risk even in patients without psychiatric disease Avoid in uncontrolled narrow-angle glaucoma (causes mydriasis) Hepatotoxic; avoid in alcoholics even if signs/symptoms of hepatic disease are absent.

BA, bioavailability; BP, blood pressure; CEE, conjugated equine estrogens; CrCl, creatinine clearance; CYP450, cytochrome P-450; DR, delayed-release; MI, myocardial infarction; PV, per vagina; Sign., significantly; TD, transdermal; TE, thromboembolism.

Alpha-Adrenoceptor Agonists[4]

Open and randomized controlled trials utilizing clinical and urodynamic endpoints have supported the use of a variety of α-adrenoceptor agonists, including phenylpropanolamine, ephedrine, and pseudoephedrine, in the therapy of mild and moderate SUI. In addition, several studies have demonstrated clinical and urodynamic benefits for combination estrogen–α-adrenoceptor agonist use over those of the individual agents. Phenylpropanolamine was removed from the United States market in late 2000 due to the risk of ischemic stroke in women taking this drug.[18] However, this drug is still available via the Internet, so clinicians need to monitor and discourage its use. Although still available by prescription, ephedrine is considerably more toxic than other α-adrenoceptor agonists and its use is not recommended. Although phenylephrine is now available in oral formulations, the lack of data regarding its use in SUI and the reported lack of efficacy in maximum recommended doses for rhinitis suggest that this agent should be avoided at present.

This leaves the clinician with only one practical agent to use: pseudoephedrine (Table 50–4). Side effects include hypertension, headache, dry mouth, nausea, insomnia, and restlessness.[19] ⑩ *The major impediment to using the α-adrenoceptor agonist class is the extensive list of contraindications (Table 50–4).* In the past, α-adrenoceptor agonist therapy was generally added to estrogen therapy in those insufficiently improved with estrogen alone and in whom its use was not contraindicated. With the recent availability of duloxetine, treatment is now available for estrogen non- or hypo-responders who cannot take α-adrenoceptor agonists.

Duloxetine[20]

Duloxetine is a selective serotonin-norepinephrine reuptake inhibitor similar pharmacologically to venlafaxine. Approved for the treatment of major depression and painful diabetic peripheral neuropathy, its use in SUI is off-label. Duloxetine enhances central serotonergic and adrenergic tone which is involved in ascending and descending control of urethral smooth muscle and the internal urinary sphincter. Urethral and urinary sphincter smooth muscle tone during the filling phase are thus enhanced.[21,22] The pharmacokinetics, contraindications/precautions, and dosing of duloxetine are illustrated in Table 50–4.[20,23] Clearly, duloxetine has demonstrated modest efficacy in SUI and a major question is its role in SUI compared to estrogen and α-adrenoceptor agonists. In the absence of head-to-head clinical trial data, this is a difficult question to answer, at least for the comparison of duloxetine to α-adrenoceptor agonists. ⑪ *The use of duloxetine in stress UI is complicated by (1) the potential for multiple clinically-relevant drug-drug interactions with cytochrome P450 (CYP450)2D6 and CYP4501A2 inhibitors, (2) withdrawal reactions if abruptly discontinued, (3) high rates of nausea and other side effects, (4) hepatotoxicity contraindicating its use in patients with any degree of hepatic impairment, and (5) its mild hypertensive effect.*

Patient Encounter, Part 3: Creating a Care Plan

Based on the information presented, create a care plan for this patient's UI. Your plan should include: (1) a statement of the drug-related needs and/or problems, (2) the goals of therapy, (3) a patient-specific detailed therapeutic plan, and (4) a plan for follow-up to determine whether or not the goals have been achieved and adverse events avoided.

Overflow Incontinence Due to Bladder Underactivity[4]

⑫ *In overflow UI due to atonic bladder, a trial of bethanecol may be reasonable if contraindications do not exist.* There is no established effective pharmacologic therapy for OUI due to poor bladder contractility (atonic bladder). The efficacy of the cholinomimetic bethanecol (25 to 50 mg three or four times daily) is uncertain and in well done clinical trials it has had mixed results. In addition, its cholinomimetic effect is not urospecific and its side effects are bothersome, including muscle and abdominal cramping, hypersalivation, diarrhea, and potentially life-threatening bradycardia and bronchospasm. α-Adrenoceptor blockers such as prazosin, terazosin, doxazosin, tamsulosin, and alfuzosin may benefit this condition by relaxing the bladder outflow tract and hence reducing outflow resistance. If pharmacologic therapy fails, intermittent urethral catheterization by the patient or caregiver three or four times per day is recommended. Less satisfactory alternatives include indwelling urethral or suprapubic catheters or urinary diversion.

Overflow Incontienence Due to Obstruction

⑬ *In overflow UI due to obstruction, the goal of treatment is to relieve the obstruction.*

OUTCOME EVALUATION

- Monitor the patient for symptom relief. Have the desired outcomes jointly developed by the health care team and the patient/caregiver been achieved and to what degree? Inspect the daily diary completed by the patient/caregiver since the last clinic visit and quantitate the clinical response (e.g., number of micturitions, number of incontinence episodes, and pad use). If a diary has not been used, ask the patient how many incontinence pads have been used and how they have been doing in terms of "accidents" since the last visit. If appropriate, administer a short-form instrument used to measure symptom impact and condition-specific quality of life and compare previous result(s).
- Elicit adverse effects of drug therapy using a non-leading approach and ask the patient/caregiver to judge their severity and what measures, if any, the patient used to ameliorate them. Assess adherence (ask patient about missed doses or do a pill count if the prescription container was brought to the visit).

- The balance of clinical response and tolerability will dictate the approach to adjusting drug dosage. Potential approaches include dosage increase, maintenance, or decrease. If adverse effects are quite bothersome to the patient and patient safety and/or adherence are compromised, stop, or taper, the offender and initiate another drug option.

Patient Care and Monitoring

1. Assess the patient's symptoms to determine if patient-directed therapy is appropriate or whether the patient should be evaluated by a physician. Assessment includes the types and severities of symptoms and the presence or absence of exacerbating factors. Does the patient have any UI-related complications?
2. Review any available diagnostic data to determine disease status.
3. Obtain a thorough medication history, including use of prescription, non-prescription, and complementary and alternative drug products. Determine which, if any, treatments in the past had been helpful as judged by the patient. Could any of the patient's current medications be contributing to UI?
4. Educate the patient on lifestyle modifications that may improve symptoms, including but not limited to, smoking cessation (for patients with cough-induced stress UI), weight reduction for those patients with stress and urge UI, prevention of constipation in patients at risk, caffeine reduction, and modification of diet and fluid intake (e.g., timing and quantity of fluid intake and avoidance of foods or beverages that worsen UI).
5. Is the patient taking the appropriate drug(s) for his or her type(s) of UI? Are the dose(s) appropriate? If not (to either question), why?
6. Develop a plan to assess efficacy after a minimum of 4 weeks.
7. Assess changes in quality of life (physical, psychological, social functioning, and well-being).
8. Evaluate the patient for drug-related adverse events, allergies, and interactions (drug-drug and drug-disease).
9. Stress the importance of adherence with the prescribed regimen, including lifestyle modifications. Recommend the most "patient-friendly" treatment regimen possible.
10. Provide patient education regarding the disease state, lifestyle modifications, and drug therapy:
    - Causes of UI and what things to avoid (see #3 and #4, above)
    - Possible UI complications
    - Timing of medication intake
    - Potential adverse events (limit to most frequent and/or clinically-relevant)
    - Potential drug-drug interactions

PEDIATRIC ENURESIS

Pediatric enuresis is not a disease but a symptom, which can present alone or at the same time as other disorders, in children and adolescents. It is defined as the repeated voiding of urine into bed or clothes at least twice a week for at least three consecutive months in a child at least 5 years old (per the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision).[24,25] Enuresis can still be present even if the above frequency and duration parameters are not met, provided that associated distress or functional impairment exists. The terms "nocturnal" and "diurnal" refer to periods during sleep and while awake, respectively. Primary enuresis refers to a process wherein the patient has never been consistently dry throughout the night. Secondary enuresis refers to a process wherein the patient has resumed wetting after a period of dryness of at least 6 months in duration. Lastly, monosymptomatic and polysymptomatic enuresis should be differentiated. Monosymptomatic enuresis refers to wetting at nightttract symptoms and no daytime symptoms. Polysymptomatic enuresis refers to wetting at nighttime associated with other urinary tract symptoms (e.g., urge or freqime without any other urinary uency) and daytime symptoms as well.

Enuresis is not a benign disorder that children will just "grow out of." Emotional and/or physical abuse of the child by adult caregivers lead to secondary problems such as chronic anxiety, low self-esteem, and delayed developmental milestones such as attending camp or going on "sleepovers" at the homes of friends. The emotional and developmental damage produced by enuresis may be more significant to the child than the enuresis itself.

The American Academy of Child and Adolescent Psychiatrists and the International Children's Continence Society (ICCS) have published practice guidelines for the assessment and treatment of pediatric enuresis.[24,25]

EPIDEMIOLOGY AND ETIOLOGY

Five to seven million children and adolescents in the United States suffer from nocturnal enuresis. Primary enuresis is twice as common as secondary enuresis. Enuresis is twice as common in boys as compared to girls. The incidence of enuresis varies as a function of age[24,25]:

- 40% in 3-years-old
- 12% to 25% in 4-years-old
- 15% to 20% in 5-years-old
- 10% in 6-years-old
- 6% to 10% in 7- and 8-years-old
- 5% in 10-years-old
- 2% to 3% in 12-years-old
- 1% to 3% in adolescents
- 0.5% in adults

Five to ten percent of children with enuresis will suffer the condition as adults. It may also predispose to UUI in adults. In the enuretic population, 80% to 85% are monosymptomatic, 5% to 10% are polysymptomatic, and under 5% have an organic cause. The spontaneous annual cure rate (i.e., restoration of continence) ranges from 14% to 16% (exception: at about 4 or 5 years of age, it may be as high as 30%).

The etiology of enuresis is poorly understood, but there is a clear genetic link. The incidence in children from families in whom there are no members with enuresis, where one parent had enuresis as a child, and where both parents had enuresis as children are 14%, 44%, and 77%, respectively. Loci for enuresis have been located on chromosomes 12, 13, and 22. Sleep disorders are not considered major contributors with the exception of sleep apnea. Enuresis occurs in all sleep stages in proportion to the time spent in each stage. However, a small proportion of individuals are not aroused from sleep by bladder distention and have uninhibited bladder contractions preceding enuresis.

PATHOPHYSIOLOGY

The vast majority of children with enuresis have normal urodynamics, including nocturnal bladder capacity. Functional bladder capacity can be estimated using this formula: age in years + 2 = ounces of capacity. In some children, there appears to be a relationship between developmental immaturity (motor and language milestones) and enuresis, but the mechanism is unknown. Drugs like lithium, clozapine, risperidone, valproic acid, and theophylline can rarely cause and aggravate enuresis. Psychological factors are clearly contributory in only a minority of individuals. The most frequent example of this is secondary enuresis precipitated by a stressor such as divorce, school trauma, sexual abuse, or hospitalization. In rare cases, the family may be so dysfunctional that the child has never been properly toilet-trained.

Clinical Presentation and Diagnosis

Proper assessment of the child or adolescent with enuresis should explore every aspect of urinary incontinence, especially the genitourinary and nervous systems. The minimum assessment should include[24,25]:

- Interview of child and parent(s), being sensitive to the emotional consequences of the enuresis
- Direct physical examination, looking for enlarged adenoids/tonsils, bladder distention, fecal impaction, abnormal genitalia, spinal cord anomalies, and abnormal neurologic signs (look for an organic cause amenable to surgery or drugs; Table 50–5)
- Obtain a urinalysis (consider a urine culture at the same time)

A 2-week diary of wet and dry nights prior to intervention is useful in that it can be used to monitor the response to treatment. A first-morning urine specific gravity may help to predict response to desmopressin therapy. Polysymptomatic presentation may require a more elaborate work-up, including voiding cystourethrogram, renal and/or bladder ultrasound, urodynamics, and sleep studies.

TABLE 50–5. Major Potentially Treatable Organic Causes of Enuresis

Potentially Treatable by Surgery
• Ectopic ureter
• Lower UTI (correct congenital anomalies)
• Neurogenic bladder
• Bladder calculus (stone) or foreign body
• Obstructive sleep apnea
Potentially Treatable by Drugs
• UTI
• Diabetes mellitus
• Diabetes insipidus
• Fecal impaction
• Constipation

UTI, urinary tract infection.

TREATMENT

Desired Outcomes

- Restoration of continence, which may not be an initially realistic outcome
- Reduction in the number of enuresis episodes
- Prevention or amelioration of disease complications including adverse psychological effects on the patient and caregivers or delay in developmental milestones
- Avoidance or prevention of adverse treatment effects
- Minimization of treatment costs
- Improvement in the patient's and caregivers' quality of life

General Approach to Treatment

Treatment is guided by the findings of the patient assessment. Daytime wetting, abnormal voiding such as unusual posturing, discomfort, straining, or poor stream, history of recurrent UTIs, and abnormalities of the genitalia suggest the need for referral to a urologist. In the rare circumstance of a true psychological cause, individual and/or family psychotherapy and crisis intervention are recommended.

In the absence of an identified cause and comorbidities, monosymptomatic nocturnal enuresis is present which can be amenable to nonpharmacologic and pharmacologic therapies. Nonpharmacologic therapy should be utilized initially, provided that the patient and family are sufficiently motivated. Use of one nonpharmacologic method at a time is reasonable, provided that each is given an adequate trial period. If response is suboptimal after 6 months, a different method should be substituted or added. There is some evidence to

justify combination therapy. There is no consensus as to when pharmacologic therapy should be added to or substituted for nonpharmacologic therapy. ⓮ *Considering that pharmacotherapy is inferior to select nonpharmacologic treatment modalities in pediatric enuresis, pharmacotherapy will be most valuable in patients who are not candidates for nonpharmacologic therapy due to non-adherence or who do not achieve the desired outcomes on nonpharmacologic therapy alone.*

Nonpharmacologic Treatment[26]

The standard first-line therapy is supportive in nature. This involves education about the condition, demystification, and assurance that the parents do not punish the child for enuresis. Journal keeping, fluid restriction, and nighttime awakenings of the child to preempt "accidents" make for a high level of caregiver involvement. The behavioral treatments of enuresis are explained in Table 50–6. Alarms, overlearning, and dry-bed training are the most complex and effective nonpharmacologic treatments available and compare favorably to pharmacologic therapy. A 3- to 6-month trial is recommended. Once dryness is achieved, relapse rates are low.

Measures that *do not* help include:

- Bladder stretching exercises (done by delaying voiding despite the urge to do so)
- Hypnotherapy
- Dietary changes
- Desensitization to allergens
- Acupuncture[27]
- Chiropractic

Pharmacologic Treatment

The two primary agents used to treat enuresis are desmopressin and imipramine (Table 50–7). ⓯ *Desmopressin is the drug of choice in pediatric enuresis.* Anticholinergics have a limited role (Table 50–7). Other agents have been studied with inconclusive results.[28]

Desmopressin (DDAVP) [29,30]

A synthetic analogue of antidiuretic hormone (ADH), desmopressin (DDAVP) was first studied in enuresis in the 1970s. It was approved by the Food and Drug Administration (FDA) in 1990 for the treatment of nocturnal enuresis in children at least 6 years of age. It decreases the number of wet nights per week by a mean of 1.34. The between-study variability in response to DDAVP is quite large, with a frequency of wetting ranging from 10% to 91% of patients, but only 25% become completely dry on the drug. Response is dose-independent for the nasal formulation (20 = 40 = 60 mcg); however, 20 mcg is the minimum dose resulting in therapeutic benefit. Response is dose-dependent for the oral formulation (for example, the number of wet nights fell 27%, 30%, and 40% with 0.2-, 0.4-, and 0.6-mg doses, compared to 10% with placebo in one study). Benefit exists only as long as

TABLE 50–6. Behavioral Treatments For Enuresis

Lifting	Procedure wherein the caregiver takes the child to the toilet at regular intervals during the night to urinate without fully awakening him or her
Night awakening	Procedure wherein the caregiver fully awakens the child to void shortly before he or she would usually have wet the bed; once the child is consistently dry, the frequency of awakening drops or (for single awakenings) the time of awakening is gradually moved to earlier in the night (i.e., closer to bedtime) until the child is dry when awakened 1 hour after going to bed
Alarm	An alarm device and a moisture-sensitive sensor are used in combination, with the sensor being placed under the sheets, or more commonly, attached to the child's pajamas or underwear near the urethra
Overlearning	This is commenced at a minimum of 2 weeks after the alarm has rendered the child dry; the child drinks 500 mL during the hour before going to bed; alarm use is continued until he or she is dry for 14 consecutive nights with the extra fluid intake; is used to reduce relapse rates seen with alarm use alone
Dry-bed training	This begins with an intensive first night of training which involves increased fluid consumption, hourly awakenings, praise when the bed is dry at hourly awakenings, and, when the alarm goes off, a mild reprimand and cleanliness training (child changes wet clothes and bed linens, remakes the bed, resets the alarm); before going to bed and after each wetting, the child engages in 20 practice trials of appropriate toileting (i.e., positive practice): for each practice trial, the child lies in bed, counts to 50, arises and attempts to urinate in the toilet, then returns to bed; on subsequent nights, child is woken only once, usually about 3 hours after the child has gone to bed; after a dry night, the night awakening moves up 30 minutes earlier; it is discontinued when it is scheduled to occur 1 hour after bedtime; after 7 consecutive dry nights, the alarm is discontinued, but is reinstituted if two episodes of wetting occur in a 1-week period

TABLE 50–7. Dosing of Pharmacologic Treatments of Enuresis

Desmopressin	Nasal: Start with 10 mcg 1 hour before bedtime and titrate upward in 10 mcg increments every week to a maximum of 40 mcg per day Oral: Start with 0.2 mg 1 hour before bedtime and titrate upward in 0.1 mg increments every week to a maximum of 0.6 mg per day
Imipramine	Start with 1 mg/kg per day (approx. 25 mg in 5- to 8-years-old and 50 mg in older children and adolescents) and titrate in 0.5 mg/kg-per-day increments every 2 weeks to a maximum of 2.5 mg/kg per day
Oxybutynin	Start with 0.1 mg/kg per day and titrate upward; available in oral solution to facilitate pediatric dosing.

the patient takes DDAVP, with relapse rates of up to 94% after discontinuation. Insufficient data are available to judge the relative efficacies of the two formulations. DDAVP appears to work better with monosymptomatic versus polysymptomatic enuresis. The oral route is generally preferred since nasal congestion and sinusitis can reduce the bioavailability of the nasal formulation. DDAVP is an ideal agent for rapid-onset, short-term use such as attendance at camp or going on a "sleepover." If the desire is for long-term therapy and if it is sufficiently effective short-term, a 3- to 6-month trial is reasonable. At the end of this period, the drug should be tapered off by 0.1 mg (oral) or 10 mcg (nasal) per month. Relapse is less likely with a tapered withdrawal compared to an abrupt discontinuation. Side effects to DDAVP are minor and infrequent.[31] The most serious complication, water intoxication, is extremely uncommon when DDAVP is used to treat enuresis, with only 50 reported cases.[31] However, electrolyte monitoring is recommended if intercurrent illness complicates the situation. Children should also not drink more than 8 ounces of fluid at dinnertime, 8 ounces in the evening, and none in the 2 hours prior to bed in order to reduce the risk of water intoxication.

Imipramine[32]

The tricyclic antidepressant (TCA) imipramine was first used in the treatment of enuresis in the 1960s. Although trials involving other TCAs have been performed over the years, there is insufficient evidence to assess the relative performance of these agents versus imipramine and the latter is considered the gold standard TCA in enuresis management. Its mechanism of action is unclear, although it is an anticholinergic and antispasmodic and may increase plasma ADH concentrations. Up to 80% of treated patients may respond, although the long-term continence rate is only about 25%. A patient can expect approximately one fewer wet night per week with imipramine use. As with DDAVP, benefit only occurs as long as the drug is being taken, with relapse rates after discontinuation of therapy of up to 50%. There is no significant correlation of drug concentration with response. If sufficiently effective short-term, a 4- to 6-month trial is reasonable, followed by a weaning-off period of 3 to 4 weeks. There is a high frequency of neurologic side effects in children, including lethargy, dizziness, and headache in 5%; irritability in 11%; anxiety in 10%; and sleep disturbances in 16%.[31] Gastrointestinal symptoms occur in about 25% of pediatric patients.[31]

Anticholinergics

Oxybutynin has no significant effect in monosymptomatic nocturnal enuresis. Oxybutynin and related agents (see adult UI section of this chapter) should be used only if the patient has concurrent daytime urgency or frequency.

Comparison of Therapies

Most of the comparisons between treatments have been made by means of meta-analyses conducted by the Cochrane Enuresis Collaborative.[28,30,32–34] Unfortunately, most enuresis treatment studies have been so poorly designed they compromise the

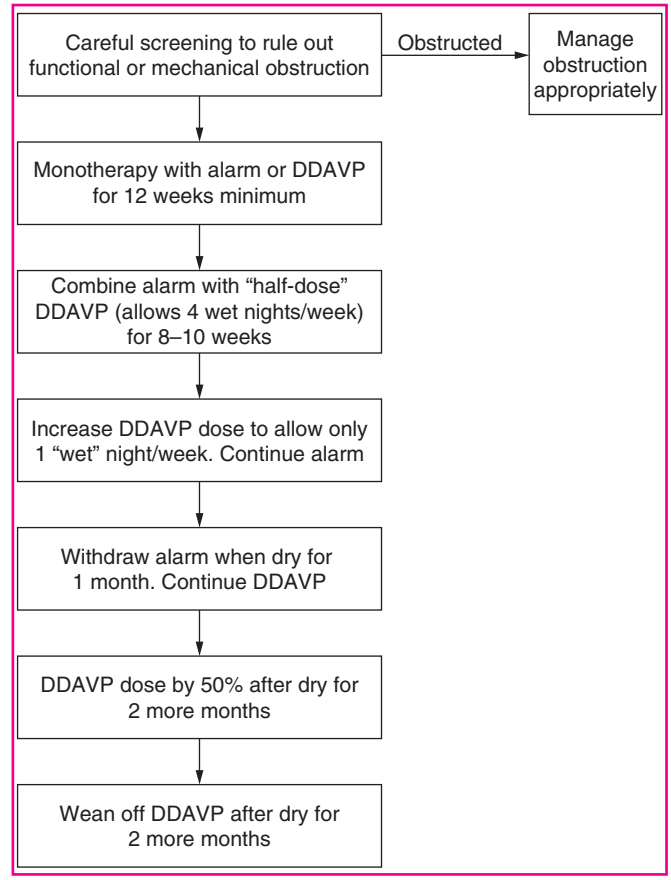

FIGURE 50–1. Preliminary (unvalidated) enuresis protocol proposed by the International Children's Continence Society (2004). DDAVP, desmopressin.

ability to pool studies for meta-analysis. With this in mind, the comparative efficacies of monotherapy and combination therapies using the best data available follow.

The most effective nonpharmacologic method is the use of bed alarms. Defining success as less than 1 wet night per month, the initial success rate for alarms is 66%, with long-term success after discontinuation occurring in 45% (versus 1% with no treatment). However, this method requires highly motivated families and the development of improvement is slow (over 4 to 12 or more weeks). Data are inadequate to compare the various commercial brands of alarms available to consumers or to compare alarms to other behavioral interventions. Supplementing this method with either overlearning or dry-bed training significantly reduces the already low relapse rates seen with alarms. Alarm therapy is also significantly more effective than DDAVP, evaluated at both the end of therapy and long-term. Similar findings are noted for the alarm-versus-imipramine comparison. There are conflicting data regarding the value of supplementing the alarm method with DDAVP. A preliminary algorithm utilizing a combination of alarm therapy and DDAVP for the treatment of pediatric enuresis has been formulated by the ICCS (Fig. 50–1).[25]

OUTCOME EVALUATION

- Monitor the patient for symptom relief. Have the desired outcomes jointly developed by the health care team, the patient, and his or her parents/guardians been achieved and to what degree? Evaluate the daily diary completed by the patient or parents/guardians since the last clinic visit and quantitate the clinical response (the number of dry nights versus the total number of nights, and the frequency of nights with greater than or equal to 2 enuresis episodes). If a diary has not been used, elicit the clinical response, in general terms, since the last visit.
- Elicit adverse events of therapy in a non-leading manner and ask the patient to judge their severity. Ask the patient or parents/guardians what measures if any were used to ameliorate them. Assess adherence (ask patient or parents/guardians about missed doses; do pill counts if the prescription vial is available).
- The balance of clinical response, tolerability, and burden on the family will dictate the approach to management. As most nonpharmacologic approaches are "all or none" and drug dosages after an initial titration period are fixed, the major decision process involves either changing therapy if clinical results are inadequate, or beginning or continuing tapering-off and discontinuation of therapy after success. There is no consensus on which approach to withdraw first, although the ICCS recommends the nonpharmacologic (alarm) therapy first, then pharmacologic (DDAVP) therapy.

Patient Care and Monitoring

1. Assess the patient's symptoms to determine if patient-directed therapy is appropriate or whether the patient should be evaluated by a physician. Assessment includes the types and severities of symptoms and the presence or absence of exacerbating factors. Does the patient have any enuresis-related complications?
2. Review any available diagnostic data to determine disease status.
3. Obtain a thorough medication history, including use of prescription, non-prescription, and complementary and alternative drug products. Determine which, if any, treatments in the past had been helpful as judged by the patient and/or caregiver(s). Could any of the patient's current medications be contributing to enuresis?
4. Educate the patient and/or caregiver(s) on lifestyle modifications that may improve symptoms or assist the clinician in monitoring the responses to therapy, including but not limited to, fluid restriction and journal keeping. The patient and/or caregiver(s) should be referred to local enuresis clinics (if available) for training in nonpharmacologic treatments such as use of bed alarms, overlearning, and dry-bed training.
5. Assess if the patient is taking the appropriate drug(s) for his or her enuresis? Are the doses appropriate?
6. Develop a plan to assess efficacy after a minimum of 3 months.
7. Assess changes in quality of life (physical, psychological, and social functioning and well-being).
8. Evaluate the patient for drug-related adverse events, allergies, and interactions (drug-drug and drug-disease).
9. Stress the importance of adherence with the prescribed regimen, including lifestyle modifications and nonpharmacologic treatment. Recommend the most "patient-friendly" treatment regimen possible.
10. Provide the patient and/or caregiver(s) with education regarding the disease state, lifestyle modifications, and drug therapy:
    - The causes of enuresis and what things the patient and/or caregiver(s) can do to reduce its frequency
    - Possible enuresis complications
    - Timing of medication intake
    - Potential adverse events (limit to most frequent and/or clinically relevant)
    - Potential drug-drug interactions.

51 Allergic and Pseudoallergic Drug Reactions

J. Russell May and Philip H. Smith

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Describe the potential incidence of allergic and pseudoallergic drug reactions and why it is difficult to obtain accurate numbers.
2. Describe the Gell and Coombs categories of reactions.
3. Identify the classes of drugs associated most commonly with allergic and pseudoallergic reactions.
4. Recommend specific treatment for a patient experiencing anaphylaxis.
5. Recommend an approach to drug selection in patients with multiple drug allergies.
6. Describe drug desensitization procedures for selected drugs.

Key Concepts

❶ Allergic and pseudoallergic reactions represent 23.8% of reported adverse drug reactions, cause considerable morbidity and mortality, and are costly.

❷ Drug allergy is an adverse immune response to a stimulus; such responses traditionally are placed in the Gell and Coombs categories: type I (immediate hypersensitivity), type II (complement-mediated antibody reactions), type III (immune complex reactions), and type IV (cellular or delayed-type hypersensitivity). However, drug exposures may stimulate several or all of these types of reactions. To complicate the picture further, drug reactions do not always fit the categories.

❸ Reactions that resemble allergic reactions clinically but lack an immune basis have been referred to as pseudoallergic. They include almost the entire range of immediate hypersensitivity clinical patterns and range in significance from the alarming but trivial anxiety or vasovagal reactions caused by local dental anesthetics to the potentially fatal reactions to ionic radiocontrast media.

❹ Penicillins and cephalosporins both have a β-lactam ring joined to an S-containing ring structure (penicillins: a thiazolidine ring; cephalosporins: a dihydrothiazine ring). Because of their structural likeness, allerginicity between penicillins and cephalosporins occurs. However, because of their structural differences, the extent of cross-allergenicity between penicillins and cephalosporins appears to be relatively low. Cross-allergenicity is less likely with newer-generation cephalosporins than with the first-generation agents.

❺ Reactions to sulfonamide antibiotics, ranging from mild (most common) to life-threatening (rare), occur in 2% to 4% of healthy patients, with rates as high as 60% in patients with acquired immune deficiency syndrome (AIDS).

❻ IgE-mediated urticarial/angioedema reactions and anaphylaxis are associated with aspirin and non-steroidal anti-inflammatory drugs. Urticaria is the most common form of IgE-mediated reaction. This class is second only to β-lactams in causing anaphylaxis.

❼ Radiocontrast media may cause serious immediate pseudoallergic reactions such as urticaria/angioedema, bronchospasm, shock, and death. These reactions have been reduced with the introduction of non-ionic, lower-osmolality products.

❽ Opiates (e.g., morphine, meperidine, codeine, hydrocodone, and others) stimulate mast cell release directly, resulting in pruritus and urticaria with occasional mild wheezing. Although these reactions are not allergic, many patients state that they are "allergic" to one or more of the opiates. Pretreatment with an antihistamine may reduce these reactions. These pseudoallergic reactions are rarely life-threatening.

❾ Drug desensitization is a potentially life-threatening procedure that requires continuous monitoring in a hospital setting with suitable access to emergency treatment and intubation. It should be undertaken only under the direction of a physician with suitable training and experience. In such hands, desensitization presents less risk than treatment failure with a less effective alternative medication.

Allergic and pseudoallergic drug reactions are reported together. They are rarely confirmed by testing, making statistical reporting imprecise, with both overreporting and underreporting. But there is no doubt that they are costly and cause considerable morbidity and mortality. ❶ *Allergic and pseudoallergic reactions may represent as many as 23.8% of reported adverse drug reactions.*[1] Between 10% and 15% of hospitalized patients incur drug reactions, with about a third possibly due to hypersensitivity; however, most allergic drug reactions are not reported.[1,3,4] Patients experiencing an allergic drug reaction require longer hospitalizations (close to 2 days) at a cost of more than $2,000 per day.[2] A potential financial burden can occur owing to the increased indirect cost of: (1) lost time and labor, (2) the use of costlier alternative medications, and (3) treatment failures. Outpatient rates are not well studied and are much more formidable to collect. Relying on a patient's history without an attempt to clarify the relationships between drugs taken and symptoms experienced results in a confusing scenario. Often, health care professionals and patients use the term "drug allergy" in such a general way that it is not useful medically and, further, perpetuates a level of fear and concern in the public and in medical practice that is inappropriate and costly. This same confusion often seems to lead medical personnel to ignore or forget "drug allergy" with sometimes catastrophic results. Clearly, an understanding of how allergic and pseudoallergic reactions occur and how they might be managed or prevented is important to health care professionals and their patients.

PATHOPHYSIOLOGY

Drug allergies are immune responses resulting from different methods of recognition and activation, and reactions are affected by multiple physiologic mechanisms. This produces a confusing spectrum of clinical pictures and complex pathophysiologic mechanisms. ❷ *Drug allergy is an adverse immune response to a stimulus; such responses traditionally are placed in the Gell and Coombs categories: type I (immediate hypersensitivity), type II (complement-mediated antibody reactions), type III (immune complex reactions), and type IV (cellular or delayed-type hypersensitivity). Drug exposures may stimulate several or all of these types of reactions, and drug reactions do not always fit neatly into the categories.*

The immune system uses many tools such as blood vessel dilation or constriction, causing fluid to flood an infected area, or designing special cells to kill bacteria or the infected cells in which they harbor. The pattern of these responses is either immediate and inborn (the innate immune response) or learned from previous infections and injuries (the adaptive immune response). Most drug reactions involve the adaptive response and certainly, in the sense that they cause more harm than good, are "mistakes."

T cells control these learned responses and decide which tools to use in the reaction. Sometimes they choose several different tools at once, and multiple reactions ensue, such as when a person becomes sensitized to penicillin and has not only **anaphylaxis** but hemolytic anemia and **serum sickness**. There are different types of T cells, and they communicate either directly with other cells or by chemical messages called **cytokines**. The pattern of cytokines released is one way T cells have of determining which kind of response will occur. They are broadly called Th1 and Th2 responses, with Th1 mostly responding to infections and Th2 often producing allergy or asthma.

Drug reactions generally represent T cell activation. The type of T cell activated determines the type of reaction to the drug. Th1 cytokines (largely interferon-γ) produce many more chronic (and at times serious) skin reactions and destruction of cells (as in hemolytic anemia or thrombocytopenia); sometimes these responses can damage tissues, such as the kidney (e.g., interstitial nephritis). Th2 cytokines tend to cause any antibodies produced to be switched to the immune globulin E (IgE) or allergic antibody class, which can result in hives or anaphylaxis. Other classes of antibodies are made frequently, and these can produce serum sickness or indirect destruction of cells (e.g., thrombocytopenia). T-cell receptors respond to one peptide only, which makes each activation response exclusive to the original stimulus (drug) or to chemical structures with very close resemblance.

Antigens

Antigen-presenting cells recognize complex three-dimensional protein molecules of at least 1000 daltons (Da) in size. Most drugs are much smaller than this and cannot be recognized on their own. Only proteins such as insulin or exogenous sera are identified and their peptides presented directly to T cells.

Drugs that are reactive chemicals may bond covalently to body proteins, altering them and forming large enough molecules for antigen-presenting cells to recognize. This process is called **haptenation**, and the smaller reactive molecule is called a hapten. Other drugs are inert until they are partially metabolized (prohaptens), and their breakdown products bind native proteins to serve as antigens. Metabolic variations in some patients may produce more active haptens or prevent these fragments from being detoxified, causing them to accumulate and make binding proteins more likely.

Gell and Coombs

Type I reactions occur when the drug or its bound hapten incites an IgE antibody response. IgE binds to high-affinity receptors on mast cells and basophils. When the original antigen cross-links the cell-bound IgE, the effector cell releases enormous amounts of preformed mediators, producing the

well-known symptoms of immediate hypersensitivity: **urticaria,** rhinitis, bronchoconstriction, and anaphylaxis.

Type II reactions are produced by IgG (or IgM) antibody. The drug or hapten that elicited the antibody response binds to target cells. When antibody binds the drug, complement activation destroys the cell. **Blood dyscrasias** such as thrombocytopenia and hemolytic anemia are the most common examples of type II reactions.

Type III or immune complex reactions also involve IgG antibody production. In this case, when the concentration of the sensitizing drug or hapten is in slight excess to the antibody, the two combine in the serum, producing lattices of antigen-antibody complexes. These are deposited, particularly in vessel walls. They activate complement, causing vasculitis. The classic forms of type III reactions are serum sickness (usually including arthralgias, fever, malaise, and urticaria that develop 7 to 14 days after exposure to the causative antigen) and the localized **Arthus reaction,** a local inflammatory response owing to the deposition of immune complexes in tissues.

Type IV reactions are mediated by T cells themselves. Delayed-type hypersensitivity reactions from positive tuberculin tests to contact dermatitis are typical type IV reactions, but understanding T-cell function allows us to further define this category, as shown in Table 51–1.

Pseudoallergic Drug Reactions

❸ *Reactions that resemble allergic reactions clinically but lack an immune basis have been referred to as pseudoallergic. They include almost the entire range of immediate hypersensitivity clinical patterns. Pseudoallergic reactions range in significance from the alarming but trivial anxiety or vasovagal reactions caused by local dental anesthetics to sometimes fatal reactions to ionic radiocontrast media.* Cytotoxic reactions, serum sickness, and severe dermatologic reactions (e.g., Stevens-Johnson syndrome and **toxic epidermal necrolysis**) are immunologic processes that are not likely to be mimicked by non-immune processes seen with pseudoallergic reactions.

Pseudoallergic reactions are important in patient counseling and management considerations. The reactions represent common biologic functions [e.g., direct histamine (H) release by vancomycin and opiates], whereas immunologic (allergic) reactions are based on the structure of the drug. Even a mild drug allergy carries significant potential for anaphylaxis on readministration. In contrast, pseudoallergic reactions tend to remain constant whether mild or severe.

Pseudoallergic reactions, then, are reactions where the tools of the immune system are used in exactly the same way as true allergic reactions but without the "learning" response by T cells and generally without the much greater danger that true immunologic sensitization implies. Pseudoallergic reactions may be thought of as a sub-type of idiopathic reactions rather than an activation of the patient's immune system with all its potential for change and variety of adverse responses. The pathophysiology of pseudoallergic reactions generally is unknown, but indicators of immune activation are not seen when they occur.

Clinical Presentation and Diagnosis

The clinical presentation of a patient experiencing an allergic reaction varies greatly. The primary reactions are as follows:

Anaphylaxis
Anaphylaxis is an acute life-threatening allergic reaction. Signs and symptoms involve the skin (e.g., pruritus and urticaria), respiratory tract (e.g., dyspnea and wheezing), gastrointestinal tract (e.g., nausea and cramping), and cardiovascular system (e.g., hypotension and tachycardia). Onset is usually within 30 minutes but can be as long as 2 hours. Treatment for anaphylaxis must begin immediately. Anaphylaxis may recur 6 to 8 hours after exposure, so patients experiencing anaphylaxis should be observed for at least 12 hours.

Cytotoxic Reactions
These reactions usually take the form of hemolytic anemia, thrombocytopenia, granulocytopenia, or agranulocytosis.

Immune Complex Reactions
These reactions involve a serum sickness like syndrome (e.g., arthralgias, fever, malaise, and urticaria) that usually develops 7 to 14 days after exposure to the causative antigen.

Dermatologic Reactions
Rashes may range from mild to life-threatening.

- *Urticaria*—itchy, raised, swollen areas on the skin, also known as *hives*.
- *Maculopapular rash*—a rash that contains both macules and papules. A macule is a flat discolored area of the skin, and a papule is a small raised bump. A maculopapular rash is usually a large area that is red and has small, confluent bumps.
- ***Erythema multiforme***—a rash characterized by papular (small raised bump) or vesicular lesions (blisters) and reddening or discoloration of the skin often in concentric zones about the lesion.
- ***Stevens-Johnson syndrome***—a severe expression of erythema multiforme (also known as *erythema multiforme major*). It typically involves the skin and the mucous membranes with the potential for severe morbidity and even death.
- *Toxic epidermal necrolysis*—a life-threatening skin disorder characterized by blistering and peeling of the top layer of skin.

PROBLEMATIC DRUG CLASSES AND TREATMENT OPTIONS

The first priority when caring for patients with an allergic reaction is to avoid doing serious harm by administering a drug that the patient cannot tolerate. We can establish the likelihood of a relationship between the suspected drug and

TABLE 51–1. Reaction Classification, Clinical Symptoms, and Potential Causative Drugs[5,6]

Gell and Coombs Classification	Immune Response	Clinical Symptoms	Potential Causative Drugs[a]
Type I	IgE	Anaphylaxis, urticaria	β-Lactam antibiotics: penicillins (primarily), cephalosporins, carbapenems Non-β-lactam antibiotics: sulfonamides, vancomycin Others: insulin, heparin
Type II	IgG	Hemolytic anemia, thrombocytopenia	Quinidine, methyldopa, penicillins, heparin
Type III	IgG and IgM	Vasculitis, serum sickness, lupus	Penicillins, sulfonamides, radiocontrast agents, phenytoin
Type IV			β-Lactam antibiotics, sulfonamides, and phenytoin
IVa	Th1 cytokines	Tuberculin reaction, eczema	
IVb[b]	Th2 cytokines	Maculopapular and bullous exanthema	
IVc[b]	Cytotoxic T cells (CD4 and CD8)	Same as IVb, also eczema, pustular exanthema	
IVd	T cells (IL-8)	Pustular exanthema	

[a]These drugs represent a list of likely causative agents. Many drugs can cause these reactions.
[b]IVb and IVc reactions may combine to produce erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis.

the observed reaction and also whether it is likely to be an immune or idiopathic reaction by examining the time course and specific signs and symptoms as precisely and objectively as possible. Re-evaluating the patient's physical examination and laboratory values (taking into account preexisting diseases) allows further clarification of the need to change treatments and to add therapy for the reaction itself.

Reviewing the original indications for the treatment that caused the reaction is important. For example, in many respiratory illnesses, a prescribed antibiotic may be unnecessary. If the disease persists and indications for some treatment are established, alternatives must be sought either by adjusting dose or administration rate, finding effective and unrelated alternative medication, or desensitizating the patient to the original drug.

When drug reactions occur, the health care provider should carefully describe the nature of the reaction and the potential for it to reoccur. Many patients have frightening associations of the term "allergy" with severe and unpredictable anaphylaxis. It is difficult to undo the fears and behaviors created by injudicious labeling of someone as allergic in the medical record. Labeling a person as allergic may hamper future medical care because patients who are labeled allergic to a certain medication simply may refuse treatment or fail to adhere to regimens containing the offending medication. If documentation clearly describes the original reaction, health care providers can appropriately counsel patients about any true dangers.

Managing patients experiencing an allergic reaction begins with stopping the offending agent. Anaphylaxis is a true medical emergency and must be treated promptly. Understanding the allergic reaction and potential for **cross-allergenicity** between similar drugs will assist in selecting an alternative medication. Desensitization is a management option if the patient truly needs the medication and alternative drugs are not acceptable. While any drug can cause an allergic or pseudoallergic reaction, several drugs and drug classes are strongly associated with such reactions. These drugs and drugs classes include β-lactam antibiotics, sulfonamide antibiotics, aspirin and non-steroidal anti-inflammatory drugs (NSAIDS), radiocontrast media, opiates, cancer chemotherapeutics agents, insulin, and anticonvulsants.

β-Lactam Antibiotics

Hypersensitivity reactions with β-lactam antibiotics, especially penicillin, may encompass any of the type I through IV Gell-Coombs classifications. The most common reactions are **maculopapular** and urticarial eruptions.[7] While rare (less than 0.05%), anaphylaxis to penicillins causes the greatest concern because they are responsible for the majority of drug-induced anaphylaxis deaths in patients, accounting for 75% of all anaphylaxis cases in the United States.[5,8] The treatment of anaphylaxis is given in Table 51–2.[9]

The health care professional is faced with a difficult task when approaching a patient who claims a history of penicillin allergy. While as many as 12% of hospitalized patients state that

Patient Encounter 1

JB, a 44-year-old man, is admitted to the hospital for treatment of a cellulitis. He states that he has no known allergies. JB is prescribed intravenous nafcillin for his infection. During the first infusion, he notices that his ears are itching, and he calls for a health care practitioner. On the practitioner's arrival, JB appears nervous and is having difficulty breathing.

- What type of allergic reaction is JB most likely having?
- What is the first action that this practitioner should take?
- Outline the medical treatment for JB's reaction and when the medical treatment should start.

TABLE 51–2. Pharmacologic Management of Anaphylactic Reactions[9]

Immediate Intervention

Epinephrine 1:1000 (1 mg/mL)
- *Adults:* Give 0.2–0.5 mg intramuscularly (IM) or subcutaneously (SC); repeat every 5 minutes as needed
- *Children:* 0.01 mg/kg (maximum 0.3 mg) IM or SC; repeat every 5 minutes as needed

Subsequent Interventions

Normal saline infusion
- *Adults:* 1 to 2 L at a rate of 5–10 mL/kg in the first 5 minutes, followed by slow infusion
- *Children:* Up to 30 mL/kg in the first hour

Epinephrine infusion

If patient is NOT responding to epinephrine injections and volume resuscitation:
- *Adults:* Epinephrine infusion [1 mg in 250 mL dextrose 5% in water (D_5W)]: 1–4 mcg/minute, titrating based on clinical response or side effects
- *Children:* Epinephrine 1:10,000 (0.1 mg/mL): 0.01mg/kg (up to 0.3 mg) over several minutes

Other Considerations after Epinephrine and Fluids

Diphenhydramine
- *Adults:* 25–50 mg intravenously (IV) or IM
- *Children:* 1–1.25 mg/kg (maximum of 300 mg/24 hours)

Ranitidine
- *Adults:* 50 mg in D_5W 20 mL IV over 5 minutes
- *Children:* 1 mg/kg (up to 50 mg) in D_5W 20 mL IV over 5 minutes

Inhaled albuterol (bronchospasm resistant to epinephrine)

2–5 mg in 3 mL of normal saline, nebulized, repeat as needed

Dopamine (hypotension refractory to fluids and epinephrine)

2–20 mcg/kg per minute titrated to maintain systolic blood pressure greater than 90 mm Hg

Hydrocortisone (severe or prolonged anaphylaxis)
- *Adults:* 250 mg IV (prednisone 20 mg can be given orally in mild cases)
- *Children:* 2.5–10 mg/kg per 24 hours

D_5W, dextrose 5% in water; IM, intramuscular; IV, intravenous; SC, subcutaneous.

TABLE 51–3. Procedure for Performing Penicillin Skin Testing

A. Percutaneous (prick) skin testing

MATERIALS	VOLUME
Pre-Pen[a] 6×10^6 M	1 drop
Penicillin G 10,000 units/mL	1 drop
β-Lactam drug 3 mg/mL	1 drop
0.03% albumin-saline control	1 drop
Histamine control (1 mg/mL)	1 drop

1. Place a drop of each test material on the volar surface of the forearm.
2. Prick the skin with a sharp needle inserted through the drop at a 45° angle, gently tenting the skin in an upward motion.
3. Interpret skin responses after 15 minutes.
4. A wheal at least 2 × 2 mm with erythema is considered positive.
5. If the prick test is non-reactive, proceed to the intradermal test.
6. If the histamine control is non-reactive, the test is considered uninterruptible.

B. Intradermal skin testing

MATERIALS	VOLUME
Pre-Pen[a] 6×10^6 M	0.02 mL
Penicillin G 10,000 units/mL	0.02 mL
β-Lactam drug 3 mg/mL	0.02 mL
0.03% albumin-saline control	0.02 mL
Histamine control (0.1 mg/mL)	0.02 mL

1. Inject 0.02–0.03 mL of each test material intradermally (amount sufficient to produce a small bleb).
2. Interpret skin responses after 15 minutes.
3. A wheal at least 6 × 6 mm with erythema and at least 3 mm greater than the negative control is considered positive.
4. If the histamine control is non-reactive, the test is considered uninterruptible.

Antihistamines may blunt the response and cause false-negative reactions.

[a]Pre-Pen is not currently commercially available. The product is anticipated to return to the market in the near future. Until it is available, skin testing is not recommended.

they have an allergy to penicillin, about 90% will have negative skins tests.[10] Table 51–3 shows the traditional regimen for penicillin skin testing.[11] However, Pre-Pen is not commercially available at this time. The product is anticipated to return to the market in the near future. Until it is available, skin testing is not recommended. This test only determines IgE-mediated reactions. A patient with a history of other serious reactions such as erythema multiforme, Stevens-Johnson syndrome, or toxic epidermal necrolysis should not receive penicillins.

❹ *Penicillins and cephalosporins both have a β-lactam ring joined to an S-containing ring structure (penicillins: a thiazolidine ring; cephalosporins: a dihydrothiazine ring). Because of their structural likeness, allerginicity between penicillins and cephalosporins occurs. However, because of their structural difference, the extent of cross-allergenicity between penicillins and cephalosporins appears to be relatively low. Cross-allergenicity is less likely with newer-generation cephalosporins than with the first-generation agents.* Anaphylactic reactions to cephalosporins are rare, with a predicted range of 0.0001% to 0.1%. Minor skin reactions, including urticaria, **exanthem**, and pruritus, are the most common allergic reactions to cephalosporins, with severe reactions seen less often than with penicillins.[13] If a patient has a history of penicillin allergy but a penicillin skin test is negative, a cephalosporin may be given. If the test is positive, an alternative drug should be selected.

For other β-lactam agents, the recommendations are fairly straightforward.[9] Carbapenems should be considered cross-reactive with penicillins. Monobactams (e.g., aztreonam) do not cross-react with any β-lactam drugs except ceftazidime because they share an identical R-group side chain.

Sulfonamide Antibiotics

Sulfonamides are compounds that contain a sulfonamide moiety (i.e., SO_2NH_2). This group includes sulfonamide antibiotics, furosemide, thiazide diuretics, sulfonylureas, and celecoxib. The sulfonamide antibiotics contain an aromatic amine at the

N-4 position and a substituted ring at the N-1 position. Because of this different chemical structure, cross-allergenicity with the other sulfonamides may not occur. However, because this has not been well studied, if a patient has a reaction to a sulfonamide antibiotic, whether or not he or she will have a reaction to these other sulfonamides remains controversial. Predisposition to allergic reactions is a more likely reason than cross-reactivity between these differing molecules.[14] The sulfonamide antibiotics are significant because they account for the largest percentage of antibiotic-induced toxic epidermal necrolysis and Stevens-Johnson syndrome cases.[15]

❺ *Reactions to sulfonamide antibiotics, ranging from mild (most common) to life-threatening (rare), occur in 2% to 4% of healthy patients, with rates as high as 60% in patients with acquired immune deficiency syndrome (AIDS).*[7] Anaphylaxis or **anaphylactoid** reactions occur within 30 minutes, most commonly after parenteral administration. Isolated **angioedema** or urticaria can occur within minutes to days. Serum sickness occurs within 1 to 2 weeks. Fixed drug eruptions (lesions) occur within a half-hour to 8 hours. These lesions resolve within 2 to 3 weeks after drug removal. The more severe conditions of Stevens-Johnson syndrome and toxic epidermal necrolysis occur 1 to 2 weeks after initiation of therapy. Because trimethoprim-sulfamethoxazole is the drug of choice for patients infected with *Pneumocystis carinii*, desensitization may be necessary. A history of Stevens-Johnson syndrome or toxic epidermal necrolysis is an absolute contraindication to the desensitization procedure.

TABLE 51–4. Multiple Antibiotic Allergies: Obtaining Background Information[15]

For ***each*** antibiotic the patient claims to be allergic to, gather the following information:

- What type of infection was being treated?
- Have you ever received the drug without experiencing a reaction?
- How many times have you received the drug and experienced a reaction?
- What was the drug dose and route of administration with the last reaction?
- How many doses did you take before the onset of the last reaction?
- How many doses did you take after the last reaction?
- Can you describe the adverse reaction?
- What was the duration of the reaction?
- What treatment was given for the reaction?
- Was there any permanent damage?

For ***each*** antibiotic that the patient has received and does not claim to be "allergic" to, gather the following information:

- What was the last type of infection being treated?
- What was the drug dose and route of administration?
- Have you received this drug more than once without reactions?

Other information to be gathered:

- Have you had adverse reactions to any other drugs? If so, give dates and describe the reaction.
- Document any risk factors for allergic reactions such as chronic urticaria, liver or kidney disease, human immunodeficiency virus, or any other immune deficiencies.

Patients with Multiple Antibiotic Allergies

Dealing with patients who claim to have multiple antibiotic allergies can be challenging. Combining knowledge of cross-allergenicity with a careful assessment of patient history may be helpful in designing an antimicrobial regimen. Table 51–4 outlines a series of questions that can be useful in developing an effective treatment plan.[16] If available, skin testing may be useful to complete the puzzle. Often, an antibiotic of choice may be used when the patient's initial history would have suggested otherwise (i.e., patient's initial history suggests the patient has an allergy to the medication). Based on data gathered, the patient's record should reflect: antibiotics that are safe to use if needed, antibiotics to be avoided, and antibiotics that can be used only after desensitization. While this table was designed with antibiotics in mind, it can be modified for any allergy situation or multiple allergy situations.

Aspirin and Non-steroidal Anti-Inflammatory Drugs

Aspirin and NSAIDs can induce allergic and pseudoallergic reactions. Because these drugs are used so widely, with much over-the-counter use, the health care professional must have a basic understanding of the types of reactions that can occur and how to prevent them. Three types of reactions occur: bronchospasm with rhinoconjunctivitis, urticaria/angioedema, and anaphylaxis. Remember that patients with gastric discomfort or bruising from these agents may describe themselves as being allergic; however, these are not allergic or pseudoallergic reactions.

Two specific conditions, aspirin-exacerbated respiratory disease (AERD) and chronic idiopathic urticaria, are important because they are seen commonly. AERD consists of asthma, rhinitis with nasal polyps, and aspirin sensitivity.[17] On exposure to aspirin or an NSAID, patients experience rhinorrhea, nasal congestion, conjunctivitis, laryngospasm, and asthma. Chronic idiopathic urticaria is a major risk factor for aspirin- or NSAID-induced pseudoallergic reactions.[18] Patients with a history of chronic idiopathic urticaria are likely to see a flare of urticaria if aspirin or a cyclooxygenase (COX)-1-inhibiting NSAID is given. Cross-reactions between aspirin and older COX-1-inhibiting NSAIDs exist in patients with AERD and chronic idiopathic urticaria. Even though product warning labels for COX-2 inhibitors state that these agents should not be used in these two conditions, there are no reports of cross-reactivity in AERD and only rare reports in patients with chronic idiopathic urticaria.[19]

❻ *IgE-mediated urticarial/angioedema reactions and anaphylaxis are associated with aspirin and NSAIDs. Urticaria is the most common form of IgE-mediated reaction. This class is second only to β-lactams in causing anaphylaxis.* The potential for cross-reactivity between agents in IgE-mediated reactions appears small, but caution is advised. Because aspirin therapy is highly beneficial in primary and secondary prevention in

coronary artery disease (CAD), aspirin desensitization should be considered in patients who have had reactions to aspirin. Desensitization is contraindicated in patients who have experienced aspirin-induced anaphylactoid reaction, hypotension, tachypnea, or altered consciousness. Alternate agents must be used. A comprehensive approach to aspirin-sensitive patients with CAD has been described.[20]

Radiocontrast Media

❼ *Radiocontrast media may cause serious immediate pseudoallergic reactions such as urticaria/angioedema, bronchospasm, shock, and death. These reactions have been reduced with the introduction of non-ionic, lower-osmolality products.* Because a small percentage of patients who have reacted previously to radiocontrast media will react if re-exposed, several steps should be taken to prevent reactions, including:

- Determine if the study is necessary.
- Be sure that the patient understands the risks.
- Ensure adequate hydration.
- Use non-ionic, lower osmolarity agents.
- Pretreat with prednisone 50 mg orally 13, 7, and 1 hour before the procedure and diphenhydramine 50 mg orally 1 hour before the procedure.

These steps also should be followed in patients with high risk factors: asthmatic patients, patients on β-blockers, and patients with cardiovascular disease.[5]

Delayed reactions with radiocontrast media occur in 1% to 3% of patients.[21] Although reactions occasionally are severe, most are mild and manifest as maculopapular rashes, fixed eruptions, erythema multiforme, and urticarial eruptions.

Opiates

❽ *Opiates (e.g., morphine, meperidine, codeine, hydrocodone, and others) stimulate mast cell release directly, resulting in pruritus and urticaria with occasional mild wheezing. Although these reactions are not allergic, many patients state that they are "allergic" to one or more of the opiates. Pretreatment with an antihistamine may reduce these reactions. These pseudoallergic reactions are rarely life-threatening.*[5] Patients also may state they are allergic if they have experienced gastrointestinal upset, a common side effect to opiates, with previous exposures. Obtaining a thorough history from the patient will prove useful. If a more serious reaction has occurred, a non-narcotic analgesic should be selected.

Cancer Chemotherapeutic Agents

Hypersensitivity reactions have occurred with all cancer chemotherapeutic agents. Reactions are most common with the taxanes, platinum compounds, asparaginases, and epipodophyllotoxins.[7] Reactions range from mild (e.g., flushing and rashes) to severe (e.g., dyspnea, bronchospasm, urticaria, and hypotension). IgE-mediated type I reactions are the most common. To reduce the risk, patients are routinely pre-medicated with corticosteroids and H_1 and H_2 receptor antagonists. The platinum compounds have produced anemia, probably via a cytotoxic immunologic mechanism.

Insulin

Allergic reactions to insulin include erythema, pruritus, and indurations,[22] which usually are transient. For the more troublesome reactions, treatment options include dexamethasone, desensitization, or change in delivery system (i.e., insulin pump or inhaled insulin).

Anticonvulsants

A life-threatening syndrome can occur following a few weeks of therapy with anticonvulsants, such as phenytoin, phenobarbital, and carbamazepine. Symptoms include fever, a maculopapular rash, generalized lymphadenopathy, and varying degrees of internal organ dysfunction. The rash may be mild at first but can progress to **exfoliative dermatitis.** The causative agent should be withdrawn immediately. Valproic acid, gabapentin, and lamotrigine may be acceptable alternatives.[5]

Drug Desensitization

Drug desensitization may be undertaken in the absence of useful alternative medications. The risk of severe systemic reactions and anaphylaxis associated with desensitization must be compared with the risk of not treating the patient. Thorough evaluation should establish that the drug probably caused the reaction by an

Patient Encounter 2

CS, a 55-year-old woman, is admitted to the hospital with an intraabdominal infection. During the patient interview, CS states that she is allergic to aspirin, codeine, sulfa drugs, penicillin, levofloxacin, and vancomycin. The reactions are described as follows:
Aspirin: Easy bruising.
Codeine: Upset stomach and itching after one dose.
Sulfa drugs: Mild rash occurred 2 hours after taking a double-strength trimethoprim-sulfamethoxazole tablet prescribed for a urinary tract infection.
Penicillin: Rash, itching, and shortness of breath.
Levofloxacin: Upset stomach.
Vancomycin: Burning sensation when the drug was infused.

- Based on CS's descriptions, which of the reactions represents an allergic or pseudoallergic reaction?
- Which medications would you want CS to avoid based on her history?
- What further questions would be useful to ask CS before developing a care plan?
- If narcotic analgesics are required to treat CS, what medication may be helpful as a pretreatment?

allergic mechanism. Because of the dangers involved with drug desensitization, a diagnostic evaluation of the patient's indication for the drug should be conducted. Consider the possibility that the patient does not really need the drug.

❾ *Drug desensitization is a potentially life-threatening procedure that requires continuous monitoring in a hospital setting with suitable access to emergency treatment and intubation if required. It should be undertaken only under the direction of a physician with suitable training and experience. In such hands, desensitization presents less risk than treatment failure with a less effective alternative medication.* The possibility of readministering a suspected drug may be safely tested by gradual dose escalation in most cases, and there are certainly many more patients who are harmed by inappropriately withholding medications than there are those who suffer significant harm from testing and desensitization.[23]

Only type I IgE-mediated allergy may be treated by classic desensitization. Most protocols achieve desensitization within hours to a few days, unlike specific immunotherapy injections for inhalant allergy (i.e., "allergic shots," which may take months of therapy before a patient realizes any benefit). The mechanism of drug desensitization is poorly understood but produces temporary drug-specific tolerance of the offending drug. Any interruption of therapy of 24 hours or more requires full repeat desensitization, and abrupt, significant increases in dosage have been reported to break through the tolerance.

The process probably involves either: (1) cross-linking small subthreshold numbers of bound IgE molecules gradually depleting mast cells of their mediators, or (2) binding of the IgE by monomers or hapten-protein entities that cannot cross-link the antibody. The low doses used at the beginning of all protocols would provide small amounts of antigen, favoring these mechanisms. Both drug-specific IgE and IgG serum concentrations increase after successful desensitization, but skin-test positivity generally decreases.[24]

Oral and intravenous protocols are available for most drugs in this category, with the oral route producing somewhat milder reactions and the intravenous route providing more precision in dosing. Intravenous administration also can be used in unresponsive patients in whom the oral route is not feasible. Protocols generally begin at about 1% of the therapeutic dose and increase in intervals defined by the patient's reaction and the distribution and metabolism of the drug itself. Half-$\log_{10}$ dose increases (about three-fold) are often tolerated.

Penicillin desensitization is the most common drug desensitization protocol and is required for penicillin-allergic patients when penicillin is clearly the best treatment option, e.g., when syphilis is present in pregnancy. Protocols have been adapted to most antibiotics. Tables 51–5 and 51–6 describe procedures for oral and intravenous penicillin desensitization.[25]

Aspirin desensitization is useful in diseases where low-level antiplatelet action is needed and in the care of patients with aspirin sensitivity and intractable nasal polyps. Lysine aspirin availability in Europe allows desensitization by inhalation at greatly reduced risk. As with all desensitizations, constant daily administration must be maintained once the desired dose is reached. Table 51–7 summarizes several similar aspirin desensitization protocols.[26] Table 51–8 depicts a 2-day alternative protocol.[27]

All desensitization procedures are expected to produce mild symptoms in the patient at some point, and the patient

10, 20, 50, 80, 150, 300	30 minutes	610
30, 60, 125, 250, 500	60 minutes	965

should be warned of this before doses are started. Mild sensitivity to the drug still remains, and large dose increases as well as missing doses should be avoided. Late complications, such as urticaria, may occur with type I desensitization, and serum sickness or hemolytic anemia also may occur with high-dose therapy in allergic, desensitized patients.

Some regimens are designed for outpatient administration over much longer time periods and have been used, for example, with allopurinol dermal reactions. Such late-onset morbiliform reactions, sometimes overlapping with erythema multiforme minor, are difficult to evaluate because it is often unclear to what extent the patients were at risk for recurrent reaction.

Severe life-threatening reactions not mediated by IgE, such as Stevens-Johnson syndrome and toxic epidermal necrolysis, are absolute contraindications to testing, desensitization attempts, and readministration.

OUTCOME EVALUATION

To treat a patient with a drug allergy or pseudoallergy successfully, several goals must be accomplished:

- Identify and quickly manage a reaction if one occurs.
- Educate the patient about the reaction.
- Avoid true drug contraindications if at all possible.
- Ensure that patients receive the medications they need or a suitable alternative.
- A suitable alternative may be drug desensitization.
- Monitor patients for adverse drug reactions.

30	30	150	330
60	90	325	655
90	180	650	1305

[a]Doses administered every 3 hours, patient observed for 3 hours after final dose.

Patient Encounter 3

RM, a 50-year-old man, is visiting the clinic for a routine check-up. Pertinent findings are as follows:

PMH
- Hypertension diagnosed 5 years ago, currently controlled
- Seasonal allergic rhinitis

FH
- Father died of myocardial infarction at age 59.
- Grandfather died of a stroke at age 62.

SH
- Smokes less than one pack per day.
- Drinks one glass of red wine daily.

Meds
- Hydrochlorothiazide 25 mg orally once daily
- Atenolol 50 mg once daily
- Fluticasone nasal spray, one spray in each nostril daily during allergy season
- Loratadine 10 mg daily during allergy season

Allergies: History of urticaria after taking aspirin for headaches

- Based on RM's history, is he a candidate for daily aspirin therapy?
- If so, is RM a candidate for aspirin desensitization? Why or why not?

Patient Care and Monitoring

1. Before administering any medication, take a thorough drug history to establish any past allergic or adverse reactions experienced by the patient.
2. For any reaction, use questions given in Table 51–4 to establish the nature of the reaction and the likelihood that it was caused by the suspected drug. For non-antibiotics, the first question regarding infection type is not needed.
3. Document the reaction, in detail, in the patient's medical record.
4. Recommend an alternative choice if the prescribed drug is contraindicated, and develop a plan to assess safety and effectiveness.
5. Consult with a physician trained in desensitization if the patient has a true allergy and no acceptable alternative medication is available.
6. Educate the patient about the allergy or pseudoallergy so that he or she is able to work with health care providers to avoid the reaction in the future.

52 Solid-Organ Transplantation

Steven Gabardi and Ali J. Olyaei

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Describe common reasons for the various solid-organ transplants.
2. Differentiate between the functions of cell-mediated and humoral immunity and how they relate to organ transplantation.
3. Describe the roles of the antigen-presenting cells in initiating the immune response.
4. Compare and contrast the types of rejection, including hyperacute, acute, chronic, and humoral.
5. Define the terms "host-graft adaptation" and "tolerance," paying close attention to their differences.
6. Discuss the desired therapeutic outcomes and appropriate pharmacotherapy used to avoid allograft rejection.
7. Compare and contrast the currently available immunosuppressive agents in terms of mechanisms of action, adverse events, and drug-drug interactions.
8. Design an appropriate therapeutic regimen for the management of immunosuppressive drug complications based on patient-specific information.
9. Develop a therapeutic drug-monitoring plan to assess both the effectiveness and the adverse events of immunosuppressive drugs.

Key Concepts

❶ T cells are the chief components initiating the immune response against the allograft. The activity of T cells is mediated largely through the synthesis and release of interleukin-2 (IL-2).

❷ An antigen-presenting cell (APC) is a cell that displays a foreign antigen complex with Major Histocompatibility Complex (MHC) on its cell surface. Its major responsibility is to present these foreign antigens to T cells. There are three main types of APCs: dendritic cells, macrophages, and activated B cells.

❸ The goal of pharmacotherapy in transplantation is to induce immunosuppression with a multidrug approach to target various parts of the immune system with resulting long-term allograft and patient survival while minimizing the complications of suppressing the immune system.

❹ The goal of induction therapy is to provide a high level of immunosuppression in the critical early posttransplant period when the risk of acute rejection is highest.

❺ The calcineurin inhibitors cyclosporine and tacrolimus block T cell activation by inhibiting the production of IL-2. They are associated with significant adverse events, such as nephrotoxicity, cardiovascular disease, posttransplant diabetes, and neurotoxicity.

❻ The antiproliferatives azathioprine and the mycophenolic acid derivatives inhibit T cell proliferation. Myelosuppression is the most significant adverse event associated with these agents.

❼ Sirolimus, a target of rapamycin inhibitor, works by decreasing the ability of T cells to respond to IL-2. The major adverse events associated with sirolimus are decreased wound healing, hyperlipidemia, and myelosuppression. This agent appears to have promising effects because it may allow calcineurin inhibitor withdrawal in some patients.

❽ Corticosteroids induce a non-specific immunosuppresion. Owing to their overwhelming incidence of adverse events, many practitioners attempt to use low-dose maintenance therapy or, in some cases, complete steroid withdrawal. Corticosteroids are also effective in reversing acute rejection.

⑨ Obtaining excellent long-term patient and allograft survival is difficult owing to complications from drug-drug interactions with the immunosuppressive agents, infectious diseases, cardiovascular disease, new-onset diabetes after transplantation, and malignancy. The goals of treating these complications are to prevent allograft damage, improve patient quality of life, and increase survival.

The earliest recorded attempts at organ transplant date back thousands of years.[1] More than a few apocryphal descriptions exist from ancient Egypt, China, India, and Rome documenting experimentation with transplantation. For example, an Indian text from the second century BC describes a procedure for nasal reconstruction surgery with the use of **autografted** skin. Also, Roman Catholic lore has saints Damian and Cosmas replacing the gangrenous leg of a man with the leg of a recently deceased man in the third century AD.[1]

French surgeon Alexis Carrel pioneered the surgical techniques for transplantation in the early 1900s.[1] Together with Charles Guthrie, Carrel experimented in artery and vein transplantation. Using revolutionary methods in anastomosis operations and suturing techniques, Carrel laid the groundwork for modern transplant surgery. He was one of the first to identify the dilemma of rejection, an issue that remained nearly impossible to circumvent for nearly half a century.[1]

Prior to the work of Carrel, malnourishment was the prevailing theory regarding the mechanism of **allograft** rejection.[1] In 1910, however, Carrel noted that tissue damage in the transplanted organ likely was caused by multiple circulating biologic factors. It was not until the late 1940s, with the work of Peter Medawar, that we began to gain a better understanding of transplant immunology. Medawar was able to define the immunologic nature of rejection using skin allografts. In addition, George Snell observed fewer rejections with grafts shared between inbred animals and greater rejections in transplants between non-inbred animals.[1]

The seminal work by early transplant researchers eventually led to the concept of histocompatibility.[1,2] Histocompatibility describes the process where polymorphic genes encode cell membrane antigens that serve as targets for immune response, even within a species. Further research in transplant immunobiology has led to an accurate understanding of the immune response after transplantation.[1,2]

Joseph Murray performed the first successful organ transplant in 1954, a kidney transplant between identical twins.[1] This was a success in large part because no immunosuppression was necessary since the donor and recipient were genetically identical. Murray's success led to attempts with other organs over the next 20 years (Table 52–1).

TABLE 52–1. Solid-Organ Transplantation History

Event	Year
First successful deceased donor kidney transplant	1963
First successful pancreas transplant	1966
First successful liver transplant	1967
First successful heart transplant	1967
First successful heart-lung transplant	1981
First successful single-lung transplant	1983
First successful double-lung transplant	1987
First successful intestine transplant	1987
First successful living-donor liver transplant	1989
First successful living-donor lung transplant	1990
First successful live-donor partial pancreas transplant	1998

EPIDEMIOLOGY AND ETIOLOGY

Heart

Functions of the Heart

The heart is located underneath the sternum and between the lungs. In most adults, it weighs between 250 and 350 grams (0.55–0.77 lb). Its major role is to provide oxygen-rich blood to all organs and areas of the body. As a secondary function, the heart secretes atrial natriuretic factor (ANF), a hormone that regulates blood pressure and volume status. The inability of the heart to pump enough blood to maintain normal body requirements is known as heart failure. Refer to Chapter 3 for more information on heart failure.

Cardiac transplantation is one option for patients with severe heart failure. Candidates for cardiac transplantation generally present with New York Heart Association (NYHA) class III or IV symptoms and have an ejection fraction of less than 25%.[1,3] The general indications for cardiac transplantation include rapidly declining cardiac function and a projected 1-year mortality rate of greater than 75%. Mechanical support with an implantable left ventricular assist device may be appropriate while patients await the availability of a viable organ.[1,3] Some additional reasons for heart transplant include:

- Cardiomyopathy (e.g., dilated myopathy, hypertrophic cardiomyopathy, restrictive myopathy)
- Congenital heart disease
- Coronary artery disease
- Retransplantation after a previous graft failure
- Valvular heart disease

Most heart transplants are **orthotopic;** however, in certain situations, heterotopic (placing a transplanted organ into an abnormal anatomic location) cardiac transplants have been performed. There have been a handful of cardiac transplants that involved living donation. Although this seems strange, this occurs when one patient receives a simultaneous heart-lung transplant but his or her native heart (native is a term meaning "belonging to"; in this case, it refers to the original heart of the

individual, not the transplanted heart) is well functioning and may be transplanted subsequently into another recipient. In other words, when a patient receives a new heart in a heart-lung transplant, that patient's native heart, which is still in good (or viable) condition, is transplanted into another individual—the heart transplant recipient is also the heart transplant donor. This procedure is referred to as a "domino heart transplant." Annually, approximately 4000 patients are listed for a heart transplant, but only about 2300 donor hearts become available for transplantation each year. There were 2127 heart transplants done in 2005.[3]

Intestine

The intestine is the portion of the gastrointestinal (GI) tract that extends from the stomach to the anus. It is divided into two major sections, the small intestine and the large intestine. The small intestine, composed of the upper intestine, jejunum, and ileum, is about 20 feet (610 cm) in length. It functions to provide extensive food digestion and absorption of nutrients. Drug metabolism also takes place in the small intestine. The large intestine, composed of the cecum, ascending colon, transverse colon, descending colon, sigmoid colon, and rectum, is wider than the small intestine but is only about 6 feet in length. Its major function is the absorption of water and excretion of solid waste materials. Some reasons for intestine transplants include:

- Functional bowel problems (e.g., **Hirschsprung's disease,** neuronal intestinal dysplasia, pseudo-obstruction, protein-losing enteropathy, microvillous inclusion disease)
- Retransplantation after a previous graft failure
- Short-gut syndrome (e.g., intestinal artresia, necrotizing enterocolitis, intestinal volvulus, massive resection secondary to inflammatory bowel disease, tumors, mesenteric thrombosis)

An intestine transplant may involve the use of an entire intestine or just a shortened segment. Most intestine transplants completed in the United States have involved the transplant of the full organ and often are performed in conjunction with a liver transplant. Although most intestine transplants involve organs harvested from a deceased donor, recent advances in the field now have made it possible for living-donor intestinal segment transplants. There were 178 intestinal transplant recipients (171 deceased donors, 7 living donors) in 2005.[3]

Kidneys

The kidneys are located on the posterior part of the abdomen on either side of the spine, below the diaphragm, and behind the liver and stomach. They are bean-shaped and weigh approximately 150 grams (0.33 lb) each. The primary function of the kidneys is excretion. They work to excrete waste products through a series of steps involving glomerular filtration, secretion, and reabsorption. The kidneys also have several endocrine (e.g., production of erythropoietin and renin) and metabolic (e.g., vitamin D activation and drug metabolism) functions.

Prevalence of Kidney Disease

Over 20 million Americans have chronic kidney disease (CKD), with another 20 million considered at increased risk for the development of kidney disease. End-stage renal disease (ESRD) constitutes only a small portion of those CKD patients, with over 450,000 patients currently diagnosed with ESRD throughout the United States. The ESRD population continues to increase, with projections estimating that more than 660,000 people will carry a diagnosis of ESRD by 2010. All patients with ESRD should be considered for renal transplantation if they are healthy enough to undergo the transplant surgery. A successful kidney transplant may offer advantages in terms of both quality and duration of life compared with other renal replacement therapies (i.e., hemodialysis and peritoneal dialysis). It is also more effective than dialysis from a medical and economic perspective. Some reasons for kidney transplant include:

- Congenital, familial, and metabolic disorders (e.g., congenital obstructive uropathy, **Fabry's disease, medullary cystic disease,** and nephrolithiasis)
- Diabetes mellitus (DM)
- Glomerular diseases (e.g., anti–glomerular basement membrane disease, focal segmental glomerularsclerosis, IgA nephropathy, hemolytic uremic syndrome, systemic lupus erythematosus, **Alport's syndrome,** amyloidosis, membranous nephropathy, and **Goodpasture's syndrome**)
- Hypertension (HTN)
- Neoplasm (e.g., renal cell carcinoma and **Wilms' tumor**)
- **Polycystic kidney disease** (PCKD)
- Renovascular disease
- Retransplantation after a previous graft (allograft) failure
- Tubular and interstitial diseases (e.g., analgesic nephropathy, drug-induced nephritis, oxalate nephropathy, **radiation nephritis, acute tubular necrosis,** and **sarcoidosis**)

Most kidney transplant procedures are heterotopic, where the kidney is implanted above the pelvic bone and attached to the patient's iliac artery and vein. The ureter of the transplant kidney is attached directly to the recipient's bladder or native ureter. The native kidneys usually are not removed, and data have shown that under most circumstances, removal of the native kidneys does not influence patient survival and **allograft survival**. Special circumstances, however, such as renal cell carcinoma and PCKD, may necessitate native kidney removal.[1,3] There were 16,477 (9914 deceased donors, 6563 living donors) kidney transplants and 903 simultaneous kidney-pancreas procedures done in 2005.[3]

Liver

The liver is the largest of the abdominal organs, weighing 1 to 2.5 kg (2.2–5.5 lb), and is located under the diaphragm on the right side of the upper abdomen. The liver is composed of two soft, wedge-shaped lobes with eight segments. This organ plays a vital role in several processes, including carbohydrate, lipid,

and xenobiotic metabolism; synthesis of plasma proteins; and production of several clotting factors and glycogen storage.[1,3] Some reasons for liver transplant include:

- Acute hepatic necrosis (e.g., chronic or acute hepatitis B or C)
- Biliary atresia
- Cholestatic liver disease/cirrhosis (e.g., primary biliary cirrhosis)
- Metabolic disease (e.g., **Wilson's disease,** primary oxalosis, and hyperlipidemia)
- Neoplasms (e.g., hepatoma, cholangiocarcinoma, hepatoblastoma, and bile duct cancer)
- Non-cholestatic cirrhosis (e.g., alcoholic cirrhosis, postnecrotic cirrhosis, and drug-induced cirrhosis)
- Retransplantation after a previous graft failure

A liver transplant may involve the use of the entire organ or a segment of the liver. In most cases, the full organ (deceased donor) is used. In recent years, segmental transplants have been gaining popularity. This procedure requires donation of the right hepatic lobe, which accounts for nearly 60% of the overall liver mass. This type of procedure is possible because the liver can regenerate; therefore, both the donor and recipient, in theory, will have normal liver volumes shortly after the transplant procedure.[1,3] There were 6445 (6122 deceased donors, 323 partial-lobe living donors) liver transplants done in 2005.[3]

Lungs

Functions of the Lungs

The lungs are a pair of highly resilient, spongy organs located in the thoracic cavity beneath the rib cage. These organs can be divided into five lobes. The left lung has two lobes, and the right lung has three lobes. Their principal functions are gas exchange, the transport of oxygen from the atmosphere into the bloodstream in exchange for carbon dioxide, and control of hydrogen ion concentration. Some reasons for lung transplant include:

- α_1-Antitrypsin deficiency
- Congenital disease (e.g., **Eisenmenger's syndrome**)
- Cystic fibrosis
- Emphysema/chronic obstructive pulmonary disease
- Idiopathic pulmonary fibrosis
- Primary pulmonary hypertension
- Retransplantation after a previous graft failure

Lung transplants may involve deceased donation of two lungs or a single lung. More recently, lobar lung transplants from blood group–compatible living donors have been performed for a small segment of the population. In a lobar transplant, a lobe of the donor's lung is removed, sized appropriately for the recipient's thoracic dimensions, and transplanted. Most of the lobar transplants have been performed on cystic fibrosis patients. On rare occasions, a simultaneous heart-lung transplant occurs. This type of procedure is reserved for patients with severe pulmonary and cardiac disease. There were 1408 (1407 deceased donors, 1 living donor) lung transplants and 33 simultaneous heart-lung transplant procedures done in 2005.[3]

Pancreas

The pancreas is a small retroperitoneal organ located behind the stomach on the posterior abdominal wall.[1,3] The pancreas has both exocrine and endocrine functions. The exact nationwide prevalence of all diseases of the pancreas has not been fully quantified; however, DM, both types 1 and 2, affect nearly 21 million people in the United States alone. Some reasons for pancreas transplants include:

- DM (e.g., types 1 and 2, DM secondary to chronic pancreatitis, and DM secondary to cystic fibrosis)
- Pancreatic cancer
- Retransplantation after a previous graft failure

Transplant of a pancreas may involve either the entire organ or a pancreas segment. Currently, whole-organ transplant is the most common procedure, with a portion of the duodenum often transplanted along with the pancreas. Living donors are often the source of segmental transplants. In recent years, isolation and transplantation of beta islet cells alone have been completed, although at the time of this publication this procedure is still considered experimental.

Some people suffering from DM also may be afflicted with ESRD. A small percentage of these patients may undergo a simultaneous pancreas-kidney (SPK) transplant, which may be accomplished using organs from deceased or living donors. There were 541 pancreas transplants and 903 SPK procedures done in 2005.[3]

PATHOPHYSIOLOGY

Major Histocompatibility Complex

The primary target of the immune response against a transplanted organ is the Major Histocompatibility Complex (MHC).[1,2] The MHC is a region of highly polymorphic genes located on the short arm of chromosome 6. The human MHC is referred to as human leukocyte antigen (HLA). Human leukocyte antigens are a set of glycoprotein products that are expressed on the surfaces of almost all cells. These proteins are involved in immune recognition, which is the discrimination of self from non-self, and are also the principal antigenic determinants of allograft rejection.[1,2] The protein products of the HLA have been classified into two major groups, class I and II:

- *Class I.* These molecules are expressed on the surfaces of all nucleated cells and are recognized by CD8+ cells, also known as cytotoxic T cells. There are three subclasses of MHC class I molecules called HLA-A, HLA-B, and HLA-C.
- *Class II.* These molecules are expressed solely on the surfaces of antigen-presenting cells (APCs). The APCs serve to

stimulate CD4+ cells, also known as helper T cells. There are three subclasses of MHC class II molecules called HLA-DP, HLA-DQ, and HLA-DR.

T and B Lymphocytes

Lymphocytes are one of five kinds of white blood cells. Mature lymphocytes are astonishingly diverse in their functions. The most abundant of the lymphocytes are T lymphocytes (also called T cells) and B lymphocytes (also called B cells).

T Lymphocytes

❶ *T cells are the chief components initiating the immune response against the allograft. The activity of T cells is mediated largely through the synthesis and release of interleukin-2 (IL-2).* There are three recognized subclasses of T cells:

- Cytotoxic T cells (CD8+) promote target-cell destruction by activating cellular **apoptosis** or aggressively killing the target cell via the release of cytotoxic proteins.
- Helper T cells (CD4+) are the great communicators of the immune response. Once activated, they proliferate and secrete cytokines that regulate **effector cell** function. Some helper T cells secrete cytokines that recruit cytotoxic T cells, B cells, or APCs, whereas others secrete cytokines that turn off the immune response once an antigen has been destroyed.
- Regulatory T cells, or suppressor T cells, suppress the activation of an immune response. The activity of these cells in organ transplant is not well elucidated.

B Lymphocytes

B cells play a large role in the humoral immune response. In humans, B cells are produced and mature in the bone marrow. However, the abbreviation "*B*" does not stand for bone marrow. It stands for the bursa of Fabricius, an organ unique to birds, where B cells originally were discovered to mature.

The human body produces several types of B cells. Each B cell is unique, with a distinctive cell surface receptor protein that binds to only one particular antigen. Once B cells encounter their antigen and receive a cytokine signal from helper T cells, they can further differentiate into one of two cells, plasma B cells and memory B cells. Plasma B cells secrete antibodies that induce the destruction of target antigens through a process known as **opsonization.** Memory B cells play an important role in long-term immunity. Once formed to a specific antigen, memory B cells are capable of responding rapidly to subsequent exposures to their target antigen.

Antigen-Presenting Cells

❷ *An APC is a cell that displays a foreign antigen complex with MHC on its cell surface. Its major responsibility is to present these foreign antigens to T cells. T cells can identify this complex using their T-cell receptors (TCRs). There are three main types of APCs: dendritic cells, macrophages, and activated B cells.* Dendritic cells (DCs) are present in tissues that are in contact with the environment, such as the skin and the lining of the nose, lungs, stomach, and intestines. They are responsible for antigen **phagocytosis.** After phagocytosis, they express the foreign antigen on their cell surfaces and then migrate to the lymphoid tissues to interact with T and B cells to initiate the immune response. The main role of macrophages is the removal of pathogens and necrotic debris. However, like DCs, macrophages also phagocytize antigens and express them on their cell membranes to present to T cells in order to initiate an immune response. The first time an antigen is encountered, the DCs and macrophages act as the primary APCs. However, if the same antigen is encountered again, memory B cells become the most important APC because they initiate the immune response quickly after antigen presentation. It appears that both the DCs and macrophages have the most activity in terms of **allorecognition.**

Allorecognition

❶❷ *Recognition of the antigens displayed by the transplanted organ (alloantigens) is the prime event that initiates the immune response against the allograft.* There are currently two accepted pathways for T cell allorecognition:

- *Direct pathway.* Donor APCs migrate out of the allograft into the recipient's lymph nodes and present donor MHC molecules to the TCRs of the recipient's T cells.
- *Indirect pathway.* Recipient APCs migrate into the graft and phagocytize alloantigens. The donor MHC molecules then are expressed on the cell surfaces of the recipient's APCs and presented to recipient T cells in the lymph nodes.

T-Cell Activation

Whether it is by the direct or indirect pathway, in order for a T cell to become activated against a transplanted organ, two interactions, or signals, must take place between the APCs and the recipient's T cells.[1,2] Signal 1 is the interaction of the TCRs with the foreign antigens presented by the APCs. The second, co-stimulatory signal, known as Signal 2, is an interaction between one of several co-stimulatory receptors and paired ligands on the cell surfaces of the APCs and T cells, respectively. This interaction is of the utmost importance because Signal 1 in the absence of Signal 2 induces T cell **anergy.**

Once activated, T cells undergo clonal expansion (they multiply) under the influence of cytokines, specifically IL-2. These steps elicit an anti–donor T cell response that results in graft destruction.

Mechanisms of Acute Rejection

After activation, cytotoxic T cells emerge from lymphoid organs to infiltrate the graft and trigger the immune response. These cells have been shown to induce graft destruction via two mechanisms: (1) secretion of the cytotoxic proteins perforin and granzyme B, and (2) induction of cellular apoptosis

through interaction with various cell surface receptors. Besides the cytotoxic T cells, several other cell lines may play a role in allograft destruction, including B cells, granulocytes, and natural killer cells.

Types of Rejection

Hyperacute Rejection

Hyperacute rejection is an immediate recipient immune response against the allograft owing to the presence of preformed recipient antibodies directed against the donor's HLA. In other words, hyperacute rejection may occur when preformed donor-specific antibodies are present in the recipient at the time of the transplant. This type of reaction generally occurs within minutes of the transplant. The organ must be removed immediately to prevent a severe systemic response. Patients at highest risk for hyperacute rejection include any patient that has preformed HLA or ABO blood group antibodies, including patients with a history of previous organ transplants or multiple blood transfusions, as well as mothers receiving transplanted organs from their children. Hyperacute rejection has been largely eliminated owing to routine surveillance testing completed prior to the transplantation.

Acute Rejection

Acute rejection is a cell-mediated process that generally occurs within 5 to 90 days of the transplant procedure; however, it can occur at any time after transplantation. This reaction is mediated through alloreactive T cells, as outlined previously. Organ-specific signs and symptoms of acute rejection are listed in Table 52–2.

Humoral Rejection

Also known as antibody-mediated rejection, humoral rejection is the process of creating graft-specific antibodies.[1,4] This type of rejection occurs less frequently than cell-mediated acute rejection. Humoral rejection is characterized by deposition of immunoglobulins and complement in allograft tissues. Treatment for this type of rejection is not well defined, yet several reports have shown that treatments such as plasmapheresis, immunoglobulin therapy, rituximab, and/or antithymocyte globulin may be effective.

Chronic Rejection

Chronic rejection traditionally has been thought of as a slow, insidious form of acute rejection resulting in worsening organ function over time. The exact immunologic processes of chronic rejection are poorly understood; however, many believe that both the cell-mediated humoral immune systems (antibody-mediated) and drug-induced toxicities play a vital role in chronic allograft dysfunction. Currently, retransplantation is the only effective treatment option for chronic allograft dysfunction.[1,5]

Host-Graft Adaptation

The term host-graft adaptation describes a decreased immune response against the allograft over time.[2] This phenomenon is evident by the reduced incidence of acute rejection episodes seen months after the transplant procedure. In theory, host-graft adaptation is thought to be secondary to a weakened T-cell response to the donor antigens when patients are receiving maintenance immunosuppression.[2] Host-graft adaptation allows for acceptance of allograft (low rejection rate) despite the low intensity of immunosuppression.

TABLE 52–2. Organ-Specific Signs and Symptoms of an Acute Rejection Episode[1, 3]

Organ	Clinical Symptoms	Laboratory Signs
Heart	Fever, lethargy, weakness, SOB, DOE, hypotension, tachycardia, atrial flutter, ventricular arrhythmias	Leukocytosis, endomyocardial biopsy positive for mononuclear infiltrates
Kidney	Fever, graft tenderness and swelling, decreased urine output, malaise, hypertension, weight gain, edema	Increased SCr, BUN, leukocytosis, renal biopsy positive for lymphocytic infiltration
Intestine	Fever and GI symptoms (e.g., bloating, cramping, diarrhea, increased stomal output)	There are no reliable biochemical markers for intestine transplant rejection, but biopsies may be helpful
Liver	Fever, lethargy, change in color or quantity of bile in patients w/ biliary T-tube, graft tenderness and swelling, back pain, anorexia, ileus, tachycardia, jaundice, ascites, encephalopathy	Abnormal LFTs, increased bilirubin, alkaline phosphatase, transaminases, biopsy positive for mononuclear cell infiltrate with evidence of tissue damage
Lung	Fever, impaired gas exchange, SOB, malaise, anxiety	Decreased FEV, infiltrate on CXR, biopsy positive for lymphocytic infiltration
Pancreas	Fever, graft tenderness and swelling, abdominal pain, ileus, malaise	Increased FBS, leukocytosis, decreased human C-peptide and urinary amylase levels

BUN, blood urea nitrogen; CXR, chest x-ray; DOE, dyspnea on exertion; FBS, fasting blood sugar; FEV, forced expiratory volume; GI, gastrointestinal; LFTs, liver function tests; SCr, serum creatinine, SOB: shortness of breath.

Tolerance

Tolerance is the process that allows organ-specific antigens to be accepted as self.[2,6] This would mean that the immune system would cease to respond to the allograft, and immunosuppressive medications would not be necessary. Immune tolerance has not been accomplished successfully in humans.[2,6]

TREATMENT

Desired Outcome

The major focus of transplant therapy is to achieve long-term patient and allograft survival.[2,7] Short-term outcomes (i.e., acute rejection rates and 1-year graft survival) have improved significantly since the first successful transplant owing to an improved understanding of the immune system and enhancements in surgical techniques, organ procurement, immunosuppression, and posttransplant care. Despite the success in improving short-term outcomes, the overall frequency of graft loss remains higher than desired.[1,2]

It is imperative that transplant practitioners be aware of the specific advantages and disadvantages of available immunosuppressants, as well as their adverse drug reaction and drug-drug interaction (DDI) profiles.

There are three stages of medical immunosuppression: (1) induction therapy, (2) maintenance therapy, and (3) treatment of acute rejection episodes. ❸ *The goal of pharmacotherapy in transplantation is to induce immunosuppression with resulting long-term allograft and patient survival while minimizing the complications of suppressing the immune system. Overall, the immunosuppressive regimens use multiple medications that work on different targets of the immune system.* Please refer to Table 52–3 for a list of currently available immunosuppressive agents.

Immunosuppressive Therapies: Induction Therapy

❹ *The goal of induction therapy is to provide a high level of immunosuppression in the critical early posttransplant period, when the risk of acute rejection is highest.*[2,7–10] This stage of immunosuppression is often initiated intraoperatively or immediately postoperatively and generally is concluded within the first 7 to 10 days of transplantation. Induction therapy is not a mandatory stage of recipient immunosuppression. However, since acute rejection is a major concern in solid-organ transplant recipients and its impact on chronic rejection is undeniable, induction therapy is used often to optimize outcomes.[2,7–10]

Goals of Induction Therapy

The induction agents are highly immunosuppressive and, when given prior to some organ transplants (e.g., kidney transplant), allow for significant reductions in acute rejection episodes and improved 1-year graft survival. Also, owing to their unique pharmacologic effect, these agents often are considered essential for use in patients at high risk for poor short-term outcomes, such as patients with preformed antibodies, a history of previous organ transplants, multiple HLA mismatches, or transplantation of organs with prolonged cold ischemic time or from expanded-criteria donors. Specifically, in renal transplant recipients, induction therapy plays an important role in preventing early-onset calcineurin inhibitor–induced nephrotoxicity. With the use of induction agents, initiation of calcineurin inhibitors can be delayed until the graft regains a modicum of function.[7,9,10]

The improved short-term outcomes gained from induction therapy come with a degree of risk. By using these highly immunosuppressive agents, particularly the antilymphocyte antibodies (ALAs), muronomab-CD3 (OKT-3), and the antithymocyte antibodies, the body loses much of its innate ability to mount a cell-mediated immune response, which increases the risk of opportunistic infections and cancer.[7,10]

Currently Available Induction Therapies

Basiliximab and Daclizumab

Basiliximab and daclizumab are considered monoclonal antibodies. Daclizumab is a humanized antibody that is approximately 10% murine and 90% human, whereas basiliximab is a chimeric antibody that is approximately 30% murine and 70% human.[9,11] These agents bind with high affinity to the IL-2 receptor, where they act as CD25 receptor antagonists. These receptors are present on almost all activated T cells. Their role in induction therapy involves inhibiting IL-2-mediated activation of lymphocytes, which is an important step for the clonal expansion of T cells.

The dose of basiliximab is 20 mg intravenously (IV) given within 2 hours prior to the transplant, followed by a second 20 mg dose on postoperative day 4.[7,9,11] This dosing schedule can be used for both children weighing 35 kg (77 lb) or more and adults. Two 10 mg doses with the same dosing schedule should be used for children weighing less than 35 kg (77 lb). No specific dosage adjustments is needed in renal or hepatic impairment.[7,9,11]

The Food and Drug Administration (FDA) approved dose of daclizumab is 1 mg/kg within 24 hours of transplant surgery and then 1 mg/kg administered every 2 weeks after surgery for a total of five doses.[7,9,11] No dose adjustment is necessary in renal impairment, but no data are available for dose adjustments in hepatic dysfunction. Several trials have shown that a shorter dosing regimen of daclizumab, two doses given in a similar manner as basiliximab, may be as safe and effective as the full five-dose course.[12,13]

The most common adverse reaction with daclizumab is hyperglycemia, with clinical studies showing that a total of 32% of patients developed hyperglycemia.[9,11] Most of the high glucose levels occurred the day after transplantation or in

TABLE 52–3. Currently Available Immunosuppressive Agents[2, 7, 11]

Generic Name (Brand Name)	Common Adult Dosage	Common Adverse Effects	AWP (per Dose or per Dosage Form)
Induction Therapy Agents			
Lymphocyte immune globulin, antithymoglobulin equine (ATGAM®)	15 mg/kg IV × 3–14 days	Flu-like symptoms, chills, rigors, fever, rash, myelosuppression	$21,797–$101,720
Antithymocyte Globulin Rabbit (Thymoglobulin®)	1.5 mg/kg IV × 3–14 days	Flu-like symptoms, chills, rigors, fever, rash, myelosuppression	$5,434–$25,358
OKT-3 (Orthoclone OKT-3®)	5 mg IV × 7–14 days	Headache, hypertension, pulmonary edema, tremor, fever, aseptic meningitis, hypersensitivity reactions	$6,935–$13,871
Daclizumab (Zenapex®)	1 mg/kg IV × 5 doses	Hyperglycemia (only after infusion)	$6,907
Basiliximab (Simulect®)	20 mg IV × 2 doses	None reported compared with placebo	$3,401
Maintenance Immunosuppressants (Capsules and Tablets)[a]			
Cyclosporine (Sandimmune®, Neoral®, Gengraf®)	4–5 mg/kg by mouth twice a day	Neurotoxicity, gingival hyperplasia, hirsutism, hypertension, hyperlipidemia, glucose intolerance, nephrotoxicity, electrolyte abnormalities	Sandimmune: 25 mg = $1.74 100 mg = $6.93 Neoral: 25 mg = $1.53 100 mg = $6.11 Gengraf: 25 mg = $1.38 100 mg = $5.50
Tacrolimus (Prograf®)	0.05–0.075 mg/kg by mouth twice a day	Neurotoxicity, alopecia, hypertension, hyperlipidemia, glucose intolerance, nephrotoxicity, electrolyte abnormalities	1 mg = $3.97 5 mg = $19.74 0.5 mg = $1.98
Azathioprine (Imuran®)	1–2.5 mg/kg by mouth once a day	Myelosuppression, gastrointestinal disturbances, pacreatitis	50 mg = $1.30
Mycophenolate mofetil (CellCept®)	0.5–1.5 g by mouth twice a day	Myelosuppression, gastrointestinal disturbances	250 mg = $3.11 500 mg = $6.21
Enteric-coated MPA (Myfortic®)	720 mg by mouth twice a day	Myelosuppression, gastrointestinal disturbances	180 mg = $2.53 360 mg = $5.05
Sirolimus (Rapamune®)	1–10 mg by mouth once a day	Hypertriglyceridemia, myelosuppression, mouth sores, hypercholesterolemia, gastrointestinal disturbances, impaired wound healing, lymphocele, pneumonitis	1 mg = $6.57 2 mg = $13.15 5 mg = 32.87
Prednisone (Deltasone®)	Maintenance: 2.5–20 mg by mouth once a day	Mood disturbances, psychosis, cataracts, hypertension, fluid retention, peptic ulcers, osteoporosis, muscle weakness, impaired wound healing, glucose intolerance, weight gain, hyperlipidemia	2.5 mg = $0.07 5 mg = $0.04 10 mg = $0.06 20 mg = $0.11

patients with preexisting DM. All other adverse events in the daclizumab clinical trials showed no statistically significant difference compared with placebo. The incidence of all adverse reactions with basiliximab was similar to placebo in clinical trials.[9,11]

Lymphocyte Immune Globulin, Antithymoglobulin Equine (ATG)

ATG contains antibodies against several T-cell surface markers, including CD2, CD3, CD4, CD8, CD11a, and CD18. After binding to these cell surface markers, ATG promotes T-cell

depletion through opsonization and complement-mediated T cell lysis.[7,8,11] The common dosing strategy for ATG when used for induction therapy is 10 to 30 mg/kg per day IV for 3 to 14 days. The first dose usually begins shortly before or after transplantation.[7,8,11]

After T cell lysis, there is a cytokine release. Owing to this phenomenon, ATG is associated with several adverse reactions.[7,8,11] The most common include fever (63%), chills (43%), headache (35%), back pain (43%), nausea (28%), diarrhea (32%), dizziness (25%), malaise (4%), and myelosuppression [**leukopenia** (30%) and **thrombocytopenia** (44%)]. Overall incidence of opportunistic infections is 27%, with **cytomegalovirus (CMV) disease** occurring in 11% of patients.[7,8,11]

Antithymocyte Globulin Rabbit

Antithymocyte globulin induces T cell clearance, but more important, it alters T cell activation, homing, and cytotoxic activities. Compared with ATG, this agent causes less T cell lysis owing to its multiple mechanisms of immunosuppression. It is also believed that antithymocyte globulin plays a role in inducing T cell apoptosis. Antithymocyte globulin has been dosed at 1 to 4 mg/kg per day (typically dosed at 1.5 mg/kg per day) and usually is administered for 3 to 10 days after transplantation.[7,8,11] Many renal transplant centers aim to initiate the first dose intraoperatively to help reduce organ reperfusion injury.

Adverse reactions are common and may include fever (63%), chills (57%), headache (40%), nausea (37%), diarrhea (37%), malaise (13%), dizziness (9%), leukopenia (57%), thrombocytopenia (37%), and generalized pain (46%).[7,8,11] The incidence of infection is 37%, with CMV disease occurring in 13% of patients. There are no reported drug-drug interactions (DDIs) with the use of antithymocyte globulin at this time.[7,8,11]

Muronomab-CD3

Muronomab-CD3 (OKT-3) is a murine monoclonal antibody that targets the CD3 receptor. The CD3 receptor is only found on activated T cells and medullary thymocytes.[10,11,14] After binding with the CD3 receptor, complement-mediated T cell lysis occurs rapidly. This agent is dosed at 5 mg/day. This dose is given daily for 10 to 14 days. Lower doses have been used successfully in liver transplant recipients.[14]

Owing to its ability to cause widespread T cell lysis after the first dose, OKT-3 has several severe adverse effects that manifest within 3 hours after administration.[10,11,14] These adverse reactions often are referred to as the first-dose effect and usually are secondary to cytokine release. The adverse-reaction profile of OKT-3 includes fever (77%), chills (43%), dyspnea (16%), nausea (32%), vomiting (25%), diarrhea (37%), and tachycardia (26%). One of the major complications of OKT-3 is the development of severe pulmonary edema.[11,15,16] In reported cases of this complication, patients were fluid overloaded at the time of the initial dose. Another problematic adverse reaction is the development of nephropathy.[11,17]

Comparative Efficacy: Induction-Therapy Agents

Improvements in short-term outcomes gained from the use of induction therapies cannot be denied. Despite these improvements, use of induction therapy has not affected long-term allograft function or survival. There are a few studies that help to delineate the ideal induction-therapy agent. For example, studies comparing antithymocyte globulin and ATG show that antithymocyte globulin is more effective in lowering acute rejection rates and improving 1-year allograft survival.[18] Conversely, studies evaluating the use of basiliximab versus antithymocyte globulin demonstrate similar short-term efficacy between both

Patient Encounter, Part 1: The Medical History, Physical Examination, and Diagnostic Tests

JJ is a 52-year-old woman who presents to your transplant center for a living, related renal transplant.

PMH

ESRD secondary to PCKD and failed previous transplant. One prior renal transplant that occurred in 1995 (received kidney from husband), which failed secondary to chronic allograft nephropathy in 2004 (presumably from multiple rejection episodes within the first few years after transplant). For the previous transplant, the patient was maintained on cyclosporine, mycophenolate, and prednisone.
Hypertension
Hyperlipidemia
Insomnia

FH

Father died of a myocardial infarction at age 53, whereas mother is alive and living with HTN, systemic lupus erythematosus, DM, and osteoporosis at the age of 75.

SH

The patient works as a secretary. Was a heavy tobacco user (25 pack-years) but quit 3 years ago. She denies alcohol and IV drug use.

Admission meds

Calcitriol 0.25 mg by mouth once a day
Calcium acetate 1334 mg by mouth three times a day
Ferrous sulfate 325 mg by mouth once a day
Epoetin Alfa 4000 units intravenously every hemodialysis session
Simvastatin 20 mg by mouth once a day at bedtime
Metoprolol 100 mg by mouth twice a day
Aspirin 81 mg by mouth once a day

Allergies

"Codeine causes upset stomach."
"Penicillin causes hives."
"Sulfa causes rash."

- Identify your treatment goals for JJ.
- Create a plan for induction therapy (i.e., would you recommend induction therapy? If so, why? Which agent?).

groups.[19] When choosing an agent for induction therapy, one must weigh the risks versus the benefits. For the most part, the ALAs (OKT-3, ATG, and antithymocyte globulin) are considered to be most effective but are associated with a higher incidence of infectious disease and cancer.

Immunosuppressive Therapies: Maintenance Therapy

❹ *The goals of maintenance immunosuppression are to further aid in preventing acute rejection episodes and to optimize patient and graft survival.* Anti-rejection medications require careful selection and dosage titration to balance the risks of rejection with the risks of adverse events. Common maintenance immunosuppressive agents can be divided into four basic medication classes:

- Calcineurin inhibitors (cyclosporine and tacrolimus)
- Antiproliferatives [azathioprine and the mycophenolic acid (MPA) derivatives]
- Target of rapamycin (ToR) inhibitors (sirolimus)
- Corticosteroids (prednisolone derivatives and dexamethasone)

❸ *Maintenance immunosuppression generally is achieved by combining two or more medications from the different classes to maximize efficacy by specifically targeting unique components of the immune response.* Figure 52–1 presents a schematic representation of these different drug mechanisms, and Fig. 52–2 shows an example protocol for administration of immunosuppressive medications after transplantation. This method of medication selection also helps to minimize adverse events by choosing agents with different adverse-event profiles. Immunosuppressive regimens vary between organ types and transplant centers, but most often they include a calcineurin inhibitor with an adjuvant agent (antimetabolite with or without corticosteroids). Selection of appropriate immunosuppressive regimens should be patient-specific. The transplant practitioner must take into account the patient's preexisting disease states, medication regimens, and preferences.

Calcineurin Inhibitors

❺ *Cyclosporine and tacrolimus belong to a class of immunosuppressants called the calcineurin inhibitors. These agents are considered by many to be the cornerstone of medical immunosuppression. The calcineurin inhibitors work by complexing with cytoplasmic proteins (cyclosporine with cyclophylin and tacrolimus with FK binding protein 12). These complexes then inhibit calcineurin phosphatase, which results in reduced IL-2 gene transcription. The final outcome is a decrease in IL-2 synthesis and a subsequent reduction in T cell activation.*[7,11,20,21]

Cyclosporine

Cyclosporine USP was first approved by the FDA in 1983 but was associated with a variable oral absorption. The development

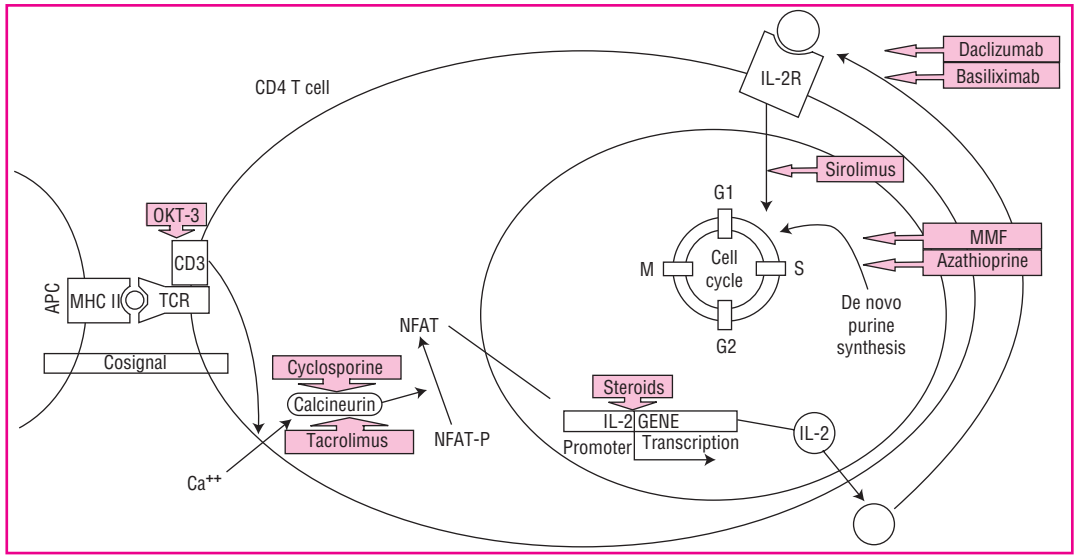

FIGURE 52–1. Stages of CD4 T-cell activation and cytokine production with identification of the sites of action of different immunosuppressive agents. Antigen–major histocompatibility complex (MHC) II molecule complexes are responsible for initiating the activation of CD4 T cells. These MHC-peptide complexes are recognized by the T-cell recognition complex (TCR). A co-stimulatory signal initiates signal transduction with activation of second messengers, one of which is calcineurin. Calcineurin removes phosphates from the nuclear factors (NFAT-P), allowing them to enter the nucleus. These nuclear factors specifically bind to an interleukin-2 (IL-2) promoter gene facilitating IL-2 gene transcription. Interaction of IL-2 with the IL-2 receptor (IL-2R) on the cell membrane surface induces cell proliferation and production of cytokines specific to the T cell.
APCs, antigen-producing cells; MMF, mycophenolate mofetil; OKT-3, muronomab-CD3. (Adapted from Mueller XM. Drug immunosuppressive therapy for adult heart transplantation: I. Immune response to allograft and mechanism of action of immunosuppressants. Ann Thorac Surg 2004; 77: 354–362, with permission.)

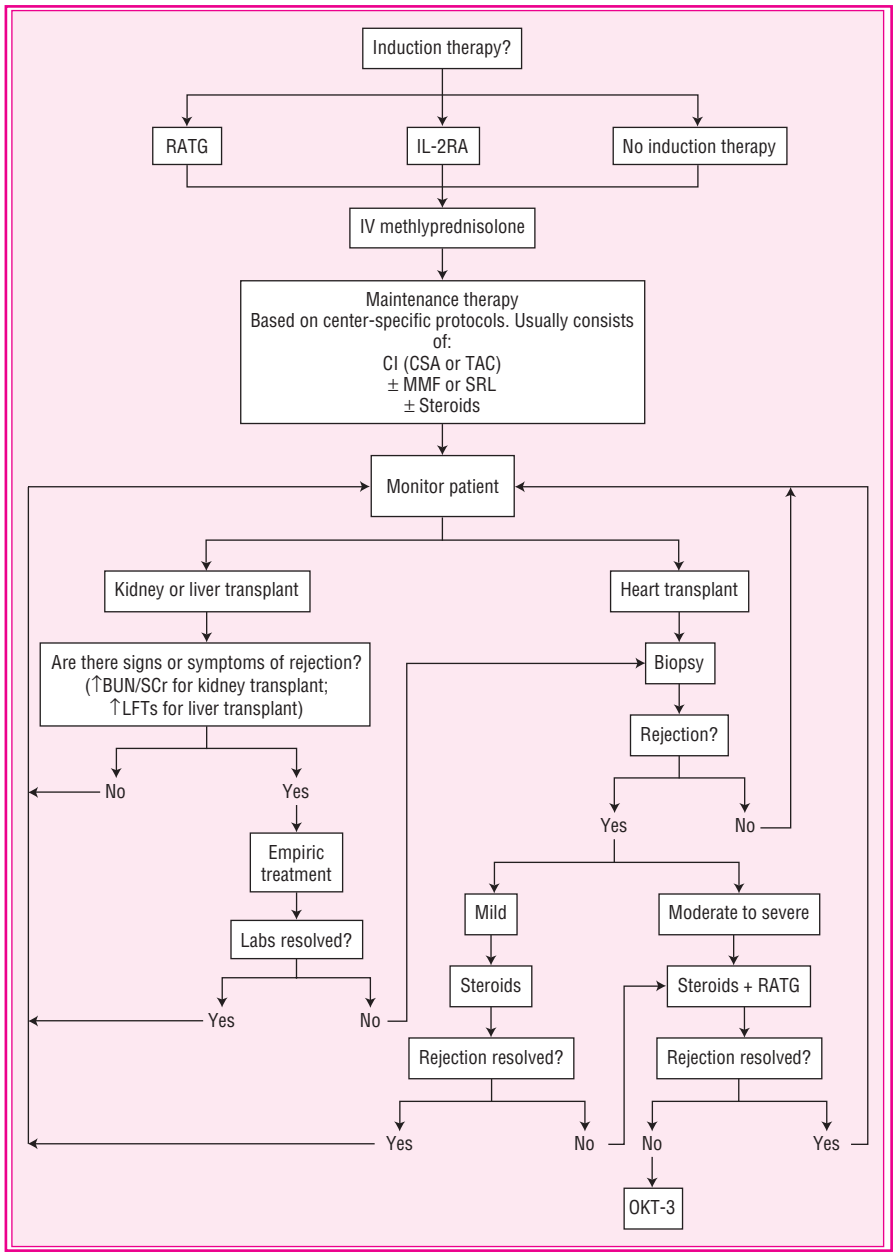

FIGURE 52–2. Center-specific protocols may use RATG, an IL-2RA, or no induction therapy. In any situation, patients receive IV methylprednisolone prior to, during, or immediately following the transplant operation. The patient then will begin the maintenance immunosuppressive regimen. The center-specific protocol will specify which calcineurin inhibitor (cyclosporine or tacrolimus) is used in combination with mycophenolate mofetil or sirolimus with or without steroids. Patients then are monitored for signs and symptoms of rejection. If rejection is suspected, a biopsy can be done for definitive diagnosis, or the patient may be treated empirically for rejection. Empirical treatment generally involves administration of high-dose corticosteroids. If signs and symptoms of rejection are resolved with empirical therapy, the patient will continue to be monitored according to the center-specific protocol. If rejection is confirmed by biopsy, treatment may be based on the severity of rejection. High-dose corticosteroids are used most frequently for mild to moderate rejection. RATG can be used for moderate to severe rejections or steroid-resistant rejections. Severe rejection episodes that are not resolved with steroids or RATG are treated with OKT-3.

of a newer formulation, cyclosporine microemulsion USP, introduced in 1994, allowed for a more consistent drug exposure owing to a more reliable pharmacokinetic profile.[22] Cyclosporine microemulsion is the formulation of choice for most transplant centers that use cyclosporine for maintenance immunosuppression owing to the aforementioned benefit. The two formulations are not interchangeable.

The usual adult oral dose of cyclosporine ranges from 4 to 18 mg/kg per day in two divided doses.[11] Appropriate selection of the starting dose usually depends on the organ type, the patient's preexisting disease states, and other concomitant immunosuppressive agents used. Cyclosporine microemulsion is available as 25 and 100 mg individually blister-packed capsules and an oral solution. An IV formulation is also available. When converting a patient from oral to IV administration, the dosage should be reduced to approximately one-third the oral dose.[11]

Cyclosporine whole-blood trough concentrations traditionally have been obtained to help monitor for efficacy and safety. Therapeutic trough levels (C_0) may range from 50 to 400 ng/mL (41–329 mmol/L). Target levels should be individualized for each patient, usually depending on the organ transplanted, the patient's condition, and the time since transplant and type of assay [high-performance liquid chromatography (HPLC), TDX, or monoclonal antibody]. Newer studies suggest that monitoring of concentrations at 2 hours postdose (C_2) correlates better with toxicity and efficacy than C_0.[23]

Tacrolimus

Tacrolimus (also known as FK506) is the second calcineurin inhibitor and was approved by the FDA in 1997. Even though cyclosporine and tacrolimus both belong to the same general medication class, there are several differences between the two. For example, some studies suggest that tacrolimus-based regimens are associated with improved short-term survival when compared with cyclosporine-based regimens.[24] However, newer data suggest that there is no significant difference in acute rejection rates between cyclosporine and tacrolimus.[25]

Oral starting doses of tacrolimus range from 0.1 to 0.2 mg/kg per day in two divided doses. Tacrolimus is available in 0.5, 1, and 5 mg capsules and as an injectable.[11] The IV formulation usually is avoided owing to the risk of anaphylaxis because of its castor oil component. Tacrolimus C_0 whole-blood levels should be monitored (12 hours after the last administered dose) and maintained between 5 and 15 ng/mL; again, desired serum concentrations depend on the transplanted organ, the patient's condition, and the time since transplant.[11] A once-daily modified formulation of tacrolimus is being studied currently.

Adverse Drug Reactions

❺ *One of the major drawbacks of calcineurin inhibitors is their ability to cause acute and chronic nephrotoxicity.* Acute nephrotoxicity has been correlated with high calcineurin inhibitor doses and usually is reversible. Chronic toxicity, however, typically is irreversible and is linked to chronic drug exposure. Table 52–4 expands on the more common calcineurin inhibitor–induced adverse events.

Comparative Efficacy: Calcineurin Inhibitors

Several studies have assessed the clinical efficacy of cyclosporine versus tacrolimus. Most of the studies have shown similar long-term patient and allograft survival, whereas some renal transplant studies have demonstrated improved renal function in tacrolimus-treated patients. The most significant difference between the two agents appears to be their adverse-reaction profiles (Table 52–4).

Antiproliferatives

These agents generally are considered to be adjuvant to the calcineurin inhibitors or possibly sirolimus. ❻ *The antiproliferatives azathioprine and the mycophenolic acid (MPA) derivatives inhibit T cell proliferation.*

Azathioprine

Azathioprine was originally approved by the FDA in 1968 as an adjunct immunosuppressant for use in renal transplant recipients. It is available in oral and IV dosage forms.[11] Prior to the advent of cyclosporine, the combination of azathioprine and corticosteroids was the mainstay of immunosuppressive therapy. Over the past 10 years, the use of azathioprine has declined markedly due in large part to the success of the MPA derivatives, which are more specific inhibitors of T cell proliferation. Azathioprine is a pro-drug for 6-mercaptopurine (6-MP), a purine analog. 6-MP acts as an antimetabolite and inhibits DNA replication with a resulting reduction in T-cell proliferation.[11] The typical oral dose of azathioprine for organ transplantation is 3 to 5 mg/kg once a day.[11] The IV and oral doses are equivalent (1:1 conversion). The maintenance dose usually is reduced to l to 2 mg/kg per day within a few weeks of transplantation. In patients with severely impaired renal function, dose reductions may be necessary because 6-MP and its metabolites are eliminated renally.[11] Trough concentrations of 6-MP are not monitored; however, most clinicians often monitor for signs of myelosuppression and liver dysfunction. ❻ *Myelosuppression (mainly leukopenia and thrombocytopenia) is a frequent dose-dependent and dose-limiting complication (greater than 50% of patients) that often prompts dose reductions.*[11] Other common adverse events include hepatotoxicity (2% to 10%) and GI problems (10% to 15%, mostly nausea and vomiting). Importantly, pancreatitis and veno-occlusive disease of the liver occur in fewer than 1% of patients following chronic azathioprine therapy.[11]

Mycophenolic Acid Derivatives

Mycophenolate mofetil was approved by the FDA in 1995, and enteric-coated mycophenolic acid was approved in 2004. Both agents are considered to be adjunctive immunosuppressants. Mycophenolic acid acts by inhibiting inosine monophosphate deydrogenase, a vital enzyme in the de novo pathway of purine synthesis. Inhibition of this enzyme prevents the proliferation of most cells that are dependent on the de novo pathway for purine synthesis, including T cells.[7,11,26–28]

Mycophenolate mofetil is available in 250 mg capsules and 500 mg tablets, an oral suspension (100 mg/mlL, in cherry syrup), and an injectable.[11] Usual doses of mycophenolate mofetil range from 1000 to 3000 mg/day in two to four divided doses. The conversion between oral and IV mycophenolate mofetil is 1:1. Enteric-coated mycophenolic acid is available in 180 and 360 mg tablets. For conversion between mycophenolate mofetil and enteric-coated MPA, 1000 mg mycophenolate mofetil is equivalent to 720 mg enteric-coated MPA.[26,29] The recommended starting dose of enteric-coated mycophenolic acid is 720 mg given twice daily.[11] It appears that conversion of mycophenolate mofetil to enteric-coated mycophenolic acid is safe, but more studies are needed to determine the exact role of enteric-coated MPA in the immunosuppressive armamentarium. Mycophenolic acid trough concentrations can be monitored, but they are not recommended routinely.

❻ *The most common adverse events associated with these agents are GI (18% to 54%, namely, diarrhea, nausea, vomiting, and gastritis) and myelosuppression (20% to 40%).*[7,11,26–28] Despite its enteric coating, to date, mycophenolic acid has shown no significant benefit in terms of reduction in GI adverse events compared with mycophenolate mofetil in renal transplant recipients.[26]

TABLE 52–4. Management of Common Adverse Effects of Calcineurin Inhibitors[1, 7, 11]

Adverse Effects	AZA	MMF	Steroids	CSA	TAC	SRL	IL-2RA	ATG	OKT-3	Management
Adrenal suppression			+							Taper doses slowly; administer every other day; patient identification card
Cataracts/glaucoma			+							Annual eye exams or as indicated
Hypertension[a]			++	++	++					Monitor blood pressure; sodium restriction and antihypertensive medications as needed
Tremor (fine hand)[b]				++	++					Adjust dose as needed
Gastrointestinal abnormalities	++ Nausea, vomiting	++ Diarrhea, nausea, abdominal pain	+ GI bleeding	+	++ Diarrhea, nausea, vomiting, anorexia					AZA: administer after meals; MMF: decrease or divide dose, administer with food; TAC/PRED: administer with food; ulcer prophylaxis
Respiratory abnormalities					++				+	TAC: pleural effusion, dyspnea; OKT-3: pulmonary edema
Nephrotoxicity				++	++	+				Monitor SCr/BUN; adjust dose and discontinue as needed
Headache				+	++					Check drug concentration; adjust dose
Hepatotoxicity	+			+	++					Monitor liver enzymes; AZA-associated toxicity is reversible and usually occurs within the first 6 months of therapy; adjust dose and discontinue as needed
Hyperlipidemia[a]			++	++	+	++				Dietary counseling; pharmacotherapy as needed
Glucose alterations[b]			++	+	++					Monitor glucose; adjust doses of hypoglycemics or immunosuppressants
Osteoporosis/aseptic necrosis			+/++							Annual bone exams; weight-bearing exercise
Personality changes			++							Patient and family education
Weight gain			++							Patient education; exercise
Acne			+	+						Dose reduction; increased hygiene; topical agents (e.g., retinoic acid)
Gingival hyperplasia				++						Patient education; appropriate dental hygiene; consider TAC
Hirsutism				++						Patient education; consider TAC
Pruritus					++					Treatment when appropriate
Thrombocytopenia	++	+			+	++				Monitor platelets
Leukocytosis			++		++					Monitor WBCs
Leukopenia	++	++		+		++				Monitor WBCs; dose-dependent and reversible with AZA/MMF
Hyperkalemia				+	++					Monitor serum electrolytes
Hypokalemia							+			
Hypomagnesemia				+	++					Monitor serum magnesium

[a]Tacrolimus is associated with hypertension and hyperlipidemia, but to a much lower extent than cyclosporine.
[b]Cyclosporine is associated with hyperglycemia and central nervous system (CNS) toxicities, but to a much lower extent than tacrolimus.
ATG, lymphocyte immune globulin, antithymoglobulin equine; AZA, azathioprine; BUN, blood urea nitrogen; CSA, cyclosporine; GI, gastrointestinal; IL-2RA, interleukin 2 receptor antagonist; MMF, mycophenalate mofetil; OKT-3, muronomonab-CD3; PRED, prednisone; SCr, serum creatinine; SRL, sirolimus; TAC, tacrolimus; WBC, white blood cell.
Adapted from DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005, Table 87–4, p. 1622.

Comparative Efficacy: Antiproliferatives

MPA derivatives have replaced azathioprine as the antiproliferative agent of choice in most organ transplant centers. The MPA derivatives generally are considered to provide a more specific immunosuppressive effect compared with azathioprine. Mycophenolate mofetil and enteric-coated mycophenolic acid have similar safety and efficacy data in renal transplant recipients.

Target of Rapamycin Inhibitors

Sirolimus

Sirolimus is currently the only FDA-approved ToR inhibitor. One of its derivatives, everolimus, is in phase III clinical trials and has been approved for use in some European countries.[30] Sirolimus is a macrolide antibiotic that has no effect on calcineurin phosphatase.[11,31,32] ❼ *Sirolimus inhibits T cell activation and proliferation by binding to and inhibiting the activation of the mammalian ToR, which suppresses cellular response to IL-2 and other cytokines (i.e., IL-4 and IL-15).*[11,31] Studies have shown that sirolimus may be used safely and effectively with either cyclosporine or tacrolimus as a replacement for either azathioprine or mycophenolate mofetil.[33] However, when using both sirolimus and cyclosporine as part of a patient's immunosuppressant therapy, because of a drug interaction between the two resulting in a marked increase in sirolimus concentrations, it is recommended to separate the sirolimus and cyclosporine doses by at least 4 hours. ❼ *Sirolimus also can be used as an alternative agent for patients who do not tolerate calcineurin inhibitors due to nephrotoxicity or other adverse events.*[34]

Sirolimus is available in 1 and 2 mg tablets and a 1 mg/mL oral solution. The current FDA-approved dosing regimen for sirolimus is a 6 mg loading dose followed by a 2 mg/day maintenance dose.[11] It was recommended that this agent not require therapeutic drug monitoring. However, many centers do check trough concentrations and adjust doses to reach goal concentrations.[35] Many clinicians who prescribe sirolimus use a loading dose of 5 to 15 mg/day for 1 to 3 days to achieve adequate immunosuppression more rapidly.[31,33,34] Maintenance doses of sirolimus usually range from 1 to 10 mg/day given once daily. Sirolimus blood C_0 (trough) levels should be obtained and then maintained at between 5 and 20 ng/mL depending on the institution-specific protocols.[35] Of note, sirolimus has a half-life of approximately 62 hours, which means that it will not reach steady state after dosage changes for several days.[11]

❼ *The most common adverse events reported with sirolimus are leukopenia (20%), thrombocytopenia (13% to 30%), and hyperlipidemia (38% to 57%).*[11,31] Other adverse effects include delayed wound healing, anemia, diarrhea, arthralgias, rash, and mouth ulcers. Sirolimus has an FDA black-box warning in newly transplanted liver and lung recipients.[11] In liver transplant recipients, use of sirolimus immediately after transplant is associated with an increased risk of hepatic artery thrombosis, graft loss, and death. In lung transplant recipients, bronchial anastomotic dehiscence, including some fatal cases, has been noted in patients treated with sirolimus, tacrolimus, and corticosteroids.

Corticosteroids

Traditional triple-therapy immunosuppressive regimens have consisted of a calcineurin inhibitor, an antiproliferative or ToR inhibitor, and corticosteroids. In recent years, many protocols have focused on corticosteroid sparing or avoidance. Avoidance or sparing of corticosteroids has been supported in the literature, although more studies are needed to better characterize which patients should follow these protocols.[36–39]

❽ *Corticosteroids have various effects on immune and inflammatory response systems, although their exact mechanism of immunosuppression is not fully understood. It is generally believed that at high doses, the agents are directly lymphotoxic, and at lower doses, the corticosteroids act by inhibiting the production of various cytokines that are necessary to amplify the immune response.*[11]

The most commonly used corticosteroids are methylprednisolone (IV and oral) and prednisone (oral), although prednisolone and dexamethasone also have been shown to be effective for organ transplantation. Corticosteroid doses vary by center-specific protocols, organ type, and patient characteristics. A typical taper would include an IV 100 to 500 mg bolus of methylprednisolone at the time of transplant and then a taper over 5 to 7 days to a maintenance dose of prednisone 20 mg/day or complete cessation.[2,7] It is important for practitioners to know that approximately 4 mg methylprednisolone is equivalent to 5 mg prednisone and 0.75 mg dexamethasone.[11] At most transplant centers, therapeutic drug monitoring of corticosteroids is not employed. ❽ *Corticosteroids are associated with a variety of acute and chronic toxicities. The most common adverse events have been summarized in Table 52–5.*

Maintenance Immunosuppressive Therapies: Common Drug-Drug Interactions

❾ *As the number of medications that a patient takes increases, so does the potential for DDIs.* Disease severity, patient age, and organ dysfunction are all risk factors for increased DDIs. In general, DDIs can be broken down into two categories: (1) pharmacokinetic interactions and (2) pharmacodynamic interactions.

Given the large number of medications consumed by transplant recipients, it is no surprise that this patient population is at high risk for DDIs. Pharmacokinetic DDIs often are considered the major problem with some of the maintenance immunosuppressants. Due to their narrow therapeutic index, DDIs involving immunosuppressant agents may be significant and could result in toxicities and/or decreased effect. In other words, pharmacokinetic interactions can result in increased concentrations of one or more agents, increasing the risk for toxic side effects, or in lowered or sub-therapeutic drug concentrations, possibly leading to allograft rejection.

TABLE 52–5. Common Adverse Events Associated with Corticosteroids[11]

Body System	Adverse Event
Cardiovascular	Hyperlipidemia Hypertension
Central nervous system	Anxiety Insomnia Mood changes Psychosis
Dermatologic	Acne Diaphoresis Ecchymosis Hirsutism Impaired wound healing Petechiae Thin skin
Endocrine/metabolic	Cushing's syndrome Hyperglycemia Sodium and water retention
Gastrointestinal	Gastritis Increased appetite Nausea, vomiting, diarrhea Peptic ulcers
Hematologic	Leukocytosis
Neuromuscular/skeletal	Arthralgia Impaired growth Osteoporosis Skeletal muscle weakness
Ocular	Cataracts Glaucoma
Respiratory	Epistaxis

Corticosteroids, Cyclosporine, Tacrolimus, and Sirolimus

Cyclosporine, tacrolimus, and sirolimus are substrates of the cytochrome P-450 3A (CYP3A) isozyme system and P-glycoprotein (P-gp) transport protein.[11] The cytochrome P-450 (CYP) isozyme system is responsible for the oxidative biotransformation of many medications. The majority of the CYP-mediated metabolism takes place in the liver, but CYP is also expressed in the intestine, lungs, kidneys, and brain. Two types of interactions usually occur with medications metabolized via the CYP enzyme system: inhibitory interactions and inducing interactions. Enzyme inhibition occurs when there is enzyme inactivation or mutual competition of substrates at a catalytic site. This usually results in a reduction of drug metabolism leading to increased whole-blood trough concentrations and prolonged half-lives of all medications involved. Enzyme induction interactions are just the opposite and occur when there is increased synthesis or decreased degradation of CYP enzymes. This type of interaction can produce decreased concentrations of medications.

Cyclosporine, tacrolimus, and sirolimus are all metabolized via the CYP3A4 pathway; therefore, it would be anticipated that they would experience similar pharmacokinetic DDIs. Table 52–6 details some clinically relevant DDIs that occur with calcineurin inhibitors and sirolimus due to inhibition or induction of the CYP enzyme system.

One of the most often overlooked DDIs in transplant recipients is the effect corticosteroids have on drug metabolism.[40] Corticosteroids are CYP3A enzyme inducers, meaning that they may reduce the whole-blood trough concentrations of cyclosporine, tacrolimus, and sirolimus.[11] This is usually not a noteworthy interaction because the doses of cyclosporine, tacrolimus, and sirolimus can be titrated to achieve target trough concentrations. However, this DDI has been problematic during steroid withdrawal protocols and is evident by increased immunosuppressant trough concentrations after complete steroid withdrawal.

Most pharmacokinetic interactions in transplantation occur due to interactions with the CYP enzyme system; however, several interactions have been shown to occur via alternative mechanisms. One of the most notable is that seen between tacrolimus and some of the prokinetic agents. Cisapride and metoclopramide have been shown to increase the absorption of tacrolimus by enhancing gastric emptying.[41]

P-glycoprotein, a plasma membrane transport protein, is present in the gut, brain, liver, and kidneys.[42] This protein provides a biologic barrier by eliminating toxic substances and xenobiotics that may accumulate in these organs. P-glycoprotein plays an important role in the absorption and distribution of many medications. Medications that are CYP3A4 substrates, inhibitors, or inducers are also often affected by P-glycoprotein; therefore, the potential for even more DDIs exists in transplant recipients.[42]

Azathioprine and the Mycophenolic Acid Derivatives

Azathioprine, mycophenolate mofetil, and enteric-coated MPA are not metabolized through the CYP isozyme system; therefore, they do not experience the same DDI profiles as cyclosporine, tacrolimus, and sirolimus. Azathioprine's major DDIs involve allopurinol, angiotensin-converting enzyme (ACE) inhibitors, aminosalicylates (e.g., mesalamine and sulfasalazine), and warfarin.[11] The interaction with allopurinol is seen frequently and has clinical significance. Allopurinol inhibits xanthine oxidase, the enzyme responsible for metabolizing azathioprine. Combination of azathioprine and allopurinol has resulted in severe toxicities, particularly myelosuppression. It is recommended that concomitant therapy with azathioprine and allopurinol be avoided, but if combination therapy is necessary, the azathioprine doses must be reduced to one-third or one-fourth of the current dose. Use of azathioprine with the ACE inhibitors or aminosalicylates also can result in enhanced myelosuppression.[11] Some case reports exist demonstrating that warfarin's therapeutic effects may be decreased by azathioprine.[43–45]

Most of the interactions with mycophenolate mofetil and enteric-coated MPA are due to reductions in intestinal absorption. Aluminum-, magnesium-, or calcium-containing antacids decrease the peak level and overall exposure of MPA from either of the preparations.[11] If a patient requires liquid antacids, they should be administered at least 4 hours before

TABLE 52–6. Potential Drug-Drug Interactions with the Calcineurin Inhibitors and Sirolimus Mediated Through the CYP3A4 Isozyme[11]

Substrates[a]		Inducers[b]	Inhibitors[c]
Alfentanil	Lidocaine	Carbamazepine	Cimetidine
Alprazolam	Loratadine	Dexamethasone	Clarithromycin
Amiodarone	Lovastatin	Ethosuximide	Clotrimazole
Amlodipine	Nevirapine	Isoniazid	Delavirdine
Atorvastatin	Nicardipine	Nevirapine	Diltiazem
Cilostazol	Nifedipine	Phenobarbital	Erythromycin
Cisapride	Omeprazole	Phenytoin	Fluconazole
Chlorpromazine	Paclitaxel	Prednisone	Fluoxetine
Clonazepam	Propafenone	Rifabutin	Fluvoxamine
Cocaine	Progesterone	Rifampin	Grapefruit Juice
Cortisol	Quetiapine	St. John's Wort	Indinavir
Cyclophosphamide	Quinidine		Itraconazole
Dantrolene	Sertraline		Ketoconazole
Dapsone	Simvastatin		Miconazole
Diazepam	Tamoxifen		Nefazodone
Disopyramide	Testosterone		Nelfinavir
Enalapril	Triazolam		Ritonavir
Estradiol	Venlafaxine		Saquinavir
Estrogen	Vinblastine		Troleandomycin
Etoposide	Warfarin		Verapamil
Felodipine	Zolpidem		Voriconazole
Flutamide			Zafirlukast

[a]Substrates of the CYP3A4 isozyme will compete with cyclosporine, tacrolimus, and sirolimus for metabolism; therefore, concentrations of both medications may be increased (usually by less than or equal to 20%).
[b]Inducers of the CYP3A4 isozyme will enhance the metabolism of cyclosporine, tacrolimus, and sirolimus; therefore, concentrations of these medications may be decreased.
[c]Inhibitors of the CYP3A4 isozyme will decrease the metabolism of cyclosporine, tacrolimus, and sirolimus; therefore, concentrations of these medications may be increased.
CYP3A4, cytochrome P-450 system 3A isozyme.

or after the MPA derivatives. Cholestyramine has been shown to decrease overall MPA exposure.[46,47] This interaction is due to the ability of cholestyramine to inhibit the enterohepatic recirculation of MPA. Through a similar mechanism, cyclosporine has been shown to reduce the overall exposure to MPA derivatives.[48] Recent studies have shown lower MPA levels in cyclosporine-based immunosuppression regimens than in tacrolimus-based regimens.

In addition to the numerous pharmacokinetic interactions seen with the maintenance immunosuppressants, there also exists the possibility for pharmacodynamic interactions. An in-depth review of pharmacodynamic interactions with maintenance immunosuppressive agents goes beyond the scope of this chapter. However, it is important to note that the addition of nephrotoxic agents, such as amphotericin B, aminoglysides (e.g., gentamicin, tobramicin, or amikacin), and non-steroidal anti-inflammatory drugs (NSAIDs; e.g., naproxen, ibuprofen, or ketorolac) may potentiate the nephrotoxic effects of the calcineurin inhibitors. The use of myelosuppressive agents, such as cotrimoxazole and valganciclovir, also could enhance myelosuppression when combined with azathioprine or the MPA derivatives.

The potential exists for multiple DDIs in transplant recipients owing to the complexity of their medication regimens. Practitioners must be diligent in reviewing all medications for potential DDIs. In addition to reviewing prescription medications, it is essential to question patients about the use of both non-prescription and complementary and alternative medications because these products also have the potential for significant interactions.

Treatment of Acute Rejection Episodes

Reduction in severity of the immune response and prevention of irreversible graft injury are the chief aims of acute rejection episode treatment. Treatment strategies include: (1) using high-dose corticosteroids (dosage is later tapered); (2) using short-term treatment with induction agents such as ATG or OKT-3; (3) increasing the dosage of the patient's immunosuppressant maintenance therapy; or (4) adding another immunosuppressant

Patient Encounter, Part 2

1. Identify your treatment goals for JJ in terms of maintenance immunosuppressants.
2. Create a plan for maintenance therapy for JJ, making sure to compare and contrast the pros and cons of the different maintenance immunosuppressants.
3. Identify the potential DDIs that may exist with the addition of the maintenance immunosuppressants to the medications that JJ is currently taking.

such as sirolimus to the patient's regimen. Choice of treatment varies by medical center and type of transplant; however, acute rejection generally is treated with a course of high-dose methylprednisolone (250–1000 mg/day IV for 3 days), which is usually sufficient to ameliorate the rejection episode. If the acute rejection episode is resistant to the initial course of steroids, a second course may be administered, or the patient then may begin therapy with antithymocyte globulin (1.5 mg/kg per day for 3 to 14 days). Acute rejection refractory to these treatments may require OKT-3. However, the use of OKT-3 to treat acute rejection has fallen out of favor due to the severe short- and long-term adverse events associated with its use.

Management of Immunosuppressive Drug Complications

Opportunistic Infections

❾ *Solid-organ transplant recipients are at increased risk of infectious diseases, which is a major cause of early morbidity and mortality.* The prevalence of posttransplant infection depends on several factors, including clinical risk factors, environmental exposures, and the degree of immunosuppression. Anti-infectives are prescribed universally in this population, and their use can be split into three different categories:

- *Prophylaxis*—antimicrobials given to prevent an infection
- *Empirical*—preemptive therapy based on clinical suspicion of an active infection
- *Treatment*—antimicrobials given to manage a documented infection

Within the first-year posttransplantation, infection and rejection are the most frequently encountered complications. The risk of infection is associated with the overall level of immunosuppression. Thus, the risk of infection is greatest during the first 3 months after transplantation and during intense immunosuppression treatment, such as seen when treating rejection episodes. The information in this section is designed only to highlight prophylaxis options used routinely in organ transplant recipients. Table 52–7 lists the agents used

TABLE 52–7. Prophylactic Options for *Pneumocystis jiroveci* Pneumonia and CMV[50,51]

Medication	Dosing	Common Adverse Events
Anti-*Pneumocystis* Prophylaxis		
Sulfamethoxazole-trimethoprim (SMZ-TMP, cotrimoxazole)	One SS tablet by mouth once a day[a] One DS tablet by mouth once a day[a] One DS tablet by mouth every M/W/F[a]	Hyperkalemia Myelosuppression Nephrotoxicity Neutropenia Photosensitivity Rash
Pentamadine	300 mg inhaled every 3–4 weeks	Bronchospasm Cough Hypoglycemia or hyperglycemia
Dapsone	50–100-mg tablet by mouth once a day	Hepatotoxicity Myelosuppression Nephritis
Atovaquone	1500 mg suspension by mouth once a day	Elevated liver transaminases Nausea Rash
Anti-cytomegalovirus		
Valganciclovir	450–900 mg by mouth once a day[a]	Stomach upset (8–41%) Myelosuppression (2–27%) Headache (9–22%)
Ganciclovir	5 mg/kg IV every day, or 1000 mg by mouth three times a day[a]	Stomach upset (13–40%) Myelosuppression (5–40%) Rash (10–15%)
Valacyclovir	1–2 g by mouth four times a day[a]	Stomach upset (1–15%) Myelosuppression (less than 1%) Headache (14–35%)
CMV IgG and polyvalent IVIG	The maximum recommended total dosage per infusion is 150 mg/kg beginning within 72 hours of transplantation Follow-up doses and time intervals depend on the type or organ transplanted	Stomach upset (1–6%) Fevers and chills (1–6%) Flushing (1–6%)

[a]Dose adjustment required in renal insufficiency.
CMV, cytomegalovirus; DS, double-strength (800 mg SMZ, 160 mg TMP); IgG, immunoglobulin G; IVIG, intravenous immunoglobulin; M/W/F, Monday, Wednesday and Friday; SS, single-strength (400 mg SMZ, 80 mg TMP).

for the prevention of *Pneumocystis jiroveci* pneumonia and CMV disease. Table 52–8 presents special pharmacotherapy considerations in transplant recipients.

Pneumocystis jiroveci Pneumonia

❾ *Without prophylaxis,* Pneumocystis jiroveci *(formerly* Pneumocystis carinii*) pneumonia occurs in 5% to 15% of transplant recipients.*[49] Anti-*Pneumocystis* prophylaxis is enormously helpful and generally is used in all organ transplant recipients. The duration of prophylaxis usually is 3 to 12 months after transplant but may be prolonged in highly immunosuppressed patients (i.e., active CMV disease and treatment for rejection) or liver or lung recipients.[50] Sulfamethoxazole-trimethoprim is the preferred agent for prophylaxis. One of its major advantages is its relatively broad spectrum of activity. Not only is it effective against *Pneumocystis* pneumonia, but it also has activity against toxoplasmosis and other common bacterial infections. Patients with sulfa allergies, glucose-6 phosphate dehydrogenase (G6PD) deficiency, or an inability to tolerate sulfamethoxazole-trimethoprim should be given one of the second-line treatments.[11] Unfortunately, the second-line agents are antiparasitics and have no meaningful activity against common bacteria. These agents include dapsone, atovaquone, and pentamidine.

Cytomegalovirus

CMV is the most concerning opportunistic pathogen in transplantation due to its association with poor outcomes.[51] **CMV infection** is present in 30% to 97% of the general population, but CMV disease typically is restricted to immunocompromised hosts.[52] The risk of CMV disease is highest among CMV-naive recipients who receive a CMV-positive organ (donor+/recipient–).[51] Other factors that augment the risk of CMV disease include organ type (lung and pancreas recipients are at highest risk) and immunosuppressive agents (ALA use increases risk). CMV disease characteristically occurs within the first 3 to 6 months after transplantation, but delayed-onset disease has been seen in patients receiving antiviral prophylaxis.[51]

Several antivirals have proven efficacy in preventing and treating CMV[51] (Table 52–7). Valacyclovir and valganciclovir, prodrugs of acyclovir and ganciclovir, respectively, have improved bioavailability compared with their parent compounds and offer the advantage of less frequent dosing. CMV prophylaxis classically is continued for the first 100 days or longer after transplantation.[52,53] Both IV ganciclovir and oral valganciclovir may be used for preemptive therapy or for treatment of established CMV disease. The adverse events are similar among these agents and include myelosuppression and GI effects.[11]

Invasive Fungal Infections

Fungal infections are an important cause of morbidity and mortality in solid-organ transplant recipients. Immunologic (e.g., immunosuppressants and CMV infection), anatomic (e.g., tissue ischemia and damage), and surgical (e.g., duration of surgery and transfusion requirements) factors contribute to the risk for invasive fungal infections. Mucocutaneous candidiasis (i.e., oral thrush and esophagitis) is associated with corticosteroid and ALA use. Oral nystatin or clotrimazole troches are effective prophylactic options for the prevention of thrush. However, clotrimazole inhibits the CYP3A system in the gut and can alter immunosuppressive levels (concentrations).[11] The use of systemic fungal prophylaxis, such as oral fluconazole, is controversial owing to the potential for DDIs and the risk of developing resistance. The choice of agents depends on the fungal risk in that particular population. For example, liver and intestine transplant recipients are at high risk for candidiasis; therefore, the use of medications that cover the *Candida* species is crucial, such as the triazole antifungals (e.g., fluconazole or itraconazole) or the echinocandins (e.g., caspofungin or micafungin). Lung transplant recipients are at high risk for aspergillosis; therefore, it is imperative to use antifungal prophylaxis that covers the *Aspergillus* species, such as the echinocandins or polyenes (e.g., amphotericin B or lipid-based amphotericin B products).[54]

Patient Encounter, Part 3

1. Identify your treatment goals for JJ in terms of antimicrobial prophylaxis.
2. Create a plan for JJ's antimicrobial prophylaxis, making sure to compare and contrast the pros and cons of the different agents for this patient.

Hypertension

❾ *Cardiovascular disease has been identified as one of the leading causes of death in organ transplant recipients.*[55] Posttransplant hypertension (HTN) is associated with an increase in cardiac morbidity and patient mortality in all transplant patients and is also an independent risk factor for chronic allograft dysfunction and loss.[56] Based on all the available posttransplant morbidity and mortality data, it is imperative that posttransplant HTN be identified and managed appropriately.

There are several underlying mechanisms responsible for posttransplant HTN. Some causes of HTN in transplant recipients may include renal dysfunction, increased sensitivity to endothelin-1 and angiotensin, increased density of glucocorticoid receptors in the vascular smooth muscle, and decreased production of vasodilatory prostaglandins.[57] However, one of the most easily recognized causes of posttransplant HTN is the use of corticosteroids and calcineurin inhibitors.[58,59] Corticosteroids usually cause sodium and water retention,[57] thus increasing blood pressure, whereas calcineurin inhibitors are associated with a number of effects that may result in HTN, including

TABLE 52–8. Special Pharmacotherapy Considerations in Transplant Recipients

Problem	Pharmacotherapy	Special Considerations
Infection		
CMV	See Table 52–7	
Perioperative prophylaxis	Bowel decontamination	Donor culture results Penicillin allergy: vancomycin
Pneumocystis jiroveci prophylaxis	See Table 52–7	Sulfa allergy
Fungal		
Prophylaxis Treatment	Nystatin, clotrimazole, fluconazole, itraconazole, ketoconazole, Amphotericin B	Inhibit P-450 3A4; monitor CSA and TAC levels; decrease doses Consider liposomal products; decrease or stop CSA or TAC to minimize nephrotoxicity Remember to adjust doses of renally eliminated drugs (e.g., acyclovir, ganciclovir, TMP-SMX)
Hyperkalemia	Restrict dietary intake; dialysis	May be exacerbated by CSA or TAC or ACEIs, acidosis, or RI; fludrocortisone acetate 0.1 mg orally every day twice daily for refractory hyperkalemia
Hyperglycemia		
Diabetes pretransplant	Insulin Oral hypoglycemics	Glucocorticoids, TAC, and CSA also increase hypoglycemic requirements; insulin requirements will increase with improving renal function
	Metformin	Avoid in those with RI
Posttransplant diabetes	Insulin	Risk factors: obesity, family history, African-American race, cadaveric kidney, TAC greater than CSA
	Oral hypoglycemics	May resolve/improve as immunosuppressive doses decrease
Ulcer prophylaxis	H_2-receptor antagonists Sucralfate Proton pump inhibitors	Adjust dose in those with RI; decreased TAC absorption; if RI, caution aluminum content; no RI, caution hypophosphatemia
Hyperlipidemia	Diet	CSA greater than TAC; consider switch to TAC; discontinue or hold SRL
	HMG-CoA reductase inhibitors (statins)	CSA/TAC may increase statin levels; start at lowest dose Monitor for muscle cramps, CPK levels and LFTs
	Gemfibrozil	Adjust dose in those with RI Caution with concomitant statin
	Ezetemibe	Often used in combination with a statin
Hypertension	Calcium channel blockers	Diltiazem, verapamil inhibit CSA/TAC metabolism Dihydropyridines may potentiate CSA-gingival hyperplasia
	ACE inhibitors; ARBs	May exacerbate hyperkalemia; monitor K^+, SCr to assess for renal allograft vascular disease; may be useful in posttranplant erythrocytosis (hematocrit greater than 55%)
Osteoporosis	Oral calcium supplementation (1000–5000 mg/day)	If daily intake less than 1000 mg elemental calcium
	Oral vitamin D Calcifediol (1000 IU/day) Calcitriol (0.5 mcg/day)	Documented deficiency If kidney functioning If kidney not functioning
	Hormone-replacement therapy	Post-menopausal women without contraindications
	Calcitonin or oral bisphosphonates	Documented loss in bone mineral density greater than 3% Data lacking for bisphosphonates in patients with RI
Malignancy		
Prevention	Minimize immunosuppressant doses; avoid sun exposure (sunblock, hats, clothing); routine self-exams (skin, lymph nodes); yearly gynecologic/prostate exams	AZA particularly associated with skin cancers CSA/TAC may be associated with lymphoproliferative disorders (lymphomas)
Treatment	Discontinue or minimize immunosuppressants Surgical, radiologic, or antineoplastic therapy	Do not abruptly withdraw corticosteroids

ACE-I, angiotensin-converting enzyme inhibitors; ARB, angiotensin-receptor blockers; AZA, azathioprine; CMV, cytomegalovirus; CPK, creatinine phosphokinase; CSA, cyclosporine; HMG-CoA, 3-hydroxy 3-methylglutaryl coenzyme A reductase; K^+, potassium; LFTs, liver function tests; RI, renal insufficiency; SCr, serum creatinine; SRL, sirolimus; TAC, tacrolimus; TMP-SMX, trimethoprim-sulfamethoxazole.

Adapted from DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005, Table 87–10, p. 1637.

reduced glomerular filtration rate (GFR) and renal blood flow (RBF), increased systemic and intra-renal vascular resistance, sodium retention, reduced concentrations of systemic vasodilators (e.g., prostacyclin and nitric oxide), and increased concentrations of vasoconstrictive thromboxanes.[60]

Although tacrolimus therapy is associated with increasing blood pressure, studies have found that tacrolimus has less dramatic effects on GFR and RBF than cyclosporine. In some clinical trials, tacrolimus caused less severe HTN and required significantly fewer antihypertensive medications at both 24 and 60 months after transplantation than cyclosporine.[61–63] Thus conversion from cyclosporine-based immunosuppression to tacrolimus-based immunosuppression may be one way to minimize blood pressure increases in transplant recipients. Conversion to sirolimus also may be an alternative to the calcineurin inhibitors in patients with difficult-to-treat HTN because sirolimus therapy is less associated with increased blood pressure. Additionally, withdrawal or tapering of steroid therapy may be an effective strategy for lowering blood pressure.

Treatment

❾ *Controlling HTN after transplantation is essential in preventing cardiac morbidity and mortality and prolonging graft survival.* The target blood pressure in kidney transplant recipients should be less than 130/80 mm Hg. This goal blood pressure may not be suitable for all organ transplant recipients. In such cases, the guidelines detailed in the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC-VII) should be followed.

Nonpharmacologic Therapy: Lifestyle Modifications

In order to achieve a goal blood pressure, lifestyle modifications, including diet, exercise, sodium restriction, and smoking cessation, are recommended.[63] Unfortunately, lifestyle modifications alone often are inadequate to control HTN in this high-risk population, and antihypertensive medications usually are needed.

Antihypertensive Agents

There is no single class of antihypertensive medications recognized as the ideal agent. Numerous factors must be considered when determining appropriate treatment for a given patient, including the safety and efficacy data of the available agents, patient-specific situations, and potential comorbidities and medication cost. A large majority of patients often require multiple medications to achieve their goal blood pressure. This conclusion is supported by the recommendations of JNC-VII, where combination therapy is regarded as an appropriate first-line therapy.

β-Blockers and thiazide diuretics have proven benefits in reducing cardiovascular disease–associated morbidity and mortality.[55] Tolerability permitting, these agents are to be considered first-line therapies in most transplant recipients. The ACE inhibitors and angiotensin-receptor blockers (ARB) have definite benefits in patients with nephropathy and are believed to have renoprotective effects in most patients. Due to their ability to cause an initial bump in serum creatinine, these agents should be used cautiously when employed in combination with the calcineurin inhibitors. The dihydropyridine calcium channel blockers have demonstrated an ability to reverse the nephrotoxicity associated with cyclosporine and tacrolimus (Table 52–8). In general, antihypertensive therapy should focus on agents with proven benefit in reducing the progression of cardiovascular disease and should be chosen on a patient-specific basis.[55] See Chapter 2 for further recommendations for treating HTN.

Hyperlipidemia

❾ *Hyperlipidemia is seen in up to 60% of heart, lung, and renal transplant patients and greater than 30% of liver transplant patients.*[64–66] As a result of elevated cholesterol levels, transplant recipients are not only at an increased risk of atherosclerotic events, but emerging evidence also shows an association between hyperlipidemia and allograft vasculopathy.[66] Hyperlipidemia, along with other types of cardiovascular disease, is now one of the primary causes of morbidity and mortality in long-term transplant survivors.[67]

Elevated cholesterol levels in transplant patients are due to a culmination of factors such as age, genetic disposition, renal dysfunction, DM, proteinuria, body weight, and immunosuppressive therapy. Many of the immunosuppressive agents can produce elevations in serum lipid levels.

Treatment

❾ *Lowering cholesterol has been shown to decrease severe rejection and transplant vasculopathy significantly and to improve 1-year survival in heart transplant recipients.*[68] Although these results cannot be extrapolated to other transplant populations, they do demonstrate the potential benefits of aggressive cholesterol-lowering in organ transplant recipients. Due to the high prevalence of cardiovascular disease among organ transplant recipients, most health care practitioners consider these patients to fall in the highest-risk category for lipid-lowering as established by the National Cholesterol Education Panel (NCEP) III guidelines. These guidelines recommend a low-density lipoprotein cholesterol (LDL-C) level of less than 100 mg/dL (2.6 mmol/L).[69]

Nonpharmacologic Therapy: Lifestyle Modifications

Generally, lowering cholesterol in patients begins with therapeutic lifestyle changes. These changes are initiated either alone or in conjunction with lipid-lowering drug therapy depending on baseline cholesterol levels and other risk factors. Therapeutic lifestyle changes entail a reduction in saturated fat and cholesterol intake and an increase in moderate physical activity.[69] As with hypertension, lifestyle modifications alone

rarely are effective enough to achieve a goal LDL-C level.[66] Modifications of the immunosuppressive regimen and use of cholesterol-lowering medications often are warranted in this patient population.

Immunosuppressive Regimen Modifications

Tacrolimus has shown the propensity to cause less severe hyperlipidemia when compared with cyclosporine. Thus conversion from cyclosporine-based immunosuppression to tacrolimus-based immunosuppression may be one way to counteract this disease in transplant recipients.[66] Studies demonstrate that steroid withdrawal in renal transplant patients lowered total cholesterol by 17% and LDL-C by 16%; unfortunately, an 18% decrease in high-density lipoprotein (HDL) levels also was noted in these patients.[66]

Cholesterol-Lowering Agents

Statins, 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, are considered to be first-line therapy for reducing LDL-C in the general population.[66,70–73] However, there is some uncertainty about the pathogenesis of cardiovascular disease in transplant recipients and whether statin therapy will have similar effectiveness in organ transplant recipients. Statins have shown definite advantages when used in heart transplantation, including a reduction in LDL-C and major adverse cardiac events (MACE), as well as an apparent cardioprotective effect. In renal transplant recipients, statins are known to lower LDL-C levels and reduce the incidence of some cardiac events; however, the ability to lower MACE may not be evident in this patient population. Despite these mixed results, statins still are considered the primary therapeutic option for hyperlipidemia in all organ transplant recipients.[66] It is important to note that statins used in combination with calcineurin inhibitors have resulted in an increased risk for muscle weakness and rhabdomyolysis. Thus close monitoring is necessary in transplant patients who are taking a calcineurin inhibitor and a statin. Monitoring should include periodic assessment of liver enzymes and creatine kinase [CK, or creatine phosphokinase (CPK)] levels, as well as assessment for muscle weakness (Table 52–8).

Fibric acid derivatives are an excellent choice for lowering triglycerides but are not as effective as statins at lowering LDL-C.[66] These agents, in conjunction with statins, play a role in treating patients with both elevated LDL-C and triglycerides. Nicotinic acid is very effective at improving the lipid panel, with excellent results in lowering LDL-C, as well as increasing HDL. However, patient tolerability issues are of concern with this agent. Bile acid sequestrants should be avoided in organ transplant recipients due to their high incidence of GI adverse events, as well as their propensity for pharmacokinetic DDIs with immunosuppressants. Although some clinical trials demonstrated that cyclosporine increased ezetimibe serum concentrations, ezetimibe appears to be an effective cholesterol-lowering agent, especially when combined with a statin. Future studies are needed to establish ideal regimens involving the antihyperlipidemic and immunosuppressive medications in order to decrease morbidity and mortality and, ultimately, prevent cardiovascular events.[66] See Chapter 9 for further guidance in treating hyperlipidemia.

New-Onset Diabetes Mellitus after Transplantation

❾ *New-onset DM after transplantation (NODAT) is a serious complication that often is underestimated by transplant practitioners.*[74] Kasiske and colleagues attempted to quantify the cumulative incidence of NODAT in renal transplant recipients and found that 8% of patients developed NODAT at 3 months after transplantation, 13% at 12 months, and

Patient Encounter, Part 4

JJ has recovered from her transplant procedure and now is doing relatively well. She returns to your clinic 1 month after the transplant.

Labs

Na: 141 mEq/L (141 mmol/L)
K: 4.9 mEq/L (4.9 mmol/L)
Cl: 100 mEq/L (100 mmol/L)
CO_2: 22 mEq/L (22 mmol/L)
BUN: 22 mg/dL (7.9 mmol/L)
SCr: 1.2 mg/dL (106.1 μmol/L)
Glucose: 89 mg/dL (4.9 mmol/L)
Lipid panel: TC = 271 mg/dL (7.0 mmol/L);
LDL-C = 180 mg/dL (4.7 mmol/L)
HDL = 30 mg/dL (0.8 mmol/L); TG = 325 mg/dL (3.7 mmol/L)

VS: BP = 154/95 mm Hg (152/88 mm Hg repeated);
HR = 60 beats/minute

Meds

Tacrolimus 3 mg by mouth twice a day
Mycophenolate mofetil 1000 mg by mouth twice a day
Prednisone 10 mg by mouth once a day
Bactrim SS 1 tablet daily
Nystatin 5 mL swish and swallow four times daily
Valganciclovir 450 mg by mouth once a day
Vitamin D 800 IU by mouth once a day
Calcium carbonate 1250 mg by mouth twice a day separated from food and mycophenolate
Simvastatin 20 mg by mouth once a day at bedtime
Metoprolol 100 mg by mouth twice a day
Amlodipine 10 mg by mouth once a day
Aspirin 81 mg by mouth once a day

- Identify why JJ is taking each medication listed.
- What are some treatment options, in addition to metoprolol 100 mg twice daily and amlodipine 10 mg daily, for JJ's elevated blood pressure?
- Design a monitoring plan for JJ's therapy.

22% at 36 months.[74] Even more alarming is that recent studies have revealed an overwhelming prevalence of impaired glucose tolerance, which is also accepted as a risk factor for long-term morbidity and mortality.[74] New-onset DM is associated with increases in cardiovascular events and an approximately 22% higher risk of mortality. Patients with NODAT are also more likely to suffer acute rejection episodes and infectious complications than patients without NODAT.[74,75]

Prevention

New-onset DM prevention consists mainly of identifying patients at risk before transplantation and controlling modifiable risk factors both before and after transplantation.[74] The major modifiable risk factors are choice of immunosuppressive therapy and body mass index (BMI). For example,

- *Immunosuppressive medications.* Steroid minimization and possibly withdrawal are effective strategies for the prevention of NODAT. Also, patients with worsening blood glucose levels after transplantation who are receiving tacrolimus may benefit from conversion to cyclosporine.[74]
- *BMI.* A reduction in body weight is always recommended in obese patients prior to the transplant procedure to help lower their NODAT risk.[74]

Treatment

Lifestyle modifications are always in order in patients who have developed or those who are at increased risk of developing NODAT.[74] Insulin therapy and oral hypoglycemic agents are used often (Table 52–8) in patients in whom lifestyle modifications alone have not controlled blood glucose levels. See Chapter 40 for appropriate treatment regimens for diabetes.

Neoplasia

Skin Cancer

Skin cancer remains the most common malignancy after organ transplantation. Skin cancers occur at rates from 3.4-fold (melanoma) up to 84-fold (Kaposi's sarcoma) higher in organ transplant recipients when compared with the general population.[77] A number of studies have shown that transplant recipients are at higher risk of cancer as a result of taking immunosuppressants after organ transplantation. The incidence of these types of cancers increases with time after transplantation, with one study showing a prevalence rate of 35% among patients within 10 years of transplant.[78] More alarming than the high prevalence is the activity of these cancers in the patient on maintenance immunosuppression. Skin cancers in transplant recipients tend to grow more rapidly and are more likely to metastasize.[77]

The most common risk factors for skin cancer development after transplantation include increased age, excessive ultraviolet (UV) light exposure, high degree of immunosuppression, Fitzpatrick skin types I, II and III, history of skin cancers, and infection by human papillomavirus.[77]

It is of the utmost importance that transplant practitioners be vigilant about educating their patients about excessive exposure to the sun.[77] Patients should be warned about the risk of skin cancer and be advised on simple methods to limit their risk:

- Use of protective clothing (e.g., long-sleeve shirts and long pants and dark-colored clothing).
- Use of sunscreen daily that is applied to all sun-exposed skin.
- Use of sunscreen with sun protection factor (SPF) 30 or higher is recommended.

Posttransplant Lymphoproliferative Disorders

❾ *Posttransplant lymphoproliferative disorders (PTLDs) are a major complication in patients following organ transplantation.*[79] The incidence of PTLD is 1% for renal patients, 2% for cardiac patients, 2% for liver patients, and 9% for heart-lung patients. The risk of developing non-Hodgkin's lymphoma is 28- to 49-fold higher in solid-organ transplant recipients than in the general population. Another independent risk factor is the presence of Epstein-Barr virus (EBV).[79–81] Lymphomas are the most common form of lymphoproliferative disease found in transplant recipients.[79]

The incidence of disease depends on certain factors. These factors include the type of organ transplanted, the age of the transplant recipient, the degree of immunosuppression, the type of immunosuppression, and exposure to EBV.[79,81] The mortality rate in these patients is about 50%, with most patients dying shortly after diagnosis. It also has been demonstrated that the risk of developing PTLD is greater in the population of patients who are EBV-seronegative at the time of transplant.[81]

Another risk factor for the development of PTLD is the type of immunosuppressive regimens used. Immunosuppressive regimens using ALAs have been proven to increase the risk of PTLD.[79]

Treatment

Treatment for PTLD is still controversial; however, the most common treatment options include reduction of immunosuppression, chemotherapy,[11,82] and anti-B cell monoclonal antibodies.[79]

PTLDs continue to be a long-term complication of prolonged immunosuppression. Current treatment options are all associated with certain risks. Prevention is the most effective treatment for PTLD. A better understanding in the future of the disease process and the risk factors involved with the development of PTLD will aid in the prophylaxis and treatment of this disorder.

OUTCOME EVALUATION

- Successful outcomes in solid-organ transplantation generally are measured in terms of several separate end points: (1) preventing acute rejection; (2) increasing 1-year graft survival; (3) preventing immunosuppressive drug complications; and (4) improving long-term allograft and patient survival.

- The short-term goals after organ transplantation revolve around reducing the incidence of acute rejection episodes and attaining a high graft survival rate. By accomplishing these goals, transplant clinicians hope to attain good allograft function to allow for an improved quality of life. These goals can be achieved through the appropriate use of medical immunosuppression and assessing the therapeutic and toxic monitoring parameters associated with each medication employed.
- Monitor transplant recipients for adverse drug reactions, drug-drug interactions, and compliance with their therapeutic regimen.
- The long-term goals after organ transplantation are to maximize the functionality of the allograft and to prevent complications of immunosuppression, which lead to improved patient survival.
- Clinicians must follow patient responses to immunosuppressant therapy, including identifying and treating the adverse sequelae associated with lifelong immunosuppression, such as cardiovascular disease, malignancy, infection, and osteoporosis, among others.
- Emphasize the importance of limiting drug misadventures and ensuring medication compliance with the therapeutic regimen to maximize desired outcomes and minimize adverse events.

Patient Care and Monitoring

The early management of transplant recipients:

1. Review any available diagnostic and laboratory data to evaluate the function of the allograft and the health of the recipient.
2. Assess the patient's current medication regimen, including

   Induction therapy agent:
   - Assess for appropriate dose and duration of therapy.
   - Therapeutic monitoring parameters (organ function)
   - Adverse-events monitoring parameters (Table 52–3)

   Maintenance immunosuppressive agents:
   - Assess for appropriate dose and duration of therapy.
   - Therapeutic monitoring parameters (organ function)
   - Adverse-events monitoring parameters (Tables 52–3 to 52–5)

   Anti-infective prophylaxis:
   - Assess suitability of chosen prophylactic agents (e.g., drug allergies, CMV donor, and recipient serostatus).
   - Therapeutic monitoring parameters (e.g., does the patient have any signs and/or symptoms of the infectious disease?)
   - Adverse-events monitoring parameters (Table 52–7)

   Medications used for comorbidities:
   - Assess appropriate selection of these medications for pharmacokinetic and pharmacodynamic DDIs (Table 52–6), need (e.g., do renal transplant recipients need to continue to take erythropoietin?), and efficacy.
   - Therapeutic monitoring parameters
   - Adverse-events monitoring parameters (Tables 52–7 and 52–8)
3. Evaluate the patient for the presence of adverse drug reactions, drug allergies, or DDIs.
4. Develop patient-specific short- and long-term therapeutic goals.
5. Provide patient education in regard to the organ transplant, the complications associated with transplantation, the need for lifestyle modifications to reduce the risk of the complications (e.g., wear sunscreen, low-sodium diet), and drug therapy.
6. Stress the importance of adherence with their therapeutic regimen.

The outpatient management of transplant recipients:

1. Obtain a thorough history of prescription, non-prescription, and complementary and alternative medication use.

   Maintenance immunosuppressive agents:
   - Assess for appropriate dose and duration of therapy.
   - Therapeutic monitoring parameters (organ function)
   - Adverse-events monitoring parameters (Tables 52–3 to 52–5)

   Anti-infective prophylaxis:
   - Assess suitability of chosen prophylactic agents (e.g., drug allergies, CMV donor, and recipient serostatus).
     - Does the patient need continued prophylaxis therapy?
     - When do you stop prophylaxis?
   - Therapeutic monitoring parameters (e.g., does the patient have any signs and/or symptoms of the infectious disease?)
   - Adverse-event monitoring parameters (Tables 52–7 and 52–8)

   Medications used for comorbidities:
   - Assess appropriate selection of these medications for pharmacokinetic and pharmacodynamic DDIs (Table 52–6), need, and efficacy.
   - Therapeutic monitoring parameters (drug- and disease-specific)
   - Adverse-events monitoring parameters (drug-specific) (Tables 52–7 and 52–8)
2. Evaluate the patient for the presence of adverse drug reactions, drug allergies, or DDIs.
3. Reassess your patient-specific short- and long-term therapeutic goals.
4. Continue with patient education in regard to the complications associated with transplantation, the need for lifestyle modifications to reduce the risk of complications (e.g., wear sunscreen, low-sodium diet), and drug therapy.
5. Emphasize the importance of adherence with the therapeutic regimen.
6. Assess patients' quality-of-life measures such as physical, psychological, and social functioning and well-being.

ABBREVIATIONS

ACE: angiotensin-converting enzyme
ACE-I: angiotensin-converting enzyme inhibitor
ALA: antilymphocyte antibodies (includes OKT-3, ATG, and antithymocyte globulin)
ANF: atrial natriuretic factor
APC: antigen-presenting cell
ARB: angiotensin-receptor blocker
ATG: lymphocyte immune globulin, antithymoglobulin equine
AWP: average wholesale price
AZA: azathioprine
BMI: body mass index
BUN: blood urea nitrogen
C_0: trough concentration
C_2: drug concentration 2 hours postdose
CCB: calcium channel blocker
CD4+: helper T cells
CD8+: cytotoxic T cells
CI: calcineurin inhibitor
CK: creatine kinase
CKD: chronic kidney disease
CMV: cytomegalovirus
CNS: central nervous system
CPK: creatine phosphokinase
CSA: cyclosporine
CXR: chest x-ray
CYP: cytochrome P-450 system
CYP3A: cytochrome P-450 system 3A isozyme
DC: dendritic cell
DDI: drug-drug interaction
DM: diabetes mellitus
DOE: dyspnea on exertion
DS: double strength
EBV: Epstein-Barr virus
ESRD: end-stage renal disease
FBS: fasting blood sugar
FDA: Food and Drug Administration
FEV: forced expiratory volume
GFR: glomerular filtration rate
GI: gastrointestinal
G6PD: glucose-6-phosphate dehydrogenase
HDL: high-density lipoprotein
HLA: human leukocyte antigen
HMG-CoA: 3-hydroxy-3-methylglutaryl coenzyme A reductase
HTN: hypertension
IgG: immunoglobulin G
IL-2: interleukin-2
IL-2RA: interleukin-2 receptor antagonist
IV: intravenous
IVIG: intravenous immunoglobulin
JNC-VII: Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure
K: potassium
LDL-C: low-density lipoprotein cholesterol
LFT: liver function test
MACE: major adverse cardiovascular events
MHC: major histocompatibility complex
MMF: mycophenolate mofetil
6-MP: 6-mercaptopurine
MPA: mycophenolic acid
NCEP: National Cholesterol Education Panel
NFAT-P: nuclear factor
NODAT: new-onset DM after transplant
NSAIDs: non-steroidal anti-inflammatory drugs
NYHA: New York Heart Association
OKT-3: muronomonab-CD3
PCKD: polycystic kidney disease
P-gp: P-glycoprotein
PRED: prednisone
PTLD: posttransplant lymphoproliferation disorder
RATG: rabbit antithymocyte immunoglobulin
RBF: renal blood flow
RI: renal insufficiency
SCr: serum creatinine
SOB: shortness of breath
SPF: sun protective factor
SPK: simultaneous pancreas-kidney
SRL: sirolimus
SS: single strength
TAC: tacrolimus
TC: total cholesterol
TCR: T-cell receptor
TG: triglycerides
TMP-SMX: trimethoprim-sulfamethoxazole
ToR: target of rapamycin
UV: ultraviolet
WBC: white blood cell

53 Osteoporosis

Beth Bryles Phillips

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Explain the association between osteoporosis and morbidity and mortality.
2. Identify risk factors that predispose patients to osteoporosis.
3. Describe the pathogenesis of fractures.
4. List the criteria for the diagnosis of osteoporosis.
5. Recommend appropriate lifestyle modifications to prevent bone loss.
6. Compare and contrast the effect of available treatment options on reduction of fracture risk.
7. Recommend an appropriate treatment regimen for a patient with osteoporosis, and develop a monitoring plan for the selected regimen.
8. Educate patients on osteoporosis and drug treatment, including appropriate use, administration, and adverse effects.

Key Concepts

❶ The most important risk factors for fracture are low bone mineral density and a personal history of adult fracture.

❷ A standardized approach for diagnosing osteoporosis is recommended using central dual-energy x-ray absorptiometry (DXA) measurements.

❸ Both pharmacologic and nonpharmacologic therapies for osteoporosis are aimed at preventing fractures and their complications, maintaining or increasing bone mineral density, preventing secondary causes of bone loss, and improving morbidity and mortality.

❹ All postmenopausal women with a personal history of osteoporotic fracture and/or low bone mineral density with risk factors for osteoporosis should receive treatment for osteoporosis.

❺ Adequate calcium and vitamin D intake is essential in the prevention and treatment of osteoporosis. Calcium and vitamin D supplements to meet requirements should be added to all drug therapy regimens for osteoporosis.

❻ Bisphosphonates are first-line therapy for postmenopausal osteoporosis owing to their established efficacy in preventing hip and vertebral fractures.

❼ Alendronate should be considered first-line treatment for primary osteoporosis in men owing to its proven benefit in reducing fractures and relative safety.

❽ For glucocorticoid-induced osteoporosis, bisphosphonate therapy is recommended in all patients who are starting treatment with glucocorticoids (prednisone greater than or equal to 5 mg/day or equivalent) for at least 3 months. For patients receiving chronic glucocorticoids (prednisone greater than or equal to 5 mg/day or equivalent), bisphosphonate therapy is also recommended if the bone mineral density is low or there is a history of fracture.

Osteoporosis is a common and often silent disorder associated with significant morbidity and mortality and reduced quality of life. It is associated with increased risk and rates of bone fracture and is responsible for over 1.5 million fractures in the United States annually, resulting in direct health care costs of over $17 billion.[1] As the population ages, these numbers are expected to increase. It is estimated that postmenopausal Caucasian women have a 50% lifetime chance of developing an osteoporosis-related fracture.[1] Common sites of fracture include the spine, hip, and wrist, although almost all sites can be affected. Only a fraction of patients with osteoporosis receive optimal treatment.

Osteoporosis is a disabling disorder with enormous impact. In addition to the initial pain associated with a new fracture, several adverse long-term complications can occur, including chronic pain, loss of mobility, depression, nursing home placement, and death. Patients with vertebral fractures may experience chronic pain, height loss, **kyphosis,** and decreased mobility

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

owing to limitations in bending and reaching. Multiple vertebral fractures may lead to restrictive lung disease and alter abdominal anatomy. Patients with hip fractures have added risks associated with surgical intervention to repair the fracture. Some patients never recover fully or regain preinjury independence; mortality is common within 1 year of hip fracture.

EPIDEMIOLOGY AND ETIOLOGY

Osteoporosis is the most common skeletal disorder, and approximately one in five Caucasian women in the United States has the disease. The prevalence of vertebral fracture in postmenopausal women is greater than 20%.[2] Only one in three patients with osteoporosis has been diagnosed, and only one in seven will receive treatment.[2]

Osteoporosis can be classified as either primary (no known cause) or secondary (caused by drugs or other diseases). Primary osteoporosis is found most often in postmenopausal women and aging men, but it can occur in other age groups as well.

The prevalence of osteoporosis varies by age, gender, and race/ethnicity. The risk of fracture increases exponentially with each decade in age over 50.[3] Residents of nursing homes may be at an even higher risk of fracture. Both men and women lose bone as they age. However, women have accelerated bone loss surrounding menopause owing to loss of estrogen. Men have some protection from osteoporosis owing to their large bone mass and size and the absence of menopause. Fragility fractures of the hip and spine are common among men, especially as age increases. Men comprise 20% of the Americans with osteoporosis. Secondary causes of osteoporosis are found more commonly in men with fragility fractures.

Most hip fractures occur in postmenopausal Caucasian women; they also have the highest incidence of fracture when adjusted for age.[4] The incidence of osteoporosis and low bone mass is highest in Caucasian women, followed by Asian, Hispanic, and African-American women, respectively.[4]

TABLE 53–1. Risk Factors for Osteoporosis

White or Asian ethnicity
Positive family history of osteoporosis
Female sex
Advanced age
Small body frame (less than 58 kg or 128 lbs)
Smoking
Inactivity or excessive exercise
Excessive alcohol use
Poor nutrition
Low calcium intake
Low 25-hydroxyvitamin D levels
Hormonal deficiencies (e.g., hypogonadal state)
Inflammatory disorders
Organ transplantation
Medical disorders (e.g., chronic renal disease, anorexia nervosa, endocrine disorders)
Drugs (e.g., glucocorticoids, anticonvulsants, aromatase inhibitors)

Many of the risk factors for osteoporosis and osteoporotic fractures are predictors of low bone mineral density, such as age and ethnicity (Table 53–1). ❶*The most important risk factors for fracture are low bone mineral density, personal history of adult fracture, age, and family history of osteoporotic fracture.* Other important risk factors for osteoporosis and osteoporotic fractures include menopausal status, smoking status, and low body weight. As bone mineral density decreases, the risk of fracture increases. However, the threshold at which individual patients develop a fracture varies, and other factors may play a role in fracture susceptibility. One such factor that can influence the development of fracture is falling.

Osteoporosis also can develop from secondary causes such as concurrent disease states and drugs (Table 53–2).

TABLE 53–2. Medical Conditions and Drugs Associated with Osteoporosis or Low Bone Mass

Medical Conditions	Drugs
Alcoholism	Anticonvulsants (phenytoin, phenobarbital)
Chronic renal disease	Aromatase inhibitors (anastrazole, exemestane, letrozole)
Cushing's syndrome	Cytotoxic drugs (e.g., methotrexate, cisplatin)
Cystic fibrosis	Glucocorticoids
Diabetes mellitus	Gonadotropin-releasing hormone analogs (e.g., leuprolide acetate, nafarelin, gosarelin)
Eating disorders	Heparin
Gastrointestinal disorders (e.g., gastrectomy, malabsorption syndromes)	Immunosuppressants (e.g., tacrolimus)
Hematologic disorders (e.g., hemophilia)	Lithium
Hyperparathyroidism	Medroxyprogesterone acetate
Hyperthyroidism	Thyroid supplements (due to overreplacement)
Hypogonadal states	Total parenteral nutrition
Organ transplantation	
Skeletal cancer (e.g., myeloma)	

Patient Encounter, Part 1: Patient History

A 74-year-old woman with a history of chronic obstructive pulmonary disease (COPD) and gastroesophageal reflux disease (GERD) presents to the clinic for follow-up. She reports intermittent daytime and nighttime sweating that comes on suddenly. She reports soaking her bed sheets when this occurs. She had a hysterectomy at age 20 and has never taken estrogen replacement. She reports good relief of reflux symptoms on her current regimen. She started taking a calcium supplement approximately 2 years ago on the suggestion of her friend because she has never gotten much calcium in her diet. She states that she does not like milk and never drank it even as a child. She occasionally eats some dairy products such as cheese and ice cream approximately once per week.

PMH
- COPD
- GERD
- S/P total abdominal hysterectomy and bilateral salpingoophorectomy at age 20
- Chronic smoking

FH
Father died at age 85 with Alzheimer's dementia; mother died at age 86 with history of colon cancer and osteoporotic fractures of the hip and spine; brother alive and well at age 71.

SH
Retired elementary school teacher; smokes 1 pack per day for the last 50 years; does not drink alcohol.

Meds
- Albuterol inhaler 2 puffs four times daily
- Ipratropium inhaler 2 puffs four times daily
- Omeprazole 20 mg daily
- Calcium carbonate 500 mg daily
- Multivitamin daily

- Do any symptoms suggest the presence of osteoporosis?
- What risk factors for osteoporosis does this patient have?
- What are her calcium and vitamin D requirements?
- How could she incorporate more calcium into her diet?

Approximately one-third to one-half of osteoporosis cases in men and half of all cases in perimenopausal women are due to secondary causes.[4] Common secondary causes in men include hypogonadism, glucocorticoid use, and alcoholism. The most common cause of drug-induced osteoporosis is glucocorticoid use.

PATHOPHYSIOLOGY

The human skeleton consists of both cortical and trabecular bone. Cortical bone is dense and compact and is responsible for much of bone strength. It is the most common type of bone and accounts for approximately 80% of the skeleton. It is generally found on the surfaces of long and flat bones. Trabecular or cancellous bone has a spongelike appearance and generally is found along the inner surfaces of long bones and throughout the vertebrae, pelvis, and ribs.

Under normal circumstances, the skeleton undergoes a dynamic process of **bone remodeling.** Bone tissue responds to stress and injury through continuous replacement and repair. This process is completed by the basic multicellular unit, which includes both **osteoblasts** and **osteoclasts.** Osteoclasts are involved with **resorption** or breakdown of bone and continuously create microscopic cavities in bone tissue. Osteoblasts are involved in bone formation and continuously mineralize new bone in the cavities created by osteoclasts. Until peak bone mass is achieved between the ages of 25 and 35, bone formation exceeds bone resorption for an overall increase in bone mass. Trabecular bone is more susceptible to bone remodeling in part owing to its larger surface area.

In osteoporosis, an imbalance in bone remodeling occurs. Most commonly, osteoclastic activity is enhanced, resulting in overall bone loss. However, a reduction in osteoblastic activity and reduced bone formation also can occur in certain types of osteoporosis. Bone remodeling accelerates during menopause, and up to 15% of bone is lost during the first 5 years after menopause. After this initial decline, bone loss continues to occur but at a much slower rate of up to 1% per year. The resulting bone loss and change in bone quality predispose patients to low-impact or **fragility fractures.**

CLINICAL PRESENTATION AND DIAGNOSIS

Presentation of Osteoporosis

General
Many patients with osteoporosis are asymptomatic unless they experience a fragility fracture.

Symptoms
Symptoms of fragility fracture include pain at the site of the fracture and immobility.

Signs
- Height loss (greater than 2 cm or 0.78 inches)
- Spinal kyphosis ("dowager's hump")
- Fragility fracture, especially of the hip or spine

Laboratory Tests
Only useful to rule out secondary causes of osteoporosis

Diagnostic Tests
Bone densitometry using dual-energy x-ray absorptiometry (DXA) reveals a *T*-score at least –2.5 SD below the mean.

Diagnosis

Osteoporosis has been defined by the World Health Organization (WHO) as a disease characterized by low bone density and weakening of bone tissue associated with an increase in fragility and vulnerability to fracture.[5] Because bone strength cannot be measured directly, an assessment of bone mineral density is used, which represents 70% of bone strength. Low bone mineral density has been associated with an increased risk of fractures. X-rays are useful only in identifying patients suspected of sustaining a fracture and are not recommended for the diagnosis of osteoporosis.

Measurement of Bone Mineral Density

Bone mineral density can be measured at various sites throughout the skeletal system and by various methods. The site of measurement can be either central (hip and/or spine) or peripheral (heel, forearm, or hand). Dual-energy x-ray absorptiometry (DXA) can be used to measure central and peripheral sites of bone mineral density. Quantitative ultrasound, peripheral quantitative computed tomography, radiographic absorptiometry, and single-energy x-ray absorptiometry are used to measure peripheral sites.

❷ *The WHO recommends a standardized approach to measuring bone mineral density for the diagnosis of osteoporosis using central measurement of bone mineral density by DXA.*[4] Central DXA is recommended for diagnosis owing to inconsistencies in *T*-scores measured between different sites and by different methods.[2] Current standards of practice consist of measuring bone mineral density at the lumbar spine and hip, although the WHO suggests that the hip is the preferred site for diagnosis.[3,5]

Peripheral bone mineral density measurements cannot be used for diagnosis because they do not correlate with central measurements. However, they are useful in identifying patients who are candidates for central DXA and who are at increased risk of fracture.[5] It also may be useful in patients who have had multiple fractures or in low-risk patients. Additionally, peripheral measurement of bone mineral density generally is less expensive than central DXA and is easily accessible. Instruments used for peripheral bone densitometry are portable, which allows bone density to be measured in pharmacies and health-fair screening booths.

Once the bone mineral density report is available, *T*-scores and *Z*-scores are useful tools in interpreting the data. The *T*-score is the number of standard deviations from the mean bone mineral density in healthy young white women. Osteoporosis is defined as a *T*-score at least –2.5 standard deviations below the mean (Table 53–3). **Osteopenia,** or low bone mass that eventually may lead to osteoporosis, is defined as a *T*-score between –2.5 and –1.0 standard deviations below the mean. The International Society for Clinical Densitometry recommends use of the WHO definition and *T*-scores for diagnosis of osteoporosis in postmenopausal women and men over age 65 and in men between the ages of 50 and 65 if other risk factors are present.[6]

TABLE 53–3. World Health Organization Definition of Osteoporosis

Skeletal Disorder	*T*-Score[a]
Normal	less than or equal to 1.0
Osteopenia	greater than 1.0 to less than or equal to 2.5
Osteoporosis	greater than 2.5

[a]*T*-score is the number of standard deviations below the mean bone mineral density in young adults.

The *Z*-score is a similar measure that is corrected for age and sex of the patient. The *Z*-score is defined as the number of standard deviations from the mean bone mineral density of age- and sex-matched controls. In premenopausal women, men under age 50, and patients who may have secondary causes for low bone mineral density, *Z*-scores may be more clinically relevant in evaluating bone mineral density.

Screening

Screening for low bone density is an effective way to identify individuals at risk for osteoporotic fracture. Much of the data regarding interpretation of bone mineral density were derived from postmenopausal women. As such, interpretation of measurements on individuals outside this group is difficult. The United States Preventive Services Task Force (USPSTF), National Osteoporosis Foundation (NOF), and American Association of Clinical Endocrinologists (AACE) recommend routine bone mineral density screening for all women over age 65.[1,2,7] Outside this group, however, differences exist in recommendations among various guidelines.

In general, osteoporosis screening is not recommended in premenopausal women owing the unclear association between low bone mineral density and fracture risk in this population. The USPSTF recommends that all women over age 65 and women between the ages of 60 and 65 with multiple risk factors be screened routinely.[7] The NOF and AACE recommend screening for postmenopausal women with multiple risk factors.[1,2] Additionally, the AACE recommends screening in women receiving long-term corticosteroids, women with secondary causes of osteoporosis that would benefit from treatment, and women over age 40 who have sustained a fracture.[2] The International Society for Clinical Densitometry recommends bone mineral density testing in men over age 70 or those with a medical condition or drug therapy associated with low bone mass or a history of fragility fracture.[8]

Laboratory Evaluation

Laboratory assessment has little value in diagnosing osteoporosis, but it can be beneficial in identifying or excluding

secondary causes of bone loss, such as hyperparathyroidism, low 25-hydroxyvitamin D levels, hyperthyroidism, hypogonadism, or cancer.[3] Biochemical markers of bone turnover such as pyridinoline, deoxypyridinoline, and *N*-telopeptides and *C*-telopeptides of type I collagen cross-links have been associated with an increased fracture risk in some trials. Variations in the normal ranges of these tests may be related to age, gender, food, and diurnal variation, making interpretation of these tests difficult.[2] For these reasons, biochemical markers of bone turnover are not recommended for the diagnosis of osteoporosis.

TREATMENT

Desired Outcomes

❸ *Pharmacologic and nonpharmacologic therapies are aimed at the following goals: (1) preventing fractures and their complications, (2) maintaining or increasing bone mineral density, (3) preventing secondary causes of bone loss, and (4) reducing morbidity and mortality associated with osteoporosis.*

Nonpharmacologic Therapy

The primary goal of nonpharmacologic therapy for osteoporosis is to prevent fractures. Strategies include maximizing peak bone mass, reducing bone loss, and using precautions to prevent falls leading to fragility fractures.

Modification of Risk Factors

Some osteoporosis risk factors (see Table 53–1) are nonmodifiable, including family history, age, ethnicity, sex, and concomitant disease states. However, certain risk factors for bone loss may be minimized or prevented by early intervention, including smoking, low calcium intake, poor nutrition, inactivity, heavy alcohol use, and vitamin D deficiency. In order to prevent certain risk factors and maximize peak bone mass, efforts must be directed toward osteoporosis prevention at an early age.

Nutrition

Good nutrition is essential for intake of sufficient nutrients and maintenance of appropriate weight. Dietary calcium intake is important for achieving peak bone mass and maintaining bone density. Adequate dietary intake of vitamin D is essential for calcium absorption. Table 53–4 lists calcium and vitamin D requirements for different age groups. Good dietary sources of calcium include dairy products, fortified juice, cruciferous vegetables (e.g., broccoli and kale), salmon, and sardines (Table 53–5). The most common source of vitamin D comes from exposure to sunlight. Ultraviolet rays from the sun promote the synthesis of vitamin D_3 (cholecalciferol) in the skin. This generally occurs within 15 minutes of sunlight exposure. Vitamin D also may be found in some dietary sources, including fortified milk, egg yolks, saltwater fish, and liver.

Exercise

Exercise can be beneficial in preventing fragility fractures. Weight-bearing exercise such as walking, jogging, dancing, and climbing stairs can help to build and maintain bone strength. Muscle-strengthening or resistance exercises can help to improve and maintain strength, agility, and balance, which can reduce falls.[1] It is important to develop and maintain a lifelong routine of weight-bearing and resistance exercise because the benefits on bone can be lost after cessation of the exercise program.[1]

Falls Prevention

Another crucial step in avoiding fragility fractures is prevention of falls. Patients with frailty, poor vision, or hearing loss and those taking medications affecting balance are at higher risk for falling and subsequent fragility fractures.[1,2]

TABLE 53–4. Recommended Daily Calcium and Vitamin D Intake

	Elemental Calcium (mg)		Vitamin D (IU)
Adolescents/Young Adults		Age less than 50	200
Age 11–24	1200–1500	Age 51–70	400
Men		Age greater than 70	600
Age 25–65	1000	High-risk individuals[a]	800
Age greater than 65	1500		
Women			
Age 25–50	1000		
Age 51–65 (postmenopausal)			
On estrogens	1000		
Not on estrogens	1500		
Age greater than 65	1500		
Pregnant and nursing	1200–1500		

[a]Elderly, chronically ill, housebound, or institutionalized persons.
IU, international units.

TABLE 53–5. Calcium-Rich Foods[a]

1 cup skim milk
1 cup soy milk (calcium-fortified)
1 cup yogurt
1½ ounces cheddar cheese
1½ ounces jack cheese
1½ ounces Swiss cheese
1½ ounces part-skim mozzarella
4 tablespoonfuls grated Parmesan cheese
8 ounces tofu
1 cup greens (collards, kale)
2 cups broccoli
4 ounces almonds
2 cups low-fat cottage cheese
3 ounces sardines with bones
5 ounces canned salmon
1 cup orange juice (calcium-fortified)

[a]Foods containing approximately 300 mg of elemental calcium.

A number of medications have been associated with an increased risk of falling, including drugs affecting mental status such as antipsychotics, benzodiazepines, tricyclic antidepressants, sedative-hypnotics, anticholinergics, and corticosteroids. Some cardiovascular and antihypertensive drugs also can contribute to falls, especially those causing orthostatic hypotension.[9]

Efforts to decrease the risk of falling include balance training, muscle strengthening, removal of hazards in the home, installation of fall-reduction measures such as handrails in the home, and discontinuation of predisposing medications.[1,2,10] Additionally, the use of hip protectors is an effective way to prevent hip fractures, although adherence to this measure is poor, and some patients may not be amenable to wearing them at all.[10]

Patient Encounter, Part 2: Physical Examination and Diagnostic Tests

ROS

(+) hot flashes, 5-cm height loss (about 2 inches) since middle age; (–) back pain

PE

- **General:** Well-developed Caucasian woman in no acute distress
- **VS:** 122/66, P 77, RR 16, T 36.3°C (97.3°F), weight 55.4 kg (122 lbs), height 5 ft, $3^1/_2$ in (162 cm)
- **Chest:** Decreased breath sounds bilaterally; air movement decreased; no rales or rhonchi
- **CV:** RRR, normal S_1, S_2; no murmurs, rubs, or gallops
- **Abd:** Soft, nontender, nondistended; normal bowel sounds, no hepatosplenomegaly
- **Exts:** No clubbing, cyanosis or edema

- What factors support drug treatment of osteoporosis?
- What type of calcium supplement would you recommend for this patient? Why?

Pharmacologic Treatment

Treatment decisions regarding initiation of therapy for osteoporosis can be complex. ❹ *Patients meeting criteria for osteoporosis (T-score below –2.5) or other high-risk patients with a history of osteoporotic fracture gain significant benefit from treatment. Drug therapy should be initiated in these patients.*

In other patients with osteopenia, it is not clear who derives the most benefit from treatment.[10] The criterion defining osteopenia (*T*-score between –1 and –2.5 standard deviations below the mean) is broad, and the threshold for fracture risk is uncertain. Current guidelines support drug therapy in patients with osteopenia and risk factors for osteoporosis because drug therapy was effective in reducing fracture risk in this population in clinical trials. The AACE recommends consideration of drug therapy in postmenopausal women with fragility fractures and low bone mineral density, women who meet the criteria for osteoporosis, women with a *T*-score below –1.5 in the presence of risk factors, and women who continue to experience bone loss or fragility fractures despite nonpharmacologic measures.[2] The NOF recommends treating women with a history of a vertebral or hip fracture, *T*-score below –2.0, or *T*-score below –1.5 in the presence of risk factors.[1]

Calcium and Vitamin D

❺ *Adequate calcium and vitamin D intake are essential for preventing and treating osteoporosis. Calcium and vitamin D supplements to meet requirements should be added to all drug therapy regimens for osteoporosis.* When the calcium supply is insufficient, calcium is taken from bone stores to maintain the serum calcium level. Calcium plays an important role in maximizing peak bone mass and decreasing bone turnover and slowing bone loss. Calcium supplementation also may correct the hyperparathyroidism seen commonly in elderly patients. Vitamin D is crucial for calcium absorption and maintenance of bone.

Calcium and vitamin D supplementation increases bone mineral density, and the combination decreases the risk of hip and vertebral fractures. Additionally, vitamin D supplementation decreases nonvertebral fractures in older men and women living independently.[11] Because of the effects of calcium on

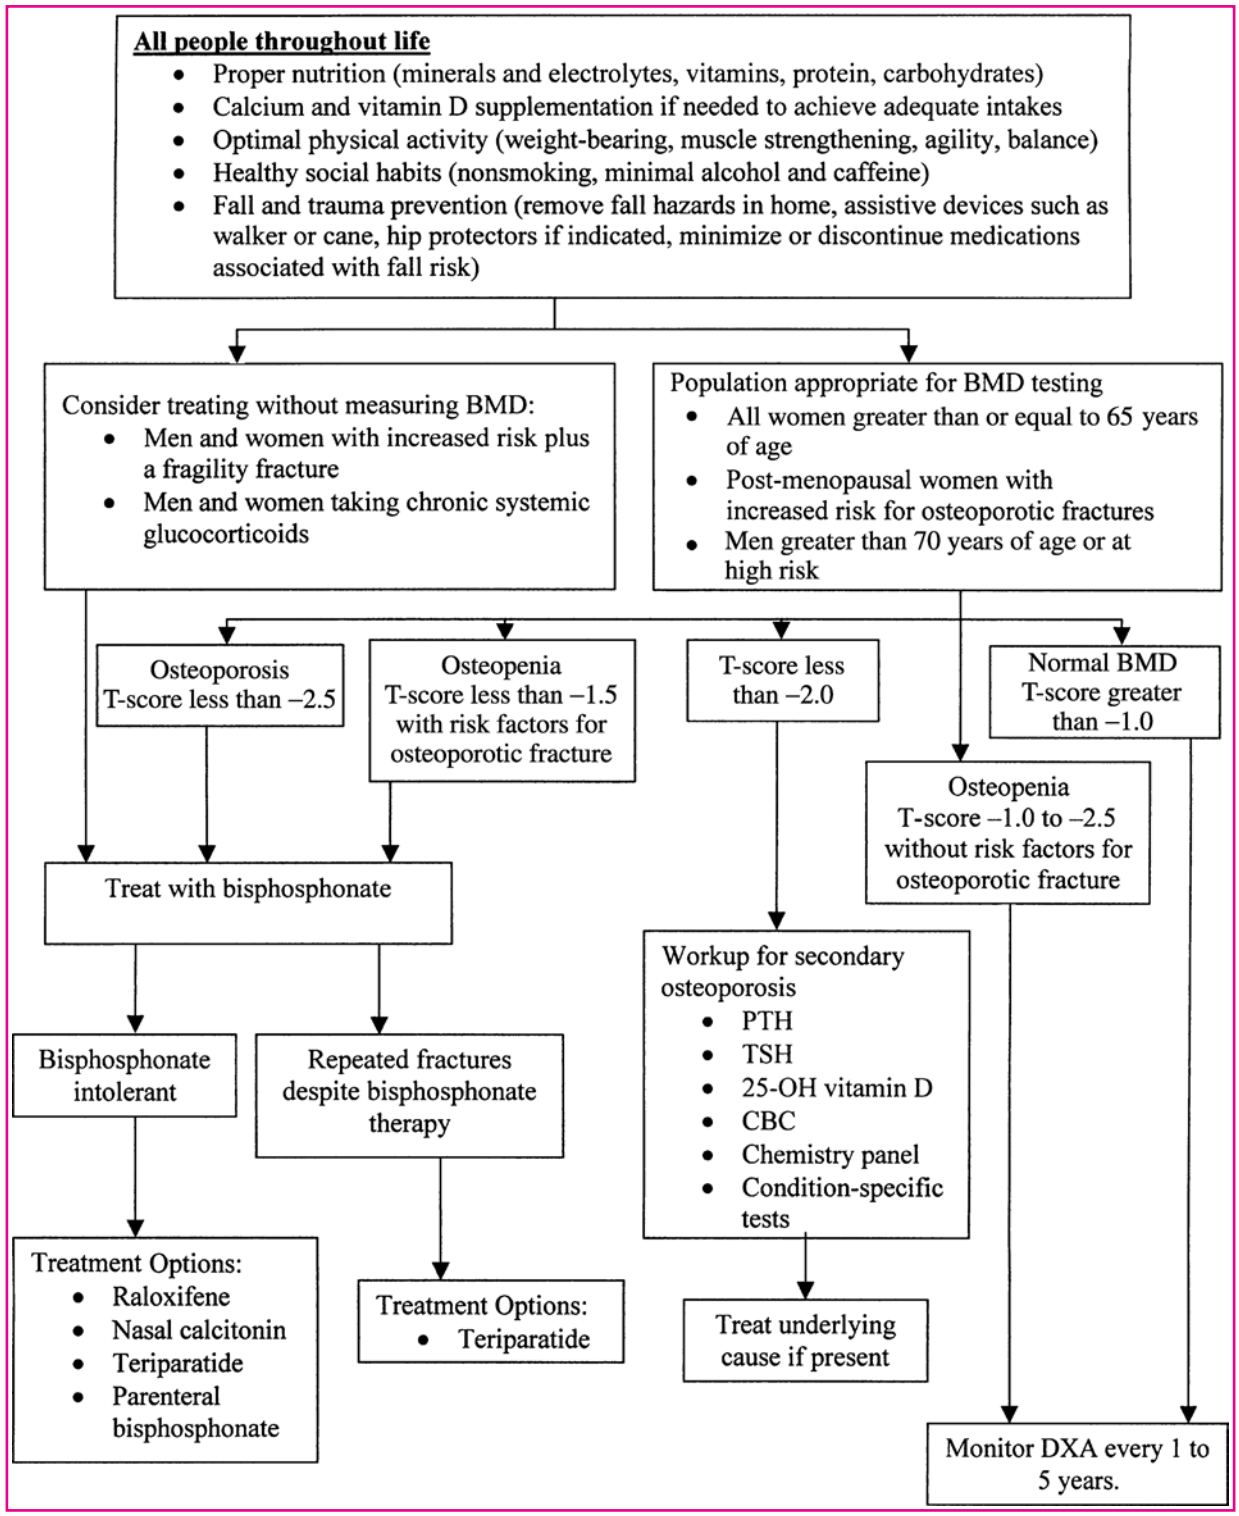

FIGURE 53–1. Algorithm for preventing osteoporotic fractures. BMD, bone mineral density; CBC, complete blood count; DXA, dual-energy x-ray absorptiometry; PTH, parathyroid hormone; TSH, thyroid-stimulating hormone. bone, adequate calcium intake and supplementation are key components for all participants of well-designed clinical trials evaluating osteoporosis interventions.

Daily calcium and vitamin D requirements are highest in postmenopausal women and elderly men: 1500 mg elemental calcium and 400 to 800 IU vitamin D (see Table 53–4). When these requirements cannot be achieved by diet alone, appropriate calcium and/or vitamin D supplementation is recommended.

For example, elderly patients living in nursing homes will not be able to meet vitamin D requirements and will need supplementation. Vitamin D deficiency is common in elderly patients owing to decreased exposure to sunlight and subsequent decreased vitamin D synthesis in the skin, decreased gastrointestinal absorption of vitamin D, and reduction in vitamin D_3 synthesis. Individuals living in northern climates also have decreased exposure to sunlight and are less likely to achieve vitamin D requirements.

Calcium supplements are available in a variety of calcium salts and dosage forms. Calcium requirements are listed in terms of elemental calcium. However, many product labels list calcium content in the salt form, so the percent of elemental calcium must be known to calculate the elemental calcium content per tablet.

Some calcium products contain lead.[12] While the clinical significance and long-term risks are unknown, it is best to use supplements without a high lead content. Because of the number of calcium supplements available, patients may find it overwhelming to choose a supplement. Health care providers can help patients find a suitable and tolerable supplement with good absorption and high elemental calcium content, necessitating fewer tablets per day. Table 53–6 lists widely available supplements with elemental calcium and vitamin D content.

A number of factors can limit calcium absorption, and special consideration must be given to calcium dosing to maximize absorption. Large amounts of calcium taken at once cannot be absorbed. Supplement doses should be limited to 500 to 600 mg of elemental calcium per dose. Calcium intake greater than 2500 mg/day should be avoided due to increased risk of toxicity, including **hypercalciuria** and **hypercalcemia.**

Calcium carbonate should be taken with food to maximize absorption. Elderly patients or patients receiving proton pump inhibitors or H_2-receptor antagonists may have added difficulty absorbing calcium supplements because of reduced stomach acidity. Better absorption may occur in this setting with calcium citrate because an acid environment is not needed for absorption; it may be taken with or without food.

Common adverse effects of calcium salts include constipation, bloating, cramps, and flatulence. Changing to a different salt form may alleviate symptoms for some patients. Calcium salts may reduce the absorption of levothyroxine, iron and some antibiotics, such as tetracycline and fluoroquinolones.

Vitamin D is often combined in varying amounts with calcium salts. A multiple vitamin is another good source of vitamin D. Most multivitamins contain 400 IU per tablet. Vitamin D is also available as a single entity. Doses above 2000 IU/day should be avoided owing to the risk of hypercalciuria and hypercalcemia. Ergocalciferol (vitamin D_2) and

TABLE 53–6. Calcium and Vitamin D Content of Common Supplements[a]

Product (% Elemental Calcium)	Elemental Calcium per Tablet (mg)	Vitamin D per Tablet (IU)
Calcium Carbonate (40%)		
Tums® 500 mg	200	—
Tums E-X® 750 mg	300	—

[a]Some calcium supplements may contain lead, and many products have not been tested. Tums E-X and Tums Ultra do not contain appreciable amounts of lead.[11]

cholecalciferol (vitamin D_3) are available in higher doses and generally are reserved for patients with vitamin D deficiency.

Bisphosphonates

❻ *Bisphosphonates are first-line therapy for osteoporosis owing to their established efficacy in preventing hip and vertebral fractures.* They are also the most commonly prescribed therapy for osteoporosis. They decrease bone resorption by binding to the bone matrix and inhibiting osteoclast activity. They remain in the bone for a prolonged period and are released very slowly. These effects increase bone mineral density. Several bisphosphonates are available currently, including alendronate, etidronate, ibandronate, pamidronate, risedronate, tiludronate, and zoledronic acid. Alendronate, risedronate, and ibandronate are oral agents approved by the United States Food and Drug Administration (FDA) for use in osteoporosis. Table 53–7 contains comparative dosing and cost information for the bisphosphonates.

In placebo-controlled clinical trials, alendronate, ibandronate, and risedronate increased bone mineral density by up to 5% to 8% in the lumbar spine and up to 3% to 5% in the hip.[13–16] Additional data suggest that bone mineral density continues to increase with long-term therapy of 7 to 10 years.[17,18] Although increases in bone mineral density have been reported at other sites, most of the clinically significant fractures occur in the hip or spine, and these sites have become clinically important measures in the trials. These increases in bone mineral density are an important marker of treatment effects and are related to the benefits found in larger trials of decreased fracture risk.

Large, well-designed trials have proven the benefits of bisphosphonate therapy in preventing vertebral and nonvertebral fractures. Several studies have found decreases in vertebral fracture risk by as much as 40% to 50% with alendronate and risedronate.[13,14,19–21] Data suggest a similar reduction with ibandronate on vertebral fractures.[16,22] Alendronate and risedronate decrease the incidence of hip and nonvertebral fractures as well.[14,19,23]

Several studies have evaluated the long-term efficacy and safety of bisphosphonates in postmenopausal women. One study evaluated the use of alendronate over a 10-year period and found no difference in adverse effects between women who received alendronate for 10 years and women who discontinued alendronate after 5 years. Women who discontinued alendronate after 5 years continued to experience sustained increases in bone mineral density compared with baseline values and a reduction

TABLE 53–7. Dosage Regimens and Cost of Prescription Agents for Osteoporosis

Drug	Product Size	Usual Dose	Administration	Monthly Cost[a]
Bisphosphonates				
Alendronate	5-, 10-, 35-, 70-mg tablets; 70-mg oral solution	Postmenopausal osteoporosis or osteoporosis in men: 10 mg orally once daily or 70 mg orally once weekly Glucocorticoid-induced osteoporosis: 5 mg orally once daily for men and women; 10 mg once daily for postmenopausal women not on estrogen	Take after an overnight fast with 6 to 8 oz plain water while sitting or standing upright at least 30 minutes prior to morning meal; do not lie down for 30 minutes after administration; do not take with other medications or fluids; do not chew or suck on the tablet	$70 for 70-mg weekly tablet
Ibandronate	2.5-, 150-mg tablets	Treatment or prevention of postmenopausal osteoporosis: 2.5 mg orally daily or 150 mg orally once monthly	Same as alendronate except administer at least 1 hour prior to morning meal and refrain from lying down for 1 hour after administration	$76 for 150-mg tablet
Risedronate	5-, 35-mg tablet	Osteoporosis or glucocorticoid-induced osteoporosis: 5 mg orally daily or 35 mg orally once weekly	Same as alendronate	$68 for 35-mg weekly tablet
Selective Estrogen Receptor Modulators				
Raloxifene	60-mg tablet	60 mg daily	May be taken with or without food	$85 for 60-mg tablet
Calcitonin				
Calcitonin	200 IU/0.9 mL, 3.75-mL nasal spray	Nasal spray: 200 IU daily	Nasal spray: Alternate nostrils on a daily basis	$93 per 3.75-mL nasal spray
Recombinant Human Parathyroid Hormone				
Teriparatide	250 mcg/mL, 3-mL prefilled pen	20 mcg SQ daily	Inject into thigh or abdominal wall; keep pen refrigerated	$590 per prefilled pen

[a]Monthly cost from drugstore.com; accessed February 6, 2006.
IM, intramuscularly; SQ, subcutaneously.

in fracture rates.[17] Another study found sustained increases in bone mineral density after discontinuation of alendronate, albeit less than in those who continued longer-term alendronate therapy.[24] A 7-year follow-up study with risedronate found continued increases in bone mineral density and no increase in adverse effects in women receiving alendronate for 7 years compared with women receiving risedronate for 2 years.[18]

The safety of long-term bisphosphonates has been evaluated in clinical trials. A number of case reports have highlighted serious adverse effects. Concern exists over the use of chronic bisphosphonate therapy due to reports of nonvertebral atraumatic fractures and jaw **osteonecrosis.**[25–27] One report described nonvertebral atraumatic fractures in nine patients and delayed fracture healing in four of those patients while receiving alendronate therapy for 3 to 8 years. Bone biopsies in all patients revealed severely suppressed bone turnover, which may have caused bone weakening owing to suppression of osteoclastic activity.[25,26] Another report described 63 cases of jaw osteonecrosis resistant to conservative measures and requiring surgical intervention in most cases.[27] Although a majority of the cases were reported in cancer patients who had received intravenous bisphosphonate, some of the cases were reported in women who had received oral bisphosphonates for osteoporosis.[27]

Oral bisphosphonates are poorly absorbed (less than 5%). Taking them in the presence of food or calcium supplementation further reduces absorption. After absorption, bisphosphonate uptake to the primary site of action is rapid and sustained. Once attached to bone tissue, bisphosphonates are released very slowly. These drugs are not metabolized and are excreted renally. They are not recommended for use in patients with renal insufficiency.

The most notable adverse effects associated with the bisphosphonates are gastrointestinal, ranging from relatively mild nausea, vomiting, and diarrhea to more severe esophageal irritation and esophagitis. Common adverse reactions reported in clinical trials include dyspepsia, abdominal pain, nausea, and esophageal reflux. Clinically significant adverse events include esophageal ulceration, erosions with bleeding, perforation, stricture, and esophagitis. Upper gastrointestinal adverse effects have been reported in up to 20% of patients.[14,20,23,28] However, in some studies, the incidence is no different from that for placebo.[20,23] Many gastrointestinal events are related to inappropriate administration. An evaluation of the Fracture Intervention Trial data found certain factors, including advanced age, previous upper gastrointestinal tract disease, and nonsteroidal anti-inflammatory drug use, increased the risk for gastrointestinal adverse events.[29] In addition to appropriate administration, once-weekly administration of oral bisphosphonates may decrease the risk of adverse gastrointestinal effects.

Proper drug administration is important for optimal absorption and prevention of adverse effects. Oral bisphosphonates should be taken 30 to 60 minutes prior to the first meal or food in the morning after an overnight fast with 6 to 8 oz of water (or 2 oz with the oral solution). Patients should remain upright and refrain from lying down for 30 to 60 minutes after administration. The tablets should be swallowed whole without chewing or sucking. Administration should be with water only and not combined with other fluids. Bisphosphonates should not be taken with other medications or dietary supplements. Bisphosphonates are not recommended for use in patients with esophageal abnormalities, hypocalcemia, and renal insufficiency or failure (creatinine clearance less than35 mL/minute).

There is considerable interest in using injectable bisphosphonates, such as pamidronate and zoledronic acid, in patients unable to tolerate or absorb oral bisphosphonates. Zoledronic acid in particular has a potential advantage of once-yearly dosing. Currently, neither drug has received FDA approval for this indication. Ibandronate has recently been approved for this indication.

Selective Estrogen Receptor Modulators

Raloxifene is a selective estrogen receptor modulator (SERM) that has estrogen-like activity on bones and cholesterol metabolism and estrogen antagonist activity in breast and endometrium. SERMs reduce bone resorption and decrease overall bone turnover. The related SERMs tamoxifen and toremifene have partial agonist and antagonist activity at various estrogen receptors. However, the latter agents are limited to the treatment of breast cancer; potential adverse effects preclude further study for long-term use in osteoporosis.

Raloxifene increases bone mineral density and reduces fracture rates. In trials of 1 to 3 years, raloxifene increased vertebral and hip bone mineral density by 2% to 3% and 1% to 2%, respectively.[30-32] In the Multiple Outcomes for Raloxifene Evaluation (MORE) trial, raloxifene decreased the risk of vertebral fractures by 30% in postmenopausal with at least one prior fracture.[30] No significant reduction in nonvertebral fractures was reported.

In addition to effects on bone, raloxifene may have effects in breast tissue and on the cardiovascular system. A secondary end point of the MORE trial evaluated the effects of raloxifene on the primary prevention of breast cancer and found a significant reduction in all types of breast cancer.[33] Raloxifene decreases total and low-density lipoprotein (LDL) cholesterol,[34] and studies are evaluating its effect on reducing the risk of cardiovascular disease.[35]

Adverse effects of raloxifene include hot flashes, leg cramps, and increased risk of venous thromboembolism. Hot flashes are very common and may be intolerable in postmenopausal women who are already predisposed to experiencing them. A more serious adverse effect is a threefold increased risk of venous thromboembolism that was found in patients treated in the MORE trial.[30] A previous history of venous thromboembolism is a contraindication to therapy.

Hormone-Replacement Therapy

Estrogen, either alone or in combination with a progestin, as hormone-replacement therapy (HRT) has a long history as an effective treatment of osteoporosis. The Women's Health Initiative (WHI) trial found a 33% reduction in both vertebral and hip fractures and a 23% reduction in other fractures in postmenopausal women receiving conjugated estrogen and medroxyprogesterone.[36] However, data from the WHI and another well-designed trial, the Hormone and Estrogen/progestin Replacement Study (HERS), found significant risks associated with HRT, including a higher incidence of breast cancer and venous thromboembolism.[36,37] For these reasons, the AACE no longer recommends estrogen or HRT for the treatment of osteoporosis.

Calcitonin

Calcitonin is a naturally occurring mammalian hormone that plays a major role in regulation of calcium levels. It inhibits bone resorption by binding to osteoclast receptors. Compared with mammalian calcitonin, salmon calcitonin has high potency and extended duration of action. Although commercial formulations of calcitonin-salmon actually are synthetic and not derived from salmon, they contain the same amino acid sequence as calcitonin of salmon origin.

Calcitonin is available in injectable and intranasal formulations. It cannot be administered orally owing to inactivation by gastric fluids. The parenteral formulation must be administered either subcutaneously or intramuscularly every other day. It is associated with significant adverse effects, including flushing, urinary frequency, nausea, vomiting, abdominal cramping, and irritation at the injection site. Additionally, the benefits of the parenteral formulation on bone may diminish over time owing to the formation of neutralizing antibodies.

The intranasal formulation is the preferred route of administration owing to ease of administration and fewer adverse effects, which mainly are local in nature. Adverse effects associated with the intranasal formulation include rhinitis, nasal irritation, and dryness. Hypersensitivity can develop with either formulation and should be considered before administering to patients with a suspected risk of hypersensitivity.

Perhaps the most benefit of calcitonin is in patients with or at risk for vertebral fractures. Nasal calcitonin increases vertebral bone mineral density by 1% to 3%.[38–40] One 5-year study found a 30% decrease in the risk of vertebral fractures.[38] Increases in hip bone mineral density and reductions in nonvertebral fractures have not been demonstrated.[38–40] Calcitonin may have analgesic effects in women with back pain from vertebral fractures.[41] However, enthusiasm for using calcitonin in this setting has waned in favor of managing fracture risk and pain separately.[10]

Anabolic Agents

Teriparatide, recombinant human parathyroid hormone(1–34), is the first anabolic agent approved by the FDA for treatment of osteoporosis. It is generally reserved for patients with moderate to severe osteoporosis. This agent differs from antiresorptive therapies in that it stimulates osteoblastic activity to form new bone with once-daily administration. Teriparatide also has many actions that are similar to endogenous parathyroid hormone, and continuous infusions actually stimulate osteoclastic activity and increase bone resorption. In one study, its bone-forming properties increased bone mineral density in the spine and hip by 9% and 3%, respectively. After 21 months of therapy, these increases led to 65% and 35% reductions in vertebral and nonvertebral fractures, respectively.[42]

The dose of teriparatide is 20 mcg given by subcutaneous injection once daily. It is available in a prefilled multiple-dose pen delivery system. Common adverse effects include nausea, headache, leg cramps, dizziness, injection-site discomfort, and hypercalcemia. Osteosarcoma has been observed in animal studies, but no cases have been reported in humans. However, this potential concern has led to the inclusion of a black-box warning in the product labeling. The warning states that teriparatide should not be used in patients at increased risk for osteosarcoma, including patients with Paget's disease of bone, unexplained elevations of alkaline phosphatase, prior radiation therapy involving the skeleton, and/or children and young adults with open epiphyses. Additionally, teriparatide should not be used in patients with preexisting hypercalcemia or skeletal radiation therapy. Patient-related concerns regarding the use of teriparatide include cost of therapy and need for subcutaneous injections. The labeling recommends treatment for a maximum of 2 years because it has not been studied for longer periods.

Combination and Sequential Therapy

Interest in combination antiresorptive therapies developed from the hope that using two agents with differing mechanisms for inhibiting bone resorption would result in greater increases in bone mineral density and reductions in fracture rates. Studies have evaluated the combination of bisphosphonates plus estrogen or raloxifene or estrogen plus calcitonin. Combination therapy produced greater increases in bone mineral density than single agents in some trials, but there was no further reduction in fracture risk. Combination therapy is also more expensive, and concern has been raised that significant reductions in bone turnover may promote bone that is more brittle.[25,43] The AACE does not recommend combination antiresorptive therapy for treating osteoporosis.

The combination of a bisphosphonate with anabolic therapy (teriparatide) should not be used because a well-controlled trial showed that women receiving the combination actually had smaller increases in bone mineral density than women receiving teriparatide alone.[44] However, sequential therapy with these agents may be more promising. In one study, women who received alendronate for 1 year directly after receiving parathyroid hormone for 1 year had greater

increases in bone mineral density than those receiving combination alendronate plus parathyroid hormone, alendronate monotherapy, or parathyroid hormone for 1 year followed by placebo for 1 year. Additionally, patients who received no therapy after 1 year of parathyroid hormone experienced decreases in bone mineral density.[45] Whether sequential therapy leads to reductions in fracture risk remains to be seen.

Other Therapies

Strontium ranelate is an oral agent possessing bone-forming and antiresorptive properties. Some data suggest significant reductions in vertebral fractures.[46] However, the benefit in nonvertebral fractures is unclear. This agent has not yet been approved for use by the FDA.

Sodium fluoride is an agent with bone-forming properties. Its use has fallen out of favor after data suggested an increased risk of fracture despite increases in bone mineral density. It is not currently available commercially in the United States.

Thiazide diuretics decrease urinary calcium excretion and may decrease bone turnover. However, their effects on bone mineral density and fracture rates have not been studied in controlled trials. Thiazide diuretics are not recommended solely for potential beneficial effects in osteoporosis.

Interest in the role of HMG-CoA reductase inhibitors (statins) in the treatment of osteoporosis came from bone-forming properties seen in animal studies. However, controlled clinical trials are needed.

Several studies have evaluated dietary supplements such as isoflavones, which are found in soy products and red clover. A well-controlled trial in more than 400 postmenopausal women evaluating a specific isoflavone, ipriflavone, found no benefits on bone mineral density or fracture rates after 3 years.[47] Nevertheless, because these therapies are available without prescription and are not regulated by the FDA, patients may choose to self-medicate with isoflavones. Lymphocytopenia appeared in several patients treated with ipriflavone in clinical trials. Additionally, ipriflavone should be used with caution in immunocompromised patients or those with renal disease. It may inhibit CYP1A2 and CYP2C9 and may interact with drugs metabolized by those pathways, such as warfarin.

Treatment of Special Populations

Premenopausal Women

Although most fragility fractures in women occur after age 50, certain groups of premenopausal women are at high risk for osteoporosis. The NOF recommends measuring bone mineral density in premenopausal women with risk factors in addition to sex and race, in whom treatment would be considered.[1] Premenopausal women at risk for osteoporosis should follow all nonpharmacologic recommendations for exercise and adequate calcium and vitamin D intake. Currently, no good data are available regarding pharmacologic therapy on fracture reduction in this population. Bisphosphonates should be used with caution in this population owing to pregnancy risks and uncertain long-term effects.

Men

Compared with postmenopausal osteoporosis, few clinical trials have been conducted evaluating therapies in men. Although alendronate and calcitonin have both been studied, only alendronate reduces fracture rates in men. Teriparatide also has been studied, but no data are available yet on fracture rates. At this time, alendronate and teriparatide are approved by the FDA for the treatment of osteoporosis in men. ❼ *Owing to proven benefit in reducing fractures and relative safety, alendronate should be considered first-line treatment for primary osteoporosis in men.* Teriparatide should be reserved as alternate therapy in this population.

Because secondary osteoporosis causes play a significant role in men, any secondary cause (e.g., **hypogonadism**) should be excluded or treated before considering other drug therapy.

Glucocorticoid-Induced Osteoporosis

Glucocorticoids play a significant role in bone remodeling. Exogenous glucocorticoid administration results in an increase in bone resorption, inhibition of bone formation, and change in bone quality. Glucocorticoids such as prednisone, hydrocortisone, methylprednisolone, and dexamethasone promote bone resorption through reduced calcium absorption from the gastrointestinal tract and increased renal calcium excretion. Bone formation is reduced through inhibition of osteoblasts. They also decrease estrogen and testosterone production.

Patients receiving long-term glucocorticoids are at increased risk of fracture. This risk is greater with higher doses and longer-term therapy. Most bone is lost during the initial 6 to 12 months of therapy, and bone mass continues to decline thereafter. Owing to the risk of bone loss and fractures, therapy is recommended for patients receiving long-term supraphysiologic doses of glucocorticoids.

In addition to nonpharmacologic measures, the American College of Rheumatology (ACR) has specific recommendations for prevention and treating patients receiving glucocorticoids.[48] Recommendations for optimal calcium and vitamin D intake are higher among patients receiving glucocorticoids. These recommendations include 1500 mg daily of elemental calcium and 800 IU daily of vitamin D for all adults receiving glucocorticoids. Patients should take a vitamin D–containing supplement to ensure that these requirements are being met.

❽ *The ACR recommends bisphosphonate therapy for all patients who are starting treatment with glucocorticoids (prednisone greater than or equal to 5 mg daily or equivalent) that will continue for 3 months or longer. For patients receiving chronic*

glucocorticoids (prednisone greater than or equal to 5 mg daily or equivalent), bisphosphonate therapy is also recommended if the bone mineral density is low or there is a history of fracture.[48] *Calcitonin may be used in patients who are intolerant of bisphosphonates.*

Gastrointestinal Disease

Various gastrointestinal disorders, including inflammatory bowel disease, celiac disease, and postgastrectomy states, are associated with osteoporosis due to impairment of calcium and vitamin D absorption, corticosteroid-induced bone changes, and chronic inflammatory states. The American Gastroenterological Association recommends bone mineral density measurement in high-risk patients and consideration of treatment for patients with a *T*-score below –2.5, history of vertebral compression fracture, or who are receiving long-term glucocorticoids.[49]

OUTCOME EVALUATION

- Evaluate patients for progression of osteoporosis, including signs and symptoms of new fragility fracture (e.g., localized pain), loss of height, and physical deformity (e.g., kyphosis). Patients should be assessed on an annual basis or more often if new symptoms present.
- Monitor for beneficial effects on bone density. The AACE recommends a follow-up DXA scan annually for the first 2 years after initiating drug therapy and every other year thereafter. Changes in bone mineral density may fluctuate from year to year.
- Assess patients for adverse effects of therapy.
- *Bisphosphonates:* Dyspepsia, esophageal reflux, esophageal pain or burning.
- *SERMs:* Hot flushes, signs or symptoms of thromboembolic disease (e.g., pain, redness, or swelling in one extremity; chest pain, and shortness of breath).
- *Calcitonin:* Nasal irritation or burning.
- *Teriparatide:* Nausea, headache, leg cramps, hypercalcemia.

Patient Encounter, Part 3: Development of a Treatment Plan

Considering all the information presented, develop a treatment plan for this patient. Include the following information: (1) goals of therapy, (2) detailed nonpharmacologic interventions, (3) recommendations for patient-specific drug therapy, including dose and frequency, (4) patient education about the chosen regimen, (5) monitoring plan for efficacy and adverse effects, and (6) consideration of alternative therapies if the initial therapy fails or is intolerable.

Patient Care and Monitoring

1. Assess patient risk factors for osteoporosis, with special attention to age, menopausal status, previous history of osteoporotic fracture, smoking status, low body weight, family history of osteoporotic fracture in first-degree relatives, and presence of secondary causes of osteoporosis.
2. Perform a thorough medication history, including prescription, over-the-counter, and alternative therapies. Pay special attention to any vitamins and calcium and vitamin D supplements the patient is taking.
3. Assess nonpharmacologic interventions for preventing osteoporotic fractures, including nutrition, weight-bearing and muscle-strengthening exercise regimens, and fall risk.
4. Determine average calcium intake from diet (see Table 53–5) and supplements (see Table 53–6). Compare with age-adjusted recommendations (see Table 53–4). Evaluate the patient's sources of vitamin D.
5. Review bone densitometry (i.e., central DXA) for the presence of low bone mass (i.e., *T*-score below –2.5 in the spine or hip for osteoporosis or *T*-score below –1.5 with presence of other significant osteoporosis risk factors).
6. Educate the patient about nonpharmacologic measures to prevent osteoporotic fractures.
7. If drug therapy is indicated, assess the patient for contraindications (e.g., esophageal disease or severe renal impairment for bisphosphonate therapy).
8. Educate the patient on the drug therapy selected, including drug name, dose, method of administration, common or serious adverse reactions, adherence, and monitoring. Pay special attention to administration instructions and monitoring for adverse effects. Include a discussion about the therapeutic goals and expectations (e.g., changes in individual *T*-scores may not necessarily correlate with benefit in fracture risk reduction).
9. Recommend appropriate calcium and vitamin D supplementation (see Table 53–6).
10. Develop a monitoring plan, including assessment of efficacy, adverse effects, nonpharmacologic measures to prevent fractures, and appropriate drug administration.

54 Rheumatoid Arthritis

Susan P. Bruce

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Identify risk factors for developing rheumatoid arthritis.
2. Describe the pathophysiology of rheumatoid arthritis, with emphasis on the specific immunologic components.
3. Discuss the comorbidities associated with rheumatoid arthritis.
4. Recognize the typical clinical presentation of rheumatoid arthritis.
5. Create treatment goals for a patient with rheumatoid arthritis.
6. Compare and contrast the available pharmacotherapeutic options, selecting the most appropriate regimen for a given patient.
7. Propose a patient education plan that includes nonpharmacologic and pharmacologic treatment measures.
8. Formulate a monitoring plan to evaluate the safety and efficacy of a therapeutic regimen designed for an individual patient with rheumatoid arthritis.

Key Concepts

❶ Comorbidities with the greatest impact on morbidity and mortality associated with rheumatoid arthritis are (1) cardiovascular disease, (2) infections, (3) malignancy, and (4) osteoporosis.

❷ Both osteoarthritis and rheumatoid arthritis are prevalent in the American population, but they differ significantly in presentation.

❸ The goals of treatment for rheumatoid arthritis are to (1) reduce or eliminate pain, (2) protect articular structures, (3) control systemic complications, (4) prevent loss of joint function, and (5) improve or maintain quality of life.

❹ Factors associated with poor outcomes are (1) early age of disease onset, (2) elevated erythrocyte sedimentation rate, (3) high titer of rheumatoid factor, (4) swelling of more than 20 joints, and (5) presence of extraarticular manifestations.

❺ It is imperative that the initiation of one or more disease-modifying antirheumatic drugs occurs in all patients within the first 3 months of diagnosis to reduce joint erosion.

❻ Most clinicians favor the "stepdown" approach to slow or reverse the early articular damage as soon as possible.

❼ Methotrexate is the disease-modifying antirheumatic drug of choice because of its documented efficacy and safety profile when monitored appropriately.

❽ The risk of infection in patients treated with biologic response modifiers must be considered when selecting and monitoring therapy.

❾ Patients of childbearing potential and their partners must be counseled to (1) use proper birth control while undergoing treatment for rheumatoid arthritis and (2) discontinue medications at least 3 months before conception.

❿ In addition to designing an individualized therapeutic regimen to control the progression of rheumatoid arthritis, the clinician must evaluate the presence of comorbidities and implement measures to control the increased risk.

Rheumatoid arthritis (RA) is a complex systemic inflammatory condition manifesting initially as symmetric swollen and tender joints of the hands and/or feet. Some patients may experience mild **articular** disease, whereas others may present with aggressive disease and/or extraarticular manifestations. The systemic inflammation of RA leads to joint destruction, disability, and premature death.

EPIDEMIOLOGY AND ETIOLOGY

RA affects approximately 1% of the United States population and 1% to 2% of the world's population.[1,2] RA arises from an immunologic reaction, and there is speculation that it is in response to a genetic or infectious antigen. Risk factors associated with the development of RA include:

- Female gender (3:1 females to males)
- Increasing age (peak onset 35 to 50 years of age)
- Current tobacco smoking. Studies have identified a direct relationship between tobacco use and RA disease severity.[3] Tobacco users also have an increased risk of pulmonary manifestations of RA. This risk is reduced when a patient has remained tobacco-free for at least 10 years.
- Family history of RA. Genetic studies demonstrate a strong correlation between RA and the presence of major histocompatibility complex class II **human leukocyte antigens** (HLA), specifically HLA-DR1 and HLA-DR4.[4,5] HLA is a molecule associated with the presentation of antigens to T lymphocytes.
- Potential environmental exposures. The number of RA cases has increased during industrialization, although a specific link to environmental factors has not been determined.[6]
- Oral contraceptive use and high ingestion of vitamin D and tea are associated with a decreased risk of RA.[7]

PATHOPHYSIOLOGY

The characteristics of a **synovium** affected by RA are (1) the presence of a thickened, inflamed membrane lining called **pannus,** (2) the development of new blood vessels, and (3) an influx of inflammatory cells in the synovial fluid, predominantly T lymphocytes. The pathogenesis of RA is driven by T lymphocytes, but the initial catalyst causing this response is unknown. Understanding specific components of the immune system and their involvement in the pathogenesis of RA will facilitate understanding of current and emerging treatment options for RA. The components of most significance are T lymphocytes, cytokines, and B lymphocytes.[4,8]

T Lymphocytes

The development and activation of T lymphocytes are important to maintain protection from infection without causing harm to the host.[9] Activation of mature T lymphocytes requires two signals. The first is the presentation of an antigen by antigen-presenting cells to the T-lymphocyte receptor. Second, a ligand-receptor complex (i.e., CD80/CD86) on antigen-presenting cells binds to CD28 receptors on T lymphocytes. Once a cell successfully passes through all stages, the inflammatory cascade is activated.[10] Activation of T lymphocytes (1) stimulates the release of macrophages or monocytes, which subsequently causes the release of inflammatory cytokines, (2) activates osteoclasts, (3) activates the release of **matrix metalloproteinases** or enzymes responsible for the degradation of connective tissue, and (4) stimulates B lymphocytes and the production of antibodies.[4,9]

Cytokines

Cytokines, proteins secreted by cells, serve as intercellular mediators (see Table 54–1). An imbalance of proinflammatory

TABLE 54–1. Cytokines Involved in the Pathogenesis of Rheumatoid Arthritis[4,6]

Cytokine	Source	Activity
Proinflammatory		
TNF-α	Macrophages, monocytes, B lymphocytes, T lymphocytes, fibroblasts	Induces IL-1, IL-6, IL-8, GM-CSF; stimulates fibroblasts to release adhesion molecules
IL-1	Macrophages, monocytes, endothelial cells, B lymphocytes, activated T lymphocytes	Stimulates fibroblasts and chondrocytes to release matrix metalloproteinases
IL-6	T lymphocytes, monocytes, macrophages, synovial fibroblasts	Activates T lymphocytes, induces acute-phase response, stimulates growth and differentiation of hematopoietic precursor cells; stimulates synovial fibroblasts
IL-17	T lymphocytes in synovium	Synergistic effect with IL-1 and TNF leading to increased production of pro-inflammatory cytokines
Anti-inflammatory		
IL-4	CD4+ type 2 helper T lymphocytes	Inhibits activation of type 1 helper T lymphocytes, decreases production of IL-1, TNF-α, IL-6, IL-8
IL-10	Monocytes, macrophages, B lymphocytes, T lymphocytes	Inhibits production of IL-1, TNF-α, and proliferation of T lymphocytes

and anti-inflammatory cytokines in the synovium leads to inflammation and joint destruction.[8] Proinflammatory cytokines including interleukin 1 (IL-1), tumor necrosis factor α (TNF-α), IL-6, and IL-17 are found in high concentration in synovial fluid. The proinflammatory cytokines cause the activation of other cytokines and adhesion molecules responsible for the recruitment of lymphocytes to the site of inflammation. Anti-inflammatory cytokines and mediators (IL-4, IL-10, and IL-1 receptor antagonist) are present in the synovium, although concentrations are not high enough to overcome the effects of the proinflammatory cytokines.[4,8]

B Lymphocytes

In addition to serving as antigen-presenting cells to T lymphocytes, B lymphocytes may produce proinflammatory cytokines and antibodies.[5,10] Antibodies of significance in RA are **rheumatoid factors** (antibodies reactive with the Fc region of IgG) and antibodies against **cyclic citrullinated peptide (CCP)**.[5] Rheumatoid factors are not present in all patients with RA, but their presence is indicative of disease severity and likelihood of extraarticular manifestations.[10] CCPs are produced early in the course of disease. High levels of anti-CCP antibodies are indicative of aggressive disease and a greater likelihood of poor outcomes. Monitoring anti-CCP antibodies may be useful to predict the severity of disease and match aggressive treatment appropriately.[10]

Comorbidities Associated with Rheumatoid Arthritis

RA reduces a patient's average life expectancy by 3 to 10 years, but RA alone rarely causes death.[11,12] Instead, specific **comorbidities** contribute to premature death independent of safety issues surrounding the use of immunomodulating medications. ❶ *The comorbidities with the greatest impact on morbidity and mortality associated with RA are (1) cardiovascular disease, (2) infections, (3) malignancy, and (4) osteoporosis.*[11,12]

Cardiovascular

Half of all deaths in RA patients are cardiovascular-related.[11] Because a patient with RA experiences inflammation and swelling in his or her joints, it is likely that there is inflammation elsewhere, such as in the blood vessels, termed **vasculitis.** C-reactive protein (CRP), a nonspecific marker of inflammation, is associated with an increased risk of cardiovascular disease; CRP is elevated in patients with RA. Chronic systemic inflammation may contribute to the relationship between RA and cardiovascular disease, but the exact mechanism is still under investigation.[11,12]

Infection

RA alone leads to changes in cellular immunity and causes a disproportionate increase in pulmonary infection and sepsis.[11] Because medications that alter the immune system are linked to an increased risk of infection, it is difficult to distinguish between an increased risk of infection secondary to RA and the medications used to treat RA. Patients and clinicians must pay close attention to signs and symptoms of infection because of this increased risk.[11]

Malignancy

Patients with RA have an increased risk of developing **lymphoproliferative** malignancy (e.g., lymphoma, leukemia, and multiple myeloma) and a decreased risk of developing cancer of the digestive tract.[11,13] The relationship between RA and cancer is not clear. To confound the issue, medications for the treatment of RA may contribute to cancer risk. Patients presenting with new onset of symptoms (e.g., fevers, night sweats, chills, or anorexia) out of proportion with disease activity and patients not responding to conventional RA treatment should be evaluated further for lymphoproliferative malignancy.[11,13]

Osteoporosis

Osteoporosis associated with RA follows a multifaceted pathogenesis, but the primary mechanism likely is mediated by **osteoclast** activity.[12] The cytokines involved in the inflammatory process directly stimulate osteoclast and inhibit **osteoblast** activity. Additionally, arthritis medications can lead to increased bone loss. Bone mineral density should be evaluated at baseline and routinely using dual-energy x-ray absorptiometry.[11,12]

Patient Encounter, Part 1

AL is a 36-year-old woman presenting to her primary care physician with a 2-month history of pain and inflammation in her hands and feet. On questioning, she indicates that she experiences pain and stiffness for at least an hour in the morning. AL is an artist and avid runner, and she wonders if her activities are causing this pain.

- What information is suggestive of RA?
- What risk factors does she have for RA?
- What additional information is necessary to differentiate between osteoarthritis and RA?
- What additional information do you need before creating a treatment plan for this patient?

CLINICAL PRESENTATION AND DIAGNOSIS

❷ *Both osteoarthritis and RA are prevalent in the American population, but they differ significantly in presentation* (Table 54–2). Figure 54–1 illustrates the typical joint involvement for patients with RA and osteoarthritis.

Presentation of Rheumatoid Arthritis

General
- About 60% of patients develop symptoms gradually over several weeks to months.
- Patients may present with systemic findings, joint findings, or both.

Symptoms
- Nonspecific systemic symptoms may include fatigue, weakness, anorexia, and diffuse musculoskeletal pain
- Patients complain of pain in involved joints and prolonged morning joint stiffness.

Signs
- The metacarpophalangeal (MCP), proximal interphalangeal (PIP), metatarsophalangeal (MTP), and wrist joints are involved frequently.
- Joint involvement is usually symmetric.
- There is often limited joint function.
- Signs of joint inflammation are present (tenderness, warmth, swelling, and erythema).
- Low-grade fever may be present.
- Extraarticular manifestations:
  - Subcutaneous **nodules**
  - *Ocular:* **Keratoconjunctivitis sicca**, **scleritis**
  - *Pulmonary:* Interstitial fibrosis, pulmonary nodules, **pleuritis**, pleural effusions
  - *Vasculitis:* ischemic ulcers, skin lesions, **leukocytoclastic** vasculitis
  - *Neurologic:* Peripheral neuropathy, **Felty's syndrome**
  - *Hematologic:* Anemia, **thrombocytosis**

Laboratory Tests
- Positive rheumatoid factor (negative in up to 30% of patients)
- Elevated erythrocyte sedimentation rate (Westergren ESR: greater than 20 mm/hour men; greater than 30 mm/hour women)
- Elevated CRP (greater than 0.7 mg/dL or greater than 7 mg/L)
- *Complete blood count:* Slight elevation in white blood cell count with a normal differential; slight anemia, thrombocytosis
- Positive anti-CCP

Other Diagnostic Tests
- *Synovial fluid analysis:* Straw colored, slightly cloudy, 5000 to 25,000 WBCs/mm^3 (5–25 × 10^9/L), negative if cultured
- *Joint x-rays:* To establish baseline and evaluate joint damage
- *Magnetic resonance imaging:* May detect erosions earlier in the course of disease than x-rays but is not required for diagnosis.

Diagnosis[1]

Seven criteria must be met to diagnose RA appropriately:

1. Morning joint stiffness lasting more than 1 hour before disappearing
2. Involvement of three or more joint areas
3. Arthritis of hand joints
4. Symmetric joint involvement
5. Presence of rheumatoid nodules
6. Elevated rheumatoid factor
7. Radiographic changes

A patient may be diagnosed with RA if four or more of these are present. Criteria 1 through 4 must be present for at least 6 weeks. Criteria 5 through 7 must be observed by a clinician.

TREATMENT

Desired Outcomes

❸ *The goals of treatment in RA are to (1) reduce or eliminate pain, (2) protect articular structures, (3) control systemic complications, (4) prevent loss of joint function, and (5) improve or maintain quality of life.*[1,7]

General Approach to Treatment

The clinician must evaluate patient-specific factors and select appropriate treatment to maximize the care of an individual patient. ❹ *Factors associated with poor outcomes are (1) early age of disease onset, (2) elevated ESR, (3) high titer of rheumatoid factor, (4) swelling of more than 20 joints, and (5) presence of extraarticular manifestations.*[1] Thirty percent of all patients with RA have radiographic evidence of erosions at the time of diagnosis; therefore, all patients should be treated early and aggressively to reduce disease progression and to prevent joint erosions.[1] Aggressive treatment is defined as one or more disease-modifying antirheumatic drugs (DMARDs) at effective doses. Delaying treatment will result in more destructive disease that is very difficult to delay or reverse to preserve joint function. Specialty care by a rheumatologist may reduce the likelihood of disease progression and joint damage.[14]

Nonpharmacologic Therapy

All patients should receive education about the nonpharmacologic and pharmacologic measures to help manage RA. Empowered patients take an active role in care by participating in therapy-related decisions. Certain forms of nonpharmacologic therapy benefit all levels of severity, whereas others (i.e., surgery) are reserved for severe cases only.

Occupational and physical therapy may help patients to preserve joint function, extend joint range of motion, and strengthen joints and muscles through strengthening exercises. Patients with joint deformities may benefit from the use of mobility or assistive devices that help to minimize disability and allow continued activities of daily living. In situations where the disease has progressed to a severe form with extensive

TABLE 54–2. Comparison of Rheumatoid Arthritis and Osteoarthritis[6]

	Rheumatoid Arthritis	Osteoarthritis
Gender prevalence (women:men)	3 : 1	1 : 1
Peak age of onset	35–50	Greater than 65
Risk factor of obesity	No	Yes
Morning stiffness	Usually greater than or equal to 60 minutes	Usually less than 30 minutes
Involved joint distribution	Symmetric	Symmetric or asymmetric
Presence of inflammation	Local and systemic	None or mild, local
Erythrocyte sedimentation rate	Elevated	Normal
Synovial fluid	Leukocytosis, slightly cloudy	Mild leukocytosis
Systemic manifestations	Yes	No

joint erosions, surgery to replace or reconstruct the joint may be necessary.[1]

Pharmacologic Therapy

❺ *It is imperative that the initiation of one or more DMARDs occurs in all patients within the first 3 months of diagnosis to reduce joint erosion.* Figure 54–2 outlines the course of treatment according to the American College of Rheumatology (ACR) *Guidelines for Management of Rheumatoid Arthritis.*[1] Combination therapy may be initiated at the time of diagnosis or after an adequate trial of a DMARD initiated as monotherapy. Starting combination therapy initially is referred to as the *stepdown approach,* wherein one or more agents are discontinued once the disease is controlled. Adding a second or third agent after an adequate trial of DMARD monotherapy is considered a *step-up approach.* ❻ *Most clinicians favor the "step-down" approach to slow or reverse the early articular damage as soon as possible.*[7] The following medication classes are prescribed commonly for the treatment of RA: (1) non-steroidal anti-inflammatory drugs (NSAIDs), (2) glucocorticoids, (3) DMARDs, and (4) biologic response modifiers (BRMs). Table 54–3 highlights dosing, safety, monitoring, and patient counseling information for the common DMARDs and BRMs.

Nonsteroidal Anti-Inflammatory Drugs

NSAIDs provide analgesic and anti-inflammatory benefits for joint pain and swelling. However, they do not prevent joint damage or change the underlying disease.[1] It is appropriate for a patient to begin taking an NSAID along with a DMARD for "bridge therapy" to provide symptomatic relief until the therapeutic effect of the DMARD is observed. Because of interpatient variability in response, patients may find relief from one NSAID and not another. For this reason, if a patient does not receive relief from one NSAID, it is acceptable to try a second one. Selecting another NSAID depends on multiple patient-specific factors including cardiovascular risk, potential for gastrointestinal-related adverse events, adherence to medication regimens, and insurance coverage or lack thereof. Clinicians must weigh these factors carefully to determine if the patient will benefit from another NSAID, if he or she should receive a cyclooxygenase-2 (COX-2) inhibitor, or if another medication class should be considered.

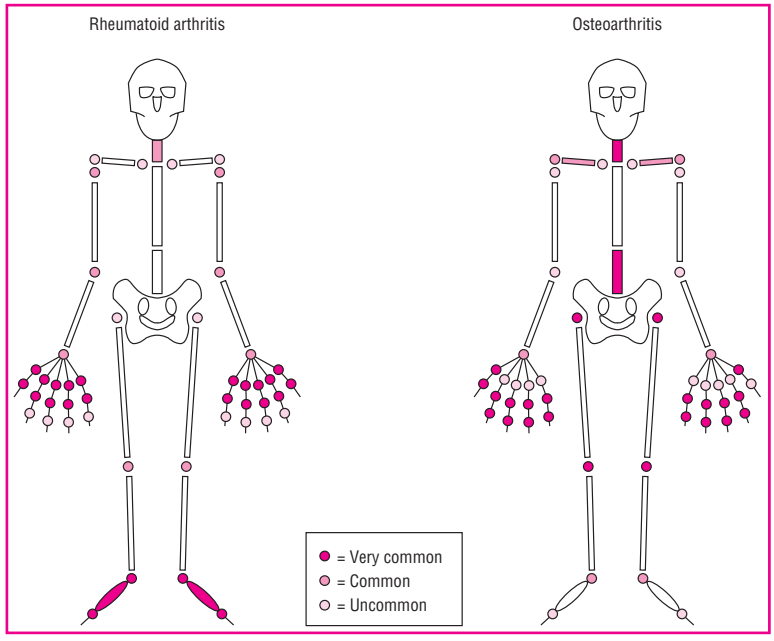

FIGURE 54–1. Patterns of joint involvement in rheumatoid arthritis. (From DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy*. 6th ed. New York: McGraw-Hill; 2005, Figure 89–3, p. 1673, with permission.)

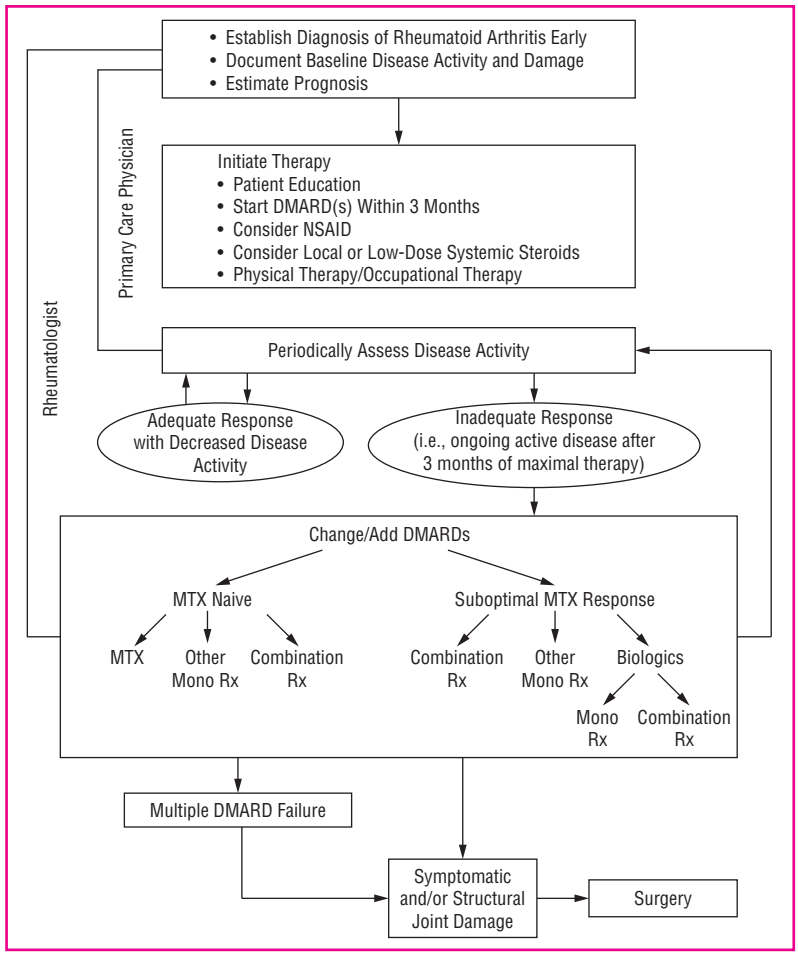

FIGURE 54–2. Outline of the management of rheumatoid arthritis. (From Guidelines for the management of rheumatoid arthritis: 2002 update. Arthritis Rheum 2002; 46(2):328–346, with permission.) DMARD, disease-modifying antirheumatic drug; NSAID, nonsteroidal antiinflammatory drug; MTX, methotrexate; Rx, therapy.

NSAID use is associated with an increased risk of gastrointestinal ulcers or hemorrhage, fluid retention, exacerbation of existing hypertension, and decreased renal function in certain patient populations.[7,15] Factors that place a patient at a higher risk of gastrointestinal-related adverse reactions include (1) history of peptic ulcer disease, (2) high doses of NSAIDs, (3) concomitant use of other medications with an increased risk of gastrointestinal hemorrhage or ulcers (e.g., anticoagulants, corticosteroids, use of multiple NSAIDs), (4) age greater than 75 years, and (5) serious underlying diseases.[1] If a patient is at an increased risk of NSAID-induced adverse reactions, gastroprotection should be considered by coinitiation of a proton pump inhibitor or histamine-2 receptor blocker or misoprostol. Misoprostol is effective in reducing the occurrence of gastric and duodenal ulcers. However, its tolerability is limited by adverse effects, specifically diarrhea. Histamine-2 receptor blockers effectively prevent duodenal ulcers (but not gastric ulcers) that occur more readily as a result of NSAID therapy. Proton pump inhibitors are the preferred gastroprotective agents due to achievement of a greater level of acid suppression, evidence of prevention of gastric and duodenal ulcers, and a tolerable adverse-effect profile.[16] Changing treatment to low-dose prednisone, a nonacetylated salicylate, or a COX-2 inhibitor is an additional option.[1]

NSAIDs may accentuate the increased risk of cardiovascular events inherent in patients with RA. Increases in blood pressure and fluid retention may exacerbate existing cardiovascular disease. With the evidence associating COX-2 inhibitors with cardiovascular disease, clinicians must carefully evaluate the potential risks of NSAID therapy against the potential benefits.[2] See Chap. 55 for additional discussion of NSAID therapy.

Glucocorticoids

Low-dose glucocorticoid treatment (prednisone less than or equal to 10 mg/day or equivalent) effectively reduces inflammation through inhibition of cytokines and inflammatory mediators and prevents disease progression.[15,17] The goal of glucocorticoid use is to minimize adverse drug events by keeping the doses low and using the drugs as infrequently as possible. Patients may receive glucocorticoids for a brief time as "bridge therapy" following DMARD initiation or via intraarticular injections to relieve symptoms of active disease. Patients taking doses more than 10 mg/day prednisone or equivalent are at an increased risk for clinically significant adverse reactions, especially bone loss leading to osteoporosis. Other glucocorticoid-related adverse reactions include Cushing's syndrome, peptic ulcer disease, hypertension,

TABLE 54–3. FDA-Approved DMARDs and BRMs for Treatment of Rheumatoid Arthritis[1,2,7,15,21,42]

Drug	Dose	Route	Time to Effect	ADRs	Monitoring	Counseling Points
Methotrexate	7.5–20 mg once weekly	Oral or IM	4–8 weeks	N, D, hepatotoxicity, alopecia, new-onset cough or SOB, MYL	CBC, creatinine, LFTs q 4–8 weeks Monitor for signs of infection	Concomitant use of folic acid Avoid alcohol Use contraception if childbearing potential
Hydroxychloroquine	200 mg bid	Oral	8–24 weeks	N, D, HA, vision changes, skin pigmentation	Eye exam every 12 mo.	
Sulfasalazine	1000 mg bid–tid	Oral	8–12 weeks	N, D, rash, yellow-orange discoloration, photosensitivity, MYL	CBC q 2–4 weeks for 3 mo. then q 3 mo.	Sunscreen use
Leflunomide (Arava)	100 mg daily for 3 days; then 20 mg daily	Oral	4–12 weeks	Hepatotoxicity, D, N, HTN, rash, HA, abdominal pain	CBC, creatinine, LFTs q mo. for 6 mo.; then q 4–8 weeks Monitor for signs of infection	Avoid alcohol Use contraception if childbearing potential
Etanercept (Enbrel)	25 mg twice weekly or 50 mg once weekly	SC injection	1–4 weeks	ISR	Monitor for infection	ISR—topical corticosteroids, antipruritics, analgesics, rotate injection sites Screen for tuberculosis
Infliximab (Remicade)	3–10 mg/kg at 0, 2, and 6 weeks; then q 8 weeks	IV infusion	1–4 weeks	IR (rash, urticaria, flushing, HA, fever, chills, nausea, tachycardia, dyspnea)	Monitor for infection	Screen for tuberculosis
Adalimumab (Humira)	40 mg every other week	SC injection	1–4 weeks	ISR	Monitor for infection	Screen for tuberculosis
Anakinra (Kineret)	100–150 mg daily	SC injection	2–4 weeks	HA, N, V, D, ISR	Monitor for infection	
Rituximab (Rituxan)	Two 1000-mg infusions separated by 2 weeks	IV infusion	4 weeks	IR	Monitor for infection	

N, nausea; D, diarrhea; HA, headache; SOB, shortness of breath; HTN, hypertension; LFTs, liver function tests; CBC, complete blood count; ISR, injection-site reactions; IR, infusion reactions; IV, intravenous; MYL, myelosuppression (watch for fever, symptoms of infection, easy bruisability, and bleeding); SC, subcutaneous.

weight gain, infection, mood changes, cataracts, dyslipidemia, and hyperglycemia.[2,17]

Disease-Modifying Antirheumatic Drugs

DMARDs are the mainstay of RA treatment because they modify the disease process and prevent or reduce joint damage. To differentiate between synthetic DMARDs and biologic DMARDs, the discussion is separated into DMARDs and BRMs. Although BRMs are considered disease-modifying agents, they are separated from traditional DMARDs because long-term data related to safety and efficacy are not as robust as with synthetic DMARDs. Until these data are available, it is difficult to justify using the medications interchangeably in clinical practice.

In addition to relying on safety and efficacy data, the initial DMARD choice depends on disease severity, patient characteristics (i.e., comorbidities, likelihood of adherence), cost, and clinician experience with the medication.[1,7] Methotrexate alone or in combination therapy is the initial treatment of choice for patients with aggressive disease. Patients with early, mild disease may receive monotherapy with sulfasalazine or hydroxychloroquine. Agents such as azathioprine, D-penicillamine, and gold salts are used rarely today because of concerns about toxicity and reduced efficacy.[1,15]

Methotrexate

❼ *Methotrexate is the DMARD of choice because of its documented efficacy and safety profile when monitored appropriately.*[1,15] Methotrexate exerts its anti-inflammatory effect through inhibition of dihydrofolate reductase, which causes the inhibition of purines and thymidylic acid, and by inhibiting the production of certain cytokines.[2] Unless the patient has contraindications to methotrexate, once-weekly doses should be initiated within 3 months of diagnosis and increased steadily until the patient has symptomatic improvement or a maximum dose of 20 mg/week is reached. Concomitant folic acid is given routinely to reduce the risk of folate-depleting reactions induced by methotrexate therapy (e.g., **stomatitis,** diarrhea, nausea, **alopecia, myelosuppression,** and elevations in liver function tests).[1,18] Serious adverse reactions include pulmonary fibrosis and hepatotoxicity. Patients should be counseled to avoid the use of alcohol, take folic acid as directed, adhere to the laboratory monitoring schedule, and immediately report symptoms of pulmonary fibrosis (e.g., cough or dyspnea) and hepatotoxicity (e.g., jaundice or abdominal pain). If monotherapy does not produce complete resolution of symptoms, methotrexate may be used in combination with other DMARDs. Combinations with evidence of efficacy and tolerability are methotrexate plus cyclosporine, methotrexate plus hydroxychloroquine and/or sulfasalazine, methotrexate plus leflunomide, and methotrexate plus infliximab or etanercept.[1,19]

Hydroxychloroquine and Sulfasalazine

The exact mechanism of action of these drugs is unknown, but both agents are fairly well tolerated. Hydroxychloroquine or sulfasalazine may be initiated on diagnosis of mild disease. Owing to their slow onset of action, each drug must be given at therapeutic doses for at least 6 months before it can be deemed a treatment failure. Hydroxycholorquine and sulfasalazine are relatively inexpensive compared with the new biologic agents. If patients do not respond to methotrexate monotherapy, adding one of these agents may provide the benefit necessary to reduce symptoms satisfactorily.[2]

Hydroxychloroquine may cause retinal toxicity, and patients must have their eyes examined at least annually to detect this abnormality. It is not associated with renal, hepatic, or bone marrow suppression and therefore may be an acceptable treatment option for patients with contraindications to other DMARDs because of their toxicities.

Starting sulfasalazine at low doses and titrating slowly will minimize the nausea and abdominal discomfort caused by the drug. Patients receiving sulfasalazine must undergo routine blood work to monitor for leukopenia.[1] Patients with a sulfa allergy should not receive sulfasalazine.

Leflunomide

Leflunomide inhibits dihydroorotate dehydrogenase, an enzyme within the mitochondria that supplies T lymphocytes with the necessary components to respond to cytokine stimulation.[20] Thus leflunomide inhibits the T-lymphocyte response to various stimuli and halts the cell cycle. Its efficacy is similar to that of moderate doses of methotrexate or sulfasalazine.[15] Because of its extended half life, leflunomide therapy begins with a loading dose followed by a maintenance dose. Patients with preexisting hepatic disease or a history of heavy alcohol ingestion should not receive leflunomide.[21] Leflunomide may be used in combination with methotrexate, but the added efficacy comes with a dramatic rise in the risk of hepatotoxicity. Liver function tests must be followed closely to prevent or minimize liver damage.[1] If therapy requires abrupt discontinuation (e.g., due to toxicity or pregnancy), administering cholestyramine will accelerate removal of leflunomide from the body.[19]

Biologic Response Modifiers

Biologic response modifiers (BRMs) are indicated in patients who have failed an adequate trial of DMARD therapy.[1] BRMs may be added to DMARD monotherapy (i.e., methotrexate) or replace ineffective DMARD therapy.[22] The decision to select a particular agent generally is based on the prescriber's comfort level with monitoring the safety and efficacy of the medications, the frequency and route of administration, the patient's comfort level or manual dexterity to self-administer subcutaneous injections, the cost, and the availability of insurance coverage.[23] In general, BRMs should be avoided in patients with serious infections, demyelinating disorders (e.g., multiple sclerosis or optic neuritis) or heart failure.[21]

Tumor Necrosis Factor Antagonists

Etanercept is a recombinant form of human tumor necrosis factor receptor.[24] Etanercept provides a therapeutic effect by binding to soluble TNF and preventing its binding with TNF receptors. It is administered subcutaneously once or twice weekly; noticeable symptomatic improvement is seen in 1 to

4 weeks. Etanercept is very effective as monotherapy or in combination with other DMARDs, except ANAKINRA.[24] There is no evidence to suggest a benefit to this combination, and there is an increased infection risk. The most common adverse reactions with etanercept are injection-site reactions. If such reactions are bothersome to patients, they should be advised to place ice on the injection site before and after administration or apply a topical anesthetic or corticosteroid to the affected area.[25]

Infliximab is a **chimeric** IgG1 monoclonal antibody that binds to soluble and bound TNF-α.[26] Methotrexate typically is given with it to suppress antibody production against the mouse-derived portion of the molecule. Infliximab is delivered via intravenous infusion every 4 to 8 weeks; however, patients may notice benefit within 1 to 4 weeks of receiving the first infusion. Infusion-related reactions including rash, urticaria, flushing, headache, fever, chills, nausea, tachycardia, and dyspnea may occur during treatment. Qualified health care personnel must be present during the infusion to respond to the infusion-related reactions, if they occur. If patients experience any of these symptoms, the reaction may be treated by (1) temporarily discontinuing the infusion, (2) slowing the infusion rate, or (3) administering corticosteroids or antihistamines.[25] Clinicians may prescribe pretreatment regimens with corticosteroids or antihistamines if the patient continues to experience infusion reactions.[25]

Adalimumab is a recombinant human IgG1 monoclonal antibody specific for human TNF.[27] Adalimumab binds to soluble and bound TNF-α. Patients may experience symptomatic relief in as early as 1 week. Adalimumab can be administered in combination with methotrexate or other DMARDs.[2]

Interleukin 1 Receptor Antagonist

Anakinra is a recombinant form of human IL-1 receptor antagonist. Anakinra inhibits the activity of IL-1 by binding to it and preventing cell signaling.[28] Patients must administer a subcutaneous injection every day, which may be less desirable than other treatment options. Anakinra may be used in combination with other DMARDs in patients not responding to or unable to tolerate DMARDs or TNF antagonists.[21] Anakinra should not be used in combination with TNF antagonists due to the increased risk of infection.[21]

Costimulation Blockers

Abatacept is the first agent in a new class of medications called *costimulation blockers.* Abatacept interferes with T-cell signaling, ultimately blocking T-cell activation and leading to anergy, or lack of response to an antigen.[29,30] Trials conducted in patients refractory to methotrexate and anti-TNF therapy demonstrated significant clinical benefit after administration of abatacept every 28 days with a dose approximating 10 mg/kg.[30] Adverse reactions reported in clinical trials were low and similar to those of placebo, with the exception of an increased incidence of headache, infections, and infusion-related reactions in the treatment group.[29,30] Abatacept is indicated as monotherapy or in combination with synthetic DMARDs. Its exact place in therapy is not yet clear; however, clinicians see a window of opportunity for patients who were intolerant to or did not receive therapeutic benefit from other DMARDs or BRMs or developed antibodies to adequate trials of anti-TNF agents, specifically infliximab.[30]

Anti-CD20 Monoclonal Antibody

Rituximab is a genetically engineered chimeric anti-CD20 monoclonal antibody that causes B-lymphocyte depletion.[31] Although the exact role of B lymphocytes in the pathogenesis of RA is not clear, a small study in patients with RA demonstrated noticeable efficacy. Further clinical trials showed a sustained therapeutic effect lasting for at least 48 weeks after the initial treatment.[31–34] Adverse effects occurring during or up to 24 hours after the first infusion included changes in blood pressure (increases or decreases), cough, rash, and pruritus. The infusion-related reactions subsided with subsequent infusions. Serious infections occurred in a small number of rituximab-treated patients.

The exact role of rituximab in RA is not clearly defined, but it is indicated for patients with moderate to severe RA with a history of inadequate response to DMARDs and other BRMs. Rituximab carries a black-box warning of fatal infusion reactions and severe mucocutaneous reactions even though these events did not occur during the RA clinical trials. The benefits of rituximab must be tempered against the safety concerns reported with use of rituximab in the oncology setting.

Investigational Agents

Anti-IL-6 receptor monoclonal antibody (MRA) inhibits the binding of IL-6 and the IL-6 receptor.[35] IL-6 is produced in high amounts in patients with RA. High levels are indicative of joint damage and disease activity. Studies in patients not responding to methotrexate monotherapy have demonstrated safety and efficacy of MRA administration.[2] A trial designed to evaluate the safety and efficacy of MRA found that patients experienced dose-dependent improvements in disease activity with an acceptable side-effect profile. Because MRA may adversely affect the cholesterol profile, the United States Food and Drug Administration (FDA) may require additional aggressive control of cardiovascular risk factors so that the benefits outweigh the potential risks.[35]

Selecting a Biologic Response Modifier

The developments in the treatment of RA are tempered by the lack of evidence describing the long-term safety and efficacy of the BRMs. In addition, the cost associated with the medications can be a deterrent to use. Long-term data are needed to determine if patients receiving BRM therapy early in the course of disease have reduced disease activity, reduced joint deformities and disability, improved quality of life, and continued function as productive members of society. Cost analyses of long-term data may indicate that the increased expenses associated with BRMs are offset by the costs avoided for the treatment of advanced RA.

8 *The risk of infection in patients treated with BRMs must be considered when selecting and monitoring therapy.*[36] Influencing the immune response to reduce symptoms of RA may influence the body's response to pathogens. Of particular concern is the

use of TNF antagonists in patients with a history of tuberculosis exposure. TNF is important in the formation of granulomas that wall off tuberculosis infection. In theory, if TNF is inhibited, patients with latent tuberculosis may have a reactivated infection. Patients receiving BRM therapy should be screened for tuberculosis and other infections. Prophylaxis should be initiated in patients with previous tuberculosis exposure or in patients at high risk of developing tuberculosis.[22] BRMs should not be initiated during an acute, serious infection and should be discontinued temporarily during times of infection.[25]

Use of TNF antagonists is associated with an increased risk of malignancy, specifically lymphoma.[21] This relationship is still under investigation because the risk of lymphoma is already increased if a patient has the diagnosis of RA, and the risk increases with the severity of disease.[21] Patients should be monitored closely for signs and symptoms suggestive of malignancy. Therapy should be discontinued once the risks outweigh the potential benefits of treatment.

Patient Encounter, Part 2: The Medical History, Physical Examination, and Laboratory Tests

PMH
- Exercise-induced asthma
- Allergic rhinitis
- Carpal tunnel syndrome

FH
Father has hypertension, diabetes, dyslipidemia; mother has RA and a history of MI; two siblings (one brother, one sister) alive and well.

SH
She is a successful artist and works from home. She drinks alcohol occasionally and does not smoke or use illicit drugs.

Allergies: NKDA

Meds
- Albuterol 2 puffs 15 to 20 minutes before exercise
- Ortho Tri-Cyclen by mouth once daily
- Budesonide nasal spray one spray each nostril daily
- Calcium (with vitamin D) 600 mg by mouth twice daily
- Ibuprofen 400 mg by mouth every 4 hours daily PRN

ROS
(+) fatigue, (–) N/V/D, HA, SOB, chest pain, cough

PE
- **VS:** 126/74, P 70, RR 18, T 38°C (100.4°F)
- **Skin:** Warm, dry
- **HEENT:** NC/AT, PERRLA, TMs intact
- **CV:** RRR, normal S_1 and S_2, no m/r/g
- **Chest:** CTA
- **Abd:** Soft, NT/ND
- **Neuro:** A & O × 3; CN II–XII intact
- **Exts:** Bilateral tender and swollen PIPs, MCPs, and MTPs (symmetric)

Labs
ESR 66 mm/hour, RF (+), HLA-DR4, anti-CCP (+)

Synovial fluid analysis: Yellow, cloudy, decreased viscosity

Hand x-rays: Soft tissue swelling, joint space narrowing, no evidence of erosions

- Given this additional information, what is your assessment of the patient's condition?
- Identify your treatment goals for this patient.
- What nonpharmacologic and pharmacologic alternatives are available for this patient?

Patient Encounter, Part 3: Creating a Care Plan

Based on the information available, create a care plan for this patient's RA. The plan should include (1) a statement of the drug-related needs and/or problems, (2) the goals of therapy, (3) a patient-specific detailed therapeutic plan, and (4) monitoring parameters to assess safety and efficacy.
Six months later, the patient comes back and mentions that she would like to become pregnant. Does this change your treatment plan? If yes, devise a new treatment plan for AL.

Fertility, Pregnancy, and Fetal Development

Women of childbearing age should be counseled about the impact of antirheumatic drugs on fertility, pregnancy, fetal development, and lactation. Some women may experience a reduction in disease symptoms during pregnancy; however, many agents used to treat RA are known teratogens. Women desiring motherhood must consult with their physicians to carefully plan for the pregnancy and reduce risks to the developing fetus.[37] Low-dose corticosteroids generally are safe and effective. Certain NSAIDs, hydroxychloroquine, and azathioprine may be considered in severe disease. Methotrexate use (FDA pregnancy category X) is associated with spontaneous abortion, fetal myelosuppression, limb defects, and central nervous system abnormalities; therefore, pregnancy must be avoided.[37] Sulfasalazine, on the other hand, may be the drug of choice in women who are pregnant or planning to become pregnant owing to its safety profile.[37] There is limited evidence of safety and long-term effects of the use of BRMs in pregnant women. Case reports of pregnancy during BRM therapy show no increased risk of fetal toxicity, but long-term data still are needed.[25,37]

Male patients with RA must receive counseling about the effects of certain medications on their fertility and potential harm to the fetus. It is difficult to establish causality between use of a medication by a male and the effect on fertility or fetal development; therefore, a conservative approach must be taken. ❾ *Patients of childbearing potential and their partners must be counseled to (1) use proper birth control while undergoing treatment for RA and (2) discontinue medications at least 3 months before conception.*[37]

OUTCOME EVALUATION

- Rheumatologists rely on standardized criteria to assess treatment interventions through measurement of disease activity. The American College of Rheumatology (ACR) uses criteria for improvement based on percent improvement in tender and swollen joint count and the presence of at least three or more of the following measures: pain, patient global assessment, physician global assessment, self-assessed physical disability, and acute-phase reactants.[38] ACR20, ACR50, and ACR70 are common efficacy endpoints in clinical trials. The number corresponds with the percent improvement. As treatment continues to evolve, the acceptable criteria for 20% improvement may be too low. For example, if a patient has 10 tender and swollen joints, reducing that by 20% to 8 tender and swollen joints is, by definition, an improvement by ACR20 criteria. However, further reduction in symptoms or disease remission may have greater clinical significance and effect on the patient's quality of life.
- Physical disability from RA can be measured through the Stanford Health Assessment Questionnaire (HAQ).[39,40] This patient self-assessment tool was developed to evaluate patient outcomes in five dimensions of chronic conditions: (1) disability, (2) discomfort, (3) drug adverse effects, (4) dollar costs, and (5) death. Clinicians and clinical studies in rheumatology use HAQ to assess longitudinally changes that influence the patient's quality of life.[39,40]
- Before starting treatment for RA, assess the subjective and objective evidence of disease. For joint findings, this includes the number of tender and swollen joints, pain, limitations on use, duration of morning stiffness, and presence of joint erosions. Systemic findings may include fatigue and the presence of extraarticular manifestations. Obtain laboratory measurements of CRP and ESR. The impact of the disease on quality of life and functional status is also important.
- At follow-up visits, compare the patient's status to baseline or previous visits using the ACR criteria for improvement of disease activity and the HAQ to assess longitudinally the influence on quality of life.
- Assess the patient's response to initiation of DMARD therapy after allowing adequate time for the medication to achieve its therapeutic effect.
- Determine whether any adverse reactions associated with each antirheumatic medication are present.
- Monitor laboratory parameters to ensure patient safety and reduce the risk of adverse reactions.

Patient Care and Monitoring

1. Assess the patient's symptoms to determine if they are consistent with RA. Evaluate the duration of symptoms and their impact on daily living.
2. Review available diagnostic data to determine the severity of disease and whether the patient is at risk of experiencing poor outcomes.
3. Obtain a thorough medication history, including prescription drugs, over-the-counter drugs, and dietary supplement use.
4. Educate the patient on nonpharmacologic measures that will improve symptoms.
5. Formulate a therapeutic plan, taking into consideration patient-specific factors.
6. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.
7. Develop a plan to assess safety and efficacy of the pharmacologic treatment plan. Determine if the appropriate doses of antirheumatic medications were used and if all medication were given a sufficient trial to achieve therapeutic benefit.
8. Stress importance of adherence with therapeutic regimen (including required laboratory monitoring, medication dosing and administration). Recommend a therapeutic regimen that is convenient and consistent with the patient's lifestyle.
9. Longitudinally evaluate the patient's clinical response to therapy and the impact on quality of life and mobility.
10. Evaluate the presence of comorbidities, and implement measures to control the increased risk.
    - *Cardiovascular:* Keep doses of NSAIDs and glucocorticoids low, consider initiation of folic acid to reduce homocysteine level elevations induced by methotrexate, consider initiation of low-dose aspirin and/or HMG-CoA reductase inhibitors (statins), and encourage smokers to discontinue tobacco use and assist with the development of a tobacco-cessation plan.[11,12]
    - *Infection:* Wash hands routinely, limit contact with individuals who are ill, and report signs and symptoms of infection immediately (e.g., fever, weight loss, and night sweats).
    - *Malignancy:* Report new onset of signs and symptoms (e.g., fever, chills, anorexia, and night sweats) immediately.[13]
    - Osteoporosis: Encourage patients to ingest adequate amounts of calcium and vitamin D, encourage smokers to discontinue tobacco use, and consider initiation of medications for osteoporosis (e.g., bisphosphonates, calcitonin, and parathyroid hormone) if the patient is taking glucocorticoids for an extended period of time or if the patient has evidence of low bone mineral density.[15,41]
11. Provide patient education in regard to RA, lifestyle modifications, and drug therapy:
    - What causes RA?
    - What are the comorbidities associated with RA?
    - How will lifestyle modifications affect RA?
    - What are the goals of therapy in the treatment of RA?
    - When and how should the medications be administered?
    - What potential adverse drug reactions may occur?
    - Which drugs may interact with therapy?
    - What are the warning signs to report to the physician?

ABBREVIATIONS

ACR:	American College of Rheumatology

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Identify risk factors associated with osteoarthritis (OA).
2. Recognize the signs and symptoms of OA.
3. Determine the goals of therapy for individual patients with OA.
4. Formulate a rational nonpharmacologic plan for patients with OA.
5. Recommend a pharmacologic plan for OA, taking into consideration individual patient factors.
6. Modify an unsuccessful treatment strategy for OA.
7. Develop monitoring parameters to assess effectiveness and adverse effects of pharmacotherapy for OA.
8. Deliver effective disease-state counseling, including lifestyle modifications and drug therapy, to facilitate effective and safe management of OA.

Key Concepts

❶ OA is the most common form of arthritis and is most prevalent in the middle to later years of life.
❷ The most common symptoms are joint pain, reduced range of motion, and brief joint stiffness after periods of inactivity.
❸ Treatment goals are to educate the patient and caregivers, relieve pain, maintain or restore mobility, minimize functional impairment, preserve joint integrity, and improve quality of life.
❹ Nonpharmacologic therapy is the cornerstone of treatment; education, exercise, weight loss, and cognitive behavioral intervention are integral components.
❺ Acetaminophen is the initial drug of choice; an adequate dose and duration of therapy should be used before resorting to other drug classes.
❻ Nonsteroidal anti-inflammatory drugs (NSAIDs) may be initiated if acetaminophen therapy fails. At equipotent doses, all NSAIDs elicit similar analgesic and anti-inflammatory responses. Selection is based on patient preference, dosing frequency, tolerability, and cost.
❼ Patients who do not respond adequately to one NSAID may respond to a different NSAID.
❽ NSAIDs are associated with gastrointestinal, renal, hepatic, and central nervous system toxicity and may increase blood pressure.
❾ NSAIDs that are selective for the cyclooxygenase-2 (COX-2) isozyme are less likely to cause gastrointestinal complications but may increase the risk of cardiovascular events. They are no more effective than nonselective NSAIDs. Selective agents should be reserved for patients at high risk of gastrointestinal complications and low risk for cardiovascular events.
❿ Glucosamine, tramadol, opioids, topical capsaicin, intraarticular corticosteroids, and surgery may be beneficial in certain situations.

❶ *Osteoarthritis (OA) is the most common form of arthritis.* Weight-bearing joints (e.g., hips and knees) are most susceptible, but non-weight-bearing joints, especially the hands, may also be involved. Because of its high prevalence and involvement of joints critical for daily functioning, the disease causes tremendous morbidity and financial burden. Recent estimates suggest that the total cost of caring for patients with OA equals or exceeds 2% of the gross national product.[1] OA ranks second only to cardiovascular disease as a cause of chronic disability; it is the most common reason for total-hip and total-knee replacement. ❶ *Osteoarthritis is strongly related to age; thus its incidence and the cost of care will*

increase dramatically in the coming years owing to a burgeoning senior citizenry. The National Arthritis Data Workgroup predicts that by the year 2020, 54.9 million Americans will be affected by OA, a nearly 3.5-fold increase from current estimates.

EPIDEMIOLOGY

The National Center for Health Statistics estimates that 15.8 million Americans have signs and symptoms of OA. The true extent of the disease is much larger; nearly everyone has radiographic evidence of OA by the eighth decade of life, but individuals without symptoms often go undiagnosed. Approximately 6% of United States adults have daily symptomatic knee OA, and 3% report daily symptoms affecting the hip.[2] After age 60, 10% to 15% of persons report such symptoms.

The prevalence of OA is higher in women, and they have more generalized disease. Women are also more likely to have inflammation of the proximal and distal interphalangeal joints of the hands, which manifest as **Bouchard's** and **Heberden's** nodes, respectively. OA of the hip occurs more frequently in men.

The prevalence of OA in Caucasians approximates the rate in African Americans, but the latter may experience more severe and disabling disease. Persons of Chinese descent rarely have hip OA; they are also less likely to develop hand OA but more likely to develop knee OA.[3]

PATHOPHYSIOLOGY

OA is characterized by damage to **diarthrodial** joints and joint structures. In the past, OA was referred to as *degenerative joint disease* (DJD), *hypertrophic arthritis,* or *osteoarthrosis;* however, such nomenclature fails to appreciate the multiple metabolic and pathologic derangements that comprise OA (Fig. 55–1). OA is a multifactorial disease typified by progressive destruction of joint cartilage, erratic new bone formation, thickening of **subchondral** bone and the joint capsule, bony remodeling, development of **osteophytes,** variable degrees of mild **synovitis,** and other changes.[4]

The earliest stages of OA are characterized by increasing water content and softening of cartilage in weight-bearing joints. As the disease progresses, **proteoglycan** content of cartilage declines, and eventually, cartilage becomes hypocellular. Increasing levels of protease enzymes, such as matrix **metalloproteinases** (MMPs), occur before changes in cartilage, suggesting that these catabolic proteinases play an important role in the initiation and progression of OA.

Subchondral bone undergoes metabolic changes, including increased bone turnover, that appear to be precursors to tissue destruction. The normally contiguous bony surface becomes fissured**.** Persistent use of the joint eventually results in loss of cartilage, permitting bone-to-bone contact that ultimately promotes thickening and **eburnation** of exposed bone. Microfractures may appear in subchondral bone, and **osteonecrosis** may develop beneath the surface.

New bone is formed haphazardly, leading to the formation of osteophytes that extend into the joint capsule and ligament attachments and may encroach on the joint space. Progressive loss of joint cartilage, subchondral damage, narrowing of joint spaces, and changes in the underlying bone and soft tissues of the affected joints culminates in deformed, painful joints.

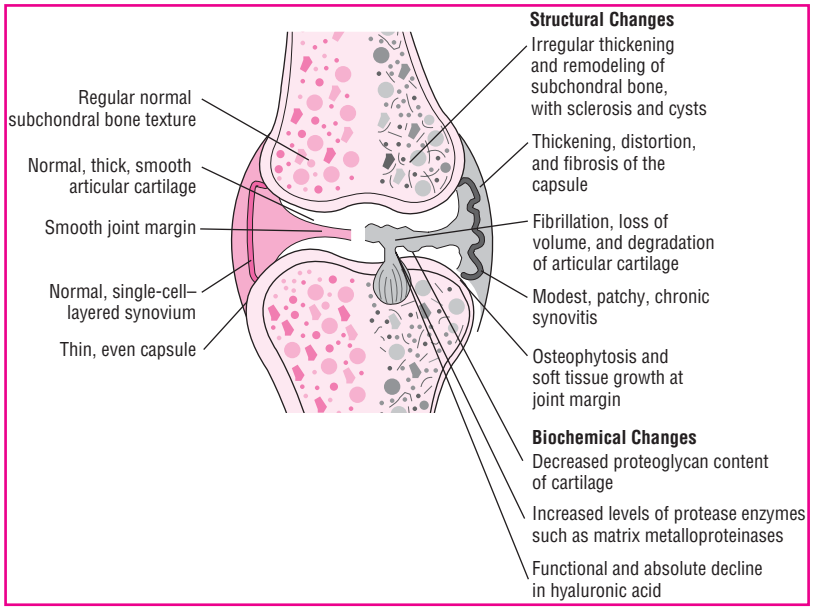

FIGURE 55–1. Characteristics of osteoarthritis in the diarthrodial joint. (Adapted from DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005, Figure 90-1, p.1687, with permission.)

Classification

OA is often divided into primary (idiopathic) and secondary disease (Table 55–1). Primary OA is the predominant form and occurs in the absence of a precipitating event. It may assume a localized, generalized, or erosive pattern. Localized OA is distinguished from generalized disease by the number of sites involved, whereas erosive disease is characterized by an erosive pattern of bone destruction and marked proliferation of interphalangeal joints of the hands. Secondary OA occurs when the disease is caused by congenital or developmental disorders or inflammatory, metabolic, or endocrine diseases.

Risk Factors

OA develops when systemic factors and biomechanical vulnerabilities combine. Systemic factors include age, gender, genetic predisposition, and nutritional status. Age is the strongest predictor of OA, although advanced age alone is insufficient to cause OA.

Joints exposed to biomechanical factors are at increased risk. Occupational and recreational activities involving repetitive motion or injury can provoke OA, although most daily activities do not produce enough joint trauma to cause OA, even after decades of repeated use. However, daily activities may lead to OA if a joint is susceptible because of previous injury, joint deformity, muscle weakness, or systemic factors. Heavy physical activity is a stronger predictor of subsequent OA than light to moderate activities.[5] This is especially true for older individuals, in whom the joint structure is less capable of coping with highly stressful activities. Obesity increases load-bearing stresses on hip and knee joints. The risk of OA increases by 10% for each kilogram of body weight above ideal body weight.[6]

TABLE 55–1. Classification of Osteoarthritis

Primary Osteoarthritis
Localized (involving one or two sites)
Generalized (involving three or more sites)
Erosive
Secondary Osteoarthritis
Mechanical incongruity of joint
Congenital or developmental defect
Posttraumatic
Prior inflammatory disease (rheumatoid arthritis, chronic gouty arthritis, pseudogout, infectious arthritis)
Metabolic disorder (hemochromatosis, ochronosis, Wilson's disease, chondrocalcinosis, Paget's disease)
Endocrinopathies (diabetes mellitus, obesity, acromegaly, iatrogenic hyperadrenocorticism, sex hormone abnormalities)
Neuropathic disorders
Intraarticular corticosteroid overuse
Avascular necrosis
Bone dysplasia

CLINICAL PRESENTATION AND DIAGNOSIS

Presentation of Osteoarthritis

General

- Patients are generally over the age of 50.
- Presentations encompass a spectrum ranging from asymptomatic to severe joint pain and stiffness with functional limitations.
- Joint involvement has an asymmetric local distribution without systemic manifestations.
- In contrast with some other forms of arthritis (e.g., rheumatoid arthritis and gout), inflammation usually is absent and is mild and localized when present.

Symptoms

- ❷ *The cardinal symptoms are use-related joint pain, typically described as deep and aching in character, and stiffness. In advanced cases, pain also may be present during rest.*
- Weight-bearing joints may be hindered by instability.
- ❷ *Joint stiffness ("gelling") abates with motion and recurs with rest.*
- ❷ *The stiffness generally lasts less than 30 minutes, limits range of joint motion, impairs daily activities, and may be related to weather.*

Signs

- One or more joints may be involved, usually in an asymmetric pattern.
- The following sites are most often involved in primary OA:
  - Distal interphalangeal finger joints (Heberden's nodes)
  - Proximal interphalangeal finger joints (Bouchard's nodes)
  - First carpometacarpal joint
  - Knees, hips, and cervicolumbar spine
  - Metatarsophalangeal joint of the great toe
- The following sites are involved most often in secondary OA:
  - Metacarpophalangeal joints
  - Wrists
  - Elbows
  - Glenohumeral joints
  - Ankles
- Joint examination may reveal local tenderness, bony proliferation, soft tissue swelling, crepitus, muscle atrophy, limited motion with passive/active movement, and effusion.

Laboratory Tests

- No specific laboratory test or value is diagnostic for OA.
- The erythrocyte sedimentation rate (ESR) and hematologic and chemistry panels are usually unremarkable.
- Aspirated synovial fluid (if obtained) often displays leukocytosis (less than 2000 WBCs/mm^3) and high viscosity.

Other Diagnostic Tests

- Radiologic evidence may be misleading because structural evidence of OA correlates poorly with symptoms.
- Radiographic changes are often absent in early OA.
- As the disease progresses, joint-space narrowing, subchondral bone sclerosis, and osteophytes may be detected.
- In late OA, there is gross deformity and possibly effusions.

Patient Encounter, Part 1

A 62-year-old obese woman presents to your clinic complaining of deep, aching pain in her right knee. The pain is provoked by walking and subsides with rest. She also notes that her knee is difficult to bend for 10 minutes after rising in the morning. The symptoms have worsened over the last several years. Your interview also reveals that she injured her knee several years ago getting out of a car.

- What information is suggestive of OA?
- What risk factors for OA does this patient have?
- What other information will you need before formulating a treatment plan for this patient?

TREATMENT

Desired Outcomes

Treatment is individualized and should consider medical history, physical examination, radiographic findings, distribution and severity of joint involvement, and response to previous treatment. Comorbid disease states, concomitant medications, and allergies are integrated into a holistic treatment approach. ❸ *Goals of therapy include (1) educating the patient and caregivers, (2) relieving pain, (3) maintaining or restoring mobility, (4) minimizing functional impairment, (5) preserving joint integrity, and (6) improving quality of life.*

General Approach to Treatment

A comprehensive treatment algorithm for OA is given in Fig. 55–2. Nonpharmacologic treatment is integral to achieving optimal outcomes in patients with OA. Pharmacologic therapy is used as an adjunctive measure to relieve pain; most treatments do not modify the disease course. Surgical intervention generally is reserved for patients with advanced disease complicated by unremitting pain or severely compromised function.

Nonpharmacologic Therapy

Nondrug therapy consists of a three-pronged approach consisting of education, lifestyle modification, and physical therapy. ❹ *Educational programs include a set of systematic educational activities designed to improve health behaviors and health status, thereby slowing OA progression.* The goal is to increase patient knowledge and self-confidence in adjusting daily activities in the face of evolving symptoms. Effective programs produce positive behavioral changes, decreased pain and disability, and improved functioning. In addition to physical outcomes, psychological outcomes such as depression, self-efficacy, and life satisfaction are positively influenced. Patients can be referred to the Arthritis Foundation (www.arthritis.org or 1-800-568-4045) for educational materials and information on support groups.

❹ *Lifestyle modification should be employed in all patients at risk for OA and in those with established disease.* Aerobic exercise and strength-training programs improve functional capacity in older adults with OA. Stretching and strengthening exercises should target affected and vulnerable joints. For example, inadequate quadriceps strength increases susceptibility of the knee joint to OA; thus quadriceps strengthening can be targeted to strengthen the knee joint and minimize risk. Isometric exercises performed three to four times weekly improve physical functioning and decrease disability, pain, and analgesic use. A major barrier to the widespread acceptance of exercise therapy in OA is the misconception that increased activity will exacerbate joint symptoms. Controlled clinical trials have invalidated this belief.[7] The American Geriatrics Society issued guidelines on the implementation of exercise in OA patients.[8] In general, it is advisable to recommend low-impact exercise be performed routinely.

Obesity's association with both the onset and progression of OA make weight loss a pivotal treatment strategy in overweight and obese patients. Women who lose an average of 5 kg lower their risk of knee OA by more than 50%. Symptomatic relief from knee OA and improved health-related quality of life occur in people with established knee OA who reduce their body weight. Weight loss should be pursued through dietary modification and increased physical activity (see Chap. 99). It is important to consider the patient's physical capabilities when implementing an exercise program.

❹ *Application of heat or cold treatments to involved joints improves range of motion, reduces pain, and decreases muscle spasms. Practical applications of heat therapy include warm baths or warm water soaks.* Heating pads should be used with caution, especially in the elderly, and patients must be warned of the potential for burns if used inappropriately.

Referral to a physical or occupational therapist may be helpful, particularly in patients with functional disabilities. Physical therapy is tailored to the patient and may include assessment of muscle strength, joint stability, and mobility; use of heat (especially prior to episodes of increased physical activity); structured exercise regimens; and implementation of assistive devices, such as canes, crutches, and walkers. The occupational therapist ensures optimal joint protection and function, energy conservation, and use of splints and other assistive devices.

Pharmacologic Therapy

Simple analgesics such as acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) are first-line agents for treating OA (Table 55–2).

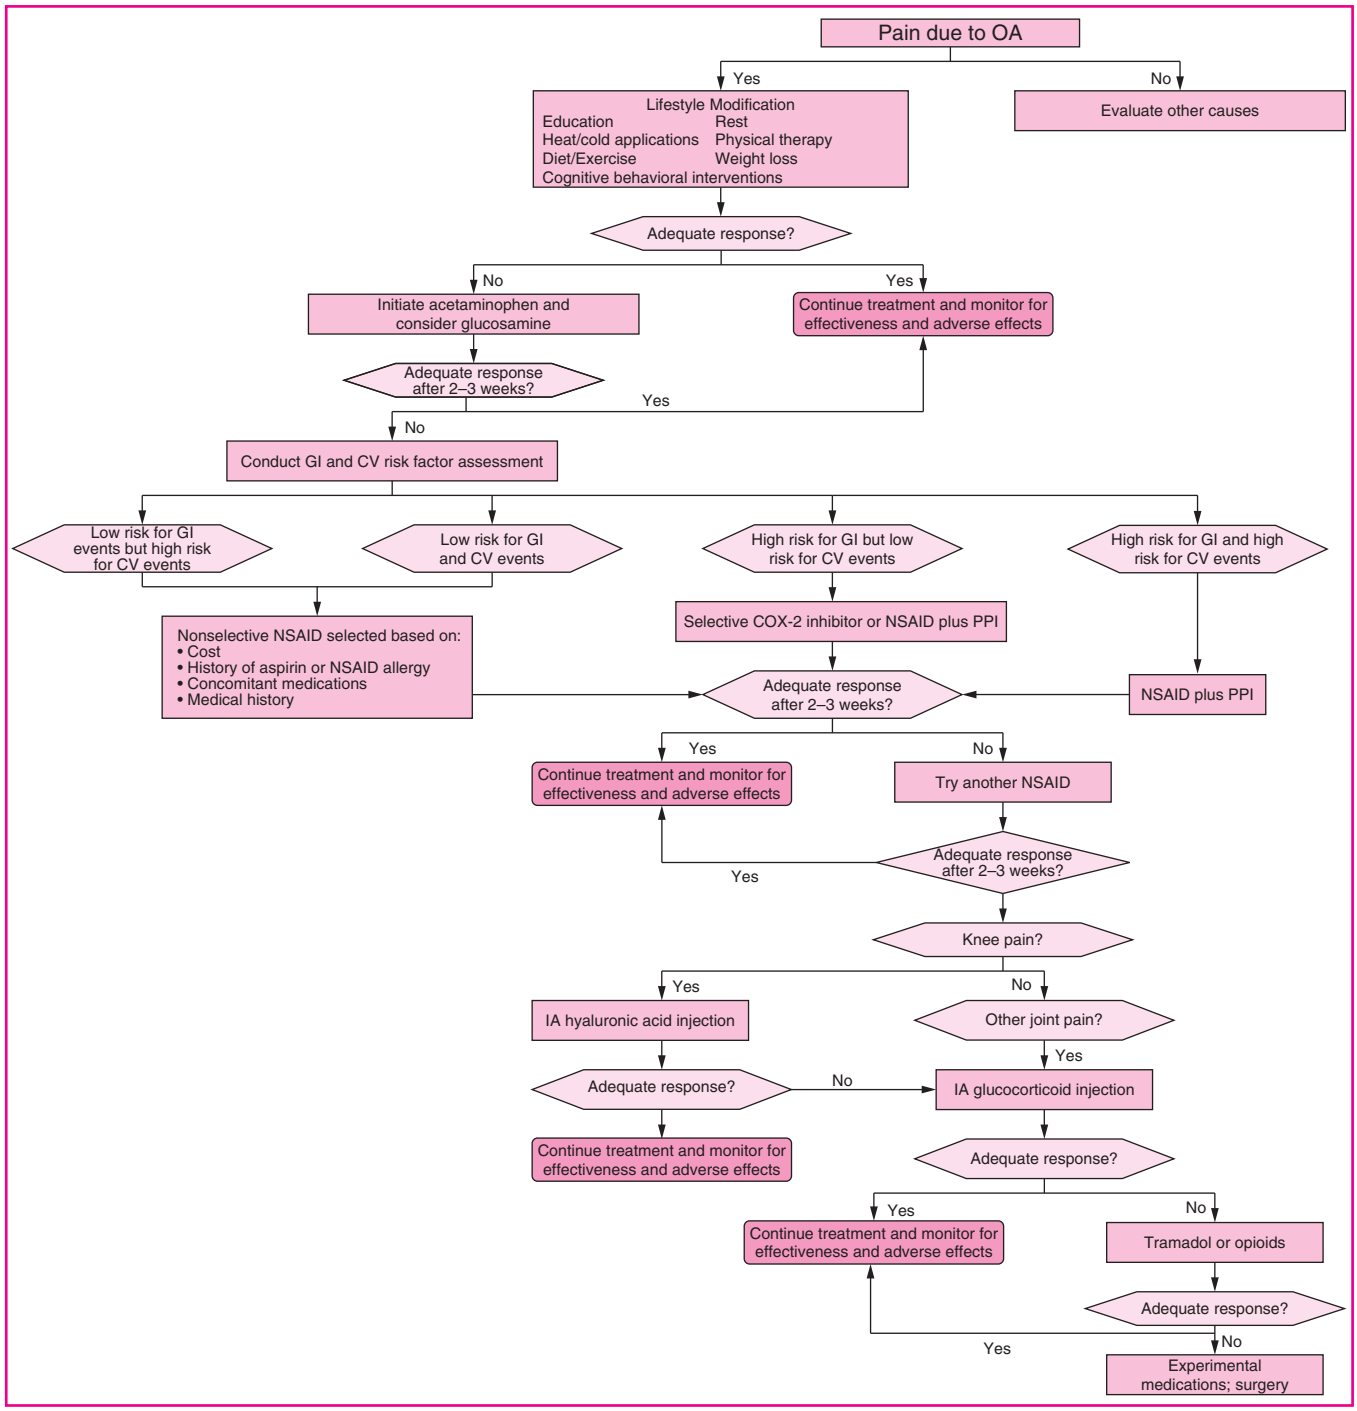

FIGURE 55–2. Treatment of osteoarthritis. OA, osteoarthritis; COX-2, cyclooxygenase-2; CV, cardiovascular; GI, gastrointestinal, IA, intraarticular; NSAID, nonsteroidal anti-inflammatory drug; PPI, proton pump inhibitor.

Acetaminophen

Acetaminophen is a centrally acting analgesic that produces analgesia by inhibiting prostaglandin production in the brain and spinal cord. ❺ *It is an effective and inexpensive analgesic with a favorable risk-benefit profile.*[9] It should be tried initially at an adequate dose and duration before considering an NSAID.[10] The American College of Rheumatology (ACR) and American Pain Society (APS) concur that acetaminophen is a first-line pharmacologic agent for treating mild pain that is unresponsive to nonpharmacologic measures.[11,12]

Acetaminophen should be administered in a scheduled manner (rather than on an as-needed basis) in doses up to

TABLE 55–2. Dosing Parameters of Agents Commonly Used to Treat OA

Medication	Dosage and Frequency	Maximum Dosage (mg/day)
Oral Analgesics		
Acetaminophen	325 mg every 4–6 hours or 1 g every 6–8 hours	4000
Tramadol	50–100 mg every 4–6 hours CrCl less than 30 mL/minute: 50–100 mg every 12 hours	400 (300 in elderly) 200
Nonselective NSAIDs by Chemical Class		
Carboxylic acid (salicylates)		
Aspirin	325–650 mg every 4–6 hours	3600[a]
Salsalate	500–1000 mg 2–3 times daily	3000[a]
Acetic acid		
Etodolac	300–600 mg twice daily 400–1000 mg once daily (extended-release)	1200
Diclofenac	50 mg 2–3 times daily 75 mg twice daily (delayed-release) 100 mg once daily (extended-release)	150
Indomethacin	25 mg 2–3 times daily 75 mg 1–2 times daily (sustained-release)	200
Nabumetone	500–1000 mg 1–2 times daily	2000
Propionic acid		
Ibuprofen	400–800 mg 3–4 times daily	3200
Naproxen	250–500 mg 2 times daily 750–1000 mg once daily (controlled-release) 275–550 mg 2 times daily (naproxen sodium)	1500 1650
COX-2-Selective Agents		
Meloxicam[b]	7.5–15 mg once daily	15
Celecoxib	100 mg twice daily or 200 mg once daily	200
Topical Analgesics		
Capsaicin		
Cream 0.025% or 0.075%	Apply to affected joint every 6–8 hours	
Nutritional Supplements		
Glucosamine sulfate	500 mg 3 times daily or 1500 mg once daily	
Chondroitin	400–800 mg 3 times daily with glucosamine	

[a]Serum salicylate levels should be monitored for doses greater than 3 g/day.
[b]Meloxicam is not considered to be a true COX-2-selective agent (see text).
CrCl, creatinine clearance; mL/minute, milliliters per minute.

4 g daily. This recommendation is based on its efficacy in placebo- and NSAID-controlled studies. Acetaminophen is as effective as NSAIDs for mild to moderate joint pain.[13] These data and a strong safety profile provide the rationale for using acetaminophen as first-line therapy in patients with OA.

A common reason for an inadequate response to acetaminophen is failure to use a sufficient dose for an adequate duration. A sufficient trial is defined as at least 2 to 3 g daily in divided doses for several weeks.

Despite being one of the safest analgesics, important adverse effects attributable to acetaminophen can occur, including hepatic and renal toxicity.[14] Total daily doses greater than 4 g are associated with an increased risk of hepatotoxicity. Concomitant use of alcohol may increase this risk; a maximum acetaminophen dose of 2.5 g daily is recommended in patients who consume more than two to three alcoholic beverages per day. Acetaminophen does not appear to exacerbate stable, chronic liver disease; it can be used with caution and vigilant monitoring of liver function in this population.[14]

Acetaminophen may worsen kidney function and increase blood pressure.[15-16] Nevertheless, acetaminophen remains the preferred analgesic for mild to moderate pain in patients with hypertension or kidney disease owing to the greater risks associated with NSAID use.[17] Monitoring specifically for these toxicities generally is unnecessary.

Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

Prostaglandins play an important role in the function of several organ systems. These compounds are synthesized via the interaction of two isoforms of the **cyclooxygenase** enzyme (COX-1 and COX-2) with their substrate, arachidonic acid (Fig. 55–3).

The COX-1 enzyme is produced normally in various body tissues (e.g., gastric mucosa, kidney, and platelets). Prostaglandins produced by the actions of the COX-1 enzyme in the gastrointestinal tract preserve the integrity of the gastrointestinal mucosa by increasing mucus and bicarbonate secretion, maintaining mucosal blood flow, and decreasing gastric acid secretion. COX-1-associated prostaglandins also promote normal platelet activity and function. In the kidney, COX-1-mediated prostaglandins dilate the afferent arteriole, thereby maintaining intraglomerular pressure and glomerular filtration rate when renal blood flow is reduced.

In contrast, the COX-2 enzyme is not produced normally in most tissues, but its production is increased rapidly in the presence of inflammation and local tissue injury. This leads to the synthesis of prostaglandins involved in pain and inflammation. Consequently, blocking the COX-2 enzyme results in analgesic and anti-inflammatory effects. The beneficial effects of NSAIDs in reducing pain, decreasing joint stiffness, and improving function in patients with OA are thought to be due to inhibition of the COX-2 isoenzyme.

Most NSAIDs (e.g., ibuprofen, naproxen, and others) inhibit both COX-1 and COX-2 isoforms. That is, they are nonselective inhibitors of the COX enzyme system. Whereas inhibition of COX-2 is responsible for beneficial effects, inhibition of COX-1 is responsible for the most common and important adverse effects of NSAIDs. COX-2-selective inhibitors have been produced and marketed in attempts to preserve the beneficial effects of COX-2 inhibition while avoiding the deleterious effects associated with inhibition of the COX-1 enzyme. This approach has not been entirely successful, as discussed below.

❻ *NSAIDs are a reasonable alternative when acetaminophen fails to provide an acceptable analgesic response.* Some authorities recommend NSAIDs over acetaminophen for patients presenting with severe pain or signs and symptoms of inflammation, but this is a matter of much contention. The rationale for this recommendation is that acetaminophen's central mechanism of action renders it ineffective against peripheral joint inflammation, and therefore, less effective.[18] Consensus guidelines support the use of NSAIDs as an alternative to acetaminophen if clinical features of peripheral inflammation or severe pain are detected.[11,12] Unfortunately, there is no validated mechanism to identify patients who are more likely to respond to NSAIDs than acetaminophen.

❻ *At equipotent doses, the analgesic and anti-inflammatory activity of all NSAIDs and aspirin are similar. The selection of a specific NSAID should be based on tolerability, previous response, and cost.* ❼ *Some patients respond to one NSAID better than to another. If an insufficient response is achieved with one NSAID, another agent from the same or a different chemical class should be tried.* Pain relief occurs rapidly (within hours), but anti-inflammatory benefits are not realized until after 2 to 3 weeks of continuous therapy. This period is the minimal duration that should be considered an adequate NSAID trial.

Inhibition of the COX-1 isoenzyme is thought to be responsible primarily for the adverse effects of NSAIDs on the gastric mucosa, kidney, and platelets. Direct irritant effects also may contribute to adverse gastrointestinal events. ❽ *Minor gastrointestinal complaints, including nausea, dyspepsia, anorexia, abdominal pain, flatulence, and diarrhea, are reported by 10% to 60% of patients treated with NSAIDs. Gastric and duodenal mucosal ulceration can be detected in 7% to 13% of patients. Perforation, gastric outlet obstruction, and gastrointestinal bleeding are the most severe complications and occur in 1.5% to 4% of patients annually.*

Several risk factors predict a greater likelihood of gastrointestinal complications in NSAID-treated patients (see Chap. 15).

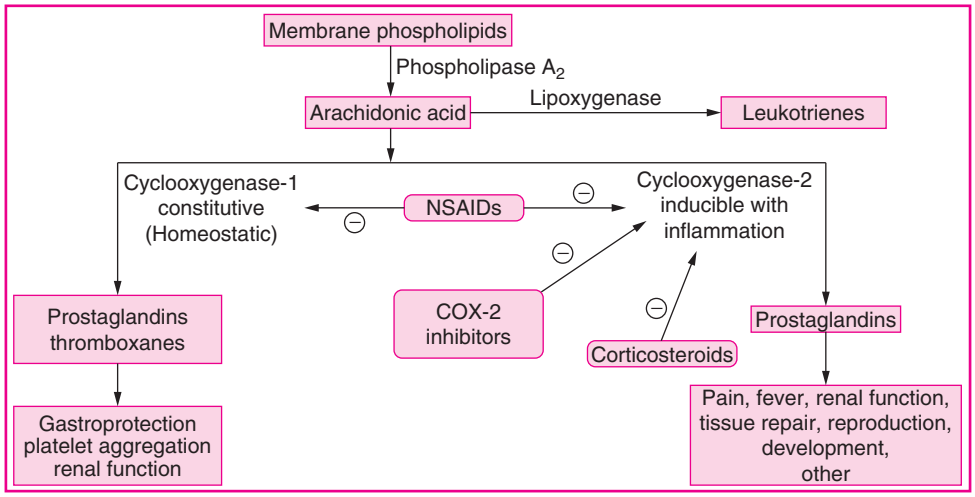

FIGURE 55–3. Synthesis pathway for prostaglandins and leukotrienes. COX-2, cyclooxygenase enzyme 2; NSAIDs, nonsteroidal anti-inflammatory drugs. (From DiPiro JT, Talbert RL, Yee GC, et al, (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 6th ed. New York: McGraw-Hill; 2005, Figure 90-3, p. 1694, with permission.)

It is not possible to detect high-risk patients based on symptoms alone because there is poor correlation between the presence of symptoms and actual gastroduodenal damage. Patients at high risk for gastrointestinal complications should be evaluated for the use of a COX-2-selective NSAID or concomitant treatment with a prophylactic gastroprotective agent such as a proton pump inhibitor or misoprostol. However, these strategies do not completely mitigate the risk of gastrointestinal complications.

❽ *NSAIDs can cause renal insufficiency when administered to patients whose renal function depends on prostaglandins. Patients with chronic renal insufficiency or left ventricular dysfunction, the elderly, and those receiving diuretics or drugs that interfere with the renin-angiotensin system are particularly susceptible.* Decreased glomerular filtration also may cause hyperkalemia. NSAIDs rarely cause **tubulointerstitial** nephropathy and renal papillary necrosis.

Caution is warranted in pregnant women and women of childbearing age because the risk of bleeding may be increased if the fetus is subjected to the antiplatelet activity of NSAIDs. Ibuprofen and naproxen are rated Food and Drug Administration (FDA) pregnancy category B in the first and second trimesters. Indomethacin and sulindac have not been rated, whereas celecoxib and etodolac are category C. NSAIDs are contraindicated during the third trimester because they may promote premature closure of the ductus arteriosus in the fetus.

NSAIDs are prone to drug interactions due to high protein binding, detrimental renal effects, and antiplatelet activity. Interactions are encountered frequently with aspirin, warfarin, oral hypoglycemics, antihypertensives, angiotensin-converting enzyme (ACE) inhibitors, angiotensin-receptor blockers (ARBs), β-blockers, diuretics, and lithium. When an interaction with an NSAID is present, vigilant monitoring is warranted for therapeutic efficacy (e.g., NSAIDs blunt the antihypertensive efficacy of diuretics) and adverse effects (e.g., NSAIDs increase the risk of bleeding in anticoagulated patients).

Selective COX-2 Inhibitors

Elucidation of the activities of individual COX isoforms led to the development of drugs that selectively inhibit the inducible form of the enzyme, COX-2. Thus COX-2 inhibitors were expected to minimize NSAID gastrointestinal toxicity and antiplatelet effects (see Fig. 55–3).[19] ❾ *A common misconception is that COX-2 inhibitors are more effective than nonselective NSAIDs in relieving pain and inflammation. In clinical trials, patients experienced similar levels of pain relief with COX-2 inhibitors and nonselective NSAIDs.*

Celecoxib is the only agent currently on the market that is a true COX-2-selective inhibitor. However, meloxicam, sulindac, and diclofenac also display preferential affinity for the COX-2 isozyme. Celecoxib reduces endoscopically detected gastrointestinal lesions; however, the clinical importance of this observation has been challenged because many of these lesions are clinically silent and resolve spontaneously. Celecoxib did not reduce the incidence of significant upper gastrointestinal toxicity compared with NSAIDs in a large clinical trial.[20] The selective agents rofecoxib (removed from the United States market in 2004) and lumiracoxib (in Phase III clinical trials at the time of this writing) decrease clinically important events such as perforations, ulcers, and bleeding.[21,22]

The advent of COX-2-selective inhibitors has led to unexpected results. ❾ *By selectively inhibiting the COX-2 isoform, COX-2-selective NSAIDs increase the risk of cardiovascular events in certain patients.*[23] COX-2 is responsible for the production of prostacyclin, a vasodilatory and antiplatelet substance. On the other hand, COX-1 controls the production of thromboxane A_2, a vasoconstrictor and platelet aggregator. Selective inhibition of COX-2 results in decreased prostacyclin levels in the face of stable thromboxane A_2 levels. An imbalance in the thromboxane A_2:prostacyclin ratio ensues, which creates an environment that favors thrombosis.

As a consequence, more selective inhibitors of the COX-2 enzyme may offer enhanced gastrointestinal safety but compromised cardiovascular safety. As shown in Fig. 55–4, when the

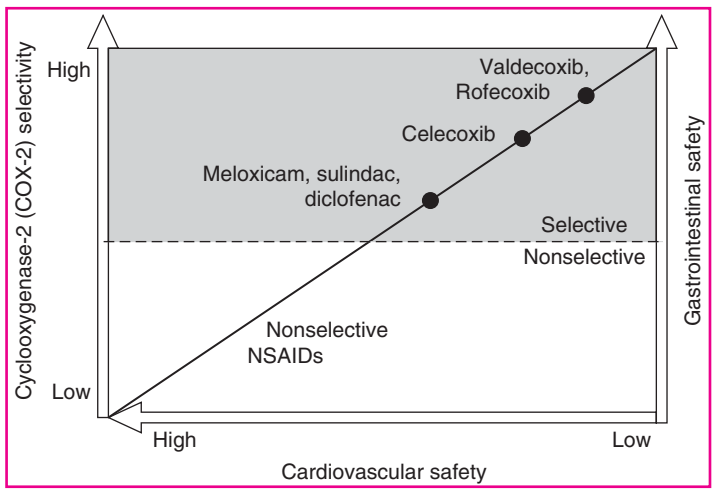

FIGURE 55–4. Relationship between COX-2 selectivity and cardiovascular and gastrointestinal safety. As NSAID selectivity for the COX-2 enzyme increases, cardiovascular safety decreases and gastrointestinal safety increases. Rofecoxib and valdecoxib are no longer available in the United States. Selectivities are approximations.

selectivity of NSAIDs increases, the risk of cardiovascular events appears to increase, whereas the risk of gastrointestinal toxicity declines. This relationship can be explained by the mechanism of theses drugs—greater selectivity results in a larger decrease in prostacyclin relative to thromboxane A_2 (favoring thrombosis) but also less gastrointestinal ulceration because of the greater preservation of mucosal protective factors.

Concomitant use of low-dose aspirin mitigates some of the increased cardiovascular risk but also obliterates the gastrointestinal safety of COX-2 selectivity.[21–23] Patients treated with a COX-2-selective agent plus aspirin experience gastrointestinal complications at a rate commensurate with that of patients given traditional nonselective agents. Use of less selective agents, such as meloxicam, to avoid cardiovascular concerns with COX-2 inhibitors may not be justified because neither gastrointestinal nor cardiovascular safety is optimized. In patients at risk for cardiovascular disease, a nonselective NSAID plus a proton pump inhibitor is a reasonable option.

The COX-2 enzyme is also produced normally in the kidney; thus COX-2 inhibitors exert renal effects similar to those of conventional NSAIDs. Both drug classes may increase sodium reabsorption and fluid retention and can provoke renal insufficiency and hyperkalemia. COX-2 inhibitors should be used with caution in patients with heart failure or hypertension.

COX-2 inhibitors are susceptible to the same drug interactions as nonselective agents. However, the interaction with warfarin is less pronounced because platelet function is affected to a lesser degree.

Glucosamine and Chondroitin

Glucosamine is believed to function as a "chondroprotective" agent, stimulating the cartilage matrix and protecting against oxidative chemical damage. Chondroitin is administered often in conjunction with glucosamine; it is thought to inhibit degradative enzymes and serve as a substrate for the production of proteoglycans. Numerous clinical trials have evaluated the efficacy of these substances for the treatment of OA; however, the quality of several of these studies has been questioned. ⓾ *In the context of such limitations, glucosamine and chondroitin reduce pain and improve mobility by 20% to 25%.*[24] *They also may slow disease progression by decreasing the rate of cartilage destruction, although the clinical impact of this effect is not clear.*[25] Glucosamine is not effective for treating acute pain; beneficial effects often mature over a period of weeks. Because these agents are loosely regulated in the United States as dietary supplements, product standards are inconsistent, and the constituents are not validated by any regulatory agency.

The landmark National Institutes of Health (NIH) study comparing glucosamine, chondroitin, glucosamine plus chondroitin, celecoxib, and placebo for OA was published recently.[26] Glucosamine, chondroitin, and their combination were no more effective than placebo in decreasing pain symptoms in 1583 patients with knee OA after 24 weeks. Celecoxib, however, was effective. In the subgroup of patients with moderate to severe OA pain, the combination of glucosamine and chondroitin appeared to have a moderate effect, although this subgroup analysis must be interpreted with caution. On the other hand, a European study (the GUIDE trial) that compared a prescription glucosamine product with acetaminophen and placebo in patients with knee OA reported that glucosamine performed better versus placebo than did acetaminophen.[27]

Interpretation of these results is challenging given the inconsistencies in study quality, differences in end points applied, preparations of glucosamine tested (glucosamine hydrochloride versus sulfate), and the comparator agents (celecoxib versus acetaminophen). Based on the available data, it appears that glucosamine and chondroitin may be effective for some patients with OA of the knee. Given the favorable safety profile of glucosamine and chondroitin, it is reasonable to present these agents as a treatment option to patients with symptomatic knee OA.

Intraarticular Therapy

⓾ *Intraarticular injection of corticosteroids or hyaluronan represents an alternative to oral agents for the treatment of joint pain.*[28] These modalities usually are reserved for patients unresponsive to other treatments because of the relative invasiveness of intraarticular injections compared with oral drugs, the small risk of infection, and the cost of the procedure.

Hyaluronan (or Hyaluronic Acid)

The mechanism of action of hyaluronan is not fully understood. Healthy cartilage is replete with hyaluronic acid, a viscous substance believed to facilitate lubrication and shock absorbency under varying conditions of load bearing. Patients with OA demonstrate an absolute and functional decline in hyaluronic acid; thus exogenous administration is referred to as *viscosupplementation.* In responders, the benefit of hyaluronan administration persists for periods that exceed its residence time in the synovium, suggesting that benefits beyond viscoelasticity are involved. Inhibition of inflammatory mediators and cartilage degradation, stimulation of the cartilage matrix, neuroprotective actions, and the ability of hyaluronan to induce its own synthesis may account in part for the benefit.

Pain and joint function have been evaluated frequently in clinical trials administering hyaluronan to patients with OA. Results are conflicting, with some suggesting dramatic improvements and others indicating no effect. In one controlled trial, hyaluronan injections relieved pain to a similar extent as oral NSAIDs.[29] Hyaluronan provides greater pain relief for a longer time than intraarticular corticosteroids, but corticosteroids work more rapidly.[29]

Several formulations of hyaluronan are available for the treatment of knee pain in patients with OA who are unresponsive to other measures. Administration typically consists of

weekly injections for 3 or 4 weeks and is well tolerated, although some patients may report local reactions. Rarely, postinjection flares and anaphylaxis have been reported. Intraarticular injection is associated with a low risk of infection (approximately 1 joint in 50,000 injections). Patients should be counseled to minimize activity and stress on the joint for several days after each injection.

Corticosteroids

Use of systemic corticosteroids is discouraged in patients with OA. 10 *However, in a subset of patients with an inflammatory component or knee effusion involving one or two joints, intraarticular corticosteroids can be useful as monotherapy or as an adjunct to analgesics.* The affected joint can be aspirated and subsequently injected with a corticosteroid. The aspirate should be examined for the presence of crystalline formation and infection. A single joint should not be injected more than three to five times per year.

The crystalline nature of corticosteroid suspensions can provoke a postinjection flare in some patients. The ensuing flare mimics the flare of arthritis and inflammation that accompanies infection; cold compresses and analgesics are recommended to treat symptoms in affected patients.

Tramadol

Use of opioid analgesics may be warranted when pain is unresponsive to other pharmacologic agents or when such agents are contraindicated. Tramadol is a centrally acting synthetic opioid oral analgesic that also weakly inhibits the reuptake of serotonin and norepinephrine. It is effective for the treatment of moderate pain but is devoid of anti-inflammatory activity. There is a low potential for abuse compared with conventional opioid analgesics. Surveillance of its abuse potential has failed to demonstrate a significant risk; therefore, tramadol is not scheduled as a controlled substance.

Tramadol is a reasonable option for patients with contraindications to NSAIDs or failure to respond to other oral therapies. 10 *For the treatment of hip or knee OA, tramadol is as effective as NSAIDs. The addition of tramadol to NSAIDs or acetaminophen may augment the analgesic effects of a failing regimen, thereby securing sufficient pain relief in some patients.* Moreover, concomitant tramadol may permit the use of lower NSAID doses.

Dizziness, vertigo, nausea, vomiting, constipation, and lethargy are all relatively common adverse events. These effects are more pronounced for several days after initiation and following upward dose titration. Seizures have been reported rarely; the risk is dose-related and appears to increase with concomitant use of antidepressants, such as tricyclic antidepressants or selective serotonin reuptake inhibitors. Tramadol should be avoided in patients receiving monoamine oxidase (MAO) inhibitors because tramadol inhibits the uptake of norepinephrine and serotonin.

Other Opioid Analgesics

Use of traditional opioid analgesics for nonmalignant pain is becoming more acceptable. Emerging evidence suggests that patients can achieve satisfactory analgesia by using nonescalating doses of opioids with a minimal risk of addiction.[30] Opioid analgesics should be reserved for patients who experience moderate to severe pain and do not respond to or are not candidates for other pharmacologic and nonpharmacologic strategies. These agents also may be useful in patients with conditions that preclude the use of NSAIDs, such as renal failure, heart failure, or anticoagulation. The APS and the American Academy of Pain Medicine (AAPM) support the use of opioids in the management of chronic nonmalignant pain when other management strategies fail.[31] Opioid analgesics should be initiated at low doses in combination with acetaminophen or an NSAID when possible. Combining opioids with other analgesics reduces the opioid requirement, thereby minimizing adverse events.

Few studies have explored the efficacy of opioids specifically for OA. The APS recommends against the use of codeine and propoxyphene for OA because of the high incidence of adverse effects and limited analgesic effectiveness. Oxycodone is the most extensively studied of the agents recommended for OA. However, other narcotic analgesics such as morphine, hydromorphone, methadone, and transdermal fentanyl are also effective.

Narcotic analgesics decrease pain, improve sleep patterns, and increase functioning in patients with OA who are unresponsive to nonpharmacologic therapy and nonnarcotic analgesics. Conservative initial doses are warranted, with the dose titrated to adequate response.

Such an approach should include an initial comprehensive medical history and physical examination, firm documentation that nonopioid therapy has failed, clearly defined treatment goals, an understanding between the provider and the patient of the true benefits and pitfalls of long-term opioids, use of a single provider and pharmacy whenever possible, and comprehensive follow-up.

Topical Analgesics

Topical analgesics sometimes are used for mild pain or as an adjunct to systemic therapy. There are limited data to support the use of salicylate-containing **rubefacients** (e.g., methyl salicylate and trolamine salicylate) or other **counterirritants** (e.g., menthol, camphor, and methyl nicotinate) in OA.[32] See Chap. 57 for more information on these products when used for musculoskeletal disorders.

Capsaicin achieves pain relief by depleting substance P from sensory neurons in the spine, thereby decreasing pain transmission. Capsaicin is not effective for acute pain; up to 2 weeks may be necessary before pain relief is appreciated. Most patients experience a local burning sensation at the site of application. The discomfort usually does not result in

Patient Encounter, Part 2: The Medical History, Physical Examination, and Diagnostic Tests

PMH
- Obesity (BMI = 34 kg/m^2)
- Hypertension for 7 years
- Type 2 diabetes mellitus
- Hyperlipidemia, currently at goal
- Gastroesophageal reflux disease (GERD)

FH
Father died of stroke at age 72; mother had OA of the hands.

SH
Works as a secretary. Denies alcohol, tobacco, and illicit drug use.

Meds
- Hydrochlorothiazide 12.5 mg once daily
- Enalapril 10 mg twice daily
- Metformin 1000 mg twice daily
- Atorvastatin 10 mg once daily
- Pantoprazole 40 mg every morning
- Enteric-coated aspirin 81 mg once daily
- Ibuprofen 200 mg prn for pain

Labs
Within normal limits.

Radiology: Radiography of the affected knee shows joint-space narrowing and subchondral bone sclerosis.

- Which parameters are consistent with a diagnosis of OA?
- What are the treatment goals for this patient?
- What pharmacologic and nonpharmacologic options are available to treat this patient?
- What factors are important to consider when selecting medications for this patient?

discontinuation and often abates within the first week. Patients should be cautioned not to allow capsaicin to come into contact with eyes or mucous membranes and to wash their hands after each application.

Topical NSAID preparations are used infrequently in North America. Theoretically, administration via a topical vehicle targets the joints involved and decreases systemic exposure. Randomized, controlled trials, typically of less than 4 weeks' duration, have suggested that topical NSAIDs are superior to placebo in relieving OA pain in the first 2 weeks of treatment, but the effect may decline over time.[33] Moreover, data are lacking to quantify the theoretical safety advantage of administering NSAIDs topically.

Surgery

⓾ *Surgery generally is reserved for patients who fail to respond to medical therapy and have progressive limitations in activities of daily living (ADL).* These patients should be referred to an orthopedic surgeon for evaluation. Most patients achieve substantial pain relief and functional restoration following total-joint arthroplasty.[34]

Patient Encounter, Part 3: Creating a Care Plan

Based on the information available, create a care plan for this patient's OA. The plan should include (1) the goals of therapy, (2) an individualized, detailed therapeutic plan, and (3) a plan for follow-up monitoring to document the patient's response and identify adverse reactions.

OUTCOME EVALUATION

- At baseline, quantify the patient's pain using a visual analogue scale, assess range of motion of affected joints, and identify activities of daily living that are impaired.
- In patients treated with acetaminophen or NSAIDs, assess pain control after 2 to 3 weeks. It may take longer for the full anti-inflammatory effect of NSAIDs to occur.
- Incorporate other measures to track disease progress. Use radiography to assess severity of joint destruction, determine 50-ft walking time and grip strength, and administer the Western Ontario and McMaster University Osteoarthritis Index (WOMAC) and the Stanford Health Assessment Questionnaire, where appropriate, to assess activities of daily living.
- Ask patients if they are experiencing side effects or other problems with their medications and follow up with more specific questions.
- In patients taking NSAIDs, monitor for increases in blood pressure, weight gain, edema, skin rash, and central nervous system adverse effects such as headaches and drowsiness.
- Evaluate serum creatinine, complete blood count, and serum tranasaminases at baseline and every 6 to 12 months in patients treated with NSAIDs or acetaminophen.
- Perform stool guaiac in patients taking NSAIDs when clinically indicated.
- Monitor for drug interactions, including alcohol, at every visit.

Patient Care and Monitoring

1. Determine whether the patient's symptoms are consistent with OA. Review the patient's medical history to determine whether other rheumatologic diseases may be involved.
2. Assess symptoms to determine if pain warrants additional attention. Does the pain affect quality of life or interfere with activities of daily living?
3. Evaluate symptoms to determine what nonpharmacologic interventions can be recommended and whether pharmacologic treatment is warranted.
4. Obtain a thorough history of previous drug use, including prescription drugs, over-the-counter drugs, and dietary supplement products. Determine whether any of these treatments have been effective. Ask the patient about the dose and frequency of previous pharmacologic agents to determine if an adequate trial was given.
5. Educate the patient about appropriate use of nonpharmacologic treatments for OA.
6. Formulate a drug therapy plan, taking into consideration the patient's medical history, concomitant medications, and previous use of medications.
7. Develop a plan to monitor the patient's response to therapy.
8. Evaluate for the presence of adverse drug reactions, drug hypersensitivity, and drug interactions.
9. Document whether the patient has had improvements in quality-of-life measures, such as improved functioning, increased ability to perform activities of daily living, and improved well-being.
10. Emphasize the value of adherence to medication regimens and lifestyle modifications. Facilitate adherence by implementing medication regimens and lifestyle plans that are simple and consistent with the patient's lifestyle.
11. Educate the patient about OA, lifestyle modifications, and medications:
    - What causes OA?
    - How will lifestyle modifications affect the disease?
    - What are the expectations of treatment?
    - When and how should medications be taken?
    - What adverse effects are most common, do they decrease during therapy, and what are the warning signs of more severe complications?
    - What prescription and over-the-counter medications should be avoided to prevent drug-drug, drug-food, or drug-disease interactions?
    - What options are available if the current regimen fails?

56 Gout and Hyperuricemia

Geoffrey C. Wall

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Recognize major risk factors for developing gout in a given person.
2. Develop a pharmacotherapeutic plan for a patient with acute gouty arthritis or uric acid nephropathy that includes individualized drug selection and monitoring for efficacy and safety.
3. Identify patients in whom maintenance therapy for gout and hyperuricemia is warranted.
4. Select an appropriate drug to reduce serum uric acid levels in patients with gout, and outline a plan for monitoring efficacy and toxicity.
5. Educate patients on appropriate lifestyle modifications to help prevent gouty arthritis attacks.

Key Concepts

❶ Gout results from deposition of uric acid crystals in joint spaces, leading to an inflammatory reaction that causes intense pain, erythema, and joint swelling.

❷ Some drugs can cause hyperuricemia and gout, such as thiazide diuretics, niacin, pyrazinamide, cyclosporine, and occasionally, low-dose aspirin.

❸ Long-term consequences of gout and hyperuricemia include joint destruction, tophi, and nephrolithiasis.

❹ Treatment of gout involves (1) acute relief of a gouty arthritis attack and (2) in some patients long-term maintenance treatment to prevent future attacks.

❺ Nonsteroidal anti-inflammatory drugs, colchicine, or corticosteroids are used for acute attacks. Selection depends on several patient factors, especially renal function.

❻ Asymptomatic hyperuricemia usually does not require treatment.

❼ Patients with recurrent attacks, evidence of tophi or joint destruction, or uric acid nephrolithiasis are candidates for maintenance therapy with allopurinol or probenecid to lower serum uric acid levels.

EPIDEMIOLOGY AND ETIOLOGY

Gout is the most common inflammatory arthritis in the United States and western Europe. The annual incidence is approximately 62 cases per 100,000 persons in the United States. The incidence increases with age and appears to be rising probably because of a larger number of patients with risk factors for gout.

PATHOPHYSIOLOGY

Gout is caused by an abnormality in uric acid metabolism. Uric acid is a waste product of the breakdown of purines contained in the DNA of degraded body cells and dietary protein. Uric acid is water soluble and excreted primarily by the kidneys, although some is broken down by colonic bacteria and excreted via the gastrointestinal tract.

The solubility of uric acid depends on concentration and temperature. At high serum concentrations, lower body temperature causes the precipitation of **monosodium urate** crystals. Collections of these crystals (called **microtophi**) can form in joint spaces in the distal extremities.

❶ *Gout results from deposition of uric acid crystals in joint spaces, leading to an inflammatory reaction that causes intense pain, erythema, and joint swelling.* Free urate crystals can activate several proinflammatory mediators, including tumor necrosis factor α (TNF-α), interleukin 1 (IL-1), and IL-8. Activation of these mediators signals chemotactic movement of neutrophils into the joint space that "ingest" monosodium urate crystals via phagocytosis. These neutrophils then are lysed and release proteolytic enzymes that trigger the clinical manifestations of an acute gout attack such as pain and swelling. These inflammatory mechanisms in gout, especially in untreated disease, can lead to cartilage and joint destruction (Fig. 56–1).

The increased serum uric acid involves either the underexcretion of uric acid (80% of patients) or its overproduction. The cause of overproduction or underexcretion of uric acid in

FIGURE 56–1. Synovial fluid containing extracellular and intracellular monosodium urate crystals. (From Reginato AJ. Gout and other crystal arthropathies. In: Braunwald E, Fauci AS, Kasper DI, et al, (eds.) Harrison's Principles of Internal Medicine. 15th ed. New York: McGraw-Hill; 2001, Figure 322–1.)

most gout patients is unknown; this is referred to as *primary gout.*

The risk of gout increases as the serum uric acid concentration increases, and approximately 30% of patients with levels greater than 10 mg/dL (greater than 595 μmol/L) develop symptoms of gout within 5 years. However, most patients with hyperuricemia are asymptomatic. Other risk factors for gout include obesity, ethanol use, and dyslipidemia. Gout is seen frequently in patients with type 2 diabetes mellitus and coronary artery disease, but a causal relationship has not been established.

Uric acid excretion is reduced in patients with chronic kidney disease, putting them at risk for hyperuricemia. In patients with persistently acidic urine and hyperuricemia, uric acid **nephrolithiasis** can occur in up to 25% of patients; in severe cases, uric acid stones can cause nephropathy and renal failure. Extreme hyperuricemia can occur because of rapid tumor cell destruction in patients undergoing chemotherapy for certain types of cancer (see Chap. 85).

❷ *Some drugs can cause hyperuricemia and gout, such as thiazide diuretics, niacin, pyrazinamide, cyclosporine, and occasionally, low-dose aspirin.* In most cases, these drugs block uric acid secretion in the kidney. ❸ *Long-term consequences of gout and hyperuricemia include joint destruction, tophi, and nephrolithiasis.*

CLINICAL PRESENTATION AND DIAGNOSIS

Presentation of Acute Gouty Arthritis

General

Patients are usually in acute distress.

Symptoms

- Severe pain, swelling, and warmth in the affected joint(s)
- The attack is usually monarticular, and the most common sites are the metatarsophalangeal and knee joints.
- In elderly patients, gouty attacks may be atypical with insidious onset and polyarticular, often involving hand or wrist joints.

Signs

- Affected joint(s) are warm, erythematous, and swollen.
- Mild fever may be present.
- Tophi (usually on hands, wrists, elbows, or knees) may be present in chronic, severe disease.

Laboratory Tests

- The white blood cell (WBC) count in peripheral blood may be only mildly elevated.
- The serum uric acid level often is elevated but may be normal during an acute attack.
- Other laboratory markers of inflammation [e.g., increased erythrocyte sedimentation rate (ESR)] are often present.

Diagnosis

Aspiration of affected joint fluid is essential for a definitive diagnosis. Joint fluid containing negatively birefringent monosodium urate crystals confirms the diagnosis. Joint fluid has an elevated WBC count with neutrophils predominating.

Although rarely performed, a 24-hour urine collection can be obtained to determine if the patient is an overproducer or an underexcretor of uric acid. Individuals who excrete more than 800 mg of uric acid in this collection are considered overproducers. Patients with hyperuricemia who excrete less than 600 mg/day are classified as underexcretors of uric acid.

Radiographs of affected joints may have characteristic appearances of gout, including cystic changes, punched-out lytic lesions with overhanging bony edges, and soft-tissue calcified masses. These signs may appear in other arthropathies as well.

TREATMENT

❹ *Treatment of gout involves (1) acute relief of a gouty arthritis attack and (2) in some patients long-term maintenance treatment to prevent future attacks.*

Desired Outcomes

The goals of therapy of an acute attack are (1) achieving rapid and effective pain relief, (2) maintaining joint function, (3) preventing disease complications, (4) avoiding treatment-related adverse effects, (5) providing cost-effective therapy, and (6) improving quality of life. Infrequent gouty arthritis is a self-limited disease, and treatment usually focuses on symptom relief.

Nonpharmacologic Therapy

Nondrug modalities play an adjunctive role and usually are not effective when used alone. Immobilization of the affected extremity speeds resolution of the attack. Applying ice packs to the joint also decreases pain and swelling, but heat application may be detrimental.

Pharmacologic Therapy

❺ *Nonsteroidal anti-inflammatory drugs (NSAIDs), colchicine, and corticosteroids are used for acute attacks. Selection depends on several patient factors, especially renal function* (Fig. 56–2). Each drug class has a unique safety and efficacy profile in gout that should be considered carefully before choosing a specific agent (Table 56–1). Generally, the earlier in the course of the arthritic attack these agents are employed, the better the outcome.

Nonsteroidal Anti-Inflammatory Drugs

The NSAIDs largely have supplanted colchicine as the treatment of choice, and many NSAIDs have been used successfully. These agents are most effective when given within the first 24 hours of the onset of pain. Most studies have shown similar results among agents, and all NSAIDs are considered to be effective. Doses at the higher end of the therapeutic range are often needed.

Indomethacin was used traditionally, but its relative cyclooxygenase-1 (COX-1) selectivity theoretically increases its gastropathy risk. Thus other generic NSAIDs may be preferred. Adverse effects of NSAIDs include gastropathy (primarily peptic ulcers), renal dysfunction, and fluid retention. NSAIDs generally should be avoided in patients at risk for peptic ulcers, those taking warfarin, and those with renal insufficiency or uncontrolled hypertension or heart failure.

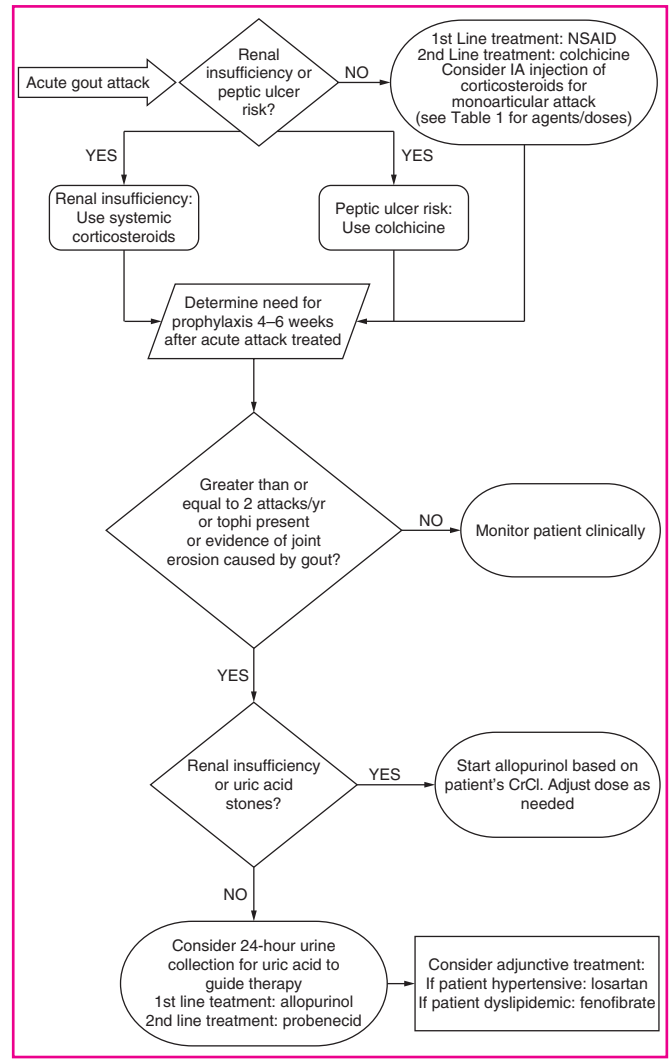

FIGURE 56–2. Treatment algorithm for gout and hyperuricemia. Renal insufficiency is defined as an estimated creatinine clearance (CrCl) of less than 30 mL/minute. IA, Intraarticular; NSAID, nonsteroidal anti-inflammatory drug.

Cyclooxygenase-2 (COX-2)–selective inhibitors produce results comparable with those of traditional NSAIDs. However, cardiovascular safety concerns and the high cost of COX-2 inhibitors argue against their use for this disorder.

Colchicine

Colchicine has a long history of successful use and was the treatment of choice for many years. It is used infrequently today because of its low therapeutic index. Colchicine is thought to exert its anti-inflammatory effects by interfering with the function of mitotic spindles in neutrophils by binding of tubulin dimers; this inhibits phagocytic activity.

Oral colchicine is absorbed rapidly from the gastrointestinal tract and metabolized extensively in the liver.

TABLE 56–1. Dosage Regimens for Acute Gout and Antihyperuricemic Treatment

Drug	Dose
Drugs for Treatment of Acute Gout	
NSAIDs[a]	
Fenoprofen	800 mg PO q 6 hour
Flurbiprofen	100 mg PO qid for 1 day, then 50 mg PO qid
Ibuprofen	600 to 800 mg PO qid
Indomethacin*	150–200 mg PO daily (in 3 divided doses) for three days, then 100 mg PO daily (in 2 divided doses) for 4 to 7 days
Indomethacin*	50 mg PO tid
Ketoprofen	50 mg PO qid or 75 mg PO tid
Meclofenamate	100 mg PO tid to qid
Naproxen*	1000 mg daily × 3 days, then 500 mg daily × 7 days *or* 750 mg PO initially, then 250 mg PO q8h
Piroxicam	40 mg PO once daily
Sulindac*	200 mg bid × 7 to 10 days
Tolmetin	400 mg PO tid to qid
Celecoxib	200 mg PO bid
Meloxicam	7.5–15 mg PO once daily
Colchicine	0.6 mg PO every hour for up to 3 doses, then 0.6 mg 1–2 times daily if desired before antihyperuricemic therapy is started; may occasionally use in low doses for prophylaxis; avoid the intravenous formulation
Local corticosteroids	
Methylprednisolone	10–40 mg × 1 dose by intraarticular injection
Systemic corticosteroids	
Prednisone (example)	40–60 mg PO once daily × 3 days, then decrease by 10 mg every 3 days
Triamcinolone acetonide	60 mg × 1 dose by intramuscular injection
Antihyperuricemic Treatment	
Allopurinol	Starting dose: CrCl greater than 90 mL/minute = 300 mg/day CrCl 60–90 mL/minute = 200 mg/day CrCl 30–60 mL/minute = 100 mg/day CrCl less than 30 mL/minute = 50 mg/day Adjust dosage based on follow-up uric acid levels; maximum 800 mg/day
Probenecid	Starting dose 250 mg PO bid; may increase to 1000 mg PO bid

[a]Drugs that are FDA approved for treatment of gout are indicated with an asterisk.
NSAIDs, nonsteroidal anti-inflammatory drugs; CrCl, creatinine clearance.

About two-thirds of patients with acute gout respond favorably if it is given within the first 24 hours of symptom onset. Unfortunately, more than 80% of patients experience adverse effects. Gastrointestinal effects (e.g., nausea, vomiting, diarrhea, and abdominal pain) are most common and are considered a forerunner of more serious systemic toxicity, including myopathy and bone marrow suppression (usually neutropenia). Some clinicians still use the strategy of continuous dosing until either pain relief or gastrointestinal side effects occur. However, systemic toxicity can occur with oral colchicine without prior gastrointestinal effects, especially in patients with renal insufficiency. Because of these problems, oral colchicine should be reserved for patients who are at risk for NSAID-induced gastropathy or who have failed NSAID therapy.

Use of intravenous colchicine to circumvent adverse gastrointestinal effects is discouraged due to the increased risk of serious and potentially fatal systemic effects with this route. The intravenous form should not be used in patients with moderate or more severe renal impairment (creatinine clearance less than or equal to 50 mL/minute), and total doses should not exceed 4 mg in a 7-day period. The potential extravasation of intravenous colchicine is also a concern.

Corticosteroids

When only one or two joints are affected, **intraarticular** corticosteroid injection can provide rapid relief with a relatively

Patient Encounter, Part 1

A 48-year-old man with a history of hypertension, peptic ulcer disease (gastric ulcer 1 year ago), and morbid obesity presents to the emergency department complaining of excruciating pain in his left big toe and both ankles. This is similar to a painful episode he had with his left toe and ankle 6 months ago. On examination, his left great toe and both ankles are red, swollen, and warm to the touch. He describes the pain as throbbing and rates it as a 10 of 10 (where 10 is the worse pain he has ever experienced). He admits to drinking a six-pack of beer on weekends. He weighs 150 kg (330 lbs) and is 5 ft, 9 in (175 cm) tall. Medications include chlorthalidone 25 mg/day and pantoprazole 40 mg/day. Serum creatinine is 1.0 mg/dL (88.4 µmol/L).

- What information suggests gout as the cause of his symptoms?
- What risk factors for gout does he have?
- If the diagnosis is an acute attack of gouty arthritis, what treatment plan would you outline for this patient?

low incidence of side effects. Joint fluid obtained by **arthrocentesis** should be examined for evidence of joint-space infection and crystal identification. If no infection is present, intraarticular injection can proceed.

Systemic corticosteroids are a useful option in patients with contraindications to NSAIDs or colchicine (primarily renal impairment) or polyarticular attacks, especially in elderly patients. A single intramuscular injection of a long-acting corticosteroid such as triamcinolone hexacetonide may be used. Oral agents may be needed, especially for severe attacks. Prednisone 40 to 60 mg (or an equivalent dose of another agent) is given daily, with a gradual taper over 2 weeks.

Too rapid tapering of corticosteroids can cause a rebound gouty flare. To prevent this flare, low-dose colchicine (0.6 mg PO daily) sometimes is added to systemic corticosteroid regimens. This is probably unnecessary if an adequate taper is prescribed.

Short-term adverse effects from corticosteroids include fluid retention, hyperglycemia, central nervous system stimulation, weight gain, and increased risk of infection. Patients with diabetes should have blood glucose levels monitored carefully during the corticosteroid course.

Corticotropin [adrenocorticotropic hormone (ACTH)] has been used for acute gouty flares. Worldwide supply problems and the possible superiority of traditional corticosteroids have resulted in decreased use.

ANTIHYPERURICEMIC GOUT PROPHYLAXIS

Gout is an episodic disease, and the number of attacks varies widely from patient to patient. Thus the benefit of long-term prophylaxis against acute gout flares must be weighed against the cost and potential toxicity of therapy that may not be necessary in all patients. ❻ *Asymptomatic hyperuricemia usually does not require treatment.*

Nonpharmacologic Therapy

Lifestyle modifications alone usually are insufficient for lowering serum uric acid levels in gout patients. Patients should be advised to lose weight if obese and to discontinue ethanol consumption. Low-purine diets are not well tolerated; instead, dietary recommendations should focus on general nutrition principles. Drugs that may cause or aggravate hyperuricemia should be discontinued if possible. Few patients adhere to lifestyle modifications long term, and pharmacologic therapy usually is needed to treat hyperuricemia adequately.

Pharmacologic Therapy

❼ *Patients with recurrent attacks, evidence of tophi or joint destruction, or uric acid nephrolithiasis are candidates for maintenance therapy with allopurinol or probenecid to lower serum uric acid level*s. Because hyperuricemia is the strongest modifiable risk factor for acute gout, prophylactic therapy involves either decreasing uric acid production or increasing its excretion (see Table 56–1). The goal of therapy is to decrease serum uric acid levels significantly, leaving less uric acid available for conversion to monosodium urate crystals.

Ideally, the selection of long-term prophylactic therapy involves determining the cause of hyperuricemia (primarily by analyzing a 24-hour urine collection for uric acid) and tailoring therapy appropriately. If less than 600 mg of uric acid is found in the 24-hour sample, the patient is considered an underexcretor. However, this approach is not used commonly for several reasons. The urine collection is inconvenient for patients and clinicians and does not identify patients who may be both overproducers and underexcretors of uric acid. Also, drugs used to increase uric acid excretion (**uricosurics**) generally are not as well tolerated as drugs that decrease production, and uricosurics increase the risk of uric acid nephrolithiasis.

Because allopurinol (which reduces uric acid production) is effective in both overproducers and underexcretors and is generally well tolerated, many clinicians forgo the 24-hour urine collection and treat patients empirically with it.

Allopurinol

Most patients in the United States are treated with allopurinol, which usually is effective if the dosage is titrated appropriately. The drug and its primary active metabolite, oxypurinol, reduce serum uric acid concentrations by inhibiting the enzyme xanthine oxidase, thereby blocking the oxidation of hypoxanthine and xanthine to uric acid.

Allopurinol is well absorbed with a short half-life of 2 to 3 hours. The half-life of oxypurinol approaches 24 hours, allowing allopurinol to be dosed once daily. Oxypurinol is cleared primarily renally and can accumulate in patients with reduced kidney function. Allopurinol should not be started during an acute gout attack because sudden shifts in serum uric acid levels may precipitate or exacerbate gouty arthritis. Rapid shifts in serum uric acid can change the concentration of monosodium urate crystals in synovial fluid, causing more crystals to precipitate. Thus some clinicians advocate a prophylactic dose of colchicine (0.6 mg/day) during initiation of antihyperuricemic therapy. Acute episodes should be treated appropriately before maintenance treatment is started.

The initial dose of allopurinol is based on the patient's renal function. Patients with creatinine clearances of 50 mL/minute or less should receive a starting dose of less than 300 mg/day to minimize adverse effects. The relationship between dose of allopurinol and its most severe side effects is controversial. However, the dose can be adjusted upward as needed and tolerated. It is reasonable to reduce the dose temporarily in patients who develop reversible acute renal failure.

Serum uric acid levels must be monitored periodically, with the first follow-up level obtained 6 months (or sooner) after starting therapy. The target serum uric acid level is less than 6 mg/dL (less than 357 µmol/L). The dose should be titrated upward (to a maximum of 800 mg/day) or downward as these levels dictate.

Allopurinol generally is well tolerated; nausea and diarrhea occur in a small percentage of patients. A generalized, maculopapular rash occurs in about 2% of patients. Although usually mild, this can progress to severe skin reactions such as Stevens-Johnson syndrome. Perhaps the most feared side effect is the so-called allopurinol hypersensitivity syndrome. This constellation of signs and symptoms includes severe desquamating skin lesions, high fever (usually greater than 39°C or 102.2°F), hepatic dysfunction, leukocytosis with predominant eosinophilia, and renal failure. Although rare, this severe reaction has a 20% mortality rate. Patients with a history of the syndrome should never again receive allopurinol (including desensitization) or oxypurinol (which is available outside the United States). Patients with a mild skin rash who require allopurinol can be desensitized to it using published protocols.

There are several important drug-drug interactions with allopurinol. The effects of both theophylline and warfarin may be potentiated by allopurinol. Azathioprine and 6-mercaptopurine are purines whose metabolism is inhibited by concomitant allopurinol therapy; the dose of these drugs must be reduced by 75% with allopurinol cotherapy. Patients taking allopurinol who receive ampicillin are at increased risk of skin rashes.

Probenecid

Probenecid is a uricosuric agent that blocks the tubular reabsorption of uric acid, increasing its excretion. Because of its mechanism of action, probenecid is contraindicated in patients with a history of uric acid stones or nephropathy. Probenecid loses its effectiveness as renal function declines and should be avoided when the creatinine clearance is 50 mL/minute or less. Its uricosuric effect is counteracted by low aspirin doses, which many patients receive for prophylaxis of coronary heart disease.

Although generally well tolerated, probenecid can cause gastrointestinal side effects such as nausea and other adverse reactions, including fever, rash, and rarely, hepatic toxicity. Patients should be instructed to maintain an adequate fluid intake and urine output to decrease the risk of uric acid stone formation. Some experts advocate alkalinizing the urine to decrease this risk.

Other Uricosuric Agents

Sulfinpyrazone was used in the past but is no longer available in the United States. Several other medications have

Patient Encounter, Part 2

The patient returns for a follow-up visit at your clinic 6 weeks later. He reports no pain or swelling in the joints affected previously. The emergency room doctor had instructed him to stop the chlorthalidone, so he is currently taking only pantoprazole.

PE

- **VS:** 164/84, P 72, RR 15, T 37.2°C (99°F)
- **Exts:** Trace edema in both ankles.

Labs

- Serum uric acid 11.5 mg/dL (684 µmol/L)
- Serum creatinine 0.9 mg/dL (79.6 µmol/L).
- Uric acid crystals were identified on arthrocentesis of the ankle 6 weeks ago.

- Given this additional information, what is your assessment of the patient's condition?
- Is the patient a candidate for antihyperuricemic therapy? If so, which agent would you choose?
- What nonpharmacologic recommendations do you have for the patient?
- What do you suggest for treating the patient's hypertension?

mild uricosuric effects and may be appropriate adjunctive therapy in some patients. Losartan increases both uric acid excretion and urine pH and may be an option in hypertensive patients with gout. Fenofibrate is also a uricosuric and may be appropriate in selected dyslipidemic patients with gout. New agents undergoing investigation for hyperuricemia include febuxostat and polyethylene glycol–bonded uricase.

OUTCOME EVALUATION

Acute Gout

- Monitor the patient for pain relief and decreased swelling of the affected joints. Both parameters should be improved significantly within 48 hours of starting acute gout therapy.
- Assess the patient's subjective complaints and objective information for adverse effects. For NSAID therapy, be alert for new-onset epigastric pain, dark or tarry stools, blood in vomitus, dizziness or light-headedness, development of edema, decreased urine output by more than 50% over a 24-hour period, or shortness of breath. For colchicine, monitor for nausea or vomiting, diarrhea, easy bruising, cold or flulike symptoms, light-headedness, muscle weakness, or pain. Counsel the patient to inform you of any new medications started or stopped while taking colchicine.
- Monitor patients receiving intraarticular corticosteroid injections for increased swelling or pain at the injection site.
- Assess patients receiving systemic corticosteroids for mental status changes, fluid retention, increased blood glucose, muscle weakness, or development of new infections.

Antihyperuricemic Therapy

- Assess for new gouty arthritis attacks or the development of tophi. If neither one develops, continue antihyperuricemic therapy as prescribed.
- Obtain the first follow-up serum uric acid level within 6 months of starting therapy. Then monitor levels at least every 6 to 12 months, and adjust the dose to achieve a target serum uric acid level of less than 6 mg/dL (less than 357 μmol/L).
- Evaluate patients taking allopurinol for development of rash, nausea, or new fever. These symptoms usually appear within the first 3 months of therapy but can occur anytime.
- Assess patients receiving probenecid for fever, nausea, or skin rash. Reevaluate therapy if a significant decrease in urine output occurs (greater than 50% in a 24-hour period).

Patient Care and Monitoring

1. Assess the patient's symptoms to determine the time of attack onset, which joints are affected, the level of pain, and other symptoms.
2. Review the patient history for contributing lifestyle factors and other disease states that may help guide therapy.
3. Obtain a thorough medication history for prescription drug, nonprescription drug, and dietary supplement use. Determine if any of these products may be contributing to hyperuricemia.
4. Educate the patient on lifestyle modifications that will improve symptoms, including weight loss, if appropriate, and avoidance of ethanol.
5. If the diagnosis of gout has not been confirmed previously, consider aspiration of an affected joint to identify uric acid crystals.
6. Initiate therapy to treat the acute gout attack without delay. Develop a plan to assess this therapy after 24 and 48 hours.
7. Select therapy based on comorbidities and potential for adverse effects. In patients with no other disease states, NSAIDs are the preferred drug class.
8. Assess the need for continuous antihyperuricemic therapy. Use patient factors such as comorbidities to select an agent. Allopurinol is the standard prophylactic agent used in the United States.
9. Do not start antihyperuricemic therapy within 4 weeks of an acute attack.
10. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.
11. Stress the importance of adherence with the therapeutic regimen, including lifestyle modifications, to prevent future gout attacks and long-term complications.
12. Provide patient education about the disease state, lifestyle modifications, and drug therapy.

57 Musculoskeletal Disorders

Jill S. Burkiewicz

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiologic principles associated with tissue injury and inflammation.
2. Identify the desired therapeutic goals and outcomes for a patient with musculoskeletal injury or pain.
3. Identify the factors that guide selection of an analgesic or counterirritant for a particular patient.
4. Recommend appropriate nonpharmacologic and pharmacologic therapy for a patient with musculoskeletal injury or pain.
5. Design a patient education plan including nonpharmacologic therapy and preventative strategies.
6. Develop a monitoring plan to assess treatment of a patient with musculoskeletal disorders.

Key Concepts

❶ The two primary goals of treatment of musculoskeletal disorders are to (1) relieve pain and (2) maintain functionality.
❷ The cornerstone of nonpharmacologic therapy for acute injury in the first 48 to 72 hours is known by the acronym *RICE: r*est, *i*ce, *c*ompression, and *e*levation.
❸ Heat should not be applied during the acute injury phase (the first 48 hours) because it promotes swelling and inflammation.
❹ There are two main approaches to pharmacologic intervention for pain relief: oral (systemic) and topical agents.
❺ Localized pain may be treated effectively with local topical therapy, whereas generalized pain may be treated best with systemic agents.
❻ Acetaminophen is the drug of choice for mild to moderate regional musculoskeletal pain without inflammation.
❼ Aspirin has not been demonstrated to be more effective than acetaminophen, and because its safety profile may be inferior it is not recommended for treatment of acute musculoskeletal pain.
❼ NSAIDs are a preferred choice over acetaminophen in musculoskeletal disorders where inflammation is evident.
❽ Patient education on proper use of counterirritants is essential to therapeutic success.
❿ Patients using capsaicin should be advised to apply it regularly and consistently three to four times daily and that full effect may take 2 to 3 weeks or longer.

The musculoskeletal system consists of the muscles, bones, joints, tendons, and ligaments. Disorders related to the musculoskeletal system often are classified by etiology. Acute soft-tissue injuries include strains and sprains of muscles and ligaments. Repeated movements in sports, exercise, work, or activities of daily living may lead to repetitive strain injury, where cumulative damage occurs to the muscles, ligaments, or tendons.[1–3] While tendonitis and bursitis can arise from acute injury, more commonly these conditions occur as a result of chronic stress.[3,4] Other forms of chronic musculoskeletal pain, such as pain from rheumatoid arthritis (see Chap. 54) or osteoarthritis (see Chap. 55), are discussed elsewhere in this text.

EPIDEMIOLOGY

Musculoskeletal disorders are commonly self-treated, so true estimates of the incidence of both acute and chronic injury are difficult to obtain. Musculoskeletal disorders, including arthritis, are among the most frequently reported health problems in the United States.[5] These disorders account for a large portion of the utilization of health care resources and are the leading cause of work-related disability in all ages, including Americans aged 65 and over.

In addition to chronic conditions such as arthritis and low-back pain, some musculoskeletal disorders are induced by

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

trauma at the workplace either via repetition and cumulative trauma or owing to a single strain.[6,7] For each reported disorder, it is likely that there are at least 10 unreported work-related musculoskeletal disorders related to repetitive stress to the bones and joints.[8] In the elderly, these injuries may not be related to work but to daily life. Instability combined with activities of daily living such as stair climbing and lifting objects may lead to strains and sprains.[2]

Muscle injuries comprise the majority of sports-related injuries, and roughly half are related to overuse.[3,9,10] The ankle and the knee are common sites of sports injuries.[11,12] Soccer, football, basketball, track and field, and other sports that require rapid acceleration or higher speeds pose a greater risk of muscle strain.[13] *Overuse musculoskeletal injury* is the phrase used to describe disorders arising from repetitive motion. This injury is common in activities such as running, particularly during periods of increased intensity or duration of training.[3] It also can occur in the workplace with repeated, unvaried motion.[14]

PATHOPHYSIOLOGY

Skeletal muscle consists of muscle fibers linked together by connective tissue. Tendons and ligaments are composed of collagenous fibers that have a restricted capability to stretch. Tendons connect the muscle to the bone, whereas ligaments connect bone to bone (Fig. 57–1).

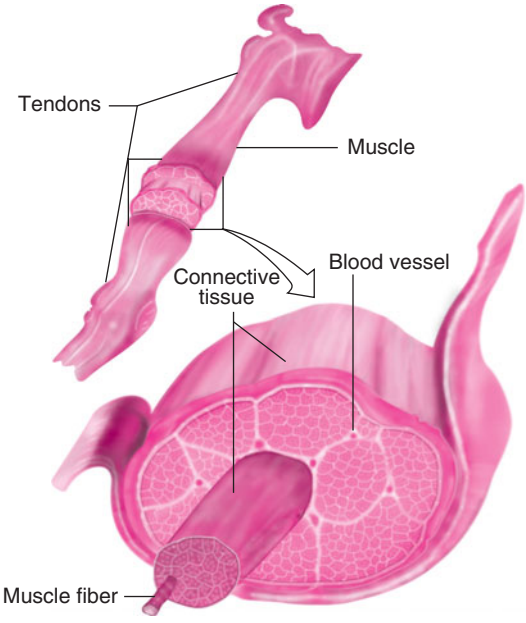

FIGURE 57–1. Skeletal muscle fiber organization. Tendons attach muscle to bone. (From Widmaier EP, Raff H, Strang KT, et al, (eds.) Vander, Sherman, & Luciano's Human Physiology: The Mechanisms of Body Function. 9th ed. New York: McGraw-Hill; 2004, Figure 9-1.)

Muscle Strains and Sprains

A **sprain** is an overstretching of supporting ligaments that results in a partial or complete tear of the ligament.[12] While a **strain** also arises from an overstretching of the muscle-tendon unit, it is marked by damage to the muscle fibers or muscle sheath without tearing of the ligament.[10] The key difference between a sprain and a strain is that a sprain involves damage to ligaments, whereas a strain involves damage primarily to muscle. One common example of muscle strain and sprain is low-back pain.[7]

Overloading the muscle and connective tissue results in complete or partial tears of the skeletal muscle, tendons, or ligaments.[9,10] This usually occurs when the muscle is activated in an *eccentric contraction,* defined as a contraction in which the muscle is being lengthened.[13] Examples of this type of contraction include setting down a large, heavy laundry basket or lowering oneself from a chin-up bar. Small tears can occur in the muscle because it is lengthening while also trying to contract to support the load. This leads to rupture of blood vessels at the site of the injury, resulting in the formation of a hematoma. Within 24 to 48 hours, an inflammatory response develops. In the inflammatory stage, macrophages remove necrotic fibers.[9,10] However, there is some evidence that activated neutrophils also release free radicals and proteases that cause further damage to the area.[15] Finally, capillaries grow into the area, and muscle fibers regenerate during the repair and remodeling phases of healing.[10]

Bursitis and Tendonitis

Bursitis is an inflammation of the bursa, the fluid-filled sac near the joint where the tendons and muscles pass over the bone. The bursa assists with movement by reducing friction between joints. **Tendonitis** (also known as *tendinitis*) is an inflammation of the tendon or, more specifically, the fibrous sheath that attaches muscle to bone.[3] **Tenosynovitis** is an inflammation of the tendon sheath.

Repetitive overuse of a tendon can cause cellular changes in the tissues. Specifically, collagenous tendon tissue is replaced with tissue that lacks the longitudinal structure of a normal tendon.[16] As a result, the tendon progressively loses elasticity and its ability to handle stress or weight. This makes the tendon vulnerable to rupture or inflammation (tendonitis and tenosynovitis).

Repeated use also may cause degradation of collagen.[17] In fact, many patients diagnosed with chronic tendonitis may not have inflammation but instead have tendinosis, a condition marked by these collagen changes. Overuse of a joint also can result in an inflamed bursa. Since the bursa serves to reduce friction within the joint space, bursitis causes stiffness and pain.

Inflammation and Peripheral Pain Sensation

Inflammation is a common pathway in soft-tissue injury of musculoskeletal disorders. Inflammatory processes lead to two outcomes: swelling and pain. Inflammatory processes

traditionally are considered to be a necessary part of the remodeling process because inflammatory cells remove damaged tissue.[18,19] However, inflammation also contributes to continued pain and swelling that limits range of motion.

The initial injury exposes membrane phospholipids to phospholipase A_2, leading to the formation of arachidonic acid (Fig. 57–2).[18,19] Next, arachidonic acid is transformed by cyclooxygenase (COX) to thromboxanes and prostaglandins, including prostaglandin E_2 (PGE_2). PGE_2 is the most potent inflammatory mediator; it increases vascular permeability, leading to redness, warmth, and swelling of the affected area. The increased permeability also increases **proteolysis**, or the breakdown of proteins in the damaged tissue.

Neutrophils, lymphocytes, and monocytes are attracted to the area, and monocytes are converted to macrophages.[18,19] The macrophages then stimulate additional prostaglandin production. Phagocytic cells and other players in the immune system release cytokines, including interleukins, interferon, and tumor necrosis factor.

In addition to increasing vascular permeability, prostaglandins also induce pain by sensitizing pain receptors to other substances such as bradykinin. Bradykinin, prostaglandins, and other inflammatory mediators lower the pain threshold through peripheral pain sensitization. These substances make nerve endings more excitable, and the nerve fibers are more reactive to serotonin, heat, and mechanical stimuli.[19] The process also facilitates production of additional prostaglandins. In a cyclic fashion, the prostaglandins then sensitize the nerves to bradykinin action. Leukotrienes produce a similar peripheral sensitization to painful stimuli.

Without interruption, the neurochemicals ultimately lead to a firing of the unmyelinated or thinly myelinated afferent neurons. This sends messages along the pain pathway in the periphery and transfers the pain message to the central nervous system. Interruption of this cycle via anti-inflammatory agents such as aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) is an important step in treating pain.

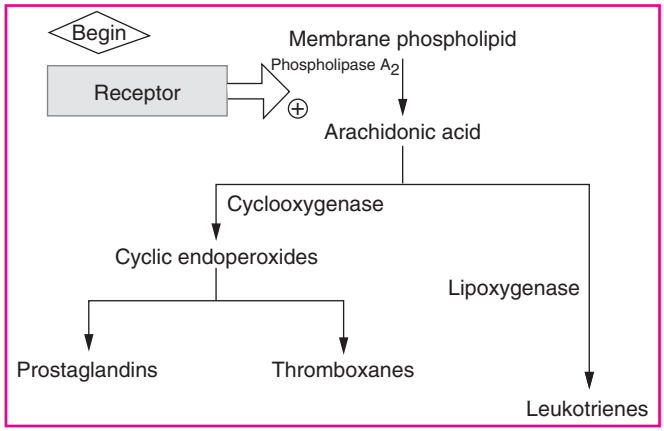

FIGURE 57–2. Eicosanoid synthesis pathway. Cyclooxygenase is inhibited by nonsteroidal anti-inflammatory drugs and aspirin. (From Widmaier EP, Raff H, Strang KT, et al, (eds.) Vander, Sherman, & Luciano's Human Physiology: The Mechanisms of Body Function. 9th ed. New York: McGraw-Hill; 2004, Figure 5-11.)

Nerve receptors, or **nociceptors,** may release substance P, a peptide that causes vasodilation when released.[20] This dilation occurs mainly through substance P–induced production of the vasodilator nitric oxide. Substance P also generates the release of histamine, leading to bradykinin release and activation of an inflammatory process. Capsaicin relieves pain by stimulating the release of substance P from sensory nerve fibers, which ultimately depletes stores of substance P.

CLINICAL PRESENTATION AND DIAGNOSIS

Presentation of Musculoskeletal Disorders[12]

General

- Clinical presentation varies based on the etiology of the disorder.
- Repetitive strain or overuse injuries may have a gradual onset.
- Musculoskeletal disorders owing to acute injury may be associated with other signs of the injury such as abrasion.
- Low-back pain may be more chronic in nature.

Signs and Symptoms of Acute Soft-Tissue Injury (Strains, Sprains)[12]

- Discomfort ranging from tenderness to pain; it may occur at rest or with motion.
- Swelling and inflammation of the affected area
- Bruising or abrasion
- Loss of motion
- Mechanical instability

Signs and Symptoms of Repetitive Strain or Overuse Injury (Tendonitis, Bursitis)[3,21,22]

- Pain and stiffness that may occur at rest or with motion.
- Localized tenderness on palpation
- Mild swelling of the affected area
- Decreased range of motion
- Muscle atrophy

Other Diagnostic Tests and Assessments[23]

- *Radiograph (x-ray):* Evaluate bony structures to rule out fracture, malalignment, or joint erosion as the primary cause of pain.
- *Magnetic resonance imaging (MRI):* Soft-tissue imaging to evaluate for tendon or ligament tears.
- *Ultrasound:* Superficial soft-tissue imaging to evaluate for tears in tendons or ligaments. Does not penetrate bone, so it is of limited usefulness for assessing tendons or ligaments deep within joints.
- *Pain scale:* Patient self-rating of pain on a scale of 0 (no pain) to 10 (worst possible pain). Used to assess pain both at rest and with movement. Determined at baseline and to assess response to therapy.

Patient Encounter 1, Part 1

A 32-year-old man presents with left ankle pain. He was playing football with friends earlier today and twisted his ankle. The pain occurs at rest and is worsened by movement and weight-bearing activities. There is moderate swelling and mild bruising of the left ankle.

- What information is suggestive of a musculoskeletal disorder?
- What is your assessment of the patient's ankle pain?
- What additional information do you need to formulate a treatment plan?

TREATMENT

Desired Outcomes

❶ *The primary goals of treatment of musculoskeletal disorders are to (1) relieve pain and (2) maintain functionality.* This is accomplished by decreasing the severity and duration of pain, shortening the recovery period, and preventing acute pain from an acute injury from becoming chronic pain. Prevention of swelling and inflammation are initial goals in acute injury because the degree of swelling is directly related to range of motion.[12] If these goals are achieved, functional limitations are decreased. Ideally, a patient should be able to continue to perform activities of daily living (e.g., eating, dressing, cooking, and doing laundry) and maintain normal functions in the workplace. Children ideally should be able to maintain usual play activities and sports schedules.

Further goals include a return to usual activity and prevention of future injury. It is also important to minimize the potential for adverse drug events during treatment.

General Approach to Treatment

Treatment of musculoskeletal disorders involves three phases: (1) therapy of an acute injury using the RICE principle, (2) pain relief using oral or topical agents, and (3) lifestyle and behavioral modifications for rehabilitation and to prevent recurrent injury or chronic pain (Fig. 57–3).

In many cases, musculoskeletal disorders may be self-treated with over-the-counter oral or topical agents. However, further evaluation may be warranted if acute pain persists longer than 7 to 10 days, symptoms worsen or subside and then return, or there are signs of a more serious condition.[12,22,24–25] Warning signs of more serious conditions include joint deformity or dislocation or lack of movement in a joint. Low-back pain accompanied by burning, radiating pain or difficulty urinating requires further evaluation.

In children and adolescents, treatment practices are similar to the approach in adults with a focus on nonpharmacologic therapy and oral analgesics. Children younger than age 2, elderly persons, and pregnant women also may need special care.

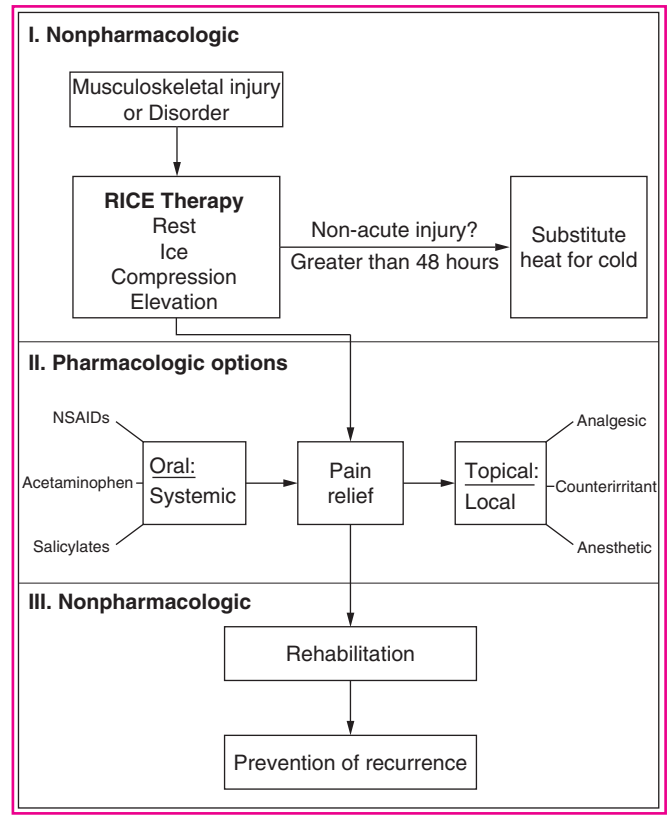

FIGURE 57–3. Treatment plan for musculoskeletal injury or disorder.

Nonpharmacologic Therapy: RICE

❷ *The cornerstone of nonpharmacologic therapy for acute injury in the first 48 to 72 hours is known by the acronym RICE: rest, ice, compression, and elevation*[10,13] (Table 57–1). Rest eases pressure on the affected area and promotes pain control during the acute inflammatory phase (the first 1 to 5 days after injury). Ice, compression, and elevation initially minimize bleeding from broken blood vessels. Cold causes vasoconstriction, assisting in prevention of a large hematoma and providing analgesia by slowing nerve impulses. Compression, achieved by wrapping the area with an elastic bandage, also reduces the size of the developing hematoma. Preventing formation of a hematoma is important because a large hematoma may limit mobility and range of motion. Both cold and compression also decrease interstitial edema and swelling that accompany the injury. Elevation decreases blood flow and increases venous return from the affected area.

In addition to minimizing the acute inflammatory response, rest prevents additional injury to the affected area.[13] The properties of the muscle-tendon unit are altered during the acute injury, with limitations on the ability of the muscles and tendons to stretch. Early activity predisposes a patient to further injury, but prolonged inactivity can lengthen recovery times.

TABLE 57–1. RICE Therapy

Therapy	General Guidelines	Therapeutic Benefit
Rest	Rest the affected area. Use supports such as slings and crutches as necessary. Employ during the acute inflammatory phase, 1–5 days after injury.	Analgesia Anti-inflammatory Prevent further injury
Ice	Cool the affected area by application of crushed ice in a plastic bag covered with a thin cloth or by cool water (55°F or 13°C). Cool the affected area for 15–20 minutes; repeat every 2 hours for the first 48 hours.	Analgesia Anti-inflammatory
Compression	Compress the affected area with an elastic bandage or support. Begin wrapping the bandage at the point most distal to the injury (e.g., at the toes for an ankle injury); apply firmly but not tightly. If the area distal to the injury (e.g., fingers, toes) throbs or turns cold or blue, the bandage is too tight and should be loosened.	Anti-inflammatory Adjunctive analgesia
Elevation	Elevate the area (especially the extremities) above heart level.	Anti-inflammatory

Clinicians should instruct patients to use crushed ice or ice chips because the area will cool more evenly than with large pieces of ice. Patients should not apply ice directly to the affected area or leave it on for longer than the recommended 20 minutes because frostbite may occur.[12] A thin sheet or napkin will protect the skin and also allow for better cold transfer than thicker material such as a towel. Alternatively, soaking the area for 20 minutes in a cool bath (55°F or 13°C) provides effective cooling.

For small areas, an ice massage for 5 to 10 minutes can cool the area and add relief.[21] This is accomplished by freezing water in a paper cup and removing the top part of the cup to expose the ice. The exposed ice is rubbed on the affected area. Any ice application should be stopped if the area becomes white or blue.

❸ *Heat should not be applied during the acute injury phase (the first 48 hours) because it promotes swelling and inflammation.*[12] After the first 48 hours, many patients find that heat decreases pain and eases muscle stiffness associated with immobility. A heating pad, heat wrap, or warm bath may be used on day 3 or later as long as no swelling develops after heat is applied. Heat should be discontinued if increased swelling occurs. Clinicians should educate patients to avoid sleeping with heating pads or sitting or lying on them because this may result in burns.

Pharmacologic Therapy

❹ *There are two main approaches to pharmacologic intervention for pain relief: oral (systemic) and topical agents.* The choice between systemic or topical options is often guided by patient preference. For example, many topical products have a medicinal odor and require frequent applications. The extent of musculoskeletal pain also guides treatment choice. ❺ *Localized pain may be treated effectively with local topical therapy, whereas generalized pain may be treated best with systemic agents.* Factors such as alcohol use, liver function, renal function, allergies, age, and comorbid conditions should be considered when choosing among therapeutic options.

Oral Analgesics

Nonopioid analgesics, including acetaminophen, aspirin, and nonsteroidal anti-inflammatory drugs (NSAIDs), are used commonly for musculoskeletal disorders. All these agents provide analgesia, but aspirin and NSAIDs also work peripherally to decrease production of the principal mediator of acute inflammation, PGE_2.[18] NSAIDs and aspirin inhibit the enzyme cyclooxygenase (COX). While the mechanism of action of acetaminophen is less clear, it appears that acetaminophen acts as a weak inhibitor of prostaglandin (PG) production. In contrast to aspirin and NSAIDs that inhibit PG production peripherally, acetaminophen exerts its effect centrally with little or no anti-inflammatory effect.[26]

Acetaminophen

❻ *Acetaminophen is the drug of choice for mild to moderate regional musculoskeletal pain without inflammation.*[27,28] Comparative trials between acetaminophen and oral NSAIDs demonstrate equivalent analgesia in some situations, but NSAIDs may be preferred in others.[28] Therefore, if adequate analgesia is not achieved with acetaminophen, switching to an NSAID is a reasonable approach. Acetaminophen offers the advantage of less gastrointestinal (GI) toxicity than NSAIDs. While tolerability of acetaminophen is high at therapeutic doses, hepatotoxicity has been reported after overdose and at therapeutic doses, especially in combination with other factors.[29] Acetaminophen should be used with caution in patients who have liver disease or consume alcohol because of the risk of hepatotoxicity.[23]

Salicylates

❼ *Aspirin has not been demonstrated to be more effective than acetaminophen, and because its safety profile may be inferior, it is not recommended for treatment of acute musculoskeletal*

pain.[28] Gastric irritation is more common with aspirin, and bleeding risk may be increased because aspirin irreversibly inhibits platelet aggregation.[28] Patients with aspirin-induced asthma should avoid aspirin and other salicylates.[29] Aspirin should be avoided in children due to a risk of Reye's syndrome.

Some salicylates are specifically marketed for musculoskeletal back pain, such as magnesium salicylate. However, no studies specifically support use of these salicylates over other systemic analgesics. Magnesium salicylate should be used with caution in renal impairment because hypermagnesemia may occur.[31]

NSAIDs

NSAIDs are used commonly for musculoskeletal pain because of their availability without a prescription and anti-inflammatory effects.[30,31] ❽ *NSAIDs are a preferred choice over acetaminophen in musculoskeletal disorders where inflammation is evident.*[27] However, there is some controversy because the inflammatory response may be necessary for healing.[13] Nevertheless, most experts recommend the use of NSAIDs early after acute injury to control inflammation and the range-of-motion limitations that may accompany swelling.[27]

NSAIDs are particularly beneficial for chronic overuse injury, where inflammation is central to the pain and loss of motion. While NSAIDs may be helpful in relieving pain and inflammation in tendonitis, many tendonopathies may not be due to inflammation. Therefore, use of a simple analgesic such as acetaminophen may relieve pain adequately.[22]

The analgesic effects of NSAIDs are attributed to inhibition of the COX-2 enzyme, whereas the negative GI effects are due to inhibition of COX-1.[28] Patients taking oral anticoagulants, those with a history of peptic ulcer disease, or others at high risk for GI complications may be considered candidates for a COX-2 inhibitor or a combination of a nonselective NSAID with a gastroprotective agent such as a proton pump inhibitor (PPI). Because most PPIs are available by prescription only, such patients should be referred to a physician.

COX-2 inhibitors such as celecoxib are associated with adverse effects such as nephrotoxicity and a potential increased risk of myocardial infarction (see Chaps. 55 and 15 for additional information). Combination of COX-2 inhibitors with alcohol may increase GI adverse effects. All NSAIDs should be used with caution in patients with aspirin-induced asthma.[31]

Opioids

Opioid analgesics can be used for patients not responding adequately to nonopioid analgesics or for moderate to severe pain.[28] These agents generally are given alone or in combination with simple analgesics such as acetaminophen. Tolerance and physical dependence are considerations but less of a concern when treating acute pain. When used in equivalent doses, opioids produce similar pain relief and adverse effects such as sedation, nausea, constipation, and respiratory depression.

Topical (External) Analgesics

Topically (or externally) applied drugs that exert an analgesic, anesthetic, or antipruritic effect locally by suppressing cutaneous sensory receptors are termed *external analgesics.*[24] These medications are applied directly to the affected area to create high local concentrations of the drug.[32,33] Formulations include gel, cream, lotion, liquid, liniment, or aerosol spray. Negligible systemic concentrations are achieved with intact skin, minimizing systemic adverse effects. Topical application should not be confused with transdermal delivery, where drug absorption into the bloodstream produces a systemic effect. Musculoskeletal disorders often are treated with topical (but not transdermal) medications.

After application, the topical medication penetrates the skin to the soft tissue and peripheral nerves.[24] Here, the drug suppresses the sensitization of pain receptors, thus reducing pain and burning. External analgesics also include counterirritant products that, in contrast, stimulate cutaneous sensory receptors, producing a burning, warming, or cooling sensation that masks the underlying pain. In effect, the irritation or inflammation caused by the counterirritant distracts from the underlying pain.

Some patients prefer external analgesics to systemic analgesics because the rubbing during application can be comforting. External analgesics are useful adjuvants to nonpharmacologic therapy and systemic analgesic therapy to provide additional relief.[34] The agents also offer a therapeutic option in patients who cannot tolerate systemic analgesics.

Topical NSAIDs

Topical NSAIDs are available commercially in Canada and Europe. In the United States, these agents may be compounded in specialty pharmacies.[35] These agents exert a local anti-inflammatory and analgesic effect.[36–38] In soft-tissue injury such as strains and sprains, topical NSAIDs are superior in efficacy to placebo and similar to oral NSAIDs.[36,37] Tissue concentrations of topical NSAIDs are high enough to produce anti-inflammatory effects, but systemic concentrations after application remain low.[36–38]

Theoretically, the risk of serious GI adverse events should be less than with oral NSAIDs, but long-term studies evaluating these events are lacking.[38] Studies comparing topical NSAIDs with other topical products, including counterirritants, are also needed.[35] Local cutaneous adverse reactions (e.g., erythema, pruritus, and irritation) occur in 1% to 2% of patients and may be due in part to the vehicle used.[38]

Local Anesthetics

Nonprescription topical anesthetics such as lidocaine and benzocaine are available in many types of products. Local anesthetics decrease discharges in superficial somatic nerves and cause numbness on the skin surface but do not penetrate deeper structures such as muscle where the pain often lies.

However, local anesthetics may be helpful when abrasion accompanies the injury.[39] Application of an over-the-counter antibiotic ointment containing an anesthetic may provide soothing relief, promote healing of abrasions, and prevent soft-tissue infection. Minor abrasions should be cleansed thoroughly with mild soap and water before application. More severe abrasions may require removal of debris or foreign bodies by a clinician followed by irrigation with normal saline.

Counterirritants

Counterirritants are categorized by the Food and Drug Administration (FDA) into four groups (groups A–D) based on their primary actions (Table 57–2). They produce a feeling of warmth, cooling, or irritation that diverts sensation from the primary source of pain. Because these irritant effects are central to the beneficial actions, counterirritants should not be combined with topical anesthetics or topical analgesics.

Counterirritants are approved for the temporary relief of minor aches and pains related to muscles and joints.[24] These symptoms may be associated with simple backache, arthritis, strains, sprains, or bruises. Many are available commercially as combination products with ingredients from different counterirritant groups. Active ingredients in marketed products sometimes change; clinicians should be aware of the current ingredients before providing a product recommendation.

TABLE 57–3. Patient Education for Counterirritants[24]

Apply up to 3 to 5 times daily to affected area.
Only use externally on the skin; do not ingest.
Do not apply to broken or damaged skin or cover large areas.
Wash hands immediately after application.
Avoid contact with the eyes and mouth.
Do not use with heating pads or other methods of heat application because burning or blistering may occur.
Do not wrap or bandage the area tightly after application.
Consult a physician if
- Symptoms worsen.
- Symptoms persist for more than 7 days.[a]
- Symptoms resolve but then recur.
- Intended for use in a child younger than age 2.

[a]Capsaicin may be used for chronic pain and must be applied consistently for efficacy.

❾ *Patient education on proper use of counterirritants is essential to therapeutic success* (Table 57–3).

Rubefacients (group A) are counterirritants that produce redness on application. Topical rubefacients containing salicylates (e.g., methyl salicylate and trolamine salicylate) are used most commonly. Turpentine oil is no longer judged as either safe or effective but remains in few products.[24] Clinical trial data evaluating the effect of rubefacients on acute pain from

TABLE 57–2. Nonprescription Counterirritant External Analgesics

Group and Effect	Agents and Concentration	Example Products	Comments
Group A			
Rubefacients: Produce redness	Allyl isothiocyanate 0.5–5%	Musterole Extra	Mustard derivative Pungent odor Avoid inhalation
	Ammonia water 1–2.5%	Made by dilution of concentrated solution with water	More concentrated solutions are highly caustic Avoid inhalation
	Methyl salicylate 10–60%	Analgesic Balm[a] BenGay Ultra Strength[a] Icy Hot Chill Stick[a]	Caution in aspirin sensitivity May produce systemic concentrations
	Trolamine salicylate 10–20%	Aspercreme	May increase INR with warfarin
		SportsCreme	Little odor unless in combination product
Group B			
Produce cooling	Camphor 3–11% Menthol 1.25–16%	JointFlex BenGay Patch Icy Hot Patch Mineral Ice	Medicinal odor Sensation of heat follows cooling Mild anesthetic effects at low concentrations
Group C			
Produce vasodilation	Methyl nicotinate 0.25–1%	ArthriCare Multiaction[b]	May produce systemic vasodilation
Group D			
Irritate without redness	Capsaicin 0.025–0.25%	Capzasin-P Zostrix	Must use regularly Burning effect subsides with regular use
	Capsicum oleoresin 0.025–0.25%	ArthriCare Multiaction[b]	

[a]Included in combination products that also contain menthol and/or camphor.
[b]Combination product with capsicum oleoresin, menthol, and methyl nicotinate.
INR, international normalized ratio.

strains, sprains, sports injuries, and chronic musculoskeletal pain are lacking.[40] A systematic review of available evidence concluded that topical salicylates may be effective for acute pain but have limited effectiveness in chronic pain.[40]

Application of topical salicylates can lead to systemic effects, especially if the product is applied liberally. Repeated application and occlusion with a wrap or bandage also can increase systemic concentrations.[41] Salicylate-containing counterirritants should be used with caution in patients in whom systemic salicylates are contraindicated, such as patients with severe asthma or aspirin allergy.[42] Topical salicylates have been reported to increase prothrombin time in patients on warfarin and should be used with caution in patients on oral anticoagulants.[43]

The group B counterirritants menthol and camphor exert a sensation of cooling through direct action on sensory nerve endings.[42,44] A sensation of warmth follows the cooling effect. The agents also have mild anesthetic activity at low concentrations.[44] In higher concentrations, they act as counterirritants and cause a burning sensation by stimulating cutaneous nociceptors. Menthol and camphor are used often in combination with rubefacients.

Menthol, also known as peppermint oil, is used widely in toothpastes, mouthwashes, gum, sore-throat lozenges, lip balms, and nasal decongestants. For topical analgesic use, it is available in creams, lotions, ointment, and patches. The patches can be trimmed to fit the affected area.

Menthol and camphor have caused respiratory distress in infants and should not be used in children under 2 years of age. Despite limits on the concentration of available products, camphor can be toxic to children even in small amounts.[45] Patients should be advised to keep the products out of the reach of children.

The group C counterirritants methyl nicotinate and histamine dihydrochloride produce vasodilation.[24] Methyl nicotinate is a nicotinic acid derivative that produces prostaglandin-mediated vasodilation.[46] NSAIDs and aspirin block the production of prostaglandins and decrease methyl nicotinate–induced vasodilation. Application over a large area has been reported to cause systemic symptoms and syncope, possibly due to vasodilation and a decrease in blood pressure.[47] Patients should be educated to apply only scant amounts to the affected area to avoid this effect.

The primary counterirritant in group D is capsaicin, a natural substance found in red chili peppers and responsible for the hot, spicy characteristic when used in foods.[32,33,48] Capsaicin stimulates the release of substance P from local sensory nerve fibers, depleting substance P stores over time. A period of reduced sensitivity to painful stimuli follows, and transmission of pain impulses to the central nervous system is reduced.[42]

As with other counterirritants, capsaicin and its derivatives (i.e., capsicum and capsicum oleoresin) exert a warming or burning sensation. With repeated application, desensitization occurs, and the burning sensation subsides. This typically occurs within the first 1 to 2 weeks. After discontinuation, resensitization occurs gradually and returns completely within a few weeks.[48]

Owing to the lag time between initiation and effect, capsaicin is not used for treatment of acute pain from injury. Instead, topical capsaicin is used for chronic pain from musculoskeletal and neuropathic disorders. Capsaicin preparations have been studied in the treatment of pain from diabetic neuropathy, osteoarthritis, rheumatoid arthritis, postherpetic neuralgia, and other disorders.[48] It is often used as an adjuvant to systemic analgesics in these chronic pain conditions.

While systemic adverse effects to capsaicin are rare, local adverse effects are expected and common.[48] Patient education regarding consistent use of capsaicin products is essential to achieving therapeutic outcomes. Product should be applied in a thin layer and rubbed into the skin thoroughly until little remains on the surface.[42] ⓫ *Patients using capsaicin should be advised to apply it regularly and consistently three to four times daily and that full effect may take 1 to 2 weeks or longer.* Patients should be assured that the burning effects will diminish with repeated application. Adherence to therapy is essential because the burning sensation may persist if applications are less frequent than recommended. Because the burning sensation may be enhanced with heat, patients should avoid hot showers or baths immediately before or after application. Wearing gloves during application can decrease the potential for unintended contact with eyes or mucous membranes.[41] Dried product residue has been reported to cause respiratory effects on inhalation,[48] and caution should be used in patients with asthma or other respiratory illnesses.

Muscle Relaxants

Where pain is worsened by muscle spasm, oral muscle relaxants may serve as a useful adjunct to therapy.[25] These agents include baclofen, metaxalone, methocarbamol, carisoprodol, and cyclobenzaprine. Muscle relaxants may decrease spasm and stiffness associated with either acute or chronic musculoskeletal disorders. These agents should be used with caution because they all may cause sedation, especially in combination with alcohol or narcotic analgesics.

Lifestyle and Behavioral Modifications

After treatment of the acute injury with RICE and pharmacologic therapy, the final phase of therapy is rehabilitation and prevention of future injury. For most injuries, prolonged immobilization can lengthen the recovery time by causing wasting of the healthy muscle fibers.[10,49] Rehabilitation starts with the development of range of motion via stretching exercises. Patient should warm the muscle first with light activity or moderate heat.[10] Warmth produces relaxation and increases elasticity. Next, the patient should start general strengthening exercises.[12,50] Resistance exercises using resistance bands available at sporting goods stores are an effective method of strengthening.[12] Strengthening exercises should be continued beyond the healing phase to prevent future injury.

Patient Encounter 1, Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH
- Asthma, well controlled with current medication regimen
- Allergic rhinitis

SH
Denies smoking. Drinks alcoholic beverages on most days.

Meds
- Fluticasone 220 mcg 1 puff twice daily
- Albuterol (salbutamol) 2 to 4 puffs four times daily as needed

Allergies: Aspirin (difficulty breathing)

Diagnostic Tests: Radiographs of left ankle show no evidence of fracture

- What are your treatment goals?
- What nonpharmacologic and pharmacologic treatments options are available?
- Are there treatment options that should be avoided? If so, which options and why?

After rehabilitation, the patient should be educated about behavior changes to prevent reinjury or the development of chronic pain.[3,23] The warm-up and strengthening routines learned in the rehabilitation phase should be continued. For overuse injury, correction of biomechanical abnormalities with proper footwear and changes in technique may correct misalignments and imbalances.[3] Repetitive trauma can be decreased with proper training (e.g., by implementing a gradual increase in mileage in a running plan).

Proper lifting techniques can decrease low-back pain.[7] Lifting methods include standing with legs shoulder-width apart, lifting with the legs and not the back, and keeping the object close to the body. In the workplace, repetitive motion can be decreased through proper ergonomic design and diversification of job tasks.[14] In pain of the lower extremity, weight loss in overweight or obese patients can assist in reduction of further inflammation and help to prevent reinjury or repetitive strain injuries.[21] Nonweight-bearing activities, such as swimming or bicycling, can be recommended for initial return to activity.[23]

Patient Encounter 1, Part 3: Creating a Care Plan

Based on the information presented, create a care plan to treat this patient's ankle injury. Your plan should include (1) the goals of therapy and desired outcomes, (2) a patient-specific therapeutic plan, including nonpharmacologic therapy, and (3) a plan to monitor the outcome of therapy to determine if goals of therapy have been met and adverse effects avoided.

Patient Encounter 2

A 40-year-old woman presents with right elbow pain. On questioning, you determine that she works in a factory performing repetitive tasks with her right arm. She reports the onset of pain as gradual over the last few months. When she wakes in the morning, she has minimal pain after rest, but the pain intensifies after a few hours at work. She tends to have less pain on the weekends. She reports decreased range of motion compared with the left side. She is a nonsmoker and does not drink. She has no significant past medical history or allergies. She takes no medications.

- Given this information, what is your assessment of the patient's elbow pain?
- What is the likely etiology of the pain?
- What nonpharmacologic and pharmacologic treatments options would be feasible?
- Based on the information presented, create a care plan for this patient's elbow injury. Your plan should include (1) the goals of therapy and desired outcomes, (2) a patient-specific therapeutic plan, including nonpharmacologic therapy, and (3) a monitoring plan to determine if goals of therapy have been met and adverse effects avoided.

OUTCOME EVALUATION

- Use a pain scale to monitor treatment interventions to ensure that pain relief is achieved. Ask the patient to rate pain on a scale of 0 (no pain) to 10 (worst possible pain) both at rest and with movement. Compare the results with baseline pain assessment to monitor the response to therapy. In pediatric patients, use a visual pain scale with facial expressions depicting various degrees of pain.
- Assess range of motion at baseline and after treatment by comparing movement with unaffected limb and functionality before the injury. Assess functionality by asking patients if they are able to perform activities of daily living or participate in exercise as desired.
- If pain from acute injury does not decrease greatly within 7 to 10 days, further diagnostic evaluation is warranted.
- For patients using capsaicin products, assess adherence to regular application for therapeutic benefit. Assess chronic pain control in 2 weeks.
- Assess medication adverse effects on a regular basis. When NSAIDs and aspirin are used, ask about GI tolerability. Inquire about local adverse effects, such as burning, when topical counterirritants are used for treatment.
- Evaluate adherence to preventative rehabilitation measures such as proper footwear, warm-up before activity, strength training, and proper lifting technique.

Patient Care and Monitoring

1. Assess the patient's symptoms to determine if empirical care is appropriate or whether diagnostic evaluation is warranted. Determine the timing of injury (if applicable), duration of pain, type and degree of pain, and exacerbating factors. Determine if the musculoskeletal disorder interferes with usual activities or range of motion.
2. Assess exacerbating or alleviating factors. Ask if the patient has tried any nonpharmacologic or pharmacologic treatments.
3. Obtain a complete medication history, including history of prescription drug, nonprescription drug, and dietary supplement use. Determine if the patient has used any successful or unsuccessful treatments for this condition in the past.
4. Gather patient history. Assess factors involved in drug selection. Inquire about social history and alcohol use. Ask the patient about drug allergies and chronic health problems such as asthma.
5. Educate the patient on nonpharmacologic therapy, including each of the steps in RICE (rest, ice, compression, and elevation). If injury is the source of the pain and it occurred more than 48 hours ago, consider heat instead of ice.
6. Assess patient preference for systemic (oral) or local (topical) therapy. Would frequent application of topical medications be possible? Would the patient accept topical medications with a medicinal odor?
7. Recommend appropriate pharmacologic therapy and educate on proper use. If a counterirritant is recommended, counsel patients on the irritant effect of the product and recommend washing hands immediately after use and to avoid heating pads. For patients using a capsaicin product, emphasize that adherence to regular application is required for effectiveness.
8. Develop a plan to assess effectiveness of pharmacologic therapy. If pain is from an acute injury, assess effectiveness within 7 to 10 days. For chronic pain treated with capsaicin, begin to assess pain control in 2 weeks.
9. Evaluate for adverse effects and drug interactions. For patients on topical therapy, evaluate for local adverse effects. For patients on acetaminophen or NSAIDs, inquire about alcohol use.
10. Stress lifestyle modifications for rehabilitation and prevention. Recommend strength training, range-of-motion exercises, and a warm-up period before exercise. In repetitive-motion injury, recommend methods to correct biomechanical abnormalities and vary work tasks as applicable. Refer to a physical therapist or sports trainer as needed.

ABBREVIATIONS

COX:	cyclooxygenase
PG:	prostaglandin
NSAIDs:	nonsteroidal anti-inflammatory drugs
GI:	gastrointestinal
INR:	international normalized ratio

Learning Objectives

Upon completion of the chapter, the reader will be able to:

1. Identify risk factors for the development of chronic open-angle glaucoma and acute angle-closure glaucoma.
2. Recommend a frequency for glaucoma screening based on patient-specific risk factors.
3. Compare and contrast the pathophysiologic mechanisms responsible for open-angle glaucoma and acute angle-closure glaucoma.
4. Compare and contrast the clinical presentation of chronic open-angle glaucoma and acute angle-closure glaucoma.
5. List the goals of treatment for patients with primary open-angle glaucoma suspect, primary open-angle glaucoma, and acute angle-closure glaucoma.
6. Choose the most appropriate therapy based on patient-specific data for open-angle glaucoma, glaucoma suspect, and acute angle-closure glaucoma.
7. Develop a monitoring plan for patients on specific pharmacologic regimens.
8. Counsel patients about glaucoma, drug therapy options, ophthalmic administration techniques, and the importance of adherence to the prescribed regimen.

Key Concepts

❶ Practitioners can play an important role in eye care by assessing patients for risk factors and referring to an ophthalmologist for appropriate screening and evaluation.

❷ Acute primary angle-closure glaucoma is a medical emergency and requires laser or surgical intervention.

❸ Patients with ocular hypertension or primary open-angle glaucoma typically have a slow, insidious loss of vision. This is contrasted by the course of acute primary angle-closure glaucoma which can lead to rapid vision loss that develops over hours to days.

❹ The goals of therapy are to prevent further loss of visual function; minimize adverse effects of therapy and its impact on the patient's vision, general health, and quality of life; control intraocular pressure in order to reduce or prevent further optic nerve damage; and educate and involve the patient in the management of their disease.

❺ Current therapy is directed at altering the flow of aqueous humor, which is the major determinant of intraocular pressure.

❻ Since primary open-angle glaucoma is a chronic, often asymptomatic condition, the decision of when and how to treat patients is difficult since the treatment modalities are often expensive and have potential adverse effects or complications; therefore the clinician should evaluate the potential effectiveness, toxicity, and the likelihood of patient adherence for each therapeutic modality.

❼ An initial target intraocular pressure should be set at 20% lower than the patient's baseline intraocular pressure. The target intraocular pressure can be set lower (30% to 50% of baseline intraocular pressure) for patients that already have severe disease or have normal-tension glaucoma.

❽ It is important to review the patient's medication history for potential drug-drug and drug-glaucoma interactions, adherence, presence of systemic and ocular adverse drug reactions, and ability to use ophthalmic preparations.

Glaucoma refers to a spectrum of ophthalmic disorders characterized by neuropathy of the optic nerve and loss of retinal ganglion cells which leads to permanent deterioration of the visual field and potentially total vision loss. Glaucoma can be classified as primary and secondary. Primary glaucoma refers to glaucoma that cannot be attributed to a preexisting ocular or systemic disease, while secondary glaucoma refers to glaucoma

that can be attributed to preexisting ocular or systemic disease. Examples of primary glaucoma include open-angle, closed-angle, and congenital. Examples of secondary glaucoma include pigmentary glaucoma, neovascular glaucoma, traumatic glaucoma, and pseudoexfoliative glaucoma.

Primary open-angle glaucoma (POAG) is characterized by normal anterior chamber angles, glaucomatous changes of the optic disc, and peripheral visual field loss. Patients with elevated intraocular pressure (IOP) without glaucomatous changes are considered to have ocular hypertension. Patients with ocular hypertension that have normal-appearing anterior chamber angles and an eye exam suspicious of early glaucomatous damage are classified as primary open-angle glaucoma suspects**.** Primary angle-closure glaucoma (PACG) is the obstruction of the anterior angle by the iris, causing moderate to high elevations in IOP. POAG and PACG represent the most common types of glaucoma and therefore will be the focus of this chapter.

EPIDEMIOLOGY

Over 66.8 million people worldwide have glaucoma, making it the second leading cause of blindness worldwide.[1] In the United States it is estimated that 2.22 million people are affected by POAG, and by 2020 this number will increase to 3.36 million. The prevalence varies with race and ethnicity and it is 3 to 5 times more prevalent in African-Americans than Caucasians. The prevalence of POAG increases with age and is rarely seen in patients less than 40 years of age.[2–4]

The prevalence of PACG is lower than that of POAG and varies significantly by race and ethnicity. It is low in patients of European descent (0.09% to 0.16%) but higher in patients of Chinese (1.3%), Eskimo (2.9% to 5%), and Asian Indian (4.33%) descent. PACG is also more prevalent with increasing age and female gender.[5,6]

Risk Factors

Primary Open-Angle Glaucoma

❶ *Practitioners can play an important role in eye care by assessing patients for risk factors and referring to an eye care specialist for appropriate screening and evaluation.* Risk factor evaluation is essential in determining the frequency of comprehensive eye exams for patients (Table 58–1). It is also useful in making decisions regarding when to initiate therapy and determining the sequence of pharmacotherapeutic or surgical treatment modalities.[2]

The five primary risk factors associated with POAG are family history, age, race, central corneal thickness (CCT), and elevated IOP (Table 58–2). Patients who have first-degree relatives with POAG are at higher risk of developing glaucoma than patients with no family history of POAG. Even though IOP is no longer a diagnostic criterion, it is associated with an increased prevalence and progression of the disease.[2,4,5] Central corneal thickness has recently been recognized as a risk factor for POAG. For instance, in the Ocular Hypertension Study, patients with ocular hypertension and thinner CCT (less than 555 microns) had a greater risk of progressing to POAG.[2,7,8]

TABLE 58–1. Recommended Frequency of Comprehensive Adult Medical Eye Evaluation[34]

Age (years)	With Risk Factors for Glaucoma	No Known Risk Factors
Greater than or equal to 65	6–12 months	1–2 years
55–65	1–2 years	1–3 years
40–54	1–3 years	2–4 years
Under 40	2–4 years	5–10 years

Reproduced with permission from Ref. 34.

The five major risk factors identified for PACG are **hyperopia**, family history of PACG, age (greater than 30 years), gender, and Eskimo or Asian ethnicity. Patients that are hyperopic, female, or of Eskimo or Asian ethnicity tend to have more shallow anterior angles which predispose the eye to angle closure. Advancing age is associated with a decrease in the depth of the anterior angles, because the lens becomes thickened and is displaced towards the anterior portion of the eye. Patients who have first-degree relatives with glaucoma are at greater risk for developing PACG, with a prevalence of 1% to 12% for Caucasians.[5,6,9]
